CHAPTER 15

Disorders of the Hematopoietic System

Bettina Dunkel

INVESTIGATION OF HEMATOLOGIC DISORDERS

An investigation of the hematopoietic system often begins with a complete blood count (CBC). The number of any cell type in the blood is determined by the balance of cell production and release from the bone marrow and removal from the circulation by loss, destruction, or extravasation. All blood cells originate from a common pluripotent stem cell, and a schematic representation of hematopoiesis can be found in Fig. 15.1.

Erythrocytes

Physiology

Erythropoiesis, the development and maturation of red blood cells (RBCs), is dependent on the presence of erythropoietin, a glycoprotein hormone synthesized by the kidney in response to renal hypoxia. Absence, such as in cases of chronic renal disease,[1,2] or excess of erythropoietin can cause severe nonregenerative anemia or erythrocytosis, respectively. Similar to people, attempts to manipulate erythropoiesis to enhance performance is an increasing concern in equine athletes. Human recombinant erythropoietin and cobalt have been abused as doping agents in racehorses. Cobalt is a chemical inducer of hypoxia-like responses that include induction of erythropoietin transcription.[3]

In contrast to other species, immature RBCs containing ribonucleic acid (RNA) (reticulocytes) produced in the bone marrow of horses are normally not released into the circulation, even during moderate to severe anemia. Until recently assessment of RBC regeneration in horses was therefore limited to size analysis of RBCs or evaluation of bone marrow biopsies. Macrocytosis (an increase in the mean corpuscular volume [MCV]; Box 15.1) usually correlates with a regenerative anemia. With increasing sensitivity of modern automated hematology analyzers that enumerate RBC-containing nucleic acids by flow cytometry, increased reticulocytes have been detected in the blood of a horse with severe anemia and in horses treated with human recombinant erythropoietin.[4]

Hemoglobin, the component that allows erythrocytes to transport oxygen, is composed of four polypeptide chains (two α- and two β-chains) and a heme moiety. Heme is the functional portion of the molecule and contains an iron atom held in place by the four pyrrole rings of a porphyrin molecule. The iron in hemoglobin must be in the ferrous form (Fe^{2+}) to bind oxygen reversibly. When the heme iron is oxidized to the ferric form (Fe^{3+}), methemoglobin is formed, and the molecule is incapable of oxygen transport. Normal concentration of methemoglobin in blood does not exceed 1% to 2% of the total hemoglobin concentration. Small amounts of methemoglobin with ferric iron are formed under normal conditions but readily converted back to the ferrous form by methemoglobin reductase. Several other cellular enzymes contain iron in their functional reduced state.

Glutathione, an important tripeptide cellular antioxidant, is present in RBCs in high concentrations and assists in maintenance of proteins in their functional, reduced state. This process is energy dependent, which in turn is glucose dependent. Because of the absence of a Krebs cycle in RBCs, glucose is metabolized in these cells via the anaerobic glycolytic Emden-Meyerhof pathway or via the hexose monophosphate shunt. Hereditary deficiency of critical enzymes in these metabolic pathways, glucose-6-phosphate dehydrogenase and flavin adenine dinucleotide, caused hemolytic anemia and hyperbilirubinemia[5] and persistent methemoglobinemia[6] in a colt and an adult horse, respectively.

Normal equine RBCs remain in the circulation for about 150 days before they are removed by mononuclear phagocytes in spleen, liver, and bone marrow. In the liver, heme is converted to biliverdin and then to bilirubin, which is released in an unconjugated form into the circulation.

Hemoglobin released into the blood during intravascular hemolysis is transported to the liver by haptoglobin. If the transport capacity of haptoglobin is saturated, free hemoglobin is present in the plasma. It is filtrated across the renal glomeruli and reabsorbed by renal tubular epithelial cells. Pigment molecules containing heme have nephrotoxic potential due to direct cytotoxic and indirect proinflammatory effects. Heme can oxidize lipids, denature proteins, disrupt the cytoskeleton, impair cytosolic enzyme activity, activate cell-damaging enzymes, and interrupt mitochondrial metabolism.[7]

Evaluation

The erythron is evaluated by measurement of RBC numbers, size, and volume; hemoglobin concentration; and determination of erythrocyte indices (see Box 15.1). These measurements are complemented by subjective evaluation of erythrocyte morphology. Hematocrit and packed cell volume (PCV) measure the percentage of the volume of whole blood that is occupied by RBCs. If both are measured by centrifugation, the terms can be used interchangeably. Hematocrit determined

BOX 15.1 Evaluation of Red Blood Cell Indices: Calculation from the Packed Cell Volume, Red Blood Cell Count (Millions), and Hemoglobin (g/dL)

MCV = (PCV × 10)/RBC count

Expressed as femtoliters (fL)
Increased in some horses with regenerative anemia
Decreased with iron deficiency anemia
Increased in older horses

MCV = (Hemoglobin × 10)/RBC count

Expressed as picograms (pg)
Increased with intravascular hemolysis
Decreased with iron deficiency anemia

MCHC = (Hemoglobin × 100)/PCV

Expressed as grams per deciliter (g/dL)
Increased with intravascular hemolysis
Decreased with iron deficiency anemia

by automated analyzers is usually a calculated value (MCV × RBC count/10). Hemoglobin concentration is approximately one third of the PCV; this percentage increases with the presence of free hemoglobin in the bloodstream (hemoglobinemia). Normal values for hematologic parameters in horses of different breeds are given in Table 15.1 and 15.2; calculations for RBC indices can be found in Box 15.1.

Peripheral blood evaluation should include a thorough examination of a stained blood smear to assess erythrocyte morphology. The normal equine erythrocyte is a biconcave disk; however, in contrast to other species, most equine RBCs lack distinct central pallor. Equine RBCs sediment quickly as a result of rapid Rouleaux formation (coinlike stacking of RBCs). This physiologic phenomenon can be differentiated from pathologic autoagglutination (diagnostic for intravascular hemolysis) by dilution of the blood with physiologic saline, which disperses Rouleaux but not autoagglutination.

Occasionally specialized tests of erythrocyte function or stability are indicated. Osmotic fragility tests measure the resistance of erythrocytes to in vitro hemolysis when

TABLE **15.1 Reference Ranges for Equine Hematologic Parameters**[a]

Parameter	Units	Light Horse[b]	Draft Horse[c]	Miniature Horse[d]	Donkey[e]
RBC count	10^6/μL	6.0–10.0	5.5–9.5	4.3–10.3	4.7–9.0

incubated in increasingly hypotonic sodium chloride (NaCl) solution. Erythrocytes from horses with immune-mediated hemolytic anemia (IMHA) are frequently more readily lysed in hypotonic solution (more fragile) than are RBCs from normal horses. Direct and indirect Coombs tests are also used to aid in the diagnosis of IMHA. The direct Coombs test detects immunoglobulin (Ig) or complement on the RBC surface by use of antibodies against IgG, IgM, and complement 3 (C3). Incubation at 10°C and 30°C detects cold- and warm-reacting antibodies, respectively. Because agglutination is the endpoint of the direct Coombs test, autoagglutination of blood is considered diagnostic of IMHA. The indirect Coombs test screens the patient's serum for presence of anti-RBC antibodies by incubating it with normal equine RBC and monitoring for agglutination.

Interpretation

Increased (erythrocytosis) or decreased (anemia) RBC numbers are indicative of increased or decreased production in the bone marrow or increased removal from the circulation by acute or chronic blood loss (Boxes 15.2 and 15.3) or intravascular or extravascular destruction (hemolysis; Box 15.4). Hemoglobinemia indicates intravascular hemolysis; extravascular hemolysis is less readily confirmed. A diagnosis of IMHA is supported by an increased osmotic fragility, positive direct or indirect Coombs test, or the presence of autoagglutination.

Morphologic examination of RBCs on a stained blood smear may reveal the following abnormalities:

Poikilocyte: Any abnormally shaped erythrocyte; usually reserved for description of RBCs that exhibit a variety of morphologies rather than one predominating shape.
Anisocytosis: Variability in RBC size, usually associated with an increased RBC distribution width.
Polychromasia: Variability in RBC color, usually caused by a variable hemoglobin and RNA content.
Spherocyte: Spherical erythrocytes might be observed with immune-mediated hemolysis.
Echinocyte: Burr cell with short, regularly spaced spicules projecting from the RBC surface; can be associated with uremia.
Acanthocyte: Spur cell with irregularly shaped spicules extending from the RBC surface; can be associated with liver disease or gastrointestinal malabsorption.
Elliptocyte: Ellipsoid or oval erythrocyte found in animals with iron deficiency or myelophthisic anemia.
Leptocyte: Thin, flat RBC frequently associated with hepatic disease or iron deficiency.
Codocyte: Target cell with a dense central area of hemoglobin surrounded by a pale zone; can be associated with hypochromic anemias or hepatic disease.
Howell-Jolly bodies: Basophilic nuclear remnants seen in the cytoplasm of erythrocytes. Approximately 10 in 10,000 erythrocytes contain Howell-Jolly bodies in the normal horse.

BOX 15.2 Differential Diagnoses for Blood Loss in the Horse

EPISTAXIS
Guttural pouch mycosis
Pulmonary abscess
Exercise-induced pulmonary hemorrhage
Ethmoid hematoma
Paranasal sinus abscess or infection
Traumatic nasogastric intubation
Upper respiratory tract neoplasm
Coagulopathy
Trauma
Rupture of rectus capitis muscle
Pneumonia/pleuritis
Hemothorax
Thoracic trauma
  Fractured rib
  Lacerated heart or vessels
Pulmonary thrombembolism
Ruptured pulmonary abscess
Ruptured great vessel
Neoplasia
Coagulopathy

HEMATURIA
Pyelonephritis
Cystitis/urolithiasis
Neoplasia
Trauma
Urethral ulceration
Coagulopathy

HEMOPERITONEUM
Trauma
  Splenic rupture
  Hepatic rupture
Mesenteric vessel rupture
Verminous arteritis
Uterine artery rupture
Phenylephrine treatment
Abdominal abscess
Neoplasia
Coagulopathy

GASTROINTESTINAL HEMORRHAGE
Ulcerations
Nonsteroidal antiinflammatory drug (NSAID) toxicity
Parasites
  Strongylus vulgaris
  Small strongyles
Granulomatous intestinal disease
  Histoplasmosis
  Tuberculosis
  Granulomatous enteritis
Neoplasia
  Squamous cell carcinoma
  Lymphosarcoma
Coagulopathy

EXTERNAL HEMORRHAGE
Trauma
Surgical complication
Coagulopathy
External parasites

Heinz bodies: Oxidized precipitated hemoglobin indicating oxidative damage to the RBC, usually resulting in intravascular or extravascular hemolysis. One may see Heinz bodies best using new methylene blue stain but may observe them in smears using Wright's stain as round structures protruding from the edge of the RBC membrane.

Iron Metabolism

Physiology

Iron is abundant in the normal horse diet, and its absorption, predominantly occurring in the small intestine, correlates with demand. It increases during iron depletion and decreases during iron abundance. After absorption into the circulation iron combines with apotransferrin forming transferrin. Excess iron is deposited in the storage form of ferritin in hepatocytes and reticuloendothelial cells in the spleen and bone marrow. Excess iron intake, especially in foals, can lead to hemochromatosis, liver cirrhosis, and liver failure.[8-10] However, experimental feeding of adult ponies with 50 mg/kg iron (22.7 mg/lb) as ferrous sulfate containing 20% elemental iron did not lead to adverse clinical signs or histopathologic liver changes.[11]

Iron deficiency is first characterized by low serum ferritin concentration and decreased stainable iron stores in the bone marrow. Once iron concentrations are sufficiently low to affect erythropoiesis, a decreased percentage of plasma transferrin saturation, an increased total iron binding capacity (TIBC), hypochromic erythrocytes (decreased mean corpuscular hemoglobin concentration [MCHC]), and ultimately release of small cells (microcytosis; decreased MCV) are noted. In healthy foals at birth, serum iron and ferritin concentrations are lower than adult levels, followed by a rapid increase in the first 24 hours as a result of absorption of colostral iron.[12] During the next 3 weeks, concentrations fall below concentrations of adults, reaching a nadir at 3 weeks. The PCV of neonatal foals correlates closely with serum iron and ferritin concentrations. In healthy foals, a higher PCV during the first days postpartum is followed by a decrease below the adult reference range and increased production of microcytes after 2 weeks.[13] This relative iron deficiency in healthy foals does not respond to supplementation, the PCV does not decrease below 32%, and morphologic abnormalities are limited to mild microcytosis.[14,15]

Evaluation

Inadequate iron intake or uncompensated loss gives rise to microcytic hypochromic iron deficiency anemia, which can be identified on blood smear evaluation and by calculation of erythrocyte indices. Iron metabolism can be directly evaluated by measuring the amount of iron in the blood

BOX 15.3 Differential Diagnoses for Nonregenerative Anemia in the Horse

IRON DEFICIENCY
Chronic hemorrhage
Nutritional deficiency (rare)

CHRONIC DISEASE
Chronic infection/inflammation
- Pleuritis/pneumonia
- Peritonitis/enteritis
- Bacterial endocarditis
- Internal abscess
- Chronic viral disease (e.g., equine infectious anemia [EIA])

Neoplasia
Endocrine disorders

BONE MARROW FAILURE
Myelophthisis
Myeloproliferative disease
Bone marrow toxins
- Phenylbutazone
- Chloramphenicol

Radiation
Idiopathic pancytopenia

MISCELLANEOUS CONDITIONS
Administration of human recombinant erythropoietin
Chronic hepatic disease
Chronic renal disease
Recent hemorrhage or hemolysis

BOX 15.4 Differential Diagnoses for Hemolysis in the Horse

INFECTIOUS DISEASES
Piroplasmosis
Equine infectious anemia (EIA)
Leptospira

Hepatic disease
Hemolytic uremic syndrome
Disseminated intravascular coagulation

OTHER TOXICITIES
Intravenous DMSO
Bacterial toxins *(Clostridium)*
Oak
Burn injury

(73–140 µg/dL), the capacity of the blood to transport iron by measuring transferrin or TIBC (231–455 µg/dL), and the amount of iron storage; ferritin[16,17] TIBC measures all iron carrier proteins in the blood, including transferrin. Because transferrin is the primary iron-binding protein, TIBC can be used as an indirect measurement of transferrin. Transferrin is produced in relationship to the need for iron. When iron stores are low, transferrin levels increase and vice versa. In healthy horses, about 30% to 40% of the binding sites on transferrin are used to transport iron. Unsaturated iron-binding capacity measures the reserve capacity of transferrin, the portion of transferrin that has not yet been saturated. Transferrin saturation represents the percentage of transferrin that is saturated with iron. Serum ferritin provides an index of stored hepatic and splenic iron and measures 152 ± 55 ng/mL in normal horses. Ferritin concentrations decrease during iron deficiency and increase during iron overload, hemolysis, liver disease, inflammation, and colic.[16,18] The effects of different diseases on iron measurements are summarized in Table 15.3.

Leukocytes

Leukocytes are categorized as granulocytes (neutrophils, eosinophils, basophils, and mast cells), monocytes and macrophages, and lymphocytes. They are essential for normal immune function and increased or decreased numbers in the circulation are most commonly secondary to other disease processes. However, on occasion diseases of the bone marrow, neoplasia, or functional abnormalities can give rise to primary disease processes.

Neutrophils

Physiology. Granulocyte-macrophage and granulocyte colony-stimulating factor (GM-CSF and G-CSF, respectively), among several other cytokines, regulate proliferation and differentiation of precursor cells into granulocytes and mononuclear phagocytes. Mature neutrophils are stored in the bone marrow. Once released, their half-life in the circulation is approximately 10.5 hours before they extravasate into peripheral tissues, where they remain active for several days. An increased demand for neutrophils in the periphery leads to release of immature band neutrophils from the bone marrow. The neutrophil pool in the blood is composed of circulating cells and

TABLE **15.3 Indices of Iron Metabolism**

Disease	Plasma Iron	TIBC/Transferrin	% Transferrin Saturation	Ferritin
Iron deficiency	Low	High	Low	Low
Chronic disease	Low	Low	Low	Normal or high
Hemolytic anemia	High	Normal or low	High	High
Iron overload	Normal or high	Normal	High	Normal or high
Normal values (mean ± SD and reference range)[a]	123 ± 37 μg/dL 73–140 μg/dL	343 ± 56 μg/dL 231–455 μg/dL	30%–40%	152 ± 55 ng/mL 43–261 ng/mL

SD, Standard deviation; *TIBC,* total iron binding capacity.

marginated cells that are localized close to the endothelium. Only circulating cells, not marginated, are included in the peripheral cell count, and changes between marginated and circulating states can explain why neutrophil counts can change very rapidly. Selectin-mediated rolling of neutrophils along the endothelium is followed by integrin-mediated adhesion if neutrophils come in contact with activated endothelial cells at sites of injury or inflammation. Stress, exercise, glucocorticoids, and epinephrine mobilize marginated neutrophils. In addition, glucocorticoids increase neutrophil release from the bone marrow and delay extravasation and apoptosis. Defense mechanisms of neutrophils include release of lytic enzymes and reactive oxygen species, phagocytosis, and the more recently described release of deoxyribonucleic acid (DNA) in the form of neutrophil extracellular traps (NETs). These NETs have the ability to bind and kill extracellular microorganisms, and their formation by equine neutrophils has been demonstrated.[19]

Neutrophil function can be affected by age and disease state. Altered hormone concentrations, as they occur in horses with pituitary pars intermedia dysfunction (PPID), decrease neutrophil oxidative burst activity and adhesion, but not phagocytosis, compared with healthy controls. Chemotaxis is greater in healthy aged horses than in young horses or aged horses with PPID. Plasma insulin–to–α-melanocyte-stimulating hormone (MSH) ratio, but not individual hormone concentrations, correlated with neutrophil oxidative burst activity.[20] Phagocytic capacities and oxidative burst activity are impaired in neonatal foals in comparison to adult horses.[21,22] Human recombinant G-CSF products have been used therapeutically in foals with neutropenia[23,24] and experimentally as a preventive agent against disease following long-distance travel (0.23 μg/kg subcutaneously [SC] once).[25] In these reports, the neutrophil count increased markedly following treatment. Interestingly, a smaller increase in platelet count was also noted.[23] Human recombinant G-CSF is also used illegally in racehorses as a doping agent.[26]

Evaluation. Neutrophil numbers and morphology can give an indication of the severity of an insult affecting the body. The presence of band (immature) neutrophils in circulation is termed a *regenerative left shift* and indicates a bone marrow response to an inflammatory stimulus. When band cells outnumber mature neutrophils in the peripheral blood, the condition is referred to as a *degenerative left shift*. Morphologic changes indicative of a toxic insult to the neutrophils (strong inflammatory stimulus) include cytoplasmic basophilia, vacuolation, and Döhle bodies (remnant RNA from rough endoplasmic reticulum, from previous maturation stages). Occasionally, infectious organisms such as *Anaplasma phagocytophilum* can be observed in the cytoplasm of neutrophils. A congenital morphologic abnormality presenting as hyposegmentation of the nucleus (Pelger Huët anomaly) has also been described in Arabian horses.[27,28] Hypersegmentation in other species is seen as an aging process with a prolonged transit time in the blood and has been associated with resolving chronic inflammation, glucocorticoid administration, and hyperadrenocorticism. In horses, it has been described in a case of hemolytic anemia secondary to hepatic disease and as an idiopathic condition in three Quarter Horses.[29-31]

Interpretation. Most changes in neutrophil numbers are secondary to systemic inflammation, infection, stress, or glucocorticoid administration. Unfortunately, the leukocyte count can also be normal despite the presence of severe inflammation or infection. Impressive leukocytosis frequently accompanies chronic bacterial infections such as *Rhodococcus equi* or *Corynebacterium pseudotuberculosis* infection. Experimentally, endotoxin is the best investigated bacterial product that induces neutropenia, sometimes followed by a rebound neutrophilia (Chapter 12). Other microbial or inflammatory mediators probably have similar capacities, and acute intraabdominal inflammation such as may occur with colitis, enteritis, or acute peritonitis is one of the most common causes of leukopenia in horses. Extreme leukopenia and neutropenia can be observed with intestinal rupture and subsequent fecal peritonitis. Neutropenia in foals is a strong indicator for systemic inflammation and sepsis. If changes are persistent or progressive, abnormalities of the bone marrow should be considered.

Eosinophils

Physiology. Eosinophils are primarily tissue-dwelling cells, and only low numbers are present in the circulation. Previously eosinophils were believed to be predominantly associated with innate immunity, particularly with parasitic infections and allergic conditions. However, several other crucial noninflammatory roles are now also recognized. Eosinophils are essential for the long-term survival of plasma cells in the bone marrow and for their maintenance in the lamina propria of the intestinal epithelium. Eosinophils are required to instigate antibody class-switch to IgA and to maintain long-term mucosal IgA plasma cells. They also play a vital role in tissue integrity and tissue remodeling.[32]

Evaluation and Interpretation. Eosinophil numbers in the peripheral blood are usually low, and eosinopenia is therefore

difficult to appreciate. Corticosteroid treatment and stress are often associated with low eosinophil numbers. Eosinophilia in horses is uncommon, but parasitism such as cyathostomiasis or forms of eosinophilic colitis, enteritis, or multisystemic disease should be ruled out in horses with a suitable history and presentation.[33-35] In humans and other species, including the horse, eosinophilia has been observed concurrently or even preceding hematologic and other malignancies, particularly types of lymphomas.[36-38]

Basophils and Mast Cells

Basophils are the least numerous leukocytes in the peripheral blood. Together with mast cells, they are regarded as effector cells of IgE-dependent allergic inflammation, rapidly releasing histamine and inflammatory mediators on cross-linking of receptor FcεR1 by IgE-allergen complexes.[39] Recently, roles in non-IgE–mediated inflammatory conditions have also been elucidated.[39] Mast cells are long-lived granulated cells derived from hematopoietic precursors but only very small numbers of their progenitors are present in the blood. Mast cells complete their differentiation and maturation in the microenvironments of nearly all tissues, often in close contact to potential targets of their mediators.[40]

Lymphocytes

Physiology. Lymphocytes were long considered the primary effector cells of the adaptive immunity, but with increasing knowledge, the borders between innate and adaptive immunity are becoming increasingly blurred. Circulating lymphocytes can be divided into B, T, and natural killer cells with an ever increasing plethora of subpopulations being recognized. Most lymphocytes are localized in the lymphatic tissues distributed throughout the body, including spleen and lymph nodes.

Evaluation and Interpretation. Investigation of lymphocyte numbers, function, and morphology becomes important when immunodeficiencies or lymphoid neoplasia is suspected. Absolute and relative lymphopenias are associated with administration or release of glucocorticoids, viral infection, old age, and severe combined immunodeficiency in Arabian foals and one Caspian and one Fell pony foal.[41-43] Lymphocytosis can be encountered during epinephrine release or administration, exercise, equine herpes virus–2 (EHV-2) infection in foals, and lymphocytic leukemia.[44] Investigation of lymphocyte types and function is discussed in Chapter 1.

Platelets

Physiology. Platelets or thrombocytes are anucleate blood cells derived as cell fragments budding from the boarders of polyploid precursor cells, megakaryocytes, in the bone marrow. In other species, platelet generation also occurs in the peripheral blood, particularly in the pulmonary circulation, which, besides the spleen, is one of the major storage sites for platelets. The daily production of platelets has been estimated to be approximately 35,000/μL. Radiolabeled equine platelets have an average life span of 4 to 5 days before they are removed from the circulation by macrophages residing in liver, spleen, and bone marrow. Although fundamentally similar, equine platelets show some subtle morphologic and functional differences in comparison to other species such as the absence of an open canalicular system and differences in responsiveness to some mediators.[45,46] In recent years it has become increasingly evident that platelets, besides their hemostatic functions, play a vital role in inflammation, immunity, tissue regeneration, and the pathophysiology of many diseases. Platelets from other species not only contain and release a myriad of inflammatory and regenerative mediators but also synthesize new factors such as interleukin-1β by rapid signal-dependent translation of mRNA acquired from the parent megakaryocyte. Recent evidence suggests that platelet generation is a highly sophisticated process. Depending on the circumstances, platelets are equipped with different subsets of mRNA strands during the budding process that later allow synthesis of different mediators. In the circulation, they interact with other cells, particularly leukocytes and endothelial cells, and play an essential part in attracting leukocytes to sites of inflammation or tissue damage. Human platelets are capable of active cell locomotion and gradient-driven chemotaxis in response to bacterial peptides and allergenic stimuli. With increasing interest in equine platelets and more widely available facilities to assess multiple aspects of platelet function, cell surface marker expression and interactions with other cells, knowledge about equine platelets is bound to expand rapidly within the near future.

Evaluation. Platelet aggregation, an indicator of platelet function, is assessed by determining platelet counts before and after stirring of samples using a magnetic stir bar and calculation of the percentage decrease. Alternatively, and more accurately, measures are made by use of aggregometers.[47] Flow cytometry is now widely used in the experimental setting to investigate surface expression of platelet membrane glycoproteins (GPs), including GP IIb-IIIa (CD41/61), GPIV, CD62P (P-selectin), lysosomal integral membrane protein (LIMP), and binding of annexin V and fibrinogen.[48-50] Platelet microparticles and platelet-leukocyte aggregates have also been detected using this technique.[49-51] Methods to detect platelet adhesion to coated microtiter plates under static conditions and to subendothelium under flow conditions have been described.[46,52] Several platelet release products can be measured in plasma and other biologic fluid samples as an indication of platelet activation and degranulation. Growth factors, serotonin, and thromboxane A_2 (TXA_2) are among the most frequently used markers.[53,54] Because of the short half-life of platelet factor 4 (PF4), a β-thromboglobulin (β-TG)/PF4 ratio greater than 2 has been used to distinguish between in vivo and accidental in vitro platelet activation.[55]

Interpretation. Thrombocytosis is frequently defined as a platelet count of greater than 400,000/μL, although counts of up to 500,000/μL might be normal in young male horses.[56] Thrombocytopenia, defined as a platelet count of less than 100,000/μL, is also a relatively rare occurrence affecting approximately 1.5% of hospitalized horses in which a CBC was performed.[57,58] Thrombocytopenia can be associated with systemic diseases and coagulopathies, immune-mediated destruction of platelets, or insufficient production (Box 15.5). Platelet activation often accompanies systemic inflammation and has been demonstrated in recurrent airway obstruction, laminitis, gastrointestinal disease, and EHV-1 infection.[49,52,55,59,60] Congenital defects in platelet function have been described in horses.[61-65] Thrombocytosis, thrombocytopenia, and platelet dysfunction are further discussed under disorders of hemostasis and hematopoiesis later in this chapter. In contrast, pseudothrombocytopenia is a common artificial reduction in the platelet count due to sampling and counting procedures. Automated platelet counts performed on ethylenediaminetetraacetic acid (EDTA)- and, less

frequently, heparin- and citrate-anticoagulated blood are often affected. In blood anticoagulated with EDTA, platelets can form aggregates following calcium chelation with subsequent artificially low counts. Inspection of a blood smear along the feathered edge and a manual platelet count can quickly establish an accurate platelet count. Rarely, true pseudothrombocytopenia secondary to EDTA-dependent antibody formation and subsequent platelet clumping are encountered in individual horses.[66,67] Use of a different anticoagulant abolishes platelet clumping.

Bone Marrow

Evaluation of bone marrow is indicated if quantitative, functional, or morphologic abnormalities of blood cells are detected that cannot be explained by an increased demand, increased cell loss, or exogenous influences.

Physiology

Production of the cellular elements of blood—namely, erythrocytes, lymphocytes, monocytes, polymorphonuclear granulocytes (neutrophils, basophils, and eosinophils), and platelets—occurs in the fetus in liver and spleen before shifting to the bone marrow as the main site of hemopoiesis in the adult horse. During aging, productive bone marrow is gradually replaced by fat, leaving the marrow of sternum, ribs, vertebra, skull, pelvis, and epiphyseal marrow of humerus and femur as the main production sites in older animals. Under the influence of not fully elucidated cytokine mediators the self-renewing pluripotent stem cells differentiate into separate cell lines (see Fig. 15.1) and after further differentiation and maturation, functional white and red blood cells and platelets are released into the bloodstream.

Evaluation

Bone marrow aspirates or core biopsies are most commonly obtained from the sternum in adult horses, but tuber coxae or proximal ribs are also possible. In the sedated horse, the cartilaginous junctions between the seventh, sixth (often partially fused), fifth, and fourth sternebrae are identified ultrasonographically. The fifth–sixth intersternebral space is often located immediately caudal to the olecranon in the standing horse, and bone marrow can be aspirated successfully from the sixth, fifth, and occasionally fourth sternebrae (located between the front legs). Marking the intersternebral spaces with clippers or a marker pen aids in identifying the middle of the sternebrae. The area is clipped, a sterile prep is performed, and local anesthetic is injected before making a small stab incision through skin and subcutaneous tissue. A Jamshidi or similar needle that is ≥16 gauge and ≥2 inches long, ideally with a stylet, is advanced until it contacts the bone surface. The index finger is placed 2 cm (¾ inch) from the skin surface, and the needle is then advanced through the bone into the marrow cavity until the tip of the finger touches the skin. This requires considerable force; rotational movements often help with insertion. In a Thoroughbred the dorsoventral diameters of the sixth, fifth, and fourth sternebrae measure approximately 3.5, 4.8, and 6.2 cm, respectively.[68] The apex of the heart is located adjacent to the seventh sternebra and xyphoid.[68] The stylet is removed and marrow aspirated into a 10-mL syringe preloaded with heparin (final concentration of 625 IU/mL bone marrow) and mixed gently as bone marrow coagulates extremely quickly. Slides can be prepared immediately or the bone marrow can be transferred into a Petri dish from which spicules can be transferred onto glass slides for staining and evaluation.

Interpretation

Evaluation includes identification of progenitor cells of different cell lines and estimation of the myeloid-erythroid ratio (M:E; 0.5–3.76 in normal horses). Ratios less than 0.5 are indicative of erythrocyte regeneration or myeloid suppression. Prussian blue staining can be used to evaluate peripheral iron stores. Bone marrow macrophages ingesting RBCs might be present in hemolytic anemia. A reduction in all cellular elements is termed *myelophthisis* and is often due to proliferation of fibrous tissue (myelofibrosis). Myelodysplasia indicates the presence of abnormal cells, often due to myeloproliferative neoplasia.

TABLE **15.4 Coagulation Factors**

Factor	Synonym
I	Fibrinogen
II	Prothrombin
III	Tissue factor, tissue thromboplastin
IV	Calcium
V	Proaccelerin, labile factor
VI	Not assigned
VII	Proconvertin, stable factor
VIII	Antihemophilic factor
IX	Christmas factor
X	Stuart-Prower factor
XI	Plasma thromboplastin antecedent
XII	Hageman factor
XIII	Fibrin-stabilizing factor
Prekallikrein	Fletcher factor
High-molecular-weight kininogen	Fitzgerald factor

Hemostasis

Physiology

Repair of microvascular and macrovascular injury is essential for survival during health but even more so at times of disease or injury. Effective hemostasis is a tightly controlled process and relies on the interaction of the vascular wall, particularly the endothelium, platelets, and soluble plasma proteins. In the uninjured vessel, spontaneous coagulation is avoided by the presence of several anticoagulant mechanisms expressed on and released by endothelial cells. The healthy endothelium is covered by a glycocalyx, a complex network of negatively charged macromolecules formed by cell-bound proteoglycans, glycosaminoglycan side chains, and sialoproteins. Further components include loosely attached soluble molecules including albumin, hyaluronic acid, heparan sulfate, thrombomodulin, and antithrombin.[69] The glycocalyx plays a key role in regulating microvascular tone and endothelial permeability, maintaining an oncotic gradient, regulating adhesion and extravasation of leukocytes, and inhibiting intravascular thrombosis.[69] Furthermore, the quiescent state of circulating platelets and presence of the circulating coagulation factors in an inactive zymogen form prevents spontaneous clot formation. Dysregulation of hemostasis, as it occurs with severe systemic inflammation, is a major source of morbidity and mortality in sick horses. The plasma-based coagulation system comprises a number of factors that loosely serve four different functions: coagulation, anticoagulation, fibrinolysis, and antifibrinolysis. Important coagulation factors are listed in Table 15.4. However, a large amount of overlap exists, and one factor might have several functions, depending on circumstances and effects of negative and positive feedback loops. The understanding of clot formation and its biologic opponent, fibrinolysis, is continuously evolving. Clot formation, or a tendency to thrombosis (hypercoagulability), is favored by a procoagulant environment, decreased anticoagulant activity, and inhibition of clot lysis (antifibrinolysis). Inhibition of clot formation, or an increased bleeding tendency (hypocoagulation), is encountered with high antithrombotic and fibrinolytic activities and a decreased activity of coagulation factors. If vascular injury occurs, the first response is intense vasoconstriction to divert blood flow away from the injury. Two main components, primary and secondary hemostasis, then initiate closure of the defect and vascular repair. Primary hemostasis refers to platelet aggregation to form a platelet plug. Platelets are activated (see section on coagulation) and adhere to the site of injury and to each other, closing the defect. Secondary hemostasis refers to the conversion of fibrinogen into fibrin by the proteolytic coagulation cascade and deposition of the insoluble fibrin to form a mesh that incorporates and stabilizes the platelet plug. These two processes happen simultaneously and are mechanistically intertwined.[70] Defects of primary hemostasis are characterized by petechiae, ecchymosis, spontaneous bleeding from mucosal surfaces (including epistaxis and gingival bleeding), hyphema, hematuria, and melena. Defects of secondary hemostasis often present as a tendency to hematoma formation and bleeding into subcutaneous tissues, body cavities, muscles, or joints. Overlap exists and particularly in acquired disorders, such as disseminated intravascular coagulation (DIC), multiple hemostatic defects cause clinical signs compatible with defects in primary and secondary hemostasis. Similarly, mild von Willebrand disease might resemble a primary hemostatic defect, but in severe cases signs of a secondary hemostatic disorder are also present.

The next section describes the four systems and their interaction in more detail. Available tests evaluating different aspects of hemostasis and normal coagulation times are summarized in Tables 15.5 and 15.6.

Coagulation. Earlier cascade or waterfall models of coagulation, dividing the process into an intrinsic and extrinsic pathway, have now been replaced by cell-based models.[71] There is extensive cross-talk between the inflammatory and coagulation systems, and many coagulation factors have proinflammatory or antiinflammatory capacities, but those will not be discussed. A key element of coagulation remains activation of prothrombin to thrombin and the subsequent conversion of fibrinogen into fibrin. The most important activator of coagulation is now thought to be tissue factor (TF). TF is highly expressed in extravascular tissue such as smooth muscle and fibroblasts and becomes exposed on vascular damage. Platelets then adhere to the damaged site, mediated by von Willebrand factor, and aggregate through interactions of platelet receptors with extracellular ligands and soluble proteins. Vascular damage–induced exposure of subendothelial TF generates trace amounts of thrombin with multiple effects on other coagulation factors and platelets. This progression can be divided into three phases: initiation, amplification, and propagation (Fig. 15.2). During the initiation phase (corresponding to the extrinsic pathway in the cascade model) exposed TF binds and activates factor VII (FVII). The TF/FVIIa complex activates FIX and FX into FIXa and FXa, respectively. FXa associates with cofactor FVa to form a prothrombinase complex on TF-expressing cells and convert prothrombin (FII) into thrombin.[71] In the amplification phase the small amounts of thrombin generated in the initiation activate further platelets that have adhered to the injury site. In parallel, thrombin converts platelet-derived FV into FVa, amplifying prothrombinase activity, and converts FVIII into FVIIIa, which acts as a cofactor to FIXa on the surface of activated platelets to support FXa generation. The propagation phase (intrinsic pathway in cascade model) occurs mainly on phospholipid-containing cell surfaces, predominantly

activated platelets. Activated FXIa converts FIX into FIXa, which then associates with thrombin-cleaved FVIII. On phosphatidylserine-exposing cell membranes, the FIXa/FVIIIa complex catalyzes the conversion of FX to FXa, which complexes with FVa complex to form enough thrombin to form fibrin fibers. As a final step, the thrombin-activated FXIIIa catalyzes covalent cross-linking between adjacent fibrin fibers, generating a fibrin clot.[71] Via multiple enforcement loops in the coagulation system and in platelet activation, large amounts of fibrin are formed, stabilizing the earlier formed platelet thrombi.[71] It is now well established that TF is also expressed by intravascular cells, particularly when activated. Endothelial cells, monocytes, platelets, and microparticles are thought to contribute to intravascular coagulation during states of inflammation. Factor VIII deficiency in horses or factor IX deficiency in other species leads to severe bleeding complications (hemophilia A and B, respectively), thus underlining the importance of these coagulation factors for normal hemostasis.

Vitamin K is an essential coenzyme for factors II, VII, IX, and X, and vitamin K deficiency can cause severe and even fatal hemostatic dysfunctions (see acquired disorders of hemostasis). It is necessary for synthesis of four coagulation factors (II, VII, IX, and X) in the liver, as well as the anticoagulation proteins C and S. Vitamin K catalyzes posttranscriptional carboxylation of glutamic acid residues on factors II, VII, IX, and X. This process is essential for their biologic activity and allows binding of calcium and localization on negatively charged phospholipid surfaces with subsequent activation of the coagulation pathway.[72-74] In the absence of carboxylation, vitamin K–dependent factors cannot bind to platelets, leading to hemostatic dysfunctions. Deficits of vitamin K can occur quickly due the short half-life of the vitamin K–dependent coagulation factors. Vitamin K is lipid soluble and present in two types: K_1 (phylloquinone) is found in greens and oils, and K_2 (menaquinone) is produced by the intestinal microflora. Absorption occurs in the intestine in the presence of bile salts.

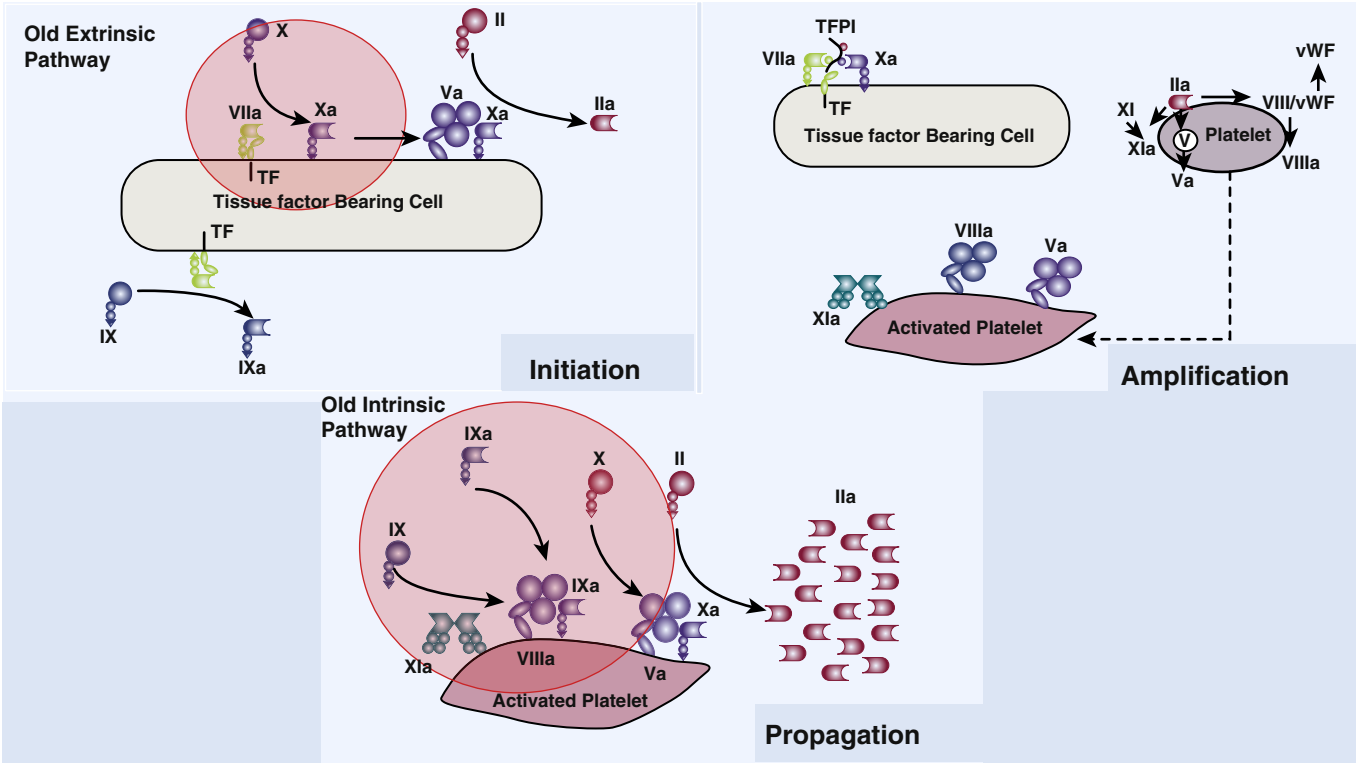

FIG. **15.2** Cell-based coagulation model. Coagulation occurs in three phases: initiation, amplification, and propagation. In the initiation, factor VIIa bound to tissue factor (TF) activates factor (F) IX and also FX. FXa then activates FV on the TF-bearing cell, complexes with factor FVa, and converts a small amount of prothrombin (II) to thrombin (IIa). In the amplification phase, the small amount of IIa activates platelets, causing release of α-granule contents including FV and activates FV, FXI, and FVIII by cleaving it from von Willebrand factor (vWF). In the propagation phase, FIXa generated by FVIIa/TF binds to the activated platelets and subsequently activates FX. This factor IXa is supplemented by factor IXa generated on the platelet surface by factor XIa. FXa and FVa then form the prothrombinase complex catalyzing a burst of thrombin generation. (Modified after Monroe DM, Hoffman M, Roberts HR: Platelets and thrombin generation. *Arterioscler Thromb Vasc Biol*. 2002; 22(9):1381–1389.)

Anticoagulation. Mechanisms of anticoagulation prevent spread of coagulation to unaffected areas and help to retain clot formation at sites of injury. The two best described pathways include the protease inhibitors antithrombin with its cofactor heparin and tissue factor pathway inhibitor (TFPI) and the protein C/protein S pathway. Antithrombin is one of the most important inhibitors of thrombin generation because of its high affinity for FIXa, FXa, and thrombin. The presence of its cofactor heparin antithrombin increases its activity up to 1000-fold. TFPI directly inhibits FXa and interacts with TF/FVIIa/FXa complex. Thrombin itself initiates anticoagulation by binding to thrombomodulin, which enables activation of endothelial-bound protein C. The complex of activated protein C (APC) and its cofactor protein S inactivates FVIIIa and FVa.

Fibrinolysis. The final step in the process of fibrinolysis is the conversion of the circulating zymogen plasminogen into active plasmin. This is mainly achieved by tissue-type plasminogen activator (t-PA) and, to a lesser degree, urokinase. In the presence of fibrin, binding of both plasminogen and t-PA to fibrin increases plasmin generation more than twofold.[75] The colocalization of both factors on fibrin aims to minimize indiscriminate fibrinolysis.

Antifibrinolysis. Plasma inhibitors (α_2-antiplasmin and plasminogen activator inhibitor [PAI]-1 and PAI-2) also limit plasmin activity locally and its generation in the circulation. The recently described thrombin activatable fibrinolysis inhibitor (TAFI), which is activated by thrombin concentrations near recently formed clots, appears to inhibit premature clot lysis by preventing docking of t-PA and plasminogen to fibrin.[75]

Evaluation

An increasing number of available tests enables the clinician to investigate all aspects of the hemostatic system, at least in the experimental setting. Unfortunately, fewer tests are available commercially, and many functional tests need to be performed on fresh blood. Most traditional coagulation profiles include platelet count, prothrombin time (PT; investigates factors V, VII, X, prothrombin, and fibrinogen), activated partial thromboplastin time (aPTT; factors V, VIII, IX, X, XI, XII, prothrombin, and fibrinogen), antithrombin (AT) activity, fibrinogen concentration, and a measure of fibrin breakdown, either fibrinogen degradation products (FDPs) or D-dimer concentrations (see Table 15.5). Although FDPs incorporate

fragments produced by degradation of fibrinogen and fibrin, D-dimers are specific for degradation of fibrin and therefore a better indicator of intravascular coagulation and subsequent fibrinolysis.

On cross-linking, a D-dimer neo-epitope is formed that is recognized by the antibodies in D-dimer assays.[76] Viscoelastic testing offers the advantage of evaluating coagulation in whole blood, taking into account cellular function and interaction with coagulation proteins. In theory, it should provide information about speed of clot formation, clot strength, and rapidity and efficiency of clot lysis as it occurs in the body. The clinician should be able to differentiate between hypocoagulable and hypercoagulable states and increased or decreased fibrinolysis in the patient. The technique has been investigated in numerous experimental and clinical studies in horses, but despite several modifications of the available assays,[77-79] many clinicians still feel that little additional information in comparison to commonly performed coagulation profiles is provided.

Interpretation

Abnormalities of the hemostatic system can be associated with disorders of the vascular wall, platelet numbers or function, and abnormalities of the plasma-based coagulation system. Disorders might be congenital or acquired. Several hereditary abnormalities have been described including deficiencies in von Willebrand factor, FVIII and prekallikrein, and functional platelet defects (see section on abnormalities of the plasma-based coagulation system). Acquired abnormalities are common with severe infectious or inflammatory systemic diseases including neoplasia and conditions causing vasculitis. Recently, acquired FVIII deficiency has also been reported.[80]

TREATMENT OF HEMATOPOIETIC DISORDERS

Hematologic abnormalities are frequently secondary to a different, primary disease, and with successful treatment of the primary process hematologic functions will normalize. However, if the hematologic abnormalities become life threatening, either due to acute blood loss, severe hypocoagulation, or inappropriate clot formation in the microvasculature, direct intervention might be necessary. Transfusion of whole blood or blood components and pharmacologic manipulation of the hemostatic system are discussed in the following section.

Transfusion Medicine

A transfusion can either be comprised of whole blood or blood components, depending on the individual needs of the patient. In equine medicine, blood is usually freshly collected whereas plasma can be prepared from fresh blood by gravity sedimentation or purchased frozen.

Approach to Acute Blood Loss

The total blood volume of a horse depends on the breed, age, and sex, with foals less than 100 days of age and stallions having higher blood volumes than animals greater than 100 days old and geldings and mares, respectively.[81,82] In Thoroughbreds, light breed horses' and draft horses' blood volume is approximately 100 mL/kg, 78 mL/kg, and 61 mL/kg (6%–10% of the body weight), respectively.[83] Horses can tolerate loss of up to 15% of their blood volume (approximately 9–15 mL/kg depending on breed; 4.5–7.5 L in a 500-kg horse) without causing overt effects on physical parameters and up to 25% to 30% (approximately 15–30 mL/kg depending on breed; 7.5–15 L in a 500-kg horse) might be tolerated without need for a transfusion. A whole blood transfusion is indicated when the oxygen-carrying capacity of an animal has decreased to a degree that oxygen delivery to the tissues is compromised. Because 98% of oxygen in the blood is carried by hemoglobin (Box 15.6), acute blood loss is much more likely to result in tissue hypoxia than many respiratory conditions. Colic, cardiac arrhythmias, and increase in cardiac troponin I (cTnI), presumably caused by tissue hypoxia, have all been reported in horses following acute hemorrhage and also secondary to methemoglobinemia.[84] The decision whether or not a transfusion is necessary depends on the amount of blood lost and the time scale over which this loss has occurred (acute blood loss is less well tolerated than chronic anemia). In people, a hemoglobin concentration of 7 g/dL has been used as transfusion threshold. Hypovolemia should be corrected first; however, overly aggressive correction is discouraged to avoid rapid increases in blood pressure and disruption of clot formation, particularly in uncontrolled bleeding. Initial hypotensive resuscitation in form of 20-mL/kg boluses of isotonic fluids or 2 to 4 mL/kg of hypertonic saline and maintaining a blood pressure of approximately 60 mm Hg has been recommended until control of bleeding has been achieved.[85] However, prolonged hypotension or failure to correct hypovolemia can also have deleterious effects, and achieving a balance can be challenging. Hydroxyethyl starch is best avoided due to its hypocoagulatory effects.[86] Commonly used clinicopathologic parameters such as heart and respiratory rate, PCV, and total plasma protein concentration are more suitable for monitoring changes in previously stable patients than for primary assessment of acute blood loss. Clinical parameters are strongly influenced by the primary disease process, whereas interpretation of PCV and plasma protein concentration requires knowledge of baseline values for the individual animal. In addition, values will not be reliable under conditions of acute blood loss as PCV and plasma protein concentration remain unchanged until lost volume is replaced by interstitial fluid. Plasma protein concentration often decreases first, and a normal or only minimally increased PCV and normal or low-normal plasma protein concentration in a clinically severely hypovolemic animal should raise suspicion of acute blood loss. Preexisting anemia, hypoproteinemia or hyperproteinemia, and splenic contraction further complicate an accurate assessment. More objective measures of tissue hypoxia and increased oxygen extraction in the periphery such as lactate concentrations, partial pressure of oxygen in the venous blood (PvO_2), and oxygen extraction ratio might be more helpful.

BOX 15.6 Calculation of Oxygen Content in the Blood

$$\text{Arterial oxygen content } (CaO_2) = (Hg \times 1.34 \times SaO_2) + (0.0031 \times PaO_2)$$

Hg: Hemoglobin (g/dL); 1.34 mL of oxygen carried per gram of hemoglobin; Sa_{O_2}: percentage of hemoglobin saturated with oxygen (%); 0.0031: mL of oxygen dissolved per dL blood per mm Hg (mL/dL/mm Hg); Pa_{O_2}: partial pressure of oxygen in arterial blood. A patient with a hemoglobin concentration of 15 g/dL, Sa_{O_2} of 98%, and Pa_{O_2} of 95 mm Hg has a blood oxygen content of 20 mL/dL.

Allogeneic Whole Blood Transfusion

Horses have seven known blood groups (A, C, D, K, P, Q, U), with each group also having multiple factors. This combination of groups and factors gives rise to approximately 400,000 possible blood types. Anti-Aa and anti-Qa antibodies are most frequently associated with transfusion reaction or neonatal isoerythrolysis, and ideally blood donors should be Aa and Qa negative. Blood donors should also not have had foals (hence a preference for geldings) or blood transfusions to decrease chances of the presence of anti-RBC antibodies. Donkey and mule RBCs carry an antigen called *donkey factor* that is presumed to contribute to the high risk of neonatal isoerythrolysis in mule foals.[87] A similar antigen is also suspected on donkey platelets, predisposing them to neonatal alloimmune thrombocytopenia.[88] Donkeys should therefore not be used as blood donors for horses and only receive horse blood free of anti–donkey factor antibodies. Major (donor's RBCs with recipient's plasma) and minor (donor's plasma with recipient's RBCs) crossmatching should include evaluation for agglutination and hemolysis. Investigation of a hemolytic response requires the addition of rabbit complement and is not carried out by every laboratory. Reassuringly, a recent study showed that incompatibility was always indicated by the agglutination test, whether or not hemolysis was also detected.[89] Because of the low natural occurrence and minimal clinical effects of alloantibodies in horses, a first transfusion is frequently carried out without prior crossmatching. However, use of a matched donor significantly prolongs the life span of transfused RBCs. If blood type is matched and crossmatches indicate compatibility, the mean life span of transfused autologous and allogeneic RBCs is approximately 89 days and 39 days, respectively, with a mean posttransfusion allogeneic RBC half-life of 33.5 days.[89,90] The half-life was reduced to 11 days and 4.7 days, respectively, if evidence of minimal or moderate agglutination was noted on the major crossmatch reaction.[89] This suggests that at least a major agglutination crossmatch should be carried out if several blood donors and time for crossmatching are available. The most antigenic group appears to be Aa, with all Aa-negative horses developing antibodies if transfused with Aa-positive RBCs; those persisted for over a year.[89,91] Antibodies against other RBC antigens develop infrequently, can be detected 1 to 154 weeks after transfusion, and might disappear again after 4 weeks.[91]

Blood donors should be free of infectious diseases, most notably equine infectious anemia (EIA). Approximately 20% of the donor's blood volume can be collected (8 L in a 500-kg horse) every 30 days. Volume replacement with isotonic fluids is recommended if greater than 15% of blood volume is collected. The aim is replacing 25% to 50% of the lost blood to ensure adequate oxygen delivery while the patient's RBCs are regenerated. In horses undergoing experimental blood loss of 15 mL/kg once or 15 mL/kg three times on consecutive days, the daily RBC production rate increased from 54,207 ± 7682 cells/μL per day to 83,620 ± 28,740 and 105,840 ± 19,290 cells/μL per day, respectively,[92] which equates to approximately 0.5% to 1.0% increase in PCV per day. The approximate amount of blood needed can be calculated using the equation in Box 15.7. Blood should be collected through a large-bore catheter (10–12 gauge) inserted in a rostral direction (against the direction of flow) into the jugular vein into blood bags containing 3.2% sodium citrate at a blood-to-anticoagulant ratio of 9:1. If blood is to be stored, citrate-phosphate-dextrose with adenine (CPDA) should be used and blood kept at 4°C. Red blood cells from autologous equine blood stored for 28 days had a half-life of 29 days whereas compatible allogeneic blood stored for 24 hours only had a half-life of 20 days.[90,93] Pretransfusion heart and respiratory rates and rectal temperature should be determined before administration of blood through an inline filter beginning slowly at 0.1 mL/kg for the first 15 minutes (3–4 mL/min for a 500-kg horse), checking vital parameters every 5 minutes. If no adverse reactions are observed, the remaining transfusion can be given at 20 mL/kg/hr, checking vital parameters every 10 to 15 minutes until the transfusion is complete. Adverse reactions occur in approximately 16% of horses[94] and can be as high as 87.5% in crossmatch-incompatible transfusions.[89] Hemolytic reactions can occur immediately or up to 24 hours and longer after the transfusion. Other adverse reactions include fever and type I hypersensitivity reactions ranging from urticaria, pruritus, and piloerection to anaphylactic shock.[95] Depending on severity, antihistamines (hydroxyzine 0.5–1.0 mg/kg PO q12h), corticosteroids (dexamethasone 0.1 mg/kg intravenously [IV]), or epinephrine (0.01–0.02 mL/kg of a 1:1000 solution IV; 5–10 mL for a 500-kg horse) may be indicated.

BOX 15.7 Calculation of Blood Volume Needed to Increase PCV by Desired Percentage

Blood transfusion volume (mL) = body weight (kg) × 80 mL/kg × [(desired PCV − actual PCV) /donor PCV]

If the recipient (500 kg) has a PCV of 12% and a PCV of 20% is desired, 9 L of donor blood with a PCV of 35% needs to be administered: 500 kg × 80 mL/kg × [(20 −12)/35] = 9142 mL = approximately 9 L.

Autologous Blood Transfusion

Autologous blood transfusions can be considered if blood loss is anticipated in advance—for example, during a planned surgery or following major body cavity bleeds, most commonly hemoabdomen. The advantage is a longer RBC half-life if blood is collected in advance and minimal risk of transfusion reaction. The half-life of RBCs obtained from a body cavity has not been investigated in horses. In the past, presence or suspicion of neoplasia has been considered a contraindication to autotransfusion; however, in people no effect on metastasis or prognosis has been established. Whether or not an anticoagulant should be added to blood collected from a body cavity is controversial as blood in contact with serosal surfaces for longer than 1 hour becomes defibrinated. Platelets and coagulation factors are also diminished, making an allogeneic transfusion potentially a better option in cases of hypocoagulation. Recommendations in dogs range from addition of 0.05 to 0.14 mL of anticoagulant per milliliter of blood, whereas in horses a blood-to-anticoagulant ratio of 15:1 (0.07 mL/mL of blood) has been suggested.[96,97] In horses, blood from the abdomen can be collected using a 30-Fr Foley catheter or 28-Fr chest drain, inserted into the abdomen through a sterile stab incision and connected to a blood collection bag. Blood can then be directly administered through an intravenous blood administration set.[97,98]

Alternative Oxygen Carriers

Hemoglobin-based oxygen carriers have been investigated experimentally and used clinically in horses (11–16 mL/kg)

and a foal (22 mL/kg).[99-102] The half-life is short (1.3–12 hours depending on size of aggregates), making it only suitable as rescue therapy until a suitable blood donor has been localized.[103] Availability of the product has been limited in recent years.

Platelet Transfusion

Platelet transfusions might be indicated in horses with severe thrombocytopenia or in horses with known functional platelet abnormalities that have sustained a trauma or are to undergo surgery. The risk of hemorrhage is dependent on platelet numbers, platelet function, and the activation state of the plasma-based coagulation and fibrinolysis system and the endothelium and vascular wall. In horses, a platelet count less than 30,000 to 50,000/μL is likely to be associated with clinical signs such as petechiae or epistaxis.[57,104,105] If the platelet count decreases below 10,000/μL, active hemorrhage such as prolonged bleeding after venipuncture or hematoma formation frequently occurs.[105-107] Clinical signs often stabilize or disappear once the platelet counts increase above 15,000 to 30,000/μL, particularly in animals with few or no comorbidities. In horses with thrombocytopenia secondary to neoplastic conditions but rarely also primary immune-mediated thrombocytopenia (ITP), clinical signs can be observed over a much wider range of platelet numbers from 20,000 to 91,000/μL, suggesting that other factors also influence the tendency to bleed. A platelet transfusion is indicated if prolonged bleeding is observed or suspected (e.g., due to a sudden decrease in PCV).[105,108] Most equine hospitals lack the ability for apheresis or to concentrate platelets, but a platelet transfusion can still be prepared if a donor horse is available. In people, six platelet antigen systems have been described to date, contributing to neonatal alloimmune thrombocytopenia, transfusion refractoriness, and transfusion reactions.[109] Potential platelet alloantigens have been identified in equids, but their clinical significance is yet unknown.[88,110] It seems likely that equine platelet antigens function similarly to their human counterparts. Citrate-based anticoagulant solutions are recommended for most platelet preparations, and care should be taken not to underfill containers because platelet function is affected by increasing citrate concentrations.[111] Glass bottles are not suitable for collection as glass surfaces activate platelets. Because of their small size, platelets remain in suspension when RBCs are allowed to settle by gravity as is commonly done for preparation of fresh equine plasma. The harvested plasma therefore contains the vast majority of the blood platelets (and leukocytes) and can be used as a platelet transfusion. If not administered immediately, the platelet-rich plasma should be stored at room temperature (22°C) as exposure to temperatures below 59°F (15°C) induces irreversible changes and significantly decreases platelet function. Platelets can be stored under constant agitation for up to 5 days, but the risk of bacterial contamination is considered to be higher at this storage temperature. In dogs, a fresh whole blood transfusion of 10 mL/kg of body weight is expected to increase the recipient's platelet count by a maximum of 10,000/μL, whereas giving 8×10^{10} platelets per 10 kg of body weight results in a maximum increase of 40,000/μL.[112] No guidelines are available for horses but similar to slightly lower increases might be expected, depending on the donor's platelet count. Administration of drugs that negatively influence platelet function (acetylsalicylic acid, clopidogrel, heparin) is probably contraindicated. Other nonsteroidal antiinflammatory drugs (NSAIDs) such as flunixin meglumine and phenylbutazone have minimal effects on in vitro platelet function, and their benefits might outweigh any theoretical negative effects.[113-115] Whether drugs that enhance platelet function or decrease fibrinolysis such as etamsylate, tranexamic, or ε-aminocaproic acid are beneficial remains to be established.[78,116,117]

Plasma Transfusion

Plasma transfusions might be indicated in horses with low oncotic pressure due to protein-losing diseases, to combat systemic inflammation, in foals with failure of passive transfer or in need of *Rhodococcus equi* prophylaxis, and in horses with coagulopathies to provide essential coagulation factors. Frozen equine plasma is commercially available or can be prepared fresh by gravity sedimentation from collected blood. Fresh frozen plasma refers to plasma separated from blood within 8 hours of collection and stored at −0.4°F (−18°C) for up to 1 year. If plasma is separated after 8 hours or stored for longer than 1 year it is referred to as *frozen plasma*. Following preparation of plasma from whole blood by gravity sedimentation over 48 hours at 41°F (5°C), clotting factors retain 66% to 95% of their activity, and all activities remain within the laboratory reference ranges. Activities for all factors except FX remain within normal ranges after storage at −4°F (−20°C) for 90 days.[118] The amount of plasma needed to increase plasma protein concentrations can be calculated as follows: Volume (L) = ([TPTarget − TPPatient] × 0.05 × Body weight [kg]) ÷ TPDonor. A 500-kg horse will require approximately 4 to 5 L of plasma to increase the plasma protein concentration by 1 g/dL. Administration of plasma follows the same guidelines as blood administration, using a filter and beginning slowly, while closely monitoring for adverse reactions. Reactions to commercial plasma have a reported incidence of 8.7% in foals and 0% in adults, while the incidence with noncommercial plasma is 10%.[118,119] In case of a reaction, the plasma infusion should immediately be discontinued. Depending on severity, treatments as outlined in the discussion on whole blood transfusions can be initiated. Frequently, administration of an NSAID such as flunixin meglumine (1.0 mg/kg IV) is sufficient to control symptoms, and the transfusions can be continued at a very slow rate once clinical signs have returned to pretransfusion values.

Pharmacologic Treatment of Hemostatic Dysfunctions

Pharmacologic options for management of hemostatic dysfunctions can be divided into procoagulants and anticoagulants, fibrinolytic drugs, and those modifying platelet function, with some drugs belonging to more than one class.

Procoagulants and Drugs That Enhance Platelet Function

Drugs promoting hemostasis include the synthetic lysine analogues ε-aminocaproic acid and tranexamic acid. Both act by reversibly blocking the lysine binding sites on plasminogen. This prevents plasmin formation and improves clot stability and longevity by decreasing fibrinolysis. Indications in horses include trauma, rupture of major vessels, and bleeding into body cavities. Anecdotally, tranexamic acid has been used in a horse with Glanzmann's thrombasthenia with apparent clinical

success. The currently suggested doses for ε-aminocaproic acid (3.5 mg/kg/min for 15 minutes followed by 0.25 mg/kg/min IV) in horses target therapeutic plasma concentration required in humans. It has been suggested that in horses, due to a lower fibrinolytic activity and higher threshold for induction of fibrinolysis, 20 times lower plasma concentration might be sufficient to achieve the desired effect.[78] Lower doses have not yet been examined clinically in horses. Pharmacokinetic data for tranexamic acid are not available for horses, but doses of 5 to 25 mg/kg PO q6–12hr or 10 mg/kg IV q 12 h have been suggested. Formaldehyde (10–150 mL of 10% buffered formalin in 1 L of isotonic fluids IV or 0.37% formaldehyde) has long been used in desperate situations. It has been suggested to enhance primary hemostasis in humans and goats by activating platelets, but experimental investigations showed no effect on coagulation parameters in horses. Use of higher doses (1 L of 0.74%–1.0% formaldehyde in lactated Ringer's solution IV) results in adverse reactions including muscle tremor, tachycardia, tachypnea, nasal and ocular discharge, restlessness, and mild colic signs. Signs resolve quickly after discontinuation of the infusion.[120] Administration of higher concentrations has been associated with hemolysis. Etamsylate, an antihemorrhagic, nonthrombotic drug promoting platelet adhesion by increasing P-selectin expression on platelets, has no effects on bleeding time in healthy horses when used at 12.5 mg/kg.[116] Tramadol, used at concentrations expected to be achieved in vivo, enhances adenosine diphosphate (ADP)-induced aggregation of platelets from fed, but not fasted, horses in vitro. The potential proaggregatory effects of tramadol need to be investigated further in the experimental and clinical setting.[121] Conjugated estrogens (0.05–0.1 mg/kg IV q 12–24 h) have been used in mares with postpartum hemorrhage.[122]

Anticoagulants and Drugs That Decrease Platelet Function

Treatment with either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) might prevent clot formation in the microcirculation. LMWH has fewer side effects than UFH, and significantly fewer jugular vein changes were noted in horses treated with LMWH compared with UFH in surgical colic cases, suggesting that it may have superior anticoagulant properties.[123] In a study investigating fibrin deposition in the microcirculation of horses with gastrointestinal disease, fibrin deposits were detected in 40% of nonsurviving horses overall but only in 1 out of 8 horses (12.5%) receiving 50 IU/kg LMWH once daily for 4 days.[124] Viscoelastic testing appears to be the best way for monitoring LMWH therapy: aPTT has a weak correlation with anti–factor Xa activity whereas thromboelastography and Sonoclot variables are significantly, albeit modestly, correlated with anti–factor Xa activity. Absolute and relative changes in the thromboelastography parameter *R* (ΔR and $\%\Delta R$) predict anti–factor Xa activity below the suggested thromboprophylactic level best, at least in healthy horses.[125] LMWH and UFH also have a dose-dependent inhibitory effect on equine myeloperoxidase (MPO) in vitro and are able to suppress MPO cell-bound activity in equine digital endothelial cells, indicating some antiinflammatory properties.[126] Recommended doses for enoxaparin are 0.35 mg/kg SC q 24 h and for dalteparin 50 IU/kg SC q 24 h in adult horses and 100 IU/kg SC q 24 h in neonatal foals.[123,127,128] Fresh or fresh frozen plasma with or without the addition of heparin (anecdotally 1500 U/L UFH) could also be used in hypercoagulation as antithrombin concentrations, one of the main anticoagulants, are frequently low in horses with systemic inflammation. Acetylsalicylic acid (aspirin) has been suggested as an antithrombotic agent in the horse because of its ability to decrease platelet aggregation in human patients and thromboxane production in horses.[54,129] However, it has a short plasma half-life in horses, and, in contrast to human platelets, the effects are largely limited to collagen-induced aggregation, which probably only plays a very minor role in inflammation-associated coagulopathies.[129,130] Nevertheless, aspirin reduces endotoxin-induced thromboxane formation and digital hypoperfusion in the experimental setting.[131] Doses vary widely, and 10 to 100 mg/kg PO q 24–48 h have been suggested. In people, up to 30% to 40% of patients do not respond to aspirin (nonresponders).[132] A nonresponse to aspirin has also been identified in several equine studies and appears to be of a similar magnitude.[54,129] Clopidogrel is an antiplatelet medication acting by inhibiting platelet ADP receptors. Experimentally, it inhibits some platelet functions in horses, such as ADP- and arachidonic acid–induced aggregation, within hours of administration of a loading dose (6.5 mg/kg PO once). This effect can be maintained on a low dose (1.4 mg/kg PO q 24 h) for the duration of treatment, and platelet function is restored within 6 days after the end of therapy.[47] Other measures of platelet function and activation, such as collagen-induced aggregation, P-selectin expression, platelet-neutrophil aggregate formation, modified thromboelastography, and flow cytometric tests for platelet fibrinogen binding and phosphatidylserine externalization, are not affected by clopidogrel (2 mg/kg PO q 24 h) or aspirin (5 mg/kg PO q 24 h).[133,134] Following experimental lipopolysaccharide (LPS) administration, decreases in ADP-induced platelet aggregation and decreased heart rates were noted in clopidogrel-treated horses. However, no significant differences in other hematologic and hemostatic variables were detected, making its clinical efficacy in equine inflammatory conditions doubtful.[50] In addition, no response to clopridogrel was seen in two of six horses in one study, potentially suggesting a nonresponder state similar to that observed with aspirin. Other treatments, including pentoxifylline and aminophylline, have no or only very limited effects on equine platelet function, and coagulation and clinical effects on the coagulation system still need to be established.[121]

Fibrinolytic Drugs

Recombinant human tissue plasminogen activator (rt-PA) has been used locally to remove intraocular and intrapleural fibrin accumulations in horses with uveitis and pleuropneumonia, respectively.[135,136] Anecdotally, it has also been used systemically in cases of suspected neonatal stroke (0.2 mg/kg IV once within 4 hours of onset of neurologic signs; Kevin Corley, personal communication, November 2015). Pharmacokinetics in adult horses have been described; 1 mg/kg (given as an infusion with a final concentration of 2 mg/mL IV over 30 minutes) is well tolerated and results in plasma levels similar to those required for thrombolysis in people.[137] Regional treatment of digital artery thrombosis with urokinase (approximately 80 U/kg/min for 60 minutes) was unsuccessfully attempted in a foal.[138] In contrast to rt-PA and urokinase, streptokinase, a human plasminogen activating enzyme secreted by streptococci species, shows experimentally minimal ability to activate equine plasminogen.[139] However, regional bolus

administration of 100 mL of streptokinase solution (7500 U/mL in 0.9% sodium chloride) reportedly showed thrombolytic effects but could not recanalize experimentally thrombosed jugular veins in horses permanently.[140] In a different report, infiltration of a thrombosed jugular vein using 6 mL of 125,000 U/mL streptokinase in 0.9% sodium chloride q 24 h for 3 days resulted in some thrombolysis.[141]

DISORDERS ASSOCIATED WITH ACUTE AND CHRONIC BLOOD LOSS

Acute blood loss from an external wound or injury is usually obvious and does not represent a diagnostic challenge, whereas bleeding into body cavities or the source of epistaxis can be more difficult to establish. With a combination of thorough history taking, physical and laboratory examination, and diagnostic imaging, particularly ultrasonography and endoscopy, the origin of blood loss can usually be identified. Box 15.2 lists possible causes of blood loss in the horse.

Hemoperitoneum

Hemoperitoneum (or hemoabdomen) is one of the more common causes of acute internal blood loss. It affects horses of all ages and breeds, but the risk might be increased in Thoroughbreds, Arabians, and mature and aged horses.[142] The clinical signs can resemble acute colic as horses are markedly hypovolemic with high heart and respiratory rates, pale to pale-pink mucous membranes with prolonged capillary refill times, and profuse sweating, and often show signs of pain or muscle fasciculations. Depression, abdominal distention, reluctance to move, weakness, and ataxia can also be noted. Laboratory analysis might show anemia and hypoproteinemia, but with acute blood loss changes in both parameters can be mild or absent or even increased.[142] The white cell count can be low, normal, or high, depending on severity and underlying cause, and the platelet count is frequently reduced. Lactate concentrations are commonly high, corresponding with a low venous oxygen tension (Pvo_2). Coagulation parameters remain initially unchanged unless the bleeding is caused by an underlying coagulopathy. Definitive diagnosis can be established ultrasonographically if free echoic fluid with the characteristic swirling appearance is observed. Abdominocentesis is rarely necessary to confirm the presence of blood and is discouraged because of the risk of introduction of an infection. The recovered fluid will resemble blood with a high PCV and protein concentration. Causes of hemoperitoneum include splenic, hepatic, or mesenteric vessel rupture, neoplasm, intraabdominal abscess with necrosis of associated vessels, complications of pregnancy, foaling and castration, pelvic injury or fracture, and coagulopathies.[142-144] Ovarian hematomas associated with hemoperitoneum have been identified in miniature horse breeds.[99,142,145] Hemoperitoneum has been observed after treatment with warfarin, and sudden death secondary to hemoperitoneum has been reported in racehorses in which traces of rodenticide anticoagulants were found.[146] Abdominal ultrasonography might help in establishing the underlying cause, but in 25% to 42% of cases an etiology cannot be established.[143,144] Management is primarily aimed at stabilizing the patient hemodynamically, using intravenous fluids and transfusions as necessary. Close observation is necessary as tissue hypoxia can predispose horses to arrhythmias, especially ventricular tachycardia, and secondary colic.[84] Celiotomy might be necessary if bleeding from a mesenteric vessel in conjunction with a surgical intestinal lesion is suspected or if bleeding continues or recurs despite medical management. In one retrospective study, the source of the bleeding could be addressed during surgery in 19% of surgically managed cases whereas in 35% the origin of the hemorrhage could not be identified.[143] Overall, 42% of surgically managed horses survived in this study and 57% in another.[142,143] Laparoscopy is probably of limited value as visualization is obscured by blood.[143] The overall prognosis for hemoperitoneum depends on the severity of hemorrhage and the underlying cause, with survival rates of 39% to 75% having been reported.[144]

Hemothorax

In foals, rib fractures are a common cause of hemothorax whereas in adult horses trauma, neoplasm, iatrogenic injury during pulmonary wedge and core biopsies, and strenuous treadmill exercise have been reported.[147-150]

Intestinal Blood Loss

Severe and potentially fatal postoperative blood loss has been reported following enterotomies and intestinal anastomoses in horses. Signs are compatible with acute blood loss, and melena might be noticed within 72 hours of surgery. Continued bleeding necessitated a second celiotomy in two of six horses in one study.[151] Mild anemia with PCV between 25% and 30% and occasionally positive occult fecal blood tests have been reported in horses with right dorsal colitis.[152,153] Fecal occult blood tests are not well validated in horses. It has previously been stated that 1 to 2 L of blood loss into the intestinal tract is necessary to produce a positive fecal occult blood test. Newer tests seem to be more sensitive. A guaiac-based fecal occult blood test reportedly has a sensitivity and specificity of 64% and 100% (any gastrointestinal ulceration), 70% and 53% (colonic ulceration), and 64% and 52% (gastric ulceration).[154] A carbonic anhydrase I (present in erythrocytes but not intestinal tract) and II isoenzyme enzyme-linked immunosorbent assay (ELISA) with the ability to detect 50 µg of hemoglobin per gram of feces has been investigated as a marker for occult blood in horses. An increase in carbonic anhydrase I was noted after oral administration of 200 mL of blood to healthy horses, but variation was large.[155] A new lateral flow immunoassay (SUCCEED Equine Fecal Blood Test) detecting equine hemoglobin at concentrations of 5 to 10 µg/g of feces is being investigated. At this sensitivity, rectal examinations cause positive results for 24 to 48 hours. A negative result probably rules out significant hemorrhage, but the clinical relevance of a positive result still needs to be established (N. Kerbyson, personal communication, November 2015).

Pulmonary Hemorrhage

Pulmonary hemorrhage secondary to *Leptospira* spp. infection causing mild to moderate anemia has been documented in foals and proposed in adult horses.[156,157] Clinical observations suggest that in light-breed horses with lone atrial fibrillation epistaxis is occasionally encountered, whereas draft horses with atrial fibrillation can experience severe exercise-induced pulmonary hemorrhage. Small thrombi forming or lodging in the pulmonary vasculature are unlikely to be noticed clinically. In contrast, massive pulmonary thromboembolism, defined as affecting more than two thirds of a lung and occluding greater than 50% of the pulmonary vasculature, or embolization in both lungs can lead rapidly to right-sided heart failure,

cardiogenic shock, reflex bronchoconstriction, and death. Clinical signs include tachypnea, epistaxis, and hemoptysis, and sudden death occurred in three of six horses.[158] Inhalation of foreign bodies can also be associated with recurrent pulmonary hemorrhage. Causes of epistaxis in the horse are listed in Box 15.2.

Phenylephrine-Associated Bleeding

Epistaxis, hemoptysis, hemothorax, hemoperitoneum, hemopericardium, and rupture of the middle uterine artery in a nonpregnant mare have been reported in five horses after phenylephrine administration for correction of nephrosplenic entrapment. Four of the five horses died, and a 64-times higher risk for phenylephrine-associated bleeding was identified for horses ≥15 years old. A mild and transient episode of epistaxis or hemoptysis immediately after administration of phenylephrine might be a prodromal sign. Horses should be monitored closely for internal hemorrhage, and preparation for a blood transfusion should be initiated immediately if any evidence of bleeding is noted, even if the amount of external blood loss initially appears inconsequential.[159]

Periparturient Blood Loss in Mares

Periparturient bleeding from the major uterine arteries or, less frequently, the ovarian, external iliac, vaginal, and adrenal arteries is a well-recognized cause of urogenital blood loss in mares. Arterial injuries occur most frequently in the proximal uterine artery, and atrophy of smooth muscle cells with fibrosis of the arterial wall is a predisposing factor.[160] Less common locations of blood loss include the placental attachment of the uterus, intrauterine or vaginal bleeding, and intramural hematomas. Hemorrhage is estimated to affect 2% to 3% of broodmares and comprises 17% of postpartum emergencies admitted to a hospital.[122,161] It also accounts for close to 40% of postpartum deaths in mares.[162] Bleeding often develops within 48 hours after foaling, but antepartum bleeding as early as during the fifth month of gestation and up to 4 months after parturition is possible.[122] Predisposing factors include older age, multiparity, and dystocia, but bleeding can occur in mares of any age or parity.[161] Mares present with signs of abdominal pain and hypovolemic shock; vaginal bleeding, ataxia, and recumbency are also reported. Laboratory evaluation is consistent with recent blood loss with a median PCV of 39% and a total protein concentration of 5.0 g/L in one report. Hemorrhage is often suspected based on history and presenting clinical and laboratory investigations, but confirmation of the diagnosis can be difficult. Transrectal palpation and rectal and transabdominal ultrasonography are considered most useful. In the past, clinicians have advised against rectal examinations due to fears of disrupting hematoma formation and worsening bleeding. A recent study found no association between rectal palpation and outcome, but a cautious approach is still advisable.[122] Prompt medical treatment aimed at cardiovascular stabilization with or without the addition of procoagulant drugs and pain management is of utmost priority. Antiinflammatory drugs and, depending on the case, antimicrobials might also be indicated. Most clinicians advise against surgical exploration if bleeding is confirmed, as surgical access to the urogenital vasculature is limited and the anesthetic risk high. However, intestinal lesions are also common in postpartum mares and concurrent presence of intestinal lesions and hemorrhage has been reported.[122,161] Abdominal exploration might become necessary if this is suspected.[122] Complications are encountered in close to 80% of surviving mares and include fever, retained fetal membranes, laminitis, arrhythmias, colic, colitis, and peritonitis in decreasing frequency. Reports on outcome vary widely, with survival ranging from 0% to 88%.[142] Anecdotally, bleeding into the broad ligament, in contrast to development of hemoperitoneum, has been suggested to be more favorable, and two reports have associated antepartum hemorrhage with a poor prognosis with no survivors.[142,143] This was not confirmed in the largest study done so far; the only factor associated with prognosis was tachycardia at admission and during hospitalization and vaginal hemorrhage, although only two mares presented with this condition.[122] Little is known about effects of periparturient hemorrhage on future reproductive performance. Arnold et al.[122] reported that 49% of surviving mares for which follow-up information was available produced at least one foal.

Renal and Urethral Hemorrhage

Renal hemorrhage severe enough to cause anemia has been reported in horses with pyelonephritis (four of seven horses were Arabians), idiopathic hematuria, and renal pseudoaneurysm in an Arabian colt.[163-165] In male horses, bleeding from urethral rents might occur, but this is rarely associated with significant blood loss. These conditions are discussed in detail in Chapter 14.

DISORDERS ASSOCIATED WITH HEMOLYSIS

Hemolysis refers to the intravascular or extravascular destruction of erythrocytes. Destruction can be immune mediated or secondary to infection or oxidative injury; a list of differential diagnoses for hemolysis in the horse is given in Box 15.4.

Immune-Mediated Hemolysis

Immune-Mediated Hemolytic Anemia

Immune-mediated hemolytic anemia (IMHA) can occur independently or concurrently with immune-mediated thrombocytopenia (IMT) in horses. Both conditions are caused by antibody-mediated destruction of RBCs and platelets, respectively. Antibodies can be directed against the unaltered cell surface (primary or idiopathic; examples include autoimmune disease, neonatal isoerythrolysis, or hemolysis following transfusion) or against a surface that has been antigenically altered by secondary causes.[166] Secondary IMHA in horses has been reported with neoplasia, *Rhodococcus equi* infection in foals, clostridial myositis, abscess formation, and drug administration.[166-172] Penicillin is one of the best established drugs causing IMHA in horses, and low titers of anti–penicillin antibodies of the immunoglobulin M (IgM) class were present in 77% of horses tested.[173-176] Hemolysis is thought to be associated with IgG antibodies and high titers of IgG antibody that agglutinated penicillin-coated equine RBCs are found in horses with penicillin-induced IMHA. Titers of anti–penicillin antibody decrease rapidly once penicillin is discontinued but remain detectable for months. Anemia might not reoccur after challenge with penicillin, but usage should probably still be discouraged in horses that have experienced penicillin-induced IMHA.[175] Trimethoprim-sulfamethoxazole has also been suspected as a cause of IMHA.[177] In addition, IMHA and increased hepatic enzyme activities were reported in four foals

17 to 20 days after initiation of treatment with doxycycline and rifampin against *R. equi* infection.[178] Treatment for IMHA includes immunosuppressive drugs, such as dexamethasone (0.1–0.2 mg/kg IV q 24 h), prednisolone (1.0–2.0 mg/kg IV, IM, or PO q 24 h), or, in refractory cases, azathioprine (3.0 mg/kg PO q 24 h).

Neonatal Isoerythrolysis

Neonatal isoerythrolysis is a common IMHA caused by an incompatibility between the mare's plasma and foal's RBCs. It is discussed in detail in Chapter 20.

Alloimmune Neonatal Neutropenia

Immune-mediated destruction of neutrophils in foals has been reported in a Thoroughbred and an Arabian colt.[24,179] A further report describes three foals of varying breeds, but sepsis was not convincingly ruled out.[180] The pathophysiology is presumed to be similar to neonatal isoerythrolysis, but the disease appears to be comparatively rare. Administration of a single injection of G-CSF (3.5–6 μg/kg SC) resulted in a considerable increase in peripheral neutrophils, but one foal required repeated injections every 3 to 4 days (four injections total). Both foals recovered completely.[24,179]

Evans Syndrome

Evans syndrome is characterized by the simultaneous presence of IMHA, thrombocytopenia, and/or leukopenia in the absence of a known underlying cause. Specific cross-reacting autoantibodies (usually IgG) are directed against red cells and platelets causing simultaneous or sequential development of hemolytic anemia and thrombocytopenia. Evans syndrome is rare, and few cases have been published in horses.[181-184]

Infectious Causes of Hemolysis

Equine Infectious Anemia

The equine infectious anemia (EIA) virus is a blood-borne RNA virus with a worldwide distribution belonging to the family of Retroviridae, genus *Lentivirus*. The disease is also referred to as *swamp fever*. The virus utilizes two enzymes, reverse transcriptase and integrase, to generate and integrate viral DNA into the host-cell genome. Virus replication occurs in monocytes, dendritic cells, tissue macrophages, and endothelial cells.[185] Once infected, horses remain lifelong carriers. Transmission occurs naturally via blood-feeding insects, particularly Tabanidae (horse and deer flies) or blood-contaminated instruments or needles. In an outbreak in Ireland, introduction of the virus into the country was traced to contaminated blood products, and aerosol spread between horses in a barn was strongly suspected.[186,187] Three distinct phases (acute, chronic, and inapparent) have been described, and clinical signs differ depending on the stage of the disease. Following an incubation period of 1 to 4 weeks, once viral burdens reach a threshold level, proinflammatory cytokine release initiates clinical signs. Fever and thrombocytopenia are considered to be the most reliable clinical indicators but are far from pathognomonic for EIA. Interleukin-6 (IL-6) and tumor necrosis factor (TNF) are thought to induce a febrile response. Thrombocytopenia is caused by a combination of immune-mediated destruction; suppression of megakaryocyte colony growth in the bone marrow by TNF and transforming growth factor–β (TGF-β); and possibly increased release of platelet agonists including thrombin, plasmin, and serotonin, triggering platelet aggregation.[188] Platelet function is also compromised, contributing to bleeding tendencies.[189] Intravascular and extravascular hemolysis and downregulation of erythropoiesis by TNF cause anemia. Depression, weakness, hemorrhage, peripheral edema, and weight loss are commonly seen in the chronic form but can also accompany the acute stages.[186,187] Inapparent carriers show no clinical signs, but periods of stress, immunosuppression, or treatment with corticosteroids can induce recrudescence. Hyperglobulinemia and glomerulonephritis can also be present. Diagnosis currently still relies on serology. Because EIA virus causes lifelong infection, presence of antibodies implies presence of virus, not mere exposure. The agar gel immunodiffusion assay (AGID; Coggins test) is still the most widely used test and detects antibodies against the major core protein p26. Other U.S. Department of Agriculture (USDA)-approved tests include several ELISA kits. In comparison to the AGID, ELISAs are considered to be less prone to human error and more sensitive, albeit less specific. A positive ELISA result therefore needs to be confirmed by AGID. Immunoblot is not an approved test but can be used to resolve equivocal results. One ELISA kit also detects glycoprotein 45 (gp45), and immunoblot can detect proteins gp90 and gp45 in addition to p26. Time from infection to seroconversion varies widely depending on viral dose, virus strain, and test used (between 21 and 180 days).[190] Proviral DNA integrated into the host cell can be detected by polymerase chain reaction (PCR) whereas viral RNA can be detected by reverse transcriptase–PCR (RT-PCR). The high variability of the viral genome and the lack of a confirmed conserved genomic region suitable as a primer binding sequence have hampered widespread implementation of this technique. In an outbreak in Ireland specific PCR and RT-PCR assays were developed for the particular strain of the virus present. These assays detected viral RNA and DNA in all tissues, nasal secretions, and genital swabs, and RNA was also detected in saliva. Viral DNA was detected in the plasma of all the seropositive horses tested, but viral RNA was detected in only 52% of these samples.[191,192]

Piroplasmosis/Babesiosis

Equine piroplasmosis or babesiosis is a tick-borne disease caused by two intra–erythrocytic apicomplexan equine-specific hemoprotozoa, *Babesia caballi* and *Theileria* (previously *Babesia*) *equi.* Although North America and Canada are considered free of the disease, the parasites and their tick vectors are endemic to most countries with tropical, subtropical, and occasional temperate climates. Central and South America, Cuba, at least parts of Mexico, Southern Europe, Asia, and Africa are considered endemic, and outbreaks in the United States have repeatedly been reported.[193,194] The fact that horses recovering from the disease remain inapparent carriers and a potential reservoir strongly affects management in endemic and nonendemic or free areas. Carrier state in untreated horses is lifelong for *T. equi* whereas *B. caballi* can be cleared from the horse. Virulence varies strongly depending on geographic location and potentially genetic differences.[195] Natural vectors for *T. equi* in North America include *Dermacentor variabilis, Boophilus (Rhiphicephalus) microplus,* and *Amblyomma cajennense* and *Dermacentor nitens* and *Dermacentor albipictus* for *B. caballi.* Transmission from dam to fetus has also been reported. Iatrogenic transmission via contaminated blood transfusions, but also tick transmission, caused recent outbreaks in Florida and southern Texas.[194,196] The life cycle of *B. caballi* and *T. equi*

differs. *B. caballi* directly invades erythrocytes whereas the first developmental stage of *T. equi* takes place in leukocytes. Intravascular and extravascular hemolysis ensues, frequently accompanied by thrombocytopenia and coagulopathies, leading to clinical signs of lethargy, fever, petechiae, edema, and hemoglobinuria. Colic, respiratory, and neurologic signs are also possible. Signs are milder for *B. caballi* compared with *T. equi* and develop within 10 to 30 days and 12 to 19 days after infestation by ticks, respectively. After intravenous transmission signs can occur as early as 5 days. Surviving horses show few or mild signs, but recrudescence under stressful conditions has been reported for *T. equi.* Horses infected with *T. equi* develop antibodies against equi merozoite antigens (EMAs) within 7 to 11 days; the immune response against *B. caballi*'s apical merozoite protein rhoptry (RAP) 1 is less well understood. Carrier status protects horses from reinfection, but coinfection with both parasites is possible. Diagnosis on microscopic identification of parasites by careful inspection of a blood smear is feasible in the acute stages. In the chronic stages, parasitemia is too low to be detected visually, making serologic tests, including complement fixation (CFT), indirect immunofluorescence assay (IFA), Western blot, and competitive enzyme-linked immunosorbent assay (cELISA), the diagnostic methods of choice. Complement fixation is very specific but not sensitive enough for detection of nonsymptomatic carriers, and cross-reactivity between both parasites occurs. The most sensitive test for chronic infection is the EMA 1 and 2 detecting cELISA; a cELISA detecting RAP-1 is also available. Immunofluorescence tests are often used as adjunctive test. A Western blot and nested PCR test are under development. Treatment during the acute stages is largely supportive. As the carrier status protects against active disease and reinfection, elimination of the parasite is not desired in endemic areas. In nonendemic areas, elimination of all transmission risk to other animals is paramount, with options being enrollment in an approved treatment program, lifelong quarantine, or euthanasia. Imidocarb diproprionate (2.2–4.4 mg/kg IM once or q 72 h for 4 doses) is the treatment of choice for parasite clearance. The anticholinesterase activity of the drug can be counteracted by preadministration of *n*-butylscopolamine (0.3 mg/kg IV). Injection site reactions are common, and increased sensitivity to side effects and even fatal reactions have been reported in donkeys and mules. Clearance of the parasite is confirmed by serial negative PCR or serology results. Control strategies vary among countries but frequently involve negative serologic results. A positive test result in the United States must be reported to federal and state regulatory officials.

Leptospirosis

Leptospirosis is a zoonosis with worldwide distribution. The seroprevalence and predominant serovar differ widely among geographic locations. Infection can be asymptomatic or present with mild and nonspecific signs. Apart from *Leptospira*-associated equine recurrent uveitis, abortion, stillbirth or premature birth, neonatal disease, and renal failure represent the most common clinical manifestations.[197-199] Anemia, epistaxis, petechiae, and ecchymotic hemorrhages were described in 4- to 12-week-old foals with *Leptospira* infection, but this appears to be a very rare manifestation.[200] Pulmonary hemorrhage in foals and adult horses is possible.[156,157]

Hemotropic *Mycoplasma* Infection

Hemotropic mycoplasmas or hemoplasmas (previously classified as Eperythrozoon and *Haemobartonella*) are bacteria that parasitize erythrocytes of a variety of species including pigs, cattle, cats, and dogs.[201,202] Infection in horses has been reported in Germany and potentially in Nigeria, but very little is known about the clinical significance and presentation of infection.[203] In other species, hemolytic anemia, ill thrift, and infertility are observed. Reported clinical signs in horses include weight loss, depression, and mild anemia, which might be worse in animals less than 1 year old.[201,202] Microscopic identification lacks sensitivity and specificity, making PCR the preferred diagnostic tool. Treatment in other species includes tetracyclines or fluoroquinolones.

Hemolysis Secondary to Oxidative Injury

Equine erythrocytes are more susceptible to oxidant-induced damage than human RBCs and experience a greater extent of methemoglobin formation, alteration of aggregation, and reduction of cellular deformability when exposed to superoxide anions.[204] Oxidants can damage erythrocytes by oxidizing the heme iron in hemoglobin from Fe^{2+} to Fe^{3+}, forming methemoglobin. Horses reduce methemoglobin via a lactate-dependent pathway, which is less efficient than the glucose-dependent pathway of methemoglobin reduction favored by erythrocytes of other species.[205,206] This, in addition to the greater methemoglobin formation, is thought to make horses more vulnerable to clinically relevant methemoglobinemia. Other forms of damage include oxidation of sulfhydryl groups in the globin part of hemoglobin leading to protein denaturation and Heinz body formation. The oxidation of sulfhydryl groups and unsaturated lipids also compromises membrane integrity, leading to increased fragility and early removal from the circulation. Reduced glutathione (GSH) is a potent antioxidant system; however, horses have a decreased GSH reduction rate, compared with humans and other species, again leaving them more predisposed to oxidative injury.[207,208]

Red Maple Leaf Toxicity

Ingestion of wilted red maple *(Acer rubrum)* leaves is a well-documented cause of hemolytic anemia and methemoglobinemia in horses. Similarly, wilted leaves of silver and sugar maple (*Acer saccharinum* and *Acer saccharum,* respectively) are also potentially toxic to horses.[209]

Most cases occur in summer and fall, often following adverse weather conditions. Fresh leaves are not toxic to ponies in the experimental setting, but dried leaves fed at a dose of 3.0 g/kg produce fatal toxicities. Leaves remained toxic for at least 30 days, and horses consuming more than 1.5 g/kg body weight are likely to show symptoms.[210] Depending on the time of year, either signs of hemolysis (before mid-September) or methemoglobinemia (after mid-September) might predominate. Gallic acid and a yet unidentified compound are thought to be responsible for the oxidative damage observed.[209] In addition, gallotannins and gallic acid present in leaves can be metabolized by *Klebsiella pneumonia* and *Enterobacter cloacae,* found in the equine ileum, to form pyrogallol, an even more potent oxidizing agent.[211] Clinical signs relate to tissue hypoxia caused by anemia and methemoglobinemia, including lethargy, tachycardia, tachypnea, fever, hemoglobinuria, and frequently also colic, renal insufficiency, and laminitis. Mucous membranes are often discolored, descriptions ranging from muddy to cyanotic and chocolate brown, while the sclera might be icteric. Laboratory analysis confirms anemia, renal compromise, and often systemic inflammation with leukopenia or leukocytosis. Total methemoglobin concentrations

of 0 to 4.08 g/dL (normal, less than 1.77 g/dL) have been measured, corresponding to up to 44% of the total hemoglobin concentration (normal, less than 3%).[212] Treatment is largely supportive including intravenous fluids, pain management, and blood transfusions if necessary. Mineral oil to reduce further toxin absorption and ascorbic acid as an antioxidant have been advocated. Vitamin C (30–50 mg/kg IV q 12 h diluted in 0.9% sodium chloride continued until hemolysis ceases; oral supplementation will take longer to achieve tissue levels) has been used in the clinical setting.[213,214] Experimentally, daily feeding of 9000 mg/day for 12 weeks significantly reduced hemolysis and methemoglobin formation in response to leaf extract, whereas 8000 U/kg α-tocopherol daily only reduced hemolysis.[215] The use of sodium bicarbonate to prevent pigment nephropathy is controversial in humans.[216] The aim of urinary alkalinization is to prevent tubular obstruction caused by cast formation by reducing the conversion of hemoglobin to methemoglobin, to reduce uptake of hemoglobin by tubular cells, lowering production of hydroxyl radicals and promoting free radical scavenging.[217] Corticosteroids are often used in an attempt to decrease RBC destruction. Complications are frequent; 44% of horses develop fever, 43% experience colic, 32% laminitis, 7% DIC, and 6% cecal impactions. The prognosis is guarded, with 41% of horses surviving in the largest retrospective study. Factors associated with mortality included lack of pyrexia on admission and corticosteroid administration whereas PCV and percentage methemoglobin were not associated with outcome.[212]

Pistacia Leaf Toxicity

Hemolytic anemia, methemoglobinemia, renal failure, and death have been reported in horses following ingestion of *Pistacia* leaves. Although not native to North America, *Pistacia atlantica, P. terebinthus,* and *P. chinensis* are found in several states ranging from the Southwest to the Southeast of the United States. *Pistacia* leaves contain gallic acid, and the clinical picture closely resembles red maple leaf intoxication.[218,219]

Garlic and Onion Toxicity

Experimental feeding at the maximal voluntary intake of garlic (0.25 g/kg PO q 12 h) resulted in mild anemia (decrease of PCV from mean 36% to 28%) with increased Heinz body formation. Excessive sweating was also observed. Signs were noted 4 days after initiation of feeding, and recovery from anemia was completed within 5 weeks after discontinuation of garlic feeding.[220] Hemolytic anemia has also been reported following natural and experimental ingestion of wild and domestic onions (*Allium canadense* and *Allium cepa*). Wild onions are only eaten by horses once all other forage has been consumed and in the experimental setting, feeding of 1.0 to 1.8 kg/day (2–4 lb/day) is necessary to create clinical and laboratory signs. Horses recover completely once ingestion stops.[221]

Envenomation by Bees or Snakes

Envenomation by snakebites and, less commonly, multiple bee stings can cause intravascular and extravascular hemolysis, thrombocytopenia, and profound coagulopathies with increased bleeding and/or excessive thrombosis, often compatible with DIC.[222,223] Effects are largely mediated by enzymatic and nonenzymatic proteins and proteases contained in the venom. Apart from antivenom, treatment is largely supportive.

Other Causes of Hemolysis

Hemolytic-Uremic Syndrome

Hemolytic uremic syndrome in humans is described as a form of thrombotic microangiopathy. The clinical picture is characterized by the combination of microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. It is often caused by exposure to Shiga-toxin producing *E. coli,* but noninfectious causes including inherited mutations of complement-regulating proteins, and disorders associated with endothelial damage also occur in people. Subsequent activation of the inflammatory system and particularly the complement system causes vascular wall thickening and deposition of fibrin- and thrombocyte-rich thrombi in the microcirculation. This compromises end-organ function, often affecting kidney or brain. Schistocyte formation and hemolysis ensue when erythrocytes are exposed to increased shear stress across vessels that are partially obstructed by fibrin. Thrombocytopenia is caused by platelet consumption caused by excessive coagulation and immune-mediated destruction.[224] Coagulation times are usually normal, differentiating the condition from DIC. In horses, the syndrome has been described in a postpartum mare with metritis and in three horses without apparent underlying cause. Clinical signs are compatible with systemic inflammation, hemolysis, thrombocytopenia, and renal failure including hemoglobinuria, epistaxis, oliguria or anuria, peripheral edema, lymphadenopathy, and altered neurologic status. Supportive treatment has been unsuccessful in all reported cases.[225-227]

Congenital Enzyme Defect

Severe deficiency of glucose-6-phosphate dehydrogenase caused persistent hemolytic anemia, hyperbilirubinemia, and Howell-Jolly bodies in a Saddlebred colt and his dam.[5] Persistent methemoglobinemia, eccentrocytosis, and pyknocytosis in a Spanish mustang mare were attributed to deficiency of flavin adenine dinucleotide (FAD) resulting from a defect in erythrocyte riboflavin metabolism.[6] Horses with erythrocyte FAD deficiency have both eccentrocytosis (attributable to severe deficiency in glutathione reductase activity) and methemoglobinemia (attributable to cytochrome b5 reductase deficiency); the dual enzyme deficiency occurs because FAD is a required cofactor for both enzymes.[228] A familial decrease in erythrocyte glutathione reductase and glutathione was suspected in a trotter mare and her dam, causing poor performance secondary to persistent methemoglobinemia and hemolytic anemia.[229]

Miscellaneous

A rare fulminant intravascular hemolytic syndrome with prominent hemoglobinuria has been reported in horses in the end stages of liver failure but also in one horse that subsequently recovered from an acute hepatic insult. This horse also had markedly decreased erythrocyte reduced glutathione (GSH) content and showed marked neutrophil hypersegmentation. The exact mechanism of hemolysis is unknown, but increased concentrations of bile acids and their salts have been suspected to play a role.[29,230] Hemolytic anemia has repeatedly occurred in horses receiving predominantly high, but also recommended (20–30 g/500-kg horse), doses of phenothiazine. Horses are reportedly one of the most sensitive species, and signs are seen 6 to 13 days after administration. Heinz bodies are a frequent finding.[231,232] Experimental oral administration of L-tryptophan causes hemolysis in ponies.[233] Selenosis

in horses predominantly manifests with skin and hoof abnormalities and neurologic symptoms, but hemolytic anemia following acute poisoning has been described in other species.

DISORDERS OF HEMOSTASIS

Hemostatic dysfunction can be caused by abnormalities affecting the vascular wall, most commonly in the form of a vasculitis, changes in platelet numbers or function, and abnormalities of the plasma-based coagulation system.

Vasculitis

Vasculitis is a pathologic term describing inflammation and often necrosis of blood vessels. It can be immune mediated, secondary to severe systemic inflammation, due to direct effects of infectious organisms on the vascular endothelium, or a combination of these mechanisms. Infectious organisms frequently implicated in the development of vasculitis include *Streptococcus equi* subsp. *equi* (strangles), equine viral arteritis virus, *Anaplasma phagocytophila, Corynebacterium pseudotuberculosis,* and, occasionally, equine infectious anemia virus.

Immune-Mediated Vasculitis/Purpura Hemorrhagica

The term *purpura hemorrhagica* refers to immune-mediated vasculitis that is frequently, but not always, secondary to *S. equi* subsp. *equi* infection. The process can be triggered by multiple factors, affect one or multiple organ systems, and vary dramatically in severity. In horses, immune-mediated vasculitis is usually secondary to another disease process, frequently exposure to an infectious organism. *S. equi* subsp. *equi* infection is the best described cause of immune-mediated vasculitis. Signs are first noticed within 2 to 4 weeks of infection, but development within 2 to 6 days has occurred in previously vaccinated horses.[234] It can also be observed secondary to other viral or respiratory tract infections, drug administration, open wounds, abscesses, vaccination against strangles, and neoplasia. Severe and frequently fatal immune-mediated vasculitis occurred in Miniature Horses following vaccination with a live spore anthrax vaccine.[235] Not infrequently, the underlying cause cannot be detected.[236] The disease can affect horses of any age ranging from 6 months to 20 years and older.[236] It is presumed that deposition of complexes of antigen and immunoglobulins in the walls of the capillaries and other small blood vessels leads to a type III hypersensitivity reaction. In horses with previous *S. equi* exposure, an association between the development of vasculitis and IgA antibodies has been suggested. IgA titers to both M-like protein and culture supernatant proteins were higher in horses with vasculitis than in either horses recently infected with *S. equi* or with no known history of exposure.[237] In addition, immune complexes with IgA and M-like proteins have been found in the sera of horses with vasculitis.[238] Microscopically, lesions are characterized by a leukocytoclastic vasculitis.[238,239] The increase in vascular permeability accounts for clinical signs of edema, petechial or ecchymotic hemorrhages in mucosal and subcutaneous tissues, serum oozing, and, less commonly, epistaxis. Edema is often well demarcated and most commonly noticed in the limbs followed by ventrum and head. Fever, tachycardia, tachypnea, anorexia, and depression are frequently present. Depending on organ systems involved, colic, reluctance to move, lameness, or neurologic signs might be noted.[240] Renal dysfunction and glomerulonephritis, multiple small intestinal intussusceptions, and muscular infarcts have also been reported secondary to presumed strangle-induced vasculitis.[241,242] Laboratory abnormalities include leukopenia or leukocytosis, anemia, thrombocytopenia, hypergammaglobulinemia, increased acute phase proteins, and increased muscle enzyme activities. A presumptive diagnosis can usually be made based on history, clinical picture, and exclusion of other causes of edema and/or hemorrhagic diasthesis. Very high SeM-specific antibody titers (greater than 1:12,800) are strongly suggestive of vasculitis secondary to strangles vaccination or exposure.[243] Skin biopsies can confirm the presence of a leukocytoclastic or nonleukocytoclastic vasculitis, but histologic evidence can be absent in horses previously treated with corticosteroids.[236] Secondary complications such as laminitis and thrombophlebitis are not uncommon; rarely, massive and even fatal hemorrhage can occur.[236] Treatment is based on removal of the underlying cause if possible and immunosuppressive treatment with corticosteroids (dexamethasone 0.1–0.2 mg/kg IV, IM, or PO q 24 h or prednisolone 0.5–1.0 mg/kg PO q 24 h). Azathioprine (3.0 mg/kg PO q 24 h) has also been used anecdotally. Supportive care, including hydrotherapy, limb bandages, mild exercise, and intravenous fluids, can be helpful. Once clinical signs are improving, the corticosteroid dose should gradually be reduced while monitoring for recurrence. Relapse of symptoms is common if doses are decreased or treatment is discontinued too quickly. Almost 50% of horses in one study required treatment for more than 21 days. The prognosis is good if no severe complications arise, with 92% of horses surviving in the largest case series.[236]

Anaplasma phagocytophila

Anaplasma phagocytophila (formerly *Ehrlichia equi*) is an obligate intracellular infection infecting neutrophils and occasionally eosinophils of several mammalian species.[244] The organism is transmitted by *Ixodes* ticks but *Dermacentor* spp., *Rhipicephalus* spp., *Hyalomma* spp., and *Haemaphysalis* spp. are also potential vectors. The organism has a worldwide distribution in the Northern Hemisphere where vectors are endemic. Recent studies suggest that multiple strains with different host tropism and pathogenicity might be circulating in wild and domestic animal populations. The organism is transmitted transstadially, not transovarially, making a mammalian reservoir necessary to infect the ticks.[245] Disease transmission from ticks to a sensitive host occurs within 2 to 36 hours while the tick is feeding on the surface of the host's body. Coinfections with other tick-borne pathogens can occur. The incubation period is approximately 10 days, and signs vary from subclinical infection to high fever (100°–106.9°F [37.7°–41.6°C] with a mean of 104.2°F [40.1°C] in one study), depression, inappetence, petechiae, reluctance to move, and distal limb edema.[244,246] On occasion, high fever with or without peripheral edema can be the only clinical sign, with horses being remarkably bright and otherwise normal. Neurologic signs including ataxia and recumbency have been reported infrequently. Neurologic signs resolved quickly following therapy with oxytetracycline in two cases but euthanasia was necessary in another that failed to improve despite treatment.[247-249] Some reports state that younger (less than 4 years old) animals experience milder clinical signs, but this has not been confirmed by others.[244,249,250] Laboratory abnormalities include often marked thrombocytopenia (less than 10,000–100,000/μL; presumed to be at least partially due

to bone marrow suppression), mild anemia (PCV usually greater than 20%), lymphopenia, and neutropenia followed by rebound leukocytosis.[246,249] The disease can be self-limiting if left untreated, and clinical signs usually last from 7 to 14 days. Relapse has been reported.[244] Diagnosis relies on identification of granulocytic inclusions, either morulae or initial bodies, in Wright-Giemsa– or hematoxylin and eosin–stained blood smears. Inclusion bodies in peripheral blood are best observed 3 to 5 days after the onset of fever and might be present in 30% to 50% of neutrophils; much lower percentages (1%–8%) of infected cells were noted in other studies.[244,251] In the later stages or in horses that have received treatment, molecular techniques such as PCR or serology demonstrating increasing antibody titers might be necessary to confirm the infection. The organism is very sensitive to treatment with oxytetracycline (7 mg/kg IV q 24 h for 3–7 days), and clinical improvement is often seen within 12 to 24 hours.[244] Doxycycline (10 mg/kg PO q 12 h) has also been used. Treatment with dexamethasone in experimental infection resulted in a higher total bacterial burden but ameliorated clinical signs slightly. Hematologic parameters did not differ between dexamethasone-treated and untreated animals.[252] The prognosis is excellent with 96% of horses recovering in one study. In this study, no abortions were observed in pregnant mares and no horse developed laminitis. Fatal cases have been reported, secondary to injury due to ataxia, failure to recover from the neurologic form, secondary infections, widespread hemorrhage, and vasculitis and thrombosis consistent with DIC.[244,249,253]

Equine Viral Arteritis

Equine viral arteritis (EVA) virus is covered in detail in Chapters 8 and 19, but infection remains an important differential diagnosis for horses displaying signs of vasculitis. Equine viral arteritis virus, a single-stranded RNA virus belonging to the family Arteriviridae, genus *Arterivirus,* has a worldwide distribution and can affect horses of all ages. Transmission occurs by venereal or respiratory routes. Semen from persistently infected stallions and aerosol from contaminated body fluids are major sources of infection. The incubation period ranges between 2 and 14 days. Most infections are clinically silent or result only in an increased temperature, but severe infection can be seen in foals and immunologically compromised animals. The virus targets mononuclear cells and endothelial cells, and clinical signs are mostly associated with vasculitis. Distinct EVA isolates vary markedly in the severity of the clinical signs they induce, and it is generally thought that the American strains are more virulent than the European isolates. Depending on the strain, extensive necrosis of small muscular arteries in multiple tissues, mild infection of terminal capillaries, or little endothelial involvement at all can occur.[254-256] Fever and leukopenia are most consistently reported, but depression, periorbital and supraorbital or dependent edema, conjunctivitis, lacrimation, petechiae, respiratory signs, and colic or diarrhea might ensue. In pregnant mares, abortion between the third and tenth months or birth of compromised foals if infected in late pregnancy is common.[257]

Platelet Disorders

Thrombocytopenia

Box 15.5 contains a list of differential diagnoses for thrombocytopenia. Thrombocytopenia secondary to decreased production in the bone marrow is discussed under disorders of hematopoiesis.

Thrombocytopenia Secondary to Systemic Disease. The most common cause of thrombocytopenia in hospitalized horses is increased utilization or destruction of platelets secondary to a primary infectious, inflammatory, or neoplastic disease process. Thrombocytopenia is also common in strangulating/ischemic gastrointestinal disorders, and platelet counts as low as 4000/μL might be encountered. Accompanying laboratory changes reflect systemic inflammation and include increased PCV, percentage of band neutrophils, leukopenia or leukocytosis, and decreased plasma protein concentrations.[58] Thrombocytopenia is often present in horses with subclinical or clinical DIC and is regarded as a sensitive indicator for the presence of DIC.[258] An association between thrombocytopenia and a poor prognosis has been demonstrated in hospitalized horses in general and in horses with colon torsion.[58,259] Thrombocytopenia is also frequently found in other diseases such as equine infectious anemia (a combined effect of immune-medicated destruction and decreased platelet production), *A. phagocytophilum* infection (presumed to be at least partially due to bone marrow suppression), babesiosis/piroplasmosis (mechanisms not well understood), neoplasia (presumed to be immune mediated), and snake or bee envenomation (a combined effect of sequestration, increased aggregation, and consumption, frequently associated with DIC).[222,260] Thrombocytopenia secondary to sepsis and also cystic hematomas has been reported in neonatal foals.[261,262]

Immune-Mediated Thrombocytopenia. Immune-mediated thrombocytopenia (IMT) is an uncommon disease in adult horses, and the diagnosis is based on exclusion of other causes. The inappropriate immune response can be directed against intrinsic platelet antigens, antigens/substances bound to the platelet membrane, or infectious agents. The term *immune thrombocytopenic purpura* is occasionally used if autoantibodies are responsible for platelet destruction. However, clinically the differentiation between a primary and secondary immune response can be difficult. Administration of penicillin and trimethoprim-sulfadoxine has been suspected to be involved in IMT, but this was not confirmed.[105] The suspicion of IMT is strengthened by detection of antibodies on the platelet membrane or on megakaryocytes by flow cytometry.[105] Platelet dysfunction secondary to bound antibodies can also be expected and bleeding can occur at relatively high platelet concentrations if function is severely affected. Clinically, a positive response to immunosuppressive therapy including dexamethasone (0.1–0.2 mg/kg IV q 24 h) or, in refractory cases, azathioprine (3.0 mg/kg PO q 24 h) is also strongly supportive.[263,264] Vincristine at the recommended human dose (1.4 mg/m^2 IV every 7–10 days; 8.4 mg in 500 mL of 0.9% NaCl) was used in a stallion with relapsing thrombocytopenia. Treatment appeared to be successful and was tolerated well with the exception of development of symmetric alopecia on head, neck, and inner thighs.[263] Relapse is not uncommon, and horses should be carefully monitored for recurrence of signs.[265,266]

Neonatal Alloimmune Thrombocytopenia. Immune-mediated destruction of platelets following ingestion of preformed antiplatelet antibodies with the colostrum has been reported in horse and mule foals and is suspected to be more common in the latter. Thrombocytopenia can be the sole abnormality or can occur in conjunction with neonatal isoerythrolysis. In mule foals, platelet destruction is suspected to be IgG mediated, targeting the collagen receptor (GP Ia IIa). Platelet dysfunction secondary to adhering antibodies has been described in these foals, highlighting the fact that

risk of bleeding is not only determined by platelet numbers but also by their functional state. A syndrome of ulcerative dermatitis, thrombocytopenia, and neutropenia has been described in six neonatal foals of varying breeds. Platelet counts varied between 0 and 30,000/μL, and four of six foals had petechiae or ecchymosis. All foals recovered completely, and thrombocytopenia appeared to be responsive to corticosteroid administration, suggesting an immune-mediated component. Although the exact etiology was not established, acquisition of antibodies or other factors via the colostrum was strongly suspected.[23]

Changes in Platelet Function

Glanzmann's Thrombasthenia. Glanzmann's thrombasthenia is a quantitative deficiency or a qualitative defect of the platelet fibrinogen receptor (also referred to as GP IIb/IIIa, $\alpha_{IIb}\beta_3$ integrin, or CD41/61). It is an autosomal recessive disorder, and the genetic defect has been localized to the gene encoding GP IIb (also referred to as α_{IIb}).[61,267,268] The disease has been reported in Quarter Horses, Thoroughbreds, Standardbreds, Warmbloods, and a Peruvian Paso.[62,269,270] Prolonged or recurrent epistaxis appears to be the most common clinical sign whereas the presence of petechiae or ecchymosis is more variable. The diagnosis is based on confirmation of a normal platelet count and coagulation profile including PT, aPTT, and, ideally, measurement of von Willebrand factor activity. Other simple clinical tests such as demonstration of a prolonged bleeding time and prolonged clot retraction are suggestive of a platelet function disorder but not diagnostic. Equally, an abnormal viscoelastic coagulation profile indicating reduced clot strength or a decreased aggregation response confirms a functional platelet defect. A definitive diagnosis requires demonstration of reduced CD41/61 expression on the platelet surface using flow cytometry. Alternatively, absent fibrinogen binding in response to stimulation might also be used. No effective treatment is available, but anecdotally, administration of tranexamic acid has decreased the frequency and severity of epistaxis in one horse. To the author's knowledge the pharmacokinetics of tranexamic acid have not been established in horses, but dosages of 10 g/kg IV q 12 h or 5 to 25 mg/kg PO q 6–12 h have been suggested. Theoretically, ε-aminocaproic acid might achieve a similar effect.

Atypical Equine Thrombasthenia/Reduced Fibrinogen Binding in Thoroughbreds. A second genetic platelet defect associated with reduced fibrinogen binding but distinct from Glanzmann's thrombasthenia has recently been identified in Thoroughbreds. Affected horses have normal fibrinogen binding in response to adenosine diphosphate (ADP) and normal levels of fibrinogen receptor (also referred to as CD41/61, GP IIb/IIIa, or $\alpha_{IIb}\beta_3$ integrin) but show decreased fibrinogen binding in response to thrombin. The defect is thought to cause an inability to generate thrombin following activation due to defective secretion of factor V from α-granules.[63] A prevalence of 0.7% in the Thoroughbred population has been estimated based on examination of 444 animals. Clinically, severe bleeding after trauma and prolonged template bleeding times were noted.[63-65,271] Laboratory abnormalities include a prolonged lag time in the aggregation response to collagen and thrombin. In contrast to horses with Glanzmann's thrombasthenia, normal quantities of CD41/61 can be demonstrated by flow cytometry and fibrinogen binding after stimulation with thrombin is only decreased, not absent.

Altered Platelet Function with Systemic Disease. The contribution of platelets to many disease processes has only been recognized in recent years. With the increasing awareness and more widespread availability of platelet function assays and viscoelastography, changes in platelet function during systemic disease are gradually elucidated. Platelet activation has been demonstrated in horses with airway inflammation, laminitis, and strangulating intestinal lesions and in response to equine herpesvirus 1.[49,52,60,272,273] Evidence linking decreased platelet function to decreased survival is beginning to accumulate in horses with acute gastrointestinal disease and in critically ill foals.[274,275] Further work is needed to delineate the contribution of platelets to the pathophysiology of equine diseases.

Abnormalities of the Plasma-Based Coagulation System

Hereditary Disorders

Von Willebrand's Disease. Von Willebrand's disease is caused by quantitative and/or qualitative defects of von Willebrand factor (vWF), a multimeric glycoprotein synthesized by endothelial cells and megakaryocytes. The factor mediates platelet adhesion/aggregation and stabilizes factor VIII (FVIII) in the circulation.[276] Without vWF platelet binding to collagen is reduced and primary hemostasis disrupted. vWF is an acute phase reactant, and natural fluctuations occur. Concentrations in mares increase from midgestation to reach near-maximal activity at parturition,[277] and changes in vWF and FVIII have been observed in strenuously exercised Standardbreds and Thoroughbreds.[278] Von Willebrand's disease can be congenital or acquired. In humans, six different types (1, 3, 2A, 2B, 2M, 2N) of the congenital form are currently differentiated. A partial quantitative defect defines type 1, whereas type 3 is characterized by the nearly complete absence of vWF in plasma and platelets. Type 2 consists of malfunctioning vWF and is divided into four subtypes. Types 2A and 2B are marked by the absence of high-molecular-weight vWF multimers, but in type 2B there is also an increased affinity of vWF for its platelet receptor, the glycoprotein Ib alpha.[276] Von Willebrand's disease is rare in horses, and so far only congenital deficiencies corresponding to human type 2A and one suspected case of type 1 have been reported.[279-281] Clinical signs in horses include bleeding from mucosal surfaces, epistaxis, hematoma formation, hemarthrosis, and prolonged bleeding from venipuncture sites, from injuries, or after surgery. Diagnosis can be achieved by measuring plasma von Willebrand antigen using an ELISA; results will be low or normal, depending on type. vWF ristocetin cofactor assay measures the ability of a patient's plasma to agglutinate platelets in the presence of the antibiotic ristocetin. Platelet agglutination caused by ristocetin can occur only in the presence of vWF multimers. Lack of agglutination indicates absence of the factor or its receptor, and the test aids in identifying types 2A, B, and M. Measurement of FVIII coagulant activity is also helpful and is necessary to identify type 2N. Without the stabilizing effect of vWF, FVIII is cleared rapidly and concentrations are frequently low. Bleeding times are prolonged whereas platelet counts and PT are normal; aPTT can be normal or increased if FVIII is deficient. Treatment in other species includes plasma transfusion or administration of desmopressin (deamino-8-D-arginine vasopressin [DDAVP]). Desmopressin is a synthetic vasopressin analog that increases release of vWF

from endothelial cells, particularly effective in type 1 cases.[282] In healthy dogs, both vWF and factor VIII are increased following DDAVP administration. In humans, the acquired form is associated with hypothyroidism, myeloproliferative and lymphoproliferative disorders, and autoimmune disorders but also with ciprofloxacin or hetastarch administration.[283]

Prekallikrein Deficiency. Prekallikrein deficiency has been diagnosed in a family of Belgian and Miniature Horses.[284,285] Excessive hemorrhage and a markedly prolonged aPTT prompted further investigation, which led to the diagnosis. It was presumed that animals with low prekallikrein activity might be homozygous for prekallikrein deficiency, whereas close relatives with values closer to normal might be heterozygous for the genetic defect.

Hemophilia A (Factor VIII Deficiency). Hereditary hemophilia A has been reported in Thoroughbreds, Standardbreds, and Quarter Horses and in an Arabian colt with multiple clotting defects including factors VIII, IX, and X and to a lesser degree factor VII and prothrombin.[286-291] The disorder is transmitted via an X-linked recessive trait, and affected colts generally suffer repeated bleeding episodes. A milder form has also been described in a Thoroughbred gelding that was 3 years old at diagnosis and had been successfully castrated.[292]

Acuired Disorders

Acquired Hemophilia A. A 23-year-old Thoroughbred was diagnosed with temporary, acquired plasma factor VIII inhibitory activity following evaluation of a coagulopathy causing hemoperitoneum, hematomas, and anemia. Coagulation testing revealed prolonged aPTT, factor VIII deficiency, and increased factor VIII inhibitory antibody activity using a Bethesda assay.[293] Treatment included transfusions and immunosuppressive therapy (dexamethasone and azathioprine). Factor VIII deficiency and signs of coagulopathy resolved, and the inhibitory antibody titer decreased. The mare remained healthy with no relapse for at least 1 year after treatment.[80]

Vitamin K Deficiency Bleeding in Neonatal Foals. Vitamin K deficiency bleeding (VKDB) has been suspected in a 4-week-old colt presenting with hemarthrosis, spontaneous bleeding from the gingiva, blood covering of feces, and hematoma formation after venipuncture. Activities of vitamin K–dependent factors II, VII, IX, and X was markedly decreased and improved following supplementation with vitamin K_1 (2 mg/kg SC q 12 h for 2 days, then 0.5 mg/kg PO q 12 h for 17 days). Subcutaneous administration is preferred to avoid hematoma formation and risk of anaphylactoid reactions after intramuscular and intravascular administration, respectively.[72] The condition was also suspected in a half-sibling colt but not further investigated. It is therefore unclear whether the condition was inherited or acquired. VKDB, formerly known as hemorrhagic disease of the newborn, is a bleeding disorder caused by low levels of vitamin K–dependent clotting factors. Acquired VKDB is more common in human neonates, which are very susceptible to vitamin K deficiency because of low stores at birth, poor placental transfer, low concentrations in milk, and lack of production by an immature intestinal microflora. Routine prophylactic administration of vitamin K has made human VKDB a rarity in most developed countries. Heritable combined deficiency of vitamin K–dependent clotting factors has been described in cats and sheep; in the sheep, defective γ-glutamyl carboxylase activity was identified as a cause of the deficiency.[294]

Warfarin/Anticoagulant Rodenticide Toxicity. Horses might come in contact with anticoagulant rodenticides when used for treatment of thrombotic diseases or by accidental consumption. Available anticoagulant rodenticides include first-generation (warfarin, diphacinone, and chlorophacinone) and second-generation (brodifacoum, bromadiolone, difethialone, and difenacoum) compounds. Second-generation rodenticides are more toxic and have longer half-lives than the first generation. Both act by competitively inhibiting vitamin K_1 epoxide reductase activity in the liver, thereby reducing circulating vitamin K–dependent clotting factors II, VII, IX, and X.[146] Brodifacoum is highly potent in horses with an LD_{50} of 0.1 to 0.2 mg/kg (approximately 1–2 kg of commercial bait per horse) and administration of 0.125 mg/kg resulting in clinical and laboratory signs of a coagulopathy.[295,296] Onset of clinical signs occurs within 3 to 7 days after exposure but might be as quick as 24 hours.[297] The half-life in horses is 1.22 days, but normalization of coagulation times can take up to 23 days following ingestion of 0.125 mg/kg.[296] Diagnosis relies on history of exposure, evidence of bleeding, and abnormal coagulation times. Large-vessel hemorrhagic diathesis including hematoma formation, epistaxis, body cavity bleeds, pulmonary hemorrhages, hyphema, melena, and hemopericardium are typical, but ecchymosis and subcutaneous bleeding have also been reported.[146,297] Due to the shorter half-life of factor VII, PT becomes prolonged before other coagulation times, and a prolongation of PT by 1.5 to 2 times has been used as target for warfarin treatment. Platelet counts are at least initially normal, differentiating the condition from DIC. Toxicity can be enhanced by hepatic dysfunction, concurrent administration of highly protein-bound substances that displace protein-bound toxin (e.g., phenylbutazone), and hypoproteinemia.[298] Corticosteroids and thyroxin also increase toxicity by increasing receptor affinity and coagulation factor catabolism. Increased microsomal enzyme activity in the liver, as it might be induced by rifampin, chloramphenicol, or barbiturates, decreases the half-life of warfarin in the blood. Specific treatment includes administration of vitamin K_1 (phylloquinone, phytomenadione, or phytonadione; 0.5–1.0 mg/kg SC q 6 h until normalization of PT). Because of the long half-life of second-generation rodenticides, treatment might need to be continued for weeks. Vitamin K_3 (menadione), a synthetic vitamin, should not be used as injection because of nephrotoxicity observed after intravenous and intramuscular administration in horses.[299,300] Poor therapeutic action when given orally had also been reported previously, but recent studies showed increased menaquinone-4 concentrations after oral supplementation with menadione but not with supplementation of vitamin K_2 (menaquinone).[301,302] A plasma or whole blood transfusion can provide coagulation factors and RBCs in cases of life-threatening hemorrhage. Activated charcoal might be indicated to decrease toxin absorption if ingestion has been recent.

Mouldy Sweet Clover (*Melilotus* spp.) Toxicity. Coumarins naturally present in sweet clover are converted into dicoumarol when hay or silage is improperly cured and mold develops. Disease is more common in cattle but can occur in horses.[303] Clinical signs, diagnosis, and treatment are as described for warfarin toxicity.

Liver Disease. Circulating coagulation factors are largely produced in the liver, and coagulopathies are not infrequently observed in horses with significant hepatic compromise.

Abnormalities of at least one coagulation parameter were observed in 58% of horses with confirmed hepatic disease, but complications secondary to percutaneous liver biopsy were only observed in four horses, and complications did not correlate with coagulation profile abnormalities.[304]

Disseminated Intravascular Coagulation. Activation of the coagulation cascade accompanies a variety of primary inflammatory, traumatic, infectious, or neoplastic conditions. In most cases, this does not lead to clinical complications because of the body's ability to maintain a balance between procoagulant and anticoagulant tendencies. However, if activation of the coagulation cascade is strong, as it frequently occurs in critically ill patients with systemic inflammation, homeostasis of the coagulation system is disrupted and the resulting coagulopathy can significantly increase morbidity and mortality. In severe cases, the coagulopathy may progress to its most extreme form, *disseminated intravascular coagulation* (DIC).[305] Subclinical or clinical DIC is characterized by dysregulation of coagulation, anticoagulation, and fibrinolysis.[306] Classically, DIC manifests first as a hypercoagulable state due to increased levels of circulating inflammatory mediators and tissue factor (TF). TF, in conjunction with coagulation factor VII (FVIIa), is now thought to be the main activator of the coagulation cascade. In addition, all major anticoagulant pathways (antithrombin III [AT], the protein C system, and TF pathway inhibitor) are substantially impaired as a result of consumption, degradation, and impaired synthesis. Moreover, the fibrinolytic system is widely suppressed during the time of maximal activation of coagulation, supporting fibrin deposition and clot formation in the microcirculation, which can lead to significant end-organ compromise.[305] Ongoing activation of the coagulation cascade causes thrombocytopenia, functional platelet abnormalities, and depletion of coagulation factors, resulting ultimately in profound hypocoagulation.[307,308] The progression of DIC is not always linear, and hypercoagulable and hypocoagulable tendencies may coexist in the same patient. Coagulopathies and subclinical or clinical DIC are common in critically ill equine patients, particularly those with gastrointestinal disease.[124,258,259,309-313] Deposition of fibrin in the microvasculature can lead to the development of ischemia, multiorgan failure, and death. In one study, fibrin deposits were detected in the kidneys, lung, or liver in 40% of nonsurviving horses with enteritis, peritonitis, and ischemic colic and in 88% of septic equine neonates, with the lungs being the most frequently affected organ.[124,312] Organ failure, although statistically not associated with fibrin deposition, occurred in 56% of these foals, and respiratory failure accounted for 25% of the organ failure cases.[312] These findings suggest that intravascular fibrin formation is a significant complication in critically ill equine patients. No universally recognized definition of DIC in horses exists, but abnormalities in ≥3 coagulation tests with (clinical DIC) or without (subclinical DIC) clinical signs is widely accepted.[258,313,314] Unfortunately, comparison of antemortem-identified coagulopathies and postmortem diagnosis of DIC found no association between the two, suggesting that our ability to identify horses in need of treatment is severely limited by the tests available.[315] Treatment apart from eliminating the underlying cause is further complicated by the coexistence of hypocoagulation and hypercoagulation. In humans, LMWH is recommended until bleeding is observed, and platelet transfusions are used to maintain a minimal platelet count between 20,000 and 50,000/μL.[316] Some investigations suggest that heparin and LMWH might be beneficial in horses with coagulopathies, but controlled studies have not been carried out.[124,314] The prognosis for horses with subclinical DIC is fair to guarded with survival of 58% reported, and studies including horses with clinical DIC stated a positive outcome in 0% to 34% of cases.[258,314,317]

Thrombosis. Thrombosis arises from an imbalance of procoagulant and anticoagulant mediators in the body when the balance is tipped toward a hypercoagulant environment. In systemically ill horses, both large-vessel and microvascular thrombi occur frequently and contribute to patient morbidity and mortality. Microvascular thrombi are discussed in the section describing DIC. Thrombosis describes the formation of a blood clot within the vascular lumen whereas thrombophlebitis includes inflammation of the surrounding vein, which in most cases triggered thrombus formation. If catheterization is the cause, infection of the thrombus might also be present.

LARGE-VESSEL THROMBOSIS. In most cases, large-vessel thrombosis is, at least partially, an iatrogenic problem caused by venipuncture or catheterization of a large peripheral vein. Cases of spontaneous thrombosis without external injury to the vessel is reported in foals and adult horses as a sequela of sepsis and systemic coagulopathies, discussed in the previous section. Thrombi involved cutaneous and limb arteries, the caudal vena cava, the right ventricle, the aortoiliac artery, and the pulmonary vasculature.[158,318-323] Aortoiliac thrombosis is discussed in Chapters 9 and 10. The incidence of catheter-associated thrombophlebitis overall varies greatly. In a mixed surgical and medical hospital population, clinically noticeable thrombophlebitis was seen in 1% of catheters placed and between 8.3% and 18% in horses undergoing emergency colic surgery.[324-326] The etiology of catheter-associated thrombophlebitis is multifactorial and influenced by the skill and technique of the person inserting and managing the catheter, substances administered through the catheter, and also to a large degree by patient-related factors. Solutions with a high osmolarity, such as parenteral nutrition, are irritating to the vascular wall and should be diluted or given in conjunction with intravascular fluids. Intravenous dextrose up to 25% (1330 mOsmol/L) has been given to horses without development of phlebitis.[327] Catheter-related complications associated with administration of parenteral nutrition range between 6% and 15% in foals and at least 5% in adult horses.[328-330] Any primary disease process associated with systemic inflammation and clinical or subclinical coagulopathies greatly increases the risk. The odds for developing catheter-associated thrombophlebitis are 4, 5, 18, and 68 times higher for horses with large intestinal disease, hypoproteinemia, endotoxemia, and salmonellosis, respectively, compared to horses without these findings.[331] Another study found a 4-times increased risk in horses with a rectal temperature of ≥101.3°F (38.5°C) when the catheter was inserted.[326] Clinical signs of thrombophlebitis can develop within minutes to hours of venipuncture or catheterization. Early signs include a subtle thickening of the vascular wall and perivenous tissues that can be appreciated by palpation or with ultrasonography. A change in the filling pattern when the vein is occluded distally to the catheter tip might also be appreciated. Changes often start at the catheter insertion site or at the distal end of the catheter where the tip of the catheter can come in contact with the endothelium.[326] Once a thrombus has formed noncompressible distention of the vessel with a palpable cord in the vascular lumen can be noted. Engorgement of the facial veins or unilateral face swelling can be observed with complete occlusion but is more common with

bilateral obstruction. Ultrasonography is more sensitive than palpation in early and subtle cases and also useful to establish the extent of the lesion. Ultrasonographically, the normal vein wall measures less than 1 mm in diameter, and thrombi appear as irregularly shaped hyperechoic luminal masses with homogeneous echogenicity or pockets of hyperechogenicity and hypoechogenicity.[326,332] In a recent study, clinically evident thrombophlebitis was noticed in 1% of cases but ultrasonographically, thickening of the vein wall was noted in 28% (31.4% of first catheter inserted) and thrombi were found in 16% of catheterized veins.[326] The intravenous catheter should be removed immediately once any sign of beginning phlebitis is observed; however, not infrequently thrombosis progresses even after removal. Ideally, the tip and a piece of catheter adjacent to the hub should be cultured and the vein not used until signs have completely resided.[326] Local increase in temperature and signs of pain on palpation might suggest the presence of an infection. In cases of infectious thrombophlebitis, aspiration of a fluid pocket under ultrasonographic guidance and culture of the retrieved material can aid in choosing the appropriate antimicrobials. Bilateral jugular vein thrombosis can lead to severe head and nasal passage edema and respiratory obstruction, necessitating tracheostomy. For this reason, many clinicians prefer not to use the opposite jugular vein for catheterization if one is already thrombosed. Lateral thoracic and cephalic veins are obvious alternatives, but on occasion, even the saphenous vein has been used. Other potentially serious complications include endocarditis and laryngeal hemiplegia.[333,334] Treatment includes hot-packing and application of topical DMSO, nonsteroidal, and/or heparin-containing gels. Systemic use of aspirin (10–100 mg/kg PO q 24–48 h), LMWH (enoxaparin 0.35 mg/kg SC q 24 h or dalteparin 50 IU/kg SC q 24 h for adult horses; dalteparin 100 IU/kg SC q 24 h for neonatal foals), or unfractionated heparin (30–40 U/kg SC q 12 h) will not resolve an existing thrombus but potentially prevent further growth. None of these treatments has been critically evaluated. Fibrinolytic therapies have occasionally been attempted. Regional bolus administration of 100 mL of streptokinase solution (7500 U/mL in 0.9% sodium chloride) reportedly showed thrombolytic effects but could not recanalize experimentally thrombosed jugular veins in horses permanently.[140] In a different report, infiltration of a thrombosed jugular vein using 6 mL of 125,000 U/mL streptokinase in 0.9% sodium chloride q 24 h for 3 days resulted in some thrombolysis.[141] Fibrinolysis of infected thrombi should probably not be attempted. In cases of septic thrombophlebitis antimicrobial treatment is indicated, ideally guided by culture and sensitivity. A variety of bacteria including *S. equi* subsp. *zooepidemicus, E. coli, Actinobacillus, Pseudomonas, Enterobacter,* and *Enterococcus* have been cultured.[326,333] Surgical treatment has been used in refractory cases. This can involve thrombectomy with removal of infected clot material, drainage of abscess material, and subsequent lavage. A prerequisite for the procedure is complete occlusion of the vein proximal and distal to the planned incision site. The prognosis depends greatly on the underlying etiology. The prognosis for horses that develop large vessel thrombosis secondary to sepsis is heavily influenced by the primary disease process and at best guarded to poor. Horses with catheter-associated thrombosis, in contrast, have a good prognosis for life and future performance. Over time, the vein frequently recanalizes with complete resolution of the thrombus. Athletic performance of non–racing horses was not affected whereas racing Standardbreds had a decreased chance of return to racing; however, in those that raced again, performance was not impaired.[335] Prevention of thrombophlebitis is difficult and not well investigated. Meticulous attention to sterility and atraumatic placement, use of the smallest gauge catheter possible, and removal as soon as intravascular access is no longer needed will help to reduce the risk. Any irritation of a catheter-containing vein is best avoided, and many hospitals have a policy of not taking blood from catheterized veins. Administration of NSAIDs through a catheter reportedly decreases the risk of thrombophlebitis but should only be used if clinically indicated.[326]

DISORDERS OF HEMATOPOIESIS

Nonregenerative/Hypoproliferative Anemia

Iron Deficiency Anemia

Iron deficiency is a rare cause of anemia in horses as iron intake via forage is usually more than sufficient to meet their needs. However, with chronic external blood loss deficiencies might be noted. Nonregenerative anemia secondary to iron deficiency is characterized by low serum ferritin concentration, decreased stainable iron stores in the bone marrow, decreased plasma transferrin saturation, normal or increased total iron binding capacity (TIBC), hypochromic erythrocytes (decreased MCHC), and microcytosis (decreased MCV) (see Box 15.1 and Table 15.3).[14] Treatment should be aimed at addressing the underlying problem. If iron supplementation is necessary, oral products containing ferrous sulfate (2.0 mg/kg) are probably safest. Alternatively, iron cacodylate (2.0 mg/kg can be given slowly IV, but caution is warranted as anaphylactic reactions might occur). Fatalities after intramuscular administration of iron dextran have been reported.[336] Iron deficiency anemia develops more rapidly in foals as forage consumption is absent or low during the neonatal period. Deficiency can develop as a result of limited storage of body iron, increased iron demand during growth, and low concentration of iron in the dam's milk.[14] Iron deficiency anemia has been reported in foals without access to pasture and in a hospitalized foal treated for presumed sepsis.[14,337] In the latter foal, microcytosis and hypochromasia were absent, but multiple erythrocyte abnormalities including echinocytosis, keratocytosis, and schistocytosis were noted.[14] In neonatal foals with confirmed iron deficiency anemia, treatment with ferric sulfate (2 mg/kg PO q 12 h) should be implemented. Prophylactic iron supplementation in healthy foals is not recommended, and acute and fatal hepatic failure has been reported following administration of products containing ferric fumarate (16 mg/kg of ferric fumarate) to neonatal foals within the first 48 hours of life. Foals with low levels of vitamin E and selenium are thought to be at particular risk. Colostrum provides large quantities of vitamin E, making administration before colostrum intake particularly perilous.[8,338-340]

Anemia Secondary to Other Deficiencies

Persistent anemia and leukopenia secondary to gelatinous bone marrow transformation, also referred to as *serous atrophy,* occurs in humans and other veterinary species and has also been reported in a malnourished pony.[341] Reasons are poorly understood, but malnutrition or maldigestion, cancer, infection, heart failure, and endocrine disorders play a role in other species. Weight loss is frequently but not always present. It is suspected that an unfavorable environment in combination

with inadequate hematopoietic substrate availability, lack of stimulation from adipocytes or fibrocytes, and deficiency of colony-stimulating factors also contributes.[341] The magnetic resonance characteristics of serous atrophy in the distal limbs of emaciated horses has been described.[342]

Anemia of Inflammation/Chronic Disease

Anemia of inflammation or chronic disease is a mild, normocytic, normochromic functional iron deficiency anemia associated with altered iron homeostasis during disease. Hypoferremia is thought to be part of the innate immune system, limiting iron availability to invading microorganisms. Anemia is caused by inflammation-driven retention of iron in macrophages, making the metal unavailable for heme synthesis. Concurrent impaired biologic activity of erythropoietin and a reduced proliferative capacity of erythroid progenitor cells further compound erythropoiesis.[343] Hepcidin, a liver-derived peptide, is thought to be the central iron-regulatory hormone and key regulator of this process. It can be induced by iron loading but also by inflammatory cytokines including interleukin-1 (IL-1) and IL-6. Hepcidin acts by binding to the iron exporter ferroportin. Subsequent ferroportin internalization and degradation inhibit the iron influx into plasma by reducing uptake of dietary iron from enterocytes. Furthermore, iron recycling by macrophages is impaired, which delivers approximately 95% of the daily iron needs for erythropoiesis.[343] Hepcidin also acts as an acute-phase protein in horses,[344] and hepatic hepcidin mRNA expression is upregulated following experimental LPS administration, resulting in hypoferremia. Laboratory findings suggestive of anemia of chronic disease include low serum iron concentrations, decreased transferrin saturation, normal to increased serum ferritin concentration, normal to decreased TIBC, and increased iron stores in the reticuloendothelial system. Anemia is generally mild, and treatment with blood products or iron supplementation is not indicated. In cases of severe anemia, other causes are likely to contribute and should be carefully ruled out.

Anemia Secondary to Recombinant Human Erythropoietin Administration

Severe anemia with PCVs as low as 4.1% has been reported in racehorses treated with recombinant human erythropoietin (rhEPO).[4,345,346] It is presumed that equine antibodies build against rhEPO and cross-react with equine erythropoietin, inhibiting its binding to erythropoietin receptors on bone marrow erythroid precursors.[345,346] Bone marrow suppression can be temporary, with horses returning to full function, or permanent and ultimately fatal.[346] Diagnosis relies on history and on identification of erythroid hypoplasia on bone marrow evaluation. Several tests exist for detection of rhEPO in equine plasma and urine within days after administration and detection of antibodies against rhEPO in the plasma.[347]

Aplastic Anemia and Pancytopenia

Aplastic anemia is a bone marrow failure syndrome characterized by bone marrow aplasia and peripheral blood pancytopenia. In humans, most cases are acquired and often idiopathic but can also be secondary to a number of causes, including bacterial or viral infections, chronic renal or hepatic disease, neoplasia, and drug therapy.[348] Pancytopenia can also be the result of *myelophthisis,* a term used when normal marrow space is infiltrated and replaced by nonhematopoietic or abnormal cells. Causes include metastatic neoplasia, myeloproliferative disorders, and marrow fibrosis, which can also be secondary to the neoplastic conditions.[349] Early clinical signs are representative of thrombocytopenia, including petechiae, epistaxis, hematoma formation, and bleeding from injection sites.[349,350] With progressive leukopenia, a propensity for infections might be noticed. Diagnosis is achieved by examination of bone marrow aspirates or biopsies; multiple samples might be necessary. Pancytopenia secondary to drug administration has been reported in horses. One animal had been treated with penicillin, oxytetracycline, trimethoprim-sulfadiazine, phenylbutazone, dipyrone, flunixin meglumine, and isoxsuprine, but the offending agent was not definitively identified.[349] The horse responded to treatment with corticosteroids, androgens, and withdrawal of the suspected drugs. Pancytopenia secondary to administration of potentiated sulfonamides, often in combination with oral folic acid supplementation, has been observed in adult horses and in foals born to treated mares. Two out of three adult horses, but none of the foals, survived.[351-353] Although one of the cases was thought to be an immune-mediated reaction,[351] the others were speculated to be secondary to folic acid deficiency. In addition to the effects of potentiated sulfonamides on folate synthesis, oral administration of folic acid in other species competitively reduces the absorption of the active form of folic acid. This paradoxically worsens folic acid deficiency and also teratogenic effects of pyrimethamine. Administration of folinic acid can prevent these complications but might counteract the antimicrobial properties of potentiated sulfonamides.[352,353] Pancytopenia responsive to corticosteroid treatment occurred in a horse with equine multinodular pulmonary fibrosis. Equine herpesvirus 5 inclusion bodies and DNA were identified in the bone marrow, and an immune-mediated cell destruction was suspected.[354] Mild anemia (PCV 25%–30%) has been observed in horses with chronic renal failure.[2] Other causes of pancytopenia in horses include fatal myelofibrosis of unknown etiology,[355] and transient pancytopenia associated with a presumed splenic hematoma was described in a donkey.[356] In several cases an underlying cause cannot be established.[350,357,358] In contrast to cattle, horses do not develop aplastic anemia after acute bracken fern toxicosis but rather present with neurologic signs.[359] Treatment is often unrewarding unless pancytopenia is immune mediated. Possible offending medications and supplements should be discontinued, and treatment with corticosteroids and androgens (nandrolone decanoate 250 mg/500-kg horse IM) can be attempted.[349]

Familial Myeloid and Megakaryocytic Hypoplasia in Standardbreds

Moderate to severe neutropenia in combination with intermittent thrombocytopenia due to myeloid and megakaryocytic bone marrow hypoplasia was diagnosed in eight Standardbred horses. All were sired by the same stallion, making a familial basis likely. Horses were between 4 months and 3 years old on first examination and presented for persistent fever, malaise, and nonhealing wounds. Evaluation of serial neutrophil counts in two horses suggested cyclic variations in neutrophil numbers with increased lymphocyte counts and decreased platelet counts when neutrophil counts were low. Myeloid progenitor cells were present and able to respond to exogenous

growth factors, suggesting that a bone marrow microenvironment or growth factor defect was responsible for the observed changes. Seven of the eight horses died or were euthanized; the surviving horse had moderate neutropenia and a normal platelet count and raced for 3 years.[360]

Erythrocytosis

Erythrocytosis describes an increase in RBC numbers in the circulation and can be relative (following hemoconcentration and/or splenic contraction) or absolute (true increase).

Primary Erythrocytosis/Polycythemia Vera

Primary absolute erythrocytosis, sometimes referred to as polycythemia vera, is caused by proliferation of cells of the erythroid lineage without an increase in erythropoietin. Polycythemia vera in people is a myeloproliferative neoplasm associated with a genetic mutation of the *JAK2* gene causing erythrocytosis (with or without an increase in erythropoietin); other cell types might also be increased. The disease is slowly progressive with long survival times but carries the risk of leukemic or fibrotic transformation.[361] Primary absolute erythrocytosis was diagnosed in one and suspected in another horse. The former horse was initially treated with a combination of repeated phlebotomy, hydroxyurea (up to 29 mg/kg q 24 h), and dexamethasone. Eventually, all treatment was discontinued, and the horse lived with a PCV between 65% and 70% without apparent ill effects during a 2-year follow-up period.[362] In the other case, a granular cell myoblastoma was also identified, and therefore secondary polycythemia could not conclusively be ruled out.[363]

Secondary Erythrocytosis

Secondary absolute erythrocytosis is triggered by a physiologic or pathologic increase in erythropoietin concentrations. Secondary erythrocytosis can be congenital, due to genetic abnormalities (not reported in horses) causing hypersensitivity of erythroid progenitors to erythropoietin, or acquired.[364] Secondary acquired erythrocytosis can be driven by hypoxia and was previously referred to as secondary appropriate erythrocytosis. Chronic pulmonary disease, high altitude, congenital cardiac anomalies, and local renal hypoxia are common causes.[365] In horses, erythropoietin concentrations only increased transiently at 3800 m, whereas increase in PCV at the same altitude was variable but longer lasting.[366-368] Overall, altitude ≤3800 m probably does not contribute to significant resting erythrocytosis in horses. The degree of hypoxia necessary to induce erythrocytosis in horses is not known, but Pao_2 of less than 60 to 80 mm Hg (Sao_2 less than 90%–92%) has been suggested. Low-dose rhEPO (50 IU/kg body weight rhEPO/3 mL saline 3 times/week for 3 weeks) administration increases RBC volume and aerobic capacity without altering anaerobic power.[369] Pathologic erythropoietin production (also called inappropriate secondary erythrocytosis) is caused by release of erythropoietin or erythropoietin-like substances without underlying physiologic demand and is often associated with neoplasia, particularly hepatoblastoma and hepatocellular carcinoma.[370-374] Administration of performance-enhancing drugs such as human recombinant erythropoietin might cause erythrocytosis in horses. Cobalt is used as a doping agent in human and equine athletes and in the treatment of anemia in people. Cobalt acts by preventing degradation of hypoxia-inducible factor 1α (HIF1α), which regulates expression of erythropoietin. Administration of a single dose of cobalt (109 mg cobalt chloride or 169 mg cobalt gluconate) did not increase erythropoietin or RBC numbers in horses, but a cumulative effect cannot be ruled out.[375]

Thrombocytosis

Primary or Clonal Thrombocytosis

Primary (also referred to as essential or clonal) thrombocytosis is a rare chronic myeloproliferative disorder that has been suspected in one horse with a platelet count of 1,104,000/μL.[56] The condition is associated with sustained megakaryocyte proliferation causing increased numbers of circulating platelets. Other cell types might also be increased. In humans, the disease is slowly progressive with long survival times but, similar to polycythemia vera, carries the risk of leukemic or fibrotic transformation.[361] Because of an increased risk of thrombosis, treatment with platelet-suppressing drugs is often implemented. Interestingly, in the suspected equine case pulmonary thrombosis and laminitis were noted, raising the suspicion that a similar risk might also be present.[56]

Reactive or Secondary Thrombocytosis

Secondary thrombocytosis with platelet counts of 400,000 to 839,000/μL is rare and affects approximately 1% of hospitalized horses in which a platelet count is performed.[56] Thrombocytosis is associated with young age (less than 3 years), intact male gender, tachycardia, pyrexia, and infectious or inflammatory conditions and is often accompanied by hyperfibrinogenemia, leukocytosis, hypoproteinemia, and anemia. A relation between thrombocytosis and *Rhodococcus equi* infection in foals has been suggested but not confirmed.[376,377] Excessive cytokine release (IL-1, IL-4, IL-6, TNF-α, thrombopoietin, etc.) is thought to activate cytokine-mediated megakaryocyte proliferation. Although a statistically significant link to decreased survival could not be established, 33% of horses with thrombocytosis in one study did not survive. Much smaller increases in platelet numbers have been reported in pregnant mares toward the time of parturition. It has been speculated that this is part of a protective hypercoagulable response.[378]

Lymphoproliferative Disorders

The lymphomas (malignant lymphoma or lymphosarcoma) are a diverse group of neoplasms that originate from lymphoreticular cells. They usually arise in lymphoid tissues such as lymph nodes and spleen but can originate from almost any tissue in the body. This is in contrast to primary leukemias, which arise in the bone marrow and/or peripheral blood from lymphoid, myeloid, monocytic, or erythroid cells, often with the presence of neoplastic cells in the circulation. The term *secondary leukemia* is used if the bone marrow is invaded by metastases from another site (e.g., multicentric lymphosarcoma). Lymphosarcoma and leukemia of the same cell type are regarded by some as different manifestations of the same disease process.[379]

Lymphosarcoma/Lymphoma

Lymphosarcoma is the most common equine hematopoietic tumor affecting horses of all ages, even fetal stages. Human classification systems are not readily applied to animals, and the nomenclature can be confusing. In horses, immunophenotypes including B cells, T cells, T-cell–rich B cells, and potentially natural killer cells have been described. Further classifications include large, small, and mixed cell types. Based on localization, multicentric (generalized); alimentary;

mediastinal, thymic, and thoracic; subcutaneous and cutaneous; hepatosplenic and splenic; nasal, paranasal, and nasopharyngeal; nervous system; and ocular lymphosarcoma can be differentiated.[379] Clinical signs are determined by localization and extent of the tumor. Common laboratory findings include anemia, presumably caused by immune-mediated hemolysis, chronic inflammation, myelophthisis, blood loss, neutrophilia, hypoalbuminemia, hypogammaglobulinemia with decrease/absence of IgM, hypergammaglobulinemia (with polyclonal or monoclonal gammopathy), hyperfibrinogenemia, and hypercalcemia. Paraneoplastic syndromes described in horses with lymphosarcoma include alopecia and pruritus,[380] hypercalcemia,[381] pseudohyperparathyroidism,[382] immune-mediated hemolytic anemia and/or thrombocytopenia,[168] polycythemia due to erythropoietin gene expression,[371] and hypereosinophilia.[38] The prognosis depends on location and extent of the tumor and whether or not metastasis has occurred. Complete surgical excision, if possible, can be curative, and in rare cases, successful chemotherapy has also been described.[383,384]

Leukemia

The term *leukemia* describes abnormal proliferation and development of one or more cell lines in the bone marrow. Classifications of leukemias involve cell type and stage of differentiation. Acute leukemias are often rapidly progressive and poorly differentiated forms, whereas in chronic leukemias slowly progressive accumulation (rather than proliferation) of cells in the bone marrow and peripheral tissues predominates.[379] Replacement of the normal hematopoietic tissue in the bone marrow by tumor cells can occur before the onset of overt leukemia. Clinically, immunosuppression and susceptibility to secondary infection might be noted, and in laboratory investigations, a degree of bone marrow failure such as anemia, thrombocytopenia, neutropenia, and/or lymphopenia is evident.[379,385-387] Bone marrow necrosis secondary to T-cell lymphoma has also been reported.[387] Leukemias for every white cell line present in the bone marrow are described. Myeloid leukemias reported in horses include acute myelomonocytic leukemia with concurrent proliferation of neutrophilic and monocytic cell lines, acute monocytic leukemia, eosinophilic myeloproliferative disorder, and acute erythroid leukemia (erythemic myelosis) in a 10-week-old foal.[386,388-392] Lymphoid leukemias of B- and T-cell origin have been described with potentially T-cell forms predominating in horses.[393-395]

Multiple Myeloma

Multiple myeloma is a highly malignant neoplasm derived from plasma cells or plasmacytoid lymphocytes (large B lymphocytes with some resemblance to plasma cells) in the bone marrow. Monoclonal gammopathy, hyperviscosity of the blood, osteolysis, bone pain, and myelophthisis are common characteristics.[379,396,397] Light-chain amyloidosis secondary to multiple myeloma developed in a Quarter Horse gelding secondary to multiple myeloma.[398]

VASCULAR TUMORS

In humans, the nomenclature of vascular anomalies has been defined by the International Society for the Study of Vascular Anomalies (ISSVA). Vascular tumors are differentiated from vascular malformations based on their clinical appearance, radiologic and pathologic features, and biologic behavior. Vascular tumors can arise from blood or lymphatic vessels and grow by endothelial hyperplasia, whereas vascular malformations have a quiescent endothelium and are considered to be localized defects of vascular morphogenesis.

Hemangiosarcoma and Hemangioma

Hemangiosarcomas often present as a disseminated malignancy involving the spleen, heart, lung, liver, and soft tissues of the trunk and extremities, whereas hemangiomas are typically benign, solitary, deep dermal tumors.[399] Hemangiosarcoma, a malignant neoplasm of vascular endothelial cells also known as malignant hemangioendothelioma or angiosarcoma, is rare, but Thoroughbreds might be overrepresented.[400,401] It occurs mainly in middle-aged horses, but young animals and even neonatal foals can be affected.[400-402] Solar radiation might play a role in development of the neoplasm.[403] Hemangiosarcomas can present as cutaneous, locally invasive, or disseminated forms and can affect any organ system or location. Local invasions of the vertebrae and spinal cord, oral cavity, eye, third eyelid, tarsal sheath, and frontal sinus, as well as disseminated disease, have been reported.[402,404-406] Because of the varying locations, a wide range of clinical findings can be encountered. In adult horses, lungs, pleura, spleen, and skeletal muscle are most commonly affected, whereas in young animals skin and limbs are frequently involved.[400,401] Subcutaneous or muscular swellings, tachypnea, epistaxis, and lameness often prompt examination, and not infrequently the tumor is initially mistaken for a nonresolving hematoma or continuously bleeding wound.[400,407] Progression can be extremely rapid, with new masses occurring within days with a median time between onset of clinical signs and euthanasia of 17 days (range 0 days to 4 years) or more prolonged over several months.[400,401] Laboratory examination might identify anemia, thrombocytopenia, leukocytosis, and hyperfibrinogenemia or hypofibrinogenemia. More profound hematologic changes than what would be expected with simple trauma can alert the clinician to the presence of a hemangiosarcoma. In advanced cases, coagulation abnormalities or disseminated intravascular coagulation might be observed. Results of diagnostic imaging are often nonspecific, with an ultrasonographic appearance resembling tissue disruption and hematoma formation. Cytology from aspirates or paracentesis is usually consistent with blood.[401,408] Histology is required to obtain a definitive diagnosis, and multiple biopsies might be necessary before a clinical suspicion can be confirmed. Sample collection can be hampered by massive hemorrhage. Although the disseminated form in adults appears to be uniformly fatal, curative excision of cutaneous or locally invasive masses and even spontaneous regression in horses less than 3 years old have been reported.[400]

Hemangiomas have largely been described in the skin of young animals (median age of 8 months in one study), but cases in adult horses also occur.[399] Lesions are either present at birth or develop over weeks to months with progressive enlargement.[409,410] The masses frequently affect the extremities, head, or neck, but synovial involvement has also been reported. Resection is often curative, but repeated surgeries might be required.[409,411]

Lymphangioma and Lymphangiosarcoma

Lymphangiomas and lymphangiosarcomas are very rare in horses. Lymphangiosarcomas display infiltrative behavior, and differentiation between tumors originating from lymphatic or blood vessels can be difficult because of the overlapping morphologic features. Confirmation relies on a combination of clinical, gross, microscopic, immunohistochemical, and

ultrastructural findings.[412] Lymphangiosarcoma affecting the forelimb, third eyelid, and internal organs in adult horses and cutaneous lymphangiomas in young horses involving limbs and neck have been described.[412-418]

CHAPTER 16

Disorders of the Endocrine System

Disorders of Calcium and Phosphorus

Ramiro E. Toribio

Calcium and phosphorus have structural (mechanical) and nonstructural (ionic) functions, and their concentrations in the extracellular and intracellular compartments are influenced by physiologic and pathologic conditions. Disorders of calcium and phosphorus metabolism are frequent in horses and foals with various diseases, infectious and noninfectious, acute and chronic, and in many instances their blood concentrations have been associated with disease severity and outcome.[1] Progress in elucidating how equine pathologies alter calcium and phosphorus homeostasis has been made[1-7]; however, major knowledge gaps still exist. These minerals are highly interactive with other ions (Mg^{2+}, Na^{+}, K^{+}) and analytes (glucose), and imbalances should be assessed in the context of laboratory and clinical findings.

CALCIUM

Calcium is essential for physiologic processes such as muscle contraction, neuromuscular excitability, blood coagulation, enzyme activation, hormone secretion, cell division, and cell membrane stability.[8] It is also involved in processes leading to cell injury and cell death, including free radical production, protease activation, vasoconstriction, and apoptosis. Because of the importance of calcium in intracellular and extracellular processes, maintenance of steady calcium concentrations is essential.[9]

Distribution and Physical Properties of Calcium

Calcium is found in three main compartments: the *skeleton,* the *soft tissues,* and the *extracellular fluid.* The skeleton contains approximately 99% of the total body calcium as hydroxyapatite crystals ($Ca10(PO^4)6(OH)^2$). As part of the skeleton (structural function), calcium provides support against gravity, protection of vital internal organs (brain, spinal cord, thoracic organs), and a niche for blood-forming elements. The skeleton also acts as a reservoir for calcium. The nonstructural functions are related to calcium as a regulatory ion. The remaining 1% of total body calcium is present in cell membranes, mitochondria, endoplasmic reticulum (0.9%), and extracellular fluid (0.1%).[8] In blood, virtually all calcium is in plasma, and within plasma calcium exists as a free (or ionized) form, is bound to proteins (40%–45%), or is complexed to anions such as citrate, bicarbonate, phosphate, and lactate (5%–10%) (Fig. 16.1).[8,10] In horses, serum ionized calcium represents 50% to 58% of the total serum calcium concentration.[4,11,12] Free, unbound, or ionized calcium (Ca^{2+}) is the biologically active form of calcium. Of the protein-bound calcium, approximately 80% is associated with albumin and 20% with globulins.

Plasma Ca^{2+} binds to anionic proteins (albumin), and its affinity for negatively charged sites is pH dependent. During acidosis, Ca^{2+} binding to albumin is reduced due to increased H^{+} concentrations, leading to higher Ca^{2+} concentrations; during alkalosis, Ca^{2+} concentrations are lower. Total calcium concentrations remain unchanged. Hypoalbuminemia results in total hypocalcemia (pseudohypocalcemia), with Ca^{2+} concentrations remaining within the normal range unless the primary cause of hypoabuminemia is also altering calcium homeostasis (e.g., as with sepsis or gastrointestinal disease). Plasma and serum calcium concentrations are lower in foals than in adult horses.[13]

Cytosolic Ca^{2+} (Ca^{2+}_i) concentrations are very low (10^{-6}–10^{-7} M) compared with extracellular Ca^{2+} concentrations (10^{-3} M). This 10,000-fold Ca^{2+} gradient between extracellular and intracellular compartments increases the utility of calcium for signal transduction. Approximately 95% of Ca^{2+}_i is sequestered within the endoplasmic reticulum and mitochondria (see Fig. 16.1). Mechanisms that control changes in Ca^{2+}_i concentrations include Ca^{2+} channels in the plasma membrane (PM), the endoplasmic reticulum (ER), and the sarcoplasmic reticulum (SR). Some of the mechanisms that remove Ca^{2+}_i from the cytosol include Ca^{2+} ATPases and Na^{+}/Ca^{2+} exchangers in the PM, ER, and SR. The mitochondria are also important in regulating Ca^{2+}_i by providing energy for active calcium transport and by storing Ca^{2+}_i.

The release of calcium from intracellular stores depends on messenger-activated channels present in the ER, SR, and mitochondria. For example, by interacting with specific cell membrane receptors, hormones may activate phospholipase C to hydrolyze phosphatidylinositol 4,5-biphosphate to inositol 1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 is highly diffusible and interacts with IP_3 receptors on the ER and SR, opening calcium channels and increasing Ca^{2+}_i concentrations. The ryanodine receptors are intracellular calcium channels present in excitable cells (myocytes, neurons), and their activation mediates calcium-induced calcium release (CICR) from the sarcoplasmic reticulum.

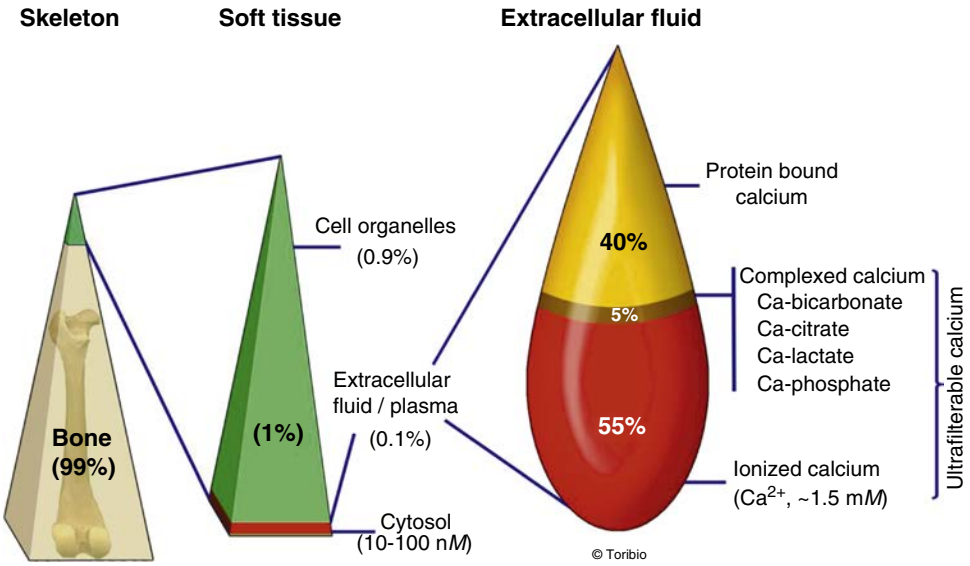

FIG. **16.1** Calcium distribution in the body. The skeleton contains approximately 99% of the total body calcium. The remaining 1% of calcium is present in the cell membrane, mitochondria, endoplasmic reticulum, and extracellular fluid. In blood, calcium exists as a free or ionized form (Ca^{2+}), bound to proteins, and complexed to anions such as citrate, bicarbonate, phosphate, and lactate. In horses, serum ionized calcium represents 50% to 58% of the total serum calcium concentration.[4,11,12] (Courtesy Dr. R. E. Toribio, The Ohio State University.)

Ca^{2+} channels (slow channels) are slightly permeable to Na^+ and are abundant in cardiac and smooth muscle where they regulate action potentials. Because Ca^{2+} channel ion kinetics are slow, depolarization in smooth muscle cells is slow and Ca^{2+} dependent. In contrast, Na^+ channels (fast channels) are abundant in skeletal muscle and neurons where they regulate neurotransmitter release and rapid cell depolarization. During hypocalcemia, fast Na^+ channels open with small changes in the membrane potential, rendering nerve and muscle fibers very excitable. This is associated with hyperexcitability, muscle fasciculations, and tetany. Extracellular Ca^{2+} binds to Na^+ channels to reduce Na^+ entry, increasing the depolarization threshold, thus stabilizing the cell membrane. This is the mechanism by which Ca^{2+} antagonizes the effects of hyperkalemia.

In skeletal muscle, almost all Ca^{2+} required for excitation and contraction comes from the SR. In contrast, in the smooth muscle cell, the SR is a rudimentary organelle, and most of the Ca^{2+} required for contraction comes from the extracellular fluid. This has clinical implications and explains why hypocalcemia frequently results in ileus and hypotension and can contribute to conditions such as retained fetal membranes.

Ca^{2+} (factor IV) is necessary for the process of coagulation. Ca^{2+} is a cofactor for factors II, VII, IX, X, XI, XII, and XIII (procoagulant) and proteins C, S, and Z (anticoagulant). Of interest, vitamin K–dependent factors (II, VII, IX, X, proteins C, S, Z) contain γ-carboxylated glutamic acid (Gla) residues that allow them to bind Ca^{2+} to perform their specific functions. The Gla residues of osteocalcin, a bone protein secreted by osteoblasts, bind to calcium in hydroxyapatite crystals to facilitate conformational changes and bone formation. The Ca^{2+} concentrations required for coagulation are minimal, and low Ca^{2+} concentrations do not seem to interfere with the clotting process. However, prolonged or severe hypercalcemia may reduce coagulation times.[14]

TABLE **16.1** Calcium and Phosphorus Requirements in Horses[15]

	Percent in Diet		Daily (g)	
	Ca	P	Ca	P
Foals (less than 6 months)	0.80	0.55	33	20
Weanlings	0.60	0.45	34	25
Yearlings	0.50	0.35	31	22
Two-year-old	0.40	0.30	25	17
Mare, late pregnancy	0.45	0.30	34	23
Mare, lactation	0.45	0.30	50	34
Mature horses	0.30	0.20	23	14

Adapted from Schryver HF, Hintz HF Minerals. In Robinson NE (ed.): *Current Therapy in Equine Medicine*, 2nd ed. Philadelphia: W.B. Saunders, 1987: 393-405.[15]

Requirements

Calcium and phosphorus requirements in horses and ponies depend on the age, physiologic status, and amount of work or exercise performed (Table 16.1). Horses do not have a nutritional drive to meet their calcium needs, which are highly dependent on dietary intake. However, there appears to be a nutritional drive for phosphorus, as animals with phosphorus deficiency will eat or lick foreign materials (dirt, rocks, and bones) in a condition known as pica. Because extracellular Ca^{2+} is under the homeostatic control of several factors, serum Ca^{2+} concentration is not a reliable indicator of dietary calcium intake. An acceptable diet for horses must have 0.15% to 1.5% of calcium and 0.15% to 0.6% of phosphorus in feed dry matter (DM) (Table 16.2). A calcium:phosphorus ratio less than 1:1 may have negative effects on calcium absorption and skeletal development, whereas calcium:phosphorus ratios as high as 6:1 for growing equids may not be detrimental if

TABLE **16.2 Acceptable Ranges of Minerals and Vitamins in Feed of Horses**[16,17,36,37,51]

	In Dry Matter
Ca (%)	0.25–1.5
P (%)	0.15–0.6
Mg (%)	0.08–0.16 (14 mg/kg body weight)
Vitamin D (IU/kg)	300–800

TABLE **16.3 Calcium and Phosphorus Content (%) in Some Mineral Supplements**[1,15,23,25,43,46,214]

	Ca (%)	P (%)
Bone meal	30	13
Calcium carbonate	39	0
Defluorinated phosphate	32	18
Dicalcium phosphate	22	19
Ground limestone	34	0
Monocalcium phosphate	16	22
Monobasic sodium phosphate[a]	0	23
Dibasic sodium phosphate[a]	0	22
Monobasic potassium phosphate[a]	0	23
Dibasic potassium phosphate[a]	0	18
Calcium gluconate 23%[b]	2.14	0

Phosphorus bioavailability for these supplements is 40%–50%.
[a]Phosphorus content based on chemical-grade anhydrous salts. Sodium phosphate enemas contain monobasic and dibasic sodium phosphate.
[b]Elemental calcium calculated on the basis of molecular weight of calcium gluconate hemicalcium salt. Each mL of the 23% parenteral solution contains 21.4 mg of elemental calcium.

phosphorus intake is adequate.[18] Adult horses should receive approximately 40 mg of calcium/kg of body weight (BW) per day. These requirements depend on the physiologic status of the animal. Pregnant mares require around 50 to 60 g of calcium/day, and lactating mares and growing horses may require 50 to 75 g of calcium/day.

The daily calcium requirements of the lactating mare at the onset of lactation are double the maintenance amount. Mares' milk calcium concentration ranges from 1.3 g/L of fluid milk during the first 2 weeks of lactation to 0.8 g/L of milk during weeks 15 to 17.[19,20] For a 500-kg mare producing 15 L of milk/day with a calcium concentration of 1.2 g/L of milk, this represents a demand of 36 g of calcium (15 kg of milk × 1.2 g of calcium × 50% absorption) a day, in addition to her maintenance needs.

It has been estimated that the average horse must absorb 20 to 25 mg of calcium and 10 to 12 mg of phosphorus/kg BW/day to balance losses.[21-23] According to the American National Research Council (NRC),[24] the maximum tolerable content of dietary phosphorus in horses fed adequate amounts of calcium is 1%. Calcium and phosphate content in some mineral supplements and equine feeds are presented in Tables 16.3 and 16.4.

Absorption

Horses absorb a larger proportion of dietary calcium compared with other species.[26] Horses absorb calcium and phosphorus with high efficiency and with little effect of age.[23,26] Horses fed

diets with adequate amounts of calcium absorb 50% to 75% of the calcium and less than half of the phosphorus present.[23,27] Calcium in most forages for horses is more than 50% digestible (Table 16.5). The efficiency of calcium absorption is inversely related to the calcium content of the diet. The proximal half of the small intestine is the main site for calcium absorption in the horse, followed by the distal small intestine and the dorsal colon (Fig. 16.2).[23,28] The amount of calcium absorbed in the dorsal colon is minimal, and the cecum and ventral colon are mainly secretory sites for calcium (see Fig. 16.2). Intestinal absorption of calcium is paracellular and transcellular. Paracellular absorption is passive and driven by high luminal calcium concentrations. Transcellular calcium absorption is an active process mediated by epithelial calcium channels for apical uptake, calcium-binding proteins (calbindins) to move calcium across the cell, and basolateral proteins for extrusion.

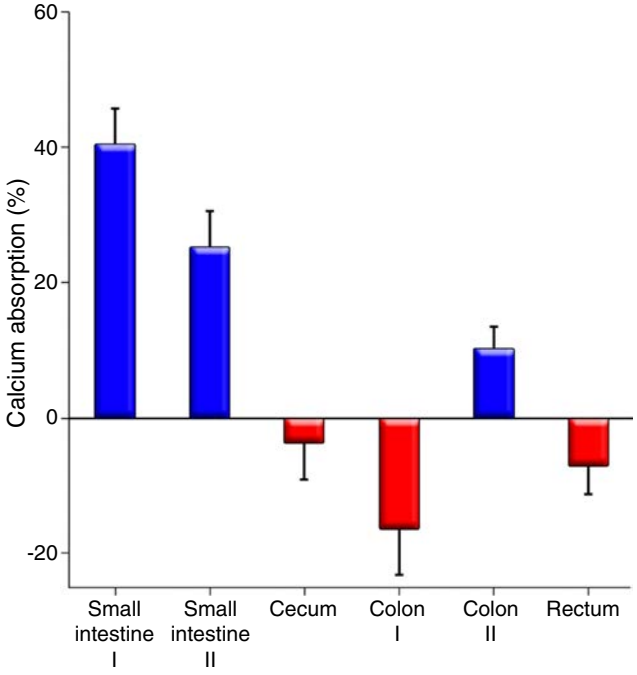

FIG. **16.2** Net absorption of calcium from the intestine of the horse. The intestine was divided into six regions: proximal (small intestine I) and distal (small intestine II) halves of the small intestine, cecum, proximal (colon I) and distal (colon II) large colon, and transverse colon and rectum. (Adapted from Schryver HF, Craig PH, Hintz HF, Hogue DE, Lowe JE. The site of calcium absorption in the horse. *J Nutr.* 1970; 100:1127-1131.[28])

Transcellular absorption is regulated by $1,25(OH)_2D$. For specific mechanisms involved in transepithelial calcium transport see the section on the physiologic effects of parathyroid hormone in the kidney. High dietary phosphate or phytate content inhibits calcium absorption,[29] although a high dietary calcium content has minimal effect on phosphorus absorption.[30] Dietary oxalate reduces calcium absorption, with a 1% oxalate content in an equine diet reduced calcium absorption by 66%.[31] Oxalate content in the diet higher than 0.5% or a calcium:oxalate ratio below 0.5 can result in a negative calcium balance.[32] Some plants containing harmful amounts of oxalate are listed in Table 16.6.

The dietary cation-anion balance (DCAB) affects Ca^{2+} absorption—anionic diets with a low DCAB increase intestinal Ca^{2+} absorption and serum Ca^{2+} concentrations,[33] whereas a high-DCAB diet has the opposite effect.

Glucocorticoids affect the calcium metabolism in the horse. Dexamethasone decreases intestinal absorption of calcium, decreases bone resorption, and increases urinary excretion of calcium.[34,35]

There is limited information on the effect of magnesium on calcium and phosphorus absorption from the gut in the horse. [36,37] No changes in serum calcium and phosphorus concentrations were detected in foals fed a magnesium-deficient diet, although mineralization of the aorta was present.[36]

Elimination

Calcium is eliminated through urine, milk, sweat, feces, and the fetus. Because horses absorb a greater proportion of dietary calcium, fecal calcium content is lower than in ruminants when fed equivalent diets.[23,26] Endogenous losses of calcium in horses are estimated to be 20 to 25 mg/kg BW/day.[21]

TABLE **16.6 Plants Containing Harmful Amounts of Oxalate**[a]

Scientific Name	Common Name
Amaranthus spp.	Red-rooted pigweed[b]
Bassia (Kochia) scoparia	Summer cypress, Mexican fireweed[b]
Beta vulgaris	Sugar beet
Brachiaria spp.	Para grass
Cenchrus ciliaris	Buffel grass
Chenopodium spp.	Lambsquarter
Cynodon dactylon	Bermuda grass
Digitaria eriantha	Pangola
Halogeton glomeratus	Halogeton[b]
Oxalis spp.	Soursob, Shamrock[b]
Panicum spp.	Panicgrass, kleingrass
Paspalum dilatatum	Dallisgrass, Dallas grass
Panicum virgatum	Switchgrass
Panicum (Megathyrsus) maximum	Guineagrass
Pennisetum clandestinum	Kikuyu, kikuyo
Pennisetum polystachion	Mission grass
Pennisetum purpureum	Napier grass
Pennisetum typhoides	Pearl millet
Phytolacca americana	Pokeberry
Portulaca oleracea	Purslane, pigweed, verdolaga
Rheum rhaponticum	False rhubarb, rhapontic rhubarb
Rumex spp.	Sorrel, curly dock[b]
Salsola spp.	Russian thistle, tumbleweed
Sarcobatus vermiculatus	Greasewood[b]
Setaria incrassate	Purple pigeon grass
Setaria sphacelata	Setaria, pigeon grass, bristle grass[b]
Setaria spp.	Foxtail grass

[a]These plants have an oxalate content higher than 0.5% dry matter (DM) or a calcium:oxalate ratio less than 0.5.
[b]Oxalate content in these plants is higher than 5% DM. Their ingestion can result in calcium deficiency and clinical signs consistent with nutritional secondary hyperparathyroidism. Some of these plants may also cause gastrointestinal irritation, diarrhea, renal injury, and signs of acute hypocalcemia.

Assuming a 50% calcium digestibility, a 500-kg horse would require 20 g of calcium to replace losses, or 40 mg/kg BW/day. Growing and lactating horses can double these requirements. Calcium elimination depends on physiologic status, amount of calcium ingested, presence of substances that interfere with calcium absorption (phosphates, oxalates, phytates), and diseases. The urinary fractional excretion of calcium and the ratio of urinary to serum calcium and phosphorus have been proposed as methods to estimate calcium intake.[38] However, interpretation of calcium excretion is difficult due to the large amounts of calcium eliminated in the equine urine.[39] A large proportion of the ultrafiltered calcium is reabsorbed in the proximal convoluted tubules (PCTs), cortical thick ascending loop of Henle (CTAL), and distal convoluted tubules (DCTs) by different mechanisms. The principles of intestinal calcium absorption (paracellular and transcellular mechanisms) apply to renal reabsorption of calcium.

TABLE **16.7 Normal Serum Concentrations of Calcium, Phosphorus, Magnesium, Vitamin D, and PTH and Urinary Excretion of Calcium, Phosphorus, and Magnesium in Horses**

Total calcium (mg/dL)[a]	11.1–13.0
Ionized calcium (mg/dL)[a]	6.0–7.0
Phosphorus (mg/dL)[b]	2.0–4.8
Total magnesium (mmol/L)	0.53–0.91
Ionized magnesium (mmol/L)	0.46–0.66
PTH (pmol/L)	<4.0 (<40 pg/mL)

FP (%)	<0.5%[4,6,7]
FMg (%)	15%–35%[6,7,40]
$25(OH)D_3$[a]	<2.0 ng/mL[113] 4.7 ± 1.0 ng/mL[113c] 1.90 ± 0.23 ng/mL—winter[110] 2.43 ± 0.09 ng/mL—summer[110] 4.2 ± 0.34 µg/L—winter[111d] 6.2 ± 0.36 µg/L—summer[111d] 11.42 ± 3.26 ng/mL[114] 14.3–37.2 ng/mL[115] 9.5–19.2 ng/mL[3,115a]
$1,25(OH)_2D_3$	18.6 ± 7.3 ng/L—winter[111c] 18.7 ± 8.0 ng/L—summer[111c] 55.0 ± 24.0 pmol/L[107] 7.1–16.5 pmol/L[3c] 8.6 ± 4.7 pg/mL[120] 13.4 ± 5.9 pg/mL[120e]

Values from the laboratory at the College of Veterinary Medicine, The Ohio State University.
$25(OH)D_3$ = 25-hydroxyvitamin D_3; $1,25(OH)_2D_3$ = 1,25-dihydroxyvitamin D_3.
[a]Serum/plasma values are lower in foals than adults.
[b]Serum/plasma values are higher in foals.
[c]D_2 metabolite.
[d]Includes D_2 and D_3 metabolites.
[e]Values from donkeys.
Calcium conversion: mg/dL = mmol/L × 4; mmol/L = mg/dL × 0.25
Magnesium conversion: mg/dL = mmol/L × 2.43; mmol/L = mg/dL × 0.415
Phosphorus conversion: mg/dL = mmol/L × 3.1; mmol/L = mg/dL × 0.32
PTH conversion: pg/mL = pmol/L × 0.105; pmol/L = pg/mL × 9.5
Calcitonin conversion: pg/mL = pmol/L × 3.42; pmol/L = pg/mL × 0.29
$1,25(OH)_2D$ conversion: pg/mL = pmol/L × 2.4; pmol/L = pg/mL × 0.42
25(OH)D conversion: ng/mL = nmol/L × 2.5; nmol/L = ng/mL × 0.40

The urinary fractional excretion of calcium or phosphorus can be calculated using the following formula.

$$\left(\text{Urine } Ca^{2+} \text{or P/Serum } Ca^{2+} \text{or P}\right) \times \left(\text{Serum creatinine/Urine creatinine}\right) \times 100$$

The fractional excretion of calcium and phosphorus in healthy horses is 3% to 10% and less than 0.5%, respectively (Table 16.7).[4,6,7] For most healthy horses the clearance of phosphorus is less than 0.2%.[7] Recent feeding can influence these values to some extent.

Deficiency

Calcium deficiency can be acute or chronic. Signs of acute calcium deficiency are usually associated with increased neuromuscular excitability, whereas chronic calcium deficiency presents as abnormal cartilage and bone development, developmental orthopedic disease (DOD), and lameness. However, neuromuscular signs can develop in chronic cases. When calcium deficiency is suspected, feed analysis is recommended to determine whether dietary calcium and phosphorus content are adequate.

PHOSPHORUS

Phosphorus (or phosphate) represents approximately 1% of the body weight, with most (85%) located in the bone matrix (hydroxyapatite), 15% in blood and soft tissues, and less than 0.1% in the extracellular fluid. In blood, phosphate exists in organic (70%) and inorganic (30%) forms. Most phosphate in the extracellular fluid is inorganic. Organic phosphate is bound to lipids, proteins, and blood cells; however, only inorganic phosphate (PO_4; P_i) is measured. In plasma, PO_4 exists as ionized PO_4 (40%–50%), is complexed to cations (Na^+, Ca^{2+}, Mg^{2+}; 30%–40%), and bound to proteins (1%–15%) (Fig. 16.3). There are four forms of PO_4 in the extracellular compartment: H_3PO_4, $H_2PO_4^-$, HPO_4^{2-}, PO_3^{2-}. However, at physiologic pH only divalent (HPO_4^{2-}) and monovalent ($H_2PO_4^-$) PO_4 are present at relevant concentrations in a 4:1 ratio. During acidosis this ratio might be as low as 1:1, whereas in alkalosis it can be as high as 9:1.[41] Like intracellular Ca^{2+}, free cytosolic PO_4 concentration is very low. Phosphate is the main intracellular anion existing in organic (phospholipids, nucleic acids, phosphoproteins, creatine phosphate, adenosine triphosphate [ATP], guanosine triphosphate [GTP], cyclic adenosine monophosphate [cAMP], nicotinamide adenine dinucleotide phosphate [$NADP^+$], thiamine pyrophosphate, 2,3-diphosphoglycerate [2,3-DPG or 2,3-BPG], inositol triphosphate, DNA, RNA) and inorganic forms. Therefore phosphorus is important for nerve function, muscle contraction, electrolyte transport, oxygen transport, enzyme activity, and gene transcription; metabolism of proteins, carbohydrates, and fats; and cell proliferation. The regulation of extracellular PO_4 is closely associated with Ca^{2+} homeostasis.

Phosphorus requirements depend on age, physiologic status, and physical activity (see Table 16.1). In horses, phosphorus absorption ranges from 20% to 55% and takes place in the small and large intestines (Fig. 16.4).[23,42-47] The apparent phosphorus digestibility is higher for yearlings than mature horses.[45] True phosphorus digestibility for growing horses is estimated at 45%,[45] whereas for mature horses it is around 25% to 35%.[45-47] Phytate (organic phosphorus; phytic acid; inositol polyphosphate) has low digestibility, is the main form of phosphorus present in grains and forages, and requires bacterial phytase in the equine large colon to liberate phosphorus and increase its absorption.[48] Age does not influence phytate digestibility, and yearlings can utilize organic phosphorus (phytate) at a similar level to adults, suggesting that diets without inorganic phosphorus may be acceptable for growing equids.[45] Horses have a good capacity to degrade phytate[45,49,50]; however, it is unclear how much of the released phosphate is absorbed. It is assumed that most phosphate from phytate degradation is excreted in feces.[50] Results on the beneficial effect of supplementing equine diets with phytase to increase phosphate absorption have been controversial.[50] In one study, phytase supplementation had more influence on calcium than PO_4 absorption, suggesting that it could be useful in horses fed phytate-rich diets.[47] However, digestibility results from a recent study in yearlings and adult horses indicate that phytase supplementation may not be necessary

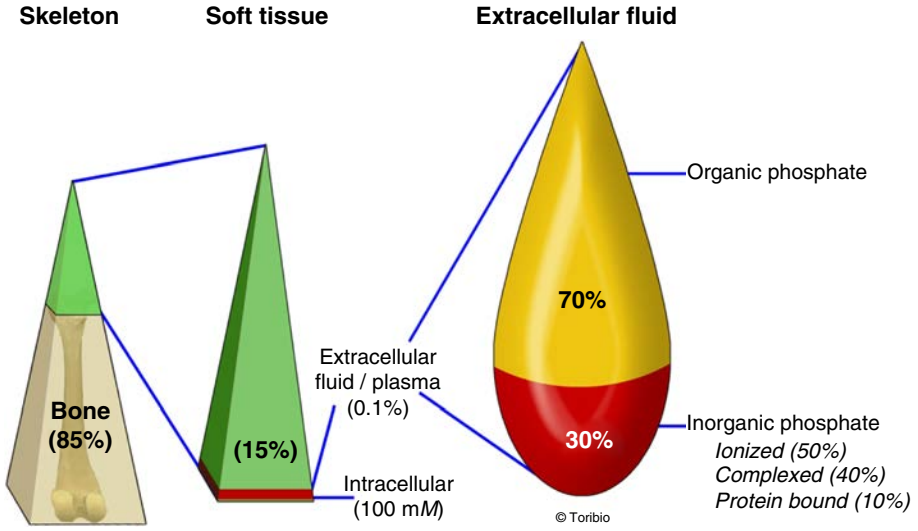

FIG. **16.3** Phosphorus distribution in the body. The skeleton contains approximately 85% of the total body phosphorus. The remaining 15% of phosphorus is present in soft tissues and the extracellular fluid. In blood, phosphorus exists in organic (70%) and inorganic (30%) forms. Inorganic phosphorus, which is measured clinically, is present in an ionized form, complexed to cations such as Na^+, Ca^{2+}, and Mg^{2+}, and bound to proteins. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

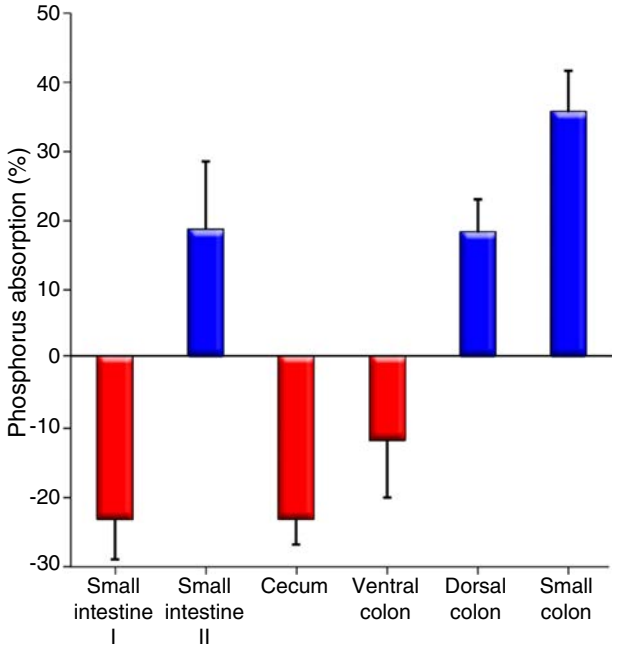

FIG. **16.4** Net absorption of phosphorus from the intestine of ponies fed an alfalfa diet. (Adapted from Schryver HF, Hintz HF, Craig PH, Hogue DE, Lowe JE. Site of phosphorus absorption form the intestine of the horse. *J Nutr.* 1972; 102:143-148.[42])

as they can digest most of the phytate in the diet.[45] Unlike other species, excess dietary aluminum or magnesium does not appear to interfere with PO_4 absorption in horses.[48,51,52] Most renal PO_4 reabsorption (greater than 80%) occurs in the proximal tubules by Na^+-dependent mechanisms (sodium-dependent phosphate transport protein [Na^+/P_i cotransporter; NPT2 cotransporter), with minimal reabsorption in the distal nephron, and the urinary fractional excretion of PO_4 in horses is low (less than 0.5%). Chronic excess of dietary phosphorus is associated with clinical signs of calcium deficiency, which include lameness, abnormal cartilage and bone development, fractures, and osteodystrophia fibrosa (nutritional secondary hyperparathyroidism). Chronic phosphorus deficiency is manifest as weight loss, weakness, depraved appetite (pica), lameness, and DOD. Serum PO_4 concentrations are more indicative of dietary phosphorus intake and status than serum calcium concentrations because the homeostatic control for PO_4 is not as precise as that of Ca^{2+}.

Serum PO_4 concentrations are higher in foals (up to 9.0 mg/dL; 2.9 mmol/L) than horses (2.5–5.0 mg/dL; 0.8–1.6 mmol/L) as a result of increased intestinal absorption and renal reabsorption of PO_4 to supply the growing skeleton and other tissues. Alkaline phosphatase activity is also higher in foals from increased osteoblastic activity and bone formation. Normal PO_4 concentrations are presented in Table 16.7.

The atomic weight of phosphorus is 31. Therefore for unit conversion, 1 mmol/L = 3.1 mg/dL (1 mmol = 31 mg); mg/dL × 0.32 = mmol/L (1 mg/dL = 0.32 mmol/L; 1 mg = 0.032 mmol); 1 mmol/L = 1.8 mEq/L.

Acute renal failure and hypoparathyroidism are associated with hyperphosphatemia. Serum PO_4 concentrations in horses with chronic renal failure are variable.

Conditions that result in cell lysis (hemolysis, rhabdomyolysis, tumor necrosis) and acidemia may cause acute hyperphosphatemia. Hyperphosphatemia is also a common finding in hospitalized foals from acid-base and endocrine disorders. Conditions associated with hypophosphatemia include inadequate intake, decreased intestinal absorption, renal waste, hyperparathyroidism, sepsis, and PO_4 shift to the intracellular compartment (insulin, alkalosis). PO_4 translocation to the intracellular compartment is a frequent cause of hypophosphatemia in critically ill humans, and occasionally occurs in horses with starvation, refeeding syndrome, parenteral nutrition (hyperglycemia, hyperinsulinemia), and hyperlipemia (hypertriglyceridemia). Acute hypophosphatemia can lead to cell membrane fragility and lysis (hemolysis, rhabdomyolysis).

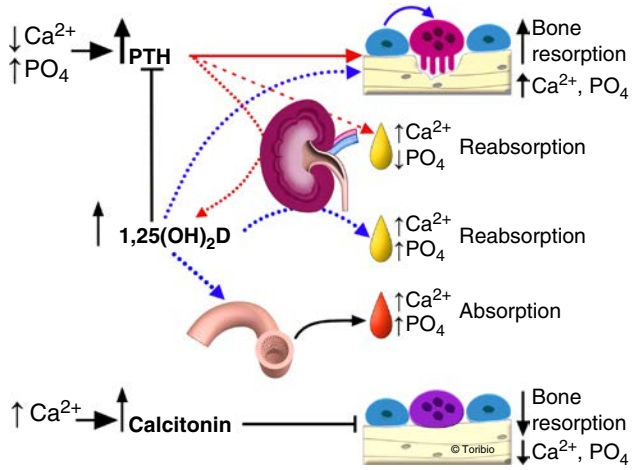

FIG. **16.5** Calcium and phosphate homeostasis. A decrease in calcium (Ca^{2+}) or increase in phosphate (PO_4) concentrations will stimulate PTH secretion. PTH increases renal reabsorption of Ca^{2+}, excretion of PO_4, and activation of vitamin D to $1,25(OH)_2D$. In bone, PTH promotes osteoclastic differentiation, bone resorption, and subsequent release of Ca^{2+} and PO_4 into systemic circulation. After activation, $1,25(OH)_2D$ increases intestinal absorption and renal reabsorption of Ca^{2+} and PO_4, facilitates bone remodeling, and inhibits PTH secretion. Elevations in Ca^{2+} concentrations stimulate the thyroid gland C cells to release calcitonin that will suppress osteoclastic bone resorption. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

Treatment of hypophosphatemia should be based on the extracellular deficit. This deficit should be overestimated as PO_4 is a major intracellular anion, and cell depletion is likely to be present in animals with hypophosphatemia. A preferred parenteral solution is potassium phosphate, although sodium phosphate is a good alternative. Critically ill horses can also be supplemented with oral potassium phosphate or sodium phosphate (chemical-grade or phosphate-based enema solutions). Hypokalemia and hypomagnesemia are frequent findings in horses with hypophosphatemia due to their intricate interactions. For chronic phosphate deficiency oral supplementation with dicalcium phosphate is a good option (see Table 16.3).

Calcium and Phosphorus Homeostasis

Extracellular calcium concentrations are regulated by a complex homeostatic system that includes three major hormones: parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$, or calcitriol).[4,10,53] Parathyroid hormone–related protein (PTHrP) shares considerable homology with PTH, binds and activates the PTH-1 receptor, and is important for calcium homeostasis in the fetus (but not in the adult).[54,55] PTH increases during hypocalcemia whereas CT increases during hypercalcemia (Fig. 16.5). Fibroblast growth factor 23 (FGF23) and klotho (FGF23/klotho axis) play central roles in phosphorus, calcium, PTH, and vitamin D regulation.

Parathyroid Hormone

The main function of PTH is to maintain calcium concentrations within narrow physiologic limits. PTH is secreted by the chief cells of the parathyroid gland in response to hypocalcemia. The relationship between serum Ca^{2+} concentrations and PTH secretion in horses is inverse and sigmoidal, which allows the parathyroid gland to rapidly respond to minimal changes in Ca^{2+} concentrations.[4,9,56-59] Extracellular Ca^{2+} concentrations are detected by a Ca^{2+}-sensing G protein–linked cation receptor (CaSR) in the parathyroid cells.[60]

Horses have four parathyroid glands. The parathyroid glands IV (cranial or upper) are usually located in the fat dorsolaterally to the cranial pole of the thyroid gland and along the thyroid artery; however, they can be found in any location around the thyroid gland. A number of horses may also have parathyroid gland tissue embedded within the thyroid gland. The parathyroid glands III (lower, caudal) can be located at the bifurcation of the bicarotid trunk, at the cranial pole of the thymus, or within the thymus (young horses), and in general are twice the size of the upper parathyroid glands. Parathyroid glands consist of chief cells, oxyphil cells, and clear cells, which represents different morphologic and metabolic stages of the same parenchymal cells. The chief cells are considered the most active.

Mature equine intact PTH is a straight chain of 84 amino acids (molecular weight [MW]: 9393 Daltons in the horse; MW: 9500 Daltons in humans).[61] Other forms of PTH (amino- and carboxy-terminal peptides) can be found in circulation following cleavage in different organs.[62] From 50% to 90% of PTH immunoreactivity in blood is from carboxy-terminal fragments.[63-65] The plasma half-life of PTH in various species is approximately 2 minutes.[65-68] However, the half-life of equine PTH is unknown. The rapid metabolism of PTH, together with the fast response of the parathyroid chief cells to changes in Ca^{2+} concentrations, ensures that PTH concentrations can rapidly adjust to changes in Ca^{2+}. Approximately 60% to 70% of PTH is removed in the liver, about 25% by the kidney, and the rest by other organs.[65,66,68]

PTH gene expression and secretion are under the influence of extracellular Ca^{2+}, PO_4, $1,25(OH)_2D_3$, and fibroblast growth factor 23 (FGF23) concentrations. The role of vitamin D metabolites on equine parathyroid gland function and calcium regulation remains unclear, although it is well accepted that $1,25(OH)_2D_3$ decreases PTH gene expression and secretion.[69] This concept is important in order to understand the role of the kidney in vitamin D metabolism and parathyroid gland physiology. In the chief cells, vitamin D binds to the vitamin D receptor, which acts as a transcription factor to decrease PTH gene transcription and secretion. Unlike vitamin D, the effects of Ca^{2+} and phosphorus in the regulation of PTH secretion are not only mediated by gene transcription but also by altering PTH mRNA stability and translation.[70] Low Ca^{2+} concentrations increase PTH mRNA expression in equine parathyroid chief cells.[5]

Physiologic Actions of Parathyroid Hormone

Kidney. The kidney is the main target organ for PTH, where it increases Ca^{2+} reabsorption, reduces phosphate reabsorption, and promotes $1,25(OH)_2D_3$ synthesis (see Fig. 16.5). These effects are mediated by the PTH-1 receptor (PTH1R), which is widely distributed throughout the nephron.[71] The PTH1R is coupled to G proteins to activate adenylate cyclase and increase intracellular cAMP. PTH also activates phospholipases (A_2, C, D), protein kinase A, and protein kinase C.[71,72]

a. Effect on Ca^{2+} and Mg^{2+} Reabsorption. It has been estimated that 60% of the filtered calcium and 20% of the filtered magnesium are reabsorbed in the renal proximal tubules (the PCTs) by paracellular passive processes driven by the high luminal concentrations of Ca^{2+} and Mg^{2+}.[73,74] In the cortical thick

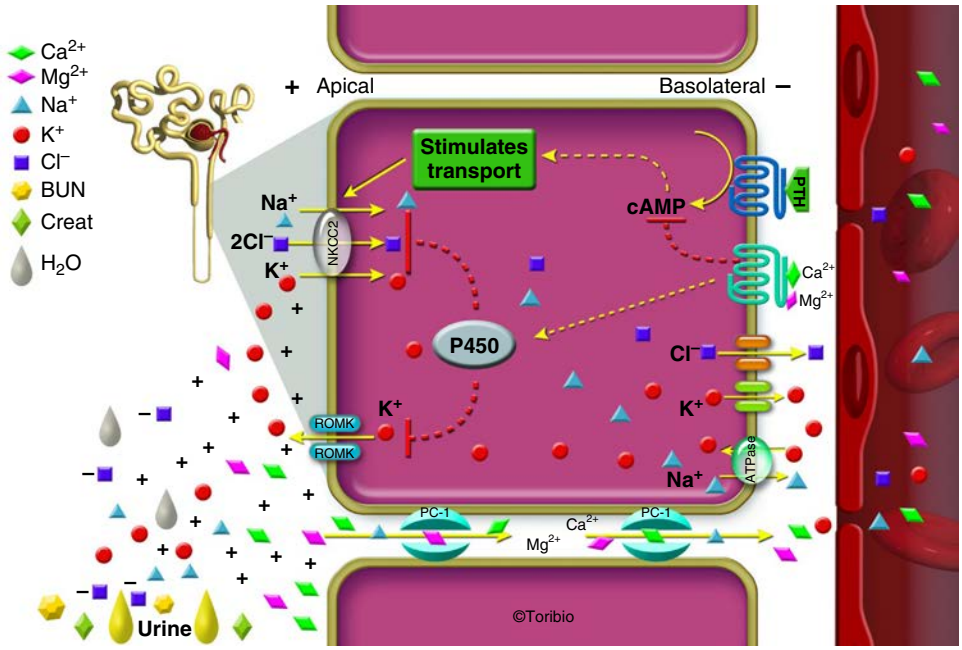

FIG. **16.6** Schematic representation of renal paracellular transport of Ca^{2+} and Mg^{2+} in the cortical thick ascending loop of Henle (CTAL). The CTAL lumen is positively charged and the electroneutral $Na^+/K^+/2Cl^-$ cotransporter (NKCC2) is the main force for the paracellular movement of Ca^{2+}, Mg^{2+}, and Na^+. Most K^+ that enters the tubular cells via NKCC2 returns to the lumen via the renal outer medullary K^+ channel (ROMK), hyperpolarizing the apical cell membrane. The basolateral Na^+/K^+-ATPase indirectly drives luminal NKCC2. PTH, via cyclic adenosine monophosphate (cAMP), enhances NKCC2 and ROMK activity and paracellular Ca^{2+} and Mg^{2+} transport, while extracellular Ca^{2+} (and to a lesser extent Mg^{2+}) through the calcium-sensing receptor inhibits NKCC2 and ROMK activity, decreasing Ca^{2+} and Mg^{2+} reabsorption.[74,76] Paracellin-1 (PC-1) facilitates paracellular permeability to Ca^{2+} and Mg^{2+}. PTH also increases renal vitamin D activation (not shown). (Courtesy Dr. R. E. Toribio, The Ohio State University.)

ascending loop of Henle (CTAL), Ca^{2+} and Mg^{2+} transport is also paracellular, but in this segment there is more permeability to Mg^{2+} (60% for Mg^{2+} vs. 20% for Ca^{2+}). The CTAL lumen is positively charged, and the main force for paracellular movement of Ca^{2+}, Mg^{2+}, and Na^+ is the transepithelial voltage gradient generated by the electroneutral $Na^+/K^+/2Cl^-$ cotransporter (NKCC2).[75] Most of the K^+ that enters the tubular cells via NKCC2 returns to the lumen via the renal outer medullary K^+ channel (ROMK), hyperpolarizing the apical membrane.[76] The Na^+/K^+-ATPase at the basolateral drives the NKCC2. In addition, basolateral Cl^- movement enhances the voltage gradient. PTH, through the PTH1R and cAMP, enhances NKCC2 and ROMK activity, while extracellular Ca^{2+} (to a lesser extend Mg^{2+}) via the calcium-sensing receptor (CaSR) inhibits NKCC2 and ROMK activity, as well as paracellular reabsorption of Ca^{2+} and Mg^{2+}[74,76] (Fig. 16.6). Hypercalcemia induces diuresis in horses because NKCC2, the target for loop diuretics, is also blocked by Ca^{2+}.[7] Hypercalcemia also promotes diuresis by blunting vasopressin-mediated apical insertion of aquaporin channels and water reabsorption in the collecting ducts. Paracellin-1 (claudin-16) is an essential protein for paracellular permeability of Ca^{2+} and Mg^{2+} in the CTAL.[76,77] PTH has minimal effect in the DCTs where $1,25(OH)_2D$ seems to be the main calcium-regulating hormone. Unlike the PCT and CTAL where calcium transport is paracellular, calcium transport in the DCT is transcellular, mediated by epithelial calcium channels (transient receptor potential cation channel subfamily V member 5 and 6 [TRPV5; TRPV6]), calcium-binding proteins (calbindin D_{9k}, calbindin D_{28k}), basolateral proteins (plasma membrane calcium ATPase [PMCA], Na^+/Ca^{2+} exchanger [NCX]), and regulated by $1,25(OH)_2D$ (Fig. 16.7).[78,79] TRPV5 is the main renal epithelial calcium channel, and TRPV6 is expressed in the intestine, kidney, and other epithelia in multiple species, including the horse.[80,80a] Calbindin D_{9k} is more important for intestinal calcium transport than calbindin D_{28k}, while both calbindins participate in renal calcium movement.[80] In horses, renal expression of calbindin D_{28k} is higher than calbindin D_{9k}.[80]

b. Effects on Phosphorus. The movement of PO_4 in the PCT occurs against electrochemical and concentration gradients and is mediated by Na^+/P_i cotransporters (NPT2 cotransporters). PTH lowers Na^+ and PO_4 transport across the brush border by enhancing the degradation of Na^+/P_i cotransporters.[71,81,82] The end result is decreased PO_4 reabsorption and phosphaturia. Low PTH concentrations will lead to hyperphosphatemia, whereas the opposite occurs with high PTH.

c. Effects on Vitamin D Metabolism. PTH, through cAMP, increases renal $1,25(OH)_2D_3$ synthesis by enhancing 1α-hydroxylase activity and suppressing 24-hydroxylase, the enzyme that inactivates $1,25(OH)_2D_3$.[71]

Bone

Bone is a very active organ that is in a continuous process of formation (osteoblasts) and resorption (osteoclasts). In adult vertebrates, formation is in equilibrium (coupled) with resorption. However, in growing animals, bone formation exceeds bone resorption, whereas in old animals and humans

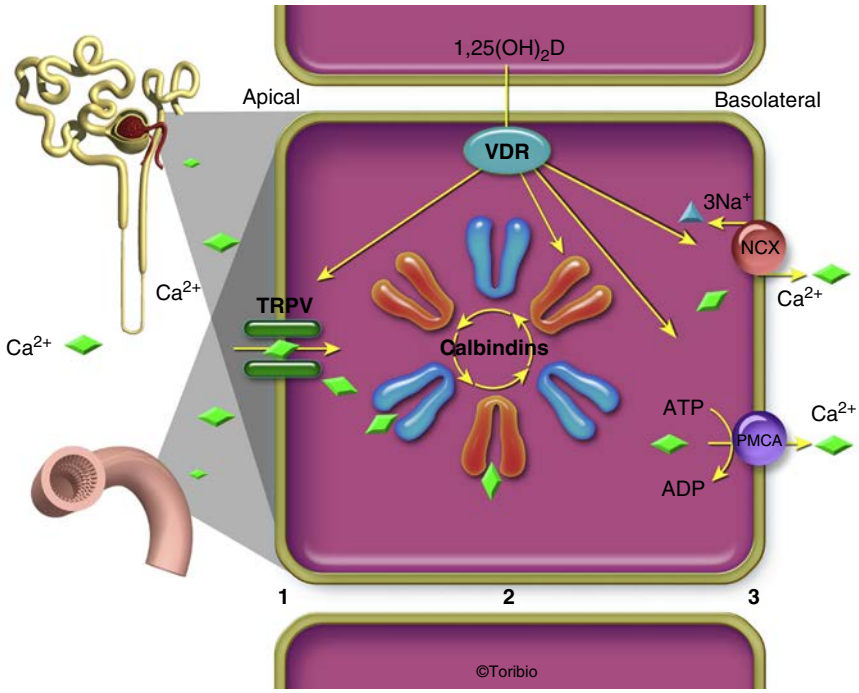

FIG. **16.7** Schematic representation of transcellular transport of calcium (Ca^{2+}) in the small intestine and kidney. Transcellular Ca^{2+} transport is considered a three-step process in which calcium (1) enters the cell passively via epithelial calcium channels (transient receptor potential cation channel subfamily V [TRPV]), (2) diffuses through the cytosol facilitated by calcium-binding proteins (calbindins), and (3) at the basolateral membrane calcium is extruded by a plasma membrane Ca^{2+} ATPase (PMCA) and a Na^{+}-Ca^{2+} exchanger (NCX). Through the vitamin D receptor, $1,25(OH)_2D$ increases all three steps of transcellular calcium transport. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

the opposite occurs. Of interest, higher PTH concentrations were measured in older compared with younger mares in late pregnancy.[83] There are no PTH receptors in osteoclasts but there are in osteoblasts. Thus the effect of PTH on osteoclast activation is mediated by the osteoblast. On PTH stimulation, osteoblasts secrete a series of factors, including macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor kappa B (RANK) ligand (RANKL).[84] These two factors (M-CSF and RANKL) are essential for osteoclast function (Fig. 16.8). Monocytes and preosteoclasts express RANK, the membrane receptor for RANKL, and the interaction of RANKL with RANK and M-CSF with its receptor results in osteoclast recruitment and activation. To keep formation and resorption in balance, the osteoblasts also release osteoprotegerin (OPG), a decoy receptor for RANKL that blocks its action on osteoclasts.[85] Other factors that stimulate osteoclast differentiation include $1,25(OH)_2D$, tumor necrosis factor–alpha (TNF-α), interleukin-1 beta (IL-1β), interleukin-6 (IL-6), and interleukin 11 (IL-11). Osteoclasts create resorption pits (Howship's lacunae) that are sealed by $\alpha_v\beta_3$ integrin to conserve the acid conditions necessary for mineral resorption. Through the ruffled border, osteoclasts release H^+ ($H_2O + CO_2$ → carbonic anhydrase → HCO_3^- + H^+) and Cl^- (exchanged with HCO_3^-) into the pit, lowering the pH, dissolving mineralized bone matrix, and releasing Ca^{2+}, PO_4, and other products. Cathepsin K is a key protease that degrades extracellular matrix proteins including type I collagen. Matrix metalloproteinases (MMPs) are zinc-containing endopeptidases that facilitate bone resorption. Tartrate-resistant acid phosphatase (TRAP) is necessary for osteoclast activity, dephosphorylates osteopontin and bone sialoprotein to allow osteoclast migration, and generates reactive oxygen species that participate in bone degradation (see Fig. 16.8).

Markers of bone formation in horses include serum osteocalcin, N-terminal peptide of type I procollagen, and bone-specific alkaline phosphatase.[86-88] Markers of bone resorption include urinary or serum collage type 1 cross-linked carboxy-terminal telopeptide (CTX), urinary collagen type 1 cross-linked N-terminal telopeptide (NTX), urinary hydroxyproline, urinary total pyridinoline, and serum TRAP 5b.[86,88]

Intestine

PTH has minimal direct actions on intestinal absorption of calcium and phosphorus. However, indirect effects are mediated by $1,25(OH)_2D$.

Vitamin D

Vitamin D plays important roles in calcium and phosphate homeostasis and to a lesser extent in magnesium metabolism. Vitamin D derives from dietary sources (vitamin D_2 or ergocalciferol from fungi and plants; vitamin D_3 or cholecalciferol from animal-based diets) and from cutaneous activation of 7-dehydrocholesterol into cholecalciferol. In mammals, ultraviolet light (290–315 nm) photolytic cleavage of 7-dehydrocholecalciferol results in previtamin D_3, which, after thermal isomerization, forms vitamin D_3 (cholecalciferol).[89] From the skin, vitamin D_3 is translocated to the liver by a vitamin D binding protein (DBP) where it is hydroxylated at carbon 25 by a mixed function P_{450} oxidase (25-hydroxylase) to form 25-hydroxyvitamin D_3 ($25[OH]D_3$; calcidiol). Other tissues

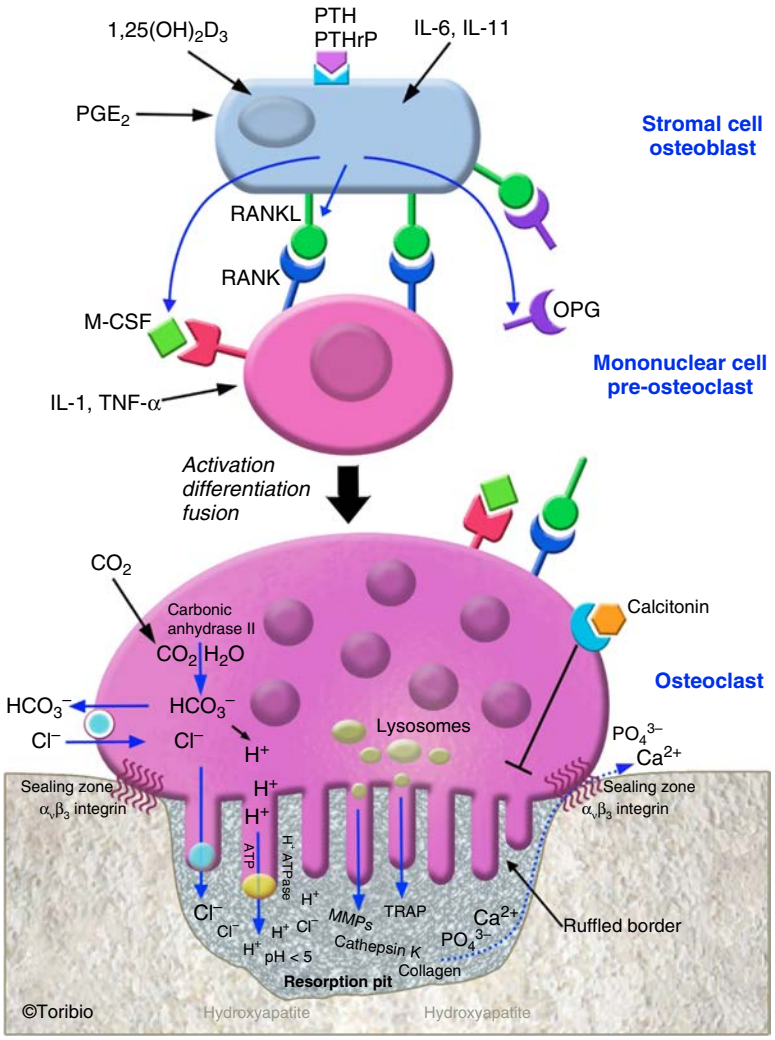

FIG. **16.8** Representation of osteoclastic activation and bone resorption. Factors that indirectly through osteoblasts stimulate osteoclast differentiation include parathyroid hormone (PTH), PTH-related protein (PTHrP), 1,25(OH)$_2$D, IL-6, IL-11, and prostaglandin E_2 (PGE_2). In response, osteoblasts secrete macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor kappa B (NF-κB) (RANK) ligand (RANKL). Mononuclear cells, osteoclast precursors, and osteoclasts express RANK (receptor for RANKL) and M-CSF receptors. Osteoblasts also release osteoprotegerin (OPG), which is a soluble decoy receptor for RANKL. IL1 and TNF-α promote osteoclast differentiation. Calcitonin inhibits osteoclast activity. Osteoclasts create a resorption pit that is sealed by $\alpha_v\beta_3$ integrin to facilitate an acid environment for mineral resorption. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

can also activate vitamin D_3, in particular under pathologic conditions. The conversion of vitamin D_3 into 25(OH)D_3 is a poorly regulated reaction, and therefore its plasma concentrations are an indicator of the vitamin D status.

From the liver, 25(OH)D is transported to the kidney by DBP where it is converted by another cytochrome P_{450} mixed function oxidase, 25(OH)D-1α-hydroxylase (1α-hydroxylase), to the active metabolite of vitamin D, 1,25-dihydroxyvitamin D_3 (1,25[OH]$_2D_3$; calcitriol). The kidney is considered the main site for 1,25(OH)$_2D_3$ synthesis, although other organs (placenta, skin, monocytes) also have 1α-hydroxylase activity.

In the case of ergocalciferol, the skin steps do not occur. Instead, after intestinal absorption ergocalciferol is converted to 25-hydroxyvitamin D_2 (25[OH]D_2) in the liver and subsequently to 1,25-dihydroxyvitamin D_2 (1,25[OH]$_2D_2$) in the kidneys, by the same enzymes.

Unlike 25-hydroxylase, 1α-hydroxylase is a tightly regulated enzyme (PTH, PO_4, 1,25[OH]$_2D_3$, FGF23). Mutations of the 1α-hydroxylase gene in humans and laboratory animals results in vitamin D–dependent type I rickets.[90] We will refer to both vitamin D active metabolites, 1,25(OH)$_2D_2$ and 1,25(OH)$_2D_3$, as 1,25-dihydroxyvitamin D (1,25[OH]$_2$D). In blood, 1,25(OH)$_2$D concentrations are 1/1000 the concentrations of 25(OH)D. The half-life of 25(OH)D can be measured in weeks, whereas the half-life of 1,25(OH)$_2$D is measured in a few hours. Both 25(OH)D and 1,25(OH)$_2$D are inactivated at the target organs by 24-hydroxylase.

Regulation of Vitamin D Metabolism

Blood concentrations of 1,25(OH)$_2$D are regulated by PTH, Ca^{2+}, PO_4, 1,25(OH)$_2$D, and FGF23. Low PO_4 and PTH increase, whereas high Ca^{2+}, PO_4, 1,25(OH)$_2$D, and FGF23

concentrations suppress renal 1α-hydroxylase activity and therefore $1,25(OH)_2D_3$ synthesis.

The role of calcitonin on vitamin D metabolism remains unclear. The FGF23/klotho axis is a recently discovered homeostatic mechanism for vitamin D synthesis.[91,92] FGF23 secreted by osteocytes binds to its receptor and klotho (coreceptor) in the renal tubular cells to suppress 1α-hydroxylase activity and $1,25(OH)_2D_3$ synthesis.[91,92] It also inhibits Na^+/P_i cotransporters to promote phosphaturia (phosphatonin action).

Actions of Vitamin D

The actions of vitamin D are mediated by the vitamin D receptor (VDR) that is found in organs involved in mineral homeostasis and bone health (intestine, bone, kidney, parathyroid gland — classic actions of vitamin D), as well as in organs not involved in mineral regulation (skin, pancreas, the immune system, and reproductive organs — nonclassic actions of vitamin D).[93] The vitamin D–activated VDR forms a heterodimer with the retinoid-X receptor to bind specific DNA sequences (vitamin D response element [VDRE]) in the promoter region of target genes to increase or decrease their expression depending on the organ or cell type.

In the intestinal tract and kidney, $1,25(OH)_2D$ promotes transcellular Ca^{2+} transport in a three-step process: (1) calcium entry by epithelial calcium channels (TRPV5/6), (2) calcium diffusion across the cytosol that is facilitated by calcium-binding proteins (calbindins), and (3) calcium extrusion at the basolateral side by plasma membrane Ca^{2+} ATPases (PMCA) and Na^+-Ca^{2+} exchangers (NCX) (Fig. 16.7).[94,95] Vitamin D increases the expression of these proteins. In addition to its effects on intestinal and renal calcium transport, $1,25(OH)_2D$ also promotes PO_4 transport by increasing the number of Na^+/P_i cotransporters.

In the kidney, $1,25(OH)_2D$ stimulates Ca^{2+} reabsorption (DCT) and phosphorus reabsorption (PCT).[93] In the skeleton, $1,25(OH)_2D$ is essential for bone remodeling; both bone formation and resorption are vitamin D–dependent processes. Vitamin D stimulates FGF23 secretion by the osteocytes, which in turn will suppress renal 1α-hydroxylase activity, creating a bone-kidney feedback system. Vitamin D deficiency results in rickets in growing animals and osteomalacia in adults. No cases of rickets or osteomalacia have been documented in horses.

As previously mentioned, PTH increases renal 1α-hydroxylase activity, increasing $1,25(OH)_2D_3$ secretion, which will suppress parathyroid chief cell proliferation and PTH secretion.[96] This is the explanation for the development of parathyroid hyperplasia and hyperparathyroidism in humans and animals with chronic kidney disease and vitamin D deficiency.

Vitamin D also has nonclassical functions. Anemia, predisposition to infections from impaired immune function, skeletal muscle weakness, cardiomegaly, reduced pancreatic glucose-mediated insulin secretion, infertility, and critical illness are among conditions reported with vitamin D deficiency.[93,97-99] Vitamin D is important in skin and hair development, modulates cell proliferation and differentiation, and has antibacterial properties through cathelicidins and defensins.[97-101] Because of these properties, several vitamin D–based compounds with antiproliferative and prodifferentiation properties have been developed to treat a number of pathologic conditions in humans and small animals (seborrhea, psoriasis, secondary hyperparathyroidism, breast cancer, prostate cancer, leukemia).[93] Reduced vitamin D concentrations have been associated with a multitude of human pathologies,[98,102-106] and more recently were linked to sepsis and mortality in critically ill newborn foals.[3]

Vitamin D Metabolism in the Horse

There is limited information on vitamin D in equids. Compared with other domestic animals (except rabbits), horses have high serum total and ionized calcium concentrations, high intestinal absorption of calcium, high urinary fractional excretion of calcium, a high Ca^{2+} set point, and low serum concentrations of vitamin D metabolites ($25[OH]_2D$ and $1,25[OH]_2D$).[3,4,23,107-115] Despite the low vitamin D concentrations, rickets or osteomalacia have not been documented in horses.[116] Horses with limited access to sunlight and fed a vitamin D–deficient diet had decreased growth, lameness, and lower bone density.[116,116] In northern latitudes, the synthesis of $25(OH)D_3$ and $1,25(OH)_2D_3$ in horses during winter months is low.[110,111] A similar phenomenon was seen in horses in the Southern Hemisphere where 25(OH)D, $25(OH)D_2$, and $1,25(OH)_2D_3$ concentrations were higher in spring and summer compared with winter months.[117] This increase in serum $25(OH)D_2$ concentrations during warmer months could be an effect of daylight on the synthesis of ergocalciferol by plants. Diurnal variations in $25(OH)D_3$ concentrations were reported in horses with peaks in the early afternoon.[118] A circadian rhythmicity for $1,25(OH)_2D$ occurred during the longest days of the year in horses in New Zealand.[119] One study in which horses were covered with blankets year around found no differences in serum $25(OH)D_2$, $25(OH)D_3$, and $1,25(OH)_2D$ concentrations between covered and uncovered horses.[117] Of interest, serum $25(OH)D_3$ concentrations were undetectable, but $25(OH)D_2$ were not. The authors concluded that horses produce minimal amounts of vitamin D_3, and that vitamin D_2, not vitamin D_3, is the main form of vitamin D in equids.[117] As previously stated, other studies have measured both vitamin D metabolites, opening the question on whether these discrepancies are statistical (sample size, study population), analytical, or vitamin D_2 is more important in horses.

Plasma 25(OH)D and $1,25(OH)_2D$ concentrations were very low or undetectable in healthy horses and ponies compared with vitamin D metabolite concentrations from other species.[107] In the same study, renal 1α-hydroxylase activity could not be detected. Serum 25(OH)D and $1,25(OH)_2D$ concentrations are lower in healthy foals than horses.[3,115] Another study found higher calcitriol concentrations in donkeys than horses[120]; however, these values were similar to concentrations measured in horses by other groups.[107,111] Both vitamin D metabolites were lower in hospitalized foals and linked to severity of disease and mortality.[3] This information supports a potential role for $1,25(OH)_2D_3$ as a modulatory factor in immunity, inflammation, and metabolism. One study found that physical activity reduced vitamin D_3 concentrations in horses.[121]

The fact that vitamin D is important for immune modulation and indirectly has antimicrobial properties suggests that vitamin D deficiency contributes to a proinflammatory state and immune deficiency in critically ill foals.[3] In the same foals of this study, low concentrations were inversely associated with PTH concentrations, supporting the importance of $1,25(OH)_2D$ in regulating parathyroid chief cell function and PTH secretion in sick foals and, probably, in adult horses. We have proposed that hypovitaminosis D could be a

potential explanation for the high PTH concentrations measured in critically ill foals and horses and also in other species. For additional information on this topic see the phosphorus section in which a potential role of the FGF23/klotho axis is incorporated into the discussion of hypovitaminosis D and increased PTH secretion.

Normal vitamin D metabolite concentrations in horses, foals, and donkeys are listed in Table 16.7.

Calcitonin

Calcitonin (thyrocalcitonin; CT) is a 32-amino-acid peptide that inhibits osteoclast function. It is secreted by the parafollicular cells (C cells) of the thyroid gland in response to hypercalcemia. Equine CT has 90% homology to human calcitonin.[122] Secretion of CT is controlled by several factors, Ca^{2+} and gastrin being the most important. The C cells sense changes in extracellular Ca^{2+} concentrations by the same calcium-sensing receptor (CaSR) present in parathyroid chief cells and renal tubular cells.[123] CT decreases plasma Ca^{2+} and PO_4 concentrations by suppressing osteoclastic bone resorption and increasing urinary Ca^{2+} and PO_4 excretion. Despite these effects, the importance of CT on mammalian Ca^{2+} homeostasis remains unclear. It has been proposed that CT may be protective against extreme hypercalcemia, but that in the day-to-day Ca^{2+} variations it may not be as relevant.[10,124] Based on recent research, it seems the most important CT function in mammalians is to prevent excessive bone resorption during lactation.[125] Postprandial increases in serum CT concentrations are mediated by gastrin, and this is likely a preemptive mechanism to avoid hypercalcemia after a calcium-rich meal. Few studies have evaluated CT in the horse.[80,126-129] Equine C cells are highly responsive to hypercalcemia.[80]

Unlike terrestrial vertebrates, CT is important to regulate extracellular Ca^{2+} concentrations in saltwater fish, where ambient calcium concentrations are extremely high (10 mM; 40 mg/dL).

Parathyroid Hormone–Related Protein

Parathyroid hormone–related protein (PTHrP), first discovered as the factor responsible for humoral hypercalcemia of malignancy (HHM),[54] has important physiologic functions in skeletal development. PTH and PTHrP share homology in their first 13 amino acids and act through the same receptor (PTH1R). Unlike PTH, which is exclusively synthesized by the parathyroid glands, PTHrP is produced by almost every tissue and has a broad range of functions.[53,55] The *physiologic* functions of PTHrP are considered to be paracrine, autocrine, and intracrine, whereas the *endocrine* actions of PTHrP are considered pathologic (HHM). PTHrP is central to fetal calcium regulation, but it has minimal effect on calcium homeostasis in the adult. Depending on the protein domain involved, PTHrP has varying functions: the amino-terminus interacts with the PTH1R, initiating PTH-like actions (bone resorption, renal Ca^{2+} reabsorption; PO_4 excretion); the midregion PTHrP participates in transplacental Ca^{2+} transport; and the carboxy-terminal inhibits osteoclastic bone resorption.[55] PTHrP is essential for mammary development and lactation; transgenic animals lacking the PTHrP gene do not develop mammary tissue.[130] High PTHrP concentrations are found in the milk of lactating humans and animals, including mares.[131] Although the functions of PTHrP in milk are unclear, PTHrP enhances Ca^{2+} transport into milk and perhaps promotes intestinal Ca^{2+} absorption in the newborn. It has been proposed that during lactation, PTHrP release into the systemic circulation is necessary to promote osteoclastic activity to meet the calcium demands from milk production.[130] Increased circulating PTHrP concentrations have been correlated with decreased bone mass in women and rodents,[130] but information in mares is lacking.

HHM, a paraneoplastic syndrome associated with excessive secretion of PTHrP by some tumors, has been reported in horses with lymphoma, gastric and preputial squamous cell carcinoma, ameloblastoma, and multiple myeloma.[132-136]

Fibroblast Growth Factor 23 and Klotho Axis

Fibroblast growth factor 23 (FGF23) and klotho play central functions in calcium, phosphorus, vitamin D, and PTH regulation. FGF23 is considered the main PO_4-regulating hormone and is secreted by osteocytes and osteoblasts in response to $1,25(OH)_2D$, PTH, and PO_4 concentrations.[91,137,138] It promotes renal PO_4 excretion *(phosphatonin)* directly by decreasing renal Na^+/P_i cotransporter number and indirectly by suppressing 1α-hydroxylase activity ($1,25[OH]_2D$ synthesis).[137-141] FGF23 also inhibits PTH synthesis and secretion.[137-141] Klotho is a transmembrane protein that functions as the coreceptor for FGF23 to promote renal phosphorus excretion, reduce $1,25(OH)_2D$ synthesis, and decrease PTH synthesis.[91,138,142] Abnormalities in FGF23 and klotho could lead to disorders in multiple body systems.[143]

CALCIUM DISORDERS IN THE HORSE

Equine calcium dysregulation is associated with hypocalcemic or hypercalcemic disorders. Conditions associated with abnormal calcium homeostasis include foal hypocalcemia,[144] hypoparathyroidism,[145,146] primary hyperparathyroidism,[147-149] nutritional secondary hyperparathyroidism,[150] hypercalcemia of malignancy,[134-136] vitamin D toxicity,[151] renal failure,[152] exercise-induced hypocalcemia,[56,153] and systemic inflammatory response syndrome (SIRS)/sepsis.[4,154,155] Normal calcium concentrations of horses are presented in Table 16.7.

Hypocalcemia

Different pathologies are associated with hypocalcemia in the horse (Table 16.8). Clinical signs of acute hypocalcemia result from increased neuromuscular excitability and decreased smooth muscle cell contractility (Table 16.9). Extracellular

TABLE **16.8 Conditions in Which Hypocalcemia Has Been Reported in Horses and Foals**

Colic	Pancreatitis
Enterocolitis	Furosemide administration
Sepsis/septicemia	Excessive administration of $NaHCO_3$
Endotoxemia	Oxalate ingestion
After endurance exercise	Primary hypoparathyroidism
Late pregnancy	Hypomagnesemia
During lactation (lactation tetany)	Cantharidin toxicosis
During transport (transit tetany)	Liver disease
Acute renal failure	Dystocia
Chronic renal failure	Malignant hyperthermia
Rhabdomyolysis	Magnesium toxicosis
Pleuropneumonia	Retained placenta
Heat stroke	Postoperative myopathy

Ca^{2+} concentrations affect the voltage at which Na^+ channels in nerve and muscle fibers are activated; Ca^{2+} decreases Na^+ permeability and raises the depolarization threshold. Thus Ca^{2+} can be seen as a natural Na^+ channel blocker. When Ca^{2+} concentrations are low, Na^+ channels are easily activated, leading to nerve and muscle fiber hyperexcitability, muscle fasciculations, tremors, and tetany. Tachycardia and cardiac arrhythmias may be present during hypocalcemia, although bradycardia may develop with severe hypocalcemia (probably from decreased cardiac muscle contractility). Depending on the severity, clinical signs of hypocalcemia may include anxiety, depression, synchronous diaphragmatic flutter (see discussion that follows), hyperexcitability, ataxia, stiff gait, tetany, muscle fasciculations and tremors, tachypnea with flared nostrils, upper airway stridor, dyspnea, dysphagia, hypersalivation, hyperhidrosis, ileus, seizures, hypotension, recumbency/collapse, and death (see Table 16.8).

Synchronous Diaphragmatic Flutter

Synchronous diaphragmatic flutter (SDF; thumps, hiccups) refers to a rhythmic movement on the flank resulting from diaphragmatic contractions that are synchronous with the heartbeat. SDF results from ionized hypocalcemia and/or hypomagnesemia, and it has been reported in horses with gastrointestinal disease,[4,156] lactation tetany (eclampsia),[157] thoracic hematoma,[158] blister beetle toxicosis,[159] urethral obstruction,[160] endurance exercise,[161] hypoparathyroidism,[146,162] idiopathic hypocalcemia,[144] and sepsis.[4] Depolarization of the right atrium stimulates action potentials in the hyperexcitable phrenic nerve as it crosses over the surface of the heart. This condition is frequent in horses after prolonged exercise, in which significant amounts of electrolytes (Ca^{2+}, Na^+, K^+, Mg^{2+}, Cl^-) are lost in sweat.[163,164] During alkalosis there is increased binding of Ca^{2+} and Mg^{2+} to plasma anions, in particular albumin, lowering their concentrations. Exercising horses often develop alkalosis from hyperventilation (respiratory alkalosis) and sweat loss of Cl^- (metabolic hypochloremic alkalosis).[158] Proximal gastrointestinal disorders associated with Cl^- loss (duodenitis/jejunitis) can also cause metabolic alkalosis. Calcium is a natural Na^+ channel blocker, and a reduction in Ca^{2+} concentrations increases Na^+ permeability, decreasing the cell membrane depolarization threshold and increasing neuromuscular excitability. Serum Mg^{2+} concentrations are often low in horses with SDF, and similar to hypocalcemia, hypomagnesemia also increases neuromuscular excitability. Low Mg^{2+} concentration facilitates Na^+ channel conductance. Hypokalemia is common with alkalosis (K^+-H^+ exchange) and may contribute to SDF. Hypokalemia raises the resting cell membrane potential and increases neuromuscular excitability, likely by keeping Na^+ channels open longer. Hypomagnesemia should always be included in the differential diagnosis of hypocalcemia and SDF.

TABLE **16.9 Clinical Signs Reported in the Literature of Horses with Hypocalcemia**

Anxiety	Hypersalivation
Asphyxia	Hyperthermia
Ataxia	Ileus
Bruxism	Laryngeal spasm
Cardiac arrhythmias	Muscle fasciculations
Colic	Seizures
Convulsions	Stiff gait
Death	Synchronous diaphragmatic flutter
Depression	Tachycardia
Dysphagia	Tachypnea
Dyspnea	Tetany
Excitation	Tremors
Hyperhidrosis	Trismus

Tetany

Low Ca^{2+} concentrations increase cell membrane excitability, and some horses may develop excessive and sustained skeletal muscular contractions or tetany. Lactation tetany occurs in mares from 2 weeks before foaling up to few days after weaning. The predisposing cause of lactation tetany is the calcium losses in milk. Mares producing large amounts of milk and eating a low-calcium diet, and performing physical work (draft mares), are at higher risk. Some horses transported for long distances may develop hypocalcemia and transit tetany.[157] Hypomagnesemia, which is often present, can worsen the signs of hypocalcemia.

Hypocalcemic Seizures

As for peripheral nerves, a drop in extracellular Ca^{2+} concentrations in the central nervous system (CNS) will increase neuroexcitability. Hypocalcemic seizures have been reported in foals and horses with hypocalcemia, sepsis, and hypoparathyroidism.[144] Clinical signs usually improve with calcium supplementation, although some animals may require repeated treatments with calcium salts. Others, in addition to calcium supplementation, also require magnesium therapy. Horses with hypocalcemic seizures have a poor prognosis for recovery.

Ileus

Smooth muscle cells have more voltage-gated Ca^{2+} channels and fewer voltage-gated Na^+ channels than skeletal muscle fibers, and therefore Na^+ is less important for the action potential and muscle contraction. This results in slower and more sustained contractions (Ca^{2+} channels are slow channels). In skeletal muscle almost all Ca^{2+} required for contraction comes from the sarcoplasmic reticulum, but in smooth muscle cells the sarcoplasmic reticulum is a rudimentary organelle; these cells depend on extracellular Ca^{2+} for contraction. Therefore any pathologic condition that reduces Ca^{2+} affects smooth muscle contractility. This is evident in horses that develop ileus and colic secondary to hypocalcemia (e.g., after exercise, transport, or sepsis). A recent study found that low ionized calcium concentrations were associated with colic in pregnant mares.[165] Treatment with calcium gluconate may restore gastrointestinal motility.

Retained Placenta

The incidence of retained fetal membranes in mares has been reported to be up to 10% of foalings.[166] Low serum total and ionized calcium concentrations are frequently seen in mares with retained placenta and acute endometritis. As for gastrointestinal motility, it is likely that decreased uterine tone and contractility may result from a similar mechanism as ileus. One study found that mares with retained placenta had statistically lower serum total calcium concentrations than mares without retained placenta.[167] Furthermore, 64% of mares treated with a combination of oxytocin in a calcium/magnesium

borogluconate solution responded to treatment compared with 44% of the mares treated with oxytocin in saline solution. No differences in serum magnesium concentrations were found in this study.

Treatment of Hypocalcemia

When treating hypocalcemia, consider calcium deficit, maintenance, losses, and sequestration. However, because the skeleton is a major calcium reservoir, therapy should be focused on correcting the deficit. Calcium therapy is essential in horses that develop rapid hypocalcemia and in horses with impaired parathyroid gland function that cannot restore normocalcemia. The decision to treat horses with hypocalcemia should be based on the existence of hypocalcemia and not necessarily on the presence of signs of hypocalcemia. Most horses with ionized hypocalcemia do not show signs of hypocalcemia, or signs are very subtle and difficult to detect and delaying therapy may result in additional complications (e.g., ileus). Horses with mild hypocalcemia in general restore normocalcemia without calcium administration. However, calcium administration is unlikely to be harmful, may hasten recovery, and therefore should be considered. Horses with functional kidneys can rapidly eliminate large amounts of calcium, and hypercalcemia from excessive intravenous calcium administration is rare, particularly if the horse is receiving fluid therapy.

The use of standard formulas to calculate electrolyte deficits based on extracellular fluid and body weight do not apply to calcium. Calcium can rapidly be eliminated or sequestered in different compartments, and larger doses of calcium are often required.

To calculate Ca^{2+} deficit the following formula is used:

$$([6.5 - Ca^{2+}][0.3][BW][10])/Ca^{2+}\ \text{ratio} = Ca^{2+}\ \text{deficit}$$

In this formula, the difference between the measured Ca^{2+} and normal Ca^{2+} (6.5 mg/dL) is multiplied by the extracellular fluid volume, the body weight (kg), and a factor of 10 (Ca^{2+} is expressed in dL, but body weight is in kg = L) and then divided by the Ca^{2+} ratio (Ca^{2+}/total calcium). For a 450-kg horse with a serum Ca^{2+} concentration of 4.5 mg/dL and a total calcium of 10 mg/dL, the estimated Ca^{2+} deficit will be 6000 mg:

$$([6.5 - 4.5][0.3][450\ \text{kg}][10]) = 6000\ \text{mg}$$

This is a deficit of elemental calcium, and calcium gluconate or borogluconate are the salts of choice for parenteral treatment. Calcium gluconate contains 9.3% of elemental calcium; in other words, every 100 mL of calcium gluconate 23% solution contains 2.14 g of elemental calcium or 21.4 mg/mL. The horse in this example would require approximately 300 mL of calcium gluconate 23% solution over 24 hours to replace the Ca^{2+} deficit. Ca^{2+} conversion factors are mg/dL = mmol/L × 4; mmol/L = mg/dL × 0.25.

Most veterinary laboratories do not measure Ca^{2+} concentrations; however, total calcium concentrations can also be used to calculate the overall deficit. By replacing measured and normal total calcium (12.0 mg/dL) in the same formula, and dividing by a 0.5 Ca^{2+} ratio, this formula gives a close approximation of the calcium deficit. It is important to mention that total calcium has more variability and is less tightly controlled than Ca^{2+} concentration. A horse may have total hypocalcemia, but serum Ca^{2+} concentrations may be within the normal range and in such a case calcium administration may not be necessary.

Frequent monitoring of calcium concentrations is recommended to adjust dosing. Some horses with severe gastrointestinal disease and sepsis remain hypocalcemic despite aggressive calcium therapy. In horses with colic, the response to calcium therapy was associated with outcome—survivors showed a steady return to normal values that was not seen in nonsurvivors.[168] Rapid administration of calcium may result in cardiovascular complications, particularly in septic animals, which may be more vulnerable to the cytotoxic effects of calcium. Fortunately, horses can handle large calcium dosages.[7,169] Based on experience treating critically ill horses, calcium doses of 2 mg/kg/hr are safe in horses. This represents approximately 50 mL of calcium gluconate 23% solution for a 500-kg horse per hour, while receiving fluid therapy. In horses with signs of hypocalcemia, higher doses are indicated.

Calcium chloride may be another option to treat hypocalcemia; however, it is not available in large volumes, it is more expensive, and it may cause irritation at the administration site. Do not add calcium salts to fluid solutions containing bicarbonate because calcium carbonate complexes may form and precipitate.

Oral treatment with calcium salts is feasible in horses with non–life-threatening hypocalcemia. Dicalcium phosphate and calcium carbonate (limestone) can be used safely (see Table 16.3). The management of horses with reduced calcium intake, which typically develop signs of orthopedic diseases, is different and directed to increase dietary calcium. This typically occurs in horses ingesting high phosphate or oxalate diets.

There is no clear evidence that vitamin D therapy affects outcome in foals or horses with refractory hypocalcemia. However, it should be considered in situations where clinical signs are persistent and the animal remains refractory to routine therapies. Based on recent work from our group showing that hypovitaminosis D is highly prevalent in critically ill equine patients,[3] if a decision to use vitamin D is made for an animal refractory to calcium therapy, it is recommended to use calcitriol ($1,25[OH]_2D_3$) rather than precursors because it displays rapid onset of action, renal activation is not required, and it has a short half-life (less potential for toxicity). The calcitriol dose for equids is unknown. Daily recommended calcitriol dose for small animals is 0.025 to 0.06 μg/kg. For children over 6 years of age and adults with hypoparathyroidism, the oral dose is 0.5 to 2 μg/day, and the intravenous (IV) dose is 1 to 2 μg 2 to 3 times weekly.

Hypocalcemic Disorders

Hypoparathyroidism

Hypoparathyroidism is a condition characterized by hypocalcemia, hyperphosphatemia, and decreased serum PTH concentrations. Hypomagnesemia may be present. Primary hypoparathyroidism results from decreased synthesis and secretion of PTH, whereas secondary hypoparathyroidism most commonly results from hypomagnesemia or sepsis. Mg^{2+} is required for PTH secretion and PTH1R activation; therefore Mg^{2+} depletion impairs PTH release and action.

Primary Hypoparathyroidism

This condition has been reported in horses.[146,162] Horses present with clinical signs of hypocalcemia, including ataxia, seizures, hyperexcitability, SDF, tachycardia, tachypnea, muscle fasciculations, stiff gait, recumbency, ileus, and colic. The diagnosis is based on the determination of serum concentrations

of Ca^{2+}, Mg^{2+}, phosphorus, and PTH. Hypocalcemia, hyperphosphatemia, hypomagnesemia, and low serum PTH concentrations are the features of primary hypoparathyroidism.[146,162] Low PTH leads to hypocalcemia and reduced renal PO_4 excretion and contributes to hypomagnesemia because PTH also promotes Mg^{2+} reabsorption in the distal nephron. Horses with primary hypoparathyroidism may benefit from $MgSO_4$ or $MgCl_2$ administration.

Secondary Hypoparathyroidism

Secondary hypoparathyroidism as a pathologic entity has not been described in horses; however, septic horses with hypocalcemia and impaired parathyroid gland function most likely have a form of secondary hypoparathyroidism from hypomagnesemia and increased concentrations of inflammatory mediators. This has been shown to be the case in horses with acute gastrointestinal disease.[4] It also has been demonstrated that inflammatory mediators known to be increased in critically ill horses (IL-1, IL-6, TNF-α) impair PTH secretion.[4-6] A number of foals with hypocalcemia do not have the expected increase in intact PTH concentrations, suggesting hypoparathyroidism.[2,3,144] Of interest, most hospitalized foals with hypocalcemia have an appropriate PTH response to hypocalcemia.[2,3] Secondary hypoparathyroidism with hypercalcemia was reported in an 11-year-old Andalusian gelding with chronic renal failure and polycystic kidney disease.[145]

Sepsis and Systemic Inflammation

For reasons not yet clearly understood, hypocalcemia is a frequent finding in critically ill humans and animals.[2-4,154,155,170-172] Sepsis is the most common cause of hypocalcemia in equine patients,[4,168] particularly in hospitalized newborn foals[2,3] and horses with severe gastrointestinal disease,[4,154,155,168,173] and the hypocalcemia can contribute to the patient's death. Total and ionized hypocalcemia are highly prevalent in horses with enterocolitis with 75% of these patients having total hypocalcemia, 80% exhibiting ionized hypocalcemia, and 70% having ionized hypomagnesemia.[4] Similar prevalence of hypocalcemia was documented in horses with colic.[168] Horses with severe hypocalcemia were more likely to die than those with normocalcemia.[168]

The mechanisms responsible for the development of hypocalcemia during critical illness are poorly understood. It is believed that in most acutely ill horses and foals, endotoxemia is the trigger leading to hypocalcemia.[1] Horses with gastrointestinal disease may have detectable endotoxin in plasma,[174-176] and parenteral administration of endotoxin to healthy horses has been shown to cause hypocalcemia.[6,177] Possible causes of hypocalcemia include renal loss of calcium,[178] calcium sequestration in the gastrointestinal lumen,[179] intracellular calcium accumulation,[180] impaired calcium mobilization,[181-183] tissue sequestration,[170,178] reduced calcium release in response to PTH,[178] failure to synthesize $1,25(OH)_2D$,[171] and parathyroid gland dysfunction.[4] Renal loss of calcium seems unlikely, as horses with endotoxemia, enterocolitis, and hypocalcemia have been shown to have low fractional urinary excretion of calcium.[4,6]

Some horses with evidence of SIRS and hypocalcemia have inappropriately low serum concentrations of PTH, indicating parathyroid gland dysfunction.[4] Most hospitalized foals with hypocalcemia have an adequate PTH response.[2] However, a number of them remain hypocalcemic, with PTH concentrations below or in the normal range, which is consistent with functional hypoparathyroidism secondary to critical illness. In some cases, low Mg^{2+} concentrations could explain the low PTH, but in other instances Mg^{2+} concentrations are in the normal range. It is likely that inflammatory byproducts, endotoxins, and cytokines (IL1-β, IL-6, and TNF-α) disrupt parathyroid chief cell function.[6] It has been shown that in endotoxemia, IL-1β and IL-6 could decrease PTH mRNA transcription and secretion by equine parathyroid chief cells.[5] It is well documented that these cytokines are increased in foals and horses with systemic inflammation.[6]

Hypocalcemia in Foals

Sepsis, SIRS, hypomagnesemia, acute renal injury, pancreatitis, and acute muscle injury have been linked to hypocalcemia in newborn foals. *Idiopathic hypocalcemia* is a broad term used to describe a hypocalcemic condition that occurs in young foals for reasons poorly understood. From experience, idiopathic hypocalcemia likely represents multiple disorders, due to increased inflammatory cytokines, abnormal parathyroid gland function, hypomagnesemia, and calcium shifts to different compartments. It is also possible that genetic disorders may explain this disorder in some foals.

Exercise-Induced Hypocalcemia

Electrolyte and acid-base abnormalities are frequent in horses undergoing intense physical activity. Unlike human athletes, who develop either ionized hypocalcemia or hypercalcemia, ionized hypocalcemia is more common in exercising horses.[153,184,185] Hypocalcemia in these horses could be explained by sweat loss of calcium,[163,186] calcium shift to the intracellular compartment,[187] and increased Ca^{2+} binding to albumin due to alkalosis.[182] Exercising horses develop respiratory alkalosis from hyperventilation, metabolic alkalosis from Cl^- loss in sweat (hypochloremic), or a combined alkalosis. Serum Ca^{2+} decreased while serum PTH increased in jumping horses, suggesting that parathyroid gland dysfunction as the cause of hypocalcemia was unlikely.[56] One study in endurance horses found that serum PTH concentrations did not increase in all horses that developed hypocalcemia, indicating that in some horses impaired parathyroid gland function could be a contributory factor.[153] Renal loss of calcium as a cause of hypocalcemia during exercise is unlikely because urinary calcium concentrations decrease in performance horses.[164] Dietary calcium and phosphorus supplementation did not impair PTH secretion in exercising horses.[185]

Common clinical signs in horses with exercise-induced hypocalcemia include SDF, muscle weakness, muscle fasciculation, ileus, colic, excitation, and cardiac arrhythmias.

Cantharidiasis

Equine cantharidiasis (blister beetle toxicosis) is a condition reported in the central, southern, and midwestern United States and is produced by the ingestion of alfalfa contaminated with blister beetles (*Epicauta* spp.), which produce cantharidin (cantharidic acid).[159,188,189] Cantharidin is such a caustic compound that it is being used in human dermatology to treat recalcitrant warts and molluscum contagiosum.[190] Horses are very susceptible to the irritant effects of this toxin on mucosal surfaces (gastrointestinal and urinary tracts). Cantharidin causes necrosis and sloughing of the intestinal mucosa, acute tubular necrosis/renal failure, and myocardial necrosis. Laboratory abnormalities are a consequence of gastrointestinal, renal, and myocardial dysfunction. Acute hypocalcemia

and hypomagnesemia are consistent findings. Clinical signs include SDF, muscle fasciculations, ataxia, dyspnea, laryngeal spasm, cardiac dysrhythmias, colic, diarrhea, endotoxemia, dehydration, hypotension, hematuria, stranguria, pollakiuria, and sudden death.[1,159,188,189] Additional systemic signs are the result of multiple abnormalities, including acid-base, electrolyte, proinflammatory, and hemodynamic changes.

Acute Renal Failure

Hypocalcemia and hypomagnesemia are common findings in horses with acute renal injury. Reabsorption of Ca^{2+} and Mg^{2+} by the nephron is highly dependent on functional epithelial cells, which are very susceptible to various insults (hypoxia, toxins). Damage to tubular epithelial cells leads to reduced absorptive capacity for Ca^{2+} and Mg^{2+}. Additional details are provided in Chapter 14.

Exertional Rhabdomyolysis

The pathogenesis of hypocalcemia in exertional rhabdomyolysis is unknown. Speculations include muscle fiber damage during intense exercise resulting in Ca^{2+} influx and sequestration into the sarcoplasm and SR. A several-fold increase in sarcoplasmic $Ca^{2+}{}_i$ concentration has been reported in horses with exertional rhabdomyolysis,[191] indicating that elevations in $Ca^{2+}{}_i$ concentrations may be important in the pathogenesis of ER. It is also possible that alterations in the acid-base status during exercise, alkalosis in particular, could contribute to the development of hypocalcemia in some horses. See Chapter 10 for additional information on this topic.

Pancreatitis

Pancreatitis is a well-recognized cause of hypocalcemia in people and small animals; however, there are few reports of pancreatic disease in foals or horses.[192-195] Pancreatitis is rare in horses and when present is often associated with gastrointestinal disease.[193] Hypocalcemia associated with pancreatitis and seizures was reported in a newborn foal.[195] The foal had diarrhea, abdominal distention, peritoneal effusion, increased lipase and amylase activities, hypoglycemia, and hypertriglyceridemia. It was unclear whether the hypocalcemia was a consequence of pancreatic disease or SIRS. Pancreatitis should be in the list of differentials in foals and horses with hypocalcemia and acute abdominal disease, and assessing lipase and amylase activities and triglyceride concentrations should be considered in animals without a clear diagnosis. Low calcium concentrations were reported in horses with pancreatic disease, many of which also had large intestinal pathologies.[194]

Oxalate Toxicity

The rapid ingestion of oxalate-containing plants (see Table 16.6) can cause signs of acute hypocalcemia. More commonly, one sees chronic oxalate toxicity from prolonged consumption of these plants. The clinical presentation is associated with orthopedic problems (lameness, fractures) as a consequence of secondary hyperparathyroidism and reduced bone mass from (see Nutritional Secondary Hyperparathyroidism section later in this chapter). Some of these animals may develop neuromuscular signs from hypocalcemia.

Other causes of hypocalcemia include excessive administration of tetracyclines, furosemide, and bicarbonate. Hypovitaminosis D remains to be documented as a cause of hypocalcemia in horses.

Hypercalcemic Disorders

Hypercalcemic disorders can be divided in two categories: (1) hypercalcemia associated with parathyroid gland dysfunction (parathyroid-dependent hypercalcemia) and (2) hypercalcemia independent of the parathyroid gland function (hypercalcemia develops despite parathyroid gland suppression). Parathyroid-dependent hypercalcemia in the horse is limited to primary hyperparathyroidism, whereas parathyroid-independent hypercalcemia occurs from various conditions (secondary hyperparathyroidism, chronic renal failure, cancer, vitamin D intoxication).

Primary Hyperparathyroidism

Primary hyperparathyroidism (PHPT) is an endocrinopathy in which the chief cells of the parathyroid glands autonomously secrete excessive amounts of PTH and do not respond to the negative feedback of Ca^{2+}. In horses, PHPT results from parathyroid adenomas or parathyroid hyperplasia.[148,149,196] Parathyroid carcinoma has not been reported in the horse. In the kidneys, PTH will increase Ca^{2+} reabsorption (hypocalciuria), reduce phosphorus reabsorption (hyperphosphaturia), and promote $1,25(OH)_2D_3$ synthesis, whereas in bone it will enhance osteoclastic activity. Thus hypercalcemia, hypophosphatemia, and increased intact PTH concentrations are typical laboratory findings of PHPT. Osteodystrophia fibrosa (also known as "rubber jaw" or "big head") from excessive bone loss may ensue. Primary hyperparathyroidism associated with osteodystrophia fibrosa has been reported in ponies and horses.[147,197-200] These horses may have enlargement of the facial bones, lameness, and a poor body condition. Radiographic findings include reduced bone density, particularly in flat bones, and loss of the lamina dura dentes surrounding molars and premolars.[147] Endoscopic examination may reveal narrowing of the nasal passages. Previous attempts to identify abnormal equine parathyroid tissue by nuclear scintigraphy failed.[196] However, nuclear scintigraphy and ultrasonography were successfully used to detect functional parathyroid adenomas in horses.[148, 148a] Ultrasonography alone was useful to identify parathyroid tissue (adenoma) within the thyroid gland of a horse with clinical and laboratory findings consistent with PHPT, including hypercalcemia, hypophosphatemia, increased serum PTH concentration, and low urinary fractional excretion of calcium.[149]

Tests to rule out other conditions associated with hypercalcemia include assessment of renal function, urinary excretion of electrolytes, and measurement of PTHrP and vitamin D metabolite concentrations.

Postmortem findings in horses with PHPT include enlargement of the maxilla and mandible, stenosis of the nasal passages, and loosening of premolars and molars. Histologic examination of the parathyroid gland is important to confirm the diagnosis of PHPT (chief cell hyperplasia); however, finding the parathyroid glands in horses can be challenging due to their small size and variable location.

Secondary Hyperparathyroidism

In secondary hyperparathyroidism, excessive PTH secretion is the response of the parathyroid gland to hypocalcemia and/or hyperphosphatemia and/or hypovitaminosis D from renal disease or from nutritional imbalances.

Renal Secondary Hyperparathyroidism

In the case of renal secondary hyperparathyroidism in small animals and humans, phosphorus retention from renal disease

and decreased $1,25(OH)_2D$ synthesis stimulate PTH secretion.[201] In addition, hyperphosphatemia lowers serum Ca^{2+} concentrations and inhibits renal 1α-hydroxylase, which is required for $1,25(OH)_2D$ synthesis. Reduced concentrations of $1,25(OH)_2D$ lower intestinal Ca^{2+} absorption, further contributing to hypocalcemia and PTH release. Hypercalcemia is a consistent finding in horses with chronic renal failure (CRF); however, phosphorus concentrations are variable. Of interest, hypercalcemia in horses with CRF is not the result of high PTH concentrations (hyperparathyroidism) but rather a consequence of calcium intake and retention. Serum PTH concentrations in horses with CRF and hypercalcemia are often in the normal range.[145,202] Because equine intestinal calcium absorption is high and poorly regulated, normal renal function is crucial to eliminate excess calcium. Any reduction in glomerular filtration from chronic renal injury will impair excretion, resulting in hypercalcemia.

Nutritional Secondary Hyperparathyroidism

Nutritional secondary hyperparathyroidism (NSHPT) is the result of increased PTH secretion (hyperparathyroidism) from reduced intestinal calcium absorption rather than a hypercalcemic disorder per se. If anything, it can be classified as a hypocalcemic disorder because, unlike other forms of hyperparathyroidism, hypercalcemia is not a feature of NSHPT. Disorders resembling NSHPT appeared in the peer-reviewed literature in the nineteenth century[198,203]; however, there are reports as early as the fourth century of a condition described by Vegetius as animal osteomalacia,[198] which can be assumed to be NSHPT.

Horses fed a diet low in calcium, high in phosphorus, or high in oxalate may develop NSHPT. This condition, also known as bran disease, miller's disease, big head, osteodystrophia fibrosa, fibrous osteodystrophia, osteitis fibrosa, and equine osteoporosis, can affect one or many animals in a herd. Balanced equine diets should have a calcium:phosphorus ratio greater than 1.5:1 to meet daily requirements. Diets with a calcium:phosphorus ratio less than 1:3 predispose horses to NSHPT.[150,204] This condition is uncommon in developed countries; however, a young horse may occasionally present with signs of NSHPT, including enlargement of facial bones, upper respiratory noise, and lameness. The condition is endemic in some regions of Latin America, North America, Africa, Asia, Australia, and Europe.[32,150,205-211] In old horses, facial bone enlargement is variable but in general not as evident as in young animals. In the past, NSHPT was associated with grain-rich diets (high phytate-PO_4 content); however, with improvements in animal nutrition, NSHPT is rarely associated with excessive grain feeding. Rather it is more commonly linked to the ingestion of plants containing large amounts of oxalate (oxalic acid) (see Table 16.6), which bind dietary calcium to form insoluble calcium oxalate (CaC_2O_4), thus decreasing calcium absorption (Fig. 16.9).[206-212] A 1% oxalate content in the equine diet can reduce calcium absorption by about 67%.[31] Diets with greater than 0.5% oxalate or a calcium:oxalate ratio less than 0.5 are detrimental to the calcium balance in horses and ponies.[32] Ruminants are more tolerant to oxalate toxicity than monogastric animals because rumen bacteria degrade a major part of oxalate into formic acid and carbon dioxide.[213] Some plants containing harmful amounts of oxalate are listed in Table 16.6. Many of these plants can contain up to 20% of their dry weight as soluble and insoluble oxalates.[211,212] Oxalate also binds magnesium, but the resulting complex (MgC_2O_4) is more soluble

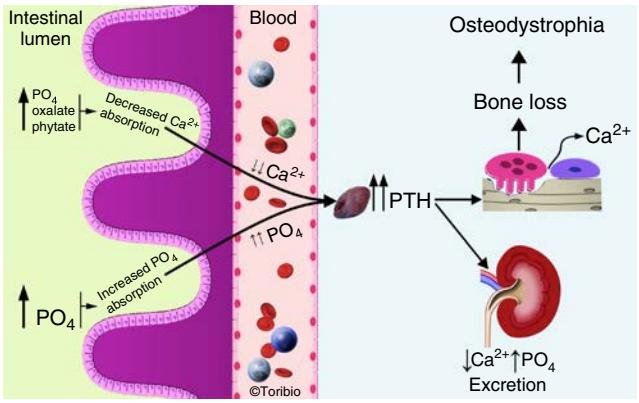

FIG. **16.9** Pathogenesis of nutritional secondary hyperparathyroidism. The ingestion of diets rich in phytates, phosphates (PO_4), or oxalates that interfere with calcium (Ca^{2+}) absorption stimulate the parathyroid gland to release excessive amounts of parathyroid hormone (PTH). In the kidneys PTH will promote Ca^{2+} reabsorption and PO_4 excretion, whereas in bone PTH will increase osteoclastic bone resorption leading to bone loss that will be replaced with unmineralized fibrous tissue. This results in signs consistent with nutritional secondary hyperparathyroidism (see Figs. 16.10 and 16.11). (Courtesy Dr. R. E. Toribio, The Ohio State University.)

than CaC_2O_4 and more likely to be absorbed. If dietary calcium is low, soluble oxalate can be absorbed and combine with calcium or magnesium in circulation to form crystals that precipitate in the kidneys, causing renal failure. However, this is not as widely a recognized problem in horses as in other species.

Excessive dietary phosphorus reduces calcium absorption, leading to hypocalcemia, hyperphosphatemia, and hyperparathyroidism (see Fig. 16.9).[198] Hyperphosphatemia stimulates PTH secretion but inhibits renal $1,25(OH)_2D$ synthesis. Given that $1,25(OH)_2D$ is a suppressor of parathyroid cell function, low $1,25(OH)_2D$ concentrations will further contribute to parathyroid cell hyperplasia and PTH secretion. As previously mentioned, PTH will increase osteoclastic activity, bone resorption, and bone loss.[214] Facial bone loss and excessive accumulation of unmineralized bone matrix (osteodystrophia fibrosa) results in facial enlargement (big head) (Fig. 16.10). Because this is a slowly progressive condition, the homeostatic mechanisms that regulate extracellular Ca^{2+} concentrations (PTH, vitamin D, calcitonin) may be effective at maintaining Ca^{2+} close to or within the normal range. Thus these animals rarely have abnormal calcium concentrations.

Clinical signs of NSHPT may include intermittent, shifting lameness, and a stiff gait.[211,215,216] In most cases there is swelling of the facial bones. Young animals may develop physeal enlargement and limb deformities.[204] Bone resorption around the lamina dura dentes of molars and premolars may cause masticatory problems. These animals are weak and may be in poor body condition. In severe cases, teeth may become loose, and spontaneous fractures may occur. Vertebral abnormalities and compressive neurologic signs may develop.[211] Epiphora may be present from obstruction of the nasolacrimal duct. Upper airway obstruction from deformation of nasal passages and turbinates may impair airflow, causing stridor and dyspnea.[205,211,217] Signs of acute hypocalcemia may develop in some animals as a consequence of high dietary oxalate content combined with a low-calcium diet.[211] In addition, absorption of soluble oxalate can chelate calcium in the circulation (and to lesser extent, magnesium), leading to hypocalcemia.

FIG. **16.10** Belgian yearling presented to The Ohio State University Veterinary Medical Center with clinical signs consistent with NSHPT, including enlargement of facial bones and upper respiratory noise. The horse was fed excessive amounts of grain. Narrowing of the nasal passages, loss of bone mass, and excessive accumulation of unmineralized bone matrix (osteodystrophia fibrosa) was evident. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

Differential diagnoses linked to excessive bone loss include NSHPT, PHPT, HHM, and bone fragility syndrome (silica-associated osteoporosis). However, there are unique clinical, laboratory, and epidemiologic features characteristic of these conditions. PHPT and HHM affect single animals and are characterized by hypercalcemia and hypophosphatemia, with either increased PTH but low PTHrP (i.e., PHPT) or increased PTHrP and low PTH (i.e., HHM). Body condition tends to be better with NSHPT and PHPT than HHM and bone fragility syndrome.

Typical laboratory findings during active disease include mild hypocalcemia and hyperphosphatemia although these values may be within the normal range.[218,219] Depending on the inciting cause, serum phosphorus concentrations could be increased (high dietary phosphate), low, or within normal limits (oxalate toxicity). Serum PTH concentrations may be increased.[209,215] Urinary excretion of calcium is low (normal 3%–10%) and of phosphorus is high (normal less than 0.5%).[209] Calculating the urinary fractional excretion of phosphorus may be useful to assess phosphorus intake and PTH activity. Phosphaturia is a consequence of hyperphosphatemia when dietary phosphate is high but also reflects the phosphaturic actions of PTH. In the case of oxalate toxicity, phosphaturia is mostly mediated by high PTH concentrations. Serum alkaline phosphatase activity may be increased. Markers of bone resorption will likely increase, but they have not been investigated in horses with this condition.

Radiologic findings include decreased bone density[215,219]; however, bone mass must be decreased 30% before it is radiographically detectable.[219,220] Resorption of the dental alveolar sockets may be present before any other radiographic changes are evident. Radiolucency, diffuse osteolysis, and osteopenia may be detected in long bones, vertebrae, and ribs early in the process and can progress to a patchy osteoporotic pattern from excessive bone resorption, particularly with chronic oxalate toxicity (Fig. 16.11). Taking radiographs with similar settings from age-matched healthy animals for comparison purposes is recommended. This is also useful for radiographic follow-up in response to therapy.

Pathology findings include facial bone enlargement, in particular maxillae and mandible, weak bones, reduced cortical thickness, fractures, and deformities in appendicular and axial skeleton.[198,211] The kidneys are in general normal, but there could be mineralization. Histologically, there is thin porous cortical and trabecular bone, fibrous periosteal thickening, and active bone remodeling with increased osteoclast number.[211] There is parathyroid gland hypertrophy with chief cell hyperplasia, consistent with chronic hypocalcemia or hyperphosphatemia.[198,211]

Dietary supplementation with calcium carbonate (limestone; $CaCO_3$) or dicalcium phosphate (dibasic calcium phosphate; $CaHPO_4$) has resulted in clinical improvement.[150] An affected animal may require a total of 100 to 300 grams/day, and the diet should have a Ca:P ratio of 3 to 4:1. Limestone may decrease feed palatability, and adding molasses can improve palatability. Oxalate-rich plants with high calcium content (e.g., legumes) are considered safe for equids.[213,221] The addition of alfalfa hay and a reduction in grain intake may be helpful. Confinement of severely affected horses is advised. The use of nonsteroidal antiinflammatory drugs (NSAIDs) may be indicated in horses and ponies with severe pain. Supplementation with vitamin D has been proposed. Young horses may require up to 12 months for complete recovery. For animals consuming feeds with high oxalate content, 20 additional mg of calcium/kg and 10 mg of phosphorus/kg BW per day may be necessary.[32]

Prognosis for NSHPT varies depending on age, duration, severity of clinical signs, inciting cause (phosphorus vs. oxalate ingestion), and response to treatment. Young animals have a fair to good prognosis if treated early. Animals with mild clinical signs have a good prognosis, whereas those with severe facial deformation, dental loss, orthopedic complications, and

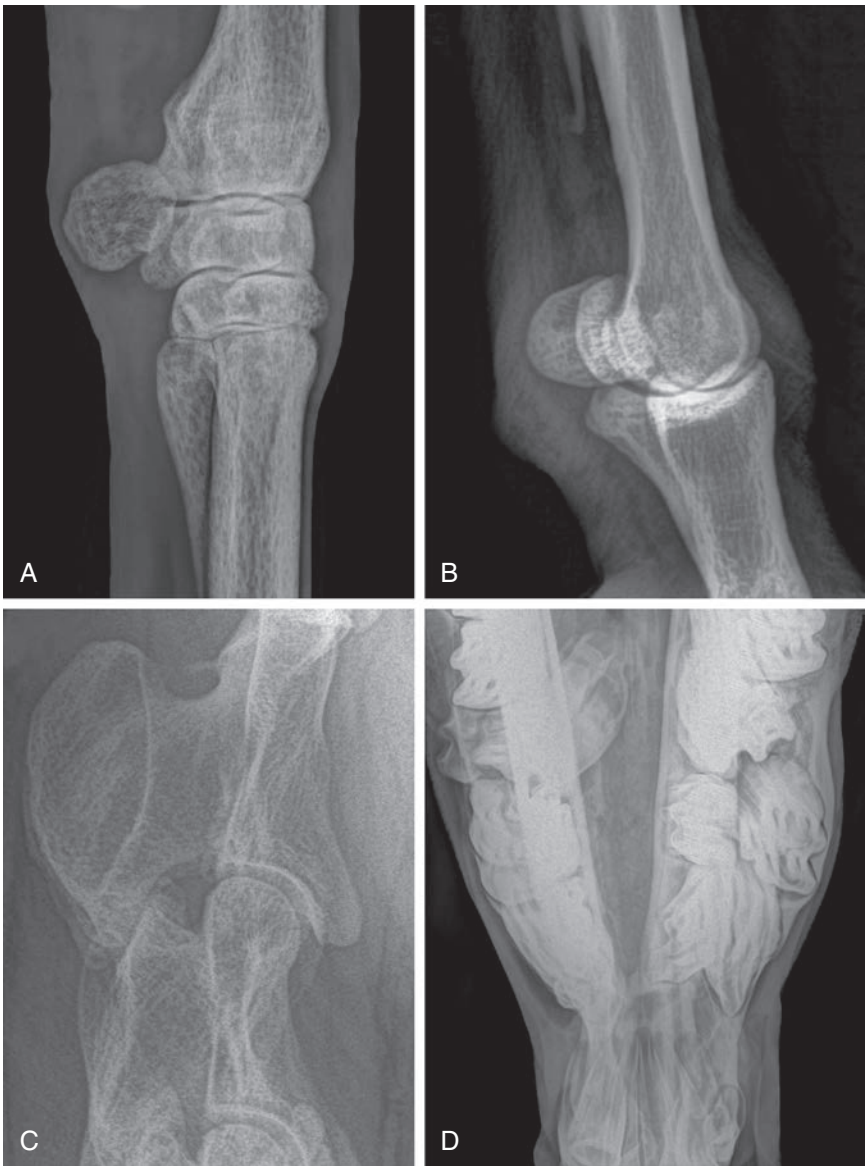

FIG. **16.11** Radiographs of adult miniature horses with nutritional secondary hyperparathyroidism associated with oxalate toxicity from chronic ingestion of soursob *(Oxalis pes-caprae).* Lateral views of the carpus (A) and fetlock (B) show diffuse and excessive bone loss and osteolysis, reduced density (osteopenia), widespread radiolucency (evident in accessory carpal and sesamoid bones), and thinning of cortical bone. A similar pattern is present in the cervical vertebrae (C). Dorsoventral view of the skull reveals reduced bone density, dental displacement, and loss of the laminae dura (D). (Courtesy Dr. E. W. Herbert, Adelaide Plains Equine Clinic, Gawler, Australia.)

neurologic signs have a guarded to poor prognosis. Signs tend to be more severe with oxalate toxicity.

Hypervitaminosis D

The ingestion or administration of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) causes disturbances of calcium and phosphorus homeostasis in domestic animals.[151,222-229] Intoxication with both forms of vitamin D have been reported in horses.[151,223,229] Ingestion of plants containing 1,25$(OH)_2$D-like compounds results in clinical signs of vitamin D toxicity.[224,226-228,230] *Solanum glaucophyllum (S. malacoxylon)* is associated with a condition known as "enteque seco" in Argentina and "espichamento" in Brazil.[222,228,230] In Hawaii, the ingestion of *S. sodomaeum* and *S. torvum* results in hypercalcemia.[230] *Nierembergia* spp. have also been linked to hypervitaminosis D in Brazil and Uruguay.[230] Jessamine *(Cestrum diurnum),* a shrub widely distributed in the southern United States (from Florida to California), Jamaica, and Cuba may cause hypervitaminosis D.[224,230] In Europe, *Trisetum flavescens* has been linked to enzootic calcinosis in ruminants and horses.[230-233] Hyperphosphatemia is the most consistent and early laboratory finding in horses with vitamin D intoxication.[223] Serum calcium concentrations may be within the normal range or increased.[151,223,227,229] Because vitamin D is a negative regulator of parathyroid cell proliferation, parathyroid cell atrophy and low PTH concentrations may be present.[225]

Clinical signs include anorexia, weight loss, polyuria, polydipsia, lameness, and reluctance to move.[223,229,233] Acute death from severe cardiovascular mineralization has been reported.[151] Renal mineral deposition may precede mineralization elsewhere, leading to renal failure, uremia, hyposthenuria, polyuria, and polydipsia.[151] Lameness is probably due to calcification of ligaments and tendons. Radiographically, these horses have increased bone density, reduced medullary cavity lumen, and increased calcification of soft tissues.

The prognosis for horses with hypervitaminosis D is poor. Treatment may include reducing dietary calcium intake. The use of calcium-binding agents such as sodium phytate, which is high in many cereals, has been proposed.[229] Glucocorticoids are used in humans with hypervitaminosis D, with the rationale that they may inhibit the vitamin D–mediated intestinal calcium absorption. Dexamethasone administration to pony foals decreased intestinal calcium absorption, reduced bone resorption, and increased urinary excretion of calcium.[34,35] Dexamethasone has been administered to horses with hypervitaminosis D with inconclusive results.[229]

Postmortem examination may reveal mineralization of soft tissues. Extensive cardiovascular mineralization of the endothelium of the aorta and pulmonary vessels, as well as of the endocardium of the atrium and ventricles, is frequent. Mineralized plaques may be present in the endothelium and endocardium. Mineralization may be found in the kidney, liver, lymph nodes, lungs, ligaments, and tendons. Osteopetrosis of the epiphyses and metaphyses may be present. Atrophy of the parathyroid chief cells may be severe.[225]

Hypercalcemia of Malignancy

Humoral hypercalcemia of malignancy (HHM) refers to a paraneoplastic condition in which tumors secrete PTHrP (pseudohyperparathyroidism) leading to hypercalcemia. In horses, HHM has been described with gastric, vulvar, and preputial squamous cell carcinomas, adrenocortical carcinoma, lymphosarcoma, multiple myeloma, and ameloblastoma.[132-136,234,235] These animals have hypercalcemia, hypophosphatemia, low to normal PTH concentrations, reduced urinary excretion of calcium, increased urinary excretion of PO_4, and, over time, reduced bone density. Most clinical signs are the result of the primary problem rather than hypercalcemia. Severe hypercalcemia can potentially reduce gastrointestinal motility, induce diuresis, and disrupt neurologic function.

Neonatal Hypercalcemia and Asphyxia

Clinical observations indicate that a number of critically ill newborn foals develop hypercalcemia that is not associated with renal failure or excessive PTH secretion. These foals are usually recumbent, have severe hypotension, and often die of asphyxia. Factors to consider in the pathogenesis of this condition include high PTHrP and $1,25(OH)_2D$ concentrations; however, this remains to be investigated.

Idiopathic Systemic Granulomatous Disease

This appears to be an immune-mediated disorder that has been documented in horses and ponies (equivalent to human sarcoidosis) in which crusty and exudative skin lesions develop in different locations, as well as along the coronary bands and mucocutaneous junctions.[236-238] In horses, cattle, and human beings with systemic granulomatous disease, there is perivascular granulomatous and lymphoplasmacytic inflammation in multiple organs, including lungs, liver, gastrointestinal tract, kidneys, and skin.[236,239,240] Some animals may develop hypercalcemia.[236,239,240] It has been proposed that excessive production of vitamin D or PTHrP by granulomatous cells leads to hypercalcemia in these animals.[1] At least in one case, increased expression of PTHrP in mononuclear cells was documented in a pony with this condition.[236] In horses, lesion distribution may resemble that of multisystemic eosinophilic epitheliotropic disease. In cattle, hairy vetch *(Vicia villosa)* toxicity has been linked to infiltration of many organs and skin by monocytes, lymphocytes, eosinophils, and multinucleated cells.[241] These animals have dermatitis, pruritus, diarrhea, and wasting.[241] A similar disorder has been recognized in horses grazing hairy vetch,[237,238] which showed crusting dermatitis, alopecia, conjunctivitis, lymphadenopathy, ventral edema, diarrhea, and weight loss.[236-238]

Calcinosis

Calcification of soft tissues (liver, heart, kidney, lungs, vessels, muscle), hyperphosphatemia, elevation of the calcium × phosphorus product, and evidence of calciphylaxis were reported in a number of horses with various pathologies.[242] Calcinosis has been defined as mineralization or calcium deposition in soft tissues. This disorder is different from enzootic calcinosis due to ingestion of plants with vitamin D–like activity. Calciphylaxis is a form of extraskeletal calcification (as calcinosis) but more specifically refers to calcification and necrosis of vascular structures leading to organ damage. In people, calciphylaxis mostly occurs with advanced chronic kidney disease. The underlying mechanisms by which these horses developed calcinosis and hyperphosphatemia are unclear. However, calcium phosphate precipitation due to a high calcium × phosphorus product can be seen simply as a consequence.

Equine Bone Fragility Syndrome (Osteoporosis, Silicosis)

The equine bone fragility syndrome (BFS) or silica-associated osteoporosis (SAO) is a progressive and chronic disorder of horses characterized by exercise intolerance, increased respiratory efforts, skeletal deformation, lameness, stiffness, and fractures.[243,244] Lordosis, bowing of appendicular bones (scapula in particular), and neurologic signs as a result of vertebral deformation and spinal cord compression also occur.[243,244] Horses of any age are affected, with median ages of 9 and 14 years (4–25 years).[243,245] The condition has been documented in animals as young as 6 months old.[244]

The pathogenesis of this condition is unclear, but there is a strong association with pulmonary silicosis (a form of pneumoconiosis). Radiographically, in the skeleton there is osteopenia whereas in the respiratory tract the pattern is consistent with silicosis. Cytologic examination of bronchoalveolar cells reveals the presence of silica crystals. Histologically, there is excessive osteoclastic activation and bone resorption. In the respiratory tract there is pulmonary granuloma formation, fibrosis, and lymphadenitis.[246] Intracellular crystals within pulmonary and lymphoid macrophages and dystrophic calcification are consistent findings in horses with SAO.[246] These crystals have been identified as cytotoxic silica dioxide polymorphs.[246] Of interest, high concentrations of a cytotoxic and fibrogenic form of silicate (cristobalite) are found in regions of California where the condition is more common (Monterey shale soil).[243,244,246,247]

The precise mechanisms leading to excessive bone loss in these animals, in which initial manifestations tend to be

respiratory signs, remain to be elucidated. It has been proposed that inflammatory cytokines known to be produced in excess in human pulmonary silicosis (IL-1, IL-6, TNF-α), as well as the release of RANKL, may be activating osteoclastogenesis.[246] The role of the calcium and phosphorus homeostatic system in the development of BFS remains to be determined. Some horses could have increased PTH concentrations, but this is an inconsistent finding.[246]

Some of the bone multifocal and lytic distribution in BFS resembles Paget's disease of bone in people, in which there are pathologic fractures, skeletal deformation, excessive osteoclastic activity, and increased cortical thickness. However, BFS is progressive and affects horses of any age, whereas Paget's disease, once it develops, is more static and mainly affects the elderly.

Even though certain findings are shared with secondary hyperparathyroidism (lameness, lordosis, fractures, high PTH), others are different. For example, the association with respiratory disease, normal skull morphology, increased cortical bone width, and lack of parathyroid hyperplasia are consistent with BFS. Whether a mechanism similar to hypertrophic pulmonary osteopathy (Marie's disease) contributes to skeletal disease with this condition remains to be documented. At the end, evidence indicates that this is a disorder secondary to pulmonary silicosis rather than a primary bone disease. This is further supported by lack of measurable silicon levels in bone tissue from affected horses.[246]

The diagnosis of BFS is made based on clinical history, clinical findings, geography, and imaging (ultrasonography, radiography, and scintigraphy). Scintigraphy remains the best diagnostic modality, although scapular ultrasonography can be diagnostic in animals with severe disease.[245] Serum chemistry and markers of bone remodeling do not appear to have diagnostic value.[245]

The management of these horses depends on predominant clinical signs and prevention. Nonsteroidal antiinflammatory drugs (e.g., phenylbutazone) should be considered in animals with orthopedic pain, keeping in mind that excessive ambulation can increase the risk of fractures. There must be a good justification for the use of glucocorticoids, perhaps for pulmonary disease, as they also favor bone loss. This is one of the few equine conditions in which bisphosphonates may be indicated. Data from one study showed benefits in most horses with BFS 6 months after zoledronate administration.[248] However, no controls were included in that study to provide an objective assessment of the results. Reduction in physical activity and dietary manipulation are indicated.

Hypertrophic pulmonary osteopathy, or Marie's disease, is a condition described in humans and domestic animals associated with intrathoracic space-occupying lesions (neoplasia, abscesses, chronic pneumonia), but less frequently with abdominal masses, that results in periosteal proliferation and mineralization of appendicular bones. Involvement of the calcium-regulating endocrine system in the pathogenesis of this condition has not been demonstrated. However, it should be considered as a differential diagnosis in endocrine, metabolic, and paraneoplastic syndromes of horses that alter bone mass and structure.

Treatment of Hypercalcemia

Hypercalcemia is rarely presented as an equine emergency; however, the differential diagnosis of hypercalcemia is important in the treatment of this disorder. Mild to moderate hypercalcemia in general is not life threatening, and treatment should be directed to the primary cause (primary hyperparathyroidism, chronic renal failure). Hypervitaminosis D can be fatal when there is mineralization of vital organs. Surgical removal of epithelial tumors may be a successful treatment in some patients. In cases of severe hypercalcemia that require treatment, initial therapy should include the administration of 0.9% saline solution and loop diuretics. Furosemide is the diuretic of choice because it inhibits the $Na^+/K^+/2Cl^-$ cotransporter in the distal nephron, increasing urinary excretion of calcium. Thiazide diuretics are contraindicated because they stimulate calcium reabsorption. Glucocorticoid administration should be considered.

PHOSPHORUS DISORDERS IN THE HORSE

Disorders of phosphorus homeostasis can be acute or chronic, resulting in hypophosphatemia or hyperphosphatemia. In critically ill equids hypophosphatemia is more frequent whereas in foals hyperphosphatemia is more common.[3] Genetic conditions leading to hypophosphatemia or hyperphosphatemia remain to be documented in horses.

Hypophosphatemia

Hypophosphatemia develops from three mechanisms: (1) reduced intestinal PO_4 absorption, (2) increased urinary PO_4 excretion, and (3) intracellular shift of PO_4 (redistribution). Acute hypophosphatemia could reflect PO_4 redistribution between intracellular and extracellular compartments and might not necessarily imply total body PO_4 depletion. However, in horses that have been sick for many days one should assume that PO_4 depletion may be present. Based on clinical experience, hypophosphatemia occurs more often in Miniature Horses, ponies, and donkeys than in horses, usually associated with hyperlipemia and parenteral nutrition.

Absorption

Intestinal absorption of PO_4 is decreased by gastrointestinal pathologies (diarrhea, inflammatory bowel disease, enteritis), hypovitaminosis D, diets deficient in PO_4, and interfering substances. Hypovitaminosis D can result in hypophosphatemia for multiple reasons. Vitamin D promotes intestinal absorption and renal reabsorption of calcium and PO_4. A reduction in $1,25(OH)_2D$ leads to hypocalcemia, which increases PTH secretion, and subsequently enhances urinary PO_4 excretion. In addition, low $1,25(OH)_2D$ concentrations exacerbate PTH secretion as $1,25(OH)_2D$ is a negative regulator of parathyroid chief cell function and PTH secretion.

Excretion

The urinary excretion of PO_4 is increased with hyperparathyroidism, hypovitaminosis D, tumors, renal failure and drugs (aminoglycosides, diuretics). Hyperparathyroidism (primary and secondary) was previously discussed. Hypophosphatemia from cancer is mainly the result of increased urinary PO_4 excretion. Cancer-induced hypophosphatemia occurs by two mechanisms: (1) phosphaturia from increased PTHrP concentrations (PTHrP activates PTH receptors in association with HHM) and (2) phosphatonin-mediated phosphaturia.[1] Data on phosphatonin-mediated hypophosphatemia are lacking in domestic animals.

Hyperphosphatemia and hypocalcemia are the hallmarks of acute renal failure in horses, whereas chronic renal failure is characterized by hypercalcemia and hypophosphatemia.[1] Diuretics increase the urinary excretion of PO_4, with those acting in the proximal tubules (carbonic anhydrase inhibitors) having the most phosphaturic effects, as this is the main site for PO_4 reabsorption.[249,250] Neurogenic and nephrogenic diabetes insipidus may be associated with hypophosphatemia from renal loss as well. In other species, renal distal tubular acidosis, metabolic acidosis, and Fanconi syndrome can result in hypophosphatemia as additional causes of decreased renal reabsorption of PO_4.[249,251]

Redistribution

Phosphate redistribution is the main cause of hypophosphatemia in critically ill human patients.[252-254] Redistribution is likely to be important in the development of hypophosphatemia in critically ill horses, ponies, and foals. Causes of PO_4 redistribution include insulin-mediated shift of PO_4, increased catecholamine concentrations, and respiratory alkalosis.[252-254] Sepsis, high-carbohydrate diets, hyperglycemia, insulin administration, starvation, refeeding syndrome, hyperlipemia, and parenteral nutrition (hyperglycemia, hyperinsulinemia) all decrease serum PO_4 due to insulin-mediated intracellular shift of PO_4 and enhanced glycolysis. Hypophosphatemia from these disorders is well documented in critically ill humans and small animals.[249] Clinical experience indicates that hypophosphatemia is associated with similar conditions in acutely ill equine patients. Catecholamines, similar to insulin, stimulate the activity of the Na^+/K^+ ATPase and the requirements for PO_4. In respiratory alkalosis, as blood and intracellular CO_2 decrease, the pH rises. Alkalosis stimulates phosphofructokinase activity (glycolysis), and the need for PO_4 increases to synthesize ATP. As a result, PO_4 from the extracellular compartment moves into the cell, leading to hypophosphatemia. Hyperventilation (respiratory alkalosis) is considered the main cause of hypophosphatemia in human intensive care units (ICUs).[254,255] Even though diabetes mellitus is rare in horses, it has been linked to hypophosphatemia in other species.[249] Diabetic individuals develop hypophosphatemia from reduced insulin concentrations (type 1 diabetes), insulin resistance (type 2 diabetes), and polyuria leading to PO_4 wasting. Insulin therapy can induce or worsen hypophosphatemia, a factor to consider when treating equine patients with energy dysregulation. This is typically seen in ponies or miniature horses with hyperlipemia. Ketoacidosis is not a common consideration in equine practice.

In horses with a history of malnutrition, close monitoring of serum PO_4 concentrations is highly indicated once caloric intake is increased as they may develop refeeding syndrome.[256] The shift from a catabolic to an anabolic state increases the intracellular needs for PO_4. Insulin secretion contributes to the intracellular redistribution of PO_4 during refeeding syndrome.

Hypophosphatemia can be spurious from laboratory error or improper sample handling (long storage at room temperature). High doses of mannitol can cause pseudohypophosphatemia.[257]

Clinical Signs of Hypophosphatemia

The clinical signs of acute hypophosphatemia are a consequence of skeletal and smooth muscle as well as neurologic dysfunction, whereas signs of chronic hypophosphatemia are mainly linked to behavior and the skeleton. Hypophosphatemia can be classified as severe (less than 1.0 mg/dL; 0.32 mmol/L), moderate (1.0–2.0 mg/dL; 0.32–0.65 mmol/L), and mild (2.1–2.5 mg/dL; 0.66–0.8 mmol/L).

Clinical signs of hypophosphatemia in horses often go unnoticed, and when present, serum PO_4 concentration is usually less than 1.0 mg/dL. These signs relate to PO_4 regulatory functions on energy metabolism, cell membrane stability, and ion transport.[1] These include muscle weakness, fasciculations, dysrhythmias, neuromuscular excitability, ileus, and cell membrane fragility and lysis (hemolysis, rhabdomyolysis) from impaired glucose use, decreased ATP synthesis, and altered cell membrane potential.[249,254,258] Signs associated with mild or moderate hypophosphatemia are difficult to document. Hypophosphatemia can potentially result in tissue hypoxia from reduced erythrocyte content of 2,3-bisphosphoglycerate (2,3-BPG; or 2,3-diphosphoglycerate [2,3-DPG]), shifting the hemoglobin dissociation curve to the left and impairing oxygen release. In humans, ruminants, and dogs, hypophosphatemia has been associated with muscle weakness, rhabdomyolysis, myocardial dysfunction, dysrhythmias, hemolysis, seizures, and pontine myelinolysis.[249,252,259] Hypophosphatemia can also predispose to infections from impaired leukocyte phagocytosis.[254]

Chronic hypophosphatemia is rare in horses and manifests as weight loss, weakness, depraved appetite (pica), reduced bone density, DOD, lameness, and hemolysis.[1] Rickets from PO_4 deficiency or hypovitaminosis D is poorly documented in growing equids.

Laboratory Findings

Laboratory findings associated with hypophosphatemia could include hyperglycemia, hyperinsulinemia, hypokalemia, and hypomagnesemia. Hemolysis has been reported in small animals, ruminants, and humans.[254,259,260-262] Muscle enzyme activity may be increased.

Treatment of Hypophosphatemia

Information on the therapeutic management of hypophosphatemia in horses is minimal.[263] Phosphate-containing supplements are listed in Table 16.3. Critically ill equids are rarely treated for hypophosphatemia, but considering the myriad of processes that depend on PO_4 as a regulatory ion, therapy should be considered. Hypokalemia and hypomagnesemia are frequent abnormalities in horses, ponies, donkeys, and foals with hypophosphatemia, and their serum concentrations should be assessed as part of the therapeutic management of hypophosphatemia.

Most PO_4 in the body (similar to K^+ and Mg^{2+}) is intracellular, and deficit calculations based on serum concentrations do not reflect the total body PO_4 status. The PO_4 deficit can be calculated from standard electrolyte formulas, and if anything, this amount should be overestimated, particularly during prolonged hypophosphatemia because cellular depletion is likely to be present. In people, hypophosphatemia from respiratory alkalosis does not require PO_4 supplementation.[255]

Injectable and oral products formulated for other species to treat hypophosphatemia (Tables 16.10 and 16.11) can be used in horses. Potassium phosphate is a good parenteral option for acute hypophosphatemia, in particular when hypokalemia is also present; however, sodium phosphate is also available and a good alternative. Sick horses and foals can also be supplemented via nasogastric intubation with chemical-grade potassium or sodium phosphate salts. Products formulated for cattle that contain Ca^{2+}, Mg^{2+}, and K^+ should be contemplated. Sodium phosphate enemas containing monobasic and dibasic sodium phosphate given via nasogastric intubation may be useful. There are anecdotal reports of their use intravenously without complications, but this should only be considered

TABLE **16.10 Products Used for Parenteral Supplementation of Phosphate**

Product	Composition/mL	Phosphorus/mL	Potassium/mL	Sodium/mL	Presentation	Company
Potassium phosphate[a]	236 mg of K_2HPO_4 224 mg of KH_2PO_4	3 mM or 93 mg	4.4 mM or 170 mg	0	5, 15, 50 mL	American Reagents, Inc.
Sodium phosphate[a]	142 mg of Na_2HPO_4 276 mg of NaH_2PO_4	3 mM or 93 mg	0	4 mM or 92 mg	5, 15, 50 mL	American Reagents, Inc. Hospira, Inc.
Phosphaid[b,c]	200 mg of NaH_2PO_2	2 mM or 60 mg	0	46 mg	100 mL	Vedco, Inc.
Phos-Aid[b,c]	200 mg of NaH_2PO_2	2 mM or 60 mg	0	46 mg	100 mL	Neogen, Inc.
Phos P 200[b,c]	200 mg of NaH_2PO_2	2 mM or 60 mg	0	46 mg	100 mL	Phoenix, Inc.
CMPK[b,d]	5 mg of NaH_2PO_2 16 mg of KCl	1.5 mg	0.4 mM or 16 mg	1.1 mg	500 mL	Vedco, Inc.

[a]For human use.
[b]Approved for cattle. Contains phosphinic acid (hypophosphorous acid [H_3PO_2]; sodium hypophosphite [NaH_2PO_2]).
[c]Dose for adult cattle ranges from 1 mL/25–50 kg (50–100 lb) of body weight.
[d]To treat hypocalcemia and hypomagnesemia in cattle. Suggested dose for adult cattle is 500 mL/360–450 kg (800–1000 lb) of body weight. Also contains magnesium, calcium, and potassium.
Other formulations that contain phosphorus include Norcalciphos (Zoetis, Inc.) and Cal-Phos (Vedco, Inc.).
K_2HPO_4 = dibasic potassium phosphate/KH_2PO_4 = monobasic potassium phosphate.
Na_2HPO_4 = dibasic potassium phosphate/NaH_2PO_4 = monobasic potassium phosphate.

TABLE **16.11 Phosphate-Containing Products Used For Enteral Supplementation in Humans and Small Animals[a,b]**

Product	Phosphorus/mL	Potassium/mL	Sodium/mL	Presentation	Company
Neutra-Phos	250 mg (8.1 mM)	278 mg (7.1 mM)	164 mg (7.1 mM)	Per tablet or 75-mL solution	Baker Norton
Neutra-Phos-K	250 mg (8.1 mM)	566 mg (14.2 mM)	0	Per tablet or 75-mL solution	Baker Norton
K-Phos-Neutral	250 mg (8.1 mM)	45 mg (1.1 mM)	298 mg (13 mM)	Per tablet	Beach
Fleet Phospho-soda	129 mg (4.15 mM)	0	110 mg (4.8 mM)	Per 45-mL oral solution	Fleet
Fleet Enema[c,d]	43 mg (1.38 mM)	0	37 mg (1.6 mM)	Per 118 mL	Fleet
Fleet Enema Extra[c,d]	25 mg (0.8 mM)	0	23 mg (1 mM)	Per 197 mL	Fleet

[a]Other formulations are available on the market.
[b]Sodium and potassium phosphate salts (chemical grade) can be used via nasogastric intubation in horses.
[c]Phosphate enemas contain monobasic (19 g) and dibasic (7 g) sodium phosphate in 118 mL or monobasic (19 g) and dibasic (7 g) sodium phosphate in 197-mL solution.
[d]Phosphate enemas are often used intravenously in ruminants to treat hypophosphatemia. There are anecdotal reports of their used in horses.

when other parenteral products are not available. It is important to verify their phosphate content as strength varies.

The rate of phosphate administration is determined by the duration and severity of hypophosphatemia (deficit, depletion) and the presence of clinical signs. Phosphate can be replaced within a short period of time (hours) in animals showing clinical signs. Data on enteral or parenteral rates of PO_4 supplementation for horses is minimal. Rates of 0.01 to 0.06 mmol/kg/hr are considered safe in small animals.[249] In people, rates of 0.08 to 0.16 mmol/kg/hr are recommended.[254] However, higher doses (0.2–0.6 mmol/kg/hr) are indicated for patients with severe hypophosphatemia.[252,264,265] Recumbent cows with severe hypophosphatemia can be treated with a drench of 200 g of sodium phosphate or with 23 g of sodium phosphate intravenously in saline solution.[266] In critically ill people, there is evidence that rapid correction of hypophosphatemia may be beneficial.[267]

During rapid PO_4 replacement therapy it is important to monitor serum calcium concentrations because high PO_4 doses could cause hypocalcemia.

Hyperphosphatemia

Hyperphosphatemia, defined as a serum PO_4 concentration greater than 5.0 mg/dL (1.6 mmol/L) in horses (greater than 8.5 mg/dL [2.75 mmol/L] in foals), results from increased PO_4 absorption, renal injury, hypoparathyroidism, vitamin D toxicity, metabolic acidosis, cell lysis (hemolysis, rhabdomyolysis, tumor necrosis), or iatrogenic causes.[249,1] Lactic acidosis and ketoacidosis may cause hyperphosphatemia by shifting PO_4 into the extracellular compartment. Metabolic acidosis and high intracellular ATP levels inhibit phosphofructokinase, a key enzyme in glycolysis and PO_4 use. In newborn foals, overuse of phosphate-based enemas can cause hyperphosphatemia.

Improper sample handling can result in spurious hyperphosphatemia, often associated with hyperkalemia. Hemolysis, hyperbilirubinemia, hyperlipemia (hypertriglyceridemia), and hyperproteinemia can falsely increase PO_4 concentrations (pseudohyperphosphatemia).[257] Multiple myeloma can also cause pseudohyperphosphatemia due to immunoglobulins interfering with PO_4 determination.[257,268,269] These samples require deproteinization for correct PO_4 measurement.

Acute hyperphosphatemia may result in hypocalcemia due to the interaction between PO_4 and Ca^{2+} (mass law) and reduced renal synthesis of $1,25(OH)_2D_3$. In other species, hyperphosphatemia and a serum calcium × PO_4 product greater than 70 are risk factors for soft tissue mineralization.[249,270] However, there is no evidence that this applies to horses, except for those with vitamin D toxicity.[223] Soft tissue calcification and hyperphosphatemia have been documented in horses with a number of diseases, including enterocolitis, respiratory distress, and muscle necrosis.[243] The definitive cause of calcinosis in these animals remains unclear. Hyperphosphatemia is common in critically ill foals.[2,3] There are reports of humans developing hyperphosphatemia from bisphosphonate therapy, and blood work should be monitored in horses undergoing similar treatment.[271]

For the pathogenesis of chronic hyperphosphatemia see nutritional secondary hyperparathyroidism in this chapter.

Clinical Signs of Hyperphosphatemia

The signs of acute hyperphosphatemia are those of acute hypocalcemia and include tetany, hyperexcitability, muscle fasciculation, colic, and dysrhythmias. Signs of chronic hyperphosphatemia are those of calcium deficiency including lameness, orthopedic pathologies, fractures, and osteodystrophia fibrosa (nutritional secondary hyperparathyroidism).[258] Developmental orthopedic diseases can be a problem in growing animals. Soft tissue mineralization (calcinosis) can be present, although it is rare.

Treatment of Hyperphosphatemia

Based on primary pathology and duration, therapy to reduce serum PO_4 may not be necessary. If acute hyperphosphatemia is a consequence of acute cell lysis (e.g., rhabdomyolysis) or iatrogenic (e.g., phosphate enemas), fluid therapy and diuretics are the treatment of choice. Diuretics, in addition to decreasing the deleterious effects of pigment nephropathy, also increase PO_4 excretion.

In humans and small animals, chronic renal failure is a common cause of hyperphosphatemia, although this rarely occurs in horses. Dietary PO_4 restriction must be implemented when treating chronic hyperphosphatemia. Dialysis and phosphate binders are either impractical or very expensive in horses. In addition, conditions associated with prolonged hyperphosphatemia usually carry a poor prognosis. In horses with chronic hyperphosphatemia from vitamin D toxicity glucocorticoid therapy is unlikely to be beneficial. Calcium carbonate is a cheap phosphate binder that also provides calcium supplementation. Calcium acetate is another alternative. In people and small animals, phosphate-binding polymers (e.g., sevelamer) are the most effective way to treat chronic hyperphosphatemia.

Magnesium and Disease

Ramiro E. Toribio, DVM, MS, PhD, Dipl ACVIM

MAGNESIUM

Magnesium (Mg) is an essential macroelement involved in physiologic processes such as enzymatic activation, intermediary metabolism of carbohydrates, fats, and proteins, nucleic acid metabolism, regulation of membrane function, nerve function, muscle contraction, and cell proliferation.[272,273] Over 600 enzymatic reactions require Mg as a cofactor or activator.[274] Extracellular Mg is not under tight hormonal homeostatic control like calcium (Ca) is, and plasma concentrations depend on gastrointestinal absorption, renal excretion, and bone exchange.[272,273] However, various hormonal and nonhormonal factors influence extracellular Mg concentrations.[272] Because a multitude of cellular processes are highly dependent on Mg, intracellular concentrations are tightly regulated.[274] Many transporters and channels involved with intracellular Mg homeostasis have been recently identified, and their importance is evident in genetic disorders linked to Ca and Mg disturbances.[274] Similar to total calcium and ionized calcium (Ca^{2+}), total magnesium (tMg) in biologic fluids exists in fractions bound to proteins, chelated to organic anions, and ionized/active/free Mg (Mg^{2+}). Because Mg as a solute interacts with more water molecules than other biologic cations and its binding to water is very stable, transmembrane permeability for Mg is lower than for Na^+, K^+, or Ca^{2+}.[274-277] Thus Mg movement through channels and carrier proteins is highly energy dependent.[274-277] In addition, because of its chemical and electrical characteristics, Mg is a powerful Ca antagonist.[274-278] Despite similar electrochemical properties, in biologic systems Ca can be a death trigger whereas Mg is not, and Mg can block Ca-induced cell death.[276]

Mg concentrations are higher in the intracellular compartment, where it binds to negatively charged molecules (such as ATP, DNA, and RNA), enzymes, and other proteins. Any ATP-dependent reaction also requires Mg^{2+} because ATP is associated with Mg^{2+} ($ATP{\cdot}Mg^{2+}$).[274-277] A similar dependency exists for GTP ($GTP{\cdot}Mg^{2+}$). Approximately 90% of the intracellular Mg is bound to ribosomes, polynucleotides, and to the phosphate backbone of nucleic acids to facilitate base pairing.[277] Mg^{2+} is required for genomic stability, nucleotide repair, and DNA replication fidelity.[274,279] Mitochondria function as intracellular stores for Mg^{2+}. By interacting with various proteins, Mg affects the cell cycle and stabilizes cell membranes.[274,276-279] Mg^{2+} interacts with Ca^{2+} in the intra- and extracellular compartments.[274,276-278] Depending on the physiologic system or binding molecule, Mg^{2+} and Ca^{2+} interact in the following ways: (1) Mg^{2+} and Ca^{2+} can have similar biologic effects, (2) Mg^{2+} and Ca^{2+} can bind to molecules with different affinities, resulting in synergy or antagonism, (3) they can antagonize each other, or (4) their effects can be interdependent. The pathophysiology of Mg-related disorders is often complicated by the Ca^{2+} status of the affected animal. Likewise, Ca^{2+}-related pathologies can be confounded by Mg^{2+} status. Hypomagnesemia exaggerates the effects of Ca^{2+} whereas hypermagnesemia may antagonize the actions of Ca^{2+}. Hyperexcitability from hypocalcemia can be exacerbated by low Mg^{2+} concentrations.[274]

Mg concentrations in body fluids are reported in mg/dL, mEq/L, or mmol/L. As the atomic weight of Mg is 24.3 and its valence is 2+, 1 mEq of Mg is equal to 12.15 mg (0.5 mmol) of Mg. Conversion factors are as follows: mmol/L = mg/dL × 0.41; mg/dL = mmol/L × 2.43; mg/dL = mEq/L × 1.21; mmol/L = mEq/L × 0.5. Dietary magnesium is reported as %, g/kg, or parts per million (ppm; mg/kg).

Magnesium Requirements in the Horse

Based on urinary and fecal losses of Mg, it has been estimated that adult horses must absorb 5 mg/kg BW of Mg to

replace daily obligatory losses.[46] With an average absorption of 40%, dietary Mg requirements for adult horses are around 12.5 mg/kg BW/day (7.5–12.0 g/horse/day).[46] A daily supply of 13 to 15 mg/kg BW/day should cover the requirements for most adult horses,[51] but these needs can be higher depending on the animal's physiologic status. Growing, lactating, and exercising animals have higher demands; mares in early lactation and horses undergoing intense exercise may require 15 to 30 mg/kg of Mg (10–15 g/horse/day).[46] A daily Mg intake of 5 to 6 mg/kg has been associated with hypomagnesemia.[17] Mg content is lower in grasses, particularly rapidly growing spring pastures, and grains (0.1%–0.2% DM), compared with legumes (0.2–0.3% DM). Content in meals from the vegetable oil industry (soybean, cottonseed, peanut, linseed, safflower, sunflower) and molasses varies from 0.3% to 0.8%.[46] In fish meal, Mg content varies from 0.1% to 0.3%.[46]

Distribution of Magnesium within the Body

Magnesium is the fourth most abundant cation in the body behind Ca^{2+}, Na^+, and K^+, but it is the second most abundant intracellular cation after K^+.[280] Mg distribution resembles that of K^+, and their intra- and extracellular dynamics are interrelated. The body of domestic animals contains 0.05% Mg by weight of which 60% is in the skeleton (0.5%–1% bone ash), 38% in soft tissues, and 1% to 2% in the extracellular fluid (Fig. 16.12). Approximately 30% of bone Mg is surface limited and readily available to serve as an exchangeable pool to buffer acute changes in extracellular Mg concentrations, whereas the remaining 70% has structural functions as part of the hydroxyapatite lattice, and its release depends on bone resorption. Cells with higher metabolic activity have higher Mg content. Although most Mg is in the intracellular compartment, free intracellular and extracellular Mg concentrations are similar, and the transmembrane gradient is small compared with that of Ca. Red blood cell Mg concentrations are around 3 times the serum Mg concentrations and have been used to assess the Mg status of individual animals.

In circulation, total magnesium (tMg) is bound to proteins, chelated to organic anions (carbonate, sulfate, lactate, citrate), and ionized or free (Mg^{2+}) (see Fig. 16.12). Mg^{2+} is the form of Mg that is important for most biologic processes, in particular those related to neuromuscular excitability. When possible, it is better to measure Mg^{2+} than tMg concentrations. In equids, 60% of the serum tMg is ionized, 30% is protein bound, and 10% is complexed to weak acids[6,7,12,13,40,120,281] (see Fig. 16.12). Serum tMg concentrations depend on protein concentrations (albumin), whereas Mg^{2+} concentrations depend on the acid-base status. Acidosis increases Mg^{2+}, and alkalosis does the opposite. This is clinically relevant, as conditions associated with alkalosis (nasogastric reflux, duodenitis/proximal jejunitis, exercise-associated alkalosis from hyperventilation, and Cl^- loss) can lead to low Mg^{2+} concentrations, with potential clinical signs of hypomagnesemia despite normal tMg concentrations. Feeding an acidic diet with a low dietary cation anion balance (DCAB) will increase the percentage of Mg^{2+}.[40]

Reported normal serum concentrations in horses are tMg = 1.4 to 2.2 mg/dL (0.6–0.9 mmol/L) and Mg^{2+} = 0.9 to 1.5 mg/dL (0.42–0.6 mmol/L).[4,6,7,12,13,40,120,281] In foals, normal concentrations are tMg = 1.3 to 2.4 mg/dL (0.55–1.0 mmol/L) and Mg^{2+} = 1.0 to 1.9 mg/dL (0.42–0.8 mmol/L).[13,2,282] One study found higher tMg concentrations in donkeys.[120] Serum tMg and Mg^{2+} concentrations tend to be higher in foals.[13] Additionally, seasonal effects on tMg concentrations in equids have been reported, with higher serum tMg concentrations measured in summer compared with winter months.[119]

Magnesium Absorption

Mg is absorbed as a freely diffusing ion (Mg^{2+}) by paracellular (passive, nonsaturable, concentration-dependent) and transcellular (saturable, active transport) mechanisms (Fig. 16.13; also see Fig. 16.6).[273,283] Mg absorption occurs in the distal small intestine and colon of monogastric animals,[37,273,284,285] whereas in ruminants, the rumen is the main site for Mg absorption.[273,284] Transcellular Mg absorption is mediated by

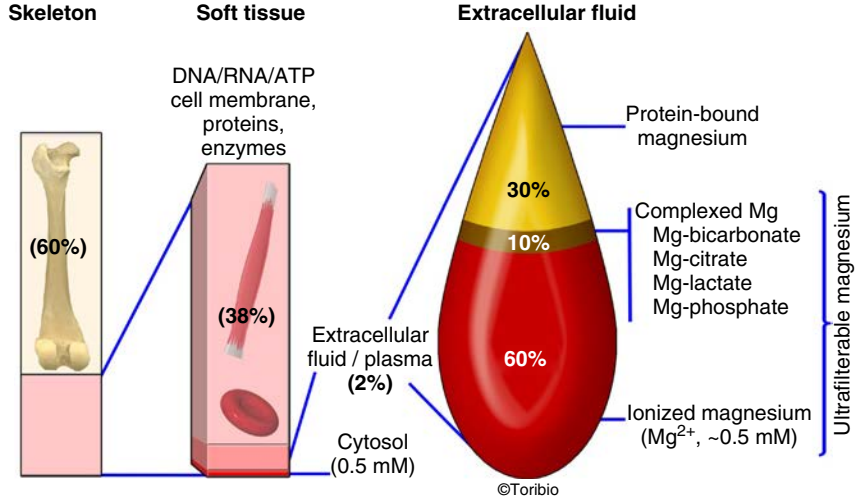

FIG. **16.12** Magnesium distribution in the body. Approximately 60% of the total body Mg is in the skeleton, 38% is in soft tissue, and 2% is in the extracellular fluid. Although most Mg is in the intracellular compartment bound to proteins and nucleotides, free cytosolic Mg concentrations are similar to extracellular Mg concentrations. In equine blood, 60% of Mg exists as a free or ionized form (Mg^{2+}), 30% is bound to proteins, and 10% is complexed to anions such as citrate, bicarbonate, phosphate, and lactate.[6,7,12,13,40,120] (Courtesy Dr. R. E. Toribio, The Ohio State University.)

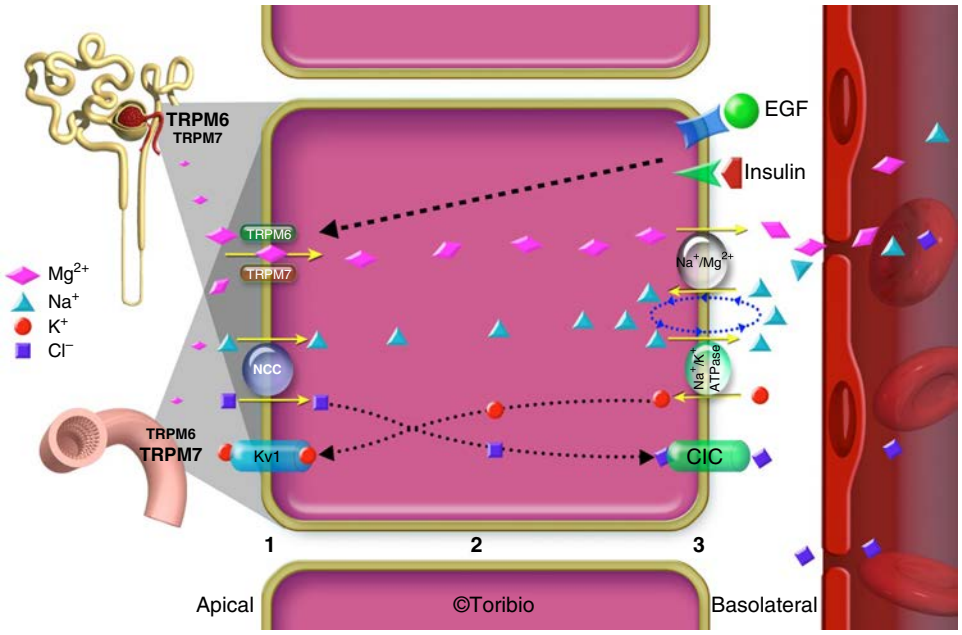

FIG. **16.13** Intestinal absorption and renal reabsorption of magnesium.[76,274,286] Apical Mg^{2+} uptake is mediated by the transient receptor potential channel melastatin member 6 (TRPM6) and member 7 (TRPM7). TRPM7 expression is ubiquitous to all segments of the intestinal tract, whereas TRPM6 is mainly present in the distal small and proximal large intestine. In the renal distal convoluted tubules, TRPM6 is the main epithelial Mg^{2+} channel. Epidermal growth factor (EGF) and insulin promote apical Mg^{2+} uptake. The Na^+/Cl^- cotransporter (NCC) enhances transcellular Mg^{2+} movement. The basolateral Na^+/K^+-ATPase creates a transcellular gradient to move Mg^{2+} across the epithelium. The voltage-gated K^+ channel (Kv1) contributes to maintaining this voltage gradient by transporting K^+ to the lumen. A putative Mg^{2+}/Na^+ exchanger moves Mg^{2+} to the basolateral side. A basolateral Cl^- channel (ClC) is responsible for Cl^- extrusion. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

the transient receptor potential channel melastatin member 6 (TRPM6) and 7 (TRPM7) (see Fig. 16.13). In other species, TRPM7 expression is ubiquitous in all segments of the intestinal tract, whereas TRPM6 is mainly present in the distal small intestine, proximal large intestine, and kidneys.[274,286] Unlike calcium, for which transcellular transport is vitamin D dependent, vitamin D has minimal effect on TRPM6 expression and Mg absorption.[287]

In horses, most Mg^{2+} absorption occurs in the small intestine, with approximately 25% being absorbed in the proximal small intestine, 30% to 35% in the distal small intestine, and 5% to 10% in the large colon.[37] Intestinal Mg absorption is proportional to dietary Mg content, but its absorptive efficiency decreases as dietary Mg content increases.[273,284] High dietary Mg leads to increased serum, erythrocyte, and tissue Mg concentrations, especially in bone.[273,288] Dietary Ca content has minimal effect on Mg absorption in monogastric animals.[273] The digestibility of Mg ranges from 30% to 50% depending on diet, activity, and age.[27,36,37,44,289,290] These values are higher in horses than other herbivores.[37] Alfalfa and alfalfa hay have the highest Mg digestibility (50%) compared with pelleted feed and cereal grains (approximately 20%–30%).[27] Digestibility of oral supplements such as MgO, $MgSO_4$, and $MgCO_3$ is similar, ranging from 50% to 70%. Magnesium digestibility is higher in foals.[36] Excessive amounts of fatty acids, oxalates, phosphates, and fiber reduce intestinal Mg^{2+} absorption. High dietary phosphate content reduces Mg absorption in horses[290]; however, phytates, calcium, and aluminum have minor influence.[37,45,289,290,291] One study found that phosphorus intake has minimal effect on Mg digestibility.[44] Malabsorption syndromes and enteropathies may decrease absorption. Prolonged use of proton pump inhibitors (e.g., omeprazole) has been linked to hypomagnesemia in people, apparently from reduced intestinal absorption.[292] This phenomenon has not been documented in veterinary medicine to date.

Magnesium Excretion

The principal routes for Mg excretion are (1) the gastrointestinal tract, (2) the kidneys, and (3) the mammary gland during lactation. In addition, Mg can be lost in sweat and to the developing fetus in pregnant animals.

The kidneys play a central role in Mg regulation, where Mg is reabsorbed in the proximal convoluted tubules (PCTs), cortical thick ascending limb (CTAL) of the loop of Henle, and the distal convoluted tubules (DCTs).[7,272,293-295] Renal Mg excretion is tightly matched to gastrointestinal Mg absorption; Mg absorbed in excess from the gastrointestinal tract is excreted by the kidneys. Tubular reabsorption is regulated by dietary availability of Mg, serum Ca^{2+} and Mg^{2+} concentrations, urinary Ca^{2+} excretion, and multiple hormones.[7,272,293,294]

Ionized and anion-bound Mg (ultrafilterable Mg) is filtered by the glomerulus, whereas protein-bound Mg is not (see Fig. 16.12). Approximately 70% of the blood Mg^{2+} is filtered by the glomeruli, with 70% to 90% being reabsorbed in different segments of the nephron.[7,294] Around 10% to 20% of the filtered Mg is reabsorbed in the PCT, 50% to 70% is reabsorbed in the CTAL, and the remaining 5% to 10% is reabsorbed in the DCT.[272] The DCT seems to be the site determining ultimate

urinary excretion of Mg.[7,283] Renal reabsorption of Mg is paracellular (PCT, CTAL) and transcellular (DCT). Paracellular reabsorption occurs in the PCT (passive, concentration-dependent) and CTAL (active, voltage-dependent), whereas transcellular (active) reabsorption takes place in the DCT (see Fig. 16.13).[7,76,286] Paracellular reabsorption of Mg in the PCT is mostly dictated by Mg concentrations in the ultrafiltrate. The mechanisms driving paracellular Mg reabsorption in the CTAL are described in detail in the calcium section (see Fig. 16.6). Claudins are intercellular proteins that determine ion permeability of epithelial tight junctions. Claudin-16 (paracellellin-1) is required for Ca^{2+} and Mg^{2+} transport at the CTAL.[76,286] Claudin-16 is more selective for Mg^{2+}, and people with inactivating mutations develop hypomagnesemia, hypercalciuria, and nephrocalcinosis.[76,286] A comparable disorder occurs with claudin-19 mutations.[76,286] Similar to Ca^{2+} transport in the CTAL, parathyroid hormone (PTH), Ca^{2+}, and Mg^{2+} at the basolateral membrane regulate paracellular reabsorption of Mg^{2+} in different species, including the horse.[7,76,274,286] A multitude of factors affect renal Mg^{2+} reabsorption (see later discussion).

In the DCT, Mg^{2+} transport is transcellular and mediated by the transient receptor potential channel melastatin member 6 (TRPM6) and 7 (TRPM7). However, TRPM6 is considered the main channel for Mg uptake.[76,274,286] The mechanisms for basolateral Mg extrusion remain unclear, but they seem to depend on Na^+ uptake and are driven by the Na^+/K^+-ATPase.[76,274,286] The Na^+/Cl^- cotransporter (NCC) enhances transcellular Mg^{2+} movement (see Fig. 16.13). Thiazide diuretics, which inhibit NCC, increase Mg^{2+} excretion, and their prolonged use in people can result in hypomagnesemia.[76,274,286] Gitelman syndrome, a human inherited condition arising from inactivating mutations of the NCC, is characterized by hypomagnesemia, hypocalciuria, hypokalemia, metabolic alkalosis, and hyperreninemic hyperaldosteronism.[286] There appears to be crosstalk between NCC and TRPM6, and a reduction in activity of one is followed by a concomitant decrease in the other.[286]

In addition to Na^+ and Cl^-, a normal K^+ status is necessary for Mg^{2+} reabsorption; the basolateral Na^+/K^+-ATPase creates ionic gradients in the CTAL and DCT. Therefore there is interdependency between Mg^{2+} and K^+; apical Mg^{2+} entry requires basolateral K^+ uptake, which also requires ATP, and therefore Mg^{2+}. Hypokalemia is often linked to hypomagnesemia in horses and foals with gastrointestinal disease and sepsis.[2,4,6,7]

PTH and 1,25-dihydroxyvitamin D ($1,25[OH]_2D$; calcitriol) do not appear to play major roles in Mg^{2+} entry in the DCT. More important in this segment are epidermal growth factor (EGF), insulin, and extracellular concentrations of Mg^{2+}.[76,274,286] Activation of the EGF receptor enhances trafficking and activity of TRPM6, and absence of EGF causes hypomagnesemia.[76,274,286] Genetic disorders of Mg transport remain to be documented in the horse. In contrast, a number of genetic conditions affecting different Mg transporters in the CTAL and DCT occur in people.[76,274,286]

The mammary gland actively secretes Mg into milk. Mg output into milk is estimated at 3 to 6 mg/kg BW/day, and daily Mg requirements in lactating mares are 15 to 30 mg/kg BW.[46] Mg concentrations in mare's milk change from 470 mg/L at foaling (colostrum) to 90 to 120 mg/L on week 1, to 60 to 120 mg/L on week 2 to 8, and 40 to 60 mg/L by the end of lactation.[19,20,296,297] Higher values have been measured in zebras.[19,20] Mares producing larger volumes of milk are more likely to develop clinical hypomagnesemia.

Horses can also lose Mg in their sweat.[163,298] It has been proposed that the salivary glands may contribute to Mg excretion and homeostasis in the horse.[44]

Magnesium Homeostasis

There is not a precise homeostatic system for Mg^{2+}, and its extracellular concentrations depend on gastrointestinal absorption, renal excretion, and bone exchange.[272,273] However, hormonal and nonhormonal factors influence Mg absorption, excretion, and extracellular concentrations.[272,273] Hormones that *increase* renal reabsorption of Mg^{2+} include parathyroid hormone (PTH), parathyroid hormone–related protein (PTHrP), epidermal growth factor (EGF), antidiuretic hormone (vasopressin), insulin, glucagon, β-adrenergic agonists, aldosterone, and, to lesser extent, $1,25(OH)_2D$.[272,293,299-303] Activation of the calcium-sensing receptor (CaSR) in the CTAL by hypercalcemia and hypermagnesemia in various species, including the horse, increases the urinary excretion of Ca^{2+} and Mg^{2+} (see Fig. 16.6).[7,304] Impaired Mg^{2+} reabsorption occurs with osmotic diuresis (volume expansion, hyperglycemia), loop diuretics, thiazide diuretics, hypercalciuria, hypercalcemia, hypermagnesemia, hypokalemia, hypophosphatemia, renal tubular acidosis, metabolic acidosis, prostaglandins, and various toxicities (aminoglycosides, amphotericin B, cyclosporine, cantharidin).[76,274,286,293,304-307] Furosemide and hypercalcemia decrease serum tMg and Mg^{2+} concentrations in healthy horses.[7,305] Both hypercalcemia and loop diuretics act by a similar mechanism (inhibition of the $Na^+/K^+/2Cl^-$ cotransporter) in the CTAL.[7,304] PTH, on the other hand, increases the activity of the $Na^+/K^+/2Cl^-$ cotransporter and renal outer medullary K^+ channel (ROMK) in the CTAL, thereby increasing paracellular reabsorption of Ca^{2+} and Mg^{2+} (see Fig. 16.6).[1,7,76,274,286,307] PTH indirectly increases Mg^{2+} release from the skeleton during bone resorption. Hypermagnesemia decreases PTH secretion, serum Ca^{2+} concentrations, and renal Ca^{2+} reabsorption in horses by activating the CaSR in the CTAL and parathyroid chief cells.

Magnesium and the Central Nervous System

In the central nervous system (CNS), Mg^{2+} is directly or indirectly (via ATP) required for processes involving transmembrane ion traffic and neurotransmitter release. Mg^{2+} interacts with Ca^{2+} in the intracellular and extracellular compartments, and these interactions can be additive, synergistic, or antagonistic. For example, hypocalcemia can alter neuronal function, and the Mg status can worsen the severity of clinical signs. Mg ions are necessary for the activity of the Na^+/K^+-ATPase, Mg^{2+}-ATPase, H^+/K^+-ATPase pump (proton pump), plasma membrane Ca^{2+} ATPase (PMCA), Na^+/Ca^{2+} exchanger (NCX), *N*-methyl-D-aspartate (NMDA) receptor (NMDAR), Ca^{2+} channels, and other proteins involved in neuronal and glial function. The neuroprotective actions of Mg^{2+} are mainly due to its ability to compete with Ca^{2+} at a number of proteins (e.g., NCX, NMDAR, Ca^{2+} channels) that increase intracellular Ca^{2+} concentrations. Mg^{2+} also blocks Na^+ channels. In addition, Mg^{2+} may protect brain cells against free radical injury, neurotoxicity, and inflammation.[308]

The NMDAR is a cation-selective (Ca^{2+}, Na^+) channel that mediates neuronal plasticity, rhythmicity, and excitability. Upon excessive activation by glutamate, Ca^{2+} and Na^+ influx triggers excitotoxic death, a process that is blocked by cations such as Zn^{2+} and Mg^{2+}.[309,310] This protective action by Mg^{2+} may have therapeutic implications to acute brain injury,

ischemia, and hypoxia. This might be even more important in the developing neonatal brain, where the NMDAR is a predominant mediator of excitotoxicity.[309] Under this premise, Mg^{2+} has been used to treat foals with hypoxic ischemic encephalopathy and horses with brain injury[311-313]; however, controlled studies on the therapeutic benefits of Mg^{2+} in horses or foals with cerebral injury are lacking. The clinical scenario appears to be different under experimental conditions of brain injury, where several studies have shown that $MgSO_4$ improves outcome.[314,315] By blocking Ca^{2+} channels in vascular smooth muscle, Mg^{2+} is a vasodilator[316] (an effect that could be beneficial or not, depending on the condition and severity).

Mg^{2+} is also a modulator of the pain response. Similar to ketamine, Mg^{2+} reduces neuronal Ca^{2+} entry by antagonizing the NMDAR, which reduces excitability or nociception. This is likely the justification for using intravenous $MgSO_4$ in combination with chloral hydrate in earlier equine general anesthetic combinations. In addition, this knowledge has been used in humans to manage excessive nociception and pain hypersensitivity (wind-up syndrome). The analgesic benefits of Mg^{2+} for equine conditions remains to be demonstrated. Mg is also often used in show horses under the premise of its calming effects; however, this is inappropriate, given that the intent of use is to confer a competitive advantage.

Mg^{2+} reduces neuroexcitability and nerve conduction by blocking presynaptic Ca^{2+}-dependent acetylcholine release and excitation-secretion coupling.[8,284] High Ca^{2+} promotes whereas high Mg^{2+} inhibits the release of acetylcholine from the presynaptic terminal.[317] Mg depletion contributes to tetany by increasing the release of acetylcholine at the neuromuscular junction and delaying its degradation by acetylcholinesterase.[8,284]

The Ca^{2+} blocking actions of Mg^{2+} on smooth muscle are being used in human medicine to treat conditions such as hypertension and asthma.[318]

Disorders of Magnesium

Hypomagnesemic conditions are well described in the literature, whereas hypermagnesemic disorders are rarely encountered. In people, low Mg concentrations have been linked to a multitude of chronic conditions, including cardiovascular (hypertension, dysrhythmias), neurologic (migraines, attention deficits, depression, irritability, Alzheimer disease, eclampsia), respiratory (asthma), endocrine (low PTH secretion, PTH resistance, hypovitaminosis D, vitamin D resistance, osteoporosis), metabolic (insulin resistance/type 2 diabetes mellitus, metabolic syndrome), and electrolyte (hypokalemia, hypocalcemia) disorders.[318] Equine veterinary medicine has not yet solidified the importance of Mg depletion in chronic diseases of the horse.

Acute Mg deficiency may occur with gastrointestinal and renal diseases, sepsis, endotoxemia, endocrine dysfunction, alterations of acid-base status, and cell lysis. Stress hormones, such as catecholamine and insulin, can worsen the clinical signs of hypomagnesemia by stimulating intracellular Mg^{2+} shifts.[284] The severity of hypomagnesemia is the result of reduced dietary intake, decreased absorption, excessive mobilization of endogenous stores, increased urinary excretion, tissue redistribution, or a combination of these effects.

Hypomagnesemia and Equine Disease

In large animals, hypomagnesemia is most frequently diagnosed in ruminants, but in recent years, it has become a subject of clinical attention in acutely ill horses and foals.[4,40,284,319-321] Hypomagnesemia was identified as the most common electrolyte abnormality in critically ill canine and feline patients.[322] Chronic hypomagnesemia is usually linked to inadequate dietary Mg^{2+} intake, whereas acute hypomagnesemia can be the result of multiple disorders.[284,321] In the case of ruminants, primary hypomagnesemia (grass staggers, tetany) is typically observed in animals feeding exclusively on fresh rapidly growing pastures that are low in Mg content in early spring.[40,284,321]

Mg plays essential roles in inflammation, protection against free radical injury, and neurotoxicity.[323,324] However, information on the role of Mg in equine inflammatory conditions is limited.[4,36,40,325] Hypomagnesemia has been associated with increased cytokine production and systemic inflammation.[323,324] A similar process is likely to occur in critically ill horses and foals where the same proinflammatory cytokines are elevated.[4,6,326,327] Horses and foals with gastrointestinal disease often have endotoxemia and hypomagnesemia.[2,4,6,327,328] The induction of experimental endotoxemia in healthy horses decreased both tMg and Mg^{2+}, supporting a role for Mg in equine inflammatory disease.[6]

One study in horses that had colic surgery found that serum tMg and Mg^{2+} concentrations were below the reference range in 17% and 54% of animals, respectively.[155] The same study found that nonsurviving horses had significantly lower preoperative serum Mg^{2+} concentrations. Toribio and colleagues found that 78% of horses with severe gastrointestinal disease had ionized hypomagnesemia.[4] In another study in hospitalized horses, 48.7% of animals were hypomagnesemic although no association with mortality or length of hospitalization was found.[320] An association between hypomagnesemia, severity of disease, and mortality has been demonstrated in other species, and there is increasing evidence that this also applies to sick horses and foals.[2,4,6,155,320] Hurcombe and colleagues did not find an association between serum Mg^{2+} concentrations and mortality in critically ill septic foals, although 15% of foals were hypomagnesemic.[2] Another study found higher tMg concentrations in foals with evidence of perinatal asphyxia syndrome compared with healthy and septic foals.[282] The same study found higher tMg concentrations on admission in nonsurviving compared to surviving sick foals.[282]

Equine cantharidiasis (blister beetle toxicosis) is a condition characterized by acute hypomagnesemia and hypocalcemia. It is reported in the central, south, and midwestern United States and associated with the ingestion of alfalfa contaminated with blister beetles (*Epicauta* spp.), which produce cantharidin (cantharidic acid).[159,188,189] Cantharidin causes necrosis of the intestinal mucosa, renal tubules (acute tubular necrosis), and myocardium. Clinical signs include synchronous diaphragmatic flutter (SDF; thumps), muscle fasciculation, ataxia, dyspnea, laryngeal spasm, cardiac dysrhythmias, colic, diarrhea, endotoxemia, dehydration, hypotension, hematuria, stranguria, pollakiuria, and sudden death.[159,188,189]

An association between hypomagnesemia and hypocalcemia has been demonstrated in lactating mares, transported horses, and horses with intestinal strangulation, ileus, enterocolitis, endotoxemia, SDF, and blister beetle poisoning.[4,6,155,189,329] Patients with hypocalcemia and hypomagnesemia often fail to respond to calcium therapy until normomagnesemia is restored.[330] The mechanisms through which hypomagnesemia can promote hypocalcemia are numerous. Mg depletion can impair PTH synthesis and secretion and could lead to target organ resistance to PTH.[331] This translates into decreased renal reabsorption of Ca^{2+} and Mg^{2+}

(waste), reduced bone resorption, and less renal synthesis of active vitamin D (1,25[OH]$_2$D). In other words, hypocalcemia from Mg deficiency may be attributed to impaired PTH secretion (parathyroid gland dysfunction) combined with target organ (bone, kidney) insensitivity to PTH.

Contrary to other species in which there is a link between hypomagnesemia and metabolic conditions,[332] an association between obesity, insulin resistance, laminitis, and Mg deficiency has not been demonstrated in the horse.[333] Mg^{2+} is important for insulin receptor signal transduction and glucose metabolism, and insulin increases intracellular Mg^{2+} shifts.[332] Insulin is also important for renal Mg^{2+} reabsorption.[76,274] Thus, insulin resistance may lead to renal Mg^{2+} wasting from increased tubular flow (hyperglycemia) and decreased Mg^{2+} reabsorption.[332] Subsequently, Mg depletion could worsen insulin signaling, creating a vicious cycle.

Magnesium and Electrolytes

Mg is a cofactor for the Na^+/K^+-ATPase that maintains the cell membrane potential. Hypomagnesemia leads to loss of intracellular K^+, intracellular Na^+ accumulation, and lowering of the resting membrane potential, which causes hyperexcitability, seizures, arrhythmias, muscle weakness, muscle fasciculations, SDF, and cardiac arrhythmias. Information on a cause-effect relationship between hypomagnesemia and electrolyte abnormalities in horses or foals is minimal; however, hypomagnesemia is often associated with hypokalemia, in particular in foals and ponies receiving parenteral nutrition. Interestingly, hypophosphatemia is also a frequent finding in these animals. Because of their close interactions, interdependency, and homeostasis, more often than not horses with hypomagnesemia also have hypocalcemia. As previously mentioned, PTH secretion and action require Mg^{2+}, and at the same time, PTH promotes renal Mg^{2+} reabsorption.

Clinical Signs of Magnesium Deficiency

Hypomagnesemia results from reduced Mg intake (poor nutrition, low-Mg diets), reduced absorption (diarrhea, malabsorption, intestinal resection), redistribution (third space and intracellular sequestration), and increased losses (renal tubular disorders, gentamicin and/or furosemide administration, hypercalcemia, gestation, lactation, and intense exercise). Specific clinical signs of hypomagnesemia are often overlooked in horses and foals.

Mg depletion is associated with muscle weakness, tremors, seizures, hypokalemia, hypocalcemia, cardiac arrhythmias (ventricular arrhythmias, supraventricular tachycardia, atrial fibrillation), ileus, and SDF. Electrocardiographic changes associated with hypomagnesemia include prolonged P-R interval, widening of the QRS complex, depression of the ST segment, and tall T waves.[334] Hypocalcemic tetany has been reported in adult horses and ponies[329,335] and in foals fed Mg-deficient diets.[325] Affected foals exhibited nervousness, muscular tremors, ataxia, profuse sweating, hyperpnea, collapse, and convulsions.[325] On necropsy, all foals had severe mineralization of the elastic fibers of the aorta and pulmonary artery.[36,325] In one study of colic patients, nonsurviving horses had significantly lower preoperative serum Mg^{2+} concentrations.[155]

Diagnosis of Hypomagnesemia

The easiest way to assess the Mg status is by determining serum tMg and Mg^{2+} concentrations. Serum Mg^{2+} is more reliable because it is the active form of Mg and is minimally affected by protein concentrations. In animals with respiratory or metabolic alkalosis (observed after prolonged exercise, proximal enteritis), serum Ca^{2+} and Mg^{2+} concentrations may be low from increased protein binding. Methods to assess total body Mg status include 24-hour urinary Mg excretion, % Mg retention following parenteral Mg loading, and red blood cell Mg content. Of these, the 24-hour urinary excretion and the retention tests have been validated in horses.[40]

To assess renal excretion of Mg, urine is collected over 24 hours; Mg excretion is then expressed as mg/kg/day. Urinary Mg excretion is useful to assess dietary intake. Mg excretion is low when dietary intake is reduced.[40] The fractional excretion of Mg (FMg) can be determined by expressing the renal Mg excretion relative to creatinine excretion.[6,7,40] FMg in healthy horses ranges from 15% to 35%,[6,7,40] and values less than 6% indicate inadequate dietary Mg intake.[40] Muscle Mg content has been used to estimate total body stores in foals and horses.[40,336] One study evaluated Mg muscle content and intracellular Mg^{2+} concentrations in horses fed a Mg-deficient diet, with no differences found in muscle Mg content compared with control horses; however, intracellular Mg^{2+} concentrations were lower in Mg-deficient horses.[40]

The Mg retention test to assess total body status was evaluated in horses receiving Mg-deficient diets.[40] $MgSO_4$ was administered at 10 mg/kg IV of elemental Mg (100 mg/kg of $MgSO_4$). The percent retention (%Ret) was calculated as %Ret = (1 − [Mg excretion in 24 hours]/[Mg infused]) × 100). In this study, the 24-hour Mg excretion was a more sensitive indicator of reduced Mg intake than the Mg retention test, and the spot FMg reflected the 24-hour excretion of Mg.[40] Thus a spot FMg can be used as a simpler way to assess the Mg status.

The value of measuring cerebrospinal fluid and vitreous humor Mg concentrations as a postmortem tool to confirm equine hypomagnesemia remains to be evaluated. This is a well-accepted approach to diagnose hypomagnesemia in ruminants, however.

Treatment of Hypomagnesemia

Mg for oral administration is available as magnesium sulfate ($MgSO_4$; Epsom salts), magnesium oxide (MgO), magnesium carbonate ($MgCO_3$), magnesium chloride ($MgCl_2$), and magnesium hydroxide (Mg[OH]$_2$). $MgSO_4$ and $MgCl_2$ are available for intravenous administration. The type of salt and the route of administration are important when supplementing Mg. For $MgSO_4$ (9.7% Mg), a dose of 100 mg/kg will provide 9.7 mg/kg of elemental Mg whereas for $MgCl_2$ (25.5% Mg) a dose of 100 mg/kg will provide 25.5 mg/kg of elemental Mg. Attention to this detail is important, as overdosing can be fatal. Likewise, excessive oral (nasogastric) supplementation with $MgSO_4$ can be laxative and induce depression.

Recommended IV doses of $MgSO_4$ in horses vary from 25 to 150 mg/kg/day diluted in 0.9% NaCl, dextrose, or polyionic isotonic solutions. Constant rate infusions (CRI) of $MgSO_4$ at 100 to 150 mg/kg/day meet the daily requirements in foals and horses. For most horses with gastrointestinal disease and hypomagnesemia, supplementing 1 g of $MgSO_4$ per liter of crystalloid solution at 1 to 2 times the maintenance fluid rate should restore normomagnesemia or at least replace renal and intestinal losses. Horses tolerate 10 to 20 g of $MgSO_4$ IV administered over 10 to 20 minutes well. Some animals may require higher doses of $MgSO_4$, in particular those with evidence of systemic inflammation receiving intravenous calcium salts at the same time.

In foals, $MgSO_4$ can be given as a bolus (40–60 mg/kg IV) over 10 to 20 minutes, in replacement fluids, or via CRI. $MgSO_4$ CRI rates used in foals with hypoxic ischemic encephalopathy and seizures (50 mg/kg/hr loading dose, followed by 10–25 mg/kg/hr) work well in animals with severe hypomagnesemia. Alternatively, an initial dose (40–60 mg/kg IV) over 10 minutes followed by 25 to 50 mg/kg every 4 to 6 hours or a CRI of 50 to 150 mg/kg/day is safe. To put it in perspective, $MgSO_4$ doses used in children with hypocalcemia and hypomagnesemia range from 25 to 50 mg/kg IV or IM over 10 to 20 minutes every 4 to 6 hours, slowly, or via CRI at 30 to 60 mg/kg/day. Monitoring Mg^{2+} concentrations is strongly recommended to facilitate adjustment of dosage if necessary.

$MgSO_4$ is used to treat ventricular arrhythmias, in particular quinidine intoxication (torsades de pointes) and should be considered in horses with refractory ileus and SDF. Doses of $MgSO_4$ for ventricular arrhythmias vary from 2 to 6 mg/kg/min IV, up to a total of 50 mg/kg.

Oral supplementation with MgO, $MgCO_3$, or $MgSO_4$ should be considered in animals with chronic hypomagnesemia, malabsorption, renal disease, and exercise-associated hypomagnesemia. Recommended doses are 30 to 50 mg/kg/day for MgO, 60 to 80 mg/kg/day for $MgCO_3$, or 80 to 100 mg/kg/day for $MgSO_4$. These doses are safe for horses, in particular compared with the cathartic doses of $MgSO_4$ (0.5–1.0 g/kg).

Oral administration of Mg failed to improve morphometric measurements and insulin sensitivity in obese horses with evidence of insulin resistance and laminitis.[333]

A combination of enteral psyllium (1 g/kg) and $MgSO_4$ (1 g/kg) for multiple days was more effective than each constituent alone at removing sand from the large colon of horses.[337]

Hypermagnesemia

Hypermagnesemia is rarely documented in horses and in general is iatrogenic from Mg overdose, associated with renal failure, or observed in animals with extensive cellular damage (myonecrosis, cancer, hemolysis, severe sepsis). The presence of hyperkalemia and hyperphosphatemia is another indicator that suggests cellular damage. Hypermagnesemia has been reported in horses treated with Epsom salts and dioctyl sodium sulfosuccinate for large colon impaction.[338] Clinical signs in these horses included sweating, hyperexcitability, muscle tremors, recumbency, flaccid paralysis, tachycardia, tachypnea, widening of the QRS complex, and prolonged PQ interval. Very high Mg^{2+} concentrations can induce depression, bradycardia, and hypotension. Treatment of hypermagnesemia includes 0.9% NaCl, furosemide, and parenteral calcium administration. Sodium sulfate (Na_2SO_4) is considered a safer and more efficacious treatment for large colon impactions than $MgSO_4$.

Thyroid Gland

Ramiro E. Toribio

The thyroid gland has two embryologic origins: the *endoderm of the primitive larynx* that will give origin to the follicular cells that secrete thyroid hormones and the *ultimobranchial body of the fourth pharyngeal pouch* that contains neuroendocrine cells (from the neural crest) that will give rise to the C cells (parafollicular cells) that secrete calcitonin.

In the horse, the thyroid glands are two discrete, firm lobes located in the dorsolateral aspect of the third to sixth tracheal rings.[339,340] The two lobes are connected by a narrow isthmus that contains fibrous tissue. In most healthy horses the thyroid glands are not visible but can be palpated as firm and movable structures. The weight of the thyroid glands relative to body weight is largest for fetuses and foals (mean, 0.28 g/kg; range, 0.12–0.67) and decreases with age, and the ratio for adults is 0.08 g/kg (range, 0.01–0.15).[341] For average size horses, the weight of both thyroid lobes is 30 to 40 g. Total gland weight for newborn foals is around 15 g.[342] The glands are very vascular, receiving blood supply from two major arteries that arise from the external carotid and subclavian arteries. Thyroid gland blood supply is relatively greater (4–6 mL/min/g) than other highly vascular organs. One study found equine thyroid gland blood flow (1655 ± 339 mL/min/100 g) to be threefold that of the kidneys.[343]

Gland size does not parallel function, and functional tests must be used to establish an accurate diagnosis of thyroid dysfunction.

Thyroid Hormone Function

Understanding thyroid hormone (TH) biology is important in the diagnosis, treatment, and prognosis of thyroidal and nonthyroidal disorders. Thyroid hormones (THs; triiodothyroidine—T_3; thyroxine—T_4) are essential for cell growth, differentiation, and metabolism in nearly all tissues. The circulating THs include total T_4 (tT_4), free T_4 (fT_4), total T_3 (tT_3), free T_3 (fT_3), and reverse T_3 (rT_3).

The synthesis and secretion of THs are regulated by a negative feedback system that includes the hypothalamus, the pituitary gland, and the thyroid gland (hypothalamus-pituitary-thyroid axis; HPTA). Hypothalamic parvocellular neurons projecting to the median eminence release thyrotropin-releasing hormone (TRH; thyroliberin) into capillaries of the hypophyseal-portal system. Subsequently, TRH stimulates thyrotropes in the anterior pituitary (pars distalis) to secrete thyroid-stimulating hormone (TSH, thyrotropin).[344] The hypothalamus also inhibits TSH secretion through dopamine and somatostatin.[345] TSH is a glycoprotein with two subunits (α and β)—the α subunit is shared with other pituitary and placental glycoprotein hormones (LH, FSH, eCG), and the β subunit dictates its receptor affinity and specificity. Post-translational modifications (glycosylation) are essential for the function and metabolism of TSH. These modifications have limited the use of human and canine immunoassays to measure equine TSH concentrations. TSH stimulates thyroid follicular cells (thyrocytes) to release T_4 and T_3 into systemic circulation. Subsequently, T_3 decreases TSH synthesis and TSH response to TRH stimulation (pituitary gland) and TRH mRNA expression and secretion (hypothalamus).[346-348] In various species, including the horse, TRH is also a releasing factor for prolactin and adrenocorticotropin (ACTH) release.[349-353]

In the CNS and pituitary gland, T_4 is converted to T_3 by type II deiodinase. For T_4 to gain access to hypothalamic neurons it must be transported through the choroid plexus to the lateral ventricles bound to transthyretin (T_4-binding protein).

Because of their type of placentation, in humans and rodents a great proportion of fetal THs come from placental

transfer.[354,355] Thus maternal THs are important for fetal development and maturation at the end of gestation in these species. However, this does not appear to be case for animals with epitheliochorial placentation, which depend on transplacental iodine transfer and their own thyroid glands for T_4 and T_3 synthesis.[355] In the developing fetus, T_4 and T_3 concentrations are low, whereas concentrations of the inactive metabolite, reverse T_3 (rT3), are high, reflecting maturation of the HPTA and coordination with the deiodinase system.[354] Although the physiologic significance of low T_3 concentrations throughout gestation is unknown, it has been suggested to be an ontogenic adaption to avoid excessive thermogenesis and facilitate the anabolic state of the rapidly growing fetus.[354]

Thyroid Hormone Metabolism

A major function of the thyroid gland is to actively trap and conserve iodine against a large concentration gradient (30–40×).[339,356,357] Iodine is absorbed in its soluble form, iodide (I^-), via the intestinal mucosa or any moist body surface or broken skin.[339] Iodide is actively transported and concentrated into the thyroid gland by an Na^+/I^- symporter (NIS), which is coupled to an Na^+ gradient generated by the Na^+/K^+-ATPase to promote I^- accumulation.[358,359] The transport of I^- across the thyrocyte apical membrane to the cell-to-colloid interface is mediated by pendrin.[359] Once in the lumen, the trapped I^- is oxidized to iodine by thyroid peroxidase and incorporated into tyrosine residues of thyroglobulin to form the inactive precursors, monoiodotyrosine (MIT) and diiodotyrosine (DIT). Coupling of these precursors results in the synthesis of thyroxine (T_4) and triiodothyronine (T_3). The iodinated thyroglobulin containing MIT, DIT, T_3, and T_4 is stored as an extracellular polypeptide in the follicular colloid.[360] When needed, T_4 and T_3 are cleaved from thyroglobulin, picked up by the follicular cells via endocytosis, and transferred to the systemic circulation.[339,357] Most of the TH released into circulation is T_4, and serum tT_4 concentrations are 20 times higher than tT_3. Hormone synthesis and release are mainly controlled by TSH and iodine availability. The feedback regulation of TSH is closely linked to circulating concentrations of free (unbound) THs (fT_4 and fT_3).[339,357]

Conversion of T_4 (prohormone) to T_3 (active hormone) occurs through removal of an iodine from the outer ring. Iodine removal from the inner ring results in T_4 conversion to rT_3. All circulating T_4 is directly derived from the thyroid gland whereas only 10% to 20% of T_3 in circulation is directly secreted from the thyroid gland. The major pathway for the production of T_3 is the 5′-monodeiodination of T_4 by type I deiodinase (a selenoprotein) in peripheral tissues. This is referred to as "T_3 neogenesis." In the fetus, T_3 neogenesis is low due to low type I deiodinase activity, and most deiodinase activity converts T_4 to rT_3. A switch in enzymatic activity near birth, partly due to the influence of glucocorticoids, leads to high T_3 concentrations in newborns, including foals.[355,357,361-365] THs circulate bound to plasma proteins (thyroid-binding proteins; TBP). Thyroxine-binding globulin (TBG) is the major protein (70% of T_4 and T_3 are bound to TBG); transthyretin (thyroid-binding prealbumin; TBPA) and albumin bind THs to a lesser degree. In horses, the percentages of circulating T_4 bound to TBG, TBPA, and albumin were found to be 61%, 22%, and 17%, respectively.[366] T_3 is bound to TBG and albumin but not to TBPA. Transthyretin is important to transport T_4 into the CNS. Because THs are reversibly bound to transport proteins they act as TH reservoirs. T_4 has greater protein-binding affinity and is considered the prohormone. Because a large fraction of THs are bound to plasma proteins, changes in protein concentrations may change total TH concentrations. Only free, unbound THs cross the capillary endothelium to exert their biologic functions.[367] T_3 is much more potent than T_4, and it has a shorter half-life. The half-life of T_4 in horses is approximately 50 hours.[368]

The enzymes responsible for the production of T_3 and rT_3 are also responsible for their inactivation. There are three classes of 5′-deiodinases (iodothyronine deiodinases). *Type I deiodinase* is predominantly found in peripheral tissues such as thyroid gland, kidney, and liver; is responsible for the conversion of T_4 to T_3 and rT_3; and is inhibited by propylthiouracil (PTU). Type I deiodinase activity is increased by TSH and T_3 and in hyperthyroidism but reduced in hypothyroidism. *Type II deiodinase* is found in thyroid gland, brown adipose tissue (BAT), brain, reproductive tract, and pituitary gland. It is the main T_4 to T_3 converting enzyme,[360] controls intracellular availability of T_3, and is not affected by PTU.[357] Because type II deiodinase can only deiodinate the outer T_4 ring, it cannot produce rT_3. Type II deiodinase activity is increased in hypothyroidism, likely to sustain intracellular T_3 concentrations despite low peripheral T_4 concentrations, especially in the CNS. *Type III deiodinase* is mainly found in the placenta, developing brain, and skin, only deiodinates the inner ring of T_4 and T_3, and its primary function is to regulate T_3 availability during development by inactivating T_4 and T_3 (converts T_4 to rT_3; T_3 to T_2 [diiodothyronine]). It also prevents excessive access of maternal THs to the fetus. The generation of inactive rT_3 by type I and III deiodinases is essential in TH homeostasis. Metabolites are excreted via the urine, and some are conjugated and enter the enterohepatic circulation. Most iodine is returned to the thyroid gland.

The thyroid gland is also the site of production of calcitonin, secreted by the parafollicular cells (C cells). Calcitonin is involved in calcium homeostasis.[214,339,357] (See calcium section.)

Molecular Actions of Thyroid Hormones

The function of the thyroid gland is to provide THs to meet metabolic needs, based on physiologic status and pathologic conditions. The actions of the THs are mediated by TH receptors, which belong to the superfamily of nuclear receptors. There are two types of TH receptors (TR-α and TR-β). Upon binding to T_3, TH receptors form homodimers or heterodimers with the retinoid X receptor (RXR) that are transcriptionally active, binding specific DNA sequences (response elements), to increase or suppress gene expression, depending on the target organ.

Growth, differentiation, thermogenesis, and the energy metabolism are highly dependent on THs. T_3 stimulates thermogenesis, oxidative phosphorylation, oxygen consumption, protein synthesis, metabolic rate, carbohydrate absorption, insulin sensitivity, glucose metabolism, lipid metabolism, lipoprotein lipase, lipolysis, and the conversion of cholesterol to bile salts. T_3 also promotes growth, maturation, erythropoiesis, heart rate, cardiac output, and blood flow, and it is essential for cerebral and neuronal development in young animals.[339,356] THs are also crucial for the function of other endocrine organs (adrenal gland, pancreas).

Factors that Affect Thyroid Gland Function and Testing

Many endogenous and exogenous factors can influence thyroid function and test results. Being aware of these factors is relevant to the interpretation of TH measurements as well as in the diagnosis, prognosis, and therapeutic management.

Age

There are age-related differences in TH concentrations in horses and donkeys (Tables 16.12 and 16.13).[361-365,373-377] Late in gestation there is a major drive to stimulate the HPTA.[367] Serum concentrations of T_3 and T_4 in foals are very high at birth and decrease with age,[361-365,373-380] with most of the decline occurring in the first 3 to 4 months of life.[363,380,381] Concentrations of tT_4, fT_4, tT_3, and fT_3 in the umbilical cord blood of newborn foals were 14, 5, 7, and 3 times the adult concentrations, respectively.[367] Plasma rT_3 declined rapidly as tT_3 concentrations rose for the first 24 to 48 hours after birth.[367] Another study found that plasma tT_3 concentrations decreased from 7.9 ng/mL at birth, to 0.9 ng/mL at 6 months, to 0.7 ng/mL at 9 months of age.[365] Plasma tT_3 concentration in the mares was 0.5 ng/mL. In the same study, tT_4 concentrations decreased from 233 ng/mL at birth to 49 ng/mL at 14 days and 35 ng/mL at 6 months of age.[365] Thus TH concentrations in newborn foals are approximately tenfold higher than in adult horses, and TH concentrations in the range of adults may indicate a hypothyroid state.

Gender and Breed

There is not a clear association between gender and TH concentrations. Various studies have found higher TH concentrations in males,[361,382,383] lower concentrations in stallions and

geldings,[374,384] similar or lower in geldings than stallions,[383] and lower concentrations in mares than in stallions,[382] whereas others have found no differences.[377,381,385-387] There is no evidence that TH concentrations differ among breeds,[361,387] although one study found higher T_3 and T_4 concentrations in donkeys compared with horses.[377] This could be attributed to genetic differences as well as metabolic size.

Physiologic Status

Mares tested at all stages of the estrous cycle had no differences in TH concentrations.[386] T_4 concentrations, however, were lower following ovulation, which is the opposite pattern seen in other species. Higher TH concentrations have been reported in pregnant mares,[388] which is similar to other mammals.[357] This may be due in part to the increased TBG concentrations during gestation.[357] T_4 concentrations were statistically higher between days 49 and 55 of gestation compared with mares in advanced pregnancy.[389] A couple of studies found no effect of pregnancy on T_4 concentrations,[383,390] although tT_3 and fT_3 concentrations were higher in pregnant mares.[383] Lower T_3 concentrations were found at the end of pregnancy[390]; however, other studies showed no differences in THs between pregnant and nonpregnant mares and jennets.[368,384,391,392] Serum TH concentrations were not different between mares that did and did not become pregnant,[393] suggesting that thyroid dysfunction is an uncommon cause of infertility. This finding also questions the practice of supplementing mares with thyroid hormones to increase pregnancy rates.[393] Serum T_4 and T_3 concentrations are higher in lactating compared with nonlactating mares.[391] TH concentrations increased during lactation in donkeys.[394]

Hormones

Exogenous and endogenous glucocorticoids suppress TSH secretion, decrease the response of TSH to TRH, inhibit deiodination (except in the perinatal period where the conversion of T_4 to T_3 is enhanced), and decrease TH release.[357,395] Glucocorticoids decrease serum T_4 and T_3 concentrations, with the effect being more profound on T_3.[396] In one study, dexamethasone administration to healthy horses for 5 days did not change tT_3 and tT_4 concentrations but increased serum rT_3 and fT_3 concentrations and blunted the fT_3 response to TSH stimulation.[397] In another study, topical dexamethasone suppressed T_4 and T_3 concentrations.[398] Catecholamines enhance the rate of deiodination of T_4 to T_3 and have potentiating effects.[399] Estrogen enhances TBG production whereas androgens tend to suppress it.[357] Oral administration of levothyroxine to healthy horses resulted in weight loss; increased tT_4, fT_4, and rT_3 concentrations; and reduced the TSH and TH response to TRH stimulation.[400]

Season and Daily Rhythm

Thyroid hormones are essential for thermogenesis and regulating resting energy expenditure, in particular during cold exposure.[401] This is a process mediated by uncoupling proteins (UCP-1, UCP-2, and UCP-3) in BAT and skeletal muscle, with involvement of the sympathetic nervous system to increase ATP production and use.[401] Cold temperatures stimulate and high temperatures inhibit the HPTA.[368,402,403] The effect of season was minimal in pregnant compared with nonpregnant mares.[391] A daily rhythm in TH concentrations has been identified in horses.[380,390,404,405] In geldings, T_4 peaked around 4:00 PM with the lowest T_4 values around 4:00 AM. T_3 peaked between 8:00 AM and 4:00 PM, with the lowest T_3 values around midnight.[404] Higher T_4 concentrations between 5:00 and 8:00 PM with lowest concentrations at 8:00 AM were reported in another study.[405] No diurnal rhythmicity in TH concentrations was found in foals.[380] Diurnal variations in glucocorticoid concentrations appear to control the diurnal variations in TH by suppressing the pituitary response to TRH.[406]

Activity

Variable results on the effect of physical activity on TH concentrations have been reported.[362,407-409] One study in young Standardbreds found that serum T_4 concentrations decreased early in the training period.[410] In the same study, serum T_4 concentrations were lower in horses with maladaptation to training. Increases in T_4 within 30 minutes after exercise with minimal differences in T_3 have been reported.[385,388] Five minutes after a maximal speed race (1200 m), serum T_3 concentrations increased in Thoroughbred racehorses although T_4 concentrations did not change.[411] Significant increases in T_3 and T_4 concentrations were found 1 hour after swimming.[412] Serum T_4, T_3, and rT_3 concentrations decreased progressively in the course of a multiday ride.[413] In a study with ponies, metabolic rate, resting heart rate, and locomotor activity were positively correlated with total T_3 but negatively correlated with total T_4 concentrations.[409]

Feeding

Feeding high-energy and high-protein diets to horses stimulates TH secretion.[414,415] Soluble carbohydrates rather than protein appear to be responsible for this increase.[416] The conversion of T_4 to T_3 following a carbohydrate meal was associated with insulin release.[417] The TH response to carbohydrates is age-dependent; by the time horses are 12 to 14 months of age, feeding high-carbohydrate and protein diets has minimal effect on TH concentrations.[417] Ponies fed once daily had greater T_3 concentrations than animals fed six times a day.[418] Another study in ponies found no effect of feed restriction on T_4 concentrations.[419]

Starvation in different species, including horses, reduces T_3 and fT_3 concentrations.[420-422] Energy deprivation inhibits the deiodination of T_4 to T_3 by the type I deiodinase to decrease T_3 but increase rT_3 concentrations. This could be a biologic adjustment to reduce metabolic rate and conserve energy. In these animals, TSH concentrations are low or within the normal range despite low TH concentrations. When the effect of food deprivation on baseline TH concentrations was evaluated in euthyroid horses, it was found that serum T_3, fT_3, and fT_4 concentrations decreased whereas rT_3 concentrations increased after 1 day of food withdrawal.[422] Serum tT_3 concentrations were lowest after 2 days of deprivation, and tT_4, fT_3, and fT_4 reached their lowest concentrations on day 4 of deprivation. Three days after the horses were placed on their normal ration, serum tT_4 and fT_4 concentrations increased significantly, and rT_3 concentrations decreased.[422] Prolonged food restriction to Shetland ponies also decreased serum tT_3 and fT_3 concentrations.[423] These studies provided valuable information in the interpretation of TH concentrations in anorectic and sick horses. For example, if a decrease (greater than 50%) in serum T_3 and T_4 concentrations can occur in 1 to 2 days of food deprivation, then the validity of measuring TH in diseased horses is questionable.

The mechanisms that regulate thyroid gland function during starvation remain unclear. Leptin, the adipocyte-derived

hormone that controls hunger, appears to be key neuroendocrine signal that regulates the HPTA during fasting and disease.[424,425] Leptin concentrations decrease during starvation in order to increase appetite and conserve energy. A decrease in leptin concentrations reduces activity of hypothalamic TRH neurons, resulting in less TRH and subsequently less TSH and TH secretion. This seems to be part of a thrifty strategy by which a reduction in leptin promotes hunger and reduces HPTA activity. This process is likely to apply to horses, by which feed restriction decreases while caloric intake increases leptin concentrations,[426-428] with THs following similar leptin patterns.[420-422]

Even though information on leptin has been published in horses and foals,[426,429,430] its direct role on thyroid gland function remains unknown.

Diseases (Nonthyroidal Illness Syndrome, Euthyroid Syndrome)

Illnesses, systemic inflammation, stress, and starvation suppress the HPTA. Because there is no clinical evidence that low TH concentrations during disease are associated with hypothyroidism, this condition has been called the *low T_3 syndrome,* the *euthyroid sick syndrome,* and more recently the *nonthyroidal illness syndrome (NTIS)* because it does not make assumptions on the metabolic status of the patient.[421] In NTIS, T_3 concentrations decrease, whereas T_4 concentrations can be low, normal, or elevated. In critically ill human patients, a significant decrease in T_4 and T_3 or an increase in rT_3 concentrations is associated with increased mortality rate.[421]

Recent studies provide evidence that NTIS is highly prevalent in horses and foals.[375,378,379,431] Low tT_3, fT_3, tT_4, and fT_4 concentrations have been measured in premature, septic, and hospitalized foals.[375,378,379] Systemic diseases reduce TH concentrations in adult horses, and this effect is more profound than the effect of fasting, glucocorticoids, or NSAIDs.[431] In at least one study, tT_3 concentrations decreased before other THs.[431] Serum TH concentrations were lower in hospitalized horses that died or were euthanized.[431] TH concentrations also decreased in sick horses in proportion to disease severity.[431] Serum fT_3, fT_4, and TSH concentrations were lower in hospitalized and premature foals that died compared with survivors.[378,379] TH and TSH concentrations were negatively correlated with the sepsis score in hospitalized newborn foals.[378,379] In septic foals, rT_3 concentrations were positively associated with the sepsis score.[378]

Based on the lack of rise in TSH concentrations in sick horses with low THs, it seems that NTIS alters all levels of the HPTA.[431] It also appears that hypothalamic and pituitary dysfunction is central to the pathogenesis of NTIS,[421] as administration of TRH to patients with NTIS increases TSH, T_4, and T_3 release.[432] This further supports the central role of leptin on the HPTA. Although NTIS can be seen as a hypothyroid state, there is no evidence that target tissues are chemically hypothyroid.[421] Any acute or chronic condition is likely to reduce HPTA activity, which does not equate to hypothyroidism.

Cytokines, glucocorticoids, and leptin are key candidates in the pathogenesis of NTIS. Cytokines such as IL1-β, IL-6, and TNF-α suppress TSH, T_4, and T_3 synthesis and secretion. IL1-β impairs TH synthesis, whereas IL-6 and TNF-α decrease T_4 and T_3 concentrations and increase rT_3 concentrations. Glucocorticoids are negative regulators of thyroid function; increased cortisol concentrations are common in horses and foals under different conditions, including stress, gastrointestinal disease, pain, sepsis, obesity, insulin resistance, and pituitary pars intermedia dysfunction (PPID; Cushing disease),[378,379,431,433-435] and low TH concentrations can be measured in the same animals.[378,379,431] As previously mentioned, the role of leptin in the pathogenesis of NTIS relates to caloric intake and energy conservation.

Low TH concentrations are commonly measured in horses with insulin resistance (equine metabolic syndrome) and laminitis; however, the clinical value of these measurements is limited. Leptin concentrations tend to be high, not low, in horses with metabolic syndrome and prone to laminitis[436,437] and, similar to people with central obesity, also have low TH concentrations, supporting the concept of impaired leptin signaling at the hypothalamic level.

There is no evidence that TH replacement therapy in humans or animals with NTIS is either beneficial or harmful.[421] Some believe that replacement therapy may be harmful because exogenous TH may inhibit the HPTA. The only clear indication for exogenous supplementation of THs in horses is to induce weight loss and enhance insulin sensitivity in obese animals, particularly those with metabolic syndrome.[438]

Exogenous Compounds

Goitrogenic substances such as thiocyanate and perchlorate compete with iodide uptake. Iodide oxidation and coupling of iodotyrosines are inhibited by drugs such as sulfonamides, phenylbutazone, phenothiazines, thiouracils, thiopental, and methimazole. One study found no suppressive effect of trimethoprim-sulfadiazine on equine thyroid function.[439] Soybean meal, linseed meal, and plants of the *Brassica* family (i.e., rapeseed) contain goitrogenic substances.[339,356] Phenylbutazone administration decreases TH concentrations in horses,[405,440] and this effect can last up to 10 days after discontinuation of phenylbutazone.[440] The TSH stimulation test may be normal or exacerbated in horses receiving phenylbutazone.[405] High levels of nitrates in the water may induce thyroid gland hypertrophy in people,[441] as nitrates reduce the iodine transport into the thyroid gland.

Propylthiouracil (PTU), in addition to affecting iodine metabolism, inhibits the peripheral conversion of T_4 to T_3. Substances that compete for TH binding sites on transporting proteins could potentially lead to a hypermetabolic state by increasing their free fractions (fT_4, fT_3).[395] Human athletes receiving anabolic steroids had decreased TSH, T_4, T_3, and TBG concentrations[441a]; however, anabolic steroid administration to horses did not affect thyroid function tests.[442]

Exogenous compounds containing iodine or iodides are of particular interest. Both iodine excess and deficiency can induce thyroid dysfunction and interfere with thyroid tests.[443] Horses are exposed to iodine or iodide compounds in the form of feedstuffs, expectorants, leg paints, shampoos, injectable counterirritants, radiographic contrast media, and antiprotozoal drugs (iodochlorhydroxyquin). Animals can respond to excessive amounts of iodine by either suppressing or accelerating hormone production.

Iodine excess reduces thyroidal iodine uptake and organification (incorporation into inactive MIT and DIT) and decreases TH concentrations and the response to the TSH and TRH stimulation tests. The end result could be hypothyroidism, which is known as the "Wolff-Chaikoff effect." Iodine-containing drugs such as amiodarone have been shown to cause this effect in people and dogs[444] but not in horses. The

second way animals and people can respond to excessive iodine exposure is by elevating TH production. This is referred to as "Jod-Basedow phenomenon" that in general is seen in individuals with iodine deficiency.[357]

Newborn foals of mares grazing *Neotyphodium coenophialum*–infected fescue had lower T_3 concentrations than controls, with no differences in T_4 and rT_3 concentrations.[445] Endophyte alkaloids are D_2 dopamine receptor agonists, and dopamine is an inhibitor of TSH secretion. It remains unclear whether the low TH concentrations in these foals are a direct consequence of the alkaloids on the fetal HPTA or an indirect effect through placental and fetal development. Endophyte alkaloids do not appear to alter thyroid function in adult horses.[446]

Diagnostic Tests

Unlike human practice in which functional and direct measurements of THs are often used, in equine medicine we are far from assessing thyroid gland function in an organized manner. Our routine approach is to determine TH concentrations, compared with reference values, make a diagnosis and specific recommendations, in many instances, ignoring the underlying cause of abnormal TH concentrations. Normal TH concentrations have a wide range of values and vary among laboratories and measuring methods (see Tables 16.12 and 16.13). For consistency, the practitioner should use the same laboratory. Ratios of circulating hormones may be indicative of dysfunction.

Equilibrium dialysis has been considered the most accurate method to measure the free fractions of THs; however, immunoassays are more often used due to practicality and increasing sensitivity. There are immunoassays available to measure tT_4, fT_4, tT_3, fT_3, and rT_3 concentrations. Radioimmunoassays (RIAs) have been validated to measure equine THs.[387,447] Quantification of T_4 and T_3 with RIA is not affected by hemolysis.[448] Enzyme-linked immunosorbent assays (ELISAs) and immunoluminescence methods are becoming popular due to their simplicity, safety (no need to work with radioactive material), and detection limits. The unbound or free fractions of THs must be measured to determine available hormone to target tissues.[449]

Serum is the preferred sample to measure T_4 and T_3 concentrations, although heparin or EDTA plasma can be used. T_4 is stable in serum at 4°C for several weeks. Avoid hemolyzed and lipemic samples, and samples from horses receiving "thyroid supplements." The T_4 secretion rate is a functional test that calculates T_4 secretion after ^{131}I injection. This method is not practical.[362]

Free THs circulate in equilibrium with protein-bound THs, and changes in TBP (TBG, TBPA, albumin) can affect TH concentrations. Immunoassays to determine human TBG and transthyretin concentrations are available but not validated for horses.

In healthy horses, the tT_4 to tT_3 ratio was 23:1, and the fT_4 to fT_3 ratio was 1.83:1.[383] A more recent study found a tT_4 to tT_3 ratio of 21:1 and an fT_4 to fT_3 ratio of 13:1.[431] In healthy newborn foals, the tT_4 to tT_3 and fT_4 to fT_3 ratios were 32:1 and 10:1, respectively.[379] These ratios increased in sick horses and foals.[379,431] Serum rT_3 concentrations are often increased in hyperthyroidism and NTIS.[19]

Commercial assays to determine human and canine TSH concentrations are available, but they have failed to measure equine TSH. Increased TSH concentrations are expected in hypothyroidism and the opposite in hyperthyroidism.[352,450] Equine TSH concentrations have been determined with customized assays.[430,439,450-452] Breuhaus validated an equine-specific double-antibody TSH RIA in an equine model of hypothyroidism.[451] In that study, hypothyroidism was induced in healthy horses by administering PTU for 6 weeks. Serum tT_3 and fT_3 fell rapidly, whereas fT_4 and tT_4 did not decrease until weeks 4 and 5, respectively. TSH concentrations remained steady until week 5, increasing thereafter. The TSH response to TRH stimulation (1 and 5 mg) was exaggerated. Similar studies of PTU-induced primary hypothyroidism found a decrease in serum of T_3, T_4, and rT_3 and an increase in TSH concentrations.[352,450]

Hormone response tests are useful to differentiate primary from secondary thyroid dysfunction, and they remove the potential influence of endogenous and exogenous factors on the results.

Thyroid-Stimulating Hormone Stimulation Test

The TSH stimulation test consists of injecting 2.5 to 5.0 IU of TSH intravenously and comparing preinjection and postinjection TH concentrations.[453,454] In normal horses, T_4 peaks 3 to 4 hours after injection at a concentration 2.4 times the preinjection values. T_3 doubles within 30 minutes and peaks at 2 hours at a concentration that is five times baseline values.[455] A normal response is characterized by a T_3 rise before the T_4 increase. When 5 IU of TSH were given intramuscularly to horses, T_4 peaked at 2 times baseline value 3 to 12 hours after injection, and T_3 peaked in 1 to 3 hours.[405] No differences in T_4 concentrations were found between 2.5 and 5 IU of TSH.[453] The suggested protocol for the IV TSH response test is to measure TH concentrations at baseline and 3 to 4 hours after injection.[455] For the intramuscular protocol, measure hormone concentrations at baseline and 3 and 6 hours after injection.[405] The protocol for newborn foals is to measure T_3 concentrations at baseline and 1 and 3 hours after the IV injection of 5 IU of TSH. A normal response is a 50% increase by 3 hours. T_4 values after TSH stimulation are variable in foals.[456] An insufficient hormonal response is consistent with primary hypothyroidism. Phenylbutazone decreases TH concentrations in horses, but it does not affect the response of the TSH stimulation test.[405] Dexamethasone blunts the TH response to the TSH stimulation test.[397] This information should be taken into account in the interpretation of the TSH stimulation test.[405,455] Treatment with dopamine agonists does not appear to affect serum T_3, T_4, rT_3, or TSH concentrations in horses.[450]

Cost and availability of medical-grade TSH limit the clinical use of this test. Instead, the TRH stimulation test is much easier and cheaper to perform.

Thyrotropin-Releasing Hormone Stimulation Test

The TRH stimulation has become a widely used method to assess thyroid gland function and PPID in horses.[453,457-462] TRH is administered intravenously, 1 mg to horses and 0.5 mg to ponies and foals, with hormone measurements at baseline, 2 and 4 hours later. In a normal response both hormones should increase twofold to threefold. An inadequate TH response occurs with primary (thyroid) or secondary (pituitary) hypothyroidism. In normal animals, T_4 peaks at 4 hours[453,459] and T_3 at 2 hours after TRH administration.[459] Side effects of TRH administration include salivation, urination, defecation,

miosis, tachycardia, tachypnea, yawning, lip movements, and trembling.[458] A low response to TRH administration suggests dysfunction at either the pituitary or the thyroid gland level. Additional tests (TSH concentrations, TSH stimulation test) may be necessary to differentiate thyroid from pituitary disease. Low TH and high TSH concentrations and a low response to TSH stimulation are consistent with thyroid gland dysfunction. Low TH concentrations with low or normal TSH concentrations indicate hypothalamic or pituitary gland dysfunction. Low TH and TSH concentrations with a normal TSH and TH response to TRH indicate a hypothalamic disorder (tertiary hypothyroidism). Levothyroxine administration blunts the response to the TRH stimulation test.[400]

Thyroid Suppression Test (T_3 Suppression Test)

Autonomous TH secretion (TSH independent) can be demonstrated by the thyroid suppression test. Exogenous administration of TH should suppress TSH and TH secretion. After T_3 administration, T_4 concentrations are expected to drop in euthyroid horses, whereas minimal to no changes in T_4 concentrations are anticipated in hyperthyroid animals (primary hyperthyroidism). This test has been used to diagnose hyperthyroidism in horses with thyroid adenomas and adenocarcinomas.[463,464] For the test, 2.5 mg of T_3 (3,3′,5-triiodo-L-thyronine) diluted in 5 mL of sterile saline solution is administered intramuscularly at 8:00 AM and 6:00 PM on days 1, 2, and 3 and at 8:00 AM on day 4. Serum T_4 and T_3 concentrations are measured 5 minutes before each T_3 dose. Additional blood samples are collected at 6:00 PM on days 4 to 10.[463,464] Failure of T_4 to suppress after T_3 administration indicates autonomous secretion of THs, which is consistent with hyperparathyroidism. In euthyroid horses, T_4 concentrations decrease by day 4 and remain low until day 10, and it takes 2 to 3 weeks for T_4 concentrations to return to baseline values.[463]

Imaging

Nuclear scintigraphy (technetium 99m [^{99m}Tc]) is useful in assessing equine thyroid gland function.[465] Abnormal uptake patterns have been seen with thyroid carcinoma in horses.[466-468] Ultrasonographic evaluation of the glands can differentiate solid structures from cystic ones.[357] Ultrasonography is the most commonly used imaging modality to assess equine thyroid gland morphology.[463,469]

Biopsy

Aspirate or biopsy sampling can help differentiate cysts, neoplasia, hyperplastic goiter, colloidal goiter, and inflammation.

Hypothyroidism

There is no evidence that hypothyroidism is common in horses or foals, although it is frequently diagnosed based on low TH concentrations. Many conditions, including obesity, insulin resistance, metabolic syndrome, laminitis, anhidrosis, rhabdomyolysis, agalactia, infertility, alopecia, and hypothermia have been attributed to low TH concentrations in horses and donkeys.[350,470-475] In foals, hypothyroidism has been linked to respiratory insufficiency, gastric ulcers, and skeletal abnormalities.[476-481]

In general terms, hypothyroidism is defined as TH deficiency, inadequate thyroid follicular activity, or disruption of the HPTA. Hypothyroidism can be classified as primary (thyroid gland), secondary (pituitary gland), and tertiary (hypothalamus). Hypothyroidism occurs from diseases that affect thyroid gland function, exogenous compounds that interfere with TH synthesis, and less frequently by disorders of the hypothalamus or pituitary gland. The liver, muscle, skeleton, kidney, heart, pancreas, adrenal, gastrointestinal tract, respiratory system, and CNS are the main target organs for THs during development.[357] Hypothyroidism manifests in many ways, and the diagnosis can be challenging because a multitude of nonthyroidal factors can alter TH concentrations, leading to result misinterpretation. Primary hypothyroidism can be caused by iodine deficiency (endemic goiter) or excess (Wolff-Chaikoff effect), thyroiditis, neoplasia, biochemical defects, thyroid agenesis, or ingestion of goitrogenic compounds that block TH synthesis. Of these, iodine deficiency, iodine excess, and neoplasia have been reported as causes of equine hypothyroidism. Goiter with no evidence of hypothyroidism has been described in foals born of mares fed excess iodine during gestation.[482] Histologic lesions consistent with Hashimoto thyroiditis were recently described in horses.[483]

Horses with primary hypothyroidism have decreased T_4 and T_3 concentrations and increased TSH concentrations.[451] Central hypothyroidism occurs from pituitary or hypothalamic dysfunction. There are reports of low TH concentrations in horses with pituitary adenoma.[457,484,485] TH resistance or insensitivity (Refetoff syndrome) denotes a defect in TH signaling,[486] which remains to be documented in domestic animals.

Hypothyroidism in Foals

The consequences of inadequate circulating TH can be devastating for the developing fetus and newborn foal. Recovery is unlikely once critical developmental stages are passed. Tests to evaluate thyroid gland function may be within normal limits at the time of examination, making it difficult to confirm a previous transient or in utero TH deficiency.[367] Iodine deficiency may result in hyperplastic goiter in foals (Fig. 16.14).

Signs

Clinical signs in hypothyroid foals relate to the essential functions of THs in the development and maturation of the nervous, respiratory, and musculoskeletal systems during the prenatal and postnatal periods. Hypothyroid foals are often affected at birth. Signs include stillbirths, prematurity, weakness, and long haircoat[342,487]; weak suckle reflex[488]; respiratory insufficiency and distress[479,,489]; incoordination[363]; lethargy, depression, and rough coat[490]; cold intolerance and hypothermia[367]; physeal dysgenesis[481]; defective ossification with carpal and tarsal bone collapse[480,481]; hypoplastic carpal bones, common digital extensor tendon rupture, forelimb contracture, and prognathism[478,491]; and delayed incisor eruption, growth retardation, and death.[492] Foals can be born apparently normal but develop skeletal lesions weeks later.[490]

Cause

The major cause of hypothyroidism in foals is nutritional. Congenital thyroid enlargement (congenital goiter) with decreased thyroid function is associated with both inadequate and excessive iodine intake by the mare. There are several reports of goiter and hypothyroidism in foals associated with ingestion of excessive amounts of iodine, in particular with kelp-supplemented rations.[342,425,443,487,493-495] The dams of these foals may or may not be affected.[425,443] Feeding 40 mg or more of iodine daily can produce this syndrome.[488]

FIG. **16.14** Newborn foal presented with respiratory distress and thyroid gland enlargement (congenital goiter). Thyroid hormone concentrations were normal, but biopsy of the thyroid gland revealed follicular hyperplasia.

Diagnosis

Because reduced iodine intake is considered the main cause of neonatal hypothyroidism and goiter, pituitary gland function (TSH secretion) may be normal or increased. The lack of TH negative feedback on pituitary thyrotropes leads to excessive TSH secretion, thyroid follicular cell hyperplasia, and thyroid enlargement (goiter).

Foals with signs of hypothyroidism, with or without enlarged thyroid glands, are suspects. The nutrition of the mare as well as other horses in the premises should be examined. Thyroid gland enlargement does not imply hypothyroidism or hyperthyroidism. Other conditions should be ruled out (e.g., branchial cysts) before performing functional tests (TSH and TRH stimulation tests) to confirm the diagnosis of hypothyroidism. When assessing TH concentrations in sick foals it is crucial to compare results to age-matched healthy foals.[378,379] It is also important to remember that high TH concentrations are normal in healthy foals (see Table 16.13). Premature and septic foals may have lower TH concentrations than controls, which does not imply hypothyroidism but NTIS.[378,379] Serum rT_3 concentrations in premature and septic foals may be lower, similar, or higher than in term foals.[378,452,496] A foal with clinical evidence of hypothyroidism could have normal TH concentrations, suggesting that TH deficiency occurred during development. Hypothyroidism in foals carries a poor prognosis, even after TH replacement therapy.

Congenital Hypothyroidism and Dysmaturity Syndrome in Foals

A syndrome in newborn foals characterized by thyroid gland hyperplasia, multiple congenital musculoskeletal deformities, and high mortality rates was first recognized in western Canada and northwest of the United States in the late 1970s.[381,476,489,491,497-500] In some outbreaks 30% to 100% of the newborn foals were affected,[476] with no sex or breed predilection.[498] Gestation is often prolonged, but these foals show signs of dysmaturity including weak to stand, silky and short hair coat, floppy ears, tendon laxity, doming of the head, and incomplete closure of the abdominal wall.[476] Musculoskeletal abnormalities include prognathism, osteochondrosis, angular and flexural limb deformities, rupture of the common digital extensor tendons, and delayed ossification of carpal and tarsal bones (Fig. 16.15).[476,498-500] Even though thyroid enlargement is rare, there is thyroid gland hyperplasia.[499] This syndrome is referred to as congenital hypothyroidism and dysmaturity (CHD). The etiology remains unknown. A case-control study found that foals with CHD had a longer gestation time and that mares grazing irrigated pastures, fed greenfeed, not receiving mineral supplements, or that left their home farm were more likely to produce affected foals.[476] High nitrate intake has been proposed as the possible cause. Nitrates can cross the placenta and impair thyroid gland function.[441] Greenfeed can concentrate high levels of nitrate and nitrite. Alfalfa, ryegrass, timothy, and cereal crops such as wheat, oats, rye, and barley also accumulate nitrate. In addition, these plants have low levels of iodine. Nitrates can also be in high concentrations in the water, particularly in areas with high use of fertilizers, feedlots, and dairies.[476] TH concentrations in foals with CHD are low or within the normal range, and their response to TSH stimulation is poor.[478] Of interest, foals with musculoskeletal disease from TH deficiency have a normal adrenocortical response to ACTH,[501] suggesting that THs more than glucocorticoids play essential roles in skeletal differentiation, at least in late pregnancy.

In the past it was believed that CHD was restricted to western Canada and the northwestern United States; however, sporadic cases in eastern Canada and the midwestern United States have been reported.[500,502,503] Of interest, CHD was recently documented in Finland.[504]

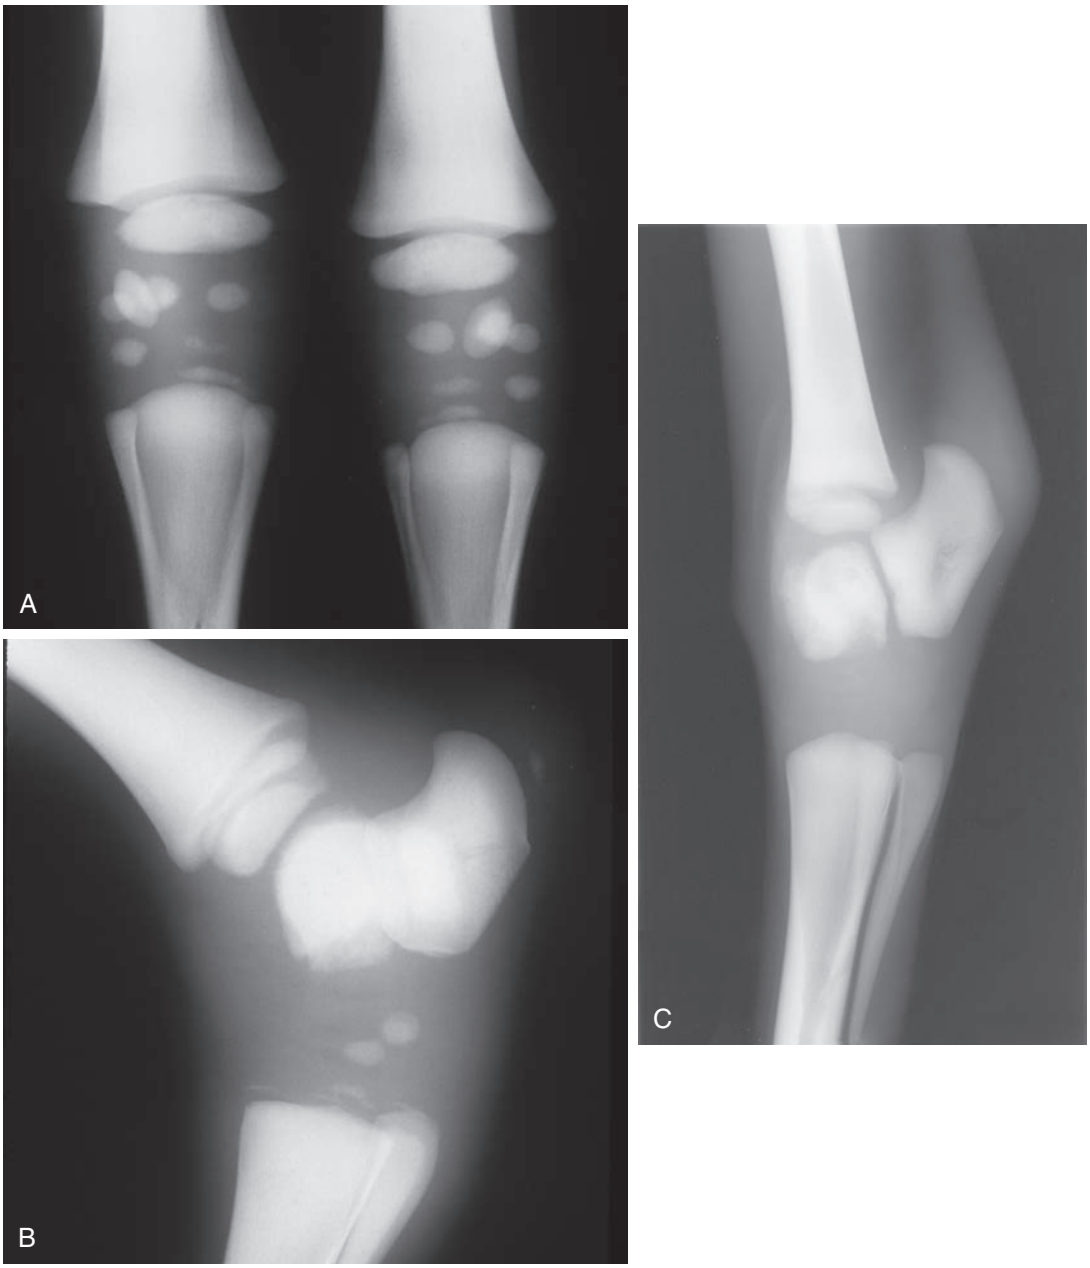

FIG. **16.15** Radiographs from newborn foals with evidence of congenital hypothyroidism and dysmaturity syndrome. Notice the (A) incomplete ossification of the cuboidal bones in the carpus and (B, C) tarsus. (A, B, Courtesy M. T. Hines. C, The Ohio State University.)

It is important for the clinician to be aware that the clinical presentation of CHD could be variable, from the foal that appears weak but otherwise mature compared with those with typical signs of the disease. This could have diagnostic, prognostic, and epidemiologic implications.

The prognosis for foals with CHD is grave, and most foals die or are euthanized within a few days after birth.[500,504] Foals that survive are likely to develop other abnormalities, particularly orthopedic disorders.

Hypothyroidism in Adult Horses

Hypothyroidism in horses is a rare condition, and unlike in foals is not life threatening. Increased cholesterol concentrations, hypothermia, bradycardia, and anemia are potential indicators of hypothyroidism; however, they are not considered reliable markers. Low-grade anemia, decreased body temperature, heart rate, respiratory rate, and cardiac output, rear- limb edema, coarse haircoat, and decreased appetite have been reported in thyroidectomized horses.[485,505,505-507] Lethargy, rearlimb edema, coarse haircoat, and decreased appetite were seen in thyroidectomized mares.[507] Reproductive problems in hypothyroid mares are irregular and absent estrus cycles.[342,505] Thyroidectomized mares could conceive and carry a foal to term.[507] Stallions exhibit decreased libido.[472,505] Thyroidectomized stallions had decreased total sperm count but normal semen characteristics and could sire foals.[492,507] Bradycardia, obesity, and lethargy were seen in mares whose thyroid function was suppressed from excessive

iodine ingestion.[342] Alopecia attributed to iodinism and low circulating TH values were documented in a horse treated with an expectorant containing iodide and topical povidone iodine.[508] One report found low T_4 concentrations in agalactic mares.[350] Poor performance in racehorses in warm seasons could be related to low TH concentrations.[407] Hypothyroidism has been implicated as a cause of anhidrosis. Low or no differences in T_3 and T_4 concentrations have been found in anhidrotic horses.[470,509,510] The TH response to the TRH stimulation test was not different between anhidrotic and matched control horses.[470]

Low TH concentrations may be present in horses with PPID and laminitis, but it is unlikely that hypothyroidism is the cause of the laminitis in these animals.[511] TH concentrations are low, whereas TRH and TSH concentrations are elevated in hypothyroid horses.[512]

Treatment of Hypothyroidism

When hypothyroidism is suspected, it is important to determine whether the animal is receiving appropriate amounts of iodine. Differentiating hypothyroidism from NTIS is critical as animals with NTIS may not require TH supplementation. Furthermore, TH therapy to euthyroid horses may be harmful, inhibiting the HPTA, and suppressing endogenous TH synthesis and secretion. The National Research Council recommends daily intakes of iodine of 1 to 5 mg per horse depending on age, physiologic status, and body weight.[342] The soil in some geographic areas (e.g., Great Lakes region) has low or marginally low iodine content. Iodinated casein and thyroprotein (5 g/day PO) have been used to reverse the effects of hypothyroidism.[473,492]

Hormone supplementation with T_4 can be effective at treating hypothyroidism unless there is a deiodination defect. A starting oral T_4 dose of 20 µg/kg/day is recommended.[385] There is a place for using levothyroxine (L-thyroxine, T_4) in horses and foals correctly diagnosed with hypothyroidism. Unfortunately, thyroid supplements are widely used for a multitude of equine conditions that not surprisingly also have low TH concentrations (obesity, laminitis, insulin resistance, infertility, poor performance, dermatopathies, anhidrosis, others).[471] According to the manufacturer, levothyroxine sodium is indicated for horses with low TH concentrations, presumably hypothyroidism, at an oral dose of 0.01 to 0.06 mg/kg. The animal should be monitored for clinical response to therapy, which can take at least 2 weeks. Periodic TH measurements are important to adjust dosing if the desired response is not achieved.

Hyperthyroidism

Hyperthyroidism is a hypermetabolic state consequence of high concentrations of free T_4 and T_3. High TH concentrations can be found in physiologic states such as pregnancy, fetuses in late pregnancy, and the first weeks of life.[361-365,367,373,374,381,389] Few documented cases of equine hyperthyroidism exist.[463,469] Tremors, excitability, tachycardia, sweating, and weight loss have been described in racehorses suspected of hyperthyroidism.[407,513] There are no reports of hyperthyroidism associated with autoimmune conditions in the horse. Hyperthyroidism from thyroid adenomas and adenocarcinomas has been documented in horses.[463,464,469] The T_3 suppression test was used to confirm the diagnosis of hyperthyroidism.[463,464]

Horses are at risk for accelerated TH production when exposed to increased quantities of iodine-containing compounds such as expectorants, counterirritants, contrast media, drugs, leg paints, and povidone-based shampoos (Jod-Basedow phenomenon).[357]

As part of the treatment of hyperthyroidism, it is important to eliminate exposure to iodine-containing compounds. Glucocorticoids may alleviate clinical signs in severe cases.[357] Hemithyroidectomy can be successful at restoring TH concentrations in horses with unilateral thyroid tumors. Horses may improve with antithyroid therapy of potassium iodide (1 g/day PO).[402,407] PTU (8 mg/kg PO q 24 h) was used successfully to treat a 19-year-old mare with a thyroid adenocarcinoma and hyperthyroidism.[464] Measuring TH in the first 2 weeks of treatment is recommended to adjust dosing.[464] Administration of PTU every other day for weeks to months appears to be safe, effective, and inexpensive. The prognosis for hyperthyroid horses is variable, depending on the cause and response to treatment. For unilateral thyroid tumors, prognosis after surgical excision is good. The use of thyroidectomy to improve behavior in unmanageable horses had variable success.[492]

Thyroid Tumors

Tumors of the thyroid gland tend to occur more frequently in lightweight breeds than in draught horses and more often in aged than in young horses.[514] There are three cell types in the equine thyroid gland: undifferentiated cells, parafollicular cells (secrete calcitonin), and follicular epithelial cells. A survey of aged horses found thyroid tumors in 30% of the animals,[515] with no tumors in horses younger than 18 years old. Masses in the throat or retropharyngeal areas could also be branchial remnant cysts, which are reported in young and mature horses.[516]

Adenoma

Adenoma is the most common neoplasia of the equine thyroid.[463,494,515,517-522] It is an age-related phenomenon, occurring mainly in horses older than 16 years. It is benign, usually unilateral, and is not associated with thyroid dysfunction. Occasionally its size may warrant surgical excision. Prognosis is good. A thyroid adenoma associated with hyperthyroidism was diagnosed in a 23-year-old gelding.[463] In this case, the diagnosis was aided by percutaneous biopsy and the use of the T_3 suppression test, in which T_4 concentration did not suppress after the IM administration of T_3. Hemithyroidectomy of the affected gland restored TH concentrations. Immunohistochemistry of equine benign thyroid tumors in old horses revealed that adenomas are often misclassified as follicular when in fact many of them originate from the C cells.[523]

Adenocarcinoma

Malignant neoplasia of the thyroid occurs less frequently. In reported cases of thyroid adenocarcinomas, horses have been euthyroid, hypothyroid, and hyperthyroid.[464,466-469,524] One case of thyroid carcinoma with systemic metastasis and concurrent pituitary adenoma was reported.[525]

Medullary Carcinoma

Medullary carcinomas (C-cell or parafollicular cell tumors) have been documented in horses.[340,526,527] In most cases, tumors are unilateral. Benign C-cell adenomas are common in old horses with no evidence of disease or endocrine dysfunction.[523,528] In one horse, a C-cell adenoma associated with multiple endocrine neoplasia was documented at necropsy.[526]

C-cell hyperplasia has been described in horses as young as 3 years of age.[518] Depending on mass size, surgical removal could be recommended to alleviate clinical signs.[340] In other cases, esthetics is the main reason for surgery. Immunohistochemistry or electron microscopy may be necessary to distinguish C-cell tumors from other thyroid neoplasias.[523]

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN) is a human syndrome characterized by multiple neoplasia of glands with a neuroendocrine origin. One case of a 22-year-old Thoroughbred mare with a C-cell adenoma, a pheochromocytoma, and multicentric bilateral nodular hyperplasia of the adrenal medulla was reported.[526] A retrospective evaluation of endocrine tumors in horses that underwent necropsy suggested that hyperplasia and neoplasia of the thyroid and adrenal glands, as occur in humans with MEN, also occur in the horse.[525,526]

Treatment

In circumstances that warrant surgical excision the prognosis is best when the condition is unilateral. Potential surgical complications include infection, hemorrhage, and laryngeal hemiplegia. As the equine parathyroid glands in general are not connected to the thyroid gland, hypocalcemia is unlikely to be a complication.

Hypothalamic-Pituitary-Adrenal Axis, Steroids, and Neuroactive Steroids

Katarzyna A. Dembek and Ramiro E. Toribio

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS PHYSIOLOGY

The hypothalamic-pituitary-adrenal axis (HPAA) represents a complex regulatory system that modulates multiple homeostatic systems (metabolism, pain, hunger, thirst, blood pressure, electrolyte balance, autonomic activity, immunity, and sexual behavior), as well as the stress response to internal and external stimuli, to ensure organ function and survival. Major advances have been made in understanding HPAA physiology and pathophysiology in people and animals with various acute and chronic disorders.

Hypothalamus

The hypothalamus is located in the ventral diencephalon and below the thalamus. It is part of the limbic system (with the hippocampus, amygdala, thalamic nuclei, mammillary body, limbic cortex, and other structures) and mediates autonomic, endocrine, and behavioral functions. It is the master regulator of numerous physiologic processes.[529,530] It generates and receives humoral and neural information; coordinates different levels of autonomic communication between the CNS and central and peripheral organs; and regulates body temperature, hunger, thirst, circadian and circannual rhythmicity, sleep, reproductive drive, sexual dimorphism, growth, behavior, metabolic activity, and other essential functions.[529-531] The hypothalamus connects via neural circuits to other structures of the CNS but also sends and receives humoral information. A good example of hypothalamic humoral connection is with the pituitary gland via the portal system in the median eminence.[529,530]

Histologically, the hypothalamus is arranged in a series of nuclei with magnocellular and parvocellular neurons that secrete releasing (e.g., corticotropin-releasing hormone [CRH], thyrotropin-releasing hormone [TRH], growth hormone–releasing hormone [GHRH], gonadotropin-releasing hormone [GnRH]) and inhibitory (e.g., somatostatin, dopamine) factors into the pituitary portal system to control hormone synthesis and secretion by the adenohypophysis (e.g., adrenocorticotropic hormone [ACTH], growth hormone [GH], thyroid-stimulating hormone [TSH], prolactin).[532,533] The hypothalamus also produces peptides that are stored in the neurohypophysis (e.g., oxytocin, vasopressin), as well as factors that modulate melanotrope activity in the pituitary pars intermedia (e.g., dopamine, serotonin, TRH). The hypothalamus is responsive to peripheral hormones (leptin, ghrelin, insulin, steroids, thyroid hormones), metabolites (glucose), electrolytes (sodium), neural stimuli (light, smell, touch, vascular pressure, pheromones, temperature, input from the thorax, gastrointestinal tract, and reproductive tract), cytokines, and microbial products. The level at which hypothalamic neurons are stimulated or suppressed is dictated by set-points specific to each function (e.g., thermoregulation, thirst, osmolality, blood pressure).[532,533]

Peptides and large molecules are sensed or gain access to hypothalamic neurons through circumventricular organs, including the subfornical organ and the organum vasculosum of the lamina terminalis. These structures have a fenestrated endothelium and lack an effective blood-brain barrier allowing the hypothalamus to continuously sample systemic circulation and relay information to different parts of the CNS and are essential for feedback regulatory mechanisms that modulate neuroendocrine function.[533]

Hypothalamic-Pituitary-Adrenal Axis Dynamics

CRH, ACTH, and cortisol are secreted in a circadian fashion mediated by inputs from the pineal gland and the suprachiasmatic nucleus of the hypothalamus, with the highest concentrations observed in the morning and the lowest in the evening. Interestingly, circadian rhythm in cortisol secretion was reported in adult horses but not in neonatal foals (less than 5 days old).[534] The mean 24-hour cortisol concentration was lower in foals compared with adult horses; however, the daily endogenous cortisol production was higher in foals than in horses.[534] ACTH is released in irregular (time and amplitude) peaks that occur about 10 times per hour in the horse.[535] Seasonal variations in ACTH and cortisol secretion in fall and winter months have been documented in horses.[536-540] Therefore seasonally specific reference ranges are required to properly assess ACTH concentrations.[536-540]

Under stress or physiologic needs, the hypothalamus secretes CRH (CRF, corticoliberin, 41 amino acids [41aa]) and arginine vasopressin (AVP, antidiuretic hormone, 9aa). CRH is synthesized by parvocellular neurons located in the paraventricular nucleus (PVN).[529,532,533] In response to stress, CRH is released in the portal system of the median eminence by neurosecretory terminals of these neurons and acts on the pituitary corticotropes via the CRH-1 receptor (CRH-1R) to elicit the secretion of ACTH (39aa) and other proopiomelanocortin (POMC)-derived peptides, including β-endorphin (β-END)

and α-melanocyte–stimulating hormone (α-MSH).[529,532,533] Factors that modulate CRH secretion include brain-derived neurotropic factor (BDNF), cytokines, lipopolysaccharides (LPS), glucocorticoids, neurosteroids, nitric oxide, glutamate (via NMDAR), and γ-aminobutyric acid [GABA] (through $GABA_A$ receptors).[541-544] BDNF is a key stimulatory factor for CRH secretion.[542] AVP is synthesized by magnocellular neurons (AVP-ergic) located in the PVN and supraoptic nucleus (SON). These neurons release AVP in the portal system to stimulate the corticotropes to release ACTH, via the AVP receptor 3 (AVPR3, V1bR).[545,546] Factors that regulate AVP secretion include BDNF, LPS, cytokines, nitric oxide, angiotensin-II, and hypocortisolemia.[547-551] The regulation of AVP as it relates to the HPAA is different than AVP stored in neurosecretory terminals (Herring bodies) of the neurohypophysis where its secretion is controlled by osmolality and blood pressure.[541,546]

In humans and rats, CRH and AVP colocalize to the same parvocellular neurons[552,553]; however, data on their hypothalamic cellular distribution in the horse is minimal.[549] The relative importance of CRH and AVP to stimulate the secretion of ACTH is species dependent.[554] An in vitro study on the dynamics of ACTH secretion by equine anterior pituitary cells showed that in horses, CRH is a major pituitary ACTH secretagogue.[555] Another study in adult horses found that endotoxemia stimulates both CRH and AVP secretion and concluded that AVP appears to be more important than CRH in stimulating ACTH release during illness.[556] More recently, it has been shown that CRH and AVP are synergistic in evoking ACTH in horses, particularly during hypocortisolemia.[549] The HPAA is also regulated by neuroactive steroids via GABAergic signals.[544,557] Thus stress-derived neurosteroids and centrally generated steroids may alter the HPAA as well as other hypothalamic functions.[544,554,558,559]

The periventricular nucleus (not to be confused with paraventricular nucleus) is a diffuse group of hypothalamic neurons responsible for somatostatin, TRH, gastrin, and dopamine secretion. Periventricular TRH-ergic neurons increase and dopaminergic neurons suppress proliferation and hormone secretion by melanotropes in the pituitary pars intermedia. Dysfunction of these dopaminergic neurons in geriatric horses has been linked to the development of pituitary pars intermedia dysfunction (PPID, Cushing disease), resulting in excessive and unregulated secretion of POMC-derived peptides, including ACTH and α-MSH.[560]

Pituitary Gland (Hypophysis)

The pituitary gland is located in the sella turcica, a depression within the sphenoid bone, and connected to the hypothalamus through the infundibular stalk.[561] Histologically, the pituitary gland consist of an anterior lobe (adenohypophysis), an intermediate lobe (pars intermedia), and a posterior lobe (pars nervosa, neurohypophysis).[561,562] The anterior lobe is further divided into a pars distalis that contains most cells and a pars tuberalis, which is the proximal part of the anterior lobe surrounding the infundibulum closer to the median eminence (ventral hypothalamus). In equids, the distinction between anterior, intermediate, and posterior lobes does not reflect pituitary anatomy described for other species because the equine anterior lobe wraps the other two lobes. Therefore *pars distalis, pars intermedia,* and *pars nervosa* are better terms.[530]

Stimulatory and inhibitory factors released in the median eminence are transported to the pars distalis through the hypophyseal portal system. The proximal or primary plexus is located in the median eminence. From here, factors are transported via the hypophyseal portal vein to the distal or secondary plexus to reach target cells in the pars distalis.

Cells in the pars distalis include somatotropes, gonadotropes, lactotropes, thyrotropes, and corticotropes. Based on staining properties, these cells are chromophils and chromophobes. Chromophils include acidophils (somatotropes, lactotropes) and basophils (gonadotropes, thyrotropes, and corticotropes).[561] The somatotropes (somatotrophs) produce growth hormone (GH), lactotropes (lactotrophs, mammotrophs) produce prolactin, gonadotropes (gonadotrophs) produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH), thyrotropes (thyrotrophs) produce thyroid-stimulating hormone (TSH), and corticotropes (corticotrophs) produce adrenocorticotropic hormone (adrenocorticotropin, corticotropin, ACTH).[561,562]

The pars intermedia forms the junction between the pars distalis and neurohypophysis. The melanotrope (melanotroph) is the main cell in the pars intermedia, and after cleavage of POMC the main products include α-MSH, ACTH, β-lipotropin, β-endorphin (β-END), and corticotropin-like intermediate peptide (CLIP).[531,554,560,561] The pars intermedia is under the control of hypothalamic neurons mainly through dopaminergic inhibition.

The pars nervosa consists of axons from magnocellular neurons extending from the SON and PVN. These neurons store and release AVP and oxytocin.[530,561] AVP is released in response to hypotension and hyperosmolality. Oxytocin secretion into systemic circulation is affected by a number of tactile, stretch, and visual stimuli.

For the purpose of this section, we will focus on the corticotropes as they are responsible for the synthesis and secretion of ACTH. In the pars distalis, ACTH is the main POMC-derived peptide whereas in the pars intermedia α-MSH is the main POMC product. ACTH stimulates the adrenal gland cortex to secrete cortisol and to a lesser extent other adrenocortical layers to release other steroids.[563-567] In addition to AVP and CRH, the synthesis and secretion of ACTH is regulated by cytokines, LPS, TRH, glucocorticoids, and nitric oxide.[568,569]

Adrenal Gland

In horses, the adrenal glands lie retroperitoneally and embedded in the fat on the medial cranial pole of each kidney. They are red-brown, 7.0–8.0 × 3.0–3.5 cm, and weigh 15–20 g each. Blood supply to the adrenal gland is from the adrenal artery, which arises from either the aorta or the renal artery.[529-531] Innervation involves sympathetic fibers from the splanchnic nerve.[570] Accessory adrenal cortical tissue may be found in the adrenal gland capsule, periadrenal or perirenal adipose tissue, mesorchium, and in the vicinity of the equine testis.[570] The adrenal glands develop from two separate embryologic tissues: the medulla is derived from neural crest cells originating in proximity to the dorsal aorta, and the cortex develops from the intermediate mesoderm (urogenital ridge).[571]

The medulla is functionally related to the sympathetic nervous system and consists of chromaffin cells that secrete catecholamines (epinephrine, norepinephrine, and dopamine) in response to sympathetic stimulation.[529,531] The chromaffin cells are considered modified postganglionic neurons directly controlled by preganglionic fibers of the autonomic nervous system. Epinephrine (adrenaline) is the main adrenomedullary hormone.

The adrenal cortex derives from the mesoderm and secretes different types of steroids, which are synthesized from cholesterol. The adrenal gland cortex consists of three zones: the outermost *zona glomerulosa,* which secretes mineralocorticoids (aldosterone) in response to the renin-angiotensin-aldosterone system (angiotensin-II in particular), hyperkalemia, and changes in extracellular fluid osmolality (sodium, chloride); the *zona fasciculata,* which secretes glucocorticoids (cortisol) in response to ACTH stimulation; and the *zona reticularis,* which produces sex steroids, mostly androgens.[434,530,570]

Adrenocortical function (mainly glucocorticoid synthesis) is controlled by the HPAA. As previously mentioned, the hypothalamus secretes CRH and AVP to stimulate pituitary ACTH secretion, which in turn stimulates the adrenal cortex to secrete cortisol and to a lesser extent aldosterone and other steroids.[434,529] Subsequently, cortisol inhibits CRH, AVP, and ACTH secretion as part of a negative feedback control mechanism.[434,529]

The adrenal gland cortex is involved in a wide variety of body functions, including maintenance of fluid and electrolyte balance, immunity, defense, and energy metabolism. The adrenal gland also secretes steroids with neuroactive activity, as well as steroids that could be used as precursors in other organs. Removal or destruction of the adrenal glands leads to death unless exogenous adrenocortical hormones are administered.[529,570] Aldosterone increases renal sodium reabsorption and excretion of potassium. Cortisol increases gluconeogenesis, causes mobilization of amino acids from extrahepatic tissues to enter the gluconeogenesis, decreases glucose utilization, increases glucose concentrations, and inhibits insulin actions on glucose uptake and lipogenesis. Cortisol increases fat and amino acid mobilization to make them available during stress.[529] Endogenous glucocorticoids are antiinflammatory and immunosuppressors; hypercortisolemia results in eosinopenia and lymphopenia. Cortisol is also essential for organ maturation and differentiation (lung, gastrointestinal, endocrine), a critical step in the developing fetus and newborn.[529,531]

Function of the Fetal Adrenal Gland

Compelling evidence shows that rapid maturation of the HPAA in foals takes place in the last 5 days of gestation and continues into the first weeks of life, much later than described in other species.[572,573] Cortisol synthesis depends on three key enzymes: cholesterol side chain cleavage (cytochrome P450-scc; CYP11A1), 3β-hydroxysteroid dehydrogenase (3β-HSD), and 17α-hydroxylase (P450-17; CYP17A1). Cytochrome P450-scc is expressed in the fetal adrenal cortex from as early as 150 days of gestation, and 3β-HSD that synthesizes progesterone from pregnenolone is present from about 280 days of gestation.[573] However, P450-17, which is required for cortisol production, is expressed 5 days before birth.[572,573] Therefore premature foals (gestational age less than 320 days) have lower basal concentrations of cortisol with higher endogenous ACTH than full-term foals after birth, in part due to the lack of negative feedback. Moreover, these foals show a blunted cortisol response to ACTH stimulation compared with normal foals.[574]

Interestingly, all three enzymes are present at birth and show no change in their expression in the perinatal period. An increased response to exogenous ACTH has been described in late gestation and birth with a positive correlation between the cortisol response of a neonatal foal and its gestational age at delivery. This suggests that other factors such as ACTH receptor (MC2R) density, ACTH clearance, and adrenal blood flow may be involved in the cortisol response to ACTH in newborn foals.[572,573]

Steroidogenesis

Adrenal steroids are synthesized from cholesterol through initial steps similar to other steroidogenic organs (testes, ovaries) (Fig. 16.16). Adrenocortical cells store small amounts of steroids; therefore a fast steroid response requires a highly coordinated enzymatic machinery for rapid hormone synthesis and secretion. ACTH regulates steroidogenesis by acute and chronic effects on the adrenal gland. ACTH binds to the G protein–coupled melanocortin type 2 receptor (MC2R) to stimulate steroidogenic acute regulatory protein (StAR) transcription and translation.[575,576] StAR increases cholesterol transfer from the outer to the inner mitochondrial membrane, where it is converted to pregnenolone in the first and rate-limiting steroidogenic step.[575,576] ACTH also increases cholesterol uptake from circulation. In fact, most cholesterol in the adrenal cortex comes from outside the gland, although this remains to be documented in horses, particularly because the equine adrenal cortex is rich in lipids. Chronically, ACTH promotes the transcription of genes encoding various steroidogenic enzymes, including cytochrome P450 and hydroxysteroid dehydrogenases. Moreover, ACTH stimulates the synthesis of basic fibroblast growth factor, epidermal growth factor, and insulin-like growth factor II (IGF-II), and these mediators stimulate adrenocortical hyperplasia and hypertrophy.[575,576]

Pregnenolone is transported to the endoplasmic reticulum to be converted to progesterone and 17α-hydroxyprogesterone, which in the zona glomerulosa and fasciculata become aldosterone or cortisol, respectively. Androgens such as dehydroepiandrosterone (DHEA), androstenedione, and

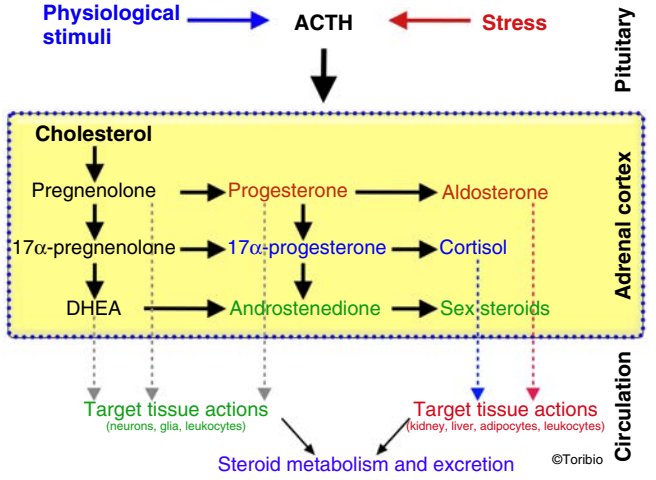

FIG. **16.16** Adrenocortical steroidogenesis. In the adrenal cortex, steroids are synthesized from cholesterol resulting in progestogens (pregnenolone, progesterone), glucocorticoids (cortisol), mineralocorticoids (aldosterone), and androgens (DHEA, androstenedione). The main products of the adrenal cortex are cortisol and aldosterone. Steroid precursors are also released into systemic circulation to exert multiple functions but are also used in other organs (e.g., nervous system) as precursors for other steroids (e.g., neurosteroids). *ACTH,* Adrenocorticotropic hormone; *DHEA,* dehydroepiandrosterone. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

epitestosterone are synthesized from 17α-hydroxyprogesterone and 17α-hydroxypregnenolone in the zona reticularis. A fraction of progestogens are released into systemic circulation to exert specific actions or are used as precursors for other steroids.

In humans, there are several genetic disorders in early steroidogenesis causing primary adrenal insufficiency such as adrenoleukodystrophy or Wolman disease (cholesterol ester storage disease).[575,576] Equivalent disorders have not been described in horses.

In the brain, progesterone, DHEA, and pregnenolone can be converted into neuroactive steroids (e.g., allopregnanolone, allotetrahydrodeoxycorticosterone [THDOC]) to promote neurogenesis, neuronal plasticity, and neuroprotection (Fig. 16.17)[577] and modulate BDNF, CRH, and AVP synthesis and secretion,[558] thus directly and indirectly influencing the HPAA. Allopregnanolone is a potent neurosteroid with a multitude of actions, including modulation of the HPAA and protection against seizures and neuronal death.[558] In humans, blood concentrations of these steroids are being used to assess adrenal gland function,[563,565-567,578,579] as well as neurologic conditions such as bipolar disorders, depression, and Alzheimer's disease. (See neurosteroid section later in this chapter.)

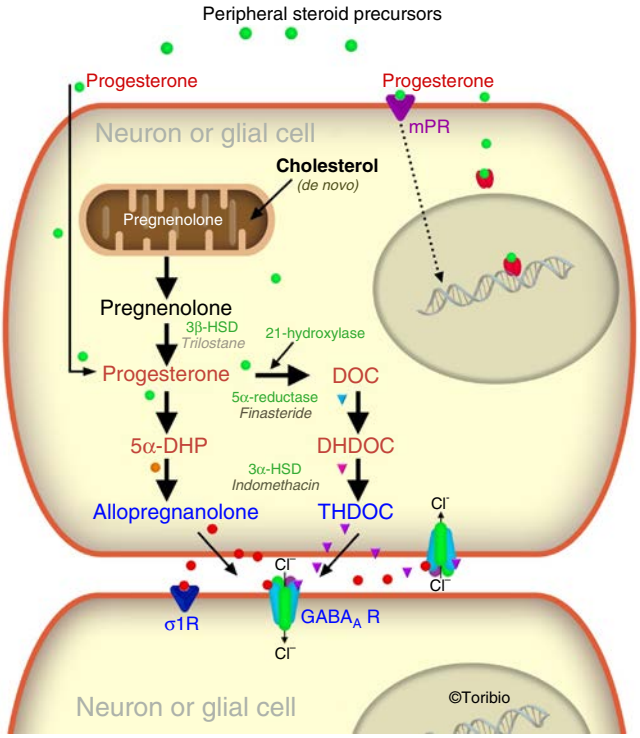

FIG. **16.17** Synthesis of neuroactive steroids by neurons and glial cells in the central nervous system. Progesterone and other steroid precursors from peripheral circulation can be taken by neurons and astrocytes to be converted into neurosteroids. These cells also have the enzymatic machinery for de novo synthesis of neuroactive steroids from cholesterol. Neuroactive steroids mainly function through the cell membrane $GABA_A$ receptor, but other receptors exist. Progesterone acts through traditional nuclear receptors as well as through cell membrane progesterone receptors (mPRs). Trilostane, finasteride, and indomethacin can inhibit specific enzymes necessary for steroidogenesis. *3α-HSD,* 3α-hydroxysteroid dehydrogenase; *3β-HSD,* 3β-hydroxysteroid dehydrogenase; *5α-DHP,* 5α-dihydroprogesterone; *DHDOC,* dehydrodeoxycorticosterone; *DOC,* deoxycorticosterone; *THDOC,* allotetrahydrodeoxycorticosterone; *$GABA_AR$,* γ-aminobutyric acid (GABA) type A receptor; *mPR,* membrane progesterone receptor; *σR,* sigma-1 receptor. Sepsis and the Hypothalamic-Pituitary-Adrenal Axis

Inflammation, cytokines (TNF-α, IL1-β), and LPS activate the HPAA in humans and animals.[568,580,581] In other species, inflammatory cytokines increase CRH, AVP, and ACTH mRNA expression and secretion.[582] CRH, AVP, ACTH, and cortisol concentrations are also increased in experimental models of endotoxemia.[545,556,568,580] The LPS effects on CRH mRNA expression and ACTH secretion are in part mediated by nitric oxide.[583] IL1-β and TNF-α can stimulate or suppress cortisol secretion, depending on the duration of exposure.[584] Although ACTH concentrations increase in foals with systemic inflammation,[585] the prevalence of ACTH hyposecretion in the context of HPAA dysfunction is low. Similarly, the role of hypothalamic dysregulation (decreased AVP and CRH) in the development of HPAA dysfunction is minimal compared with adrenocortical failure because most critically ill foals have high AVP[585] and CRH concentrations. Critical illness in newborn foals independent of blood pressure or osmolality can stimulate AVP secretion.[585] In humans, sepsis can lead to irreversible damage to the hypothalamus and pituitary gland.[586] Pituitary necrosis is a well-documented phenomenon in septic human patients that could lead to multiple endocrine failure (GH, ACTH, AVP, thyroid hormones).[586] A similar process may occur in foals with severe sepsis and multiorgan failure.

Adrenal Insufficiency

Adrenal insufficiency (AI) in general terms is defined as a reduced capacity of the adrenal gland to secrete adrenocortical steroids in sufficient amounts to meet physiologic needs, thus resulting in clinical and laboratory disturbances. The primary problem leading to AI could be at any level of the HPAA, but it is ultimately steroid deficiency that causes the signs of this condition that has been documented in foals and horses. It should be noted that the pathogenesis of AI in noncritically ill horses (chronic AI) is different from the AI of acute illness in horses and foals.

Types and Definitions of Adrenal Insufficiency

- *Irreversible adrenal insufficiency* or hypoadrenalism (Addison disease) results from failure of the adrenal gland to produce adrenocortical hormones (mineralocorticoids and glucocorticoids).[531]
- *Relative adrenal insufficiency (RAI)* is a transient form of AI that often occurs in critically ill people, neonatal foals, and horses. RAI is defined as an inadequate production of cortisol in relation to an increased demand during periods of severe illness and stress, and it is characterized by high ACTH/cortisol ratios.[434,531,587]
- *Critical illness–related corticosteroid insufficiency (CIRCI)* is a term promoted in recent years instead of RAI because it takes into consideration clinical findings, an exaggerated proinflammatory response from cortisol deficiency, and tissue refractoriness to corticosteroids.[531,588]

- *Iatrogenic AI,* caused by chronic glucocorticoid administration leading to suppression of the HPAA, is the most common type of AI in people and adult horses.

Adrenal insufficiency can be also classified based on the level of the HPAA that is affected.

- *Primary AI:* caused by damage or dysfunction of the adrenal gland cortex.
- *Secondary AI:* caused by impaired ACTH secretion by the pituitary gland.
- *Tertiary AI:* caused by reduced CRH and/or AVP secretion from the hypothalamus into the median eminence.

Adrenal Insufficiency in Horses

In horses, AI is also known as adrenal exhaustion, hypoadrenocorticism, turn-out, or steroid letdown syndrome, which is characterized by low cortisol concentrations and a poor response to the ACTH stimulation test. Adrenal insufficiency also occurs in critically ill horses (colic, enterocolitis, endotoxemia, sepsis) and septic foals, in part because the adrenal gland is a shock organ in equids (adrenal hemorrhage, thrombosis, and cortical necrosis are common in sick equids). Animals that recover could potentially develop adrenal atrophy and dysfunction.[531,589,590]

In adult horses, AI has been associated with the chronic administration or discontinuation of glucocorticoids or anabolic steroids.[591] The adrenal gland response to exogenous ACTH in Thoroughbred horses was not altered by training,[592] and cortisol concentrations were within normal limits in racehorses with a history of poor performance.[593] High plasma cortisol and ACTH concentrations were found in horses after maximal exercise.[594-597] Endurance horses in a 160-km ride had significantly higher midride plasma cortisol concentrations than preride concentrations.[598] A sixfold increase in cortisol secretion rate and a threefold increase in plasma cortisol concentrations was also found in exercising horses.[599] Increased total serum cortisol concentrations were reported in horses with colic[435] and lunged Royal Dutch Sport horses with altered head-and-neck position.[600] These findings suggest that the main reason for noncritically ill horses to develop AI is iatrogenic. We want to emphasize that this type of AI has a different pathogenesis from AI from critical illness.

Endogenous and exogenous glucocorticoids suppress the HPAA, and chronic exposure can induce atrophy of the zona fasciculata. The zona glomerulosa may be morphologically minimally affected, but electrolyte abnormalities are frequent. This indicates that AI in horses can involve multiple adrenocortical layers.

Horses suspected of having AI present with a history of depression, anorexia, exercise intolerance, weight loss, poor haircoat, lameness, abdominal discomfort, and seizures.[531,590,591,601-603] Therefore it is important to obtain a complete history, including performance, previous diseases, drug administration, and stressing conditions. Serum biochemical analysis may be normal, or hyponatremia, hypochloremia, hyperkalemia, and hypoglycemia may be present.[531,590,591,601-603]

Some of the clinical features of equine hypoadrenocorticism (hyponatremia and hyperkalemia without evidence of renal disease) resemble Addison disease in humans and small animals although Addison disease has not been documented in the horse. One case of an autoimmune polyendocrine syndrome with insulin-dependent diabetes mellitus and clinical signs similar to Addison disease was described in a 5-year-old Thoroughbred-cross mare.[604] Clinical abnormalities included lethargy, poor appetite, weight loss, polyuria, polydipsia, persistent hyperglycemia, hyponatremia, hypochloremia, and hyperkalemia. The mare was diagnosed postmortem with lymphocytic pancreatitis and thyroiditis, as well as AI secondary to lymphocytic adrenalitis.[604]

Adrenal insufficiency is rarely diagnosed in equine practice. However, it should be suspected in any horse with a history of anorexia, lethargy, poor body condition, poor exercise performance, history of glucocorticoid administration, electrolyte imbalances (hyponatremia, hypochloremia, hyperkalemia), and hypoglycemia.[591,604] Baseline cortisol and ACTH concentrations, as well as the ACTH stimulation test, are critical to achieve a diagnosis. Cortisol has daily fluctuations, and single measurements may not provide enough information to make a diagnosis of hypoadrenocorticism. Therefore the ACTH stimulation test is more useful in assessing adrenal gland function.[601,603,605] Horses with AI have low cortisol concentrations and do not respond or have a minimal response to the ACTH stimulation test.[601,606] In addition, measuring ACTH concentrations is important to determine other causes of hypoadrenocorticism (iatrogenic, adrenal, pituitary). It is anticipated that exogenous glucocorticoids will decrease ACTH concentrations (secondary hypoadrenocorticism), whereas adrenocortical dysfunction (primary hypoadrenocorticism) will be associated with increased ACTH concentrations from reduced glucocorticoid negative feedback. In horses with increased plasma ACTH concentrations, PPID should be ruled out.

In the ACTH stimulation test, 1 IU/kg of natural ACTH gel is administered intramuscularly.[606] For cortisol measurements, take a pre-ACTH blood sample in heparinized or plain tubes, and administer ACTH between 8:00 and 10:00 AM. Take post-ACTH blood samples 2 and 4 hours after ACTH administration. Horses with a functional adrenal gland should have twofold to threefold increases in plasma cortisol concentrations compared with baseline values.[602,606] In the synthetic ACTH ($ACTH_{1-24}$, cosyntropin, tetracosactide, tetracosactrin) stimulation test, 100 IU (1 mg) of cosyntropin (Cortrosyn®) is administered intravenously between 8:00 AM and noon.[607] Take a pre-ACTH blood sample, administer cosyntropin, and take a post-ACTH blood sample 2 hours later. Plasma cortisol concentrations should be at least twice baseline. Cosyntropin (25 IU; 250 µg) can increase cortisol concentrations twice baseline in horses. More recently, a dose of 0.1 µg/kg of cosyntropin was reported to induce maximal adrenal stimulation 30 minutes after administration in healthy horses.[605] Depending on disease duration and severity, necropsy findings in horses with hypoadrenocorticism vary from adrenocortical hemorrhages and necrosis to adrenocortical atrophy and fibrosis.

Treatment of hypoadrenocorticism involves rest, correction of serious clinical and laboratory abnormalities, and glucocorticoid replacement therapy. The duration and dose of exogenous steroids that induce adrenocortical atrophy in healthy horses are unknown. However, there is information on doses that inhibit adrenocortical secretion in horses. Dexamethasone doses as low as 4 mg suppressed the HPAA for up to 24 hours.[602] Dexamethasone (0.044–0.088 mg/kg) every 5 days for six treatments reduced cortisol concentrations for up to 4 days but did not change the response to ACTH stimulation.[608] Toutain and colleagues[609] found that dexamethasone (50 µg/kg IV or IM) suppressed adrenocortical function for up to 4 days, prednisolone sodium succinate (0.6 mg/kg IV or IM) for less than 24 hours, and prednisolone acetate

suspension (0.6 mg/kg IM) for up to 21 days. Dexamethasone (0.044 mg/kg IM) and triamcinolone (0.044 mg/kg IM) produced HPAA suppression for 7 and 14 days, respectively.[610,611] Plasma cortisol concentrations remained below baseline for 4, 10, and 15 days after intravenous, intraarticular, and intramuscular injection of triamcinolone acetonide (0.04 mg/kg), respectively.[612] A single intraarticular dose of methylprednisolone acetate (200 mg) suppressed adrenocortical function for up to 10 days.[613,614] A single intraarticular dose of betamethasone (30 mg) suppressed plasma cortisol concentrations for 3 days in Thoroughbred horses.[615] Data on the use of parenteral hydrocortisone (cortisol) in horses to treat hypoadrenocorticism are lacking; however, due to its rapid elimination in horses and foals (less than 24 hours),[534] it could be a good short-term therapeutic alternative. In fact, hydrocortisone is the recommended glucocorticoid for critically foals with AI.[616] Based on this information (half-life, adrenocortical suppression), when treating hypoadrenocorticism, hydrocortisone or prednisolone sodium succinate should be the first choice, low-dose dexamethasone the second option, and triamcinolone acetonide and prednisolone acetate should be avoided. Oral prednisolone (200–400 mg/horse) is a good option for prolonged use. Prednisone was successfully used to treat a horse with AI secondary to anabolic steroid administration and a foal with AI.[591,601] The efficacy of prednisone in horses is questionable because it is poorly absorbed in horses and the active metabolite, prednisolone, is minimally produced.[617] It is likely that animals treated with prednisone improved for reasons other than this drug.[617] This is further supported by the lack of cortisol suppression following prednisone compared with prednisolone administration.[617] In contrast, oral prednisolone has excellent bioavailability and may be more useful as a therapeutic agent in horses. As with any long-term glucocorticoid therapy, slow withdrawal is recommended.

Long-term glucocorticoid therapy is often recommended in the management of recurrent airway obstruction (RAO, equine asthma). Inhaled beclomethasone dipropionate (500 µg - 1500 µg q12h) suppressed endogenous cortisol secretion in a dose-dependent manner for 1 to 4 days after administration in horses with RAO.[618,619] Similarly, inhaled fluticasone propionate (2 mg once a day to 3 mg twice a day) was reported to reduce cortisol concentrations for 8 to 24 hours after treatment in horses with RAO.[620] Despite suppressed adrenocortical function, no clinical signs of AI or adverse systemic effects, such as laminitis or bacterial infections, occurred in treated horses.

The exaggerated proinflammatory response that occurs in foals and horses with systemic inflammatory response syndrome (SIRS) and severe sepsis can be in part attributed to adrenocortical failure and suppression of the HPAA. However, experimental and clinical data suggest that tissue resistance to glucocorticoids may be involved in HPAA dysregulation.[531,588,590] One study found that horses with SIRS that died had lower glucocorticoid binding affinity compared with survivors, suggesting that in addition to HPAA dysfunction, impaired glucocorticoid receptor activity contributes to their proinflammatory state.[590]

Adrenal Insufficiency in Foals

Our understanding of HPAA activity in healthy and sick foals has improved in recent years.[434,585,621,622] However, beyond cortisol and aldosterone, we are far from having an integrated view of the different endocrine factors released from the equine adrenal cortex, their functions, interactions, and metabolism. *Adrenal insufficiency* as a diagnosis in critically ill foals or horses is a broad term because the problem could be at any level of the HPAA. Therefore having the ability to measure key hypothalamic, pituitary, and adrenocortical factors could be valuable to narrow which component of the axis is affected. In septic foals, altered steroidogenesis seems to be the main reason for AI.[434] Another issue to consider is that single cortisol measurements may not reflect adrenal function, and comparing cortisol concentrations in proportion to ACTH concentrations may provide a better assessment of adrenocortical function. For this particular reason, the term *RAI/CIRCI* seems more appropriate because it incorporates two components of the HPAA, and the ratio between ACTH and cortisol will support a good or poor adrenocortical response. RAI/CIRCI occurs secondary to critical illness such as sepsis, severe trauma, major surgery, or acute respiratory distress syndrome (ARDS) in human patients.[587,588] Likewise, severe illness has been associated with RAI/CIRCI in equine neonates with sepsis, septic shock, and multiple organ dysfunction.[622-624]

Recent studies have shown that pituitary and adrenocortical dysfunction are frequent in critically ill foals and in many instances are linked to mortality.[434,585,622] Hart and colleagues found that 40% of septic foals had HPAA dysfunction.[622] Gold and colleagues determined the ACTH/cortisol ratio in septic foals and found that RAI was common, with nonsurviving foals having the highest ratio.[621] In a similar study, Hurcombe and colleagues assessed the AVP/ACTH and ACTH/cortisol ratios in septic foals and showed that HPAA dysfunction at the pituitary and adrenal level was frequent in these foals.[585] AVP is a major secretagogue for ACTH in the horse,[556] and a high AVP/ACTH ratio suggests a decreased ACTH response to AVP stimulation (pituitary insufficiency). Similarly, high ACTH/cortisol[585,621] and ACTH/aldosterone[434] ratios indicate decreased adrenal response to ACTH (RAI) in critically ill foals. The low cortisol concentrations observed in premature foals do not appear to be due to ACTH insufficiency as high ACTH concentrations are frequent in these foals,[625] supporting AI as a major problem in premature foals. Studies have found that both low and high cortisol concentrations were associated with nonsurvival in septic foals.[434,621,622]

Pathophysiology of Relative Adrenal Insufficiency and Critical Illness–Related Corticosteroid Insufficiency

The pathogenesis of RAI/CIRCI in horses and other species is unclear, but it is likely multifactorial and includes decreased production of CRH, ACTH, and cortisol, as well as complex interactions between the endocrine and immune systems.[531,626,627] The equine adrenal gland is a highly vascular organ; therefore it is susceptible to hemorrhages and necrosis, which are often documented in septic nonsurviving foals. Prolonged hypotension and hypoperfusion from sepsis and septic shock may lead to irreversible adrenocortical damage in critically ill foals, similar to the Waterhouse-Friderichsen syndrome described in humans.[531,588] Low cortisol concentrations in foals with AI are mainly the result of adrenocortical failure (primary AI) rather than dysfunction at the pituitary (secondary AI) or hypothalamic level (tertiary AI), which occurs less frequently. Several mechanisms can directly or indirectly lead to HPAA dysfunction, including (1) reduced CRH, AVP, and ACTH secretion; (2) decreased target tissue sensitivity to

CRH, AVP, or ACTH; (3) decreased concentrations of bioactive ACTH; (4) impaired adrenocortical steroidogenesis; (5) tissue resistance to cortisol; and (6) reduced cortisol metabolism leading to decreased ACTH secretion from the negative feedback resulting in hypocortisolemia.[531,628,629] Several drugs (e.g., ketoconazole and rifampin) are known to directly inhibit HPAA activity in critically ill humans and animals[588]; however, they are rarely used in newborn foals.

Inflammatory cytokines (IL-1α, IL-1β, IL-6, TNF-α) and endotoxin (LPS) can directly stimulate the HPAA, increasing CRH, AVP, ACTH, and adrenal steroid concentrations.[568,588,626] This would be an appropriate response to the stress of systemic inflammation. However, prolonged exposure to proinflammatory cytokines and LPS can directly impair all levels of the HPAA.[568,588,626] Inappropriately low ACTH release due to increased TNF-α and IL-6 concentrations has been documented in people with severe sepsis and septic shock.[568,588] Interestingly, high ACTH concentrations were positively associated with IL-6 mRNA expression in peripheral leukocytes in septic foals.[630] High TNF-α and IL-6 concentrations were also associated with impaired glucocorticoid receptor binding in an ovine model of acute lung injury and in a rodent burn model. It is unknown, however, how a proinflammatory state affects glucocorticoid receptor expression and function in critically ill foals or horses.

Finally, hypocortisolemia may also result from substrate deficiency, as plasma high-density lipoprotein concentrations are often low in septic human patients.[631] Data on high-density lipoprotein and very-low-density lipoprotein (VLDL) levels in healthy and sick foals with RAI are lacking.

The concept of RAI was recently challenged in a study because critically ill human patients often had hypercortisolemia and reduced cortisol clearance that was attributed to decreased expression and activity of 11β-hydroxysteroid dehydrogenase type 2 (kidney) and 5β/5α-reductase (liver).[628] These patients also had lower ACTH concentrations that according to the authors were a consequence of cortisol-mediated ACTH suppression. Therefore *ACTH to cortisol dissociation (ACD)* has been introduced as a more appropriate term to describe HPAA dysfunction in people. Prolonged ACTH suppression could have adverse effects on the integrity of the HPAA that ultimately will result in AI.[628,632,633] These observations are in contrast to critically ill newborn foals with RAI that often have increased ACTH and low cortisol concentrations with increased ACTH/cortisol ratios.[434,585,621] For this reason *ACTH to cortisol imbalance (ACI)* is suggested as a more appropriate term to describe foals with RAI.[633a] This is a good example in which one must be cautious in extrapolating information from other species. Nevertheless, impaired metabolism of adrenocortical steroids might partially explain HPAA dysfunction in critically ill equine neonates.

Physiologically, about 90% of cortisol and 95% of progestogens and androgens are transported in the circulation by albumin, corticosteroid-binding globulin (CBG; transcortin), and sex hormone–binding globulin (SHBG). In neonatal foals, a significantly larger amount of circulating cortisol (30%–60%) is unbound to CBG.[6] Unbound or "free" steroids are biologically active and therefore more clinically relevant. Clinical studies in septic human patients have shown better correlation between basal and ACTH-stimulated free cortisol concentrations with disease severity and outcome than with total cortisol.[588,634] Of interest, Hart and colleagues found that baseline or ACTH-stimulated free cortisol concentrations were no better than total cortisol to diagnose CIRCI or predict disease severity and mortality in septic foals.[635]

Diagnosis

The clinical relevance of CIRCI, as well as diagnostic criteria to diagnose CIRCI, has become a controversial issue in human and veterinary critical care medicine due to conflicting data from clinical studies. Methods to diagnose RAI/CIRCI include baseline cortisol concentrations, cortisol and ACTH measurements after stimulation testing with synthetic ACTH (cosyntropin), insulin-induced hypoglycemia, and metyrapone test.[531,588] There are commercial methods to measure cortisol and ACTH concentrations in horses. Data are limited on the use of insulin-induced hypoglycemia and metyrapone test to assess HPAA activity in foals or horses.

In healthy animals and people, cortisol concentrations exhibit circadian and circannual rhythms. In addition, environmental factors, drugs, and diseases influence cortisol concentrations. Glucocorticoid concentrations during sepsis vary significantly over the time course of the illness, being highest in the early stage of sepsis, with a gradual decline in the later phases.[626] Therefore a basal cortisol concentration can sometimes be difficult to interpret and does not provide an accurate diagnosis of the HPAA dysfunction in critically ill humans and foals.[531,588] The most commonly used dynamic test for HPAA integration is the ACTH stimulation test, which permits assessment of adrenal responsiveness to exogenous synthetic ACTH (cosyntropin). Cosyntropin is traditionally used in critically ill people at high (250 μg) and low (1 μg) doses.[588] Blood samples are collected at baseline and at 30 or 60 minutes after stimulation. There are a number of definitions of CIRCI, but the most widely studied diagnostic criteria in humans are as follows: a baseline cortisol concentration less than 10 μg/dL, an increase after cosyntropin stimulation of less than 9 μg/dL (delta cortisol), or a blunted cortisol response to 1 μg of ACTH.[588,636] However, the lack of sensitivity and poor reproducibility of the ACTH stimulation test to define CIRCI limit its clinical use in critically ill people. Therefore current guidelines recommend treating pressor-resistant septic shock patients with hydrocortisone without testing the HPAA function.[587] The latest 2012 Surviving Sepsis Campaign guidelines do not recommend using the ACTH stimulation test to determine which patients should be treated with cortisol replacement therapy.[587] Interestingly, Boonen and colleagues have proposed treating critically ill patients for adrenal failure if they demonstrated clinical signs of unexplained vasoplegia, overwhelming inflammation, or coma for more than 6 days with basal plasma cortisol of less than 6 μg/dL and with an incremental cortisol response to an ACTH stimulation test (250 μg) of less than 6 μg/dL.[633] Similar criteria have not been investigated in critically ill foals.

Similar to human patients, specific criteria for CIRCI in critically ill foals are not very well established. Baseline cortisol concentrations, a cosyntropin test, and ACTH/cortisol ratio have been studied in healthy and septic foals.[585,621,622,637-639] Basal cortisol concentrations change over time in neonatal foals. Therefore age-related variation need to be considered when assessing HPAA function. Hart and colleagues reported basal cortisol concentrations in healthy foals of less than 13.5 μg/dL at birth, less than 6.7 μg/dL at 12 to 24 hours, less than 4.4 μg/dL at 36 to 48 hours, and less than 2.7 μg/dL at 5 to 7 days of age.[534] Interpretation of a single random cortisol concentration can be difficult because of individual variability and

changes during time of day and season. Therefore measurement of cortisol and other steroid concentrations in conjunction with ACTH provides more adequate assessment of the HPAA integrity. Documentation of high ACTH/cortisol,[585] as well as ACTH/aldosterone,[434] ratios in critically ill foals may suggest CIRCI; however, specific cutoff values are not very well defined because of wide ranges in these ratios. Dynamic tests such as the ACTH stimulation test are more adequate to diagnose CIRCI in critically ill people and foals.[588,622] In general, ACTH doses used to assess adrenocortical function in foals are divided into high-dose (1.0–2.0 μg/kg or higher) and low-dose (0.01–0.2 μg/kg) protocols.[622,637-640] After blood collection for baseline cortisol concentrations ACTH is administered intravenously or intramuscularly, and additional blood samples are collected 30 and 90 minutes after stimulation. High-dose ACTH produces the maximum cortisol release; therefore it is considered supraphysiologic and may be less sensitive to diagnose CIRCI. Δ-Cortisol (values at 30 minutes–baseline) concentrations are highly variable in healthy and critically ill foals, and cutoff points have not been established.[622,637-640] However, an increase from baseline cortisol concentrations of less than onefold to twofold 30 minutes after low-dose ACTH stimulation and less than threefold to fourfold 90 to 120 minutes after high-dose ACTH stimulation may be indicative of CIRCI in horses and foals.[622,637]

Insulin-induced hypoglycemia (IIH), the metyrapone test, and the CRH test assess integration of the whole HPAA axis. Metyrapone inhibits adrenocortical 11β-hydroxylase, which converts 11-deoxycortisol to cortisol. When given to individuals with normal adrenal function the reduction in cortisol concentrations stimulates ACTH and CRH release, increasing adrenocortical steroidogenesis and accumulation of 11-deoxycortisol.[531,588] IIH is considered the gold standard test for the diagnosis of HPAA dysfunction in people.[531,588] After exogenous insulin is administered, the cortisol and ACTH response to hypoglycemia is determined. The clinical use of this test in critically ill foals is limited because hypoglycemia is a frequent abnormality, ACTH and cortisol concentrations are often elevated, and insulin administration may be contraindicated. The CRH stimulation test has been described in horses using ovine CRH.[641] However, there are no data in foals on the ACTH and cortisol release in response to CRH, and most critically ill foals have elevated baseline ACTH concentrations. Therefore this test is not recommended for diagnosis of CIRCI in equine neonates.

Treatment

Currently, hydrocortisone replacement therapy (200 mg/day) is recommended in human patients with vasopressor-unresponsive septic shock. The use of the ACTH stimulation test to identify critically ill patients who should receive hydrocortisone is no longer recommended because the response to exogenous ACTH does not predict a faster resolution or better outcome.[587] Bolus administration of hydrocortisone has been associated with hyperglycemia and hypernatremia in ICU patients; therefore continuous IV infusion rather than bolus injection is preferred.[587,636] Recommendations regarding the use of hydrocortisone in septic foals are based on daily endogenous production in healthy foals.[534] The ideal diagnostic test for CIRCI in foals has not been established. Therefore a short tapering replacement therapy of hydrocortisone (1.3 mg/kg/day IV divided every 4 hours) is recommended in foals with clinical signs of CIRCI such as vasopressor-unresponsive hypotension, hypoglycemia, or persistent SIRS.[531]

Steroid Precursors and Neuroactive Steroids

Neuroactive steroids (neurosteroids) represent a multitude of steroids that directly or indirectly modify neuronal and glial cell activity, and therefore behavior, stress response, and endocrine functions. They are influenced by the reproductive cycle, pregnancy, acute and chronic stress, neurologic disorders, and injury.[642] Neurosteroids are classified as pregnane (allopregnanolone, allotetrahydrodeoxycorticosterone [THDOC]), androstane (androstanediol, etiocholanone), and sulfated (pregnenolone sulfate, dehydroepiandrosterone sulfate [DHEAS]) neurosteroids. Most research on neurosteroids has been focused on pregnenolone, progesterone, 5α-dihydroprogesterone, allopregnanolone, dehydroepiandrosterone (DHEA), and THDOC.[643,644] They are crucial for neuronal and glial plasticity, excitability, myelination, synaptic transmission, and organization of brain connectivity. DHEA is produced in the adrenal gland cortex, gonads, and neural tissue, and its main function is to serve as a precursor for the synthesis of androgens and estrogens. DHEA is the most abundant steroid in circulation, and most is in the form of DHEA sulfate, with concentrations being around 300 times higher than free DHEA.

The effects of neuroactive steroids on the CNS are mediated by classic and nonclassic pathways.[645] The classic actions are mediated by nuclear receptors leading to changes in gene transcription. This is considered the traditional mechanism by which steroids work. The nonclassic actions are rapid and involve steroid binding to cell membrane receptors including the γ-aminobutyric acid (GABA) type A receptor ($GABA_A$ receptor [$GABA_AR$]), the *N*-methyl-D-aspartate receptor (NMDAR), the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)/kainate receptor, the 5-hydroxytryptamine type 3 (5HT3) receptor, and the sigma-1 receptor (σ1R).[645-648] There are also membrane-specific progesterone receptors (mPRs), which are G protein–coupled receptors that bind progestins. There is evidence that mPRs mediate the neuroprotective effects of progesterone and allopregnanolone by promoting cell survival and suppressing apoptosis.[649] These receptors are mainly expressed in neurons but are also present in astrocytes. $GABA_A$ receptors are widely distributed on neurons and astrocytes where they mediate the actions of neurosteroids during ischemia, brain injury, and ammonia-induced cytotoxicity. $GABA_A$ receptors are members of the ligand-gated ion channel superfamily that is coupled to the chloride channel. Opening of chloride channels in neurons causes membrane hyperpolarization and inhibition of neuronal activity, reducing neurotransmission and propagation of the action potential.

Neurosteroids modulate the acute stress response and HPAA balance by downregulating CRH and ACTH gene transcription.[643,644] However, under chronic stress, HPAA modulation by neurosteroids may be impaired due to reduced neuronal and glial 5α-reductase activity and subsequent reduction in allopregnanolone concentrations. Neurosteroid concentrations in the CNS vary dynamically depending on physiologic and pathologic conditions, including stress, anxiety, depression, and other disorders.[643] Neurosteroids may be neuroprotective during cell injury from acute hypoxia and trauma.[642,644] Both neurons and glial cells (astrocytes and oligodendrocytes) have the enzymatic machinery for de novo neurosteroid synthesis or conversion of peripheral

steroids (e.g., progesterone) into neuroactive metabolites (see Fig. 16.17).[650]

Progesterone is considered a reproductive hormone mainly produced by ovarian luteal cells and the placenta. Progesterone is also synthesized in the adrenal gland as a precursor for various adrenocortical hormones. De novo synthesis of progesterone also occurs in the CNS where it acts directly as a neurosteroid, but it can also be converted to other steroids that influence neuronal and glial activity (see Fig. 16.17).[642] Allopregnanolone is synthesized from progesterone in a two-step process that requires 5α-reductase and 3α-hydroxysteroid dehydrogenase. These enzymes are highly expressed in brain regions where GABAergic and glutamatergic neurons are present.[643,651] Peripherally, allopregnanolone is produced in the adrenal cortex and gonads. THDOC is a 21-hydroxylated derivative of deoxycorticosterone with similar properties. The major source of THDOC in the brain following stress is the adrenal cortex. Allopregnanolone and THDOC are deemed the most important neurosteroids. They have inhibitory actions including sedation, anticonvulsant effects, and anxiolytic effects and have been implicated with behavioral conditions such as bipolar disorder in humans.[652]

Sulfated neuroactive steroids such as pregnenolone sulfate and DHEAs are mainly excitatory, with anxiogenic and proconvulsant functions.[650] DHEA is a positive allosteric modulator of the NMDAR, a negative allosteric modulator of the $GABA_A$, and an agonist of σ1R. Allopregnanolone and similar steroids (THDOC) are positive allosteric modulators of the $GABA_A$ receptor but have minimal action on NMDA and AMPA receptors, which are excitatory and mediate neurotoxicity and cell death.[650] Progesterone, on the other hand, acts through nuclear and membrane receptors (NMDAR, $GABA_AR$, mPRs).[653]

Altered $GABA_A$ receptor function has been proposed as a cause of neurologic dysfunction in people (e.g., autism spectrum disorder). In immature fetal neurons, the $GABA_A$ receptor is a primary excitatory receptor.[654,655] However, just before birth, there is a transient reduction in intracellular chloride concentrations leading to an excitatory-to-inhibitory switch in the $GABA_A$ receptor. This shift in $GABA_A$ receptor signaling is in part mediated by oxytocin.[654,655] It is possible that a similar process might be involved in the pathogenesis of neonatal maladjustment syndrome in foals. Interestingly, high oxytocin, progesterone, 17α-hydroxyprogesterone, and pregnenolone concentrations on admission were associated with neurologic dysfunction in hospitalized neonatal foals.[656]

In addition to neurologic diseases, allopregnanolone and THDOC have been associated with systemic disorders such as hepatic encephalopathy (HE) and obesity.[657] The mechanisms responsible for increased neurosteroids in the brain of people with HE remain unknown, but upregulation of translocator protein TSPO (cholesterol-transporter protein) after exposure to ammonia and manganese has been proposed.[658] With regard to obesity, several neurosteroids have been associated with food intake. Allopregnanolone increased the consumption of calorie-dense food in rodents and was linked with obesity in girls.[659,660] The association of neurosteroids with HE and obesity in horses remains to be investigated.

Neuroactive Steroids and Equine Disease

Compared with other species, maturation of the HPAA in equine neonates occurs late in gestation and continues in the postnatal period.[573,661] Activity of the HPAA in the equine fetus increases 25 to 5 days before delivery.[573] As a result, the adrenal cortex develops morphologically and releases high concentrations of pregnenolone, which is converted to several progestogens by the placenta. In the last 5 days of gestation, the equine fetal adrenal cortex begins expressing 17α-hydroxylase that is required for cortisol production from progesterone.[573] Neonatal foals have high pregnane concentrations at birth that decrease gradually over the first 48 hours after foaling.[623,662] Increased pregnane and neuroactive concentrations have been associated with disease severity, neurologic abnormalities (neonatal maladjustment syndrome [NMS]), prematurity, and mortality in hospitalized foals.[623,624,656,662-665]

The mechanisms leading to pregnane elevation in critically ill foals remain unknown, although it has been proposed that high neurosteroid concentrations are a consequence of altered transition from intrauterine to extrauterine life, with subsequent neurologic dysfunction.[666] Based on their effects on $GABA_A$ receptors and pharmacologic evidence that steroid agonists can suppress neuronal function, exogenous compounds have been developed for veterinary and medical use (e.g., alphaxalone [alfaxalone]). Under this premise, one can speculate that increased steroid concentrations in sick foals can suppress neuronal activity inducing neurologic signs. To further elucidate their importance in neuronal and glial function in sick foals, neurosteroid measurements in the cerebrospinal fluid will be necessary.

Neurosteroid balance in the peripartum period could potentially explain many clinical abnormalities in these foals.[662,664,666] After all, increased neurosteroid levels at the end of gestation promote neuronal development and protect against hypoxia and ischemia.[667] It remains to be determined whether progestogen increase in critically ill foals represents a neuroprotective response to injury or a consequence of the disease. Progesterone and 17α-hydroxyprogesterone concentrations are higher in critically ill than in healthy and sick nonseptic foals.[623,656] Based on these findings and the fact that mPR-mediated actions of progestins are neuroprotective,[649] one can speculate that these steroids may have protective functions in sick foals.

Increased and decreased neuroactive steroid concentrations could be detrimental to neuronal function, depending on the condition and steroids involved. Compounds with GABAergic activity, as well as steroidogenic enzyme inhibitors (trilostane, finasteride, indomethacin), have been developed and some are under clinical evaluation for neurologic disorders (see Fig. 16.17). For example, ganaxolone, a derivative of allopregnanolone, is a selective positive allosteric modulator of the $GABA_A$ receptor under trial for the treatment of epilepsy, anxiety, and other neurologic disorders.[651] Alphaxalone is a neuroactive steroid and potent $GABA_A$ receptor agonist used as an anesthetic in dogs, cats, and horses.[668,669] Finasteride and dutasteride are 5α-reductase inhibitors used for alopecia and prostatic hypertrophy in men.[670] These compounds block the conversion of testosterone to 5α-dihydrotestosterone but also the conversion of progesterone to 5α-dihydroprogesterone, a key precursor for allopregnanolone. Under this premise we can speculate that if high concentrations of progesterone derivatives are involved in the pathogenesis of NMS, reducing their concentrations in the CNS could be beneficial. On the other hand, if progesterone derivatives are neuroprotective, blocking some of these pathways could be detrimental. This remains to be evaluated prospectively in sick foals with and without evidence of neurologic disease.

Trilostane is a competitive 3β-hydroxysteroid dehydrogenase inhibitor that blocks conversion of pregnenolone to progesterone, reducing cortisol synthesis.[671,672] Finasteride blocks terminal steps in the allopregnanolone synthesis; however, trilostane inhibits the second reaction in the steroidogenesis that may cause more side effects associated with adrenal steroid deficiency.

OTHER DISORDERS OF THE ADRENAL GLAND

Hyperadrenocorticism

Hyperadrenocorticism from pituitary pars intermedia dysfunction (PPID; equine Cushing disease) is discussed elsewhere in this chapter. Iatrogenic and adrenal hyperadrenocorticism is less common than pituitary-dependent hyperadrenocorticism (PPID) but has been described in horses.[673-675] Iatrogenic hyperadrenocorticism was induced in a horse treated for a pruritic skin condition after inject on of 12 mg of triamcinolone acetonide followed by two injections of 200 mg of the same compound, all within 6 weeks.[673] Clinical signs included depression, polyuria/polydipsia, weight loss, and laminitis. Blood and urinalysis abnormalities (neutrophilia, lymphopenia, hyperglycemia, glycosuria) were similar to those of PPID. However, this horse also had increased serum activity of γ-glutamyl transferase, aspartate transaminase, and bile acid concentrations, indicating steroid-induced hepatopathy.

The diagnosis of iatrogenic hyperadrenocorticism is based on clinical history, low baseline ACTH and cortisol concentrations, and a low cortisol response to the ACTH-stimulation test. Treatment consists of discontinuing exogenous steroids and perhaps replacement therapy with short-acting steroids.

One case of pituitary-independent (adrenal-dependent) hyperadrenocorticism has been documented.[675] In this case, a 12-year-old gelding presented with clinical signs of pituitary-dependent hyperadrenocorticism. Baseline cortisol and ACTH concentrations were within the normal range, and the cortisol response to the ACTH-stimulation test was normal. The horse was treated with bromocriptine with no improvement, and over the next 11 months the clinical signs worsened. On necropsy, an adrenocortical adenoma associated with pituitary gland and contralateral adrenal gland atrophy was present.

Adrenocortical Neoplasia

Adrenocortical tumors are rare in horses,[234,675-677] and the few cases reported in the literature were nonfunctional tumors. One case of a 12-year-old Dutch Warmblood gelding with a functional adrenocortical adenoma and clinical signs consistent with Cushing disease (hyperadrenocorticism) was recently reported.[675] Adrenocortical carcinoma characterized as a locally aggressive primary tumor with multiple metastases to abdominal and thoracic organs, lymph nodes, and proximal humerus has been describe in an 18-year-old Thoroughbred gelding and a 14-year-old Quarter Horse stallion.[234,678]

Pheochromocytoma

Pheochromocytomas are tumors that arise from the chromaffin cells of the adrenal medulla, which are part of the sympathochromaffin system (together with the sympathetic nervous system). During fetal life the chromaffin cells are associated with the sympathetic ganglia, and after birth most of them degenerate, and the few remaining cells constitute the adrenal medulla. In humans, approximately 90% of pheochromocytomas arise from the adrenal medulla and often are associated with a condition known as multiple endocrine neoplasia (MEN).[679,680] Extraadrenal pheochromocytomas have been described in humans but not in horses. In horses, these tumors have low incidence of malignancy and are usually unilateral.[681,682] Pheochromocytomas (functional and nonfunctional) are rare in horses, with a postmortem examination incidence of 0.95%.[680] Functional pheochromocytomas secrete catecholamines at a rate sufficient to cause clinical signs.[682] Thus functional pheochromocytomas are diagnosed with more frequency than nonfunctional pheochromocytomas.[680,683] It has been shown that most equine pheochromocytomas are nonfunctional and go undiagnosed.[680,684] Both epinephrine and norepinephrine have been identified as the catecholamines produced by equine pheochromocytomas.[685]

Functional pheochromocytomas in horses have no breed or gender predilection[682] and have been described in horses with a median age of 17 years (range, 13–38).[680,683,686] Because clinical signs are of acute onset and of rapid progression from intense adrenergic stimulation, they resemble those of colic, rhabdomyolysis, acute laminitis, enterocolitis, and hyperkalemic periodic paralysis. Clinical signs include abdominal pain from large hematomas or gastrointestinal distention secondary to ileus, anxiety, tachycardia, tachypnea, profuse sweating, muscle tremors, hyperthermia, dry and pale mucous membranes, increased capillary refill time, ataxia, and mydriasis.[680,682,683,686] Abortion has been documented. Clinical signs from nonfunctional pheochromocytomas in general are consistent with abdominal pain, and the median age of those horses is 27 years (range, 16–27 years).[680,682-684,686]

Hematologic abnormalities of functional pheochromocytomas include hemoconcentration, stress leukogram (mature neutrophilia with lymphopenia),[686] and leukopenia with neutropenia.[683] Hemoconcentration likely results from epinephrine-induced splenic contraction rather than dehydration.[683,684,686] Epinephrine and epinephrine-induced steroid release may be responsible for the stress leukogram. Serum biochemical abnormalities are nonspecific and include hyperlactatemia, hyperglycemia, azotemia, metabolic acidosis, hyponatremia, hyperkalemia, hypocalcemia, and hyperphosphatemia.[680,682,686] Hyperlactatemia may have been associated with catecholamine-mediated vasoconstriction or hemorrhagic shock in horses with hemoperitoneum, as well as the metabolic effects of catecholamines on gluconeogenesis. Hyperglycemia is a likely consequence of increased α- and β-adrenergic activity.[679] Hyponatremia with hyperkalemia, hypocalcemia, and hyperphosphatemia suggests acute renal failure; however, renal function in most reported cases was normal.[683,684] Hyperkalemia, hypocalcemia, and hyperphosphatemia could be from prolonged muscle activity, ischemia, and metabolic acidosis.[682-684,686] Hyperkalemia is unlikely to be from increased catecholamine concentrations as catecholamines induce hypokalemia by shifting potassium to the intracellular compartment (β-receptor mediated) and by increasing the activity of the renin-angiotensin-aldosterone system.[687] Glucosuria is also a frequent finding. Pheochromocytomas may secrete other hormones of neuroendocrine origin (calcitonin, parathyroid hormone, ACTH, CRH, somatostatin, vasoactive intestinal peptide, leu-enkephalin)[683,688-690]; however, they remain to be determined in horses.

The clinician should be aware that this condition carries a poor prognosis, and euthanasia may be a reasonable decision. Measurement of blood catecholamines or their metabolites in urine is valuable in establishing a diagnosis; however, this assessment can be a challenge and most laboratories do not measure these hormones.[682,683,686,691] Ultrasonography and measurement of blood pressure can support the diagnosis.[680]

If a diagnosis is reached, adrenalectomy can be attempted; however, the location of the adrenal glands, as well as the proximity of major blood vessels, tumor size, and arrhythmias (interaction between catecholamines and anesthetic agents),[684] make this a difficult decision.[682,684,686] Hypotensive α-adrenergic antagonists such as phentolamine, phenoxybenzamine hydrochloride, and prazosin hydrochloride are used in humans with functional pheochromocytomas before surgery.

Functional pheochromocytomas in horses do not appear to metastasize, are unilateral, and tend to bleed, and at necropsy the tumor is frequently found to be ruptured. Myocardial infarction and degeneration may be present, probably as a result of increased concentrations of catecholamines.[682-684]

Malignant pheochromocytomas have been documented in young and old horses.[526,692] A malignant pheochromocytoma was reported in a 6-month-old filly with a history of hindlimb lameness and spinal cord disease.[692] Both adrenal glands had multiple and well-circumscribed yellow masses and metastases were found in the liver, lungs, vertebral canal, left scapula, and azygous vein. A malignant pheochromocytoma was also diagnosed in a 22-year-old mare that died of massive intrauterine hemorrhage.[526] This mare also had a thyroid C-cell medullary adenoma and bilateral nodular hyperplasia of the adrenal medulla, findings that were consistent with MEN. This was the first documented case of MEN in the horse, although previous reports have been consistent with MEN.[525] A retrospective study found concurrent endocrine abnormalities including thyroid adenoma, adrenal hyperplasia, PPID, and C-cell carcinoma in 73% of horses diagnosed with pheochromocytoma postmortem. Twenty-one percent of those horses had changes consistent with MEN.[680]

The Equine Endocrine Pancreas

Teresa A. Burns and Ramiro E. Toribio

ANATOMY OF THE ENDOCRINE PANCREAS

The pancreas lies mainly on the right, in the very dorsal part of the abdomen. It has a triangular shape, composed of left and right lobes and a body. The body lies within the sigmoid flexure of the duodenum and has two regions (duodenal and intermediate). The lobes are less distinguishable than those of other species. The left lobe is longer than the right, crosses the midline, and abuts the stomach. The right lobe is close to the descending duodenum, in contact with both the right kidney and the base of the cecum. The ventral surface is attached to the right dorsal colon and base of the cecum. The dorsal surface is in direct contact with the right kidney and the liver. The portal vein perforates the pancreas at the pancreatic ring. Both the pancreatic and accessory ducts persist throughout development in equids. Exocrine pancreatic secretion is virtually constant but increases after feeding. This provides the small and large intestines with a steady supply of buffered solution, which facilitates digestion and creates a favorable environment for the microbiota. The distribution of islets of Langerhans, as well as their cellular composition, varies with location in the horse.[693,694] Islets in the left and right lobes and intermediate region contain a central mass of α-cells surrounded by β-cells, with few δ- and γ-cells.[694] Islets in the duodenal region are smaller compared with the rest of the pancreas, containing mostly β- and δ-cells but scarce α-cells. Some islets in the right lobe and duodenal region are abundant in γ-cells.[694] Regardless of location within the pancreas, α-cells are located mostly within the center of the islets, β-cells form a ring around the α-cells, and δ- and γ-cells are interspersed.[693,694] Changes in islet cell distribution with age have been documented in horses but are not well characterized otherwise (including the effect of disease).[695]

PHYSIOLOGY OF THE ENDOCRINE PANCREAS: GENERAL CONCEPTS

The regulation of energy metabolism requires coordination among different systems, including the hypothalamus, pituitary gland, gastrointestinal tract, liver, skeletal muscle, adipose tissue, and pancreas. The endocrine pancreas is the chief controller of energy homeostasis by sensing energy status and releasing hormones that facilitate energy storage during excess and promote energy release when demands increase. Pancreatic hormone secretion is influenced by endocrine and paracrine factors, metabolites (glucose, amino acids), and the autonomic nervous system. Dysfunction of the endocrine pancreas is associated with loss of glycemic control and can accompany a multitude of disorders.

The islets of Langerhans are the endocrine functional units of the pancreas. Each islet contains four primary cell types (α-, β-, δ-, and γ-cells)—α-cells secrete glucagon, β-cells secrete insulin, δ-cells secrete somatostatin, and γ-cells (PP-cells) secrete pancreatic polypeptide (PP). The β-cells also secrete urocortin-3 and C-peptide, whose functions are described later. Insulin and glucagon are considered the primary pancreatic hormones. Blood glucose and amino acid concentrations are important regulators of insulin and glucagon secretion. Insulin release is stimulated by glucose, glucagon, some amino acids, and incretin hormones (although not all to the same degree; glucose remains the primary and most profound insulin secretagogue), and it is suppressed by somatostatin. Glucagon secretion increases with hypoglycemia. Pancreatic endocrine function is also regulated by sympathetic and parasympathetic fibers through the actions of norepinephrine, epinephrine, and acetylcholine. The sympathetic system inhibits insulin and stimulates glucagon secretion, and the parasympathetic system stimulates insulin secretion during food intake.[696,697] There are CNS mechanisms that regulate insulin and glucagon secretion; however, specific pathways by which they influence the endocrine pancreas remain unclear.

Glycogenolysis is the release of glucose from stored glycogen in response to metabolic demands. Insulin suppresses glycogenolysis by activating protein phosphatase–1 and phosphodiesterase and inhibiting glycogen phosphorylase. This process is enhanced by glucagon and epinephrine. Insulin also promotes glycolysis through activation of protein phosphatase–1 and

pyruvate kinase. *Glycolysis* is a cytosolic enzymatic process in which glucose is converted into two molecules of pyruvate to generate energy (ATP) in the absence of oxygen. Through glycolysis, glucose is converted into fructose 1,6-bisphosphate (trapping), which is cleaved into phosphorylated three-carbon products that generate energy (ATP) during their oxidation to pyruvate. *Glycogenesis* is the synthesis of glycogen from glucose when energy is present in excess (in the form of glucose or ATP) to be stored in the liver and/or skeletal muscle. *Gluconeogenesis* is the synthesis of glucose from noncarbohydrate substrates such as glycogenic amino acids (e.g., alanine, glutamine, arginine, serine), triglycerides (glycerol), pyruvate, and lactate. In ruminants, as a result of the metabolic activity of the ruminal microbiota, gluconeogenesis is virtually constant using propionate as the primary substrate. The goal of gluconeogenesis is to maintain blood glucose concentration within a relatively narrow (physiologic) range during fasting or exercise. In other species, it is often linked to ketosis. It mainly occurs in the liver and kidney, with some in the brain and skeletal muscle. Insulin promotes glycogenesis and inhibits glycogenolysis and gluconeogenesis.

Insulin is the primary hormone controlling energy metabolism and storage. Its actions involve three major organic substrates (carbohydrates, proteins, and fats) and three major tissues (liver, skeletal muscle, and adipose tissue). In the liver, insulin decreases glycogenolysis, gluconeogenesis, and ketogenesis and stimulates glycogenesis, glycolysis, and fatty acid synthesis. In *adipose tissue,* insulin decreases lipolysis and stimulates fatty acid uptake, synthesis, and esterification. Hormone-sensitive lipase is an intracellular enzyme expressed in adipose and steroidogenic tissues, and its function is to mobilize stored fats through the hydrolysis of triglycerides into fatty acids. It is also important for cholesterol release from cholesteryl esters during steroidogenesis. Its activity is suppressed by insulin during energy excess and stimulated by catecholamines, adrenocorticotropic hormone (ACTH), and glucagon when energy needs increase. In *skeletal muscle,* insulin decreases proteolysis and amino acid output and increases glucose and amino acid uptake, protein synthesis, and glycogen synthesis.[698] Insulin increases the activity of adipocyte and endothelial cell lipoprotein lipase, which mediates lipoprotein (e.g., VLDL) uptake and triglyceride hydrolysis. Deficiency or mutations in lipoprotein lipase are associated with hypertriglyceridemia in other species,[699,700] although triglyceride overproduction rather than removal seems to be the main reason for hyperlipemia in ponies.[701,702] Other functions of insulin include modulation of vascular compliance, intracellular K^+ shift via Na^+/K^+ ATPase, cellular phosphate uptake, and DNA synthesis.

The main sites for insulin clearance are the liver and the kidneys. Most insulin released by the pancreas is cleared by the liver at the first passage, whereas the kidneys may be more relevant for removing insulin from systemic circulation, at least in other species.[703] Insulin removal does not necessarily imply degradation, as some receptor-bound insulin is released by the cell back into circulation.[703] Information on the kinetics (half-life, compartmental modeling) of endogenous equine insulin is limited. For humans, using the hyperinsulinemic euglycemic clamp technique, a five-compartment model has been proposed in which endogenous insulin has a mean residence time of 71 minutes: bound to hepatic receptors for 62 minutes, attached to peripheral receptors for 6 minutes, and persisting in the extracellular fluid for 3 minutes.[704] It has also been estimated that approximately 80% of total insulin is bound to hepatic receptors, suggesting that the liver is the largest reservoir for insulin.[704]

The connecting peptide (C-peptide) is the sequence within proinsulin that links the A- and B-chains of insulin. After a series of steps within the Golgi apparatus, C-peptide is removed, stored, and released with insulin in equimolar amounts. Traditionally, C-peptide has been measured as a byproduct of insulin processing as an indicator of β-cell function because unlike insulin, C-peptide is minimally metabolized by the liver. Insulin and C-peptide have different kinetics, with insulin half-life measured over the course of a few minutes, whereas C-peptide's half-life is around 30 minutes.[705] There is evidence that C-peptide is not an inert molecule but has physiologic functions, most of which remain to be elucidated.[705] It binds to a pertussis-toxin–sensitive G-protein–coupled receptor with high affinity.[705] Animal studies have shown that C-peptide ameliorates some of the complications of type 1 diabetes, including nephropathy and neuropathy.[705,706] It is believed that a major function of C-peptide is to promote normal endothelial and microvascular function. It decreases the formation of reactive oxygen species through adenosine monophosphate–activated protein kinase (AMPK), enhances nitric oxide production, reduces leukocyte adhesion, lowers proinflammatory cytokine release, and has antiapoptotic actions.[705,706] It also appears that C-peptide promotes glucose utilization and contributes to the actions of insulin at peripheral tissues. This effect does not seem to be direct but rather through facilitation of insulin-initiated signaling cascades.[705,706]

This information could be relevant to our understanding of the pathogenesis of equine disorders such as equine metabolic syndrome (EMS), pituitary pars intermedia dysfunction (PPID), hyperlipemia, and polysaccharide storage myopathy.

Glucagon has opposing effects to those of insulin on glucose metabolism. Its main targets are the liver and adipose tissue. Its key function is to increase glucose concentrations during hypoglycemia by promoting glycogenolysis and gluconeogenesis. By suppressing glycolysis, glucagon shifts intermediates to the gluconeogenic pathway. In adipose tissue, it enhances lipolysis, although this seems to be a minor effect. Glucagon secretion is stimulated by hypoglycemia, catecholamines, acetylcholine, cholecystokinin, and glucose-dependent insulinotropic polypeptide (GIP). Autonomic inputs promoting glucagon secretion are stimulated by hypoglycemia. Glucagon synthesis is suppressed by insulin, somatostatin, hyperglycemia, and neural inputs, some of which are at the hypothalamic level.[707]

Pancreatic polypeptide is secreted by the γ-cells (PP-cells), and its chief function is to reduce appetite. It also slows gastrointestinal motility, delays gastric emptying, and reduces ghrelin secretion. Vagal cholinergic activation is the main stimulus for PP secretion. Gastrin, motilin, vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), ghrelin, and hypoglycemia also increase PP secretion. Somatostatin, glucocorticoids, and hyperglycemia inhibit PP secretion.

Catecholamines inhibit glucose-stimulated insulin secretion and raise glucose concentrations, both directly through hepatic effects and indirectly via modulation of glucagon secretion.

Growth hormone (GH) has a multitude of functions what will not be comprehensively discussed here. It counteracts insulin's actions on glucose and lipid metabolism and is

important in setting the basal glucose concentrations (glucostat).[698,708] There is extensive research supporting positive effects of GH on islet cells. It is involved in maintaining β-cell mass, promoting islet endocrine secretion, and contributing to normal insulin sensitivity and glucose homeostasis.[709] Most actions of GH have been attributed to insulin-like growth factor–1 (IGF-1; somatomedin-C), which is mainly synthesized by the liver (somatomedin hypothesis). Although this concept remains valid, it is also true that many GH actions are independent of IGF-1. This appears to be the case for GH's effects on the endocrine pancreas, where GH receptors are present in the β-cells whereas IGF-1 receptors are localized to endothelial and α-cells.[709] Despite these positive effects of GH on the islets of Langerhans, in peripheral tissue GH promotes insulin resistance, in part by uncoupling phosphatidylinositol 3-kinase, reducing phosphorylation of the insulin receptor and insulin receptor substrate–1 (IRS-1).[710] GH also mediates lipolysis during fasting, which seems to be a direct effect and also a consequence of interfering with insulin signaling.

Somatostatin (SST), or growth hormone–inhibiting hormone (GHIH), is a peptide produced in the hypothalamus, endocrine pancreas, proximal duodenum, and pylorus. Axons from hypothalamic SST neurons descend through the median eminence and terminate at the level of the pituitary portal venous system, from where SST will reach pituitary somatotropes to suppress GH secretion.[711] Hypothalamic SST neurons respond to high GH and IGF-1 concentrations by releasing SST as part of a feedback system. These neurons are also activated by hyperglycemia, adding another explanation for the suppressive effects of glucose on GH secretion.[712] In the pituitary gland, SST also inhibits the secretion of thyroid-stimulating hormone (TSH) and prolactin (PRL). SST may suppress ACTH secretion in other species, but information in the horse is lacking. Multiple SST agonists (octreotide, lanreotide, and pasireotide) have been developed to suppress GH, PRL, and TSH secretion in humans with acromegaly/gigantism, prolactinomas, and thyrotropinomas. In the endocrine pancreas, SST inhibits insulin, glucagon, and PP secretion. SST secretion is stimulated by urocortin-3, a peptide coreleased with insulin by the β-cells as part of the paracrine negative feedback system for glycemic control.[713] Urocortin-3 deficiency results in impaired SST secretion and exaggerated insulin secretion, creating an imbalance that has been linked to the pathophysiology of diabetes.[713] Abnormal SST has other actions within the gastrointestinal tract (reduces motility and exocrine pancreas secretion) and enteroendocrine system (inhibits most gastrointestinal hormones). Because of its multitude of actions on the pituitary gland, gastrointestinal tract, and endocrine pancreas, and considering that metabolic disorders linked to insulin dysregulation are well documented in the horse (EMS, PPID, hyperlipemia), the role of hypothalamic and pancreatic SST deserves investigation in this species.

The *enteroinsular axis* comprises enteroendocrine factors known as incretins (INtestinal seCRETion of INsulin) that regulate the secretion of pancreatic hormones. Incretins include glucagon-like peptide–1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP; gastric inhibitory polypeptide), which promote insulin release and suppress glucagon secretion.[714,715] In other species, GIP is secreted by K cells in the proximal small intestine and GLP-1 by L cells in the distal small intestine.[714,715] Soluble carbohydrates, amino acids, and fatty acids promote incretin secretion. There are also neurogenic factors influencing incretin secretion. The incretin effect explains the rise in insulin concentrations before there is an increase in glycemia, which has been proposed to be a preemptive mechanism to avoid hyperglycemia and facilitate rapid peripheral glucose uptake. GLP-1 and GIP also have a multitude of nonpancreatic functions; they slow gastric emptying and acid secretion (GLP-1 in particular), promote fat deposition, enhance insulin sensitivity, modulate skeletal muscle metabolism, stimulate bone formation, increase microvascular blood flow, and reduce appetite.[714,716] Understanding the physiology of enteroendocrine cells and the gut-pancreatic-brain axis has become a major area of research, in particular to develop therapeutic strategies to modulate incretin activity in diabetes, obesity, and hypertension.[717] From all this information, it is reasonable to assume that incretin dysregulation may contribute to equine conditions related to metabolic activity, insulin secretion and sensitivity, nutrient uptake, inflammation, obesity, and satiety. There is evidence that equids have a functional enteroinsular axis.[718-721] Oral and IV soluble carbohydrates increase GIP, GLP-1, and insulin secretion in horses and ponies,[718-721] and these effects are more evident for oral than IV glucose administration.[719] Relevant to EMS and endocrinopathic laminitis, it was recently shown that insulin-resistant ponies have a hyperresponsive enteroinsular axis to oral and IV glucose.[719]

The *hypothalamic-pituitary-adrenal axis (HPAA),* specifically ACTH and cortisol, has been shown to influence β-cell function.[722] This was recently documented in foals overexposed to glucocorticoids in response to ACTH administration that had a reduced insulin response to glucose stimulation.[722] Increased free cortisol concentrations have been associated with hyperinsulinemia in horses with endocrine disease.[723] Thyroid hormones are also essential for the differentiation of other endocrine organs, including the pancreas and adrenal cortex. It is reasonable to assume that low thyroid hormone concentrations in late gestation could result in abnormal β-cell function and energy dysregulation. Insulin, through induction of hypoglycemia, also influences all levels of the equine HPAA in horses and donkeys.[724,725] Insulin administration to healthy horses increased corticotropin-releasing hormone, arginine vasopressin, ACTH, and cortisol release.[725]

Information on the role of the CNS in regulating the equine endocrine pancreas is lacking; however, it is reasonable to assume that neurologic abnormalities may contribute to disorders of insulin secretion and sensitivity (e.g., EMS, PPID). In rats, for example, before glucose enters the small intestine following consumption of a meal, insulin is secreted secondary to activity in neural inputs that appear to originate in the taste buds.[726,727] In addition, there are glucose-sensing mechanisms at the gastric, hepatic, and hypothalamic levels that are not linked to incretins.[727,728] Rodent peripheral and central ablation studies have shown that the hypothalamus senses and regulates glycemia (brain–endocrine pancreas axis) via insulin and glucagon secretion.[728,729] The parasympathetic tone to maintain β-cell proliferation and function is increased with lesions of the ventral hypothalamus, supporting the importance of vagal control.[728]

THE EQUINE ENDOCRINE PANCREAS

Relatively little is known about pancreatic physiology and pathophysiology in equids. Not only are primary pancreatic diseases reportedly rare in horses and ponies,[194] the organ itself is difficult to access for antemortem anatomic and

physiologic evaluation, sampling, or imaging. Insulin resistance (IR) and resultant hyperinsulinemia have emerged in recent years as risk factors for the development of endocrinopathic laminitis in horses and ponies based on results of several cross-sectional epizootiologic studies.[730-731] Further, experimental hyperinsulinemia has been shown to induce laminitis in normally insulin-sensitive horses and ponies.[732,733] Therefore, although the mechanistic role of insulin in the pathophysiology of laminitis remains incompletely characterized, the emerging importance of this hormone to various equine diseases is clear. It is well known that insulin resistance in equids can result in hyperinsulinemia; however, it is unknown whether this observation results from enhanced insulin secretion, decreased insulin clearance, or both. It has been proposed that hyperinsulinemia in horses with PPID results from high cortisol concentrations, whereas hyperinsulinemia in horses with EMS is a consequence of local (adipose, hepatic, lamellae) production of cortisol from inactive cortisone via 11β-hydroxysteroid dehydrogenase.[734] Administration of medications, such as glucocorticoids, has been associated with IR in horses and ponies,[735,736] likely from peripheral mechanisms rather than direct actions on the endocrine pancreas. Taking into consideration that IR is a risk factor for equine laminitis and glucocorticoids reduce insulin sensitivity, this may be a potential explanation for the development of laminitis in horses and ponies after glucocorticoid administration (not reliably reproduced experimentally, however). Functional studies will be required to clarify the importance of these mechanisms to equine IR, hyperinsulinemia, and EMS. These studies are challenging for many reasons, not the least of which are described next.

The ontogeny of equine endocrine pancreatic function has been evaluated in several studies.[737-739] The equine endocrine pancreas is functional before birth. Pancreatic β-cell maturation in the equine fetus occurs in late gestation,[739] but insulin is detectable by day 150.[738] Before day 230, glucose has no effect on fetal insulin release; however, after day 290, glucose administration evokes a rapid insulin response.[739] Fetal pancreatic insulin secretion is linked to cortisol concentrations, with a more rapid and profound insulin release observed in foals with higher cortisol concentrations near term.[739] Premature foals with low cortisol concentrations have a poor insulin response to glucose stimulation.[739,740] Variations in intrauterine growth rate have been shown to affect postnatal insulin secretion in the horse.[741] Overgrowth, not growth retardation, in utero alters equine β-cell function in the immediate neonatal period and leads to higher baseline insulin concentrations and greater insulinemic responses to glucose in affected foals.[741] Equine β-cells are responsive to glucose and arginine and release both insulin and proinsulin during the immediate postnatal period.[742] Immediately after birth, the equine β-cells are responsive to glucose administration; however, foals develop physiologic insulin resistance on the first day after birth that is likely related to high cortisol concentrations,[742] as they become very responsive days later.[740] Circumstances surrounding delivery during foaling have been shown to influence pancreatic endocrine function in foals; foals born following induction of labor have decreased insulinemic responses to glucose infusion, and this finding is correlated with a twofold to threefold increase in plasma cortisol concentration in induced foals.[743] Sex appears to play a role in the acute pancreatic response to glucose in neonatal and weanling-age foals, as filly foals were noted to have a more profound insulinemic response to glucose infusion than colt foals, even though their glucose disposal rates were similar (suggesting IR in female foals relative to their male counterparts).[744] These same authors also showed that HPAA activation may affect pancreatic insulin secretion in neonatal and weanling foals, with foals treated with ACTH daily for 5 days after foaling displaying lower insulinemic responses to glucose infusion than untreated foals.[722] This is further supported by another study in which both pregnant mares treated with dexamethasone and their foals had altered insulin dynamics following maternal treatment.[744] Another factor that could influence postnatal pancreatic β-cell function is nutrition. Insulin secretion and β-cell sensitivity to glucose were enhanced in foals born to mares that had experienced caloric restriction during midgestation.[745] Pancreatic α-cells are also functional in utero in the equine fetus, producing glucagon; however, this secretion is responsive to arginine but unresponsive to glycemia until the postnatal period.[746]

As mentioned earlier (see section on anatomy of endocrine pancreas), the pancreas is a markedly heterogeneous organ.[747] It has both exocrine and endocrine functions, with endocrine islets of Langerhans interspersed within exocrine acinar tissue. The size and distribution of islets have been shown to be quite heterogeneous across the pancreas in other species,[747] varying with both age of the animal and anatomic location of the sampled tissue (e.g., from the head, tail, or body of the pancreas); this also appears to be true in equidae.[693,694] To increase the validity of conclusions drawn from studies of islet morphology and function in horses (important for further characterization of the β-cell's role in initiation and perpetuation of equine IR), pancreatic samples of similar size should be collected from a similar anatomic location in all subjects. As the equine pancreas is often somewhat amorphous and difficult to locate within the abdomen (even during a postmortem examination), this may be a difficult task.

The endocrine tissue of the pancreas is surrounded by exocrine acinar pancreatic tissue, which is rich in proteases, lipases, amylases, and nucleases. This makes sensitive and labile analytes, such as RNA, easily degraded during extraction from pancreatic tissue homogenates, complicating gene expression studies. Additionally, autodigestion of pancreatic tissue is reported to be rapid at room temperature, requiring prompt and appropriate handling (i.e., small tissue sections to ensure rapid fixation) of pancreatic samples that are to be processed for histologic studies. Further, this propensity for autodigestion has been linked to clinical signs of pancreatic disease (such as severe abdominal pain) and the development of hypocalcemia in affected individuals associated with enzymatic saponification of regional fat. Finally, the pancreas is difficult to access surgically for antemortem sampling in the adult horse because of its location within the abdomen. Even if it were easily accessible, pancreatic biopsies are associated with a greater risk of causing iatrogenic tissue injury than other tissues as a result of the high enzymatic content and risk of pancreatitis. For these reasons, studies that involve collection of fresh pancreatic tissue in horses, although needed to advance our knowledge of equine pancreatic physiology, are practically difficult. Studies of pancreatic hormone secretion are similarly complicated; pancreatic endocrine hormones are secreted into the pancreatic veins, which coalesce to join the portal vein. A hepatic first-pass effect on pancreatic secretions complicates any assessment of these secretions that is based on sampling of peripheral venous blood. To adequately

characterize pancreatic insulin secretion—the contribution of which to equine hyperinsulinemia and IR remains incompletely described—cannulation of the portal vein and collection of postpancreatic, prehepatic blood samples would be very useful.

INSULIN SECRETION FROM THE ENDOCRINE PANCREAS

Following ingestion of a meal, the nutrient components are broken down into their respective elements by salivary, gastric, pancreatic, and intestinal enzymatic activity. Although an average grain meal (e.g., a 10% sweet feed preparation) for horses contains protein, lipid, and carbohydrate, the majority of the ration is carbohydrate (especially starch and simple sugars). Degradation of dietary starch and sugars to hexoses (glucose, galactose, and fructose) results in their absorption by simple and facilitated diffusion (cotransport with sodium) across the gastrointestinal mucosa into the portal venous blood and ultimately the systemic circulation. Although the appearance of other diet-derived substances in blood (such as certain amino acids) can induce pancreatic insulin secretion, the postprandial increase in plasma glucose concentration is a potent (and the most physiologically important) secretagogue for insulin from the β-cells of the endocrine pancreas. For the past 30 years, it has been held that transport of glucose into the β-cell (primarily through the non–insulin-dependent glucose transport proteins GLUT2 and GLUT1) during times of hyperglycemia results in increased glycolysis and ATP production. An ATP-responsive potassium channel is present on the plasma membrane of the β-cell; increased cytosolic ATP concentrations ultimately result in inhibition of this channel, reducing potassium conductance from the β-cell and resulting in relative depolarization of the cell. Increased activation of voltage-gated calcium channels on the plasma membrane and increased calcium influx activates calcium-dependent mechanisms responsible for fusion of insulin-containing cytoplasmic vesicles (also containing equimolar amounts of C-peptide) with the plasma membrane, exacting insulin release into the interstitial fluid and, ultimately, the pancreatic venous blood.

Recent work in cultured islets suggests that this mechanism is likely not the only one responsible for insulin release, however. Two phases of insulin secretion are observed in response to an enteric glycemic load: an initial, rapid phase (i.e., within the first 10 minutes) and a delayed, sustained phase (i.e., beginning approximately 15 minutes after the first phase). Pharmacologic inhibition of the ATP-sensitive potassium channels described earlier significantly attenuates the initial rapid phase of insulin secretion but has limited effect on the sustained secretion observed later. Gut-derived incretin hormones (GLP-1 and GIP) are likely responsible for this second phase of sustained insulin release and, as previously mentioned, have become attractive therapeutic targets for the treatment of relative insulin deficiency in humans with type 2 diabetes mellitus. Incretins were discovered and subsequently described following the initial observation that an oral glucose load/meal would reliably elicit a twofold to threefold greater insulinemic response than a similar glucose load given intravenously (thereby bypassing the gastrointestinal tract); the incretin response is severely impaired in humans with type 2 diabetes mellitus, an abnormality that can be reconstituted surgically (through gastric bypass procedures) or pharmacologically (through the administration of GLP-1 analogs [such as exendin-4 homologs, e.g., exenetide] or inhibitors of the enzyme that degrades incretins, dipeptidyl peptidase-4 [such as sitagliptin]).

Factors that are likely to modify this response in a horse consuming a meal of concentrate feed include, first, the composition of the meal, particularly its "glycemic index." The *glycemic index* is technically a term applied to human foodstuffs and is defined as the ability of a specific dose of the food in question to raise blood sugar compared with a similar quantity of white bread. This has been modified somewhat for use in equine nutrition, and the "relative" glycemic indices of certain cereal grains have been reported (e.g., the glycemic response of the horse to a corn meal is higher than that to one of barley). Because postprandial plasma glucose concentration is the most physiologically important secretagogue for insulin, the ability of the ingested meal to raise plasma glucose concentration would be expected to have a profound effect on the insulinemic response to that meal. This is exploited therapeutically in the dietary management of horses and ponies with EMS, as attempts are made to minimize the amount of nonstructural carbohydrate (NSC) in their diets and subsequent postprandial hyperinsulinemia.

The functional pancreatic β-cell mass, which correlates with the insulinemic response to enteral and IV glucose challenges in experimental animals, is an important variable to consider when evaluating an animal's insulinemic response to a meal. This has not been effectively characterized in equine populations, but β-cell failure (insufficient insulin response to carbohydrate challenge) appears to be uncommon in this species. Further, β-cell mass is virtually impossible to measure accurately in vivo (and presents challenges ex vivo); it can be measured experimentally, which may shed light on the mechanisms by which equine β-cell function is preserved in the setting of prolonged hyperinsulinemia (where type 2 diabetes would be expected to develop in humans).

The relative insulin sensitivity of the primary insulin-responsive tissues (skeletal muscle, liver, and adipose tissue), which are responsible for the majority of postprandial glucose disposal, has important ramifications for the insulin secretory response. Animals that are systemically insulin resistant show decreased glucose disposal from the plasma following a meal, and they display increased plasma fatty acid concentrations in both the fasting and fed states (decreased insulin-mediated inhibition of hormone-sensitive lipase in adipose tissue, decreased inhibition of hepatic synthesis and secretion of VLDL). Experimental glucotoxicity, lipotoxicity, or both have been shown to decrease insulin secretion from cultured islets in vitro over the course of several hours of glucose and lipid incubation or infusion; the mechanism for this remains to be clarified, but given that metabolic cycling of pyruvate metabolites (i.e., isocitrate-malate, citrate-malate, pyruvate-malate) is suspected to be involved in insulin secretion, the dramatic addition of metabolites to these pathways can be expected to affect this outcome (insulin secretion). Additionally, the expression and functionality of incretin receptors on β-cells have been shown to be blunted in the setting of insulin resistance; again, the mechanism for this is unclear, but this is an active area of investigation in human medicine. Finally, although the pancreas is not responsible for a large amount of insulin-dependent glucose disposal, it is insulin responsive; insulin receptor signaling is thought to be involved in

pancreatic insulin secretion, which may become dysfunctional in the setting of systemic insulin resistance (the relative importance of which is completely unknown in horses and ponies currently).

DISEASES

Diabetes Mellitus

As mentioned, diabetes mellitus is very uncommon in equids, much less common than in humans and other domestic species (such as dogs and cats). That said, the condition has been documented in horses, and it may occur more frequently than has been previously reported; whether this represents a true increase in the incidence of the disease or an increase in detection capability and/or awareness is unclear. Type 1 diabetes mellitus (insulin-dependent) was diagnosed in a 5-year-old Thoroughbred mare, for whom glycemic control was successfully achieved for 18 months following diagnosis through the administration of exogenous insulin. At necropsy following the mare's spontaneous death, lymphocytic infiltration of the pancreas (along with several other endocrine organs) was noted, suggesting an immune-mediated component to the condition.[604] Type 2 diabetes mellitus (non–insulin dependent) has been described in a Spanish Mustang.[748] Frequently sampled insulin-modified glucose tolerance testing with minimal model analysis has been used to diagnose the disease in three horses of another report, clearly documenting not only severe systemic IR but also blunted acute insulin response to glucose; the cases described in this report responded positively to medical management with diet modification, metformin, glibenclamide, and pergolide and experienced restored euglycemia.[749]

ROLE OF THE EQUINE PANCREAS IN EQUINE METABOLIC SYNDROME

Obesity, insulin resistance, and endocrinopathic laminitis have emerged as critical issues in equine medicine, causing significant morbidity, mortality, and economic loss to the equine industry.[750,751] In obese humans and experimental rodent models of nutritional obesity, systemic insulin resistance and hyperinsulinemia are followed temporally in a majority of individuals by decreased glucose tolerance, pancreatic β-cell failure, and type 2 diabetes mellitus.[752] The mechanisms by which this occurs are not completely understood; however, investigations in recent years have revealed that progressive changes in both the function and morphology (particularly increased insulin production/secretion and β-cell hyperplasia) of the endocrine pancreas occur over time in response to conditions known to increase risk for type 2 diabetes mellitus, such as genetic or nutritionally induced obesity,[64,65] high-carbohydrate feeding,[755] and high-fat feeding.[754] Failure of increased insulin secretion and β-cell hyperplasia in response to these stimuli is considered a hallmark of type 2 diabetes mellitus.[756]

In stark contrast to humans, obese horses and ponies with systemic IR chronically remain in what is termed a "prediabetic" state in human IR, characterized by hyperinsulinemic euglycemia.[757] Although increased pancreatic insulin secretion has been suggested to be responsible for the hyperinsulinemia resulting from systemic insulin resistance in equids (and evidence exists for increased pancreatic insulin secretion in response to glucose infusion in insulin-resistant equids),[758] the contribution of altered hepatic insulin clearance to increased basal insulin concentrations in these animals has been poorly characterized to date.[759] Endocrine pancreatic function (and dysfunction) would seem to be critically important to the pathophysiology of EMS, but surprisingly little information exists describing the biology of the equine endocrine pancreas in the chronically insulin-resistant equid.

Although alterations in pancreatic islet morphology are well characterized in the states of obesity and systemic insulin resistance in other species,[756] particularly in response to high-glucose diets or infusions,[755] these alterations do not appear to occur in the obese, insulin-resistant equid. Pancreatic β-cell hyperplasia has been reported to occur in the setting of the obese, chronically insulin-resistant human and rodent before the onset of secretory failure and type 2 diabetes mellitus.[747,753,760] However, this morphologic change in the pancreatic islets has also been reported to occur in response to parenteral glucose infusions over the course of as few as 6 days.[755] No association was found between body condition score or systemic insulin sensitivity and pancreatic histomorphometry in ponies in one study[761]; similarly, there was no association between pancreatic insulin content measured by ELISA and pancreatic histomorphometry, body condition score, or systemic insulin sensitivity. The results did not support morphologic changes in the equine endocrine pancreas following short-term high-carbohydrate feeding.

Given the relatively modest changes in pancreatic islet surface area that accompany marked increases in serum insulin concentrations in ponies fed a high-NSC diet, it seems important to assess both β-cell function and insulin clearance mechanisms in future studies to delineate the mechanism(s) of hyperinsulinemia in this species. Systemic IR and subsequent basal and postprandial hyperinsulinemia have been increasingly well characterized in equids over the past decade.[762-764] Hyperinsulinemia in this setting has been broadly assumed to be the result of pancreatic hypersecretion in response to hyperglycemia[731,765,766]; however, this has not been quantified well to date. Plasma insulin concentration is regulated not only by the rate of pancreatic insulin secretion (which is initially increased in the setting of systemic insulin resistance secondary to β-cell hyperplasia) but also by the rate of hepatic insulin clearance. Attempts have been made to clarify the role of hepatic insulin clearance in the setting of hyperinsulinemia in horses via assessment of plasma C-peptide concentrations following a frequently sampled IV insulin-modified glucose tolerance test.[759] However, although the results suggest that insulin clearance decreases as pancreatic secretion of insulin increases in response to dextrose infusion (supporting a role for altered clearance in hyperinsulinemia), this study was performed on a small number of horses, and the conclusions drawn should therefore be considered preliminary. Further study, including a more specific assessment of pancreatic insulin secretion (possibly through sampling of portal venous blood following administration of an insulin secretagogue), needs to be performed to further clarify this issue, which is important as it speaks directly to the pathophysiology of EMS in horses and ponies. Further, understanding the physiology of the equine endocrine pancreas in the setting of chronic systemic insulin resistance may shed light on why it is that IR in horses (analogous to "prediabetes" in humans) uncommonly progresses

to overt type 2 diabetes mellitus. Comparative, translational research on this subject may ultimately yield benefits for both veterinary and human medicine.

PANCREAS AND PITUITARY PARS INTERMEDIA DYSFUNCTION

Insulin resistance as a consequence of PPID is poorly understood. A number of horses with PPID have increased insulin concentrations,[433] but this could be reflective of excessive glucocorticoid secretion, POMC-peptides interfering with insulin signaling, or central mechanisms that influence β-cell function.

Pancreatitis

Pancreatitis, though common in other species (such as cats, dogs, and humans), appears to be an uncommonly diagnosed clinical entity in equids. This may in part be due to the fact that it is rather difficult to make this diagnosis in horses and ponies antemortem due to the lack of available definitive diagnostic tests; most published case reports of equine pancreatic disease describe a diagnosis made at necropsy.[193,194,767,768] When it does occur, however, gross and histologic features of pancreatitis in horses are reported to be similar to other species; for example, a Friesian gelding who was euthanized for chronic colic was diagnosed with chronic fibrosing pancreatitis with acinar-ductal metaplasia and ductal dysplasia, common preneoplastic changes found in humans.[767] An apparent breed, age, or sex predisposition has not been described, but conditions such as grain overload, endocrine disease (especially PPID), and parasite migration have been associated with pancreatitis in equids.[194] Additional associations have been made between pancreatitis in horses and gastrointestinal,[193,768] reproductive,[193,769] and endocrine disease.[193] Retrospective evaluation of pancreatitis cases diagnosed postmortem suggests that most cases of pancreatitis in this species are secondary or associated with another condition; however, 6 out of 43 horses in one study were diagnosed with primary pancreatitis, and therefore it seems that clinicians should at the very least be aware of this possibility.[193] The disease has also been reported in very young foals, suggesting that horses of widely variable demographics are susceptible.[192,195,770] Clinical findings reported to be most common among horses with acute pancreatitis include colic, nasogastric reflux, gastric dilation, peritonitis, and abdominal fat necrosis.[193] Evaluation of serum and peritoneal fluid lipase and amylase activities may be helpful in supporting a diagnosis, and at least one report of successful treatment of a horse with acute pancreatitis has been published.[771] More careful monitoring and diagnostic evaluation in the future may reveal pancreatitis to be more common in equidae than previously assumed.

Neoplasia

Pancreatic neoplasia, like other pancreatic disease, appears to be uncommon to rare in equidae. Exocrine pancreatic adenocarcinoma appears to be the most common tumor type, having been reported in several horses[772-775]; occasional patients have had widely disseminated disease.[774,775] Endocrine pancreatic tumors have also been reported in the horse, but again, these appear to be quite rare. Multiple glucagon-producing pancreatic neuroendocrine tumors were diagnosed in one horse,[776] and a pony with recurrent bouts of hypoglycemia was found to have multiple islet tumors and hyperinsulinism.[777]

Insulin Dysregulation and Equine Metabolic Syndrome*

Teresa A. Burns and Ramiro E. Toribio

INTRODUCTION

Obesity and insulin resistance/dysregulation (IR) are increasingly important problems in both human and veterinary medicine, and complications associated with obesity (such as type 2 diabetes mellitus, cardiovascular disease, and certain neoplasms) are diagnosed frequently in many species. Correlations have been drawn between the pathophysiology of obesity in humans to that in horses, and although similarities do exist, so do prominent species differences. Pituitary pars intermedia dysfunction (PPID; also called equine Cushing syndrome) and equine metabolic syndrome (EMS) are the two most common endocrine disorders diagnosed in horses. PPID affects older horses, whereas EMS typically develops in young and middle-aged animals. Horses with EMS often exhibit a predisposition toward obesity that becomes evident when they reach maturity, and this problem is aggravated by environmental conditions that involve high-carbohydrate feeding and/or promote weight gain. IR is a key feature of EMS and the primary reason for the condition receiving the assignation as an endocrine disorder. However, IR also occurs in a subset of patients with PPID, as well as in the setting of other systemic diseases (such as endotoxemia and sepsis); IR is therefore a clinicopathologic finding and not a disease per se. Laminitis is the most important complication of EMS, and early recognition of at-risk equids might improve detection and prevention of this painful and frequently debilitating condition.

Human Metabolic Syndrome: A Comparative View

Definition and Overview of Human Metabolic Syndrome

Obesity in humans has long been associated with adverse effects on health. More recently, a clustering of risk factors linked to obesity has been shown to predict the onset of cardiovascular disease and type 2 diabetes mellitus in affected individuals; this syndrome of risk factors, previously known as syndrome X, the cardiometabolic syndrome, or insulin resistance syndrome, is now referred to as the human metabolic syndrome (HMS).[778] The first formal definition of HMS was created by a working group of the World Health Organization in 1998.[779] The definition adopted by this group included evidence of systemic insulin resistance and at least two additional risk factors from a list of criteria including obesity, hypertension, hypertriglyceridemia, low serum high-density lipoprotein concentration, and microalbuminuria. Although seemingly inclusive, this definition has proven to be difficult to apply globally to the many diverse disease states that involve insulin resistance (such as antiretroviral therapy for HIV/AIDS, congenital lipodystrophies, polycystic ovary syndrome, Cushing syndrome, obesity, etc.), and exceptions

* With contributions to the section on equine metabolic syndrome written by Dr. Nicholas Frank derived from the third edition of this book.

to the diagnostic criteria are easily identified, particularly by individuals working in different medical specialties caring for affected patients (e.g., cardiologists, endocrinologists, gerontologists, infectious disease specialists). Consequently, the definition of metabolic syndrome in human medicine has emerged as a somewhat controversial issue.[780,781] A joint interim statement recently issued as a collaborative effort involving the International Diabetes Federation Task Force on Epidemiology and Prevention, the National Heart, Lung, and Blood Institute, the American Heart Association, the World Heart Federation, the International Atherosclerosis Society, and the International Association for the Study of Obesity in 2009 suggested that the diagnosis of metabolic syndrome be made in an individual who displayed three out of the following five criteria: hypertension, hypertriglyceridemia, lowered high-density lipoprotein cholesterol, elevated fasting plasma glucose concentration, and central/truncal obesity.[782] Of these diagnostic criteria, this collaboration emphasized the importance of *body/adipose tissue morphometrics* (waist circumference, as a proxy for central/truncal obesity) as a useful screening tool for at-risk patients. The value of establishing a uniform set of diagnostic criteria to guide physicians in their management of these patients is based on both the severity of the adverse sequelae of metabolic syndrome (creating urgency to identify at-risk individuals for the purpose of prevention of these events), and the large (and increasing) number of patients affected globally; clear correlations with the management of obese equids in equine veterinary medicine can be noted here.

From an epidemiologic perspective, obesity and its associated metabolic and cardiovascular consequences have emerged over the past 10 to 15 years as critically important disease states in human medicine worldwide, creating an increasing economic burden on the health care systems of developed nations.[783] In fact, in the United States and the United Kingdom, two thirds of all adults are reported to be either overweight or obese[784-786]; accompanying this finding are increasing rates of atherothrombotic cardiovascular disease, stroke, type 2 diabetes mellitus (and all of its associated comorbidities), degenerative joint disease, and certain types of neoplastic diseases.[787,788] Perhaps more alarming is the ballooning rate of obesity among young people in industrialized countries[789,790]; in fact, the current generation of school-age children has been projected to have a life expectancy shorter than that of their parents, which is historically unprecedented.[791] Clearly, obesity is a critical health care issue in human medicine, both for the well-being of human populations and for the prioritization of the spending of increasingly limited health care funding allocations. With this economic imperative, a strong research effort has been put forth in recent years to elucidate risk factors for systemic insulin resistance and the metabolic syndrome in humans and to characterize the role that the expanded adipose tissue itself may play in the pathogenesis of the cardiometabolic sequelae of the syndrome.

Equine Metabolic Syndrome

Definition and Overview of Equine Metabolic Syndrome

Equine veterinarians have long known from clinical experience that overweight and obese horses are prone to developing laminitis. Similar to humans, obesity in horses has also been associated with peripheral insulin dysregulation/resistance.[437,766] As HMS was increasingly well described in the medical literature, correlations were drawn between this syndrome of obese humans and that noted clinically in obese horses.[792] Over time, the equine syndrome of obesity (particularly regional adiposity), peripheral insulin resistance, dyslipidemia, and an increased risk of endocrinopathic laminitis was coined the *equine metabolic syndrome* (EMS).[437,792]

The ACVIM Consensus Statement on EMS published in 2010[757] collated and synthesized most of the available research and evidence regarding this condition in horses and ponies, identifying three primary criteria for the diagnosis of EMS: increased adiposity (generalized, regional, or both, with emphasis placed on nuchal ligament and tail head adipose tissue accumulations), systemic insulin resistance (assessed in a variety of ways; see later discussion), and a predisposition to laminitis in the absence of another risk factor for the condition, such as septic disease[793] or gross enteral carbohydrate overload.[794,795] Other factors that have been reportedly associated with EMS, such as hyperleptinemia,[436,796,796] reduced adiponectin concentrations,[798] high incretin concentrations,[718,719] seasonally increased mean arterial blood pressure,[799] and altered reproductive cyclicity in mares,[800] were not included in the currently accepted diagnostic criteria. Based on recent and ongoing research findings, it is likely that these (and other) factors will be incorporated into the forthcoming definition and classification of EMS. Although the currently accepted criteria have all been subjected to reasonable objective evaluation, there remain potential flaws in their interpretation (methodology, sensitivity, etc.) that decrease their accuracy in laminitis risk prediction. Even the definition of the outcome variable, laminitis, may be ambiguous under certain circumstances.

Horses affected with EMS are typically overweight to obese, with body condition scores (BCSs) ranging from 7.0 to 9.0.[436,437,801] All breeds may be affected, although most reports indicate that breed predispositions exist, with pony breeds, Morgans, Tennessee Walking Horses, American Saddlebreds, Spanish Mustangs, Andalusians and other Spanish breeds, and Warmblood breeds overrepresented[802,803] Phenotypically and clinically, the condition is also common in Paso Fino, Criollo, and other Spanish-derived breeds in Latin America. Within at-risk breeds, affected individuals often display pronounced regional adiposity, particularly over the nuchal ligament and tailhead.[804] One report suggests that morphometric assessment of the neck of insulin-resistant horses (which incorporates assessment of the degree of nuchal ligament adiposity) can differentiate these horses from insulin-sensitive horses,[437] Interestingly, although the degree of insulin resistance has been shown to correlate reasonably well with body weight in horses,[765,766] not all obese horses are insulin resistant. Conversely, some relatively lean horses may be profoundly insulin resistant, particularly if they are members of a predisposed breed. Similar observations have been made in human medicine, and abnormalities in adipocyte function have been implicated in some of the more severe forms of insulin resistance (e.g., congenital lipodystrophy).[805] The underlying physiologic mechanisms that predispose some breeds to EMS have not yet been elucidated, but it is a tenable hypothesis that some facet of adipocyte structure and/or function is involved, at least in part. It has been suggested that components of the somatotropic axis (e.g., somatostatin) may be implicated in equine insulin dysregulation or that pancreatic cells are refractory to autoregulatory mechanisms that control insulin secretion.[806] Somatostatin is a peptide expressed by hypothalamic

neuroendocrine cells and suppresses growth hormone secretion by the pituitary gland. It is also secreted by delta cells in the pylorus/duodenum and endocrine pancreas and inhibits insulin and glucagon secretion. Under the premise that pancreatic endocrine dysregulation is involved in the pathogenesis of EMS, octreotide, a somatostatin analog, was administered to horses to assess their insulin regulation status (octreotide response test). Octreotide suppressed insulin secretion, although this effect was less evident in horses with insulin dysregulation; these findings support lack of β-cell inhibition as a potential mechanism for equine hyperinsulinemia.[806]

It is important to emphasize that the association between morphometric variables and IR is breed dependent, and although general principles apply, extrapolating from one to another type of equid may not reflect their insulin sensitivity and regulatory status.[807] It is possible (even likely) that reference ranges for interpretation of laboratory assessments of insulin dysregulation that are breed (and species) specific will be created in the future to improve the ability of clinicians to predict both disease and laminitic complications from these data.

Unlike humans with metabolic syndrome, horses with EMS do not appear to suffer from significant cardiovascular complications of their metabolic dysfunction. Although one report suggests that insulin-resistant ponies may be hypertensive,[799] no concrete evidence of cardiovascular complications related to EMS has been published. However, these horses are at increased risk for the development of laminitis,[436,808] which has been suggested (but not confirmed) to share an inflammatory pathophysiology with the more severe cardiovascular complications of obese humans, specifically, atherosclerotic coronary artery disease.[809,810] Several studies have revealed a robust correlation between markers of EMS in ponies (namely, BCS, plasma triglyceride concentration, and degree of insulin resistance) and the incidence of pasture-associated laminitis, which is perhaps the most common manifestation of endocrinopathic laminitis in horses.[436,730] In fact, the presence of more than three clinical findings of EMS in one study correctly predicted the development of laminitis in 11 of 13 ponies when these animals were exposed to a high-starch pasture.[730] Anecdotal evidence supports the contention that EMS is perceived by many equine veterinarians to be the most common cause of laminitis.

Insulin resistance in humans is often associated with increased plasma concentrations of certain markers of inflammation (notably TNF-α and IL-1β), linking abnormal carbohydrate metabolism in these people with chronic, low-grade inflammation.[811] This phenomenon has also been described in veterinary species, including dogs, mice, rats, and horses.[812,813] Obesity and insulin resistance have been loosely positively correlated with plasma concentrations of TNF-α and IL-1β in horses,[813] and several authors have suggested (based on tissue and systemic concentrations of inflammatory mediators) that EMS is associated with a systemic, low-grade inflammatory state.[813-815] The cause of laminitis in insulin-resistant equids is unknown but has been postulated to be related to a chronic proinflammatory state associated with insulin resistance[816]; this has yet to be documented conclusively in the horse, and evidence exists supporting the contention that the laminar lesions of EMS-associated laminitis are minimally inflammatory, at least acutely.[817]

Although much of the characterization for the diagnostic criteria for EMS has been performed in research animals, these criteria are meant to be applied to clinical patients for the purpose of guiding their medical care. Improving the accuracy of the diagnostic criteria will hopefully improve laminitis prevention, and improving the ease of diagnostic sample collection would potentially increase testing of general equine populations (and thus data collection, which may also be useful for research purposes). Increasing the predictive value of EMS diagnostic criteria and increasing the ease of sample collection (by validating single time point blood samples or by validating diagnostic evaluation of easily sampled tissues, such as nuchal ligament adipose tissue, skeletal muscle, or liver) would be reasonable steps to take to improve the diagnostic criteria for EMS.

The diagnosis of EMS is meant to define risk of laminitis in horses and ponies; adequate assessment of this risk requires measuring the incidence of laminitis in cohorts separated by various risk factors. Although small prospective studies on inbred populations of ponies have been performed evaluating the incidence of laminitis following exposure to pasture,[436,730] this work has not been repeated on a larger scale (or with more genetically diverse equine populations). Additionally, the same criteria defining laminitis risk in the aforementioned cohort of inbred ponies are extrapolated to light breed horses, populations on which this same type of study has not been performed. Large, prospective cohort studies (somewhat akin to the Framingham Cohort,[818] a seminal study defining risk factors for coronary artery disease and myocardial infarction in humans that has spanned several decades) would lend validation to (and perhaps reveal more accurately predictive) risk factors for endocrinopathic laminitis related to obesity in equids. If performed in conjunction with certain breed registries (breeds predisposed [gaited breeds, ponies, mules, donkeys] and breeds not predisposed [Quarter Horses, Thoroughbreds], e.g.,), data might be collected on individual animals over the lifetime of the animal (at shows, etc.). Documentation of familial tendencies and, ultimately, identification of candidate genes through linkage analyses, may lead to recognition of specific genetic determinants of abnormal carbohydrate or lipid metabolism (mitochondrial biogenesis, insulin degrading enzyme, insulin receptor [IR], anti-IR antibodies, PI3K, etc.) in horses and ponies.

Serum biomarkers that have positive correlation with metabolic risk have been fairly well characterized in human populations; although initial work incorporating serum biomarkers (such as leptin and insulin) into a "prelaminitic metabolic syndrome" has been done in ponies,[436,730] these studies have not evaluated the biomarkers that are most tightly correlated with IR in humans (namely, C-reactive protein,[811,819] plasminogen activator inhibitor–1,[820,821] serum amyloid A,[822,823] adiponectin,[824] and resistin[825,826]). Identification of additional serum biomarkers of laminitis risk, such as might be done through the long-term cohort studies mentioned earlier, might allow construction of a panel of analytes that could be easily measured in a single serum sample (adipokines, serum inflammatory proteins, proinflammatory cytokines, etc.). Again, this would require evaluation in large populations of horses (light breed horses, ponies, donkeys, and mules; predisposed breeds and nonpredisposed breeds), including evaluation of response to dietary challenge, evaluation of season, and correlation with incidence of laminitis in response to pasture exposure. Validated serum sampling protocols would increase the ease of diagnostic testing for EMS and might thereby increase the frequency of testing performed by practitioners on field cases.

Ideally, validation of serum biomarkers or a panel of such to predict IR should be performed against a gold standard.

When reviewing the equine literature on diagnostic testing of insulin and glucose dynamics, there appears to be no such gold standard (or if so, it is in name only). Insulin sensitivity is assessed by equine researchers with a diverse range of techniques[763,764]; to more cohesively move the field forward, a consensus needs to be reached on how this testing should be done. Direct comparison of the commonly used techniques (fasting insulin and glucose concentration with minimal model proxies,[731] combined glucose-insulin test [CGIT],[827] and oral glucose tolerance test [OGTT][828]) in the same cohort of horses (insulin-resistant [IR] and insulin-sensitive [IS]) to a gold standard (euglycemic-hyperinsulinemic clamp [EHC] and/or frequently sampled insulin-modified IV glucose tolerance test [FSIGTT]) should be performed to evaluate their relative benefits and shortcomings. Achievement of consensus on best laboratory testing protocol to define IR in horses (that is clinically feasible) is required to advance the field.

It has become clear in human obesity and IR that the relative roles of skeletal muscle and hepatic insulin resistance may not be equivalent. In fact, hepatic insulin resistance appears to correlate better with systemic IR and adverse disease outcomes in people than does skeletal muscle IR. EHC protocols using different insulin infusion rates (lower rate for assessing skeletal muscle IR; higher rate for assessing hepatic IR) have been described to evaluate the differential role of these tissues, and these may have some benefit in evaluation of equine IR (as the respective contributions of liver and skeletal muscle in this population remains unclear). Additionally, the role of ectopic lipid—which has been shown to correlate with systemic insulin resistance and risk outcome more tightly in humans and rodents than degree, or even location, of adipose tissue—in the pathophysiology of equine IR remains poorly described (even though a significant disease associated with equine IR, hyperlipemia, is defined by ectopic lipid accumulation). The relative ease of sampling of equine skeletal muscle and liver by minimally invasive techniques and the importance of these tissues to the pathophysiology of human metabolic syndrome makes this an attractive future possibility for diagnostic evaluation of equids with EMS.

Definitions

Insulin dysregulation/resistance refers to the failure of tissues to respond normally to insulin and/or altered insulin clearance. Skeletal muscle and adipose tissues are affected because they are two important sites for insulin-mediated glucose disposal. The liver also responds to insulin. Gluconeogenesis is inhibited and glycogen synthesis promoted as blood insulin levels rise after feeding. It should also be recognized that up to 50% of the insulin secreted by the pancreas is cleared by the liver as blood circulates through this organ before entering the systemic circulation. Hyperinsulinemia may therefore reflect increased insulin secretion, reduced insulin clearance, or a combination of these mechanisms.

Compensated insulin resistance is a term used when hyperinsulinemia is detected in an animal with reduced insulin sensitivity.[731] Insulin secretion from the pancreas increases to compensate for reduced tissue sensitivity, and euglycemia is maintained. However, recent reports suggest that resting hyperinsulinemia cannot be attributed to increased insulin secretion in all cases, which suggests that insulin clearance may be affected in some animals.[759]

Uncompensated insulin resistance refers to reduced insulin sensitivity with hyperglycemia. Insulin concentrations may be elevated or within reference range, and it is assumed that uncompensated IR develops as a result of pancreatic insufficiency in equids as in other species (although not with the same frequency, however). Compensated IR is the most common form of IR in horses and ponies, but uncompensated IR should be considered when elevated blood glucose concentrations are detected. It is appropriate to use the term *type 2 diabetes mellitus* when hyperglycemia and glucosuria are present, and this condition has been recognized in horses.[748,829,830]

As mentioned, equine metabolic syndrome is characterized by (1) obesity or regional adiposity, (2) insulin resistance, and (3) subclinical or clinical laminitis.[792] Hypertriglyceridemia has also been associated with EMS, and blood leptin concentrations are often elevated in affected animals.[437,730] Leptin is a hormone released by adipose tissue that signals the hypothalamus to suppress appetite after feed consumption. Plasma leptin concentrations generally correlate with BCS and degree of adiposity, but elevated levels are sometimes detected in leaner horses, suggesting a state of "leptin resistance" and metabolic dysregulation.[437,831] Studies have been performed to compare horses with low or high plasma leptin concentrations, and a cutoff value of 7 ng/mL has been used to define groups.[797] Elevated systemic blood pressure has also been associated with laminitis and IR in ponies kept on pasture.[799] Mean arterial blood pressure was higher in laminitis-prone ponies when measured in the summer, but values did not differ from control ponies in the winter.

Obesity is defined as an increase in body weight as a result of excessive fat accumulation within the body. When the BCS system developed by Henneke and colleagues[832] is applied, *obesity* is defined by a BCS ≥7 on a scale of 1 to 9. Obesity and IR are associated in horses and ponies.[437,833] It must be recognized, however, that body condition scoring systems are sometimes inadequate for assessing horses with endocrine disorders. Some horses with EMS and many with PPID are thin across the ribs yet have pronounced adipose tissue deposits in the neck and tailhead regions. This accumulation of adipose tissue at specific locations is referred to as *regional adiposity.*

Laminitis is the most important component of EMS because of its negative impact on the welfare of the affected horse. It is the development of laminitis that often prompts a horse owner to seek veterinary attention, and this condition presents the greatest challenge with respect to management. Subclinical laminitis takes the form of divergent growth rings (also called "founder lines") on the hooves and radiographic evidence of third phalanx rotation or distal displacement. This is often referred to as *endocrinopathic laminitis* because of its association with EMS and PPID. The term *prelaminitic metabolic syndrome* has also been used to describe ponies that are at higher risk for developing pasture-associated laminitis because of IR.[730]

Etiology

Genetic predisposition plays an important role in the development of obesity and IR in horses. Ponies tend to be more insulin resistant than horses,[833] and certain breeds and genetic lines of horses appear to be more predisposed to obesity and IR.[437,792] Obesity can develop in horses of all breeds, but this problem appears to be more common in Morgan Horses, Paso Finos, Arabians, Saddlebreds, American Quarter Horses, and Tennessee Walking Horses (among others). Horses that are predisposed to obesity are sometimes referred to as "easy keepers," as they seem to require fewer calories to maintain body weight (sometimes excessive body weight).

Most horses or ponies with EMS are obese, and this syndrome likely begins with a genetic predisposition that affects the efficiency of nutrient disposition and metabolism. Affected animals seem to require fewer calories to maintain body weight and display an enhanced appetite. Owners often report that their horse spends more time grazing when turned out on pasture. The "easy keeper" concept is relevant to the issue of genetic susceptibility. Certain breeds or genetic lines may have undergone evolutionary adaptations to survive harsher environments, and these horses or ponies may be more efficient at converting poorer quality forages into energy. Lack of exercise likely also plays a role in the development of EMS, as exercise increases both short- and long-term insulin sensitivity.[834,835]

Genetics and environment interact when affected horses are given ad libitum access to pasture, particularly when a small number of animals are grazing on a large area. Carbohydrate intake from pasture is influenced by grazing time, the area grazed, geographic location, climate, soil quality, and season.[836] In many regions of the country, pasture grass is abundant and rich in nutrients. This is accentuated when certain types of grass are sown to improve pastures for cattle or when fertilizers are used. A second point of interaction occurs when susceptible horses are fed concentrate feed. This is unnecessary for metabolically efficient animals and promotes obesity and IR. Unfortunately, many horse owners feed grain to bring their horses in from pasture or because they perceive that their horse's quality of life is adversely affected if it is kept on a hay-only diet. It is a common mistake to feed grain to horses that are able to maintain their body condition on pasture or hay alone. Horses can also be overfed if they are fed as a group or if grain is used as a reward. Some horse owners deliberately feed their horse too much because they prefer higher BCSs, and these biases are sometimes reflected in the judging at horse-shows. Other horse owners simply fail to recognize that obesity has developed in their animal.

Finally, humans interfere with an important interaction between genetics and environment by feeding horses more grain in the winter to prevent weight loss. Seasonal weight loss is a natural occurrence in wild horses and is likely to correct problems with obesity that have developed during other times of the year.

Clinical Signs and Differential Diagnoses

Obesity is detected on physical examination of the horse and determining a BCS. A horse suffering from EMS is shown in Fig. 16.18. Regional adiposity is commonly detected in IR horses, and mean neck circumference has been negatively correlated with insulin sensitivity in obese horses with IR.[436,437,807] Neck circumference can be measured with a tape measure. These measurements are made by dividing the distance along a line from the poll to the cranial aspect of the withers (x) by 4 and measuring the circumference of the neck at three equidistant points within x (0.25x, 0.50x, and 0.75x). Expansion of the adipose tissue within the neck is commonly referred to as a "cresty neck" and, with the exception of stallions, this finding is suggestive of IR in horses.[437] Recent work investigating the relationship between neck circumference, nuchal adiposity, and plasma insulin and leptin concentrations in Andalusian horses suggests that although neck circumference measurements may be heavily influenced by sex (and do not seem to correlate with hormonal measurements well), ultrasonographic measurement of the thickness of nuchal ligament adipose tissue is not similarly influenced (and correlates well with hormone measurements).[837] Validation of ultrasonographic parameters/measurements that correlate with metabolic risk in horses would likely be clinically useful.

FIG. **16.18** Photograph of a 13-year-old Appaloosa gelding with equine metabolic syndrome. (Courtesy Dr. R. E. Toribio, The Ohio State University.)

Enlarged fat deposits may also be found close to the tailhead or appear as randomly distributed subcutaneous swellings. Geldings are sometimes presented for evaluation of preputial swelling, and mares may show enlargement of the mammary glands. Both of these problems are related to adipose tissue accumulation, which can also interfere with lymphatic return in these regions and result in local edema. Affected horses with edema in these areas (especially when they are stall restricted for extended periods of time) usually experience resolution with exercise. Supraorbital fat accumulation is also a frequent finding. Equine metabolic syndrome is sometimes recognized when horses develop other medical problems, including colic, hyperlipemia, and reproductive issues. Horses with EMS may develop pedunculated lipomas at a younger age, presumably because of additional fat surrounding the abdominal viscera. Obesity has also been associated with abnormal reproductive cycling in mares.[74]

Regional adiposity is a feature of EMS, but it must be recognized that fat redistribution is also seen in older horses with PPID. It is therefore necessary to examine the patient for clinical signs of PPID, including delayed hair coat shedding, hypertrichosis, hyperhidrosis, skeletal muscle atrophy, polyuria, polydipsia, and/or recurrent pyogenic infections.[433] Affected horses can enter a *transition state* when PPID develops in an animal that has previously been diagnosed with EMS. Delayed hair coat shedding is often the first sign of this transition, and owners should be advised to watch for this change.

Horses with EMS commonly suffer from laminitis, which is recognized when lameness is detected, hoof testers are applied to the feet, or pedal radiographs are performed. Divergent growth rings indicating abnormal hoof growth can be observed in horses with or without a history of laminitis (Fig. 16.19). Some horses are not lame on physical examination but have radiographic evidence of third phalanx rotation or distal displacement. Laminitis often first develops after the horse has been grazing on pasture grass that is rich in NSCs. This happens at times of the year when grass is abundant and growing rapidly or when responding to cooler temperatures in the fall. Owners of horses with recurrent laminitis also report

FIG. **16.19** Abnormal hoof growth (divergent growth rings) from a horse with equine metabolic syndrome and a history of chronic laminitis.

that laminitic episodes occur after changes in season or with the onset of cold weather.

Clinical Pathology

Complete blood count and serum biochemical analysis results are usually unremarkable, with the exception of plasma glucose concentrations, which are discussed later. Hyperglycemia is more commonly associated with PPID and may be accompanied by mature neutrophilia and lymphopenia. Elevated serum triglyceride concentrations are sometimes detected in ponies[730] or horses[437] with obesity and IR, but this finding is inconsistent in horses with EMS. Horses with long-standing EMS have been noted to have mildly elevated γ-glutamyl transferase activity, a change that may be associated with hepatic lipidosis.

Low resting total triiodothyronine (tT_3) and total thyroxine (tT_4) concentrations are sometimes measured in horses with EMS, but the significance of this finding has been overstated. It is a common misconception that obese horses suffer from hypothyroidism because obesity is associated with hypothyroidism in dogs and humans. However, serum thyroid hormone concentrations rise appropriately when thyrotropin-releasing hormone is injected intravenously,[603] suggesting that the hypothalamic–pituitary gland–thyroid gland axis is functioning normally in these patients. It is therefore likely that low serum thyroid hormone concentrations simply reflect responses to extrathyroidal changes in metabolism[838]. Breuhaus and colleagues[839] detected lower serum total T_4 and free T_4 concentrations in horses with systemic illness. Phenylbutazone also significantly lowers serum tT_4 concentrations in horses,[440] and this drug is commonly used to treat laminitis in horses with EMS.

DIAGNOSTIC TESTING

Equine Insulin Resistance

Clinical Assessment of Insulin Resistance in Equids

Assessment of systemic insulin resistance is thought to be critically important to the definition of EMS, particularly given the recent direct association of increased plasma insulin concentration with laminitis.[732,733] IR in equids is frequently measured both clinically and in the research setting; however, very often the methodology used in these two settings is different, making comparisons between larger, clinical, population-based studies and smaller experimental studies difficult. Measurement of fasting serum insulin concentration (in conjunction with an assessment of plasma glucose concentration) is the most common field test, based on the availability of the methodology and the ease with which a single blood sample can be collected. However, dynamic aspects of insulin and glucose dynamics may not be revealed by a single sample; a single "normal" insulin concentration (which is a parameter that also currently requires additional definition in horses and ponies) often does not predict normal insulin sensitivity in response to an oral or IV glucose challenge, many of which have not been directly compared in the same cohort of horses. Preliminary work comparing the results of the basal insulin concentration, the oral sugar test, and the combined glucose and insulin test to those of the frequently sampled insulin-modified IV glucose tolerance test (FSIGTT) in the same cohort of 12 horses revealed the basal insulin concentration and oral sugar test (OST) to have inadequate sensitivity for use as screening tests in the diagnosis of IR in light breed horses; although abnormal results of these tests strongly suggest IR, normal results do not rule out disease.[840] Validation of some of the more clinically feasible tests (such as fasting serum insulin concentrations or the combined glucose and insulin test) against the gold standards in experimental studies (the euglycemic, hyperinsulinemic clamp or the frequently sampled intravenous insulin and glucose tolerance test with minimal model kinetic analysis) would be helpful in gaining acceptance of a standard methodology in measuring IR in horses and ponies for future research and clinical use.

Several laboratory tests have been evaluated and utilized in humans and horses for the diagnosis and monitoring of IR, including fasting plasma insulin and glucose concentrations,[437,833] the oral glucose tolerance test,[833] the IV glucose tolerance test,[841] the modified IV insulin and glucose tolerance test,[437] the IV insulin tolerance test,[833] the euglycemic/hyperinsulinemic clamp technique,[842] and the FSIGTT.[763] Of these methods, only the FSIGTT and the euglycemic/hyperinsulinemic clamp technique are well-established methods for accurate quantitative assessment of insulin action.[843]

Baseline Blood Tests

The baseline blood tests most commonly employed in evaluation of IR in horses include fasting glucose and insulin concentrations (Table 16.14). Other analytes, such as leptin[436,437] and high-molecular-weight adiponectin,[844] may be validated as useful diagnostic biomarkers in the future. Lipid metabolites (such as triglycerides and free fatty acids) may also provide additional information about the degree of IR and negative energy balance, and liver enzymes may serve to identify animals that are at risk for hepatic lipidosis. As part of the routine evaluation of a horse with IR and laminitis, it is also recommended to measure resting ACTH concentrations, particularly in geriatric animals.[433]

Measuring basal blood glucose and insulin concentrations has been recommended as a screening test for EMS; however, recent work suggests that although this test is quite specific, its sensitivity is likely unacceptable for a test to be used for rule-out screening.[840] Horses should not be provided feedstuffs containing greater than 10% NSC on a dry matter basis within

TABLE **16.14 Guidelines for Interpreting Baseline Glucose and Insulin Concentrations in Blood Samples from Fasted Horses**

Glucose (mg/dL)	Insulin (μIU/mL)	Interpretation[a]
<100	<20	Not consistent with insulin resistance (IR) Retest at a later date or perform the combined glucose-insulin test (CGIT) if the equine metabolic syndrome (EMS) phenotype is recognized Address obesity if present
<100	>20	Normoglycemia with hyperinsulinemia Horse displays compensated IR; there may be an increased risk of laminitis Recommend weight management plan, diet changes, and exercise
<100	>100	Normoglycemia with marked hyperinsulinemia Severe compensated IR; increased risk of laminitis Strictly control diet and consider pharmacologic intervention
>100	>20	Horse is losing its ability to regulate glucose associated with pancreatic insufficiency Transitioning from compensated to uncompensated IR; high risk of laminitis Test for pituitary pars intermedia dysfunction (PPID)
>120	<20	Glucose levels are unregulated and pancreatic insufficiency has developed Horse suffers from uncompensated IR; high risk of laminitis Check urine glucose for evidence of diabetes mellitus and test for PPID

[a]Patient is not in pain or stressed; all feed withheld for 6 hours before sampling.

6 to 8 hours of testing in order to achieve the most accurate interpretation of the results; however, there is debate about the proper dietary preparation for assessment of insulin and glucose dynamics in equids, and recommendations will likely be further clarified in the near future. A standardized method of pretest preparatory feeding has been suggested,[804] in which the horse in question is fed one flake of grass hay (less than 10% NSC) overnight (after 10:00 PM), with blood collected in the morning (ideally between 7 and 10 AM). Blood samples should be submitted for analysis to a laboratory performing a diagnostic test validated for use in equine samples. Horses are considered to have IR if they display fasting glucose concentrations greater than 110 mg/dL (6.1 mmol/L) and fasting insulin concentrations greater than 20 μIU/mL.[804]

There are two important limitations that must be considered when using this test for IR in horses. First, environmental conditions significantly affect results, so care must be taken to collect blood samples under standardized conditions. Second, insulin assays vary between laboratories, so different laboratories yield different results. This does not mean that laboratories are using inaccurate assays; it relates instead to the method used. It is therefore very important to interpret results according to the reference range provided by the laboratory. Clinicians are advised to send samples to a single laboratory and to select one that routinely handles equine serum or plasma. An insulin concentration above the reference range (for horses) provided by the laboratory defines hyperinsulinemia and therefore suggests IR. A resting insulin concentration above 20 μIU/mL defines IR if the horse has been deprived of feed for approximately 6 hours. If hay has been fed, a cutoff value of 30 μIU/mL can be used to define IR, but it is advisable to recheck the patient after feed deprivation. Note that some laboratories report insulin concentrations in pmol/L, and an approximate conversion factor of 7 is used to convert units from μIU/mL to pmol/L (i.e., 30 μIU/mL is approximately equal to 210 pmol/L). Units of μIU/mL may also be written as mIU/L.

In one cohort of Welsh and Welsh cross ponies, resting insulin concentrations greater than 32 μIU/mL had a sensitivity and specificity to predict laminitis of 100% and 78%, respectively, when the ponies were exposed to spring pasture.[436] Fundamental to the poor specificity of these basal blood tests, it is now recognized that many EMS-affected animals that exhibit abnormal hyperinsulinemia following dynamic challenge tests (enteral or parenteral) have normal basal insulin concentrations. In one report, evaluation of basal serum insulin concentration was normal (less than 20 μIU/mL in 12 of 12 horses); according to FSIGTT with minimal model analysis, 7 of these horses were actually insulin resistant.[840] Based on these results, basal insulin concentration, although specific, has insufficient sensitivity to be used as a single screening test for IR in equids. Marked interday variation in serum insulin concentrations has also been reported and represents an additional limitation to interpretation of this test.

The glucose-to-insulin ratio can be calculated from basal insulin and glucose concentration measurements by dividing the glucose concentration in mg/dL by the insulin concentration in μIU/mL (or mIU/L). The correct units must be used, so insulin concentrations reported in pmol/L must be divided by 7 to provide values in μIU/mL. Proponents of this test consider a ratio below 10 to be indicative of IR and refer to horses with ratios less than 4.5 as severely insulin resistant or decompensated. If a glucose concentration of 90 mg/dL is assumed, these cutoff values are equivalent to serum insulin concentrations of 9 and 20 μIU/mL, respectively; these values fall within most normal reference ranges for insulin in fasted horses. Glucose-to-insulin ratios below 10 are commonly detected in healthy Quarter Horse and Tennessee Walking Horse mares, and some fall below 4.5 (N. Frank, personal communication). Use of the glucose-to-insulin ratio therefore leads to the overdiagnosis of IR in horses. One other important limitation of the glucose-to-insulin ratio is that insulin results differ between laboratories, depending on the testing procedure used. However, most laboratories use the same colorimetric assay to measure glucose, so these results are more consistent. When resting insulin concentrations are interpreted independently, the reference range for the laboratory can be used to account for differences in methodology. However, this flexibility does not exist for the glucose-to-insulin ratio because set cutoff values have been established. It is therefore conceivable that insulin results from one laboratory will cause the ratio to be low,

whereas results from another laboratory will give a ratio that falls within acceptable range. It should also be noted that glucose concentrations decrease in blood samples if there is any delay between collection and centrifugation. Finally, a horse with uncompensated IR or diabetes mellitus will have a high glucose concentration with a low insulin concentration, and this may result in a glucose-to-insulin ratio that exceeds 10 and will therefore be considered normal. Care should therefore be used in interpretation of this ratio if it is used in the diagnosis and management of IR in horses.

Proxy estimates of insulin sensitivity and pancreatic β-cell function from single measurements of glucose and insulin have been used for diagnosis of IR.[730,731,804] Suggested proxies have included the glucose-to-insulin ratio, the reciprocal of the square root of insulin (RISQI; $\text{insulin}^{-0.5}$), the quantitative insulin sensitivity check index (QUICKI; 1/[log(insulin) + log(glucose)]), the homeostatic model assessment of insulin resistance (HOMA-IR; [glucose × insulin]/22.5), and the modified insulin-to-glucose ratio (MIRG; 800 − 0.3 × [insulin − 50]^2/[glucose − 30]),[731] the latter being an estimate of pancreatic β-cell responsiveness. These proxy measurements were useful for distinguishing groups of laminitis-prone and control ponies,[731] but they did not accurately predict predisposition to laminitis in individual ponies. Seasonal variation in the proxy measurements of insulin sensitivity also have been observed, confounding interpretation.[845]

Most insulin-resistant horses maintain blood glucose concentrations within the reference ranges provided by laboratories, as they are most frequently in a state of compensated IR (hyperinsulinemic euglycemia). However, glucose concentrations may tend to be toward the high end of the reference range, and affected horses are likely to have exaggerated blood glucose responses to high-NSC feeds. It is therefore important to deprive horses of feed (preferred approach) for 6 hours or to feed only hay the night before blood collection for testing. Most reference ranges for blood glucose in adult horses include values of 80 to 120 mg/dL, with values from fasted horses expected to be between 80 and 100 mg/dL, barring a significantly stressful blood collection. A blood glucose concentration above 120 mg/dL suggests hyperglycemia. Glucose concentrations reported in mmol/L must be multiplied by 18 to convert to mg/dL.

It is important to measure blood glucose concentrations, because examining only resting insulin concentrations would not allow detection of uncompensated IR or diabetes mellitus. Insulin concentrations can return to reference range in these patients as insulin secretion decreases due to pancreatic insufficiency. However, blood glucose concentrations rise as a consequence of IR and reduced insulin secretion, so patients can be identified by the presence of hyperglycemia (and sometimes glucosuria).

Serum triglyceride concentration may be a useful test for diagnosis and monitoring of EMS patients. Increased serum triglyceride concentration was associated with the EMS phenotype in a closed herd of Welsh ponies (97.2 ± 10.7 mg/dL for ponies with previous laminitis vs. 52.3 ± 3.6 mg/dL for non-laminitic ponies).[730] In another cohort of mixed-breed ponies, animals with the EMS phenotype had higher serum triglycerides in summer but not in winter.[799] A recent multicenter collaborative study of a large cohort of horses and ponies (n > 600) has also demonstrated that serum triglyceride concentrations are higher in animals with a history of laminitis and other features of EMS.[846]

Further refinement of the case definition of EMS will likely include measured plasma or serum adipokine concentrations. Increased leptin concentrations have been associated with IR and laminitis in horses and ponies.[436,437] In one cohort of ponies, leptin concentrations greater than 7.3 ng/mL had a sensitivity and specificity of 83% and 78%, respectively, to predict laminitis.[436] However, in recent studies, serum leptin was not useful for the identification laminitis-prone animals although, consistent with previous work in horses and other species, leptin concentrations were positively correlated with body condition score.[847] Immunoassays for adiponectin and high-molecular-weight adiponectin have been validated for horse serum,[844] with concentrations being higher in lean horses and lower in EMS and laminitic horses.[848] This analyte shows diagnostic potential when the assay becomes commercially available to equine practitioners and reference ranges are validated.

Dynamic Testing for Equine Insulin Resistance

When results of basal insulin concentrations are variable or when fasting insulin concentration is normal in the face of clinical or historical findings suggestive of EMS, dynamic evaluation of insulin sensitivity is recommended. These tests are also useful to assess severity of IR, to monitor disease progression, and to evaluate response to treatment. Dynamic tests include the IV glucose tolerance test (IVGTT), the combined glucose-insulin test (CGIT), the oral glucose tolerance test (OGTT)/oral sugar test (OST), and the two-step insulin response test (IRT). Methods for quantitative assessment of insulin sensitivity, such as the euglycemic hyperinsulinemic clamp and minimal model analysis of a frequently sampled insulin-modified IV glucose tolerance test (FSIGTT), provide valuable information in the research setting, but these tests are impractical for clinical use.[804]

The IVGTT has historically been one of the most frequently used methods for assessment of glucose tolerance in the horse.[804] Horses should be held off feed for 6 to 8 hours before testing, as for basal insulin concentration assessment. Dextrose (150–300 mg/kg BW; 50% solution) is administered intravenously after collection of a baseline blood sample, and subsequent blood samples are collected every 30 minutes for 180 minutes. Blood glucose should be measured with a handheld glucometer at baseline and in all samples collected after dextrose administration (this can easily be done in a point-of-care fashion). In insulin-sensitive horses, glucose concentrations should be back to baseline values by 150 minutes after dextrose administration. Horses with elevated blood glucose concentration at 180 minutes are likely to have IR. This test can be simplified for field use by collecting samples at 0, 150, and 180 minutes after dextrose administration.

The CGIT has been designed to assess insulin sensitivity by determining the time when blood glucose concentrations return to baseline values after the administration of simultaneous IV boluses of dextrose and insulin.[804] An IV catheter is placed before testing. The horse is fasted as for baseline insulin concentration assessment. After collection of a baseline blood sample, dextrose (150 mg/kg BW; 50% solution) is administered intravenously and immediately followed by IV injection of regular insulin (0.1 IU/kg BW). Blood samples are collected at 0, 1, 5, 15, 25, 35, 45, 60, 75, 90, 105, 120, 135, and 150 minutes to measure glucose concentrations. Insulin concentration can be measured in a sample collected 45 minutes

after administration. A horse is considered to have IR if blood glucose concentration is above baseline or insulin concentration is greater than 100 μIU/mL 45 minutes after dextrose administration (Fig. 16.20). This test can be performed in the field, with glucose concentrations measured stall-side with a handheld glucometer. Hypoglycemia may complicate this test, especially in insulin-sensitive individuals, and dextrose solution should be available to treat affected horses if needed. A modification of this test that may be more clinically useful for on-farm use is to collect a baseline blood sample, administer the proscribed doses of dextrose and insulin, and measure glucose and insulin concentrations 45 minutes after administration (with the results interpreted as previously outlined). Extrapolating the equine CGIT to donkeys and likely ponies can be misleading.[90] In insulin-sensitive donkeys, the glucose curve is shifted to the right, reaching nadir at 120 minutes compared with 75 minutes for horses, taking 240 minutes for glucose concentrations to return to baseline compared with 150 minutes for horses.[827,849] Moreover, 45 minutes after insulin administration, donkeys could have glucose concentrations above baseline, which under equine reference criteria would categorize them as insulin resistant.[849] This indicates that for an equivalent glucose and insulin dose, insulin-mediated glucose uptake (and perhaps pancreatic insulin release) in donkeys is delayed, supporting evolutionary differences in insulin sensitivity between equid species.

The OST has recently been recommended as a preferred method for dynamic assessment of insulin dysregulation in clinical settings. Light corn syrup is administered at a dosage of 15 mL per 100 kg BW after fasting as described earlier for other tests. Blood samples are collected 60 and 90 minutes after corn syrup administration for measurement of glucose and insulin concentrations. Animals that have insulin concentration greater than 60 μIU/mL at 60 or 90 minutes after administration are likely IR. Additionally, blood glucose concentrations greater than 125 mg/dL at 60 or 90 minutes are considered excessive and associated with IR.

An in-feed OGTT has also been described for use in the diagnosis of EMS. The horse is fed a meal of dextrose powder (1 g/kg BW) mixed with a small amount (about 1 lb or 450 g) of a low-glycemic feedstuff (hay chaff). A blood sample for measurement of insulin concentration is collected 2 hours after feeding; values greater than 85 μIU/mL are considered abnormal. For both the OST and in-feed OGTT, owners may be concerned about laminitis risk associated with the administration of sugar/glucose to insulin-resistant animals; however, this risk appears to be very small based on clinical experience. Additionally, investigators who have administered hundreds of OSTs to horses and ponies for epidemiologic and genetic studies of EMS have reported no new laminitic episodes immediately after testing (Dr. Jane Manfredi, personal communication); the risk appears to be very low.

A two-step insulin tolerance test has been designed in which the blood glucose response to an IV injection of insulin (0.1 U/kg regular human insulin) is assessed. Blood glucose concentration is measured at baseline and 30 minutes after injection of insulin. The time to reach 50% reduction of glucose from baseline is calculated from these two measurements. This test has been suggested to represent a safe, rapid, and low-cost method for diagnosis of equine IR and has recently been reported to correlate moderately to the OST in horses with EMS.[850]

Hyperinsulinemia in the Insulin-Resistant Equid

Insulin Clearance. Several methods have been described in the literature attempting to quantify insulin secretion in many species (including horses and ponies). Unfortunately, the methods that are technically simplest (such as measurement of insulin in peripheral venous blood following oral or IV glucose challenge) are heavily confounded by the effect of hepatic first-pass clearance on portal blood (which contains pancreatic insulin secretion). Plasma insulin concentration can be shown to readily increase in a dose-dependent fashion in response to a carbohydrate challenge (oral vs. IV), and this is presumed to result at least in part from pancreatic secretion. However, the relative contributions of altered insulin clearance and altered pancreatic secretion cannot be evaluated effectively with this sampling method and assay (even with analysis via minimal model kinetics).

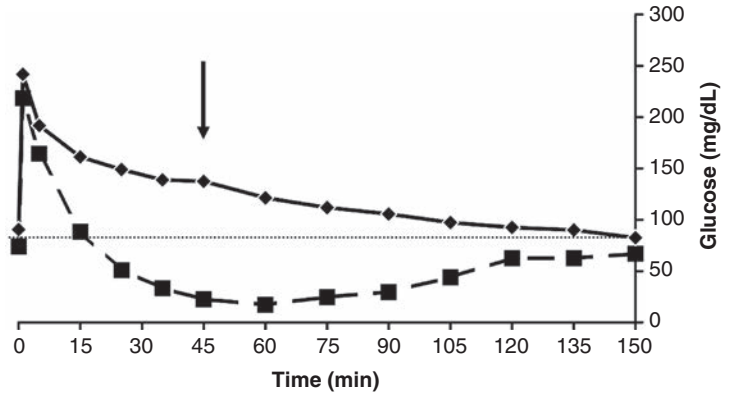

FIG. **16.20** Blood glucose concentrations during the combined glucose and insulin test (CGIT) in a healthy nonobese mixed breed horse *(dashed line)* and an obese insulin-resistant Morgan mare *(solid line).* The *horizontal line* represents the approximate baseline plasma glucose concentration, and the *arrow* indicates the time point (45 minutes after injection) selected to define insulin resistance using this test. Blood glucose concentrations remain above the baseline value for 45 minutes or longer if the horse is IR. Figure adapted from Eiler and colleagues.[827] (Courtesy Dr. N. Frank, Tufts University.)

Assessment of plasma C-peptide concentrations concurrently with determination of insulin concentrations might be more useful. C-peptide is a cleavage product of proinsulin that is secreted in equimolar amounts with insulin, but (in contrast to insulin) it is primarily excreted unchanged in the urine. Measurement of C-peptide concentrations would allow evaluation of β-cell function independent of hepatic action on pancreatic secretions and the use of this technique in the horse has been published.[759] However, C-peptide human-specific immunoassays require further validation in healthy and insulin-resistant horses and ponies. This method is also not commercially available for equine samples, limiting its use in clinical patients. Finally, single time point evaluations of plasma C-peptide concentrations (which would again be most useful for equine practitioners) have not been validated on a large scale, still requiring a glucose stimulation test to evaluate β-cell function.

Direct measurement of insulin secretion from pancreas would require sampling portal venous blood following enteral or IV carbohydrate challenge; this has been reported in experimental rodent models. This would be at best very challenging in horses and ponies, as surgical access to the portal vein is difficult and accompanied by significant risk to the animal. However, this remains the only way to truly accurately measure prehepatic insulin flux from the pancreas.[851-853]

Increased Insulin Release. Regarding the involvement of other hormones in insulin release from the pancreas, as described earlier, incretins have been shown to be critically important mediators of insulin release during increased plasma glucose concentrations (in fact, they have little effect on insulin secretion during euglycemia, increasing their attractiveness as therapeutic agents, as they are accompanied by little to no risk of hypoglycemic episodes, in contrast to insulin).[854] The enteroinsular axis is a poorly characterized system in the horse that likely contributes to equine metabolic disorders.[855] In general terms, this axis comprises factors from the gut that stimulate pancreatic islet cells but specifically refers to the incretins. Of the gastrointestinal hormones, glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide–1 (GLP-1) are considered incretins (which promote insulin release and suppress glucagon secretion). In other species, GIP is secreted by K cells (proximal small intestine) and GLP-1 by L cells (from proglucagon; distal small intestine). Nutrients within the small intestine (particularly carbohydrates) promote incretin secretion. Incretin activity explains the increase in insulin secretion that occurs before a rise in blood glucose, which is considered a preemptive mechanism to avoid hyperglycemia and facilitate peripheral tissue glucose uptake. Incretin mimetics (e.g., GLP-1 agonists such as exenatide and liraglutide) are used in humans and small animals for the treatment of type 2 diabetes mellitus. Dipeptidyl peptidase–4 (DPP-4) inactivates GIP and GLP-1. Based on this property, novel drugs (gliptins) that inhibit DPP-4 have been developed to prolong the incretin effect, promote insulin secretion, and reduce glycemia. These drugs have also been approved to be used alone or in combination with metformin to treat patients in which normalizing glycemia is difficult. In addition to their actions on the endocrine pancreas, GIP and GLP-1 have a multitude of other functions; they inhibit gastric emptying and acid secretion, promote insulin sensitivity, influence fat metabolism, and modulate skeletal muscle metabolism microvascular blood flow.[716] GIP enhances resistin secretion via MAPK, activates PI3K, and suppresses AMPK signaling.[714] Increased GIP concentrations have been linked to human obesity. Obese individuals have increased GIP levels and a higher response to a meal than lean individuals.[856] Impaired function of the enteroinsular axis has been linked to inadequate insulin secretion in people with type 2 diabetes mellitus. One can speculate from this information that incretin investigation should be considered a priority to better understand equine endocrinology and metabolism but also to elucidate the importance of the incretins in EMS. Few studies have investigated incretins in horses.[719,720,857]

The incretin effect has been shown to be present in equids,[719,857] and recent work involving administration of IV and enteral carbohydrate loads to ponies has suggested that activity of the enteroinsular axis (EIA) likely contributes to excessive postprandial hyperinsulinemia observed in these animals.[719] The EIA may ultimately be an effective therapeutic target for equids with EMS/IR, but in contrast to humans, the goal may be to suppress its activity to minimize insulin secretion in equids (rather than to promote insulin secretion, as in humans).

Another system that deserves further investigation as it relates to energy homeostasis in horses is the somatotropic axis. Consisting of growth hormone (GH) and IGF-1, the equine somatotropic axis is likely to be integrally involved with energy metabolism, insulin sensitivity, fat accumulation/distribution, and integumentary health. It is well accepted that GH has antiinsulin properties whereas IGF-1 has insulin-like actions and may be a vascular protective factor.[858,859] High and low GH concentrations have been linked to HMS, whereas low IGF-1 seems to be a consistent finding in affected individuals. A number of studies have measured GH and IGF-1 in horses and have associated their plasma concentrations with diet and BCS.[420,797] It is well documented in other species that GH can decrease insulin sensitivity by uncoupling PI3K signaling (a signaling pathway critical for insulin/growth factor receptor signaling; discussed earlier[710]). Increased GH and decreased IGF-1 concentrations have been associated with insulin resistance and the risk of developing metabolic syndrome.[860] It has also been suggested that low IGF-1 concentrations could be a useful marker to identify people at risk for IR and cardiovascular disease.[860] The role of the somatotropic axis in the pathogenesis of equine obesity and endocrinopathic laminitis has received little evaluation, although preliminary evidence suggests that serum IGF-1 concentrations are not increased in experimental animals subjected to a euglycemic hyperinsulinemic clamp (under the conditions of which lamellar gene expression of insulin receptor and IGF-1 receptor is reportedly decreased).[861] However, it is reasonable to assume that GH elevations could interfere with glucose uptake and lipid metabolism and contribute to the development of insulin resistance. Stimulation of the IGF-1 receptor may alter numerous events relative to laminitis including lamellar cell proliferation, cytoskeletal regulation, and cell adhesion processes, suggesting a connection between this signaling system and the pathogenesis of hyperinsulinemic laminitis.[861,862] This also supports potential involvement of the somatotropic axis in maintaining lamellar health.

Insulin degrading enzyme (IDE) is thought to be the primary enzyme responsible for insulin degradation following its release from the endocrine pancreas.[863] Although IDE is ubiquitously expressed (in insulin-responsive and non–insulin-responsive tissues, suggesting that it subserves alternate functions in different tissues), it is thought that hepatic IDE is

responsible for the degradation of the majority of plasma insulin (at least 60%).[863] Following binding to the insulin receptor, insulin and its receptor are internalized by endocytosis in a process that is enhanced by insulin signaling (negative feedback loop). Endosomal acidification is thought to be required for insulin release from its receptor (which can be recycled back to the plasma membrane); IDE can then degrade free insulin. IDE is present in the cytosol, cell membrane, and some organelles; it is also secreted into the extracellular space.[863] The insulin-induced IDE activity has been shown in hepatoma cell lines to be inhibited by elevated concentrations of glucose in the culture media, suggesting a mechanism by which increased alimentation (especially increased dietary NSC) could decrease liver insulin clearance and, consequently, inappropriate hyperinsulinemia.[864] Conversely, normal insulin signaling has been shown to upregulate IDE activity, most of these studies having been performed in the setting of experimental models of Alzheimer disease. (β-Amyloid is a target of IDE whose accumulation has been shown to correlate with increased risk for this condition.) Patients with Alzheimer disease show decreased IDE transcript and activity in brain tissue.[865] Further, IDE-knockout mice display hyperinsulinemia, decreased glucose tolerance, and type 2 diabetes mellitus, implicating the enzyme in some of the most characteristic aspects of the metabolic syndrome.

It is certainly possible that manipulation of insulin clearance (e.g., through pharmacologic activation of IDE or modification of the diet to increase hepatic insulin clearance) might be useful in the management of EMS. However, first it must be established that altered insulin clearance is responsible for the majority of the hyperinsulinemia observed in these patients (e.g., versus exuberant pancreatic insulin secretion in response to insulin resistance). This has not been demonstrated in equids. Experimentally, particularly if budget and time were not limiting factors, comparison of serum insulin concentrations across the liver (i.e., in portal venous blood and systemic venous blood [ideally right atrial blood]) in response to both oral and IV glucose tolerance tests with frequent sampling would identify the relative contributions of pancreatic secretion and hepatic clearance of insulin to the systemic insulin concentrations observed following the testing. Because of the technical difficulty associated with this technique, evaluation of C-peptide responses in concert with insulin responses to an oral and IV glucose tolerance test might be an easier, more efficient way to arrive at the same answer.

Insulin Signaling and Insulin Resistance. Recent research in humans and experimental rodent models has revealed the importance of aberrant insulin signaling in both the pathogenesis of the metabolic syndrome and the risk of adverse consequences in affected patients.[866,867] Not only is basal and stimulated hyperinsulinemia considered a marker/diagnostic criterion for at-risk individuals, it is also considered to play direct and indirect roles in the pathophysiology of diseases associated with metabolic syndrome.[782] Knowledge of insulin signaling in health and mechanisms by which it becomes dysfunctional in the insulin-resistant individual is imperative for the design of rational treatment and prevention programs.

Glucose, the primary carbohydrate fuel of cellular intermediary metabolism, crosses cell membranes via facilitated diffusion through various members of a family of glucose transport proteins (GLUTs), of which 14 have been described in mammalian systems to date.[868] In the postprandial state, elevation in plasma glucose concentration following its absorption from the gastrointestinal tract is a potent secretagogue for insulin from β cells in the islets of Langerhans of the endocrine pancreas. Secretion of insulin from the endocrine pancreas results in increased plasma concentration of this hormone and its subsequent delivery via the systemic circulation to its target tissues (primarily skeletal muscle, adipose tissue, and liver); here insulin binds its receptor present on the cell surface.[869]

Binding of insulin to its receptor, a heterotetrameric receptor tyrosine kinase composed of two α and two β subunits, results in autophosphorylation of critical cytoplasmic tyrosine residues on the β-chains of the receptor and recruitment of insulin receptor substrate (IRS) proteins to the cytoplasmic side of the plasma membrane.[870,871] Although several IRSs have been described (at least four), IRS-1 and IRS-2 primarily subserve the functions of signal transduction through the insulin receptor (IRS-1 is of primary importance in skeletal muscle and adipose tissue; IRS-2 is of greater importance in liver).[872] IRSs contain multiple tyrosine and serine phosphorylation sites; in general (with a few exceptions), tyrosine phosphorylation of IRSs by activated insulin receptor results in conformational changes in IRSs that activate and promote their function as docking proteins, recruiting additional SH-2 domain-containing molecules involved in insulin signal transduction through two main pathways.[872] Serine phosphorylation of IRSs is broadly inhibitory to their function in recruiting downstream effectors of signaling; although more than 50 canonical serine phosphorylation sites have been described on IRS-1, the functions of all of which have not been fully characterized to date, phosphorylation of some of these (such as Ser312/307) results in retention of IRS-1 in the cytosol in association with 14-3-3 proteins and enhanced IRS-1 ubiquitination and degradation. In this way, serine phosphorylation of IRSs serves as an important site of negative feedback of insulin action; it is also a primary mechanism responsible for acquired insulin resistance in pathologic states, such as obesity and inflammation.[867]

As mentioned, IRSs recruit effectors of two intracellular signaling cascades that are activated by insulin binding to its receptor: the mitogen-activated protein kinase (MAPK) pathway, responsible for the mitogenic and differentiation effects of insulin, does not play a significant role in glucose metabolism. Activation of the phosphatidylinositol-3-kinase (PI3K) pathway is responsible for the increased transcellular glucose conductance observed following insulin binding. Tyrosine phosphorylation of IRS-1 and/or IRS-2 results in recruitment of the p85 subunit of PI3K to the plasma membrane, where its primary substrate(s) phospholipids are located. Phosphorylation of PIP2 by the catalytic p110 subunit of PI3K and subsequent generation of PIP3 results in activation of phosphatidylinositol-dependent protein kinase (PDK1). PDK1 phosphorylates PKB/Akt, a kinase that then phosphorylates Akt substrate of 160 kDa (AS160).[752,871,873-875] Glucose transporter type 4 (GLUT4), the primary insulin-responsive glucose transporter protein in skeletal muscle, is sequestered in cytoplasmic vesicles in the absence of insulin receptor activation; AS160 is involved (likely with many other molecules) in promoting this retention. On phosphorylation and inhibition of AS160, GLUT4-containing vesicles translocate to and fuse with the plasma membrane, resulting in increased cell surface expression of GLUT4. Plasma glucose then is allowed to enter skeletal muscle cells through GLUT4-facilitated diffusion, until these transporters are resequestered following cessation of the insulin signal.[869] Other GLUTs are expressed in skeletal

muscle (e.g., GLUT1, GLUT2); however, they are not insulin responsive and their involvement in glucose transport into skeletal muscle is considered minor in comparison with that of GLUT4.[868] Intracellular glucose trapping and prevention of back-diffusion through GLUT4 are prevented via rapid phosphorylation of intracytoplasmic glucose to glucose-6-phosphate (which does not pass through GLUTs) by glucokinase/hexokinase. These are the essential steps that promote insulin-mediated glucose movement from the systemic circulation into the skeletal myocyte, which is primarily responsible for insulin-mediated plasma glucose disposal postprandially.

Insulin Resistance/Dysregulation in Obese Horses with Equine Metabolic Syndrome. Relationships between obesity and IR are complex. It should be remembered that *not all obese horses are insulin resistant and IR is not always accompanied by obesity.* However, these conditions are associated, and there is evidence that IR predisposes ponies to laminitis. Adipose tissues expand as obesity develops through an increase in adipocyte size (hypertrophy) and/or number (hyperplasia). This is manifested as generalized obesity or regional adiposity, and either can be accompanied by IR. In horses, regional adiposity increases the size of adipose tissues within the nuchal crest, and neck circumference has been negatively correlated with insulin sensitivity in obese insulin-resistant horses. Fat thickness over the rump has also been used as a measure of body fat mass in horses, and some horses develop enlarged fat pads in this area.

Horses that are evolutionarily adapted to sparse forages and harsher conditions may be predisposed to obesity because lipid accumulates more readily when excessive calories are provided in the diet. This state of overnutrition is often induced when genetically predisposed horses are turned out on pasture. The natural equine diet contains little fat, but excess glucose can be converted into fat via de novo lipogenesis. Fats are used for energy or stored as triglyceride within cells. When the storage capacity of adipose tissues is exceeded, fats are directed toward nonadipose tissues (repartitioning). Skeletal muscle, liver, and pancreatic tissues attempt to utilize fats by increasing β-oxidation, but lipid can accumulate within these tissues and alter normal cellular functions. This pathophysiologic mechanism is sometimes referred to as lipotoxicity.

Reactive oxygen species are also generated as oxidative pathways are upregulated. Oxidant damage contributes to lipotoxicity and lipid-induced programmed cell death (lipoapoptosis). Inflammation accompanies these events, resulting in the release of TNF-α and IL-6 from adipose tissues. Adipocytes release these proinflammatory cytokines that act locally or enter the blood. Hormones and cytokines released from adipose tissues are referred to as adipokines. Leptin is an adipokine that is involved in the satiety response within the brain. Obese and insulin-resistant horses often have higher plasma leptin concentrations.[436,796,876] In contrast, the release of adiponectin decreases with obesity and IR, and this may serve as a marker for EMS in the future.[798,844,877] Insulin resistance develops when insulin-sensitive adipose, liver, and skeletal muscle tissues fail to respond normally. Insulin receptors, downstream signaling pathways, and glucose transporters such as GLUT4 are potential sites of dysregulation. More insulin is released from pancreatic β-cells to compensate for reduced tissue insulin sensitivity, which results in hyperinsulinemia. Pancreatic insufficiency develops as a result of chronic IR or the effects of lipid accumulation within pancreatic tissues. Uncompensated IR occurs when the pancreas fails to sustain the higher rate of insulin secretion necessary to compensate for reduced tissue insulin sensitivity, and hyperglycemia develops as a consequence.

All of the pieces of the puzzle must be assembled before we can fully understand the relationship between IR and laminitis in horses and ponies. At present, we are limited to the knowledge that IR predisposes ponies to pasture-associated laminitis and that the disease can be experimentally induced by infusing insulin intravenously over several days. There are three broad mechanisms by which IR and obesity could predispose horses to laminitis: (1) altered blood flow or endothelial cell dysfunction within blood vessels of the foot, (2) impaired nutrient delivery to hoof tissues, or (3) a proinflammatory or prooxidative state induced by chronic obesity and IR. These processes are likely to contribute to the lower threshold for laminitis recognized in horses with EMS.

Lean Horses with Equine Metabolic Syndrome. Our current understanding of chronic IR in the lean horse is very limited, but several explanations have been proposed. One explanation is that the liver responds differently to nutrients in affected animals. In one study, ponies with IR showed exaggerated insulin responses to a meal containing fructose, which suggests that the liver responds differently to certain nutrients in horses with EMS and this may represent *hepatic insulin resistance.* Another proposed cause of IR in leaner animals is the increased production of cortisol locally within adipose tissues surrounding the abdominal organs. This is thought to result from increased 11β-hydroxysteroid dehydrogenase 1 (11β-HSD1) activity within visceral adipose tissues, which increases local cortisol production and leads to the development of IR. Johnson referred to this condition as *peripheral Cushing disease,* but this term is not recommended because it is easily confused with equine Cushing disease, which results from pituitary pars intermedia dysfunction. Further studies are required to determine the activity of 11β-HSD1 in horses with EMS.

Equine Metabolic Syndrome–Associated Laminitis (Endocrinopathic Laminitis). The equine digital laminae are a unique integumental structure in which the adhesion of the epidermal laminae (continuous with the hoof wall) to the dermal laminae (attached to the third phalanx; P3) allows for the suspension of P3 (and therefore the entire musculoskeletal system and weight of the horse) within the hoof wall. The cell type responsible for this adhesion, and which is the site of dysadhesion leading to laminar failure in laminitis, is the laminar basal epithelial cell (LBEC). The LBEC is a polarized, highly differentiated epithelial cell with critical adherence functions on its basement membrane aspect, maintaining adequate adhesion capacity to support the weight of the horse within the hoof wall. In addition to this essential function, the equine LBEC behaves similarly to keratinocytes in other locations (and species), responding to extracellular events via a multitude of signaling mechanisms related to inflammation, endocrine/paracrine factors, and epithelial stress in sepsis-related laminitis. Although there has been a great deal of effort put forth to find a common signaling pathway by which diverse systemic diseases can lead to laminitis/laminar failure, it is more likely that the reason various pathologic entities result in laminar dysfunction is that any insult to the LBEC alters their polarity, resulting in basement membrane dysadhesion and laminar separation due to the incredible stresses placed on the digital laminae. Thus the cause of laminar failure in pasture-associated laminitis (PAL) may bear little similarity to that occurring

in the other types of laminitis regarding extracellular events or even cell signaling; however, a similar laminar dysfunction results due to unique disarray of cytoskeletal and adhesion functions and subsequent dysadhesion of the LBEC from the underlying basement membrane.[794]

Although equine laminitis has been associated with many diverse causes (including gastrointestinal tract disorders, retained placenta or metritis, severe infections, and excessive weight bearing),[793] PAL is now reported to be the most common cause of laminitis, affecting primarily horses and ponies with a phenotype of obesity (especially regional adiposity) and insulin resistance when they are exposed to NSC-rich pastures.[436,730,751] Clinical observations and epidemiologic studies support that risk of PAL is highest when equids are grazing pastures with high NSC content (i.e., fructans, simple sugars, and/or starch), and theories on the pathogenesis of PAL have been extrapolated from experimental models of alimentary carbohydrate overload. However, the extent to which these severe models reflect events during development of EMS-related laminitis may be questioned. First, it is likely that the amount and rate of starch or fructan administered for induction of carbohydrate overload in these studies far exceeds the quantity of NSC ingested by grazing equids. Second, previous studies have not used animals with an EMS phenotype and thus have not addressed the interaction between diet, phenotypic, and genetic factors associated with laminitis susceptibility.

The LBEC provides the load-bearing capability of the digital laminae through its adherence to its associated basement membrane, neutralizing forces both from the weight of the animal and ground reaction. Its function is critically important, and separation/failure of the LBEC from the basement membrane results in detachment of the dermal and epidermal laminae, which often results in displacement of the pedal bone within the hoof capsule. As previously mentioned, the LBEC is a highly polarized epithelial cell whose function is critically dependent on its adherence both to its neighboring epithelial cells and to its anchoring basement membrane. It is tempting to speculate that decreased adenosine-5′-monophosphate-activated protein kinase (AMPK) activity (which has been recently observed in laminar tissue of ponies challenged with an increased dietary carbohydrate load, a stimulus that has been associated with induction of laminitis in IR equids[878]) might induce loss of cytoskeletal polarity of the laminar basal cell (such as has been observed in vitro in other epithelial cell model systems[879]) and subsequent detachment from its basement membrane. Loss of polarity of epithelial basal cells and decreased maintenance of epithelial tight junctions may lead to mechanical disruption of the laminar interface secondary to constant tension from the deep digital flexor tendon. Recent evidence of decreased AMPK phosphorylation in a model of endocrinopathic laminitis[878] suggests that laminar decreased AMPK activity may be pathologic; however, it is unclear what role it plays in normal and abnormal laminar physiology. Although the net effects of AMPK activation within the digital laminae are unclear currently, it is reasonable to assume that it plays an important role in this highly polarized cell type, as it has been shown to do in diverse epithelial cell types in other species.

Laminitis is associated with a diverse range of clinical diseases in horses, from sepsis to endocrine diseases associated with IR. IR, which has been shown to occur in obesity and in sepsis in horses, can result in hyperinsulinemia due to decreased glucose transport into insulin-responsive tissues (especially skeletal muscle). Although IR and subsequent glucose deprivation have been suggested in the past as potential mechanisms underlying laminar failure in equids with EMS, it has recently been shown that the primary glucose transporter type expressed in laminar tissue is GLUT1[880], which is neither insulin dependent nor highly insulin responsive.[128] The digital laminae may actually experience an increased glucose flux in insulin-resistant individuals, particularly after consumption of a high-NSC meal. Increased glucose uptake (passive and concentration-dependent through GLUT1) is associated with increased ATP production and a decreased intracellular AMP:ATP ratio, conditions in which AMPK phosphorylation (and activation) would be expected to be decreased.[881] If LBEC polarity (assumed to be important for their proper function) is similarly dependent on AMPK function as has been shown in other epithelial cell types in vitro,[882] this scenario may logically result in laminar failure (which is observed clinically).

Hyperinsulinemia has been repeatedly identified as an important risk factor for the development of endocrinopathic laminitis, reported by several groups independently in cross-sectional studies.[437,730,801] More recently, a direct link between insulin and laminitis has been identified through the experimental induction of laminitis via iatrogenic hyperinsulinemia in normal ponies[732] and Standardbred horses.[733] Insulin is a pleiotropic hormone whose functions have been classically limited to regulation of carbohydrate, lipid, and protein metabolism in times of energy excess (i.e., in the postprandial period).[883] However, signaling through the insulin receptor has been shown to activate not only pathways that direct the fates of nutritional metabolites through PI3K activation but also regulation of cellular replication and extracellular matrix production through activation of MAPK pathways.[871] Direct effects of insulin on laminar epidermal basal cells, with subsequent alterations of their extracellular matrix (which supports the integrity of the laminar basement membrane), may play a role in endocrinopathic laminitis. Recent studies reporting little evidence of insulin receptor expression on laminar epidermal cells make this theory less likely.[758] Insulin signaling through its receptor may have a greater effect on the perfusion of the laminae, as the insulin receptor appears to be expressed primarily within the laminar microvasculature.[758]

Incubation of endothelial cells with increased concentrations of insulin in vitro has been shown to alter their insulin responsiveness, inducing cellular insulin resistance after a relatively short exposure (24–48 hours).[884] Interestingly, it is after approximately 72 hours of experimental hyperinsulinemia that horses and ponies are observed to become laminitic.[732] Rapid downregulation of surface expression of the insulin receptor has been documented on endothelial cells in response to treatment with exogenous insulin, which may partially explain the endothelial insulin resistance observed in response to hyperinsulinemia in vivo. Signaling through the insulin receptor also tends to be self-limiting[872]; this mechanism for insulin resistance may be more important in the laminae, where endothelial expression of the insulin receptor appears to be increased in the setting of hyperinsulinemia.[758] Altered vascular responsiveness in insulin-resistant individuals is thought to result from decreased insulin-mediated elaboration of nitric oxide (NO) and its vasodilatory effects on vascular smooth muscle.[885] Attenuation of PI3K signaling results in decreased activity of endothelial NOS (eNOS) and decreased NO production. Concurrently, whereas defective PI3K signaling is observed from the insulin-bound insulin receptor in endothelial IR, signaling through the MAPK

pathway appears to be preserved. Increased production of the vasoconstrictor endothelin-1 through this pathway, along with decreased NO elaboration, is thought to result in inappropriate vasoconstriction, failure to achieve flow-dependent vasodilation, and hypertension. Local perfusion, particularly in those tissues lacking collateral circulation, may be inadequate and may activate stress kinase systems, such as MAPK and AMPK. NO also has been reported to have important antiinflammatory and anticoagulant effects, loss of which has been associated with the propagation of atherothrombotic lesions in humans and experimental animal models of metabolic syndrome.[875] In horses with IR, pathologic changes in vasomotor tone to a tissue with poor collateral circulation (the digital laminae) may promote hypoxia/ischemia, both of which have been reported to play roles in the pathogenesis of laminitis.[886] Thrombi have been noted within the laminar microvasculature in experimental and naturally occurring laminitis.[887]

Insulin may also be triggering signaling in laminar epithelial cells through the IGF-1 receptor, not the insulin receptor (which does not appear to be present at significant levels on laminar epithelial cells). Insulin has been shown to bind and activate IGF-1R at supraphysiologic concentrations in cell cultures (concentrations that have been observed in insulin-resistant equids in response to a dietary carbohydrate challenge),[888] and IGF-1R's distribution within the laminae appears to be much more extensive than that of the insulin receptor.[758] Whereas the insulin receptor appears to be limited to the laminar microvasculature, IGF-1R is present on laminar epithelial cells, endothelial cells, and fibroblasts (and likely other cell types). The importance of IGF-1R signaling in the laminar epidermis, particularly its effects on extracellular matrix and cytoskeletal components, is currently unclear but is an active area of investigation.

Necropsy Findings

Horses and ponies with EMS are obese or exhibit regional adiposity and have evidence of laminitis. Hepatic lipidosis has been noted on some pathology reports, but it is unclear whether this simply reflects increased lipid storage or provides evidence of a pathologic process.

Management

Management of IR involves three approaches: (1) reducing the sugar and starch content of the feeds provided to the horse, (2) limiting or eliminating access to pasture until IR improves, and (3) increasing exercise. The first approach involves selection of hay with a lower sugar and starch content, which can be determined by submitting a sample for analysis. Equi-Analytical Laboratories analyzes hay and provides starch, ethanol-soluble carbohydrate (ESC), and water-soluble carbohydrate (WSC) content. ESCs include simple sugars such as monosaccharides and disaccharides, whereas WSC includes fructans as well. The nonstructural carbohydrate (NSC) content of the hay should be calculated from the values provided by the laboratory. Unfortunately, researchers disagree about the appropriate method of calculating NSC content. Some think that the WSC must be included, so NSC is calculated by adding WSC and starch values together. However, others argue that only ESC is relevant because fructans are primarily digested in the large intestine and therefore do not contribute to the rise in blood glucose concentrations after a meal. At present, we recommend that NSC be calculated by adding starch and ESC together, and this level should ideally fall below 10% as-fed in the hay. It is important to recognize that the relative importance of NSC intake varies with the severity of IR. Horses with severe IR (resting insulin concentration greater than 100 μIU/mL) must be maintained on a stringent diet with an NSC content less than 10%, whereas mildly affected animals can be fed hay with higher levels. If hay has already been purchased and the NSC level is between 10% and 20%, soaking the hay in cold water for 3-6 hours before feeding should lower the sugar content to a level that is safer for EMS-affected horses.[888a]

Leaner horses with EMS are challenging to manage from a dietary standpoint because more calories must be provided without exacerbating IR. This can be accomplished by feeding one of the commercial low-sugar/low-starch (low-NSC) pelleted feeds that are now available to horse owners. These feeds vary in their NSC content, so the severity of IR must be taken into account before one is selected. It is also better to divide the daily ration into multiple small meals and to feed hay beforehand to slow gastric emptying. These strategies are employed to lower the glycemic response to the meal, which is the degree to which blood glucose concentrations rise in response to the feed. Individual horses may respond differently to the same feed, so it is advisable to recheck glucose and insulin concentrations 7 to 14 days after a new diet has been initiated. Severely insulin-resistant horses are particularly difficult to manage and may require individual diet formulation, with the help of a nutritionist. Rinsed and then soaked molasses-free beet pulp can be fed as a lower cost alternative to commercial feeds. This feed has a low glycemic response yet provides calories through hindgut fermentation and volatile fatty acid production.

Weight loss should be induced in obese horses by restricting the total number of calories consumed. In horses that are being overfed, removal of all concentrates from the diet is often sufficient to achieve the ideal body weight. Total caloric intake should initially be met by feeding hay in amounts equivalent to 1.5% to 2.0% of current BW (e.g., 18–24 lb [8–11 kg] hay per day for a 1200-lb [540 kg] horse). If the horse does not lose weight, the amount fed should be lowered over several weeks to 1.5% of ideal BW (e.g., 15 lb [6.8 kg] hay for an ideal weight of 1000 lb [450 kg]). The horse should not be restricted to less than 1.0% of its ideal body weight in forage daily at any point; this represents severe caloric restriction and, particularly when restricted acutely, may increase risk of hyperlipidemia/hyperlipemia in EMS-affected equids.

These strategies are effective for horses kept in stalls or dirt paddocks, but weight loss is more difficult to achieve when horses are grazing on pasture. Strategies for limiting grass consumption on pasture include short (less than 1 hour) turnout periods; confinement in a small paddock, round pen, or area enclosed with electric fence; or use of a grazing muzzle. Appropriate vitamin and mineral supplements should be provided to horses confined to dirt paddocks or stalls. Pasture access must remain restricted or eliminated until insulin sensitivity has improved because carbohydrates consumed on pasture can trigger gastrointestinal events that lead to laminitis in susceptible horses. Grass is also unregulated source of starch and sugar, so these carbohydrates will continue to exacerbate IR, even when other aspects of the diet have been controlled.

Laminitis must be considered when managing horses with EMS, and horses with recurrent laminitis may require permanent restriction of their pasture access. These patients can be housed in dirt paddocks so that they are able to exercise once laminitis is controlled. Mildly affected horses can be returned

to pasture if IR can be controlled, but care should be taken to restrict pasture access when the grass is going through dynamic phases, such as rapid growth in the spring or senescence in the fall. Measurement of pasture grass NSC content at different times of the day has revealed that grazing in the early morning is likely to be safer for horses with IR, except after a hard frost when grasses accumulate sugars.

Pharmacotherapy

Most horses or ponies with EMS can be effectively managed by lowering the sugar and starch content of the diet, reducing body fat mass if the animal is obese, instituting an exercise program, and limiting or eliminating access to pasture. However, it takes time for these management changes to take effect, so pharmacologic interventions can be considered to accelerate the improvement if the patient suffers from recurrent laminitis. Two options are currently available to clinicians, and each has its advantages and disadvantages. Levothyroxine sodium can be administered to accelerate weight loss and improve insulin sensitivity in obese horses but should be avoided in leaner horses because of the reduction in BW. Metformin may also be useful; this drug improves insulin sensitivity in insulin-resistant horses and ponies without affecting body weight[838]. However, the long-term effects of metformin on insulin sensitivity have not been determined, and the safety of this drug must be evaluated in horses.

Levothyroxine Sodium

Weight loss can be accelerated and insulin sensitivity improved in obese insulin-resistant horses when levothyroxine sodium is administered orally at a dosage of 48 mg (total per 500-kg horse) per day for 3 to 6 months. Smaller ponies and Miniature Horses can be given 24 mg of levothyroxine sodium per day for the same time period. Thyro L (Lloyd, Inc., Shenandoah, IA) is recommended for this purpose, and 1 teaspoon (tsp) of powder provides 12 mg of levothyroxine sodium, so 4 tsp should be administered in the feed or by mouth once daily. When levothyroxine treatment is discontinued, horses should be weaned off the drug by lowering the dosage to 24 mg (2 tsp) per day for 2 weeks and then 1 tsp (12 mg) per day for 2 weeks. The benefits of treating horses with levothyroxine at lower dosages for longer periods have not been evaluated.

Measured serum total thyroxine (tT_4) concentrations are elevated when levothyroxine is administered at a dosage of 48 mg (4 tsp) per day, but levels vary considerably within and between horses. Serum tT4 concentrations often range between 40 and 100 ng/mL in treated horses, indicating that levothyroxine sodium is being given at a supraphysiologic dosage. However, clinical signs of hyperthyroidism such as sweating or tachycardia have not been observed in treated horses. It is important for horses to be placed on a controlled diet when levothyroxine sodium is administered because it has been subjectively observed that feed intake increases in response to treatment. Weight loss is unlikely to occur if the horse is given free access to pasture, which will be perceived by owners as treatment failure.

Metformin

Energy Regulation and Insulin Resistance: Adenosine-5′-Monophosphate-Activated Protein Kinase. Adenosine-5′-monophosphate-activated protein kinase (AMPK) is a eukaryotic heterotrimeric protein complex that is highly conserved among phyla and widely distributed in most tissue types of multicellular organisms.[889,890] Activation of AMPK kinase activity results in broad changes in carbohydrate, lipid, and protein metabolism that in general serve to decrease energy consumption (anabolic pathways, such as glycogen, lipid, and protein synthesis) and increase energy production (catabolic pathways, such as glucose uptake, glycolysis, glycogenolysis, lipolysis, lipid oxidation).[891]

The role of AMPK in skeletal muscle has been shown to be responsible (at least in part) for the insulin-sensitizing and non–insulin-dependent effects on glucose transport following exercise. AMPK activation, which may occur in exercising muscle via several mechanisms (increased AMP:ATP ratio with fatiguing exercise [LKB1], increased cytoplasmic calcium concentration [CaMKK]),[892] results in phosphorylation of AS160 and translocation of GLUT4 to the cytoplasmic membrane in the absence of insulin signaling; AMPK also enhances the activity of insulin signaling at multiple levels (most importantly, IRSs), but increased glucose disposal during exercise has been shown to be non–insulin dependent (at least in part).[893]

AMPK may display significant cross-talk with insulin (and IGF-1) signaling at multiple levels.[894] For example, AMPK has been shown to phosphorylate IRS-1 at a serine site that increases its affinity for PI3K, an effect that increases insulin signaling (and thereby promotes insulin sensitivity). AMPK also promotes the oxidation of accumulated ectopic lipid in multiple tissues, lipids that likely signal through PKCè to inhibit IRS-1 and insulin signaling (again, promoting increased insulin sensitivity).[895] AMPK may also directly phosphorylate and inhibit the activity of AS160, which serves to retain GLUT4 in cytoplasmic vesicles in the absence of insulin signaling; this is likely the mechanism (or at least part of the mechanism) by which AMPK elicits non–insulin-dependent GLUT4 translocation and increased glucose disposal that is observed with muscle contraction.[894] Conversely, Akt/PKB (an important kinase effector of the PI3K pathway, signaling downstream of insulin receptor) may phosphorylate AMPK alpha subunits and inhibit their phosphorylation by LKB1. Insulin/AMPK interactions are very complex and may ultimately be determined to be highly tissue specific in the setting of metabolic syndrome.

The liver, although insulin responsive in many ways, is not dependent on insulin for many of its functions in glucose metabolism. Insulin signaling in the liver tends to inhibit glycogenolysis and gluconeogenesis, encouraging instead glycogen storage; these effects are attenuated in the setting of insulin resistance, with persistent gluconeogenesis and exacerbation of hyperglycemia (especially in patients with type 2 diabetes mellitus).[896] In skeletal muscle, however, glucose uptake occurs primarily through GLUT4, which is largely insulin responsive.[897] In muscle, insulin resistance is associated with decreased glucose disposal and the accumulation of intramyocellular lipid.[898-900] Although the role of AMPK in liver and skeletal muscle is likely complex and affected by multiple inputs, it has been suggested since the late 1990s that AMPK activation could potentially reverse many of the characteristic abnormalities of carbohydrate and lipid metabolism that are observed in insulin-resistant individuals. This has led to the development and widespread clinical use of functional AMPK agonists, such as metformin, in the treatment of humans with the metabolic syndrome and type 2 diabetes mellitus.[901]

Administration of 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR), an AMPK agonist, to healthy horses

reduced blood glucose and increased insulin concentrations, increased skeletal muscle phosphorylated AMPK, with no effect on GLUT4 and GLUT1, but increased GLUT8 protein.[902] This information supports the use of AMPK agonists to promote glucose uptake in horses with clinical evidence of IR.

Metformin, a functional AMPK agonist, is an orally bioavailable biguanide compound that has been used clinically as an antihyperglycemic and insulin-sensitizing therapeutic in the treatment of human metabolic syndrome and type 2 diabetes mellitus.[901] The pharmacokinetics and pharmacodynamics of this drug have been well characterized in humans; however, although metformin has been used empirically to treat equids afflicted with EMS[903] (and some pharmacokinetic studies have been published[904,905]), peer-reviewed pharmacodynamic information regarding metformin in equids is limited.[905,906] When the effects of metformin on insulin sensitivity were assessed in horses and ponies with IR, a positive response was detected initially without hypoglycemia developing, but long-term results were variable.[905] Metformin was administered at a dosage of 15 mg/kg orally twice daily in the aforementioned study, but the pharmacokinetics of this drug have recently been examined, and results suggest that the drug should be given every 8 hours (Anna Firshman, personal communication). Further studies are required to assess the safety and efficacy of this treatment for IR.

Additionally, it is now recognized that AMPK may have profound effects on the integrity and confluence of epithelial cells in cell culture, including their ability to remodel tight junctions following application of a cellular stressor.[882] AMPK, then, may provide an attractive link between dietary carbohydrate content, insulin sensitivity, and laminar epithelial dysfunction. Investigation of the effects of AMPK activation in the digital laminae in response to dietary carbohydrate content may open new avenues of inquiry regarding the pathophysiology of endocrinopathic laminitis, ideally leading to the development of novel therapies for treating this difficult disease.

Other Treatments for Equine Insulin Resistance

Numerous other treatments have been proposed for the management of IR in horses including magnesium supplementation, chromium, clenbuterol, cinnamon, and thiazolidinediones. Each of these therapies may be of some benefit, but further studies are required to establish their efficacy; the studies that have been performed to date do not support a significant therapeutic effect in horses. For example, multiple studies have been published investigating both the pharmacokinetics[907] and pharmacodynamics[908,909] of pioglitazone (a thiazolidinedione drug and a peroxisome-proliferator activated receptor-gamma agonist); although this drug appears to be orally bioavailable in horses, it appears to have relatively little insulin-sensitizing effect in this species, at least when administered over the short term. Additional study may reveal a utility for this class of drug in insulin-resistant equids, but current knowledge does not suggest strong therapeutic benefit for patients with EMS. Regarding neutraceutical preparations, although little research exists to guide rational clinical use of these products, preliminary work suggests that at least one commercially available nutritional supplement had no detectable effect on the degree of IR in treated horses.[333]

Pituitary Pars Intermedia Dysfunction

Teresa A. Burns, Dianne McFarlane, and Ramiro E. Toribio

A clinical syndrome associated with hypertrichosis (hirsutism), skeletal muscle atrophy, weight loss, polyuria and polydipsia (PU/PD), and laminitis is well recognized in aged horses and ponies.[676,910-914] The syndrome was originally referred to as equine Cushing disease due to similarities to Cushing disease in humans and dogs, in which there is excessive and autonomous secretion of proopiomelanocortin (POMC)–derived peptides, including adrenocorticotropic hormone (ACTH, adrenocorticotropin, corticotropin), resulting in pituitary-dependent hyperadrenocorticism. However, in equids, pituitary adenomas arise from the pars intermedia (intermediate lobe) of the pituitary gland, unlike in humans and dogs, in which pituitary adenomas commonly develop from the anterior lobe (pars distalis, adenohypophysis). As a result, in the horse, hormones from the pars intermedia are excessively secreted as described later. *Pituitary pars intermedia dysfunction* (PPID) therefore seems to be a more appropriate term to describe the syndrome because, unlike humans, adrenocortical hyperplasia and hypercortisolemia are not consistent findings in affected horses.

CLINICAL SIGNS

Clinical signs of PPID in aged horses and ponies include hypertrichosis, poor haircoat, laminitis, PU/PD, muscle wasting, weight loss/repartitioning, docility, lethargy, hyperhidrosis, narcolepsy (and other signs of CNS dysfunction, including seizure), blindness, decreased responsiveness to painful stimuli, increased appetite, and recurrent infections.[606,910,911,915,916] Although there are many clinical signs associated with PPID, only a subset of the signs typically manifest in an affected individual, perhaps due to differences in the secretion profile of POMC-derived peptides or the degree of compression of adjacent neuroendocrine tissues.

Hypertrichosis (55%–80%) is considered the most frequent clinical sign in PPID horses, although these estimates may be biased due to the increased tendency to test aged horses displaying haircoat abnormalities for PPID.[676,910,911,915,917] Hypertrichotic horses have a long, thick, often curly haircoat (Fig. 16.21). Other haircoat abnormalities may include a failure to shed in a complete or timely manner; some horses shed in late spring and grow a winter coat early in the fall. Retention of long guard hairs in the jugular furrow, on the distal limbs, within the intermandibular space, or along the ventral abdomen is also a frequent finding. The pathogenesis of hypertrichosis is unknown, but one study demonstrated that horses with PPID have a greater percentage of hair follicles that remain in anagen phase than do age-matched unaffected horses.[918] This study also reported an increased proportion of telogen-phase hair follicles in PPID-affected horses following 6 months of treatment with pergolide mesylate.[918]

Chronic laminitis occurs in approximately 30% of horses with PPID.[919] The presentation of endocrinopathic laminitis is frequently more insidious than laminitis due to other causes (such as sepsis). It has been speculated that laminitis in the setting of PPID may result from increased concentrations of endogenous glucocorticoids, which are known to be associated

FIG. **16.21** Horse diagnosed with pituitary pars intermedia dysfunction based on basal ACTH concentrations (A). The same horse 6 months later after initiation of management (dental care, deworming, diet change) and treatment with pergolide mesylate (Prascend®) (B).

with systemic insulin resistance in equids.[735,736,920-923] However, more current data suggest that insulin dysregulation (ID) or insulin resistance (IR) and the associated hyperinsulinemia more likely have a role in inciting laminitis in horses with PPID, as the connection between hyperinsulinemia and equine laminitis has become increasingly robust following intense research efforts in the past decade.[732,733] The connection with glucocorticoids is weaker, though, as hypercortisolemia is an inconsistent finding in PPID-affected equids.[924-926] Laminitis-prone ponies have been reported to have increased serum insulin concentrations compared with control ponies.[799] Experimental maintenance of prolonged hyperinsulinemia in clinically normal ponies and Standardbred horses resulted in consistent induction of laminitis within 72 hours of onset of hyperinsulinemia, suggesting that increased serum insulin concentration in the absence of hyperglycemia can induce laminitis.[732,733] Additionally, one study reported that horses with PPID displayed significantly lower mean basal rates of glucose metabolism compared with healthy and non-PPID diseased control horses when tested with the euglycemic-hyperinsulinemic clamp method.[927] This may represent an age-related (expected, normal) decrease in peripheral insulin sensitivity (similar to that well described in many species), as more recent work comparing horses with PPID to age-matched control horses with this same test showed no difference between the two groups with respect to their glucose disposal rates.[928] In geriatric horses, PPID does not necessarily impair insulin sensitivity.[928] Horses with PPID do not appear to be consistently hyperglycemic when assessed via plasma fructosamine concentrations (which provide a medium-term assessment of average blood glucose concentration); the authors of one report found no difference in fructosamine concentration between horses with PPID and control animals. Horses experiencing recent bouts of laminitis, however, were reported to have elevated fructosamine concentrations, suggesting that laminitis (or more specifically, laminitic pain) was more likely to be associated with hyperglycemia than PPID.[929] Finally, in a study comparing laminitic and nonlaminitic horses with PPID, hyperinsulinemia was documented in all of the laminitic individuals (median 74.1 mIU/L, interquartile range 49.9–349.5 mIU/L) and none of the nonlaminitic individuals (less than 20 mIU/L [less than 20 μIU/mL]), again implicating hyperinsulinemia in the pathophysiology of laminitis in this setting.[919] Regardless of the underlying cause of laminitis, PPID should be included in the differential diagnosis for any aged horse presented with chronic laminitis, even if other clinical signs of PPID are not present.[433]

Polyuria and polydipsia have been reported in up to 76% of horses diagnosed with PPID.[911] Horses housed in stalls are most likely to have obvious PU/PD, as the condition is much less likely to be detected in animals housed extensively on pasture, calling into question the accuracy of assessments of the prevalence of PU/PD in horses with PPID. The pathogenesis behind the development of PU/PD is unclear. It has been speculated that compression of the pars nervosa by an expanding pars intermedia adenoma may result in decreased secretion of vasopressin (AVP, antidiuretic hormone [ADH]).[910,930] Hyperglycemia, which may be a laboratory finding in these horses (albeit inconsistently[929]), may induce osmotic diuresis. Glucocorticoids can increase glomerular filtration rate and may contribute to diuresis, but hypercortisolemia is also inconsistent in horses with PPID.[677,926] It is important to rule out other differentials for PU/PD, including neurogenic diabetes insipidus, nephrogenic diabetes insipidus, psychogenic polydipsia, and hyperglycemia of various origins (chronic pain, pancreatic disease, pheochromocytoma, insulin resistance).

Weight loss or repartitioning is reported in the majority of horses with PPID (up to 88%) and is often an early clinical sign[911]; however, some horses may be obese or in good body condition.[931] Affected horses often have a weak and pendulous abdomen, a sway back, and a poorly developed topline. The pot-bellied appearance is probably the result of lack of tone in the abdominal musculature. The muscle wasting along the dorsal midline and elsewhere results in prominence of the tuber coxae and tuber sacrale regions. It is unclear what the effect of different POMC-derived peptides is on equine energy metabolism or muscle atrophy. Weight loss in some horses may be the result of other conditions associated with aging (such as dental problems, poor nutrition, or chronic disease) or PPID (opportunist infections including parasitism secondary to immunosuppression) rather than the direct effect of an abnormally regulated hypothalamus-pituitary-adrenal axis (HPAA) on body condition. Glucocorticoids, in addition to being immunomodulatory, can have catabolic effects on skeletal muscle; however, the role of increased concentration of cortisol on weight loss in PPID is unclear. Muscle tissue from horses with PPID shows selective atrophy of type 2 muscle fibers and differential expression of m-calpain (a major proteolytic system that may play a role in the development of muscle atrophy in horses with PPID)[932,933]; however, the specific role of POMC hormones on muscle atrophy has not been investigated. In horses with normal or low cortisol concentrations, causes other than hypercortisolemia may be responsible for the weight loss/redistribution.

Increased docility in affected horses is often reported by owners and clinicians. Horses with PPID have increased plasma and cerebrospinal fluid concentrations of β-endorphin (β-END),[934] which may explain the docility and lethargy in some of these animals. Increased β-END concentrations may also explain the decreased responsiveness to painful stimuli and corneal stimulation that is observed in affected animals.[935] The decreased corneal sensation that develops both with age and PPID may also explain the frequency of chronic ulcerative keratitis in these populations.[935]

Neurologic impairment, although uncommon, has been reported in horses with PPID and includes blindness, seizures, and narcolepsy.[433] Blindness may result due to compression of the overlying optic chiasm by the enlarged pituitary gland; however, blindness can occur in horses with PPID in the absence of postmortem evidence of optic nerve damage. An increased occurrence of narcolepsy or sleep disorders has been suggested to occur in horses with PPID. The reason that some of these horses develop narcolepsy is unknown. One explanation may be that the removal of dopaminergic control may alter the sleep-wake cycle as occurs in humans. Narcolepsy can result from decreased orexin activity in the hypothalamus. Orexins (hypocretins) are peptide neurotransmitters expressed in the lateral hypothalamus (orexinergic neurons) that are important in the sleep-wake cycle; the absence of orexin function results in narcolepsy.[936] Horses with PPID have been shown to have decreased cerebrospinal fluid concentrations of hypocretin (orexin).[937]

Excessive sweating (hyperhidrosis) and, less commonly, lack of sweating (anhidrosis) are reported in horses with PPID, although the mechanisms underlying abnormal sweating remain unclear.

The expanded supraorbital adipose tissue often observed in horses with PPID results from fat redistribution.[911] This finding may be observed in horses that do not exhibit generalized obesity. Likewise, some horses at higher body condition scores may have prominent nuchal ligament ("cresty neck") and tailhead adipose tissue accumulation (regional adiposity). It is unclear if PPID causes adiposity (generalized or regional) or if it is the consequence of EMS (or insulin dysregulation) occurring as a comorbidity in horses with PPID. Limited data would suggest that EMS is present in approximately one third of horses with PPID and that certain clinical signs, such as laminitis and adiposity, may be a result of the EMS rather than PPID.[919,928]

Skin infections (such as dermatophilosis and pyoderma), sinusitis, pneumonia, and abscess formation (dental, pulmonary, subsolar, etc.) are common sequelae of PPID. The precise mechanism resulting in immune impairment is unknown, but the increased concentration of immunosuppressive hormones, including α-melanocyte-stimulating hormone (α-MSH), cortisol, insulin, and/or β-END (or their ratios) is likely a contributing factor. Abnormalities in neutrophil function have been shown in horses with PPID compared with age-matched control horses; neutrophils from PPID-affected horses display decreased oxidative burst capacity and functional adhesion, both of which may increase the animal's risk for opportunistic infections.[938] Additionally, horses with PPID have been shown to have a shorter strongyle-type egg reappearance period following anthelmintic administration than age-matched control horses, again suggesting that the hormonal milieu associated with this disease affects the host's responsiveness to various types of infections.[939] Management of these infections is an important part of treating equine PPID.

Abnormal estrus cycles and infertility have been reported in horses with PPID.[912] This may be a direct or indirect effect of PPID, or an unrelated effect of advanced age, as fertility (particularly in mares) has been determined to significantly decline with age in otherwise healthy mares.[940-942] Compression of the pars distalis or hypothalamus by expanding diseased pars intermedia could have a profound effect on reproductive hormones. In addition, a generalized decrease in dopamine output could directly affect release of reproductive hormones, as many are under dopaminergic regulation, including gonadotropin-releasing hormone and prolactin. There are no controlled studies documenting the relationship between treated and untreated horses with PPID and fertility.

EPIDEMIOLOGY

Compared with some other equine endocrine disorders, PPID appears to be a common clinical syndrome. That said, no large-scale prospective clinical studies have accurately documented the incidence of the disease to date. Additionally, estimates of the prevalence of the condition vary somewhat. In a UK study of more than 300 horses ≥15 years of age, horses were tested using plasma ACTH (assessed with seasonally adjusted reference ranges) and α-MSH concentration, and 21.2% of horses were positive for PPID.[943] Advancing age and hypertrichosis were significantly associated with PPID diagnosis in that study, which also showed that the disease is underrecognized by horse owners.[943] An equine veterinary practice from the eastern United States reported that 30% of surveyed horse owners reported haircoat changes in their horses suggestive of PPID.[944,945] Postmortem surveys also suggest that the disease is quite common in aged horses, with rates of gross or microscopic pathology of the pars intermedia reported to be from 30% to 40% of examined horses.[46,47] An incidence of 15% to 30% is markedly greater than originally reported in the 1970s (0.075–0.15% of 4000 horses of all ages seen in an ambulatory practice diagnosed by the presence of generalized hypertrichosis).[914] Hypertrichosis had 71% sensitivity, 95% specificity, 91% positive predictive value, and 84% negative predictive value for diagnosing the disease where a definitive diagnosis was based on postmortem examination of the pituitary gland.[462] At this time, it is unclear whether this change reflects a true increase in prevalence of disease, a change in equine demographics with a larger aged population, or an increased awareness and earlier recognition of disease due to change in diagnostic testing methods or frequency.

PPID has been diagnosed in horses as young as 7 years of age (range 7–40; average 19–21).[676,910,911,931,947] Although all breeds are susceptible, ponies and Morgan Horses may be predisposed.[433,676,911,915,948] Despite earlier studies suggesting PPID to be more prevalent in females[910,949-951] or males,[911] there appears to be no sex predilection.[433,676,911,931,952] The disease also occurs in donkeys, but prevalence studies are lacking.

Pars intermedia adenomas and microadenomas are often observed at postmortem examination in elderly horses with no previous history or reported clinical signs of this condition.[462,946] The significance of these clinically silent histologic findings is unknown.

PATHOGENESIS

Pars intermedia hyperplasia and hypertrophy are consistent findings in PPID,[606,953] and data suggest that loss of inhibitory

control of pars intermedia cell function is associated with triggering unregulated cell proliferation and the development of adenomas. The pars intermedia in horses and other species is inhibited by dopamine of hypothalamic origin.[954] There are three neuroendocrine dopaminergic tracts: the tuberoinfundibular, tuberohypophyseal, and periventricular dopaminergic neurons.[955] It is the periventricular neurons that appear most critical in regulating cell proliferation and hormone production and release in the pars intermedia.[956] The periventricular neurons originate in the periventricular nucleus, adjacent to the third ventricle, and project through the infundibular stalk, terminating in the pars intermedia. In the pars intermedia, the periventricular neurons directly innervate melanotropes, where they release dopamine that interacts with dopaminergic D_2-type receptors on melanotropes. In the presence of dopamine, the D_2 receptors act to inhibit POMC mRNA expression and POMC-derived intermediate lobe hormone release. In rodents, surgical disruption of the periventricular neurons results in increased α-MSH release, confirming a melanotropic inhibitory role for the periventricular neurons.[956] In contrast, prolactin release is regulated primarily by the tuberoinfundibular dopaminergic neurons. These originate in the arcuate nucleus and release dopamine at the median eminence. From there, dopamine is transported to the anterior lobe through the hypothalamo-hypophyseal portal system.[955]

Loss of dopaminergic inhibition in horses with PPID was suggested by the data of Orth and colleagues[957] (who found that the D_2-receptor agonists, bromocriptine or pergolide, decreased POMC-derived peptide concentrations in horses with PPID) and the work of Millington and colleagues[934] (who found low concentrations of dopamine and dopamine metabolites in the pars intermedia of horses with PPID). These data suggested that although dopamine was lacking in the pars intermedia of horses with PPID, responsiveness to dopamine and exogenous dopaminergic agonists was intact (including exogenous dopaminergic agonists).[957] This understanding has made it possible to recommend dopaminergic agonists (e.g., pergolide) in the symptomatic treatment of PPID. Several studies[433,917,958,959] have documented the efficacy of dopamine agonists in the treatment of PPID as described later. Studies have suggested that the loss of dopaminergic input to the pars intermedia is a consequence of neurodegeneration of the periventricular neurons.[560] A loss of dopaminergic cell bodies in the periventricular nucleus of the hypothalamus and the nerve terminals in the pars intermedia was demonstrated in horses with PPID using immunohistochemistry.[560] In addition, in horses with PPID dopaminergic nerve terminals showed evidence of oxidative stress, suggesting that free radical damage may participate in periventricular neuronal damage and cell loss. Oxidative stress has been implicated as a contributing factor in the pathogenesis of many other neurodegenerative diseases.[960] Evidence from other species suggests that additional hypothalamic factors, such as TRH, serotonin, and GABA, are important in regulating melanotrope function in the pars intermedia.[934,961] In horses, a direct positive effect of TRH on melanotropes has been shown.[962] When equine melanotropes were maintained in culture, treatment with TRH resulted in a release of α-MSH. In addition, horses administered TRH have a rapid and substantial increase in plasma α-MSH concentration.[962] In other species, serotonin is also a positive releasing factor for pars intermedia cells.[954] However, the role of serotonin on equine pars intermedia function is unclear, and Millington and colleagues[934] found no difference in serotonin concentrations in the pars intermedia of affected versus control horses. GABA has a tonic inhibitory effect on POMC synthesis in the pars intermedia of other species[961]; however, the role of GABA in the pathogenesis of equine PPID has not been investigated.

Both the anterior lobe (corticotropes) and the intermediate lobe (melanotropes) synthesize the identical hormone precursor molecule, POMC[963]; however, in the intermediate lobe, the posttranslational cleavage and processing of POMC is different from that in the anterior lobe.[934,964] In the anterior lobe, the major products of POMC are ACTH and β-lipotropin (β-LPH) (Fig. 16.22). In the intermediate lobe, ACTH is further cleaved to produce α-MSH and corticotropin-like intermediate lobe peptide (CLIP), and β-LPH is processed to β-END.[964,965] Therefore in the pars intermedia, ACTH is a minor (2%) posttranslational product of POMC.[65] It also appears that POMC production and cleavage in the pars intermedia of the horse with PPID remains intact, but postcleavage modification of the peptides is altered.[934,963] Millington and colleagues[934] found that the posttranslational processing of β-END in normal tissues was different from that in equine pituitary adenomas, with significantly more of the active (agonist) form of β-END present in the pituitary of horses with PPID.

Although progress has been made in our understanding of the pathogenesis of PPID in horses, many questions remain unanswered. For example, why do a number of horses with PPID have low cortisol concentrations despite high ACTH concentrations? Cortisol concentrations are variable in affected horses,[457,606,951,966] and adrenocortical hyperplasia is not a consistent finding.[910,951] Therefore it is difficult to explain hyperglycemia, neutrophilia, lymphopenia, and other clinical signs such as laminitis and predisposition to infections as a result of glucocorticoid excess. Cortisol may be responsible for some of the clinical signs associated with PPID; however, many studies have found that cortisol concentrations in horses with PPID may be within or below the normal range, suggesting that unidentified factors may be as important as or more important than hypercortisolemia in the pathogenesis of this condition. Furthermore, these findings are consistent with the low frequency (20%) of adrenocortical hyperplasia in horses diagnosed with PPID.[910,951] One explanation for the low cortisol concentration in some affected horses may be that glucocorticoid synthesis and secretion from the adrenal gland is downregulated from excessive and prolonged exposure to ACTH. Alternatively, ACTH secreted in horses with PPID may be immunologically reactive but biologically inert (perhaps due to posttranslational modifications). Finally, recent work has demonstrated that although horses with PPID have similar total cortisol concentrations to control animals, their free cortisol fraction is increased; decreased plasma cortisol-binding capacity could therefore contribute to the pathophysiology of PPID, even in the absence of overt hypercortisolemia.[723]

PATHOLOGIC FINDINGS

Horses with PPID typically have a grossly enlarged pituitary due to hypertrophy, hyperplasia, and adenoma formation in the pars intermedia (Fig. 16.23). Adenomas of the pars intermedia are white-to-yellow, nodular or multinodular masses that can infiltrate or compress the pars distalis and pars nervosa.[910,951] In some horses, pituitary microadenomas (smaller than 1 cm) may be evident. Microscopically, these adenomas

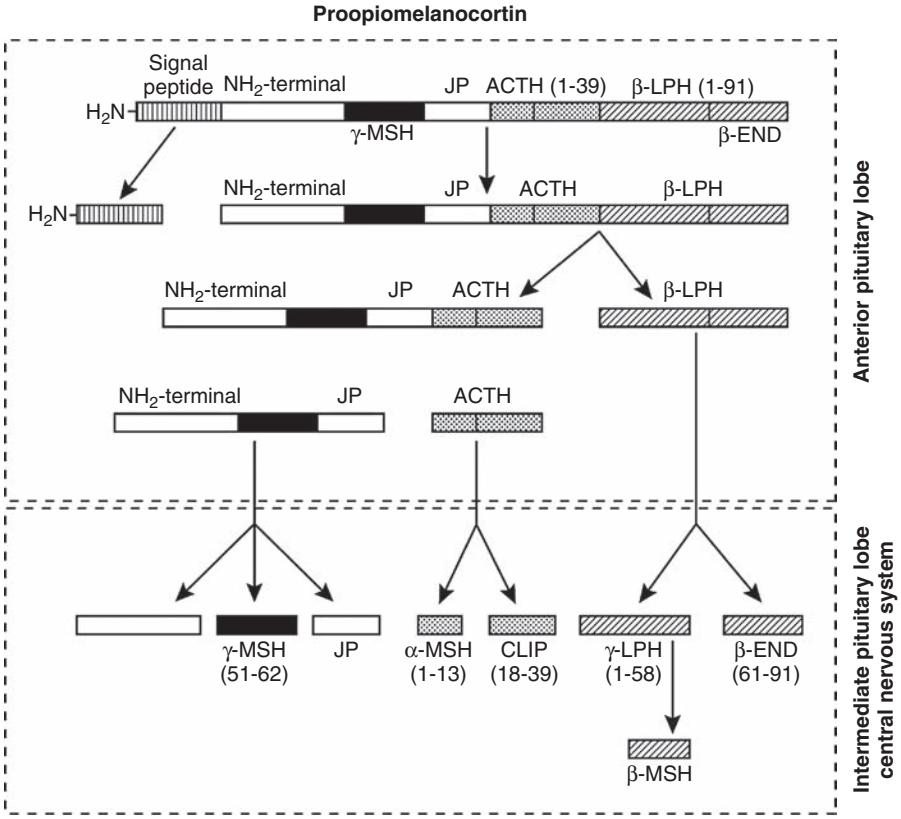

FIG. **16.22** Processing of proopiomelanocortin (POMC) in the anterior pituitary lobe, the intermediate pituitary lobe, and the central nervous system. In the anterior lobe, ACTH and β-LPH are the major products of POMC. In the intermediate lobe and in the central nervous system, ACTH is cleaved to produce α-MSH and CLIP, and β-LPH is cleaved to produce β-END. *ACTH*, adrenocorticotropic hormone; *-LPH*, β-, γ- lipotropin; *-MSH*, α-, β-, γ-melanocyte-stimulating hormone; *CLIP*, corticotropin-like intermediate lobe peptide; *β-END*, β-endorphin; *JP*, joining peptide. (Adapted from Castro and colleagues.[965])

consist of large columnar, spindle-shaped, or polyhedral cells that form palisades and pseudoacini.[910] The tumor cells are slightly acidophilic with hematoxylin and eosin staining and chromophobic with trichrome stain.[910] Pars intermedia adenomas may compress the overlying hypothalamus or optic chiasm, resulting in damage to nuclei that are important in endocrine and metabolic functions.

Adrenocortical hyperplasia is not a consistent finding; 1 of 5,[51] 4 of 19,[910] and 14 of 32[951a] horses had hyperplasia of the adrenal cortex. The lack of cortical hyperplasia in most horses with PPID supports the contention that the clinical signs in these horses are not the result of hyperadrenocorticism. The variability among affected horses to the ACTH stimulation test (measuring cortisol release) may be the result of inconsistent adrenal hyperplasia.

Skin biopsies reveal normal hair follicles in anagen phase, normal epidermis and dermal collagen, and a lack of the characteristic lesions present in dogs with Cushing disease from cortisol excess; however, a relative lack of follicles in telogen phase may characterize the skin biopsy from a patient with untreated PPID.[918] Although laminitis is a relatively common finding in horses with PPID, the histopathologic features in the laminae of these horses are not specific to this condition.[919,967]

LABORATORY TESTING

The diagnosis of PPID in many cases can be suggested by history, clinical signs, and preliminary laboratory results. Initial testing should include complete blood count, serum chemistry profile, and urinalysis. Horses with PPID may have a normal complete blood cell count and serum chemistry profile. Clinicopathologic abnormalities reported in horses with PPID include anemia, neutrophilia, lymphopenia, eosinopenia, hyperglycemia, hyperlipemia, increased liver enzymes, and glucosuria.[353,676,911,947,949-951] Persistent hyperglycemia is not uncommon in clinically affected horses; over 45% (94% in one study) of horses with PPID had hyperglycemia.[676,911,915,949,951] Many horses with PPID and hyperglycemia have insulin dysregulation (hyperglycemia and hyperinsulinemia), but neither finding should be considered diagnostic of PPID.[968] Although insulin-resistant hyperglycemia can be present, it is also possible that hyperglycemia in some horses may result from painful or stressful conditions (such as laminitis).[929] Glucosuria is a frequent finding (up to 77% in one study) in horses with PPID and hyperglycemia.[911] Hyperlipemia may be present in affected horses, but it is more frequent in ponies.[926,969]

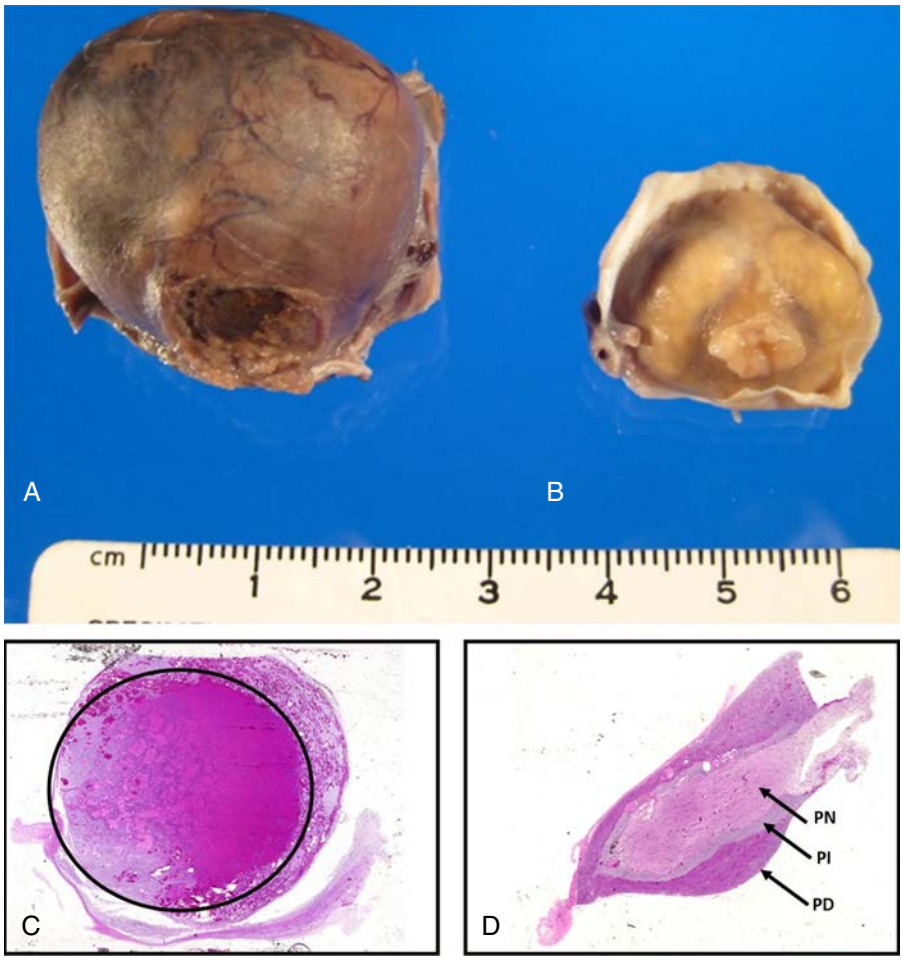

FIG. **16.23** Pituitary gland from a horse with advanced PPID showing marked enlargement and rounding (A), compared with that from a healthy horse (B). A sagittal section of the pituitary gland from A (C) shows a large adenoma *(black circle)* with compression of the adjacent pituitary structures. Three distinct lobes (pars distalis [PD], pars intermedia [PI], and pars nervosa [PN]) are apparent in the sagittal section of the pituitary gland from the healthy horse (D) from B (hematoxylin and eosin staining).

DIAGNOSTIC TESTING

Specific diagnostic testing for PPID may be indicated based on history, clinical signs, and laboratory findings. Many tests for the diagnosis of PPID have been evaluated; however, based on the limited number of horses studied and the variable results from some of these studies, it is difficult to recommend them for wholesale clinical use without additional validation. One limitation in the diagnosis of PPID is establishing a "gold standard" against which to evaluate new diagnostic tests, and currently perhaps the only well-accepted gold standard is postmortem examination interpreted in conjunction with clinical signs. In fact, even this postmortem "gold standard" (histopathologic evaluation of the pituitary gland) has been questioned as insufficiently accurate.[970] Another important consideration is the season during which the testing is performed. The secretory output of the equine pars intermedia is known to increase in the fall (Northern Hemisphere), and as a result, false-positive diagnostic tests may occur when testing is performed between August and October unless seasonally adjusted reference ranges are used for interpretation (ACTH).[537-540]

Baseline Cortisol Concentrations

Measurement of baseline plasma concentrations of cortisol has been proposed to aid in the diagnosis of PPID. However, in horses with PPID, resting plasma concentrations of total cortisol may be within the normal range,[951] mildly increased,[606] or decreased,[457,966] and therefore measuring baseline plasma cortisol concentrations to diagnose PPID is not recommended. Healthy horses have diurnal variations in plasma cortisol concentrations, with higher concentrations in the morning than in the late evening, although significant individual variation occurs.[971,972] Minimal diurnal variations in cortisol concentrations have been reported in horses with PPID.[606] However, circadian cortisol variability is commonly blunted in horses with other diseases or stress-related conditions,[973] thus precluding its usefulness as a diagnostic test.

In addition to plasma, cortisol concentrations have been determined in saliva and urine of healthy horses and horses with PPID.[925,926,972] van der Kolk and colleagues[972] measured salivary cortisol concentrations in healthy horses and found that there was a trend for higher salivary cortisol concentrations in the morning than in the evening although the

differences were not statistically significant. Those authors also found that plasma and salivary cortisol concentrations were correlated and that both increased or decreased following administration of ACTH or dexamethasone, respectively. Salivary cortisol concentration testing is not recommended for use in diagnosing PPID. Tear cortisol concentrations were increased in some horses and ponies with PPID compared with healthy controls.[974]

Although total plasma and salivary cortisol concentration have been shown to be insufficiently sensitive and specific for use in diagnosing PPID, recent work has demonstrated that the free cortisol fraction in plasma is more discriminatory for equine endocrine disease.[723] Horses with PPID, obese horses, and horses with insulin dysregulation all had higher free cortisol fractions than healthy control horses (even thought their total cortisol concentrations were similar). Although the diagnostic utility of this finding is currently unclear, free cortisol may be more relevant to the pathogenesis of equine endocrinopathies than total cortisol and warrants further study.

Urinary Corticoid:Creatinine Ratio

The urinary corticoid:creatinine (c:c) ratio has been determined in ponies and horses suffering from PPID.[925,926] van der Kolk and colleagues[925] found that horses with PPID had higher urinary concentrations of corticoids and a higher c:c ratio than healthy horses; however, in their study there was overlap in the c:c ratio between healthy and diseased horses resulting in a number of false-positive and false-negative results, thus limiting the value of this test alone for the diagnosis of PPID. In addition, horses were included in that study on the basis of the ACTH stimulation test, which itself has significant variability among horses with PPID and between healthy ponies and horses.[915] No ponies were included in the control group, and most of the affected animals were ponies. Additional studies comparing the c:c ratio to well-accepted and validated diagnostic procedures are necessary to recommend this test over other tests.

Dexamethasone Suppression Test

The dexamethasone suppression test (DST) has been a well-accepted and recommended test for the diagnosis of PPID in horses.[606,975,976] This test is based on the lack of suppression of plasma cortisol concentrations in horses with PPID at 19 to 24 hours after dexamethasone administration.[606] It has been suggested that plasma cortisol concentrations are not suppressed by dexamethasone administration in horses with PPID due to production of ACTH from melanotropes of the pars intermedia which, as described earlier, are not responsive to cortisol feedback.[606] The most commonly used protocol for dexamethasone suppression is the overnight DST. A baseline blood sample is collected for serum cortisol measurement between 4 and 6 PM, after which dexamethasone is administered (40 µg/kg IM). Blood samples are collected at 15 and 19 hours (8 AM and 12 PM) after dexamethasone administration. Many clinicians will omit the 15-hour sample and collect only a single cortisol sample at 19 hours after dexamethasone administration. Plasma cortisol concentrations should be below 1 µg/dL in horses that suppress normally; concentrations above this level suggest PPID. This test provides simplicity, is inexpensive, and is well accepted by clinicians. Although the test is useful in distinguishing horses with PPID from horses with an apparently functional HPAA, both false positives and false negatives may occur. False positives are common when horses are tested during the fall, as there are no seasonally adjusted reference ranges against which to evaluate the results of this test. Therefore this test should likely only be performed between the months of November and July (Northern Hemisphere). Donaldson and colleagues[539] reported false-positive rates of 20% and 40% in healthy ponies and horses, respectively, when tested in the fall. False-negative test results most commonly are observed in the early course of the disease. Horses with clinical indicators of PPID and normal dexamethasone suppression should be monitored and retested after 4 to 6 months; alternatively, a test that can be interpreted against seasonally adjusted reference ranges (ACTH) or a more sensitive diagnostic test (TRH stimulation test) should be performed.[977] Although many clinicians are concerned with steroid-induced laminitis as a result of the DST test, no adverse effects of this test were reported when a large number of horses with PPID were evaluated.[606] Use of this test has recently been largely supplanted by tests that are more convenient, more sensitive, less time-consuming, and easier to interpret (namely, the baseline ACTH concentration and the TRH simulation test).

Baseline ACTH Concentrations

Increased plasma concentrations of ACTH and POMC-derived peptides (such as α-MSH) have been reported in horses with PPID.[537-539,603,915,916,934,957,963,978] Couetil and colleagues[915] found that plasma ACTH concentrations for the diagnosis of PPID had a sensitivity of 90.9% in horses and 81.8% in ponies, and a specificity of 100% using dexamethasone suppression as the gold standard.[915] Other studies have reported false-positive and false-negative results.[931] Determination of resting ACTH concentrations is a good initial test for PPID, and testing in the autumn months may increase the sensitivity of this test when interpreted according to seasonally adjusted reference ranges.[537,538,952,978] Plasma ACTH concentrations are higher in the fall in normal animals, and this effect is exacerbated in animals with PPID, which enhances the sensitivity of the test (increasing the separation between normal and abnormal values). It is important to consider when determining baseline ACTH concentrations that stressful conditions may increase ACTH plasma concentrations, although the likelihood of this interfering in the interpretation of this test is considered unlikely in all but the most critically ill equine patients. Furthermore, although circadian and ultradian variation in plasma ACTH concentration has been documented in horses, this is unlikely to affect the interpretation of this test for the diagnosis of PPID.[979] Assessment of ACTH in multiple samples from the same patient has not been shown to be diagnostically superior to a single measurement.[979,980] A recent study found no advantage of paired over single ACTH measurement, with similar sensitivities and specificities.[980] Blood samples to determine ACTH concentrations should be collected in EDTA tubes (ideally plastic), kept at 4°C, centrifuged within 8 hours, and plasma shipped on ice immediately or stored frozen until analysis.[915,959] ACTH appears to be stable at room temperature longer than previously believed.[981] One study found minimal changes in ACTH concentrations over 48 hours when whole blood was stored at 4°C.[981] In the same study, concentrations did not change in whole blood over 8 hours when samples were kept at room temperature. Regardless, it is important to follow recommendations when handling samples for ACTH measurements. Pretest feeding recommendations have not been standardized for the baseline ACTH or TRH stimulation test, but fed state has recently been

shown by one group to affect the results of both of these tests (with baseline and stimulated ACTH concentrations higher in fed animals than fasted animals),[982] whereas others reported no effect of feeding conditions on either baseline or TRH-stimulated ACTH concentration.[983]

ACTH Stimulation Test

Administration of ACTH (1 IU/kg of natural ACTH gel IM; 25–100 IU [250–1000 μg] of synthetic $ACTH_{1-24}$ [cosyntropin; tetracosactide; tetracosactrin] IV) has been used in different studies with different results.[603,606,607,676,916,925] A horse with PPID would be expected to have an exaggerated (at least fourfold) cortisol response to ACTH stimulation, and when an increased response is present in a horse with elevated resting ACTH concentrations, a diagnosis of PPID can be supported.[603] Dybdal and colleagues[606] failed to detect a statistical difference in cortisol concentrations between control horses and horses with PPID after intramuscular administration of 1 IU/kg of natural ACTH gel between 8 and 10 AM, samples being collected in heparinized tubes before, and 2, 4, 8, and 12 hours after ACTH administration. van der Kolk and colleagues[916] found a significantly higher increase in cortisol concentrations in horses with PPID after IV administration of 25 IU of synthetic $ACTH_{1-24}$ at 9 AM, with samples collected in EDTA tubes just before and 2 hours after ACTH administration. Although the ACTH stimulation test is more useful in assessing adrenal gland function or exhaustion, it does not seem to be an effective test to assess HPAA function in horses suspected of having PPID. Combining the ACTH stimulation test with the DST failed to improve the tests' performance in distinguishing horses with PPID from control horses.[606]

TRH Stimulation Test

Beech and Garcia evaluated the effect of TRH administration on plasma cortisol concentrations in healthy horses and in horses with PPID.[457] They found that TRH administration (1 mg IV) to horses with PPID, in addition to increasing T_3 and T_4 concentrations, also resulted in a significant increase in plasma concentrations of cortisol within 15 minutes after TRH administration, and cortisol concentrations remained elevated for 90 minutes. No significant increases in plasma cortisol concentrations were present in healthy horses. Eiler and colleagues[966] evaluated the TRH stimulation test in two horses suspected of having PPID and three healthy horses and found that maximal cortisol concentrations overall were not statistically different between groups; however, too few horses were included to make any conclusion.[966] The sensitivity and diagnostic performance of the TRH stimulation test was subsequently shown to be improved by measuring ACTH as the output variable, rather than cortisol (see discussion of immunoreactive vs. biologically active ACTH earlier).[924] TRH has been shown to be a direct releasing factor for equine melanotropes, and TRH increases the secretion of α-MSH and ACTH in both normal horses and those with PPID. The diagnostic utility of this test lies in the fact that ACTH concentrations are higher and more prolonged following TRH administration in horses with PPID than those without.[924,984,985] This test likely has the greatest sensitivity for detection of subclinical PPID of the diagnostic tests currently available, and, as such, this stimulation test has been advocated for use in cases with vague clinical signs or equivocal results of baseline ACTH concentrations.[977] Seasonal variability in the results of this test have also been reported,[986] and although the sensitivity would be expected to be maximized during the autumn months (as with baseline ACTH concentrations), seasonally adjusted reference ranges have not yet been created for this test. Therefore testing is only recommended during the months of November–July in the Northern Hemisphere.[977]

A veterinary-labeled TRH solution is not available for equine practitioners. However, chemical-grade TRH powder can be purchased from a number of companies, diluted in saline solution, filter sterilized, and frozen in 1-mg aliquots until use. Veterinary compounding pharmacies are also offering TRH as an injectable solution. Side effects that may be observed in horses after TRH administration include yawning, lip movements, salivation, trembling, and coughing.

To administer the test, 1 mg of compounded, filter-sterilized TRH should be administered intravenously following collection of a blood sample in an EDTA tube (as for ACTH, described earlier). An additional blood sample in EDTA should be collected at 10 minutes after TRH administration, and both samples should be submitted for measurement of ACTH concentration; $[ACTH]_{10min}$ values greater than 110 pg/mL are consistent with a diagnosis of PPID.[977] A sample at 30 minutes is also acceptable using a cutoff of 65 pg/mL. The baseline sample can be omitted to improve economic feasibility.

Combined DST/TRH Test

The combination of a DST with the TRH stimulation test was evaluated as a diagnostic method for PPID in 42 horses.[462] After baseline sampling in EDTA-containing tubes, dexamethasone (40 μg/kg IV) was administered (8–10 AM). A second sample was collected 3 hours later, and then TRH (1.1 mg IV) was administered. Blood samples were collected at 3.5 (30 minutes after TRH administration) and 24 hours after dexamethasone administration. The test was considered positive if cortisol concentration was greater than 1 μg/dL at 24 hours, or the 3-hour cortisol concentration increased by ≥66% 30 minutes after TRH administration. Performance of the test was evaluated using postmortem diagnosis as the gold standard. The TRH component alone had a sensitivity of 41% and a specificity of 92%, and the DST alone had a sensitivity of 65% and a specificity of 76%. When performed as a combined test, the sensitivity (88%) and specificity (76%) improved. Disadvantages include expense and the need for multiple sample collections. This test has, like other tests, been supplanted by the baseline ACTH and TRH stimulation tests.

Resting Insulin Concentrations

An assessment of insulin regulation should be performed in all horses suspected of having PPID as hyperinsulinemia is a strong predictor of laminitis in this population. Other conditions, such as EMS and stress, are also associated with hyperinsulinemia or ID; therefore the presence of hyperinsulinemia or ID alone is not diagnostic. Although hyperinsulinemia alone is not diagnostic for PPID, it does have prognostic value, as horses or ponies with hyperinsulinemia are more likely to develop laminitis.[799,987] Horses with PPID that were laminitic were much more likely to be hyperinsulinemic than horses with PPID that were nonlaminitic in one study.[919] Therefore measurement of fasting insulin and glucose is recommended in horses suspected of having PPID. If resting insulin and glucose is not diagnostic but ID is suspected, further tests may be useful to confirm ID, such as the combined glucose-insulin test, the oral sugar test, or more involved methods (such as the

frequently sampled insulin-modified IV glucose tolerance test or the euglycemic-hyperinsulinemic clamp). Details on this testing can be found in the section on the equine metabolic syndrome.

Determination of POMC Peptides

Based on our current knowledge of equine pars intermedia dysfunction, it would be reasonable to determine plasma concentrations of POMC-derived peptides (ACTH, α-MSH, β-END, CLIP) in horses suspected of having PPID. These peptides were found to be increased in horses with PPID.[537,913,915,916,934,957,963,988] Determination of POMC-derived peptides in the clinical setting has been limited to ACTH plasma concentrations, and the use of human immunoassays to determine equine ACTH concentrations has been validated.[915]

Plasma and cerebrospinal fluid β-END concentrations were found to be increased several-fold in horses with PPID.[934] Furthermore, pars intermedia POMC peptides (α-MSH, β-END, CLIP) were disproportionally higher compared with ACTH plasma concentrations in affected horses.[957,963] The sensitivity of α-MSH, either baseline concentration or used as the output variable following TRH stimulation, has been reported to be similar to that of ACTH, but the specificity might be greater.[952,985] Although a human-based radioimmunoassay has been validated for use with horse samples,[988] this test is not currently commercially available, but it would be assumed to be clinically useful should it become so in the future.

Domperidone Response Test

Another test that has been evaluated for diagnosis of PPID is the domperidone response test.[985,989] Domperidone is a dopamine receptor antagonist. In horses with PPID, administration of domperidone is suggested to exacerbate the loss of dopaminergic inhibition and result in release of ACTH from the pars intermedia. In a study of 33 horses, plasma ACTH concentration 8 hours after domperidone administration was positively correlated with histologic PPID severity score and morphometric analysis of pars intermedia size, although not all animals considered "positive" by histology and domperidone test were exhibiting clinical signs of disease. In the absence of any clinical signs, it is difficult to determine whether the relatively mild histologic changes (diffuse pars intermedia hyperplasia) were indicative of early disease or associated with an increased function of the intermediate lobe for other reasons. In a second study, the domperidone response test was compared with the TRH stimulation test in 28 horses using histology and clinical signs as the diagnostic gold standard.[985] In this population, evaluating ACTH concentration 30 minutes after TRH administration was more accurate at diagnosing PPID than use of a doubling of ACTH following domperidone administration.[985]

Radiographic Methods

Computed tomography (CT) has been used to diagnose PPID in horses.[990-992] Although measurements of the pituitary by CT correlate reasonably well with postmortem measurements, they have marginal accuracy.[992] Ventral radiography and contrast venography were successfully used to diagnose PPID in horses and ponies.[993] Magnetic resonance imaging (MRI) is the preferred diagnostic imaging modality in human pituitary disease. MRI was useful at identifying pituitary gland and pars intermedia size in horses with PPID.[994] Pituitary microadenomas and macroadenomas could be visualized, and MRI scoring using T2-weighted images was correlated with the histologic score.[994] Although available to equine clinicians, these methods are far from being practical in the diagnosis of PPID, as they require anesthesia and expensive equipment and are not cost-effective compared with other diagnostic methods.

TREATMENT

Optimal treatment of PPID includes a combination of management and pharmaceutical interventions. PPID is observed primarily in older horses; therefore it is important to treat the dysfunctional pituitary, as well as many of the pathologic conditions associated with aging. Special attention should be given to providing optimal management including high-quality feed, dental care, deworming, and farrier care. It is also important to pay particular attention to the skin and haircoat. Many horses cannot properly shed their winter coat and as a result may develop hyperthermia. In addition, horses with PPID are prone to skin infections. The most difficult complication to manage is laminitis, which may be complicated by overfeeding of hay, grass, or grain containing excessive nonstructural carbohydrate. Therefore reducing the amount of soluble carbohydrate in the diet is advisable (even in nonlaminitic animals). Exercise is also recommended for nonlaminitic patients. Due to the insidious nature of the laminitis observed in horses with endocrinopathies, close monitoring of hoof growth and freedom of movement is desirable in all aged horses. Periodic radiographic assessment of the feet in horses at risk of PPID may be prudent.

As discussed earlier in this section, the regulation of POMC peptide synthesis and secretion is under the influence of the hypothalamic periventricular dopaminergic systems. POMC synthesis and secretion by the pars intermedia of horses with PPID typically remains responsive to similar releasing and inhibiting factors as the pars intermedia from unaffected horses and other species.[957] Based on this information, the medical treatment of PPID involves the use of dopamine agonists or serotonin antagonists.

Pergolide is the most commonly used dopamine D_2 receptor agonist for the treatment of PPID; however, others including bromocriptine and cabergoline have been investigated.[995-1001] The oral absorption of pergolide in horses is good, with a half-life similar to humans (around 20 hours).[1002] However, for an equivalent dose, plasma pergolide concentrations are higher in horses than humans, and this difference has been attributed to higher volume of distribution, lower bioavailability, and extensive first-pass metabolism in people.[1002]

Bromocriptine can be given either orally or by subcutaneous injection (0.03–0.09 mg/kg twice a day),[675,957,675] but its use in treatment of PPID is limited. Cabergoline, similar to bromocriptine, lisuride, and pergolide, is an ergot derivative with potent dopamine D_2 receptor agonist actions used in people to suppress pituitary prolactin secretion (lactotropes) in conditions associated hyperprolactinemia, as adjunctive therapy of acromegaly, and in Parkinson disease. Due to its high affinity for D_2 receptors, it has the potential to be used in the treatment of PPID. Cabergoline in a slow-release vehicle was shown to decrease PI response to stimulation in healthy mares and mares with insulin resistance; however, its efficacy in the treatment of PPID has not been explored.[1000,1001]

Oral pergolide is widely used and has been shown to be beneficial in the treatment of horses and ponies with PPID, and a

Food and Drug Administration (FDA)-approved formulation is now commercially available (Prascend™, Boehringer-Ingelheim). Lifelong treatment is recommended following diagnosis.[917,931,998] Doses of pergolide from 0.2 mg up to 5 mg/horse per day, once a day, or divided twice daily have been used in ponies and horses, with treatment durations of greater than 5 years.[958] Treatment typically starts with a total daily dose of 1.0 mg/day, and if there is no clinical evidence of improvement by 4 to 6 weeks, the dose should be increased gradually, every 3 to 4 weeks by 0.5 mg. Success of treatment should be assessed by documenting both improvement of clinical signs and normalization of diagnostic test results. Most horses show improvement within 6 to 8 weeks of treatment with doses of 1.0 to 2.0 mg of pergolide/day (see Fig. 16.21). Failure to respond to pergolide treatment may occur in very advanced disease, if a poor-quality drug is obtained from a compounding pharmacy, if the drug is not consumed completely by the patient, or if the diagnosis is incorrect. Periodic reassessments of ACTH or TRH stimulation are recommended, particularly if the patient experiences an exacerbation of clinical signs, as the dose required to control disease may change over time.[917] Long-term oral administration of pergolide is effective at reducing ACTH concentrations in aged horses, and ACTH increased to previous values by 10 days after discontinuation.[958] Of interest, 2 days after pergolide discontinuation, ACTH concentrations increased in a number of horses despite detectable plasma pergolide concentrations.[958] The pharmacokinetic properties of IV pergolide have been investigated.[1003] Although two studies found a half-life of >20 hours,[958,1002] a third study found a terminal elimination half-life of 5.6 hours,[1003] indicating that twice-daily dosing may be necessary in some horses to maintain appropriate concentrations. A number of horses treated with pergolide may develop anorexia, which typically resolves by reducing the dose.[931] Although long-term pergolide therapy has been associated with fibrotic cardiac valvular lesions in humans,[1004] similar lesions have not been reported in horses to date.

A second drug suggested to be useful in treatment of PPID is cyproheptadine, although horses treated with pergolide show a better response than horses treated with cyproheptadine.[917,931] Further, no FDA-approved formulation of cyproheptadine is currently available for horses. Cyproheptadine is a nonselective 5-hydroxytryptamine receptor blocking agent (serotonin antagonist) that reduces ACTH and β-END secretion from ACTH-producing tumors in humans.[1005] There is limited information on the serotonin functions in the hypothalamus and pituitary gland of the horse, and no difference in serotonin concentration was found between the pars intermedia of horses with PPID and control horses.[934] However, this drug has been widely used alone or in combination with pergolide to treat PPID.[917,959] Serotonin is also a histamine receptor (H_1) antagonist with weak anticholinergic activity. Serotonin has been shown to inhibit the release of prolactin from anterior pituitary cells in a non–serotonin receptor–dependent fashion by blocking calcium influx at the cell membrane.[1006] Cyproheptadine has been used for many years to treat horses with PPID with variable results. Cyproheptadine has also been proposed for the treatment of photic headshaking in horses.[1007] It is estimated that one third of horses with PPID show improvement when treated with cyproheptadine.[917,948] This drug has been recommended at 0.25 mg/kg orally once a day for 4 to 8 weeks, ideally in conjunction with pergolide treatment.[917] If there is no clinical evidence of improvement and no reduction in plasma ACTH concentrations, the dosage frequency should be increased to twice a day for 1 month, at which time ACTH concentrations should be determined or the TRH stimulation repeated.

Alternative therapeutic compounds have been suggested to treat horses with PPID. Aqueous extracts of *Vitex agnus-castus* (chasteberry, chaste tree, vitex, Evitex, and Hormonise for veterinary use) have been used to treat horses with PPID. *Vitex agnus-castus* extracts contain compounds (diterpenoids) that stimulate dopamine D_2 receptor activity and inhibit different opioid receptors.[1008] Because of its dopaminergic effects, *Vitex* has been recommended as an alternative phytotherapeutic agent in the treatment of hyperprolactinemia and premenstrual syndrome in women.[1009] In a blinded study, there was no clinical improvement or improvement in diagnostic test results in 14 PPID-affected horses treated with *Vitex agnus-castus* extract.[1010] Although there is a physiologic and pharmacologic rationale in the possible use of these extracts to increase dopaminergic activity in the equine pituitary, there is currently no evidence to recommend *Vitex* to treat horses with PPID, particularly given the other treatment options available.

Trilostane is an enzymatic inhibitor of 3-β-hydroxysteroid dehydrogenase, an important enzyme in steroid synthesis. However, there is little information on the effects of trilostane in equine steroid metabolism.[1011] Trilostane has been proposed for the treatment of PPID, as well as in the treatment of EMS.[1012] In a study of 20 horses or ponies treated over 1 to 2 years, improvement in clinical signs other than hypertrichosis was recorded; however, DST results remained abnormal, suggesting an insufficient response to the drug.[1012] Until the mid-1980s, trilostane was recommended to treat Cushing disease in humans; however, due to its lack of potency in blocking cortisol synthesis, trilostane is no longer recommended to treat this condition.[1013] In horses with PPID, only few have evidence of adrenal hyperplasia; therefore treatments directed at restoring pars intermedia function and limiting expansion of the pituitary mass are considered more appropriate than those that target cortisol synthesis inhibition.

Pituitary-Independent Hyperadrenocorticism (Adrenal Cushing Syndrome)

In pituitary- or ACTH-independent hyperadrenocorticism, the adrenal cortex secretes excessive amounts of steroids, cortisol in particular, that are not subject to negative feedback. In other species this typically occurs with adrenal tumors. Primary adrenocortical tumors are rare in horses,[234,675-677] and the few cases reported in the literature were nonfunctional tumors. A 12-year-old Dutch Warmblood gelding was presented with a history of polyphagia, polydipsia, reduced muscle mass, hyperhydrosis, lethargy, and delayed shedding of the haircoat.[675] The horse had persistent hyperglycemia and a normal adrenocortical response to ACTH stimulation. After unsuccessful treatment with bromocriptine, the horse was euthanized, and a unilateral adrenocortical adenoma was found.

Adrenocortical carcinomas have been documented in horses and are usually nonfunctional.[234,677] Of interest, one adrenocortical carcinoma in a 14-year-old Quarter Horse stallion presented for inappetance, weight loss, and abdominal pain was associated with hypercalcemia of malignancy, which is a paraneoplastic syndrome from excessive secretion of parathyroid hormone–related peptide.[234]

Anhidrosis

Ramiro E. Toribio

Equine anhidrosis (dry coat, nonsweating) is defined as the inability of horses to sweat in response to appropriate stimulation. Partial anhidrosis (hypohidrosis) is the most common presentation of this condition.

EPIDEMIOLOGY

Anhidrosis is frequent in the tropics and in areas with high temperatures and humidity, including the southern United States, Asia, Oceania, and Latin America. Earlier reports of "dry coat" were documented in tropical British colonies where Thoroughbred horses transported from England and Australia to tropical regions after arrival developed profuse sweating and subsequently transitioned to poor or insufficient sweating.[1014] It was initially proposed that anhidrosis resulted from a lack of adaptation to local conditions, in particular of horses from cold and temperate climates moving to warmer and humid areas.[1015] Some studies found no differences in the prevalence of anhidrosis between horses native to the southern United States and those from other states or countries,[510,1016,1017] whereas others showed an association between anhidrosis with the geographic origin of the horse.[1018] One study even found anhidrosis to be more frequent in horses native to Florida.[1017] These conflicting results are likely due to dissimilar sample populations, environmental conditions, inclusion criteria (geographic origin, age, breed, sex, type of activity), and data analysis.

The prevalence of anhidrosis across the United States is unknown, although it has been estimated to range from 6% to 20% in southern states.[510,1016,1017,1019] One study in Thoroughbred horses in central Florida found a prevalence of 6.1%, with horses in training and nonpregnant mares having the highest prevalence, but the disease was infrequent in young horses.[510] An epidemiologic survey of anhidrosis in Florida published in 2010 included 500 farms and 4620 horses.[1018] In that study, horses were classified as anhidrotic by the farm owner, manager, or veterinarian. Intradermal β-adrenergic receptor agonist testing was not employed because it is rarely used by field clinicians to make the diagnosis. Farms were classified as affected if they reported the condition in at least one horse. At the farm level, the prevalence of anhidrosis was 11.2% whereas at the animal level it was 1.8%. The prevalence differed from 0.08% in northern Florida to 4.3% in southern Florida. Farms located in central and southern Florida were more than twice as likely to have horses with anhidrosis than those in northern Florida. The odds of anhidrosis were higher in show and riding instruction than in ranch operations.[1018] Of interest, Thoroughbred and Warmblood horses, animals born in western or midwestern states, and those with a familial history of this condition were more likely to have anhidrosis.[1018] The disease seems to be more common in retired horses or horses used for nonracing performance than horses used for halter, pleasure, trail riding, or work.[1018] In Korea, the prevalence of anhidrosis in Thoroughbred horses, based on the intradermal epinephrine skin test, was 22%.[1020] In Pakistan, a prevalence of 12.4% was published.[1021]

Anhidrosis does not seem to be associated with exercise as previously suggested but rather with environmental conditions.[1016] There is no clear association with sex, breed, coat color, or country of origin.[510,1016,1017,1020] There seems to be a genetic component. For example, horses with a familial history of anhidrosis were 22 times more likely to be afflicted with this disorder. The influence of diet is controversial, with some clinicians claiming that anhidrosis is associated with high-protein diets and insufficient electrolyte intake.

PHYSIOLOGY

Thermal adaptation to heterogeneous environmental temperatures by endotherm animals (birds and mammals) is the result of evolutionary adjustments and selection pressure to maintain optimal biologic functions to succeed as a species. Physiologic functions are in great part dictated by the body temperature. It is clear then that there must be a thermal homeostatic system that senses and maintains body temperature within a narrow range (homeotherms) by coordinating mechanisms of heat loss, heat conservation, and heat generation. Losing the ability to thermoregulate results in hypothermia or hyperthermia, depending on surrounding temperature and humidity and results from pathologic conditions that alter temperature sensing, heat generation, or the hypothalamic temperature set-point. For heat loss, animals use radiation, conduction, convection, respiration, and evaporation. Radiation is simply the emission of infrared energy away from the body. Convection occurs when heat is transferred from the body to moving air or water. Conduction takes place when there is surface-to-surface thermal transfer to a solid structure or water. During respiration, colder air moves into the lungs, and warmer air is exhaled into the environment. In the case of evaporation (sweating), heat loss occurs through the conversion of water into gas. Specifically, vaporization removes heat from the body by converting water into vapor (evaporative cooling) through a process that requires energy.

The efficiency of each of these mechanisms depends on the species, physical activity, diseases, and environmental conditions. Conduction and convection are influenced by vasoconstriction and vasodilation. When ambient temperature is higher than body temperature, radiation, conduction, and convection become ineffective (the opposite can occur and the body may gain heat). In that case, evaporation and respiration become very important. This is evident in dogs that mostly rely on the respiratory system for heat exchange (panting). Any process that interferes with heat dissipation will lead to hyperthermia, tachypnea, stress, and, in severe cases, heat stroke, organ failure, and death.

The equine sweat glands (400–1128/cm^2) are apocrine, associated with the hair follicle (epitrichial), and consist of a secretory portion and a serpentine duct that opens into the follicular canal.[1022-1026] An important feature of the equine sweat glands compared with other species is their rich capillary network.[1023,1025] Details of equine thermoregulation are discussed elsewhere.[1027]

Sweat evaporation, followed by respiration, are the main ways for equids and humans to dissipate heat.[1028-1030] Sweating in horses is controlled by endocrine, neural, and vascular mechanisms.[1025,1031] Neural regulation mainly involves sympathetic β-adrenergic innervation whereas endocrine mechanisms consist of β-adrenergic receptor stimulation by circulating catecholamines.[1030] It appears that the neural sympathetic control of sweating in equidae is indirect by controlling regional blood flow whereas the humoral sympathetic

control is direct to the glands.[1023] This is evident in horses with Horner syndrome in which sympathetic denervation results in regional sweating that is believed to be caused by vasodilation and increased cutaneous blood flow.[1032]

The central neural pathway to the sweat gland is primarily sympathetic.[1033] Efferent fibers travel from the hypothalamus via the tegmentum to the intermediolateral column of the spinal cord to emerge from the ventral horns and synapse in the sympathetic ganglia. From here, postganglionic nonmyelinated fibers join peripheral nerves to reach the sweat glands. These sympathetic fibers control sweating, pilomotor response, cutaneous vasoconstriction, and vasodilation.[1033] Sympathetic fibers reaching sweat glands, at least in people, are cholinergic and adrenergic. In contrast to humans where neural cholinergic (muscarinic receptors) stimulation is important for sweat production,[1033] β_2-adrenergic receptor activation appears to dominate sweating in the horse.[1019,1023,1024,1026] Cholinergic innervation to the equine sweat glands has been demonstrated, and it has been proposed that it might be important in regulating regional blood flow.[1031,1034] The relative role of purinergic (ATP, adenosine) and nitrinergic (nitric oxide) stimulation remains unclear.[1023-1026,1031,1034-1038] Equine sweat glands are responsive to purinergic receptor activation.[1039] The importance of nitric oxide in equine sweat gland physiology is supported by the fact that inhibition of nitric oxide synthase attenuates sweating in healthy horses.[1036,1037] It has been proposed that the effect of nitric oxide could be through cutaneous vasodilation or by modulating the sympathetic control of sweating.[1036,1037]

PATHOPHYSIOLOGY

Even though a clear understanding on the pathogenesis of equine anhidrosis is lacking, proposed mechanisms include deficiency in β_2-adrenoreceptor agonists (deficient β_2-adrenergic stimulation), a poor sweat gland response to β_2-adrenergic stimulation (receptor refractoriness or downregulation), and inflammation.[1016] In regard to the neural control of sweating, it has been suggested that hypothalamic dysfunction from severe hyperthermia may be involved[1019]; however, there is no evidence to substantiate this hypothesis. It seems that the pathogenesis of anhidrosis results from a combination of insufficient neural and endocrine stimulation. Horses with skin denervation can sweat, although their response to thermal stimulation is impaired.[1040,1041] One study found that sweat gland innervation of horses with anhidrosis was normal,[1015] making denervation unlikely in the pathogenesis of anhidrosis.[1019,1040] A clinical example supporting that factors other than lack of autonomic innervation contribute to equine anhidrosis is equine Horner syndrome in which sympathetic denervation results in excessive sweating.

With regard to the role of the adrenal medulla in the pathogenesis of equine anhidrosis, some studies have shown that medullary dysfunction is improbable in the development of this disease.[1019,1040-1042] Similarly, vascular dysfunction to the sweat glands seems unlikely. Instead it has been suggested that abnormal dermal vascular perfusion could be relevant to the pathogenesis of equine anhidrosis.[1023,1035]

The fact that epinephrine concentrations in anhidrotic horses are normal or elevated,[1043] but sweat glands have a decreased response to adrenergic stimulation, indicates that receptor downregulation could be involved.[1015] Downregulation of β_2-adrenoreceptors has been demonstrated in anhidrotic horses.[1044] It is possible that excessive or prolonged exposure to catecholamines leads to reduced receptor signaling. The presence of sweat gland atrophy, cell flattening, and ductal obstruction on histologic examination does not imply that these changes are the cause but rather consequences of this disease.[1035,1045,1046] There is no evidence that inflammation or immune-mediated processes are central to the pathogenesis of equine anhidrosis. In humans, idiopathic sudomotor failure or idiopathic generalized anhidrosis, a condition characterized by reduced or lack of sweating, has been proposed to be caused by abnormal acetylcholine binding, reduced number of muscarinic receptors, or immune-mediated interference with cholinergic signaling.[1047] High immunoglobulin E (IgE) concentrations, the presence of pain (cholinergic urticaria), and a positive response to glucocorticoid therapy support an immune component in humans[1047] but remain unclear in horses, even though histologic abnormalities have been documented.[1023,1035,1046,1048]

It was recently shown that purinergic agonists increase intracellular calcium concentrations in sweat glands from healthy horses,[1039] and it has been suggested that purinergic P2Y receptors may be relevant to equine anhidrosis.[1049] Purinergic agonists stimulated electrolyte transport in sweat gland cells from normal horses but failed to elicit a response in cells from anhidrotic horses.[1038] Similarly, β_2-adrenergic receptor agonist stimulation failed to provoke a response in cells from anhidrotic horses.[1038] This indicates that both purinergic and adrenergic ion transport mechanisms may be involved in the pathogenesis of this condition. Assuming that abnormal β_2-adrenergic receptor signaling is central to the pathogenesis of anhidrosis, receptor polymorphisms could support the genetic predisposition of this condition. However, it is feasible that defects in other proteins, not necessarily the receptors per se, are implicated. The low expression of the water channel aquaporin-5 in anhidrotic horses may be of clinical relevance to the pathophysiology of anhidrosis, but it does not imply that is the cause.[1045]

The store-operated Ca^{2+} entry (SOCE) involves multiple proteins that increase intracellular Ca^{2+} to maintain the secretory function of exocrine cells.[1050] One of these proteins is stromal interaction molecule 1 (STIM1), which acts as a Ca^{2+} sensor at the endoplasmic reticulum membrane to modulate Ca^{2+} entry into the cell.[1050] Of interest, decreased STIM1 mRNA expression and protein activity were found in sweat glands isolated from anhidrotic horses, indicating that SOCE contributes to equine sweat production and abnormalities in this system may be involved in the pathogenesis of anhidrosis.[1051] Bestrophin-2 is an anion channel that facilitates Ca^{2+}-associated ionic transport and monovalent ion exchange into sweat via the $Na^+/K^+/2Cl^-$ cotransporter, and downregulation of these proteins has been documented in animal models of anhidrosis and suspected to occur in humans with idiopathic anhidrosis.[1052]

The role of thyroid hormones in the pathogenesis of anhidrosis is unclear. It is believed by some that anhidrosis is caused by hypothyroidism; however, there are no data to substantiate this. Some studies have found lower thyroid hormones concentrations in anhidrotic horses whereas others have not.[470,509,510,1017] Lower thyroid hormone concentrations in horses with clinical signs of anhidrosis may represent an adaptation to the disease (nonthyroidal illness syndrome). Baseline thyroid hormones and the thyroid hormone response to the TRH stimulation test were not different between anhidrotic

and matched control horses.[470] The fact that some horses may show improvement with L-thyroxine or iodinated casein supplementation indicates that thyroid hormones may enhance adrenoreceptor sensitivity, as documented in other species.[1053] It has been claimed that abnormal electrolyte concentrations are part of the pathogenesis of anhidrosis; however, in controlled studies no differences have been found between anhidrotic and healthy horses.[510]

Anhidrosis, heat stress, and exercise intolerance are documented conditions in equids with pituitary pars intermedia dysfunction, particularly in tropical climates.[1054] It has been proposed that drug-induced anhidrosis is the likely cause of hyperthermia in foals treated with macrolide antibiotics, particularly erythromycin.[1055]

CLINICAL SIGNS

Typical clinical signs include depression, anorexia, poor performance, tachypnea, hyperthermia (particularly after exercise), lack of or decreased sweating, alopecia, dry coat, and flaky skin, mainly over the face. Some areas may continue to sweat, predominantly under the saddle, mane, and inguinal and axillary regions. Initial signs are nonspecific and related to poor performance and respiratory problems. Tachypnea is the most common clinical sign in horses with anhidrosis.[1018] Early recognition of anhidrosis is important, particularly in hot climates where a delay in core temperature cooling can lead to heat stroke. In addition, anhidrosis represents a major stress to the animal, which can predispose to other diseases.

DIAGNOSIS

In general, the diagnosis of anhidrosis is based on clinical signs. The first specific method developed for the diagnosis of anhidrosis was the intradermal injection of epinephrine.[1056] Horses with anhidrosis will have a delayed or absent sweat response to this test. However, because epinephrine is not specific to β_2-receptors, α-adrenergic effects may mask the response of the sweat glands. Subsequently, tests based on β_2-receptor agonists (salbutamol, terbutaline) have been developed.[1029,1057] These methods are semiquantitative. Saline solution and serial dilutions of salbutamol or terbutaline (10^{-3}–10^{-8} w/v) are injected intradermally over the side of the neck.[1029,1057] Sweating is evident by 10 minutes, but the final response is evaluated at 20 to 30 minutes. In the terbutaline test, terbulatine sulfate (1 mg/mL [1000 mg/L]) in tenfold dilutions with 0.9% NaCl (1000, 100, 10, 1, 0.1, 0.01, 0.001, and 0 mg/L) is injected intradermally (0.1 mL) with a 25-gauge needle at 5 cm apart.[1029,1057] For the epinephrine response test, 0.1 mL of epinephrine in tenfold dilutions (1:1000, 1:10,000, 1:100,000; 1:1,000,000) is injected as previously described. Horses with anhidrosis have minimal to no response to any of the dilutions,[1019,1029,1057] whereas normal horses have a sweat response to most dilutions.

Differential diagnoses are limited to the respiratory tract as most anhidrotic and hypohidrotic horses have tachypnea and an exaggerated respiratory response (tachypnea) to exercise. In addition, body temperatures in these animals remain elevated for longer periods of time than in healthy animals. Idiopathic hyperthermia should be considered in foals of draft breeds with thermoregulatory problems. The etiology is unknown. These animals have persistent hyperthermia and tachypnea with minimal to no evidence of systemic or pulmonary disease and tend to be bright and alert. This condition resolves in 3 to 7 days with supportive management that includes cooling the environment, alcohol baths, and cooled intravenous fluids.

TREATMENT, PREVENTION, AND PROGNOSIS

There is no specific treatment for equine anhidrosis. Keeping affected horses in a cool environment and reducing physical activity is central to the palliative treatment of anhidrosis. Measures that reduce environmental temperature/increase heat loss include shades, fans, air conditioning, misting, and water cooling. Because many afflicted horses are used for various performance activities, unfortunately some management measures may not be practical or are not implemented. On hot days, it is recommended to work these horses in the coolest part of the day. In severe cases and, if feasible, moving these animals to cooler climates should be considered. Dietary modifications and mineral supplementation may help. The use of salts and electrolytes, including NaCl (table salt), KCl (light salt), $NaHCO_3$ (baking soda), and $MgSO_4$ (Epsom salt) may be beneficial, although controlled studies are lacking. A multitude of supplements containing electrolytes, amino acids, L-tyrosine (catecholamine precursor), cobalt, vitamin E (antioxidant), vitamin C (antioxidant), vitamin B_{12}, other water-soluble vitamins, and herbal remedies, to name a few, are available to treat anhidrosis, although their efficacy has not been scientifically evaluated. Methyldopa, an antihypertensive agent that decreases central sympathetic activity (sympatholytic), has also been used, but there is no research to support its efficacy in anhidrotic horses. Antihistamines have been unsuccessful. It has been reported that daily oral administration of iodinated casein (10–15 g/day) or sodium levothyroxine (0.5–3.0 mg/lb; 1–6 mg/100 kg) improved clinical signs.[1019,1035] As there is information from other species that thyroid hormones enhance β_2-adrenoreceptor sensitivity, these supplements should be considered in some horses with anhidrosis, keeping in mind potential complications (iatrogenic hyperthyroidism, weight loss, hyperthermia).

The use of β_2-receptor agonists is controversial as available information indicates that β_2-receptor downregulation is the result of excessive adrenergic stimulation. However, some clinicians report that the use of clenbuterol in horses with mild anhidrosis or hypohidrosis when environmental temperature and humidity are elevated could ameliorate the severity of the clinical signs. A recent study found no effect of prolonged clenbuterol treatment on the sweat response to intradermal epinephrine administration in Thoroughbred horses.[1058]

There is no evidence that anhidrosis is an immune-mediated process; however, glucocorticoids have been a proposed treatment. A combination of glucocorticoids with clenbuterol has been suggested under the rationale that β_2-receptor agonists may potentiate the antiinflammatory effects of corticoids. Another justification is that glucocorticoids may enhance β_2-adrenoreceptor response to agonists. Again, this approach remains unclear as excessive adrenergic stimulation seems to be part of the problem. It is also important to avoid the use of sedatives (α_2-receptor agonists) that may stimulate sweating in the horse.

Acupuncture and acupressure are nontraditional treatments claimed by horse owners, trainers, and some veterinarians to improve sweating in anhidrotic horses, particularly when other therapies have failed. In one retrospective study

that included anhidrotic horses treated with acupuncture and herbal medicine, according to the owners, clinical signs improved in treated horses.[1059] A limitation of this study was the inclusion criteria that likely introduced client bias—only anhidrotic horses with complete medical controls and the ability to contact clients for follow-up were included.[1059] A field evaluation of acupuncture combined with herbal medication in horses diagnosed with anhidrosis based on the intradermal terbutaline sweat test in Florida failed to demonstrate a clear difference between treated and placebo horses.[1060] In that study, sweating improved in treated horses but statistical significance compared with placebo horses could not be achieved.[1060] According to the author, acupuncture combined with herbal medicine may potentially improve sweating in anhidrotic horses, but the effect is short-lasting after discontinuation of treatment.[1060] One 12-oz (355 mL) can of beer every morning is recommended in some lay magazines as an effective treatment for anhidrosis. Some sources claim that dark beer is more effective.

The prognosis for horses with anhidrosis is guarded and dictated by the severity of the condition, response to therapy, geography, and implementation of palliative measures.

CHAPTER 17

Disorders of the Eye and Vision

Mary Lassaline

The equine eye is unique in its large size, lateral placement, and propensity to injury relative to other large animal species, with the latter likely associated with the horse's temperament as a flight animal that relies on running as its primary defense. Examination of the equine eye can be challenging given this temperament, particularly if the eye is painful, but having the proper setting, equipment, and knowledge of normal anatomy can facilitate this sometimes difficult task.

Ophthalmology is a visual specialty with many ophthalmic diagnoses made based on visual inspection. The ability to describe what is seen during an ophthalmic examination in complete and precise terms, whether verbally or pictorially, and distill a problem list from examination findings is critical to proceed accurately with development of differential diagnoses, as well as a diagnostic and therapeutic plan. Precision in reporting the examination findings can be optimized by translating continuous or analog information into discrete findings, such as characterizing blepharospasm numerically by the percent eyelids are open, as well as grading features such as conjunctival hyperemia, chemosis, and corneal edema as mild, moderate, or severe.

Examination

The ophthalmic examination should begin in ambient light and before sedation with a "hands off" assessment of facial, orbital, and eyelid symmetry and globe position and mobility; evaluation for the presence of ocular discharge or blepharospasm; and measurement of the menace response (which requires functional cranial nerves II and VII, as well as involving the visual cortex), dazzle reflex (which requires functional cranial nerves II and VII), and direct and indirect pupillary light reflexes (which require functional cranial nerves II and III). Assessment of the pupillary light reflexes should be repeated in a darkened examination area and is most accurately performed using a bright focal light source. Ocular discharge should be characterized by its nature (i.e., serous, mucoid, mucopurulent) and by its severity. Vision can be evaluated with behavioral tests, including ability to navigate obstacles such as stepping over cavaletti and walking around jump standards without making errors. There is not a well-established standardized routine for testing vision, but minimally, vision in each eye should be tested separately with the opposite eye masked, as well as testing binocular vision. To test vision in each eye separately, one eye can be covered with a towel tucked into the halter in a way that allows the towel to be immediately pulled off the covered eye should the horse become fractious or difficult to control. The horse's willingness to proceed and ability to walk without tripping or stumbling over obstacles can provide a rough correlate with vision. It is important to perform the vision test in both ambient light and dim light to test both photopic, or cone-driven, and scotopic, or rod-driven, vision, respectively. Some horses with mild visual impairment may only show deficits (e.g., reluctance to move forward or tripping over obstacles) when moving from light to dark or vice versa.

Following the "hands off" examination, ocular structures should be examined from front to back of the eye, with sedation as needed to facilitate examination. An auriculopalpebral (AP) nerve block, which provides akinesia of the superior eyelid and therefore can facilitate forcibly opening the eyelids, is often not required if the patient is compliant and the examiner goes slowly but is indicated if the structural integrity of the globe is threatened by a deep or perforating corneal defect. The AP nerve can be palpated as it courses over the zygomatic arch in the area of the temporofrontal suture. To block the AP nerve, 1.5 mL of 2% lidocaine or mepivacaine should be injected using a 25-gauge, ⅝-inch needle over the zygomatic arch in this area. If ocular pain makes examination difficult, anesthesia should be provided, as well as akinesia, using a topical anesthetic for corneal pain and a local nerve block for eyelid pain.

Before instillation of any solution such as a topical anesthetic onto the cornea, samples for bacterial or fungal culture and measurement of aqueous tear production should be obtained. Aqueous tear production can be measured with the Schirmer tear test (STT) using commercially available test strips. Normal wetting has been considered to be 20 mm or greater in 30 seconds, with most horses wetting the entire 35-mm strip in less than 1 minute. However, there appears to be wide variability in STT values in normal horses and ponies.[1]

Intraocular pressure (IOP) measurement should be included in a complete ophthalmic examination. Two types of tonometers, applanation and rebound, are most commonly used to estimate IOP in the equine eye. Applanation tonometers measure the force required to flatten, or applanate, a precise area of the corneal surface and, making assumptions about physical features of the cornea such as thickness and curvature, convert this force to an estimate of IOP. Rebound tonometers use characteristics of the motion created when a probe is electromagnetically

propelled to come in contact with and then rebounds from the corneal surface. In one study evaluating the use of rebound tonometers to measure IOP in normal horses, values obtained with the rebound tonometer were an average of 1 mm Hg higher in horses compared with values obtained with the applanation tonometer.[2] It is important to understand the estimates calculated by these types of tonometers. The applanation tonometer displays each individual reading followed by a measure of central tendency and a measure of agreement among the readings. The rebound tonometer, in contrast, internally averages each new reading with any prior readings in a series of six consecutive readings and displays, following each of the first five readings, the running average value rather than the individual value. After the sixth reading, the lowest and highest readings are discarded, and the average of the remaining four values is displayed, or, if there is excessive deviation among measurements, a problem with probe motion, or misalignment with the central portion of the cornea, the display shows an error message. Applanation tonometry is best performed following instillation of a topical anesthetic and allows IOP measurement with the patient in any position. Rebound tonometry, in contrast, does not require the use of a topical anesthetic but does require that the tonometer probe be parallel to the horizon.

Head position can introduce artifact into IOP tonometry measurements, with higher readings obtained when the head is positioned below the heart, as with sedation, and thus care should be taken to ensure that the head is elevated above the level of the heart when IOP is being determined.[3] Sedation can lower IOP estimates, with xylazine administration associated with a decrease in tonometry readings of over 20%,[4] and detomidine administration, similarly, can be associated with a decrease in IOP readings of 15% to 20%.[5] Topical atropine administration can be associated with changes in IOP. In one study of atropine's effect on IOP in normal horses, twice-daily administration was associated with an 11% average decrease in IOP, but one horse in that study had a significant IOP increase following atropine administration.[6]

TOPICAL ANESTHETICS

Topical anesthetics typically used to desensitize the cornea before applanation tonometry, as well as before collecting samples for corneal cytology, include proparacaine and tetracaine. Proparacaine provided corneal anesthesia for about 25 minutes in horses in one study, with maximal anesthetic effect in less than 5 minutes; however, a single dose may not provide complete corneal desensitization.[7] Tetracaine decreased corneal sensitivity for 30 to 60 minutes, depending on the concentration and volume of drug administered, with a single drop of 0.5% tetracaine lasting 30 minutes, two drops of 0.5% tetracaine lasting 60 minutes, and a single drop of 1.0% tetracaine lasting 50 minutes. A maximal anesthetic effect was achieved for about 5 minutes with a single drop of 0.5% tetracaine and for over 15 minutes with two drops of 0.5% tetracaine and a single drop of 1.0% tetracaine. Taken together, these results suggest that the use of a second drop or a stronger concentration of topical tetracaine increased both the degree and duration of the maximal anesthetic effect on the equine cornea.[8] In a study evaluating the effect and duration of proparacaine and tetracaine, maximal effect occurred at 10 minutes, and duration of a viscous tetracaine solution was longer at 30 minutes than that of aqueous tetracaine and proparacaine at 20 minutes.[9]

The anterior segment of the eye, including the lens and structures anterior to it, is best examined with a bright focal light source such as a Finoff transilluminator, although a handheld slit-lamp biomicroscope can help identify and localize lesions in the anterior segment by providing magnification and depth information. The posterior segment of the eye, including the vitreous, optic nerve, retinal blood vessels, and tapetal and nontapetal fundus, should be evaluated with both indirect and direct ophthalmoscopy. Indirect ophthalmoscopy using a 15D or 20D lens and a Finoff transilluminator provides a panoramic view of the fundus, although it is viewed as if rotated 180 degrees, whereas direct ophthalmoscopy provides a view magnified 10× relative to that seen with the 20D lens, and therefore requires looking in more locations to see a similar area of the fundus. Both should be performed.

Mydriasis is recommended for a better view of structures posterior to the iris but should not be performed if glaucoma is suspected or has been diagnosed or if lens instability or luxation is suspected or has been diagnosed. Owner consent should be obtained before instillation of a mydriatic agent to ensure that the owner gives permission to dilate pupils, as well as understands the anticipated duration of mydriasis and potential altered depth perception and visual impairment associated with mydriasis. If the owner declines to allow the pupils to be dilated, it should be made clear that lens and posterior segment examination will be limited. A short-acting mydriatic such as 1% tropicamide should be used instead of a more potent drug such as 1% atropine, which can result in mydriasis for at least 2 weeks in normal horses.[10]

Corneal aesthesiometers such as the Cochet-Bonnet can be used to estimate corneal sensitivity by measuring the threshold pressure required to stimulate corneal sensory nerve endings and thereby induce the corneal reflex, which typically results in a blink, but may also result in retraction of the globe and elevation of the third eyelid. Corneal sensitivity in horses decreases with age and in horses with pituitary pars intermedia dysfunction (PPID). Because decreased corneal sensitivity is associated with impaired wound healing, increasing age and PPID may increase the risk for nonhealing or recurrent corneal ulcers in horses.[11] One study that established reference ranges for corneal touch threshold in the horse found that the axial cornea is the most sensitive and found a negative correlation between age and corneal sensitivity in the axial, inferior, and temporal cornea.[12] Corneal sensitivity is also decreased in sick neonatal foals relative to healthy foals and adults.[13]

IMAGING

Ocular ultrasound is indicated for evaluation of intraocular contents when one or more of the ocular transmitting media are opaque, including opacification of the cornea, aqueous and vitreous humors, and the lens. The most common indications for ocular ultrasound are in eyes with a cataract to evaluate for a retinal detachment, after traumatic hyphema to assess posterior segment damage, or in eyes with severe corneal opacification. In addition, ocular ultrasound can be used to evaluate the orbit in instances of exophthalmos or orbital trauma. Ultrasound biomicroscopy can be used to determine depth of a corneal lesion such as a squamous cell carcinoma or to examine an anterior uveal mass for extent of involvement. Ocular ultrasound should not be performed if the structural integrity of the globe is suspect, because of the risk of iatrogenic globe

rupture and expulsion of intraocular contents caused by pressure on a fragile or perforated globe.

DISORDERS OF THE EQUINE EYELIDS

Normal Anatomy

Sensory innervation of the equine eyelids is provided by the supraorbital (frontal), infratrochlear, lacrimal, and zygomatic branches of the trigeminal nerve (cranial nerve V).

Entropion

The most common eyelid disorder in foals is entropion, which is inward rolling of the eyelid margin. If entropion is severe enough that facial hairs contact the cornea, corneal pain and ulceration can result. Entropion may be the result of a primary conformational abnormality or occur secondary to prematurity or dehydration in foals with enophthalmos or ocular pain resulting in spastic entropion. Manual reduction and frequent topical ocular lubrication with artificial tear ointment to prevent corneal ulceration may be the only treatment required in some foals, particularly if entropion is secondary to dehydration, and will self-correct when the systemic condition resolves. Severe or persistent entropion may be temporarily corrected by placement of three vertical mattress imbricating sutures to position the eyelid correctly. Sedation and local block is typically sufficient for suture placement. Overcorrection should be avoided to prevent the inability to close the eyelids during blinking. Primary (anatomic) entropion requiring permanent surgical correction involving skin excision is rare.

Ectopic Cilia

An ectopic cilium, an aberrant eyelash that grows through the conjunctiva directly toward the cornea, should be considered as a differential diagnosis for horses with epiphora, blepharospasm, and keratitis and in whom no foreign object can be found. In a series of seven horses with ectopic cilium, a single translucent cilium was detected in the upper eyelid palpebral conjunctiva, emerging from within a small focal region of conjunctival pallor approximately 5 mm from the eyelid margin. Corneal ulceration was not observed in any of these horses, and most responded well to transconjunctival surgical excision.[14]

Distichiasis

Distichiasis, single or multiple cilia emerging from meibomian gland openings along the eyelid margin, should be considered as a differential diagnosis for horses with chronic or recurrent ulcerative or nonulcerative keratitis. Distichia may be soft and of little clinical significance or stiff, causing corneal pain and ulceration. Treatment of distichiasis has been well described and includes epilation, cryoepilation, and tarsal plate excision. There is a breed predisposition for distichiasis in the Friesian horse, and therefore careful examination of the eyelid margins should be performed in Friesians with keratitis.[15,16]

Laceration

Eyelid lacerations should be repaired immediately, with primary closure if possible. The vascular supply to the eyelid is extensive, and many apparently avascular segments of eyelid recover after repair. Amputating pedicles of eyelid tissue should be avoided to preserve the eyelid margin and prevent subsequent corneal vascularization and ulceration associated with eyelid margin loss. Eyelid lacerations should be repaired using two-layer closure, ensuring accurate anatomic apposition of the wound edges and eyelid margin. Minor surgical repairs can be performed using sedation and local nerve blocks, but general anesthesia is warranted if the injury is severe. Postoperative therapy should include a systemic nonsteroidal antiinflammatory drug (NSAID) to reduce pain and inflammation, a systemic antibiotic to prevent infection, and tetanus toxoid. Topical medication is not required for eyelid injuries unless corneal or anterior segment damage accompanies the injury, and administration of topical ophthalmic medications may actually disrupt the laceration repair. A modified Kuhnt-Szymanowski procedure has been used to correct cicatricial ectropion resulting from removal of eyelid tissue during an initial eyelid laceration repair.[17]

FIG. **17.1** Squamous cell carcinoma (SCC) of the nictitans (third eyelid). This raised rough mass with a cauliflower-like appearance is typical for the appearance of SCC of the nictitans.

Squamous Cell Carcinoma

The most common neoplasm of the equine eyelid is squamous cell carcinoma (SCC) (Fig. 17.1). In addition, sarcoid, melanoma, mast cell tumor, lymphosarcoma, basal cell carcinoma, and papilloma can affect the eyelids. The differential diagnosis for eyelid neoplasms includes parasitic diseases such as ocular habronemiasis and other causes of granulomatous skin disease. Treatment of eyelid neoplasia depends on the location, size, tumor type, age and purpose of the horse, cost, surgical skill, and equipment available. Treatment modalities include surgical excision, radiation therapy, intralesional chemotherapy, hyperthermia, immunotherapy, cryosurgery, or a combination of these. The aim of therapy is to eliminate or halt progression of the tumor while maintaining eyelid function and preserving the eye and vision. Complete excision with primary closure is the optimal treatment but often cannot be achieved because of limitations on availability of tissue for reconstruction and the extensive and aggressive nature of many eyelid neoplasms. If eyelid margins cannot be apposed after tumor excision, more involved blepharoplastic techniques, such as advancement skin flaps, may be indicated. SCC involving the eyelid is usually erosive and ulcerative, and invasion of adjacent soft and bony orbital tissue is possible if the disease is untreated.

Cisplatin is a platinum-based chemotherapy drug that binds to and causes crosslinking of deoxyribonucleic acid (DNA), which triggers apoptosis of tumor cells. It is most commonly used intralesionally, in conjunction with surgical excision for larger tumors. A large retrospective study of 573 equids with 630 cutaneous tumors over a 10-year period confirmed the value of intratumoral chemotherapy with cisplatin with local control at 4 years in 88% of 151 tumors histologically confirmed as SCC.[18] In that study, large tumors, tumors with gross residual disease following surgical excision and debulking, and tumors that had been treated previously with another treatment modality had the lowest treatment efficacy. In treated patients, local reactions were most likely after the third and fourth treatments. The therapeutic protocol used in the Theon study[18] involved a series of four percutaneous intratumoral injections of a viscous slow-release 3.3-mg/mL cisplatin solution suspended in sesame oil to provide slow drug release, given at 2-week intervals, with 1 mg of cisplatin injected per cubic centimeter of tumor tissue. Cisplatin-containing biodegradable beads have been used to treat cutaneous SCC,[19] but these can cause adverse effects on the cornea associated with high local concentrations of the drug. The beads contain approximately 1.6 mg of cisplatin per bead, and placement of beads with 2-cm spacing between beads theoretically results in cisplatin concentrations comparable to injection at 1 mg/mL tissue.

Photodynamic therapy (PDT) involves the use of photochemical reactions mediated through the interaction of photosensitizing agents, light, and oxygen. Tumor tissue is injected with verteporfin, and laser radiation is applied. This induces oxidative damage to the microvasculature, contributing to ischemic tumor death. In one study of 10 horses with periocular SCC treated with excision and PDT, no horses demonstrated tumor recurrence with a minimum of 25 months of follow-up.[20]

Sarcoid

Equine sarcoid is the most common skin tumor in horses and can provide a significant therapeutic challenge, whether surgical or medical management is used. Periorbital sarcoids can be particularly difficult to treat given the importance of preserving eyelid function for maintaining corneal health and given the thin elastic nature of eyelid skin. Six types of sarcoid, have been described: occult, verrucose, nodular, fibroblastic, mixed, and malignant. In a review of 445 cases of sarcoid over the 25-year period from 1974 to 1999, treatment with radiation resulted in the best outcome, with almost 100% resolution in 66 cases, although treatment with bacillus Calmette-Guérin (BCG) immunomodulation for fibroblastic and nodular sarcoids was associated with good outcomes in 69% of 300 cases. Of the 42 cases that received no treatment, 27 had lesions too extensive to treat at initial referral and were euthanized. Recurrence rates for other therapeutic modalities are as follows, in order of increasing recurrence rates: gamma radiation brachytherapy, 53 cases, 8% recurrence; topical 5-fluorouracil cream application, 9 cases, 33% recurrence; AW4 topical treatment (unlicensed material containing 10% 5-fluorouracil and oil of rosemary), 146 cases, 65% recurrence; cisplatin injection, 18 cases, 66% recurrence; surgical excision alone, 28 cases, 82% recurrence; cryosurgery, 23 cases, 91% recurrence.[21] However, in a more recent retrospective study evaluating the long-term outcome of intratumoral chemotherapy with cisplatin for cutaneous tumors in horses, cure rate was 96% with a minimum follow-up of 2 years after one course of treatment with four injections for 409 sarcoids.[18]

DISORDERS OF THE EQUINE CONJUNCTIVA AND THIRD EYELID

Normal Anatomy

The conjunctiva is divided into bulbar and palpebral surfaces. The conjunctiva merges with the cornea at the limbus, with the eyelid at the eyelid margin, and the bulbar and palpebral conjunctiva join to form the fornix. In general, isolates of gram-positive organisms are more common than gram-negative organisms from normal equine conjunctiva, but fungi are commonly isolated as well.

Dermoid

Conjunctival dermoid is one of the most common congenital ocular abnormalities in horses but congenital conjunctival diseases are rare in horses. A dermoid is a congenital mass of skin and associated glands, hair, and hair follicles that can affect the cornea and adjacent conjunctiva. A dermoid that is irritating the globe or adnexa should be surgically removed by superficial keratectomy or conjunctivectomy.

Foreign Body

Conjunctival foreign bodies should be considered in any horse with a recurrent corneal erosion, ocular pain, or conjunctivitis and can be detected by examination of the superior and inferior fornices and the bulbar and palpebral surface of the nictitans after topical administration of 0.5% proparacaine. Magnification may be necessary for foreign body detection. In addition, irrigation of the nasolacrimal system may yield foreign material associated with chronic conjunctivitis or dacryocystitis.

Parasitic Disease

Parasites of the equine conjunctiva include *Thelazia lacrymalis, Habronema* spp., and *Onchocerca cervicalis.* Although parasitic infection of the conjunctiva is not typically associated with clinical signs, chronic conjunctivitis, seromucoid discharge, and conjunctival nodules can occur. Treatment includes removal of the adult worms, irrigation of the nasolacrimal system, topical corticosteroids to reduce inflammation, and fly control. Ocular manifestations of equine cutaneous habronemiasis such as intense pruritus, epiphora, and yellow caseous "sulfur granules" result when the house or stable fly deposits the larvae of the *Habronema* spp. on or around the eye. Ocular lesions of habronemiasis are most common at the medial canthus and may involve the skin, nasolacrimal duct, third eyelid, or conjunctiva. Treatment may involve excision of sulfur granules, local and systemic corticosteroid therapy, and systemic ivermectin. The aim of therapy is to kill the larvae while controlling the resulting inflammation. Fly control is an essential part of an overall management program.

The blood-sucking midge *Culicoides nubeculosus* transmits *O. cervicalis* microfilariae. After transmission the immature microfilariae migrate through lymphatics and can travel to ocular and adnexal tissues. The prevalence of equine onchocerciasis increases with age, with an overall prevalence of 50% to 60% in horses in the southeastern and midwestern United States,[22] and with a prevalence on histologic examination of the lateral bulbar conjunctiva of 10.8% in a study of

368 equine eyes.[23] The pathogenesis is thought to involve the death of the microfilariae, release of antigens, and development of hypersensitivity in susceptible horses. Treatment is indicated in those horses with active conjunctivitis, keratitis, or uveitis attributable to onchocerciasis and includes antiinflammatory agents such as topical corticosteroids and systemic flunixin meglumine and ivermectin.

Squamous Cell Carcinoma

SCC is the predominant tumor type of the third eyelid (Fig. 17.2). Other neoplasms affecting the conjunctiva and third eyelid include lymphosarcoma, melanocytoma, mastocytoma, hemangioma, and angiosarcoma. Complete surgical excision of the third eyelid can be curative for tumors that have not extended beyond the third eyelid. Surgical excision can typically be performed using sedation and local nerve blocks, without suturing the bulbar and palpebral conjunctiva closed. A rare complication of third eyelid removal without suturing the surgical incision is orbital fat prolapse, which is easily repaired by excising the prolapsed fat, creating a fresh surgical conjunctival margin with sharp dissection, and suturing the conjunctival margin closed. In one case series including 50 horses with third eyelid neoplasia, there was recurrence in 20%, occurring at a median of 1.5 years after excision, suggesting that long-term monitoring is important for all patients in which third eyelid excision is performed.[24]

FIG. **17.2** Third eyelid SCC that is more extensive. This mass was better visualized by retropulsing the globe to elevate the third eyelid.

DISORDERS OF THE EQUINE NASOLACRIMAL SYSTEM

The nasolacrimal system consists of the superior and inferior puncta and canaliculi, nasolacrimal sac, nasolacrimal duct, and nasal punctum located on the floor of the nasal vestibule. The nasolacrimal system carries tears from the medial canthus of the eye to the nasal vestibule. Abnormalities of the nasolacrimal system result in epiphora, an overflow of tears, or ocular discharge that can be serous, mucoid, or mucopurulent and must be differentiated from reflex lacrimation resulting from ocular irritation or inflammation. The Jones test evaluates nasolacrimal duct patency by instillation of fluorescein stain in the conjunctival cul-de-sac and observation of its appearance at the nasal opening. Nasolacrimal duct irrigation can be performed in an anterograde manner, from the eyelid to the nasal punctum, or retrograde, from the nasal punctum. Topical anesthetic should be used before nasolacrimal duct irrigation. Radiographic imaging of the nasolacrimal duct, dacryocystorhinography, can be performed using contrast material injected into the duct from the superior eyelid punctum. Lateral and oblique radiographic views provide the best visualization of the nasolacrimal duct. Indications for dacryocystorhinography include chronic epiphora, inability to irrigate the nasolacrimal duct, suspicion of a nasolacrimal foreign body, and evaluation of the nasolacrimal duct for congenital or acquired abnormalities. The nasolacrimal duct can also be imaged using computed tomography (CT).

Abnormalities of the nasolacrimal system can be congenital or acquired. In the horse the most common congenital abnormality is atresia of the distal portion of the nasolacrimal duct and the nasal punctum, which results in mucoid epiphora at 3 to 4 months of age. Additional congenital abnormalities include atresia of an eyelid punctum, abnormal placement of an eyelid punctum, and multiple nasal openings. Whether these conditions are inherited is unknown. Acquired conditions of the nasolacrimal system include dacryocystitis, foreign body obstruction, trauma, and involvement secondarily in neoplastic or inflammatory conditions of the medial canthus or nasal passages. Dacryocystitis appears as a mucopurulent ocular discharge without associated ocular inflammation. Dacryocystitis and foreign body obstructions are treated by nasolacrimal irrigation and bacterial and fungal culture with or without the aid of radiographic or CT evaluation. Topical broad-spectrum ophthalmic antibiotic solution should be administered after irrigation to prevent infection, and topical corticosteroids or systemic NSAIDs may reduce swelling and inflammation.

Surgical repair of the nasolacrimal duct involves surgical trephination (conjunctivorhinotomy) to create a new outflow pathway for the tears. After a new duct is created, a stent connecting the eyelid and nasal puncta is kept in place for several weeks postoperatively to keep the repaired nasolacrimal duct patent until the nasal mucosa completely lines it. These stents can become dislodged, resulting in obstruction of the repaired duct. Canaliculosinostomy to divert lacrimal secretions into the sinuses, which can be performed in the standing sedated horse, can improve epiphora caused by nasolacrimal duct obstruction and can provide a good functional and cosmetic outcome.[25]

DISORDERS OF THE EQUINE CORNEA

Normal Anatomy

The cornea consists of the epithelium, stroma, Descemet's membrane, and endothelium. The epithelium is 7 to 15 cells thick and is replaced every 7 to 10 days. The corneal endothelium is a monolayer of cells with little to no regenerative capacity, and therefore damage to the endothelium is of great significance, because complete repair is often not possible and results in permanent corneal edema. The normal cornea is transparent and avascular. Sensory innervation comes from the ophthalmic branch of the trigeminal nerve. The epithelium and anterior stroma are innervated richly with sensory

nerves, whereas the middle and inner cornea is less well supplied. Nutrition and waste removal are carried out by the tear film, aqueous humor, and diffusion to and from the scleral and conjunctival blood vessels. The cornea is maintained in a state of relative deturgescence by the mechanical barrier of the epithelium and the endothelial pump mechanism.

Changes in Corneal Clarity

The normally clear cornea can become opaque and take on a color that correlates with the mechanism underlying the corneal opacity, including white with fibrosis, yellow with a cellular infiltrate, brown with pigment, red with corneal vascularization, sparkling with lipid or mineralization, or blue with corneal edema. Corneal edema results when either the epithelial barrier or endothelial pump function is disrupted. Chronic irritation of the cornea results in superficial vascularization, whereas inflammation of the anterior uvea results in deep corneal vascularization. Corneal pigmentation often follows vascularization, as well as deep corneal infection, although this is not as common in horses as in dogs and cats. Cellular infiltration of the cornea occurs in neoplastic, infectious, and inflammatory disease. All of these processes can occur alone or in combination, resulting in an alteration of corneal transparency. In addition, scar formation or deposits of mineral or phospholipid can alter corneal transparency Establishing and eliminating causes of these changes are essential.

Corneal Ulcer

A corneal ulcer is a break in the corneal epithelium. Clinically, ulceration results in lacrimation, blepharospasm, photophobia, conjunctival hyperemia, corneal edema, and possibly miosis and aqueous flare. A corneal ulcer is diagnosed by positive fluorescein staining of the cornea, although corneal ulcers that involve a complete loss of the corneal epithelium and stroma, called *descemetoceles*, do not take up fluorescein stain (Fig. 17.3). Fluorescein stain is absorbed by the water-soluble corneal stroma but not the corneal epithelium or Descemet's membrane, giving a descemetocele its characteristic "green donut" appearance, with a ring of stain-positive stroma surrounding a dark center. Corneal ulcers should be characterized by size, depth, the presence or absence of corneal cellular infiltration, and signs of reflex anterior uveitis such as aqueous flare and miosis.

Uncomplicated Corneal Ulcers

Treatment of an uncomplicated corneal ulcer involves controlling pain and inflammation, eliminating or preventing infection, and preventing secondary complications. Healing occurs by migration and mitosis of the adjacent epithelial cells and, depending on the size of the ulcer, should be complete in 2 to 6 days. Common treatment for an uncomplicated corneal ulcer includes a topical broad-spectrum antibiotic, topical atropine to control reflex uveitis, and a systemic NSAID.

Nonhealing Ulcers

Corneal ulcers that have not healed within 7 to 10 days are generally classified as nonhealing. Causes of persistent ulceration, including infection and continued mechanical trauma, need to be ruled out before classification as nonhealing. Histologically, characteristics of nonhealing corneal ulcers in horses are similar to those in other species and include epithelial nonadherence and dysmaturity, as well as mild to moderate stromal inflammation; however, the anterior stromal acellular hyaline zone commonly found in canine spontaneous chronic corneal epithelial defects (SCCEDs) is not consistently found in horses with nonhealing ulcers.[26] The term *indolent ulcer* is usually reserved for SCCEDs in humans and dogs.

FIG. **17.3** Descemetocele with diffuse corneal edema, corneal vascularization, and hypopyon.

FIG. **17.4** Oblique corneal laceration resulting in a flap of cornea.

Medical therapy for uncomplicated ulcers is unlikely to lead to resolution of nonhealing ulcers without some additional intervention. In one case series of 23 horses with superficial nonhealing ulcer, complete reepithelialization of the cornea following a procedural intervention such as debridement, grid keratotomy, or superficial keratectomy in addition to medical therapy occurred in approximately 2 to 3 weeks.[27] Another case series of 60 horses with nonhealing ulcers of approximately 1 month's duration suggested that diamond burr debridement may be an effective treatment for nonhealing ulcers, with 92% achieving complete reepithelialization within an average of 16 days.[28]

Complicated Ulcers

Complicated corneal ulcers are those that fail to heal in an appropriate time, are secondarily infected, have an ongoing source of irritation or ulceration, have a collagenase component, are associated with corneal vascularization, or are worsening despite appropriate treatment (Figs. 17.4–17.12).

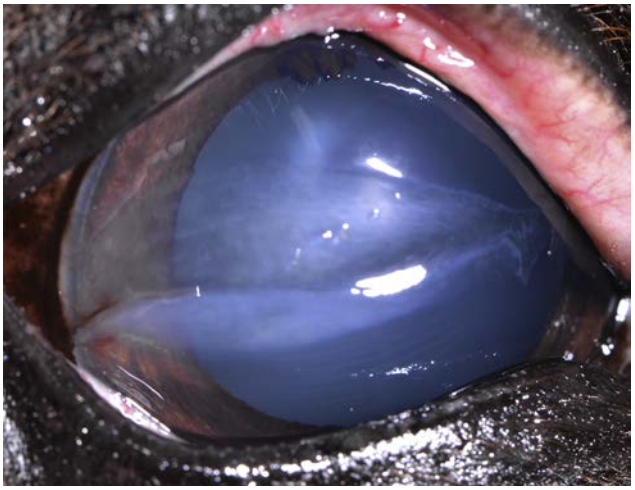

FIG. **17.5** Horizontal corneal laceration associated with corneal edema.

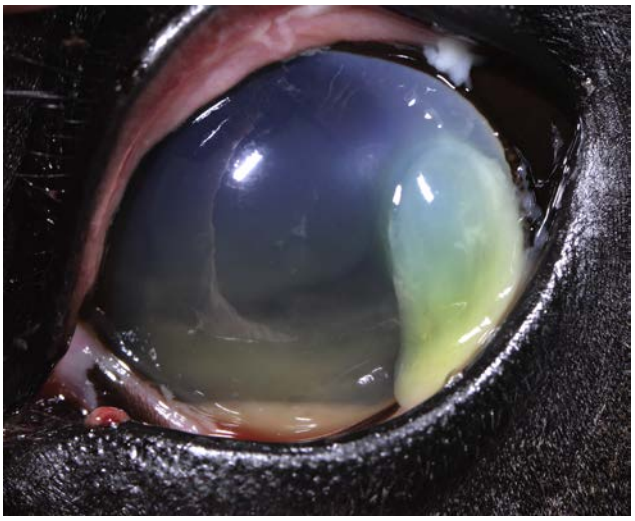

FIG. **17.6** "Melting" corneal ulcer with severe keratomalacia. This corneal ulcer should be viewed as an emergency and treated empirically until diagnostic results are available.

FIG. **17.7** Melting corneal ulcer in a foal. These often go undetected because foals with melting ulcers do not always show signs of ocular discomfort until quite late in the disease course, when the ulcer may have become full thickness.

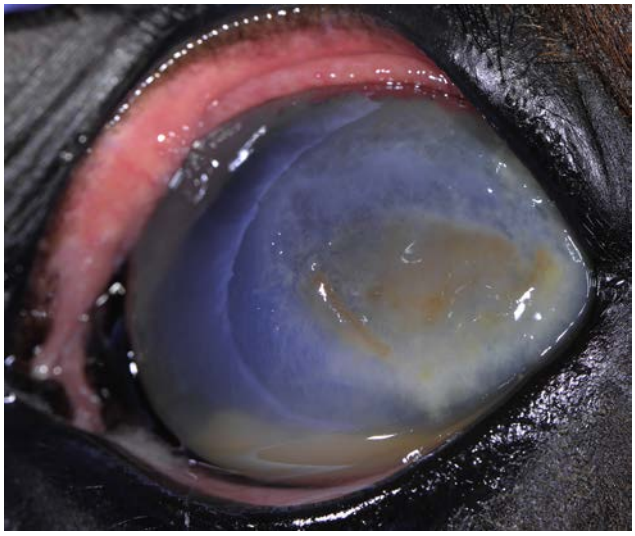

FIG. **17.8** Fungal keratitis from which a dematiaceous fungal organism was cultured. These fungal organisms have pigmented hyphae and appear pigmented clinically. Dematiaceous fungi isolated from the equine cornea include *Curvularia* and *Cladosporium*.

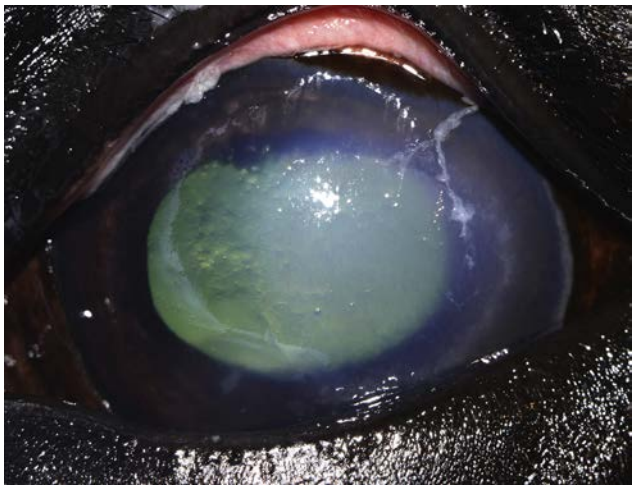

FIG. **17.9** Early fungal keratitis, characterized by only mild corneal edema but often accompanied by severe ocular pain and a rough gritty appearance to the cornea.

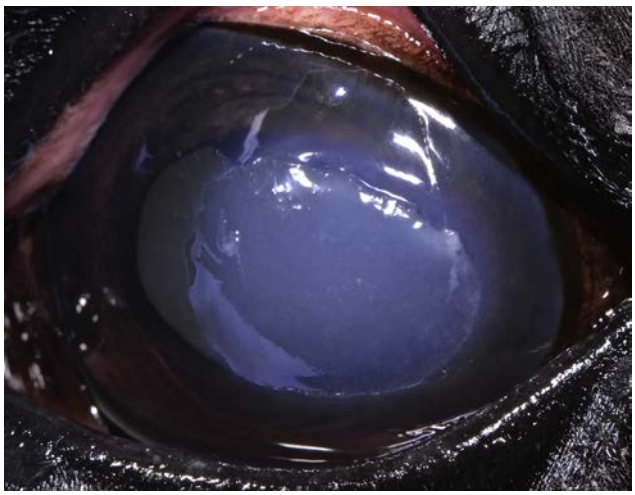

FIG. **17.10** Progression of fungal keratitis from Fig. 17.9, in which a plaque has formed over the ulcerated area. Such plaques are characteristic of fungal keratitis.

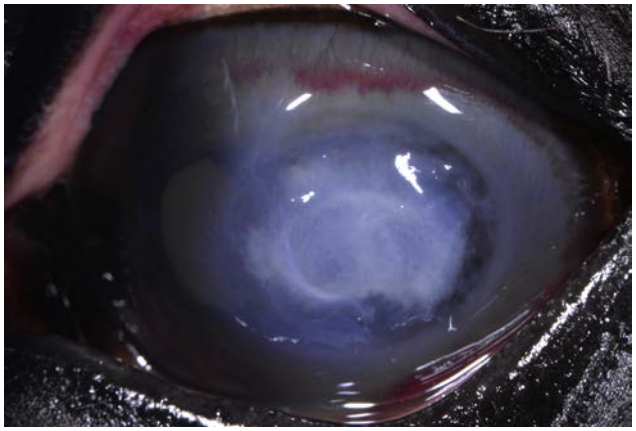

FIG. **17.11** Progression of fungal keratitis from Figs. 17.9 and 17.10, in which a deep groove has developed in the temporal periphery of the corneal ulcer.

FIG. **17.12** Progression of fungal keratitis from Figs. 17.9–17.11, in which a full-thickness perforation has developed. Ultimately, this patient underwent a corneal transplant and conjunctival graft that restored the structural integrity of the globe, and some vision was retained.

Secondary infection of a corneal ulcer is suggested by increasing pain, corneal edema, interstitial keratitis associated with an increase in stromal inflammatory cells, corneal vascularization, purulent discharge, severe anterior uveitis, and stromal necrosis and liquefaction. Diagnostics, including corneal bacterial and possibly fungal culture and corneal cytology, should guide medical therapy. In many instances complicated corneal ulcers require frequent and prolonged therapy, and placement of a subpalpebral lavage system may be indicated to ensure adequate treatment. Many complicated corneal ulcers require a combination of surgical and medical therapy to improve the likelihood of a successful outcome. In vivo confocal microscopy may provide a diagnosis that is not available using more routine diagnostics such as corneal culture and cytology.[29] Medical therapy of a complicated ulcer typically involves treatment with a topical antimicrobial, antifungal, anticollagenase, and atropine, as well as a systemic NSAID.

Antibiotics

Initial choice of antimicrobial therapy can be guided by cytology if bacterial rods or cocci are observed. If no bacteria or bacterial rods are seen, a second-generation fluoroquinolone such as ofloxacin is typically a good choice to treat for a possible *Pseudomonas* infection. A cephalosporin such as cefazolin can be added to treat for possible infection with a beta-hemolytic *Streptococcus* spp. if cocci are observed. Evaluating the transcorneal penetration of a drug can help estimate a drug's potential to reach its target corneal tissue. Many ophthalmic antibiotics have poor penetration through an intact corneal epithelium, but this is not an issue when treating an infected corneal ulcer. Second-generation fluoroquinolones such as ciprofloxacin and ofloxacin generally have good in vitro activity against common equine corneal pathogens. Ofloxacin and the fourth-generation fluoroquinolones such as moxifloxacin tend to have better in vitro activity against gram-positive pathogens. Moxifloxacin has better corneal penetration than ciprofloxacin.[30] In a retrospective study of bacterial ulcerative keratitis in 65 horses, *Pseudomonas aeruginosa* was the most common isolate (22%), followed by *Streptococcus equi* subspecies *zooepidemicus* (20%), and there was increased resistance of *Pseudomonas* spp. to both gentamicin and tobramycin over the study period.[31]

Antifungals

Natamycin is the only commercially available antifungal approved by the U.S. Food and Drug Administration for ophthalmic use. All other antifungal drugs must be compounded for ophthalmic use. In horses, voriconazole has established absorption into the aqueous humor and plasma[32] and has been shown to be well tolerated when administered both subconjunctivally[33] and intrastromally,[34] as well as topically. In one study of antifungal susceptibility of commonly isolated equine corneal fungal pathogens using banked isolates from horses with ulcerative fungal keratitis in Florida, Missouri, Tennessee, and Georgia, 14 fungal isolates, 8 *Aspergillus* and 4 *Fusarium* spp., were collectively significantly more susceptible to voriconazole than to four other antifungal agents (natamycin, itraconazole, fluconazole, and ketoconazole). In that study, *Aspergillus* spp. were most susceptible to voriconazole, miconazole, and itraconazole. *Fusarium* spp. were most susceptible to natamycin and voriconazole.[35] Silver sulfadiazine proved inhibitory and fungicidal for 17 equine corneal fungal isolates in another study.[36]

Anticollagenases

The corneal stroma can degrade rapidly, or "melt," in horses with corneal ulcers. This stromal collagenolysis is caused by proteolytic enzymes produced by microorganisms, inflammatory cells, corneal epithelial cells, and fibroblasts. There are two main enzyme families involved in corneal stromal degradation: matrix metalloproteinases (MMPs) such as MMP-2 and MMP-9, and serine proteases such as neutrophil elastase. MMP-2, synthesized by corneal keratocytes, is involved in routine repair of damaged collagen molecules, whereas MMP-9, produced by corneal epithelial cells and polymorphonuclear neutrophils, is involved in repair following corneal wounding. Protease inhibitors such as serum, which inhibits both matrix metalloproteinases and neutrophil elastase, can reduce the progression of corneal stromal ulcers, speed healing, and minimize scarring.

Several studies provide empiric support for the use of anticollagenases in the treatment of complicated corneal ulcers in horses. First, in an in vitro study of the effect of anticollagenases on MMP activity, a significant reduction in the in vitro

activity of equine MMPs was observed following treatment with several anticollagenases, including EDTA, doxycycline, *N*-acetylcysteine, and equine serum.[37] Second, in a study of the utility of oral treatment of horses with melting corneal ulcers with the antibiotic doxycycline, which has anticollagenase activity in addition to its antibiotic activity, oral doxycycline was found to be present in the preocular tear film of eight normal broodmares given 20 mg/kg of doxycycline orally once daily. This dose of doxycycline was well tolerated by horses in the study, suggesting that it may be a useful treatment for horses with melting corneal ulcers.[38]

Systemic NSAIDs

Ocular pain associated with corneal ulcers may be alleviated by systemic administration of NSAIDs that also help control ocular inflammation, but systemic NSAID administration can be associated with undesirable effects in horses, including renal and gastrointestinal tract toxicoses. To address concerns regarding the development of NSAID-associated renal toxicity, serum creatinine concentration should be measured in horses treated with systemic NSAIDs to obtain a baseline value and then monitored for the development of azotemia. It is also important to monitor horses for the development of right dorsal colitis associated with systemic NSAID use. A drop in total protein will often occur before the development of any clinical signs such as loose manure, inappetance, or weight loss in horses with right dorsal colitis, and therefore monitoring hematocrit and total protein can enable early detection of protein loss. If azotemia or hypoproteinemia is attributed to NSAID toxicity (i.e., based on additional diagnostics including urinalysis for renal toxicity and abdominal ultrasound for right dorsal colitis), systemic NSAID therapy should be discontinued to avoid permanent damage to the kidneys or gastrointestinal tract.

Topical administration of NSAIDs may reduce pain and inflammation associated with keratitis; however, toxic effects on corneal epithelial cells and prolonged healing times and even corneal malacia can result when used in the face of corneal ulceration. Topical treatment with opioid agonists-antagonists such as morphine and nalbuphine has been suggested to reduce corneal pain without interfering with corneal wound healing and to avoid the complications associated with systemic NSAID administration, but the efficacy of these drugs at reducing corneal pain in horses has not been evaluated. One study evaluating nalbuphine used topically on normal equine corneas found that it had no effect on corneal sensitivity, and thus although it appeared to cause no harm it is unlikely to provide any pain relief. Therefore its use is not recommended.[39]

Subpalpebral Lavage Catheters

A subpalpebral lavage (SPL) catheter is a convenient method of delivering medications in solution form to the equine ocular surface that is most useful when the horse is difficult to treat, treatment will be long term, the lids or cornea are very fragile, or the frequency of treatment is high. If placed incorrectly, however, corneal ulcers can result. A common reason for referral for horses with corneal ulcers is inability to administer topical medication. If there is any question that topical medications can be successfully administered without an SPL, one should be placed.

Commercial SPL kits are available through MILA International, Inc. These come equipped with a 12-gauge needle and tubing that is either 36 or 60 inches long. The shorter tubing may be insufficient to reach the withers in a larger horse, and it can be difficult to reach the injection port to administer medications when the shorter tubing is used in a patient that elevates the head and neck in anticipation of treatment. The SPL may be placed either in the superior or inferior lid.[40] Temperament of the horse may contribute to a decision to place the SPL in the inferior lid, in patients for whom it would prove challenging to replace any of the butterfly sutures holding the SPL tubing in place on the face, because of difficulty handling or restraining such a patient. An example might be a foal that has not been frequently handled, is not halter-broken, and might be unduly stressed by resuturing the tubing to the face. If the butterfly suture breaks in an inferior-lid SPL, there is little risk of the SPL footplate slipping and causing an SPL ulcer. If a suture breaks in a superior lid SPL, however, footplate migration onto the corneal surface can easily cause an ulcer that can be difficult to resolve. One study summarizing data from 135 horses treated with SPLs suggested that complications may be more frequent when SPLs are placed in the lower rather than the upper lid, although complication rates reported in this study were high overall.[41] If properly placed and monitored, complications are unlikely to occur. Adequate sedation is mandatory to place an SPL. It is typical for a higher dose of sedative than is expected to be required to achieve adequate sedation because of most patients' intense dislike of eyelid manipulation and of finger insertion between an eyelid and a painful cornea.

To place an SPL, an auriculopalpebral block should be performed both for an inferior SPL as well as a superior one, to paralyze the orbicularis muscle and thereby prevent strong blepharospasm from compromising access to the conjunctival fornix. For a superior SPL, a supraorbital block of the frontal nerve will provide anesthesia of the medial upper lid and may completely desensitize the intended SPL trochar site; however a local block may be necessary as well. For an inferior SPL, a local block at the intended SPL trochar site using 1 to 1.5 mL of lidocaine is required. Before inserting the SPL trochar through the eyelid, the cornea and conjunctiva should be desensitized with a topical anesthetic; the lid skin, cornea, and conjunctival surface prepared with dilute Betadine solution; and the adequacy of sedation and local anesthesia tested by inserting a finger under the lid through which the SPL will be placed and pushing down on that finger, through the lid, with a finger on the opposite hand. If the patient tolerates this, insertion of the SPL trochar will most likely be easily tolerated as well. Wearing sterile gloves, the SPL trochar should be held in the dominant hand and the opposite hand used to open the eyelid as needed to allow insertion of the SPL trochar, guided by the index finger, to the conjunctival fornix. It is mandatory that the trochar pass through the eyelid at the depth of the conjunctival fornix, no closer to the lid margin, to prevent footplate movement over the cornea and subsequent corneal ulceration. Inserting the trochar through the skin typically requires a strong effort on the part of the veterinarian. After the tubing is drawn the remainder of the way through the eyelid, one butterfly should be placed about 25 mm from the wound where the SPL tubing exits the skin and a single interrupted suture using 2-0 nonabsorbable suture placed through the butterfly tape on either side of the tubing. The butterfly must be well adhered to the tubing, so that the tubing does not slip toward the lid, dislodging the footplate. A second butterfly should be placed about 25 mm down the tubing from the first, as a backup in case the first breaks. The SPL tubing should

then be woven through a braid in the forelock to prevent slippage over the ear, and through several braids along the mane to secure it to the neck. A 20-gauge catheter should be inserted into the distal end of the SPL tubing by backing the stylet out of the catheter just a small distance, to prevent lacerating the SPL tubing with the stylet, and inserting the catheter into the tubing up to the catheter hub and then removing the stylet. The catheter provides stability for the end of the tubing and a place to affix an injection port to allow injection of ophthalmic solutions into the system. The patency of the SPL should be tested by injecting sterile saline or eyewash slowly through the injection port and tubing until it appears through the palpebral fissure and runs down the face. The SPL should be checked every time medication is injected through it to ensure that the tubing has not slid through the butterfly, allowing the footplate to rub on the cornea, and to ensure that medication is directed through the tubing onto the cornea rather than being injected subconjunctivally.

The volume of medication injected into the catheter is 0.2 mL of medication per dose. There are different methods of administering medications through the SPL, each with advantages and disadvantages. First, each dose of medication may be followed with 1 mL of air, to clear the tubing and deliver undiluted medication to the ocular surface. The advantage of this pattern of medication administration is that it gives the eye time to absorb the first medication before it receives any additional medication, and medications do not sit in the tube where they could become inactivated by mixing with other medications, heat, or light. Alternatively, each dose of medication may be delivered without flushing the tubing with air. The advantage of this method is that air is not blown on the corneal surface. There is some evidence that mixing medications, and that leaving medications in the tubing rather than flushing them out, may not change their efficacy.[42,43] Regardless of the method chosen, at least 5 minutes should elapse between the administration of each medication if medications are injected individually. Continuous rate infusion is another alternative.[44]

With a sensible patient, it is reasonable to allow small paddock turnout even with the SPL in place, rather than restricting activity to stall rest with hand walking as is typical for more rambunctious patients, but only with willingness to accept the risk that the SPL will be damaged or dislodged and may need to be replaced (e.g., if the patient rolls and breaks the tubing or catches it on a fence or foot). Placing a hard plastic cup mask on the horse to prevent self-trauma to the lavage system is preferred by some veterinarians, and these masks can be invaluable for protecting the SPL. However, hard cup masks can also discourage visual inspection of the eye and the SPL; provide a damp, dark, warm environment that may not be optimal for healing; and encourage development of a moist dermatitis where the hard cup contacts the skin. Additional options for protecting the SPL system include Lycra racing blinkers and Lycra hoods designed to protect the mane and keep the SPL sutures and tubing protected. Horses with corneal ulcers are unlikely to rub the eye unless there is an additional discomfort such as a poorly fitted hard cup mask or SPL footplate that has slipped onto the cornea.

Friesian Stromal Loss

A syndrome of corneal stromal loss has been described in nine Friesian horses (Fig. 17.13). This syndrome is unusual in its lack of accompanying reflex uveitis, as well as in its bilaterally symmetric location, which is typically inferiotemporal.

FIG. **17.13** Bilateral corneal stromal loss in a Friesian gelding.

Although disease is bilaterally symmetric in location, onset in asymmetric in its development in each eye. This bilateral corneal stromal loss appears to be progressive and can result in perforation but has responded well to surgical repair. This syndrome, which may be a variant of a form of corneal degeneration called pellucid margination degeneration, has been reported more frequently in males. It may have a genetic component in Friesian horses.[45]

Iris Prolapse

Full-thickness corneal perforation is often called iris prolapse (Fig. 17.14). Iris prolapse may be ulcerative or traumatic and is considered a surgical emergency in either case. In one retrospective study of 32 horses with iris prolapse repaired with a conjunctival graft, 73% of perforated globes were retained, and 37% of eyes had vision. Risk factors associated with a good prognosis for retention of the globe following surgical repair of iris prolapse include being traumatic rather than ulcerative, and risk factors associated with a good prognosis for a visual outcome include duration less than 15 days, lacerations less than 15 mm, and lacerations involving cornea alone rather than extending to, along, or beyond the limbus.[46] A more recent retrospective study including 37 horses with iris prolapse caused by corneal ulcers with keratomalacia showed that penetrating keratoplasty alone or in combination with an overlying graft of conjunctiva or amniotic membrane can achieve a successful visual outcome, with 65% of horses had vision postoperatively and 89% of affected globes retained rather than enucleated, which is an increase in globe survival and visual outcome relative to the previous study in which conjunctival graft alone was used as the surgical repair.[47]

Stromal Abscess

Stromal abscesses, which often appear clinically as yellow, tan, or white circular to multifocal stromal lesions associated with intense ocular pain, blepharospasm, tearing, variable corneal vascularization, and secondary uveitis, occur more frequently in horses than any other species (Fig. 17.15). The hallmark of a corneal stromal abscess is ocular pain that is disproportionate to the apparent severity of the lesion. Stromal abscesses occur beneath intact epithelium and are thus fluorescein negative.

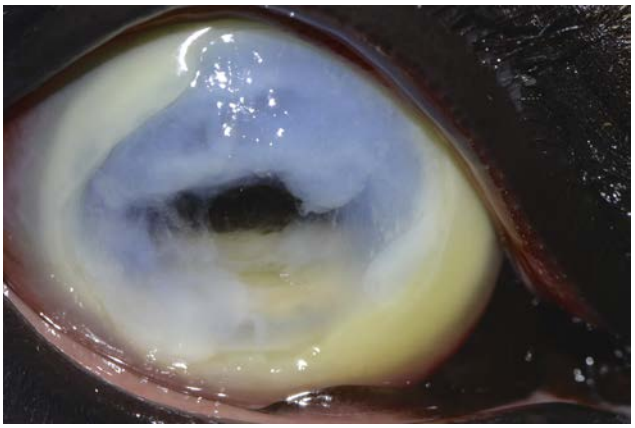

FIG. **17.14** Iris prolapse characterized by a dark brown opacity in the axial cornea surrounded by malacic corneal stroma and a severe stromal infiltrate of white blood cells.

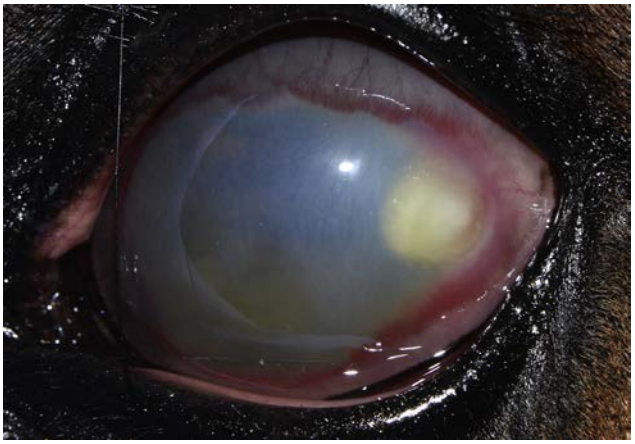

FIG. **17.15** Stromal abscess deep in the temporal cornea characterized by a yellow opacity, severe diffuse corneal edema, corneal vascularization, and a miotic pupil.

When uveitis is severe, corneal edema and vascularization may preclude view of the abscess. Extreme caution must be exercised when treating a corneal opacity that is fluorescein negative (i.e., there is no corneal ulcer present) with a topical steroid, as steroids can exacerbate an abscess. Stromal abscesses may be bacterial or fungal in etiology; however, without an epithelial defect, corneal culture and cytology are not viable diagnostics, and therefore treatment should be directed at both bacterial and fungal agents. Medical therapy is as for an infected ulcer although drug penetration may be poor through the intact epithelium. Debridement of the overlying epithelium to improve drug penetration is not recommended to avoid creation of an open wound that is susceptible to infection. Medical therapy is prolonged in many cases, from several weeks to several months, and typically involves topical antibiotics and antifungals. Stromal abscesses can be associated with severe secondary uveitis, which should be treated with topical atropine and systemic NSAIDs. Stromal abscesses that vascularize will often heal with medical therapy alone; however, lack of vascularization, or persistence or progression of the uveitis in the face of aggressive or appropriate medical therapy, may warrant surgical intervention. Surgical therapy includes excision of the abscessed stroma with supportive

FIG. **17.16** Eosinophilic keratitis, which is a characterized by a caseous pinkish white plaque often located at the limbus.

grafting procedures to return the cornea to normal tectonic strength. Surgical procedures most often involve partial-thickness grafts such as the posterior lamellar keratoplasty (PLK) or deep lamellar endothelial keratoplasty (DLEK).[48] Surgical therapy combined with medical therapy is typically associated with a shorter duration of therapy and faster recovery than treatment with medical therapy alone, although scar formation nearly always occurs.[49]

Corneal Grafting Biomaterials

A number of biomaterials have been used to reconstruct the diseased equine cornea, with the choice of biomaterial determined by the goal of reconstruction: restoration or preservation of tectonic integrity of the globe, replacement of missing or excised disease tissue, preservation or restoration of vision, or improved cosmesis. Conjunctival grafts have traditionally been used to provide a vascular supply but can cause significant scarring. Corneal tissue from a donor can replace missing tissue but can also result in significant scarring. Amniotic membrane can be used to reconstruct the ocular surface, and its use can optimize the visual outcome by reducing scarring because it is avascular, strong, antiangiogenic, and antiinflammatory.[50] Porcine urinary bladder extracellular matrix grafts, which have the advantages over other biomaterials of commercial availability and shelf storage, may be a viable alternative to other biomaterials for corneal grafting in horses, based on a 94% vision and globe retention rate in one retrospective study including 17 cases.[51]

Eosinophilic Keratitis

Eosinophilic keratitis is an inflammatory condition of the cornea characterized initially by severe pain and limbal corneal ulcers, often accompanied by a caseous discharge and severe chemosis and conjunctival hyperemia (Fig. 17.16). In early stages of the disease, clinical signs are often limited to the eyelids and conjunctiva, with severe blepharospasm, blepharitis, and conjunctival hyperemia. If treated at this stage with systemic corticosteroids, corneal disease can sometimes be prevented. The disease has a seasonal occurrence in the summer, likely associated with an environmental stimulus or insect

vector. The presence of eosinophils on cytology is diagnostic. Treatment with topical steroids is often associated with secondary fungal infection. The use of a systemic steroid such as prednisolone or dexamethasone and an antihistamine such as cetirizine may reduce disease severity. Treatment is typically prolonged. Recurrence from year to year in the same patient is reported. In one study of 27 horses diagnosed with eosinophilic keratitis, time to disease resolution averaged 3.7 months, with a significantly shorter time to resolution in horses treated with systemic dexamethasone (2.2 months) than in horses not so treated (4.2 months).[52] In that same study, only 8% of horses treated with cetirizine experienced a recurrence of clinical signs of eosinophilic keratitis in subsequent years; however, 57% of horses not treated with cetirizine experience recurrence.

Idiopathic Nonulcerative Keratitis

Immune-mediated keratitis has been described as a chronic (i.e., greater than 3 months in duration), nonulcerative corneal opacity that is not believed to be caused by an infectious agent and that typically responds to topical immunosuppressive drugs such as prednisolone acetate, dexamethasone, cyclosporine, or tacrolimus. Three types have been described based on the depth of the stromal infiltrated: superficial, characterized by a stromal infiltrate, diffuse vascularization, and response to medical therapy or keratectomy; midstromal, characterized by a stromal infiltrate, mild focal edema, vascularization, and response to cyclosporine; and endothelial, characterized by an infiltrate, diffuse edema, and the poorest prognosis. Immune-mediated keratitis is not typically associated with uveitis or with pain. Medical therapy tends to be constant, and in some cases surgery can be curative.[53]

An investigation of the histopathologic changes associated with immune-mediated keratitis identified nonspecific abnormalities including corneal cellular infiltrate, edema, neovascularization, and secondary degenerative changes. Immunohistochemistry suggested a predominantly T-cell driven process with CD3+ staining. Immunoglobulins detected in diseased cornea suggested localhumoral involvement, but corneal-binding immunoglobulins were not detected in serum or aqueous humor from horses with immune-mediated keratitis, suggesting that systemic humoral immunity is not a component of immune-mediated keratitis. Medical therapy of included corneas may have affected the results of this study.[54]

Episcleral silicone matrix cyclosporine implants have been developed to deliver immunosuppressive therapy locally in horses with immune-mediated keratitis. These implants have been shown to be well tolerated and to control keratitis (i.e., reduce severity of keratitis such that no or only one medication is required) for approximately 6 months when they are placed at an average of 4 months' disease duration for superficial immune-mediated keratitis and an average of 10 months' disease duration for endothelial immune-mediated keratitis. In the same retrospective study, keratitis was not controlled by episcleral silicone matrix cyclosporine implants when placed at an average of 16 months' disease duration for midstromal immune-mediated keratitis, with an average of 5 months of follow-up after implant placement.[55]

Squamous Cell Carcinoma

SCC may occur on the cornea, typically appearing as a vascular, raised pink lesion at the limbus (Figs. 17.17 and 17.18). Ultraviolet light has been implicated in the development of SCC by causing mutations in a tumor suppressor gene, p53. Additionally, cyclooxygenase-derived prostaglandins, specifically COX-2, may be upregulated in association with p53 mutations, stimulating tumor growth, metastasis, and angiogenesis.

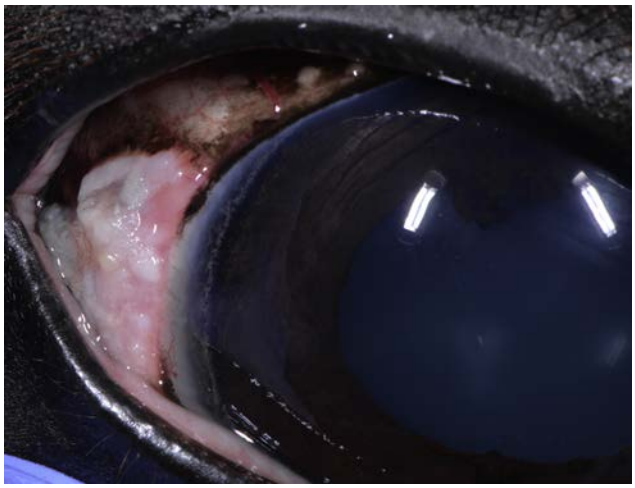

FIG. **17.17** Limbal SCC temporally that appears confined to the conjunctiva that is not covered by the upper or lower eyelid.

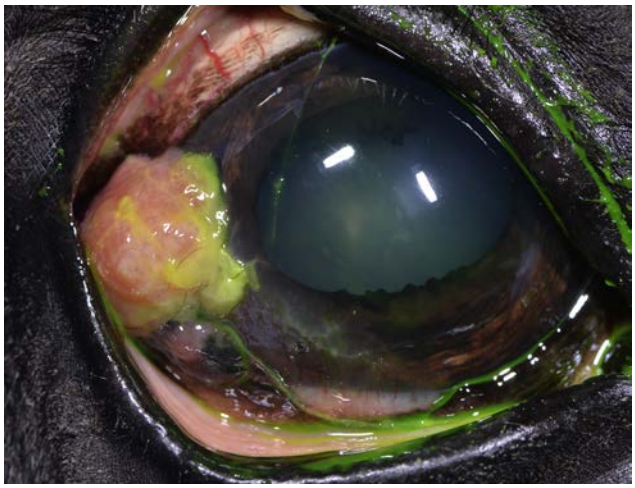

FIG. **17.18** Limbal SCC with a classic "cauliflower" appearance.

Numerous therapies exist for SCC, as with any disease for which there is no perfect treatment. The choice of therapy may not be as critical as early intervention. Excision is often combined with an adjunctive therapy. Excision of SCC involving the nictitans can typically be performed standing, if the tumor is focal and complete excision can be accomplished. Cryoablation is typically used for lesions less than 2 mm in thickness. Optimal cryonecrosis is achieved between −20°C and −40°C, using a double freeze-thaw technique. A fast freeze and slow thaw facilitates cryodestruction. Cryotherapy has the advantages of being accessible and portable. Adverse effects are uncommon, although excessive granulation tissue can be associated with cryotherapy for limbal tumors. Cryotherapy can be used for lid, nictitans, and limbal SCC.[56] 5-Fluorouracil is a pyrimidine analog that acts as an antimetabolite by noncompetitive inhibition of thymidylate synthase. It can be used topically for limbal SCC

and intralesionally for lid SCC. Mitomycin-C is an aziridine-containing natural product isolated from *Streptomyces* species. It acts as a potent DNA crosslinker. Its use topically is based on a retrospective study of 10 human patients with extensive recurrent limbal SCC.[57] Topical use in horses has been shown to be effective.[58,59]

Radiation has been used as primary and adjunctive therapy to treat SCC. Strontium 90 (Sr90) penetrates to a depth of approximately 3 mm, with 80% of the radiation dose absorbed in the first 2 mm, and thus may be effective for limbal SCC.[60] Iridium 129 (Ir129) is delivered via implants for eyelid SCC. Cobalt 60 (Co60) is associated with deeper penetration and thus does not have periocular application because of risks of collateral damage.

Haflingers may be overrepresented among horses with limbal SCC and may be diagnosed at a younger age than other breeds, with an average age at diagnosis of less than 9 years in one study. Affected Haflingers appear closely related, suggesting a possible heritable basis for limbal SCC.[61]

DISORDERS OF THE EQUINE UVEA

Normal Anatomy

The uvea, the vascular tunic of the eye, comprises the iris and ciliary body anteriorly and the choroid posteriorly. Histologically, the uvea contains blood vessels, pigment cells, smooth muscle, and, in the horse, a noncellular fibrous tapetum in the choroid. The ciliary body is the source of aqueous humor, which supplies nutrition to the cornea and lens. The choroid supplies nutrition to the retina and also serves as a heat sink to protect the photoreceptors from the heat generated by light striking the retina. The tapetum, contained within the superior choroid, reflects light back across the retina, thereby maximizing the use of available light. The uvea is the primary site of the blood-ocular barrier, an immunologic barrier to the internal components of the eye. Uveitis, or inflammation of the uveal tract, disrupts this barrier. Spasm of the smooth muscles in the iris and ciliary body occurs with uveitis and results in intraocular pain, photophobia, and constriction of the pupil, or miosis.

The equine pupil is horizontally elliptic, with the dorsal and ventral margins having pigmented prominences termed *corpora nigra*. The pupillary light reflex in the horse is similar to that of other species, with a direct and a consensual response. The afferent fibers of the pupillary light reflex are carried in cranial nerve II, and the efferent parasympathetic fibers are carried in cranial nerve III. Abnormalities in pupil response to a light stimulus result from afferent lesions involving the retina or optic nerve. Afferent abnormalities are associated with loss of vision in the affected eye. Efferent lesions are rare but include damage to cranial nerve III with an associated ventrolateral strabismus and abnormalities of the iris itself such as synechiae. Glaucoma, which is an optic neuropathy characterized by high intraocular pressure, can cause mydriasis secondary to afferent optic nerve damage and/or because of an efferent inability of the pupil to constrict in the face of high intraocular pressure. It is important to differentiate excited horses with sympathetic override, weak light source, and improper examination technique from an abnormal pupillary light response.

FIG. **17.19** Corpora nigra cyst at the inferior pupil margin. These structures originate from the posterior pigmented epithelium of the iris.

Sympathetic nerve fibers supply the dilator muscles of the iris. These fibers travel in the spinal cord, emerge in the ventral nerve roots at the first and second thoracic nerves, course through the thorax, run in association with the internal carotid artery, synapse at the cranial cervical sympathetic ganglion, and travel to the eye with the ocular arteries. Damage to the sympathetic fibers results in Horner's syndrome. Clinical signs include ptosis, miosis, enophthalmos, protrusion of the third eyelid, and sweating on the affected side of the face and neck. Treatment is directed toward the primary disease, if possible. In some horses the clinical signs of Horner's syndrome resolve without treatment.

Iris Stromal Hypoplasia

An abnormally thin iris stroma, particularly in horses with a blue iris, can protrude anteriorly as aqueous humor, formed by the ciliary body in the posterior chamber, accumulates behind the iris. This iris stromal hypoplasia can be mistaken for a solid iris mass; however, transillumination can differentiate between the two.

Corpora Nigra Cyst

Cysts of the anterior uvea are formed by the posterior pigmented epithelium of the iris (Fig. 17.19). Treatment of these cysts is not required unless they are numerous or impair sight. In a retrospective study of the use of semiconductor diode laser to deflate and coagulate anterior uveal cysts in dogs, cats, and horses, in nine horses with corpora nigra cysts at the pupillary margin, no recurrences were reported in any treated horses, and undesirable behavior such as spooking or shying that had been observed before diode laser treatment improved or resolved in all cases.[62]

Uveitis

Uveitis is an inflammation of the iris and ciliary body (anterior) and choroid (posterior). Uveitis is a common manifestation of many ocular and systemic infectious and noninfectious diseases, and as such, an attempt to ascertain the cause is essential. Differentiating uveitis from other ophthalmic diseases resulting in a red and painful eye, such as glaucoma, corneal ulceration, and conjunctivitis, is also essential.

Acute inflammation of the anterior uvea results in spasm of the iris and ciliary muscles and a breakdown in the blood-ocular barrier, leading to miosis and photophobia. Eyelids and conjunctiva may be swollen and hyperemic in the acute phase of anterior uveitis. Protein and cells leak into the anterior chamber, resulting in aqueous flare, hypopyon, and keratitic precipitates. The cornea may show diffuse edema, and the IOP will be low in acute uveitis. Chronic inflammatory changes in the aqueous humor can result in secondary corneal endothelial and lens changes such as corneal edema and cataract, as well as synechiae, which are adhesions between the iris and adjacent cornea (anterior synechiae) or lens (posterior synechiae). The lens may stain a yellow color as a result of chronic serum leakage. The corpora nigra will atrophy with chronic uveitis, appearing abnormally small and smooth. Inflammation of the choroid, because of its close association with the retina, usually also involves the retina and is termed *chorioretinitis.* Chorioretinitis is diagnosed by direct or indirect ophthalmoscopy and results in retinal and subretinal transudate and exudate, retinal vascular changes, hemorrhage, retinal detachment, and retinal degeneration. The optic nerve may show hyperemia and later atrophy. Vitreal changes may be observed in association with posterior uveitis. This may include vitreous debris, cells, liquefaction, and yellow discoloration of the vitreous. Choroidal depigmentation and areas of repigmentation or pigment clumping may be present. Other chronic changes resulting from intraocular inflammation include secondary glaucoma, retinal detachment, blindness, and phthisis bulbi (Fig. 17.20). The development of intraocular changes following uveitis is related directly to the duration and severity of the acute episode and is exacerbated by recurrent episodes of inflammation.

Uveitis may be primary or secondary to other ophthalmic or systemic disease. Ocular causes of secondary uveitis include blunt or penetrating ocular trauma, intraocular neoplasia, corneal ulceration, lens rupture, cataract, and parasitic infiltration. Corneal ulceration results in secondary anterior uveitis through a reflex pathway involving the ophthalmic branch of cranial nerve V. Fluorescein staining of the cornea therefore is indicated in eyes with anterior uveitis. The lens is considered to be an immune-privileged site and as such is capable of stimulating an inflammatory reaction. Lens protein is exposed by traumatic rupture of the lens capsule or during the degenerative process of a hypermature cataract undergoing liquefaction and leakage. Either of these processes can lead to anterior uveitis, with rupture of the lens resulting in the more severe inflammation and frequently secondary glaucoma. Uveitis resulting from direct ocular trauma may be associated with rupture of the fibrous tunic of the eye, hyphema, lens luxation, corneal endothelial damage, retinal detachment, or proptosis.

FIG. **17.20** Phthisis bulbi in an Appaloosa with chronic equine recurrent uveitis (ERU).

Systemic diseases resulting in anterior and posterior uveitis are numerous and include bacteremia, septicemia, immune-complex disease, viremia, disseminated mycoses, and the syndrome of equine recurrent uveitis. Common infectious causes of uveitis include *Streptococcus equi* subsp. *equi* (strangles) and *Leptospira interrogans* serogroup *pomona,* as well as gram-negative sepsis.

Foals with neonatal septicemia are especially prone to anterior and posterior uveitis. The uveitis in these foals is usually sterile. Systemic antimicrobial therapy, topical and systemic antiinflammatory therapy, and topical atropine 1% therapy are the treatments of choice. Copious fibrin production may result from anterior uveitis, especially in young foals, and can result in posterior synechia and opacification of the lens capsule. Intracameral tissue plasminogen activator, 25 to 75 µg administered in the first few days after fibrin formation, can result in complete lysis and resolution.

Equine Recurrent Uveitis

Equine recurrent uveitis (ERU) has been described as the leading cause of blindness in horses. Alternate names include moon blindness and periodic ophthalmia. A review of records of 224 horses with ERU correlated the high frequency of blindness, globe loss, and loss of horses' function, with change of ownership and even euthanasia being common sequelae to ERU.[63] Uveitis starts as blood-ocular barrier compromise, such that blood vessels of the iris, ciliary body, and choroid become "leaky," allowing cells and inflammatory cytokines to enter the eye. Infectious agents may initiate the initial flare-up of uveitis, but immune response shifts between different autoantigens may be responsible for recurrent episodes. Corneal, lens, and retinal autoantigens have been identified in the equine eye that are believed to be targeted by the immune system in horses with ERU; these self-antigens perpetuate the disease. ERU is mediated by a Th1 response directed against several retinal proteins, including interphotoreceptor-retinoid binding protein and cellular retinaldehyde-binding protein. Retinal Mueller glial cells may play a fatal role in uveitic disease progression by directly triggering inflammation processes through the expression and secretion of interferon-gamma.[64]

Although leptospirosis has been implicated in the initiation of ERU, the continued presence of *Leptospira* spp. organisms in the aqueous or vitreous humors does not appear to play a direct role in the pathogenesis of ERU, based on evaluation of aqueous humor, vitreous humor, and serum samples of 24 clinically normal horses, 52 horses with ERU, and 17 horses with ocular inflammation not associated with ERU for the presence of bacterial DNA and intraocular production of antibodies against *Leptospira* spp.[65] However, in another study evaluating aqueous and vitreous samples from 31 horses with ERU and 21 control horses by *Leptospira* culture, polymerase chain reaction (PCR), and microagglutination test (MAT), horses with ERU had a high prevalence of *Leptospira* infection based on PCR and MAT but not *Leptospira* culture, suggesting

that the diagnosis of intraocular *Leptospira* infection requires invasive testing.[66] Given its potential role in the pathogenesis and persistence of ERU, the complicated diagnostic picture, and the low risk of treating for *Leptospira* infection relative to the consequences associated with persistent ocular pain, inflammation, and possible blindness, treating for leptospirosis in acute uveitis cases with no other apparent underlying cause (e.g., blunt trauma, corneal ulceration, cataract) is probably reasonable.

Appaloosa horses are predisposed to ERU, suggesting a genetic link. Evaluation of the association between genetic markers on equine chromosomes 1 (ECA1) and 20 (ECA20) in 53 Appaloosas with ERU and 43 healthy Appaloosa controls showed strong associations between ERU disease status and genetic markers in the TRPM1 gene on ECA1 and the equine major histocompatibility complex (ELA) on ECA20.[67]

Cyclosporine A (CsA) implants have been developed to decrease the frequency and severity of flare-ups of ERU. Most horses with CsA implants have less inflammation and fewer attacks postoperatively.[68] Standard treatment of ERU flare-ups remains topical corticosteroids and NSAIDs, topical atropine, and systemic antiinflammatories (both corticosteroids and NSAIDs). There are risks and complications associated with long-term use of any of these drugs.

DISORDERS OF THE EQUINE LENS

Normal Anatomy

The lens originates from surface ectoderm and is a clear, avascular, biconvex structure suspended posterior to the iris by lenticular zonules arising from the ciliary body. The lens depends on the aqueous and vitreous humors to supply nutrition and remove waste products.

Luxation

Lens luxation and subluxation can be congenital or acquired. Acquired lens luxation results from glaucoma and buphthalmos, trauma, or chronic uveitis. Once luxated, the lens can be displaced anteriorly or posteriorly. A posteriorly luxated lens results in liquefaction of the vitreous from lens movement. The lens settles inferiorly, may or may not attach to the retina, and generally does not result in significant problems or require therapy. Anterior lens luxation can cause anterior uveitis and trauma to the corneal endothelium, resulting in diffuse corneal edema, obstruction of aqueous humor circulation, and secondary glaucoma (Fig. 17.21). Treatment of anterior lens luxation in a potentially visual eye involves surgical removal of the luxated lens, although the success of this procedure in the horse has not been well documented. In a blind, painful eye, enucleation is warranted. It is possible for an anteriorly luxated lens to be repositioned into the posterior segment with digital pressure; however, complications such as retinal detachment and vitreal prolapse resulting in secondary glaucoma can occur.

Cataract

A cataract is any opacity of the lens or its capsule (Figs. 17.22–17.24). Cataracts can be unilateral or bilateral and should be classified according to age of onset, location, and degree of lens affected to aid in determining the cause and likelihood of progression. In general, anterior, cortical, and equatorial cataracts are more likely to progress than are nuclear and posterior cortical

FIG. **17.22** Early immature cataract in the right eye of a young adult horse.

FIG. **17.21** Chronic anterior luxation of a lens with a brunescent cataract (a very advanced nuclear cataract that has become brown and opaque).

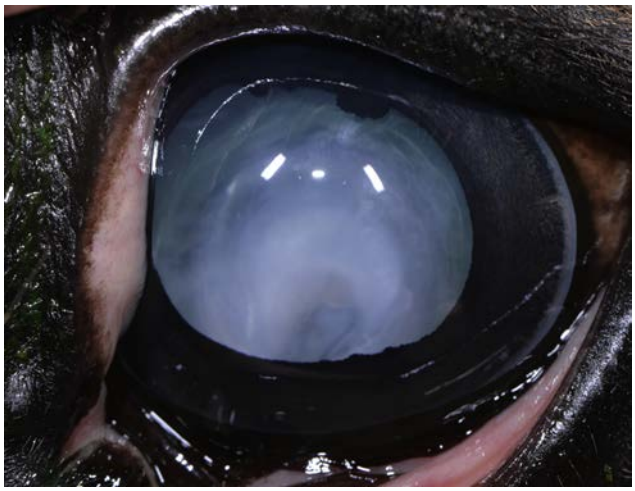

FIG. **17.23** Late immature cataract in the left eye of the horse pictured in Fig. 17.22.

FIG. **17.24** Immature cataract in a foal.

cataracts. Classification by age of onset includes congenital, juvenile, adult, and senile. Causes of cataract formation include inherited, inflammatory, traumatic, metabolic, toxic, and nutritional abnormalities, with the most common cause of cataracts in horses being secondary to ERU. Suspected inherited cataracts have been reported in several breeds of horses and are thought to occur in other breeds, but definitive support is difficult because of the small number of offspring produced. If the cause of a cataract cannot be determined and intraocular inflammation is not evident, breeding of a horse with a cataract should be discouraged. The only treatment for cataracts is surgical. Cataracts that are unilateral or not sufficiently severe to interfere significantly with vision may not warrant treatment. Many horses develop age-related cataracts that have variable effects on functional vision. A decision to treat cataracts should always be considered in the context of the degree of functional visual impairment, the presence of active inflammation, and the intended use of the horse. Before cataract surgery, retinal anatomy and function should be evaluated using ocular ultrasound and electroretinography.

Success rates of equine cataract surgery have been reported in two recent retrospective studies. In one review of records of 95 horses undergoing cataract surgery, including 44 foals and 24 horses with cataracts secondary to ERU, 95% regained vision postoperatively but the percent of horses with eye sight decreased rapidly from 87% at less than 1 month, 49% at 6 months, 35% at 1 year, and only 26% had vision at greater than 2 years. However, horses not available for follow-up were not included as 'had vision' but not removed from the denominator so were effectively counted as 'had no vision', potentially underestimating long-term success.[69] In another retrospective study of 41 horses undergoing cataract surgery, 26% with chronic uveitis, 54% had vision at an average last follow-up of 35 months. In that study, visual outcome was not associated with patient age or placement of an artificial lens, but fewer horses with uveitis (25%) had vision at last follow-up compared with horses without uveitis (65%).[70] Intraocular lenses have been developed to correct vision in the equine eye following cataract surgery.[71]

DISORDERS OF THE EQUINE RETINA

Normal Anatomy

The horse has a paurangiotic (partially vascularized) retina with 30 to 60 small retinal vessels radiating from the margin of the optic disk that are visible for a distance of one to two disk diameters. Beyond this distance, the remainder of the equine retina is avascular, with nutrition supplied to the retina from the underlying choroidal blood vessels. The equine fundus is divided into dorsal tapetal and ventral nontapetal regions, with the oval, salmon-colored optic disk located in the nontapetal fundus. Variations in tapetal color are related to coat color and include green, yellow, orange, and blue-green. The tapetum of the horse is fibrous and penetrated by small choroidal vessels that appear as dark dots in the tapetum, termed the *stars of Winslow.* The ventral, nontapetal fundus is generally dark brown or black but can appear lighter or nonpigmented depending on coat color. Retinal function can be tested by performing an electroretinogram (ERG). ERGs can be performed in standing sedated horses.[72]

Retinal Detachment

Retinal detachment can be congenital or acquired, partial or complete. Because the equine retina depends almost totally on the underlying choroid for its blood supply, detachment results in rapid severe retinal degeneration and irreversible blindness. Common causes of retinal detachment in the horse include an inherited abnormality associated with retinal dysplasia, ERU, and trauma. Treatment is limited to controlling the inciting disease and use of systemic antiinflammatory drugs, but restoration of vision is not possible. Surgical reattachment of the retina has not been successfully performed in the horse.

Chorioretinitis

Inflammation of the retina and choroid in the horse most often results from ERU and may be associated with concomitant anterior uveitis and optic neuritis. In addition, the vascular nature of the choroid results in susceptibility to blood-borne disease, as with bacteremia, septicemia, and viremia. Treatment of chorioretinitis includes systemic therapy for the primary infectious disease, if present, and flunixin meglumine to decrease inflammation. Topical treatment is indicated only with anterior uveal involvement. The sequelae of chorioretinitis include retinal degeneration, retinal detachment, and optic nerve atrophy.

Although pinpoint chorioretinal scars ("bullet hole" lesions) have been associated with chronic chorioretinitis, outer retinal function as measured by ERG does not appear to be compromised in horses with extensive bullet hole lesions.[73]

DISORDERS OF THE EQUINE OPTIC NERVE

Normal Anatomy

The equine optic nerve is oval, salmon-pink, and located in the nontapetal region of the fundus. Arterioles and venules extend a short distance from the optic nerve into the surrounding peripapillary retina. On direct ophthalmoscopic examination the margin of the optic nerve is sharp and well defined, as are the retinal blood vessels. The nerve fiber layer of the retina may be visible as linear white streaks radiating outward from the optic nerve.

Glaucoma

Glaucoma is a disease characterized by elevation of IOP that is incompatible with health of the optic nerve. In horses, glaucoma is usually secondary to uveitis. Clinical signs include

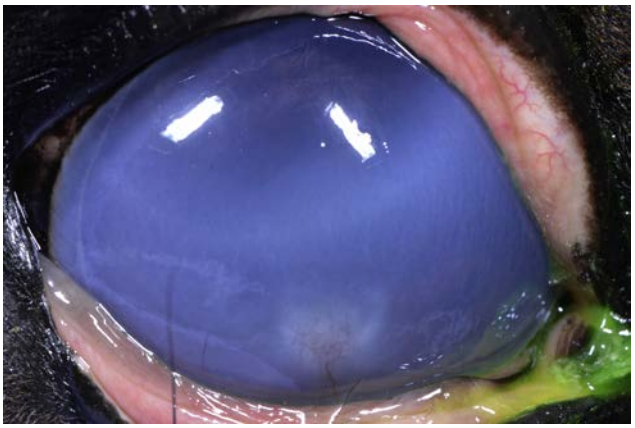

FIG. **17.25** Glaucoma characterized by severe diffuse corneal edema.

mydriasis, corneal edema, scleral injection, ciliary flush, and, in chronic cases, buphthalmos (Fig. 17.25). Haab's striae, which represent breaks in Descemet's membrane, may be associated with glaucoma but can also be seen with no apparent cause and may represent inflammatory lesions. Glaucoma is diagnosed based on clinical signs and measurement of IOP. Several different types of tonometers are commercially available and lend themselves well to field use. Glaucoma can be classified as primary, resulting from anatomic abnormalities associated with the iridocorneal angle, or secondary to other ocular disease such as uveitis, lens luxation, or intraocular neoplasia. Primary glaucoma is not well characterized in the horse.

Therapy for glaucoma can be divided into two general categories: drugs that decrease aqueous production, such as β-blockers and carbonic anhydrase inhibitors, and drugs that increase aqueous outflow, such as prostaglandin analogs. Another way of categorizing glaucoma medications would be based on their function, as rescue versus maintenance drugs. Some drugs, such as the prostaglandin analogs (e.g., latanoprost), serve both rescue and maintenance functions. Unfortunately, the prostaglandin analogs, which have proven to control IOP well in other species, do not decrease IOP in horses. The two drugs most helpful in decreasing IOP in horses with glaucoma are timolol and dorzolamide, which are available as a combination product called Cosopt. These drugs have been shown to be associated with a small but significant decrease in IOP in normal horses,[74] but no controlled studies of their efficacy in horses with glaucoma have been performed. Brinzolamide, a topical ophthalmic carbonic anhydrase inhibitor with a pH closer to physiologic and that is therefore less likely to be associated with ocular irritation, has been shown to decrease IOP in normal horses with both once- and twice-daily dosing.[75]

As with medical therapy, surgical treatments for glaucoma can be classified based on their mechanism of action as either decreasing aqueous production (e.g., cyclodestructive procedures, which damage the ciliary body) or increasing aqueous outflow (e.g., anterior chamber shunts). Diode laser transcleral cyclophotocoagulation (TSCP) can provide long-term control of IOP in horses with glaucoma but typically does not eliminate the need for long-term topical treatment.[76] TSCP can often be performed under standing sedation rather than general anesthesia. Horses undergoing TSCP typically have a 3-week period in which IOP spikes in association with laser-induced uveitis but then settles down to a stable postoperative level.

Endocyclophotocoagulation and gonioimplant placement have become increasingly commonly performed by veterinary ophthalmologists treating canine glaucoma patients, but neither of these surgical therapies has yet achieved consistent success with equine glaucoma patients. In one experimental study in which Ahmed gonioimplants were placed in seven normal eyes of four horses, IOP was significantly decreased for the entire 4-week study period, suggesting that gonioimplants may be a viable therapeutic option for horses with glaucoma.[77] A case report describing the placement of a Baerveldt gonioimplant in a horse with glaucoma documented IOP control for 402 days, suggesting that long-term IOP control may be achieved with gonioimplants.[78]

Traumatic Optic Neuropathy

Trauma to the head of the horse has been associated with acute unilateral or bilateral blindness resulting from optic nerve damage. The pupil in the affected eye is dilated, but the remainder of the ophthalmic examination may be normal initially. Occasionally, retinal hemorrhage and papilledema are present. Fundic examination 3 to 4 weeks after the traumatic episode reveals optic nerve pallor and absence of retinal blood vessels, indicating atrophy. The cause of this lesion is hypothesized to be stretching of the optic nerve with subsequent rupture of the optic nerve axons or trauma from bony fractures adjacent to the optic nerve, although anatomic studies have not been performed to confirm this. Systemic antiinflammatory therapy may be beneficial in the acute phase; however, the prognosis for return of vision is guarded. Optic nerve atrophy can also be caused by ERU and chronic glaucoma.

DISORDERS OF THE EQUINE ORBIT

Normal Anatomy

The complete bony orbital rim that protects the equine globe is formed by the frontal bone dorsally, the lacrimal bone medially, the zygomatic bone ventrally, and the temporal bone laterally.

Orbital Fracture

The zygomatic process of the frontal bone and the zygomatic arch, which form the dorsal orbital rim, are prone to fracture and resultant opening into the frontal and caudal maxillary sinuses. Epistaxis can occur when the turbinate bones are fractured, and nasolacrimal duct obstruction can result from a lacrimal bone fracture. In a retrospective study of 18 horses diagnosed with orbital fractures that were confirmed by skull radiographs or CT, 56% had orbital rim fractures, 72% had open fractures, and 83% of the fractures were displaced. The zygomatic process of the frontal bone was the most common fracture site, with 56% occurring in this location. Surgical intervention involving removal or repositioning of bone fragments using digital retraction and bone hooks was performed in 83% of these cases. The globe was retained in 89% of cases and was visual in 78%, suggesting that horses diagnosed with orbital fractures have a favorable prognosis for vision.[79]

Neoplasia

The most common orbital tumors are neuroendocrine tumors and extra-adrenal paragangliomas, which grow slowly and rarely metastasize.[80] Clinical signs of retrobulbar neoplasia include exophthalmos, strabismus, elevation of the third

eyelid, periorbital swelling, decreased retropulsion of the globe, chemosis, mydriasis, and vision loss. Ocular ultrasound may identify a mass lesion with or without indentation of the globe, but this can be difficult to interpret. CT can identify the location and extent of an orbital tumor.[80] Although the equine orbit and sinuses can provide room for orbital tumors to progress to an advanced stage before diagnosis and therefore the prognosis for globe survival is poor, exenteration can be associated with increased survival times by preventing extension beyond the orbit.

Enucleation

Enucleation may be warranted for globes that are blind and intractably painful when medical therapy or other surgical alternatives are not viable. Two standard approaches to enucleation are transpalpebral and subconjunctival. In a transpalpebral enucleation, the eyelids are closed and the eyelid margin is removed in a single bloc of tissue with the conjunctiva, third eyelid, and globe, which can minimize orbital contamination in cases of infectious or neoplastic ocular disease. In a subconjunctival enucleation, the globe is removed before removal of the eyelid margin, which can be associated with decreased surgical time and hemorrhage.

A transpalpebral enucleation in a standing sedated horse can safely be performed in most horses and eliminates the risks associated with general anesthesia.[81] In one retrospective report of 40 horses enucleated under standing sedation, acceptable local anesthesia and lid akinesia was provided using a combination of an auriculopalpebral motor block, a supraorbital block of the frontal nerve, a subcutaneous ring block around the palpebrae to desensitize the infratrochlear, lacrimal, and zygomatic nerves, and a retrobulbar four-point block using a 20-gauge bent spinal needle inserted through the eyelid skin.[82] Surgical drapes are typically not used to avoid exaggerated head movement, although a small sterile drape can be placed over the nose and cheek band of the halter after the globe is excised to cover the region ventral to the eye and thereby prevent contamination of the suture during wound closure.

The effect of unilateral enucleation on vision and potential loss of performance in horses is not well understood. In one study of 34 horses who had undergone unilateral enucleation, 74% were reported to be acutely blind at the time of enucleation, and 85% returned to their presurgical discipline. The duration of vision loss before enucleation did not appear to affect whether horses returned to their previous discipline.[83] In the Pollock study, 30 of 32 horses for whom follow-up information was available returned to their previous use, with two retired to breeding or pasture.[82]

CHAPTER 18

Disorders of the Skin

Ann M. Rashmir-Raven*

Disorders of equine skin are common and can be both debilitating to the horse and a significant source of frustration for the owner. Horses suffer a broad range of dermatitides including infectious, allergic, heritable, and idiopathic disease; immune-mediated disorders; and cancers. Evaluation of the skin in the equine patient is an important part of the physical examination. Lesions can be identified and treated while they are still small, before they have a negative impact on the horse's welfare. Some skin conditions can make a horse so uncomfortable that they interfere with riding and training, and the occasional disorder can actually be life-threatening.

In addition to providing critical vital functions such as thermoregulation, sensation, and immunosurveillance, the skin on the horse can dictate a significant portion of their value with respect to coat color and pattern and the length and thickness of the mane, tail, and feathers. Because many skin disorders share the same physical characteristics, it can be difficult for the equine veterinarian to diagnose and treat problems without detailed knowledge and a few specific skills and techniques.

STRUCTURE OF THE SKIN AND ADNEXA

The Skin

Skin thickness varies between 1 and 5 mm depending on location. Thickness is greatest on the dorsum and proximal extremities and becomes thinner on the ventrum and distal portion of the extremities. Skin is thickest on the forehead, dorsal neck, dorsal thorax, and base of the tail, and it is thinnest on the ears and in the axillary, inguinal, and perianal areas.[1,2]

The skin consists of two main layers: the epidermis and dermis. The epidermis consists of the basal, spinous, granular, clear, and horny layers. Each layer has different types of cells and differs in function. The basal layer consists of a single column of cells that are attached to the basement membrane. Typical basal keratinocytes have an oval nucleus, prominent nucleolus or nucleoli, and little heterochromatin. The basal keratinocytes contain melanosomes; various metabolic and synthesizing organelles such as mitochondria, lysosomes, rough endoplasmic reticula, and Golgi complexes; and cytoskeletal structures such as keratin intermediate filaments, microfilaments, and microtubules. Structures such as desmosomes and hemidesmosomes that help form the attachment and help to shape the basal layer are also present.[3]

The spinous layer of the epidermis comprises two to four layers. The cells become progressively differentiated as they move outward toward the skin surface. The spinous layer cells first appear polyhedral and then become more flattened as they develop and move outward. The spinous cells contain cellular organelles and keratin filaments. The cells of the uppermost one to two layers of the granular layer contain small, oval, membrane-bound organelles (300 nm) with alternating lamellae called *lamellar granules* (membrane-coating granules, keratinosomes, and Odland bodies) formed in the Golgi region. They contain polar lipids such as phospholipids, glycosphingolipids, free sterols, and other probarrier lipids and hydrolytic enzymes that convert the probarrier lipids into stacks of neutral lipid-rich lamellae that assemble in the intercellular space, coat the surfaces of the cornified cells, and provide a barrier to the permeation of the skin. The spinous cells have abundant desmosomes that consist of adhesion plaques and submembranous plaques involved in cell cohesion.[4,5]

The granular layer consists of highly differentiated cells that are flattened polyhedrons with keratohyalin granules. In this layer of the skin, dephosphorylation and proteinolysis activate filaggrin, which cross-links and bundles with keratin filaments into large macrofilaments. Filaggrin is broken down in the stratum corneum to free amino acids important for the proper hydration of the epidermis. Lamellar granules present in the granular layer aggregate beneath the plasma membrane and fuse with it, opening a channel for the release of granule contents such as polysaccharides, glycoproteins, acid hydrolases, acid lipases, and probarrier lipids into the intercellular spaces. After release, polar lipids are remodeled into hydrophobic, neutral, lipid-rich lamellae that form an effective barrier. The lipid synthesis required for barrier function occurs within all nucleated cell layers of the epidermis. These lipids are stored within epidermal lamellar bodies, which are visible at the level of the spinous layer and continue throughout the granular layer. In the outermost granular layer, the contents of lamellar bodies are secreted into the intercellular domains at the stratum granulosum–stratum corneum interface. Lamellar bodies contain cholesterol, phospholipids, and glucosylceramides, as well as hydrolytic enzymes that convert the newly secreted phospholipids, glucosylceramides, and sphingomyelins into

*The editors and authors acknowledge and appreciate the contributions of Christine A. Rees as a previous contributor to this chapter. Some of her original work has been incorporated into this edition.

free fatty acids and ceramides. Sphingomyelins also act as bioactive regulators and messengers in cutaneous homeostasis and immune-mediated responses. Ceramide is an important metabolite of sphingomyelin and is one of the main lipid components in the skin barrier.[6] Ceramides are critical for barrier function and required for repair. Alterations in epidermal lipids have been linked to atopic dermatitis in humans, and sphingomyelin seems to be a potential player in insect bite allergy of the horse because alterations in its concentrations are associated with changes in clinical signs.[7]

A dense layer of highly cross-linked proteins is deposited inside the inner leaflet of the membrane. Together with the membrane, this boundary is called the *cornified cell envelope*, which is a rigid structure that resists degradation and is rich in glutamyl-lysine isopeptide cross-links. At the uppermost aspect of this layer, substances such as keratins, filaggrin, and the cornified cell envelope are passed on to the cornified cell layer.[4,5]

The cornified layer contains the largest and most numerous cells of any zone in the epidermis. Cells are large, flattened, and polyhedral; overlap with the margins; and associate through interlocking ridges and modified desmosomes. The contents of the cell are limited primarily to disulfide-bonded keratin filaments, highly cross-linked bundles of macrofilaments, and filaggrin. The compact organization of the proteins becomes looser toward the outer epidermal surface. The breakdown of filaggrin to its constituent amino acids in the outer cell layers accounts for the greater water-holding capacity of the cells and the more diffuse organization of the filaments. Urocanic acid is degraded from filaggrin with histidase and absorbs ultraviolet light. Therefore urocanic acid is important in ultraviolet light protection. The pyrrolidone carboxylic acid derived from glutamine is hygroscopic and helps to keep the skin hydrated, even in a dry environment. The preserved trilaminar plasma membrane outside the cornified cell envelope becomes discontinuous and desquamates toward the upper portion of the cornified layer so that the envelope serves as the real cell membrane.[4,5]

The dermis contains cellular elements including fibroblasts, macrophages, histiocytes, eosinophils, and mast cells in the fibrous and nonfibrous matrix. The fibrous matrix consists of collagen and elastic fibers. The nonfibrous matrix consists of glycosaminoglycans and proteoglycans. Blood vessels, nerves, lymphatics, hair, and sebaceous and apocrine glands are found within the dermis. The sebaceous and apocrine glands in the horse are larger and more numerous compared with those in other large-animal species.[4,5]

The area that separates the epidermis from the dermis is known as the *basement membrane zone*. This layer of the skin functions as a scaffold for organization (important for growth and differentiation of keratinocytes) and repair (speeds up reepithelization), acts to regulate selective permeability by only allowing the passage of molecules of the correct charge and molecular size, provides a physical intercellular barrier (tumor containment), and links epithelia to their underlying matrices. The basement membrane consists of structures such as tonofilaments, hemidesmosomes, laminin, and fibronectin; proteins such as collagen; laminin-like molecules such as entactin and nidogen; anionic glycosaminoglycans such as heparin sulfate, anchoring fibrils, oxytalan filaments, elaunin fibers, and microthread-like filamentous threadwork; and large glycoproteins such as fibrillin.[5]

Hair

The hair growth cycle begins in the growing or anagen phase and progresses through an intermediate or catagen phase into a resting or telogen phase (Fig. 18.1). The time period that hairs are in the catagen phase is short, and finding hairs in this stage of the cycle is often difficult using a trichogram (plucking hairs and looking at them under the microscope). A variety of conditions including temperature, photoperiod, genetics, and hormones can affect the hair cycle.[1,2]

Hair follicles are located within the dermis and are associated with sebaceous and apocrine glands. Hair is important in thermoregulation and in the protection of the skin from external factors. Equine skin contains simple primary hairs that do not shed all at once; rather, their hair tends to shed in patches or in a mosaic pattern.[1,2]

Ambient temperature can affect the texture of the hair. In warm temperatures the coat is comprised of thick, medullated hairs, and piloerection aids in cooling the horse. In colder temperatures the coat is comprised of longer, finer, and poorly medullated fibers that provide more insulation from the cold. The hairs of the fetlock, mane, and tail do not generally shed like body hair.[2]

Additional Skin-Related Structures

The horse and other Equidae have skin structures unique to these species, including the ergot, chestnut, and hoof. The ergot is a small mass of cornified tissue located in a tuft of hair on the flexor surface of the fetlock. It is a vestige of the second and fourth digits of extinct Equidae. The chestnut is a mass of horny tissue on the medial surface of the radius and is believed to be a vestige of the first digit. The hoof is the horny covering over the distal end of the third digit and includes the hoof wall, heel bulbs and solar surface (frog, sulci, sole, white line, hoof wall, and bars).

APPROACH TO SKIN DISORDERS

History

A detailed history of the patient can provide the clinician with useful clues to help determine the underlying cause of a dermatologic problem. Fig. 18.2 is an example of an equine dermatologic history form. Obtaining the answer to simple questions, such as, "How long as the horse had the lesion(s)?", can help distinguish a case of equine sarcoid from dermatophytosis.

Similarly, knowing if grooming aids (brushes, curry combs, etc.) are shared may help rule in or rule out contagious or infectious diseases. Current bathing practice is an important consideration; bathing with detergent-based products that are commonly used to deep clean horses or whiten the socks, stockings, or entire body of the horse may strip the skin of its protective fats and oils and contribute to both infectious and allergic processes.

Response to previous therapy is another useful historical clue. The practitioner should determine the dose and frequency of medication administration. If the appropriate drug or drug dose is not used, the patient is unlikely to respond.

Other factors to consider include feed, stabling environment, and supplements or other medications (e.g., wormers, sprays, shampoos). If any of these factors changed before the

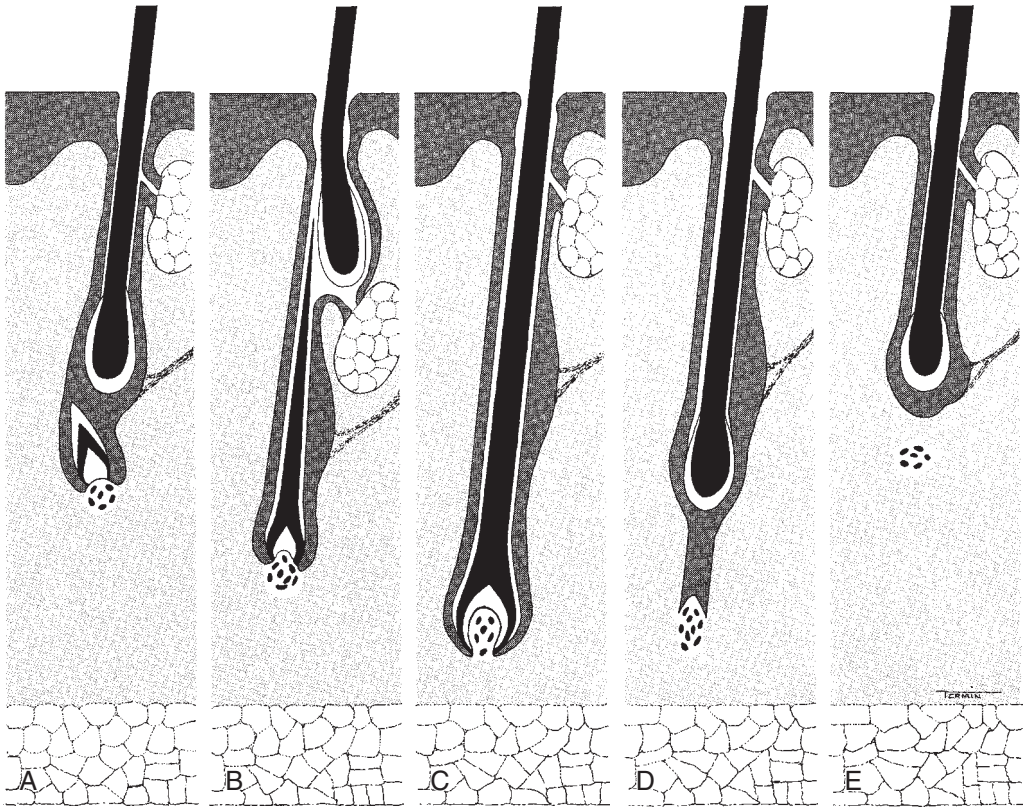

FIG. **18.1** Phases in the life cycle of a hair. (A) Anagen begins with the renewal of the intimate relationship between the papilla and the undifferentiated cells that partially enclose it. (B) As anagen proceeds, matrix cells generate a new hair that pushes upward toward the surface and in the process dislodges the old club hair. (C) Mature anagen hair follicle consists of infundibular, isthmus, and inferior segments. (D) During catagen, the entire inferior segment of the follicle shrivels upward as a thin cord of epithelial cells and is followed upward by the papilla. (E) During telogen, the club hair rests in its cornified sac at the level of the hair erector muscle. (From Moschella SL, Herley HJ. *Dermatology.* 3rd ed. Philadelphia, PA: WB Saunders; 1992.)

development of the dermatologic lesions they may be related to the problem.

Physical Examination

The examiner should consider both the character of the skin lesions and their distribution (Fig. 18.3) when performing a physical examination. Pustules, vesicles, papules, wheals or hives, erythema, and nodules are considered primary lesions. Pustules and vesicles are most common in bacterial and autoimmune skin diseases but can be so fragile that they are not easy to find. Secondary lesions include scales, crusts, excoriations, fistulae, ulcers, necrosis, hyperpigmentation, hypopigmentation, lichenification, hyperhidrosis, and scars.

Lesion location is important because many dermatologic conditions occur with a higher frequency on specific areas of the body. Parasite-related dermatologic problems are a good example of this.[1,2] For instance, pinworms can cause intense pruritus of the tail and perineum, and black flies have a predilection for the head, ears, and ventral abdomen. More detailed information concerning insect feeding preferences is presented later. In addition, special attention is given to mucous membranes, mucocutaneous junctions, the inguinal region, and feathered limbs if they are present; unless these areas are specifically examined, disease processes can be overlooked.

Patient evaluation will often include one or more of the following: grooming for mites and lice; hair sampling for dermatophytes and dermatophilus; skin scraping or a tape prep for mites, bacteria, yeast, and pinworm eggs; swabs for culture; and fine-needle aspirate or biopsy (Boxes 18.1, 18.2, and 18.3).

The clinician should also perform a complete physical examination, determining the temperature, heart rate, and respiratory rate, presence or absence of borborygmi, and quality of digital pulses. If abnormalities exist, the horse may have a systemic disease or more than one medical problem (Table 18.1). For the animal's long-term health and well-being, exploring all problems is important.

DISORDERS OF PIGMENTATION

Skin and hair color depend on melanin production in the skin. Melanocytes produce pigment at the dermal–epidermal junction and in the outer root sheath of the hair follicle. The ratio is one melanocyte for every 10 to 20 keratinocytes.

EQUINE DERMATOLOGY HISTORY FORM

Date _____

Age when purchased _____

What is this horse's use? _____

What is your complaint about the horse's skin? _____

Age of horse? _____ Age when skin problem started? _____

Where on the body did the problem start? _____

What did the skin problem look like initially? _____

_____

How has it spread or changed? _____

Is the problem continual or intermittent? _____

What season did the problem start? _____

Is the problem seasonal or year-round? _____

If seasonal, what seasons is the disease present? _____

_____

Does the horse itch? _____ If so, where? _____

_____

Do any horses in contact with the affected horse have skin problems? _____

If so, are they similar or different from this horse's problem? _____

Do any people in contact with the horse have skin problems? _____

Do you use insect control? _____ If so, describe. _____

_____

Do any relatives of this horse have skin problems? _____ If yes, explain. _____

_____

Please list any injectable, oral, or topical medications that have been used to treat the problem (veterinary or "home remedies"): _____

_____

Did any help the condition? _____ If yes, which ones? _____

Did any aggravate the condition? _____ If yes, which ones? _____

Describe the environment where the horse is kept: Indoors _____

_____ Outdoors _____

What is the horse fed? _____

What feed additives do you use? _____

What is your deworming schedule? _____

Did the horse receive ivermectin? _____ If so, when? _____

List any other major medical problems or drugs that the horse received: _____

_____

List any additional information you feel is relevant to the skin disease: _____

FIG. **18.3** Regional pruritus: differential diagnosis of pruritic skin diseases.

BOX 18.1 Collecting Samples for Fungal and Bacteriologic Culture

BACKGROUND CONSIDERATIONS

- **Indications:** Horses can develop a wide range of bacteriologic and fungal dermatoses. They also maintain a large population of resident bacteria and fungi that can make culture results frustrating if proper sampling technique is not used.
- **Equipment/supplies:** These include dermatophyte test medium (DTM) available from Remel (Lenexa, Kansas) for fungal cultures if planning to culture fungal lesions (see the following sections for culturing fungus from pulled hair samples), sterile needles of any size, and culture swabs with transport medium.
- **Special considerations**
  - Discontinue the use of topical and systemic antibiotics 36 hours prior to sampling whenever possible. Some dermatophytes require a more specialized medium.
  - Swabs taken from the surface of lesions generally have a low diagnostic value.
  - Viral culture or detection requires specialized transport media from the laboratory performing the procedure. Scabs and infected tissue packed in ice are often diagnostically useful for viral based disease.

BASIC PROCEDURE

- Do not cleanse with antiseptic prior to sampling.
- Locate an intact pustule or a recently infected area.
- Use a sterile needle to open the pustule prior to swabbing the lesion.
- Swab and immediately place the swab into transport medium.
- Alternatively, you may swab from the deeper layers of a biopsy specimen or from a fine-needle aspirate.
- If in-house culture is preferred, use the swab to directly plate onto culture medium.
- For deep lesions, a two-punch biopsy technique is the preferred method to obtain deep cultures.

PROCEDURE FOR FUNGAL CULTURES

Fungal cultures should be obtained from the rim of an active lesion. Hairs and scales scraped with a scalpel blade can be placed in a sterile container, such as a red top tube, and sent to the laboratory for culture. Alternatively, the samples can be cultured in-house by placing the plucked hairs directly on fungal culture medium (DTM). Push plucked hair firmly onto the two separate DTM bottles, but do not bury them. Either send the samples to an appropriate laboratory or incubate

Continued

BOX 18.1 Collecting Samples for Fungal and Bacteriologic Culture—cont'd

one sample at room temperature and one sample at 37°C. The samples should be monitored for 14 days, checking daily for color change and growth of fungal colonies. Pathogenic dermatophytes generally cause a red color change in 3 to 5 days and generate powdery or fluffy white or off-white colonies shortly thereafter. Color changes that occur 14 or more days after culture and brown, black, or green colonies are considered negative for pathogenic dermatophytes.

PROCEDURE FOR ANAEROBIC CULTURES

Anaerobic cultures must be inoculated into specialized culture bottles or vials to avoid rapid sample deterioration. Check with your specific laboratory prior to culture.

PROCEDURE FOR DIAGNOSIS OF DERMATOPHILOSIS

It is generally simpler to use a Gram stain on fresh lesions than to culture *Dermatophilus congolensis.* The scab is removed from a fresh lesion, and the underside of the scab is swabbed or pressed to a glass slide for staining. *Dermatophilus* has a characteristic railroad track appearance on Gram stain (2–6 parallel rows of gram-positive cocci); Diff-Quik, Giemsa, and other stains are also suitable choices. Alternatively, *D. congolensis* can be diagnosed on scab histopathology or lesion biopsy. Culture requires a laboratory with the capability to provide a 20% CO_2 environment. Scabs should be collected and moistened with distilled water or sterile saline.

BOX 18.2 Collecting Samples by Fine Needle Aspirate

INDICATIONS

Fine-needle aspirate is useful for diagnosing both solid tumors and fluid-filled cavities such as bullae and abscesses. Leaving the needle in place postaspiration will also serve as a guide for establishing drainage of deep abscesses.

SPECIAL CONSIDERATIONS

The use of a 5-MHz ultrasound transducer will help delineate the appropriate site or sites to aspirate abscesses. Thick-walled abscesses and those surrounded by cellulitis or edema (a common occurrence for abscesses that result subsequent to vaccination or other injections) particularly benefit from ultrasonography to avoid random exploration.

EQUIPMENT/SUPPLIES

Supplies include a 1-inch" or 1½"-inch sterile 19-gauge or 20-gauge hypodermic needle, 20-cc syringe or syringe of similar size, multiple clean glass microscope slides with or without cover slips, and blood culture or transport media if bacterial or viral culture. An ultrasonography will be useful if available in select cases with fluid-filled lesions.

PROCEDURE

- Introduce the needle with the syringe attached to the center of the mass.
- Apply suction for several seconds. Unless fluid is encountered redirect the needle and repeat the aspiration process for three to four attempts. Several passes may be necessary in solid lesions.
- Blood contamination is a common occurrence and should not discourage the veterinarian from submitting the samples. Withdraw the needle and syringe from the mass and then disconnect the needle from the syringe. Draw several cubic centimeters of air into the syringe. Replace the needle on the syringe and force the air from the syringe through the needle to expel needle contents onto clean glass slides.
- Repeat the last two steps as needed to dispel the entire aspirate. It is wise to smear the slides if the preparations are too thick to be read, although this may deform the cells. If significant fluid is encountered, it is introduced into blood culture vials or transport media for bacteriologic culture and sensitivity testing.

ADDITIONAL CONSIDERATIONS

Slide preparations that appear black in color to the naked eye are likely melanomas. If significant amounts of purulent material are encountered the needle may be left in place to direct abscess drainage; an uncontaminated culture may be obtained from the syringe contents.

BOX 18.3 Obtaining a Skin Biopsy

INDICATIONS

Skin biopsy is one of the most useful procedures available to the equine veterinarian confronted with skin disease. Skin biopsies can establish a specific diagnosis, eliminate erroneous diagnoses, and confirm complete tumor excision. A well-performed skin biopsy that is read by a trained dermatopathologist is diagnostic in more than 90% of cases. Even when not diagnostic, skin biopsy can help direct therapy or establish a group of diseases to consider.

EQUIPMENT/SUPPLIES

Supplies include a range of 6- to 9-mm biopsy instruments, standing sedation, ring block materials, sterile gloves, Brown-Adson or rat-tooth forceps, 4 × 4 gauze sponges, vial(s) of 10% neutral buffered formalin, small tissue forceps, needle holders, and suture material (preferably 2-0 nylon on a cutting needle) or 35 mm staples if the biopsy site is to be closed.

BOX 18.3 Obtaining a Skin Biopsy—cont'd

SPECIAL CONSIDERATIONS

- A full history of the horse should always be included with the sample so that the pathologist can appropriately adjust the investigation for maximum benefit.
- Antiinflammatory agents should be discontinued 2 to 3 weeks prior to skin biopsy.
- It is important to perform biopsies on areas that represent primary disease and not those with secondary bacterial infections. Whenever possible, secondary bacterial infections should be eliminated with systemic antibiotics prior to skin biopsy unless noninfected areas are available for biopsy. Multiple samples of lesions in various stages will provide the maximum amount of information. Do not vigorously prepare lesions, particularly if they have a crusting or scaling component; lesions to be used for culture should be rinsed in sterile saline without an antimicrobial scrub. A 10 or 20 scalpel blade with a handle may be necessary for lesions requiring larger biopsy samples, en bloc resection, bullae, pustules and vesicles, and deep sampling.
- Full-thickness biopsies of the coronary band can leave permanent hoof wall defects; therefore, the author recommends shaving coronary bend lesions as a first attempt to get a diagnosis. If shaving the lesion fails, then biopsy is recommended. Alternatively, some horses with immune-mediated disease also have lesions on their ergots or chestnuts. Biopsy of lesions in these areas are often diagnostic and recommended because they will not result in hoof wall issues associated with coronary band biopsy.

PROCEDURE

- Center the biopsy punch over the lesion to be biopsied.
- Rotate the punch in one direction only to avoid shearing artifacts.
- Once a full-thickness sample has been achieved, gently pull the biopsy punch away from the skin.
- Cut any remaining tissue strands with your scalpel blade being careful to obtain a full-thickness biopsy.
- Gently lift the sample off the punch with a 25-gauge needle. Forceps are not recommended because they may crush or otherwise distort the sample.
- Immediately place the harvested sample into formalin or other appropriate fixative. Samples being harvested for culture should be placed directly into blood culture or transport medium. In addition to routine histology, immunohistochemistry; bacterial, fungal, and viral culture; and electron microscopy can be obtained from biopsy specimens placed in the appropriate medium.
- If normal skin is not present on the harvested sample, a specimen of normal, adjacent skin may be used for histopathologic comparison.
- To obtain a *deep* sample for culture or histology the double-punch method can be used. Briefly, an 8-mm punch biopsy is used to access the deep tissue. Once the 8-mm sample is removed, a 6-mm biopsy punch is inserted in the same hole, and the tissue removed from this deeper biopsy is submitted for culture and/or histology.
- A simple interrupted or cruciate suture may be placed to close the punch biopsy site if indicated.
- If the sample is not amenable to punch biopsy, then a wedge biopsy is performed by making an elliptical incision centered over the lesion. Incisions should be placed in a vertical position along the planes of loose skin to avoid tissue compromise whenever possible. Large areas over such regions as the middorsum will have significant tension when closed and may be best left to heal by second intention.
- Extreme care should be exercised to minimize grasping of the sample with tissue forceps or otherwise crushing or damaging the sample.
- Samples larger than 1 cm should be partially transected at 1-cm increments to facilitate fixation.
- Large samples should be pressed subcutis side down onto a wooden tongue depressor prior to immersion to minimize artifacts of fixation. Immerse the tongue depressor and sample together to maintain orientation and minimize folding.
- Wound closure can be achieved with simple interrupted or cruciate sutures or skin staples.
- Ensure adequate tetanus prophylaxis.
- Fly repellents placed around the wound but not in the wound may be appropriate.
- Staples or sutures should be removed in 10 to 14 days.

TABLE **18.1 Skin Diseases with Systemic Manifestations**

Disease	Cutaneous Signs	Systemic Signs
ENVIRONMENTAL		
Gangrene	Wet: moist swelling, discoloration, malodorous, tissue decomposition Dry: dry, discolored, leathery skin	Depends on underlying cause; fever
Burns	Superficial: erythema, edema, pain, vesicles Deep: necrosis, ulceration, anesthesia, scarring	Shock, respiratory compromise
Selenosis	Painful coronary band, sloughing and necrosis of hoof, rough hair coat, progressive loss of long hairs of mane and tail	Lameness, weight loss
Arsenic poisoning	Severe seborrhea, ulcer, nonhealing wounds, hypertrichosis	Gastroenteritis, emaciation, variable appetite
Mercury poisoning	Progressive alopecia	Gastroenteritis, lameness, emaciation

Continued

TABLE **18.1 Skin Diseases with Systemic Manifestations—cont'd**

Disease	Cutaneous Signs	Systemic Signs
Iodism	Severe dry seborrhea with or without hair loss	Cough, variable appetite, joint pain, seromucoid nasal discharge, lacrimation
Hepatogenous photosensitization	Erythema, edema, pruritus, pain, in white or light-skinned area; vesicles and bullae may progress to oozing, necrosis, and sloughing	Acute: hepatic encephalopathy, icterus, depression, decreased appetite Chronic: weight loss, depression, neurologic signs
Ergotism	Swelling of coronary band; necrosis of feet; sloughing of ears, tail, feet	Lameness of hindlegs, fever, weight loss, poor appetite
Leucinosis	Hoof dystrophies, shedding of hair	Laminitis, lameness
Hairy vetch toxicosis	Cutaneous plaques and papules that ooze yellow pus; pruritus; hair loss	Conjunctivitis, anorexia, pyrexia, weight loss
BACTERIAL DISEASES		
Strangles	Limb edema; edema of lips, eyelids; petechial hemorrhages of mucous membranes and sclera	History of acute contagious upper respiratory infection; pyrexia, mucopurulent nasal discharge; abscesses in the mandibular or retropharyngeal lymph nodes
Corynebacterium pseudotuberculosis abscesses	Single or multiple deep abscesses that develop slowly or rapidly; 50% occurring in the pectoral or ventral abdominal area; ventral midline edema	Pitting edema, depression, fever, lameness, internal abscess, prolonged fever, abortion
Dermatophilosis	Exudative crusted lesions on dorsal trunk, face, pastern, or coronets	Depression, fever, lethargy, poor appetite, weight loss, lymphadenopathy; lesions on legs may cause edema, pain, and lameness
Actinobacillosis	Thick-walled abscess of soft tissue	In newborn foals, disease is a highly fatal septicemic disease, and skin lesions are rare
Clostridial infections	Malignant edema: swelling at site of infection, pitting edema, local erythema; skin may become hot to touch, painful, or slough; crepitus Blackleg: hot, painful, swelling that progresses to a cold painful swelling with edema and subcutaneous emphysema	High fever, anorexia, muscle tremors, acute death possible within 24–48 hours
Glanders (farcy) *Burkholderia mallei* (not in United States)	Subcutaneous nodules begin most often on the medial aspect of the hock; lesions rapidly ulcerate and drain a honey-colored material; lymphadenopathy and cording of lymphatics is common	Respiratory infection that rapidly leads to death
FUNGAL DISEASE		
Histoplasma farciminosa (epizootic lymphangitis)	Unilateral nodules on face, head, neck and occasionally trunk; nodules initially are firm but rupture and exude light-green, blood-tinged exudate; large ulcer may form and lesions may spread bilaterally	Lacrimation, conjunctivitis, and respiratory signs may occur
PARASITES		
Lice	Pruritus, scaling, alopecia	Anemia in severe infestations with sucking lice
Black flies	Painful papules and wheals that may become vesicular, hemorrhagic, and necrotic; lesion may be localized to ears or intermandibular areas	Toxin in bite can cause increased capillary permeability; depression, weakness, staggers, tachypnea, tachycardia, weak pulse, shock, and possible death
IMMUNE-MEDIATED DISEASES		
Atopy	Chronic pruritic urticaria, excoriations, alopecia, lichenification	Respiratory difficulty, especially on expiration
Pemphigus foliaceus	Crusts, scales, oozing, annular eruption, matting of the coat; lesions may be limited to the coronary band	Depression, weight loss, poor appetite, pyrexia
Bullous pemphigoid	Vesicles and bullae in mouth, groin, and axilla; crusts, ulcers	Anorexia, depression, fever
Systemic lupus erythematosus	Lymphedema, panniculitis, alopecia, leukoderma; scaling of face, neck, and trunk	Polyarthritis, thrombocytopenia, proteinuria, fever, depression, weight loss

TABLE **18.1 Skin Diseases with Systemic Manifestations—cont'd**

Disease	Cutaneous Signs	Systemic Signs
Transfusion reactions and graft-versus-host disease (may occur in horse after unmatched blood transfusion)	Exfoliative to ulcerative dermatitis, ulcerative stomatitis	Diarrhea, increased heart and respiratory rates, lacrimation, muscle fasciculation
Erythema multiforme	Symmetric maculopapular lesions, urticaria that results in annular arciform or polycyclic shapes; wheals that do not disappear	Occurs after pregnancy, drugs, neoplasia, connective tissue disease, and infections or may be idiopathic
Vasculitis	Purpura, edema, erythema, necrosis, crusts; purpura hemorrhagica causes edema and hemorrhagic swelling in tissue, mucosa, and viscera	May occur after strangles or influenza; depression, fever, reluctance to move, colic, diarrhea
Equine exfoliative eosinophilic dermatitis and stomatitis	Scaling and crusting that progress to generalized exfoliation, alopecia, ulceration, and exudation; variable pruritus	Severe, progressive weight loss; no diarrhea, ravenous appetite
Equine cutaneous amyloidosis	Papules, nodules, and plaques over the head and neck that develop rapidly	Diffuse nodules in upper respiratory tract may cause severe dyspnea
ENDOCRINE DISEASES		
Hypothyroidism	Dull rough hair coat, delayed shedding of coat, edema of face and limb	Anecdotal reports of laminitis, infertility, anhidrosis, anemia, myopathy; weight gain and decreased food intake; skeletal limb disorders have been reported in foals
Pituitary pars intermedia dysfunction	Long shaggy hair that fails to shed; mane and tail are unaffected	Polydipsia, polyuria, muscle wasting, weight loss, lethargy, swayback appearance, pendulous abdomen, blindness, chronic infections, neurologic disorders or signs
SWEAT GLAND DISORDERS		
Anhidrosis	Acute episode: none Chronic: dry hair coat, excessive scaling, partial alopecia, pruritus	Acute: labored breathing, fever, flared nostrils, lack of sweating, collapse, death Chronic: polydipsia, polyuria, poor appetite, loss of body condition
MISCELLANEOUS DISEASES		
Panniculitis	Firm to fluctuant nodules most commonly found on trunk in subcutaneous tissue that ruptures and drains an oily yellow-brown to bloody discharge	Anorexia, depression, lethargy, pyrexia
NEOPLASTIC DISEASES		
Hemangioma and hemangiosarcoma	Two types: well-circumscribed nodules that are blue-black in appearance; dark hyperkeratotic and verrucous lesions that bleed easily	Anemia
Lymphosarcoma	Single or multiple dermal-to-subcutaneous nodules, especially on trunk	Internal organ involvement; usually fatal

Melanin pigments have a wide range of colors, including black-brown eumelanins, yellow-red pheomelanins, and a range of intermediate pigments. Special tyrosinase-rich organelles called *melanosomes,* which are found in the cytoplasm of melanocytes, produce melanin pigment. Tyrosine is converted to dopa, which is oxidized to dopaquinone. The copper-containing enzyme tyrosinase catalyzes both reactions. Subsequent intermediate products polymerize, eventually forming melanin. Melanocytes secrete or inject melanosomes into adjacent keratinocytes. Production of melanin is controlled by genetics, hormones, local keratinocytes, and Langerhans cells. Ultraviolet light, inflammation, byproducts of the arachidonic acid cycle, androgens, estrogen, glucocorticoids, and thyroid hormone also may influence pigmentation.

The number, size, type, and distribution of melanosomes determine skin and hair color. Melanosomes are responsible for coat color, photoprotection, free radical scavenging, and heat conservation.

Hypopigmentation is a decrease in normal melanin pigmentation. Depigmentation specifically refers to a loss of preexisting melanin. Leukoderma and leukotrichia are clinical terms used to describe the loss of color in skin and hair, respectively. Amelanosis is a total lack of melanin.

Hyperpigmentation is almost always an acquired change. The skin and hair may become hyperpigmented. The usual cause of localized or patchy hyperpigmentation is chronic inflammation or irritation. Macular patches of noninflammatory hyperpigmentation, called *lentigo,* can occur in horses. It occurs most frequently at mucocutaneous junctions. The most important differential diagnosis for lentigo is cutaneous melanoma. A skin biopsy of the affected area is the most useful diagnostic test. Generalized hyperpigmentation of the coat or skin has not been reported; however, if observed, the condition may suggest an underlying hormonal disorder.

Overo Lethal White Syndrome

Overo lethal white syndrome (OLWS) is a leucism-associated disorder caused by a mutation in endothelin receptor B.[8] Despite what the name implies, the syndrome can be produced by mating solid-colored horses, although the incidence of producing an abnormal foal is much lower.[9] Color patterns with highest incidence (>94%) of heterozygotes are frame overo, highly white calico overo, and frame blend overo. White-patterned bloodlines with the lowest incidence of heterozygotes (<21%) are tobiano, sabino, minimally white calico overo, splashed white overo, nonframe blend overo, and breeding-stock solid.[9] Although a small number of white foals produced by these matings have normal gastrointestinal function, most of these foals are affected by myenteric aganglionosis, which results in fatal functional intestinal obstruction. DNA testing is recommended before breeding at-risk horses. Albinism, which can be mistaken for OLWS, is rare in horses and transmitted by an autosomal dominant gene. Affected animals have white skin and hair and hypopigmented irides and are photophobic.

Leukoderma

Leukoderma develops in areas of previous trauma or inflammation and may be temporary or permanent. Affected areas appear normal but depigmented. Leukoderma occurs commonly in horses with onchocerciasis, lupus erythematosus, pressure sores, ventral midline dermatitis, viral skin diseases, freezing, burns, or sun damage. Leukoderma can result from the contact of skin with chemicals that inhibit or interfere with melanogenesis, such as phenol and rubber products containing monobenzyl ether or hydroquinone.

The diagnosis is usually made by clinical signs, but elliptic biopsy of the junction of the pigmented and nonpigmented area confirms the diagnosis. Leukoderma causes no discomfort to the horse, but it may be a source of great agitation to the owner. No treatment is known.

Vitiligo of Arabian Horses

The term *vitiligo* refers to an idiopathic acquired depigmentation. Leukoderma develops in areas with no known history of previous trauma. Vitiligo can occur in any age, gender, or breed of horse but is most common in the Arabian for which it has been termed *Arabian fading syndrome* or *pinky syndrome* (Fig. 18.4). Vitiligo appears to be more common in pregnant or postpartum mares, suggesting a hormonal or stress influence. The condition may be hereditary.

With vitiligo, annular areas of depigmentation develop symmetrically on the muzzle, face, lips, and periocular areas. Depigmentation also can occur at the mucocutaneous junctions of the genital and anal area. Areas of depigmentation

FIG. **18.4** Horse with Arabian fading syndrome. Depigmented areas on the face are notable.

FIG. **18.5** Reticulated leukotrichia in a Quarter Horse.

vary between 1 mm to 2 to 3 cm in size, and spots may become confluent at the mucocutaneous junctions. Depigmentation may wax and wane, and rarely the skin repigments completely within 1 to 2 years.

History, physical examination, and skin biopsy are diagnostic. Skin biopsy shows complete absence of epidermal melanin and lack of an inflammatory infiltrate. There is limited to no success in treatment with topical glucocorticoids or vitamin-mineral supplementation (i.e., copper), and the condition is often considered heritable.

Leukotrichia

Leukotrichia is an acquired loss of pigment in hairs that occurs most commonly in areas of previous trauma or inflammation. Leukotrichia may also occur at the site of previous injections with a variety of compounds including dexamethasone and lidocaine with epinephrine.

Reticulated leukotrichia may be an inherited disorder in Quarter Horses, Thoroughbreds, and Standardbreds but can also occur in other breeds (Fig. 18.5).[10] There is no gender predilection. Affected horses begin to show clinical signs as yearlings. Linear crusts in a netlike to crosshatched design develop over the dorsum from the withers to the tail head region. Crusts are shed, and after the temporary alopecia resolves, new hair growth is white. The underlying skin is normal, and leukotrichia is permanent. This type of leukotrichia generally

FIG. **18.6** Spotted leukotrichia ("bird catcher" spots) on a 12-year-old Morgan gelding.

causes no discomfort to the horse or interference with training or use of the animal.

Spotted leukotrichia is a similar condition observed most commonly in Arabian horses, Quarter Horses, and Warmbloods. Permanent spots of leukotrichia develop over the hindquarters and trunk. They can vary in size and occur either as a single area or multiple large areas of white skin that can increase as the animal ages or can occur as small areas of leukotrichia that gradually increase in numbers as the animal ages. This type of presentation is often known as *bird catcher spots* (Fig. 18.6). On rare occasion, lesions resolve spontaneously. No treatment is known.

Hyperesthetic leukotrichia is a rare and painful form of leukotrichia. Single or multiple crusts that are intensely painful characterize this disorder. Lesions develop on the dorsal midline from the withers to the tail head. Within a few weeks, white hairs develop in the areas of crusting. The intense pain and crusting may last weeks to months. Eventually, lesions subside, but leukotrichia is permanent. The most common histologic features are the presence of large stellate cells, edema in the superficial dermis, perivascular to diffuse lymphocytic inflammation, pigmentary incontinence, apoptotic keratinocytes, and vesicle formation. The condition primarily affects Arabian and American Paint horses, occurs mainly in summer, and may spontaneously recur. No treatment is known, and large doses of glucocorticoids have not been of value.

DISORDERS OF HAIR

Horses have simple hair follicles, which are accompanied by a sebaceous and sweat gland and an arrector pili muscle. Photoperiods and ambient temperature predominantly govern the hair cycle. Nutrition, hormones, genetics, and general well-being also may influence hair growth. Hair replacement in the horse occurs in a random pattern (mosaic) with the exception of the coarse permanent hair of the mane, tail, and fetlock.

Hair Follicle Abnormalities

Main and Tail Dystrophy

Mane and tail dystrophy may be congenital or acquired.[10] Whether the condition is hereditary is unknown. Affected horses (juvenile or adult) have short, brittle, dull hairs on the mane and tail. No treatment is known, but the condition does not affect the health or function of the horse.

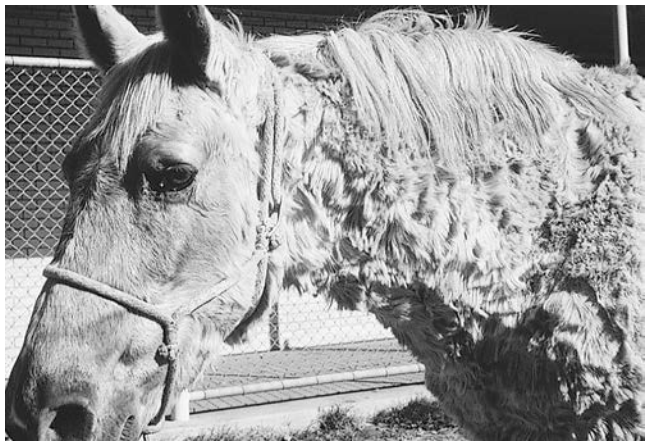

FIG. **18.7** Horse with pituitary pars intermedia dysfunction. The long hair coat did not shed in the spring.

Black or White Follicle Dystrophy

Affected horses (juvenile and adult) have abnormal hairs growing in patches of white-haired or black-haired areas. These hairs are short, brittle, and dull. Affected areas may be hypotrichotic. No treatment is available.

Curly Coat

Curly coat is a hereditary condition of Percherons, Missouri Fox Trotters, and Bashkir Horse breeds that is inherited as an autosomal recessive trait. Clinically affected horses have unusually curly coats.

Trichorexis Nodosa

Trichorrhexis nodosa is an acquired hair shaft disorder of horses caused by physical or chemical trauma. Overzealous grooming, shampoos, pesticides, alcohol, or solvents are the most common causes. The lesions are visible without magnification and appear as small white to gray nodules on the hair shaft. The hair shaft fractures and breaks easily at these sites. Microscopically, affected hairs have the appearance of two brooms shoved together. Therapy consists of identifying and eliminating the trauma.

Alopecia Areata

Alopecia areata is a rare idiopathic skin disease of horses characterized by focal areas of alopecia.[11] Lesions may be single or multiple, and the underlying skin is otherwise normal. If and when hair regrows, it may be a different color. The diagnosis is made by biopsy. Classically, in early lesions, skin biopsy shows an accumulation of lymphoid cells around the proximal end of the anagen hair follicles. This change is diagnostic but may require numerous biopsies before being observed. The prognosis is uncertain, but most horses recover within a year.

Hirsutism

Hirsutism, an excessive growth of hair with failure to shed appropriately, most commonly occurs secondary to equine pituitary pars intermedia dysfunction (PPID) as discussed in detail in Chapter 16. Abnormal pituitary function results in abnormal secretion of numerous hormones. Clinical signs are most common in older horses (12–15 years old or older), but the condition is reported occasionally in horses 7 to 10 years of age. The first clinical sign noted by an owner may be a failure to shed the coat (Fig. 18.7); however, only 10% of horses

with PPID actually demonstrate hirsutism. The coat becomes shaggy, and body hairs can reach lengths of 10 to 12 cm. Mane, tail, and fetlock hairs are unaffected. Secondary seborrhea may develop. Horses may also demonstrate abnormalities in their ability to sweat. Affected horses may be predisposed to dermatophytosis, dermatophilosis, or secondary bacterial pyoderma. Nondermatologic signs include polydipsia, polyuria, muscle wasting, lethargy, weight loss, pendulous abdomen, laminitis, and flaccid muscles. Neurologic disorders and blindness may develop.

The diagnosis is based on clinical signs and laboratory test results. Complete blood counts can reveal neutrophilia, lymphopenia, and eosinopenia. Urinalysis may reveal a low specific gravity and occasionally glucosuria. A serum chemistry panel may reveal any combination of hyperglycemia, hypercholesterolemia, and lipemia. The definitive diagnosis and treatment of PPID in horses are discussed elsewhere in Chapter 16.

Anagen Defluxion and Telogen Defluxion

Anagen defluxion refers to a condition in which a disease or drug interferes with anagen hair growth resulting in abnormal hairs or hair shaft abnormalities or both.[12] Hair loss occurs within days of the insult or drug. The condition occurs most commonly in horses with high fevers, systemic illnesses, or malnutrition (Fig. 18.8). Typically the mane and tail are not affected.

Telogen defluxion refers to a condition in which a stressful situation causes the sudden cessation of anagen hair growth and the sudden synchrony of many hair follicles in the telogen hair cycle stage.[13] Two to 3 months later a sudden shedding and a wave of new hair growth occur.

These conditions cannot be distinguished clinically. The diagnosis is based on examining the hair shaft of easily epilated hairs. Anagen defluxion is characterized by dysplastic hairs; the hair shaft may be weak or narrow, and the root end contains a root sheath. Telogen defluxion is characterized by uniform hairs with no shaft abnormalities and a nonpigmented root end lacking a root sheath. Both conditions resolve spontaneously when the animal recovers from the predisposing condition.

FIG. **18.8** Foal with telogen defluxion after illness.

Other Abnormalities of Shedding

Abnormal shedding in horses may result in large areas of alopecia that develop on the face, shoulders or over the entire body during an inappropriate time of the year (Fig. 18.9). The pathogenesis is unknown. Skin biopsy is recommended to eliminate infectious or parasitic causes of hair loss. Skin biopsy is typically normal and shows normal hair follicles in various stages of development. Horses may spontaneously recover but abnormally shed the following year. Treatment with melatonin (40 mg per horse per day PO) and thyroid hormone may be beneficial. Thyroid hormone has a hair growth stimulating effect even in the presence of normal thyroid function.

DISORDERS OF KERATINIZATION

Seborrhea

Seborrhea is a descriptive term for excessive scaling and crusting with or without greasiness, and the diagnosis is based on these characteristics. Primary seborrhea is a rare disorder of keratinization with a possible genetic predisposition in which epidermal cell turnover time and basal cell proliferation increase. Secondary seborrhea may be precipitated by any of a variety of underlying conditions such as dermatophytosis, dermatophilosis, or any inflammatory, infectious, or parasitic diseases.

Idiopathic or primary seborrhea in horses may be generalized or localized to the tail and mane. No age, gender, or breed predilection exists. Generalized seborrhea appears clinically as diffuse matting of the coat (Fig. 18.10). The texture of the coat may be oily and thick; adherent crusts are easily removed. Oily or dry scales are present at the base of the hairs. The animal may be odoriferous if affected with the oily form of the disease.

FIG. **18.9** Alopecia in a 14-year-old pony. The pony was trace-clipped and did not regrow hair for more than a year. There is also alopecia present on the point of her shoulder due to blanket rubbing.

Primary seborrhea of the mane and tail is more common and characterized by crusts or scales attached to the bases of hairs. Pain and inflammation are generally absent.

Primary seborrhea is a diagnosis of exclusion. Severe generalized seborrhea must be differentiated from pemphigus foliaceus (PF). Skin scrapings, fungal cultures, dermatophilosis preparations, and skin biopsies are indicated for all horses with suspected seborrhea. Skin biopsies may help in determining whether primary or secondary seborrhea is present. In early cases of primary generalized equine seborrhea involving little to no confounding inflammation from an opportunistic skin invader, skin biopsy findings strongly suggest a primary keratinization disorder. A significant orthokeratotic hyperkeratosis is attached to an epidermis of normal thickness. The superficial dermis shows only a noncornified epidermis, suggesting a keratinization defect. In horses with primary seborrhea that develop a secondary source of inflammation or in which the seborrheic condition is more long-standing, biopsy findings are more difficult to interpret. The cornified epidermis is acanthotic with significant orthokeratosis or parakeratotic hyperkeratosis. Superficial perivascular inflammation is often present in the superficial dermis. Fortunately, generalized primary seborrhea is rare. It tends to be symmetric, spare the appendages, and be nonpruritic unless an opportunistic bacterial or yeast infection is present. Both dry and oily forms of primary seborrhea have been described.[1,2]

Primary seborrhea is usually incurable, but satisfactory management can often be achieved with antiseborrheic shampoos. The owner should be instructed to wash the horse with a cleansing shampoo first to remove excess dirt and scale both to improve efficacy of the medicated shampoo and to decrease the amount of medicated shampoo required, thus minimizing potential for a contact reaction. Several types of shampoos may need to be explored before the most suitable shampoo is identified for an individual patient. Often, dry seborrhea responds best to sulfur-based shampoos, whereas oily seborrhea is frequently best treated with a degreasing agent such as tar-based, benzoyl peroxide, or selenium sulfide shampoos. In horses with mildly dry and flaky skin moisturizing shampoos and rinses may be adequate. Wherever possible veterinary formulations of these shampoos are recommended. Most products recommend a contact time of 10 to 15 minutes before rinsing. Thoroughly rinsing the horse is always important with any shampoo, especially in the axillary and inguinal regions, because shampoo residues commonly irritate the skin. The horse may benefit from daily shampooing for the first 1 to 2 weeks. Once the coat is normal, the owner may decrease shampooing to twice a week for the life of the horse. If shampooing dries the coat and exacerbates the seborrhea, a moisturizing spray or lotion should be used.[1,2]

FIG. **18.10** Horse with primary seborrhea.

Secondary seborrhea is much more common than primary seborrhea, and treatment requires elimination of the predisposing cause. The secondary seborrhea will then generally resolve within 1 to 2 months.

Cannon Keratosis

Cannon keratosis ("stud crud") is an idiopathic disorder characterized by the presence of plaques and patches of hyperkeratosis on the dorsal skin of the cannon bones. The rear limbs are involved much more often than the front limbs. There is no recognized age, breed, or gender predilection. Clinically, well-circumscribed plaques of tightly adherent crusts and scales with or without alopecia develop. The lesions are not pruritic.

The diagnosis is usually made by clinical examination, and skin biopsy is usually not required. Dermatophilosis and dermatophytosis should be ruled out. Treatment consists of antiseborrheic shampoos. Topical glucocorticoids may be useful. Topical vitamin A cream (tretinoin [Retin-A cream 0.1%; Ortho Pharmaceutical Corporation, Raritan, NJ]) may be beneficial but should be used judiciously.

Linear Keratosis

Linear keratosis is a fairly uncommon idiopathic disorder of keratinization. The disorder affects all ages and types of horses but Quarter Horses and Thoroughbreds may be overrepresented. Lesions develop between 1 and 5 years of age. One or more painless, nonpruritic unilateral, vertically oriented bands of alopecia and hyperkeratosis develop on the neck, forelimb, or lateral thorax. Lesions vary in size, ranging between 0.25 and 3.5 cm in width and 5 and 70 cm in length.

Diagnosis usually is based on clinical signs alone. Skin biopsy is sometimes recommended to rule out equine sarcoid, which can also occur in multiple sites in the same horse. Biopsy reveals regular, irregular, or papillated epidermal hyperplasia with significant compact orthokeratotic hyperkeratosis. Lymphocytic mural folliculitis may or may not be present.[14] Linear keratosis does not usually interfere with the function of the horse, and no treatment is necessary; surgical excision of lesions is generally not recommended because the disease will continue to progress. Topical vitamin A cream or salicylic cream may be useful keratolytics to decrease the height, width, or thickness of the keratosis, but they should be used judiciously.

DISORDERS OF COLLAGEN FORMATION

Hereditary Equine Dermal Asthenia

Hereditary equine dermal asthenia (HERDA; hyperelastosis cutis, dermatosparaxia, Ehlers-Danlos syndrome) is a specific form of Ehlers-Danlos syndrome that occurs in Quarter Horses and horses of Quarter Horse lineage including American Paint Horses and Appaloosas. HERDA is caused by a missense mutation of the peptidyl-prolyl cis-trans isomerase B gene,[15] which encodes cyclophilin B and is important in the

formation of collagen's triple helical molecule. The mutation has an autosomal recessive mode of inheritance.[16,17] Similar conditions have occurred sporadically in other breeds such as Thoroughbreds, Hanoverians, and Haflingers, but they do not share the same mutation as the Quarter Horse. Not all Quarter Horses with Ehlers-Danlos share the HERDA mutation. HERDA has become a significant concern in the Quarter Horse industry because of the high frequency of heterozygote carriers. Although HERDA occurs most frequently in cutting horse bloodlines with a carrier frequency of 28.3%,[17] horses competing in other disciplines, including reining and western pleasure, have also produced a significant number of affected individuals (9.3–12.8% carrier frequency).[17] Analysis of pedigree information from the cutting horse industry indicates that 30% of the 10 leading lifetime sires (leading lifetime cutting horse sires, all ages, all divisions) are confirmed carriers. The performance traits of these select carriers' bloodlines are highly desired, likely increasing the prevalence of HERDA.[18]

Affected homozygous horses appear normal at birth; within the first 2 years of life, however, they usually acquire loose, hyperextensible skin and wounds that result in disfiguring scars either spontaneously or from minor trauma (Fig. 18.11). Some severely affected horses also develop hematomas and seromas (Fig. 18.12). The negative effect of sunlight on the abnormal collagen has been reported as the mechanism by which most of the lesions in HERDA horses are dorsal in distribution. In addition to skin lesions, select horses affected with HERDA can be hypermobile. Most affected horses studied also suffer from abnormalities of the cornea, heart valves, tendons, ligaments, bones, and great vessels. Consequently, most affected horses are euthanized at an early age. No treatment options other than palliative therapy, which includes sunlight restriction, currently exist. The American Quarter Horse Association currently requires DNA testing for HERDA on all breeding stallions. There are currently no restrictions on the registration of horses that are heterozygous or homozygous for the HERDA mutation. Because of the autosomal recessive nature of the disease, Quarter Horse mares and horses of all breeds from HERDA-associated bloodlines should also be tested.

FIG. **18.11** Horse with severe hyperelastosis cutis.

FIG. **18.12** Horse with mild hyperelastosis cutis.

The diagnosis is based on clinical signs, physical examination, and DNA testing. When a skin biopsy is suggestive of the disease the horse should be DNA tested to confirm the diagnosis. Early lesions of HERDA show mild thinning of collagen bundles (hyperextensible areas) in the middermis.[19] As lesions progress, increased space between collagen bundles, loss of bundle compactness, and collagen bundle fraying are observed. In more advanced lesions (depending on the stage of resolution), dense inflammation or collagenous connective tissue appears to expand easily, filling a defect in the intermediate layer of the dermis. In lesions of chronically detached skin, collagen bundles become frayed with wear between the superficial and deep layers.[19] Significantly, in the absence of infection or perforation of the skin, HERDA lesions have a paucity of inflammatory infiltrate and show little evidence of physiologic repair. Biopsies taken from areas in which the skin is ulcerated often show extensive inflammation and fibrovascular proliferation, which can obscure the diagnosis. Zonal dermal separation is a distinctive histopathologic lesion associated with HERDA but will not be present in all biopsy specimens.[20] Treatment is palliative and includes sunlight restriction, dietary modification, and protection from trauma. Although most affected horses are euthanized because their fragile skin impairs their usefulness, there are a number of documented HERDA-affected horses that are able to compete successfully despite being homozygous for the condition. The prevalence and economic value of Quarter Horses that carry the genetic defect responsible for HERDA ensure that this disease will be observed for many more generations. The effect of the cyclophilin B genetic mutation on the heterozygote remains to be determined. Managed breeding strategies based on DNA testing of horses or embryos is the only method currently available to minimize the production of affected horses.

Other Collagen Disorders

Other disorders of collagen in horses include Warmblood fragile foal syndrome (WFFS) type 1[21] and junctional epidermolysis bullosa. WFFS is inherited as an autosomal recessive disorder that is caused by a point mutation in the equine procollagen-lysine, 2-oxoglutarate 5-dioxygenase 1 (lysyl hydroxylase 1) gene. Affected foals are born with thin, friable skin that is characterized by tearing and ulceration from minor trauma. Small skin lesions can occur anywhere on the body but are most noted on pressure points. Lesions may also be found on the mucous membranes. Joint laxity may be so severe that it prevents foals from standing normally. In one case report the foal was born with an open abdomen. Affected foals are humanely euthanized. Histologic examination demonstrates abnormally thin dermis and markedly reduced amounts of dermal collagen

In junctional epidermolysis bullosa type 1 (JEB-1), which affects French and Belgian Draft horses,[22-25] affected foals develop blisters, erosions, and ulceration of the skin and mucous membranes shortly after birth. These lesions quickly grow larger, creating patchy skin loss over the foal's entire body. Dental abnormalities are commonly present and include early eruption of teeth and enamel pitting. Affected foals have been known to slough their hooves. Junctional epidermolysis bullosa results in secondary sepsis, which is universally fatal. The disease is caused by an insertion in LAMC2 and has autosomal recessive mode of inheritance.

Junctional epidermolysis bullosa type 2 (JEB-2) is similar to JEB-1 and affects American Saddlebreds. It is caused by a partial deletion in the *LAMA3* gene.[24] Other skin fragility syndromes in foals include vasculitis and sepsis, which are often treatable.[26]

INFECTIOUS DISEASES OF SKIN

Bacterial Diseases

Dermatophilosis

Dermatophilosis (rain scald or rain rot) is one of the most common bacterial infections of equine skin worldwide. Infections are an acute or chronic superficial pyoderma caused by the gram-positive, facultative anaerobic actinomycete *Dermatophilus congolensis.*[27] Clinical signs of dermatophilosis include regional or generalized tufted papules and crusts that can resemble small paintbrushes. Exudate may be present under the crusts in early lesions. Lesions commonly occur on the dorsum, face, neck, and distal extremities (Fig. 18.13). Severely affected horses and those with secondary bacterial infections may be febrile, depressed, lethargic, anorectic, and have a regional lymphadenopathy.

Carrier animals are the primary source of infection. Factors that affect the ability of the host's immune system to respond to infection, such as concurrent disease and/or stress, may enable the organism to proliferate and produce clinical disease. Lesions develop when the skin is exposed to chronic moisture and sustains damage.[1,2] Moisture is required for release of the infective, motile, flagellated zoospores. The zoospores are attracted to low concentrations of carbon dioxide and migrate into the skin in which they can remain viable in crusts at ambient temperatures of 28°C to 31°C for up to 42 months.[28]

Dermatophilosis is diagnosed by demonstration of the organism in direct smears of the exudate, histopathology, or a preparation made from dried or fresh crusts. Dried crusts are finely minced in a few drops of sterile saline, the preparation is allowed to dry for 45 minutes, and the preparation is stained. A fast Giemsa, Diff-Quik, or Gram stain can be used for direct smears or dried mince preparations. The organism is visualized best under 1000× oil immersion and appears as fine-branching multiseptate hyphae with transverse and longitudinally arranged cocci (railroad track appearance; Fig. 18.14). When a skin biopsy is collected from a horse with suspected dermatophilosis, submitting a specimen with the crust attached to the skin or hairs is important. Key histologic findings include folliculitis, intraepidermal pustules, intradermal edema, and alternating layers of parakeratotic (epidermal cells with retained nuclei) and orthokeratotic (keratinized epidermal cells without nuclei) hyperkeratosis with leukocyte debris.[2] The organism is often found only in crusts, and, if needed, the crust can be submitted instead of a full biopsy specimen

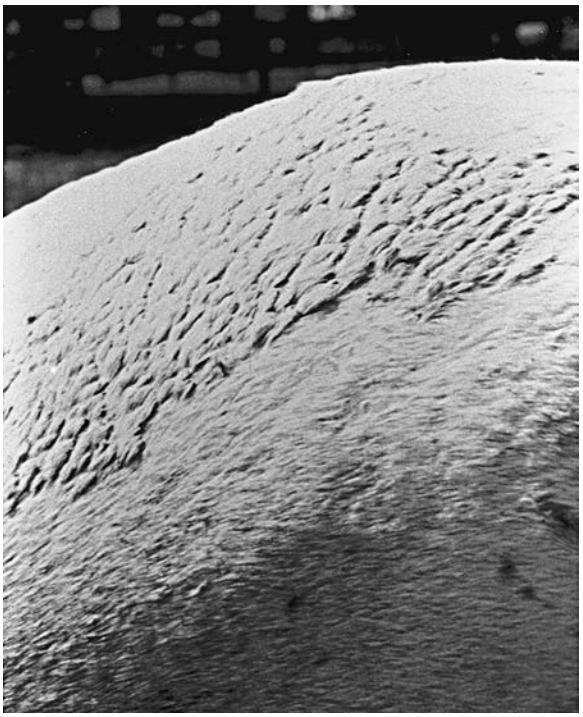

FIG. **18.13** Horse with matting of coat caused by dermatophilosis.

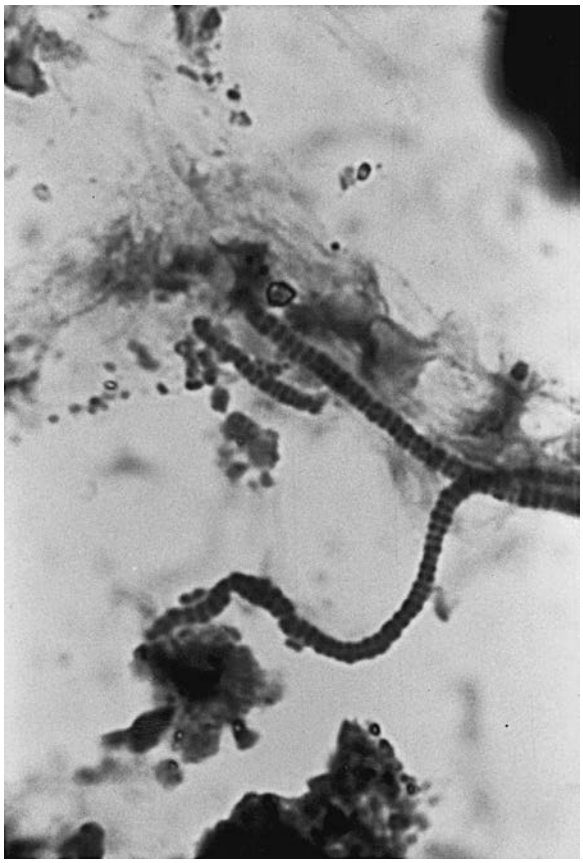

FIG. **18.14** Microscopic appearance of *Dermatophilus congolensis.*

if the history, signalment, and physical examination support a diagnosis of dermatophilosis.

Horses with mild infections can be treated by restricting their contact with moisture and providing topical antimicrobial therapy. The crusts are gently soaked and removed while bathing with a mild antibacterial shampoo such as chlorhexidine. For some horses this is quite painful and may require sedation. The horse should be dried with towels and a topical antibacterial product applied. Severely affected animals require systemic antibiotics such as procaine penicillin at 22,000 IU/kg IM twice daily for 5 to 7 days. Trimethoprim sulfa (TMS) at 10 to 15 mg/kg orally twice daily for 5 to 7 days also may be effective. In vitro sensitivity profiles suggest that doxycycline is a reasonable option for treatment of refractory cases of dermatophilosis. Regardless of all other treatment, exposure to excessive moisture must be controlled. In farm outbreaks of dermatophilosis, inadequate nutrition is a common finding, and the correction of dietary inadequacies is often enough to resolve ongoing issues.

Staphylococcal Pyoderma

Coagulase-positive *Staphylococcus* spp. are another common cause of superficial pyoderma in horses. *Streptococcus* spp. and *Corynebacterium pseudotuberculosis* can cause superficial pyodermas albeit less frequently. *Corynebacterium* infections are more commonly associated with deep pyodermas. Infections most frequently occur in the summer when heat, moisture, increased insect populations, and increased use of the horse act in concert as predisposing factors.

The pathogenesis of bacterial folliculitis in the horse is similar to that in other animals. The causative agents are normally found on the host; when the natural protective barrier of the skin is compromised, bacteria invade and multiply within hair follicles. Infection results in inflammation, destruction of the hair follicle, and shedding of the hair. In addition to the resulting alopecia, staphylococcal pyodermas often present with crusts, which can make the infection difficult to distinguish from dermatophytosis and result in staphylococcal pyodermas being underdiagnosed. Bacterial lesions tend to be more likely painful and pruritic. Infection can occur in the saddle and tack area but may be limited to the pastern on which it is a common component of the pastern dermatitis complex. Some horses with superficial (and deep) pyodermas may be in sufficient pain to present for evaluation of musculoskeletal lameness.

The definitive diagnosis of staphylococcal pyoderma is made by bacterial culture, but cytologic examination and skin biopsy will also lead to the diagnosis, sometimes more efficiently. Skin biopsy reveals varying degrees of folliculitis, intraepidermal pustules, and perivascular inflammation. Neutrophils are the primary inflammatory cell. Keratinocytes often show intracellular edema; parakeratosis and orthokeratosis are common in the crust. The bacteria can sometimes be seen within the crusts and hair follicles.

Treatment depends on severity of the clinical signs. Mild infections may be self-limiting, but moderate infections will benefit from topical therapy. Severe cases require both topical treatment and systemic antibiotics. Ideally, systemic antibiotic therapy should be based on the results of culture and sensitivity testing. Because methicillin-resistant *Staphylococcus aureus* has been cultured from horses the veterinarian should exercise caution when evaluating these horses and obtaining samples for culture. Empirically, TMS is often used as a first-line antibiotic, in part because of its spectrum of activity but also because of its ease of administration, with 15 to 30 mg/kg administered orally every 12 hours. If resistance is encountered, 2.2 mg/kg ceftiofur sodium (IM q 12 h) is often a good choice.

Corynebacterial Infections

C. pseudotuberculosis is a gram-positive, facultative, intracellular, pleomorphic bacterium with a worldwide distribution associated with many clinical forms in horses: the most common are external abscesses in the pectoral region (pigeon fever) or ventral abdominal area, internal abscess formation, and an ulcerative infection of the limbs (ulcerative lymphangitis).

Infections with *C. pseudotuberculosis* are on the rise, with infected horses being identified throughout the United States and parts of Canada. Originally reported as seasonal infections of the Western United States that occurred most often during dry, dusty conditions in the summer and fall concurrent with peak fly season, this disorder is now reported all months of the year and from horses of all ages. The organism is believed to be transmitted by flies, particularly horn flies *(Haematobia irritans),* stable flies *(Stomoxys calcitrans),* and houseflies *(Musca domestica).* The bacteria is soil borne and able to survive and persist in a wide range of environmental conditions.

Lesions develop slowly and may be single or multiple. These abscesses drain a creamy to caseous material that may be whitish to greenish. Pitting edema, ventral midline dermatitis, depression, fever, and lameness are common. The course of the disease may be chronic, and recurrent internal abscesses are frequent. Pectoral abscesses in particular are frequently quite deep (5–8 inches), and drainage can be a challenge.

In horses with ulcerative lymphangitis, lesions usually develop on the hindlimbs, especially at the fetlocks. Hard to fluctuant chains of nodules that abscess, ulcerate, and drain are most common. Old lesions heal within 1 to 2 weeks, but new lesions arise. The affected limb may be swollen and painful, and the horse may be depressed. Regional lymphatics appear corded. In chronic cases, permanent thickening of the tissue surrounding the regional lymphatics is common and can result in gait stiffness and lameness.

The diagnosis of ulcerative lymphangitis and deep abscesses is based on the appearance of the abscess and exudate. Because identifying the organism on cytologic examination of the exudate may be difficult, a culture is strongly recommended. The disease presentation seems to have a geographic component, with internal abscesses more commonly reported from California and ulcerative lymphangitis almost exclusively reported in Texas in the United States, leading to the proposal that there may be a difference in vectors in the two sites, which accounts for the difference in presentations.[29]

Treatment is protracted and is complicated by the limited response of the organism to systemic antibiotics. The veterinarian should allow the abscess to mature and then surgically incise and drain it. Administration of systemic antibiotics before abscess rupture may prolong the course of the disease with recurrence of the abscess on discontinuation of the drug. Large dosages of procaine penicillin (20,000 IU/kg IM every 12 hours) for up to 6 months have been recommended for treatment, but penicillin's lack of lipid solubility and low volume of distribution may make it a poor choice for treatment of the well-encapsulated abscesses typical of *C. pseudotuberculosis.* Based on the minimum inhibitory concentration values for a large number of isolates, doxycycline, fluoroquinolones, and potentiated sulfonamides may be better choices for first-line treatment; the final antibiotic choice should be made on the basis of culture and sensitivity.

The practitioner must initiate treatment rapidly to prevent permanent debilitation and disfigurement. In early cases treated with hydrotherapy, exercise, and surgical drainage, antibiotics should be administered for at least 30 days after clinical normalcy. Nonsteroidal antiinflammatory drugs (NSAIDs) may be beneficial. If the lesions of ulcerative lymphangitis become chronic and fibrotic, joint motion is restricted, and the prognosis is poor. Any large abscess within a body cavity or other significant structure would potentially have a poor prognosis. A vaccine against *C. pseudotuberculosis* was briefly available in 2016 but was quickly removed from the market because of adverse effects. A second generation of the vaccine may be released in the near future.

Botryomycosis

Botryomycosis, also known as *bacterial granuloma* or *staphylococcal pseudomycetoma,* is a rare problem and is most commonly seen secondary to a wound, including surgical wounds such as castration.[1] It can occur anywhere on the body, including the udder. The most commonly isolated organism found in botryomycosis is *S. aureus,* but other bacteria such as *Pseudomonas aeruginosa, Proteus* spp., *Escherichia coli,* or other nonfilamentous aerobic or anaerobic bacteria can cause the granulomatous suppuration.

Bacterial granulomas are believed to begin as traumatic injuries to the skin during which an infectious organism is inoculated into the dermis. A granulomatous reaction develops when the horse is able to contain the infection but not eradicate it. Poorly circumscribed, firm lesions that may or may not be painful are typical (Fig. 18.15). The center of the lesion may be ulcerated or drain. In some cases, variable numbers of white-to-yellow pieces of particulate matter resembling grains of sand (tissue grains) may be present in the exudate.

FIG. **18.15** Perianal bacterial granuloma. Surgical resection was curative.

Confirmation of the diagnosis is made by skin biopsy, and identification of the causative organism is confirmed by bacterial or fungal culture (if a fungus is cultured the lesion is termed a *mycetoma*). Histologic examination of the lesions typically reveals nodular to pyogranulomatous inflammation with or without tissue grains. The causative bacteria may be observed encapsulated in granules that are thought to protect it from the effects of antibiotics and phagocytosis, which leads to the chronicity of the infection. This reaction is known as the Splendore-Hoeppli phenomenon and is characterized by in vivo formation of intensely eosinophilic material around microorganisms or biologically inert material.[30]

Surgical excision or radical debulking followed by long-term antibiotic therapy based on culture and sensitivity has been the most successful treatment for botryomycosis. Organisms may be difficult to isolate from biopsy tissue samples, and the submission of large wedges of tissue obtained at the time of surgery is recommended. If possible, tissue should be obtained to submit for aerobic, anaerobic, and fungal culture from the deepest portion of the lesion using the previously described double-punch technique to increase the likelihood of isolating an infectious agent.

Viral Diseases

Viral Papillomatosis

Equine viral papillomatosis (warts) is caused by *Equus caballus* papillomavirus, a host-specific double-stranded DNA virus that belongs to the Papovavirus family. Two distinct lesions are associated with this virus: warts and aural plaques. Both lesions are characterized as benign, proliferative, epithelial, cutaneous neoplasms that are common in horses worldwide. No gender or breed predilection has been identified for either form of the disease. However, warts tend to affect young horses from 6 months to 4 years, and aural plaque is most common in horses more than 1 year of age.

Lesions originate in the basal cell layer of the epithelium following local infection by the virus. Trauma to the skin is probably required for natural infection to occur. There may be predisposing trauma caused by grazing fibrous pastures, plant thorns, insect bites, wire fence trauma, actinic dermatitis, grooming brushes, or surgical instruments. Subsequent contact of the damaged skin with contaminated combs, brushes, surgical instruments, or feeding insects can lead to infection. Black flies (*Simulium* spp.) have been strongly implicated in the transmission of aural plaques. These flies can be found feeding on the inner surface of horses' ears, producing droplets of dried blood. The papillomavirus can be transmitted through direct contact with an infected horse or indirectly through contact with contaminated fomites. Sexual contact between horses has been shown to spread the disease. The incubation period following natural infection is approximately 60 days. Warts reach maturity after a growth period of 4 to 8 weeks and tend to spontaneously regress in 3 to 4 months with the development of immunity. In contrast, aural plaques do not generally spontaneously regress.

Warts appear as multiple gray-to-pink or cream-colored cauliflower-like growths varying from 5 to 20 mm in size (Fig. 18.16). Lesions most commonly affect the muzzle, nose, and commissure of the mouth. Other sites that may be affected include other areas of the head (periocular regions),

FIG. **18.16** Warts on the muzzle of a yearling.

FIG. **18.17** Ulcerations on the tongue of a horse due to infection with vesicular stomatitis virus.

neck, distal limbs, and the external genitalia of both sexes. Warts often become necrotic before regression occurs. Most lesions are self-resolving and regress in 3 to 4 months, but some lesions may persist for up to 18 months. An inappropriate immune response should be investigated if a young horse exhibits lesions for 2 years or longer, if the horse has a generalized case of warts, or if the warts spread to atypical regions of the body. Lesions on older horses commonly persist and may remain in a static state for years.

Diagnosis of viral papillomatosis is based on the clinical appearance of the lesions. Most of the growths are unmistakable, but those on the lower limbs, anus, penis, or vulva may resemble verrucous-type sarcoids. A biopsy specimen may be obtained and submitted for histologic confirmation of the diagnosis. Histologic characteristics of papillomatosis include orthokeratotic hyperkeratosis, papillated epidermal hyperplasia with ballooning degeneration of keratinocytes, and basophilic inclusion bodies of different sizes. Aural plaques generally appear amelanotic and have a broad-based attachment.

Aural plaques are most commonly caused by a mixed infection with equine papillomavirus types (EcPV) 1 through 7.[31] The disease manifests as single or multiple, smooth or raised, gray or white lesions involving the inner surface of the pinna. Lesions tend to initially appear as small papules and enlarge progressively, eventually coalescing to become prominent hyperkeratotic plaques. Aural plaque-type lesions are less commonly found near the anus, penis, and vulva. The location of these plaques supports the belief that transmission is accomplished through insect bites and during breeding. Lesions are generally asymptomatic unless there is irritation by biting flies.

Treatment of papillomatosis lesions is not always pursued because neither warts nor aural plaques typically cause significant clinical problems. Surgical removal should be considered if lesions interfere with function. Anecdotal reports that suggest surgical removal or crushing the lesions induces remission of the lesion are unproven, and controlled studies suggest that such intervention might actually increase lesion duration. Treatment is indicated when the occasional horse with aural plaques appears to be in pain, exhibits headshaking, or develops other behavioral issues such as becoming difficult to bridle. It also may be indicated for horses with lesions that present a problem for show or sales preparation or that become irritated by trauma, insects, or secondary bacterial infections. Surgical excision, cryonecrosis, and radiofrequency hyperthermia have been advocated for the management of warts, but if large numbers of warts are present, substantial secondary trauma to normal skin can occur and result in a poor cosmetic outcome. Viral antigens released during late-phase tissue necrosis during cryosurgery treatment may enhance the body's immune response and improve the success rate of partial wart removal; spread of infection, however, is possible during this time, and the occurrence of white hairs in the region may negatively affect cosmesis. Intralesional or intravenous (IV) immunomodulatory substances and various topical caustic agents have also been used in the treatment of papillomatosis lesions. Imiquimod has demonstrated success in the treatment of aural plaques, but care must be taken to avoid overuse and excessive irritation or horses will become head shy, with some becoming difficult to bridle. Topical treatment of equine aural plaques with nitric acid, potassium nitrate, and zinc nitrate solution (Oxalic; N-vet, Uppsala, Sweden) resulted in long-term control of the lesions within 4 weeks without producing painful side effects; the lesions resolved in 91% of the horses after two treatments, with 9% of horses requiring three treatments.[32] Control of the biting insect populations will improve prognosis with any form of treatment and prevent the spread of disease. Fly masks with ear protection or application of petroleum products to the inner pinna are easy, economical means of control.

Vesicular Stomatitis

Vesicular stomatitis is a reportable viral disease that affects horses, cattle, swine sheep, goats, llamas, alpacas, and occasionally humans, in which it causes an acute influenza-like illness. The southwestern and western United States have experienced a number of vesicular stomatitis outbreaks in recent years affecting multiple states and a large number of farms. Excessive salivation is often the first sign observed. The incubation period is short (24–72 hours). Infected horses rapidly develop vesicles up to 2 cm in diameter in the mouth and on the lips. These lesions rupture, leaving large painful erosions and ulcers (Fig. 18.17). Fever and anorexia are common, and horses may refuse to drink. Rarely, lesions develop on the hooves, prepuce, and teats. Examination of the mouth initially reveals blister-like lesions along the gums, tongue, and lips with crusting scabs on the muzzle, lips, or ventral abdomen.

The disease has a seasonal occurrence in summer and fall and is believed to be transmitted to horses by insect bites. Within a group of horses, however, the disease will be transmitted via direct contact. Affected animals typically recover in approximately 2 weeks. There is no specific treatment.

Vesicular stomatitis is recognized internationally as a reportable disease with serious economic and regulatory repercussions. It is significant because of its similarity to foot-and-mouth disease and swine vesicular disease, both of which have been eradicated from the United States. Veterinarians who suspect an animal may have vesicular stomatitis or any other vesicular disease should immediately contact state or federal animal health authorities. Diagnosis is based on antibodies to fluid samples from the animal or by isolation of the virus from swabs of lesions, blister fluid, and tissue flaps. Confirmation of the diagnosis is obtained by serologic examination. Histologic findings are nonspecific and include a hyperplastic epidermis, intercellular and intracellular edema of the epidermis, reticular degeneration, spongiotic microvesicles, and focal necrosis. Superficial and deep perivascular dermatitis is present.

Owners should feed affected horses a soft gruel until oral lesions heal, usually within a few days. Permanent depigmentation may occur in areas of former ulceration. Infection results in immunity for up to 6 months.

Equine Coital Exanthema

Coital exanthema is a contagious venereal disease of horses caused by infection with equine herpesvirus type 3 (EHV-3), which is an alphaherpesvirus that is distinct from the other EHVs and endemic in most horse-breeding populations. The disease is transmitted via coitus, insects, fomites, and inhalation. Coital exanthema is characterized by the formation of painful papules, vesicles, pustules, and ulcers on the external genitalia of mares or stallions. Vesicles and bullae may be present in the mouth or nostril or on the lips. Lesions can be pruritic. Depigmentation often occurs in areas where lesions have developed and healed. Stress may precipitate recurrences.

Diagnosis is based on the appearance of lesions on the vulva, perineum, penis, or prepuce; skin biopsy; and virus isolation. Histologic findings include hyperplastic superficial and deep perivascular dermatitis with ballooning degeneration and eosinophilic intranuclear inclusion bodies.

Treatment is symptomatic, but corticosteroids are contraindicated. The negative impact of coital exanthema on equine breeding enterprises includes the forced, temporary disruption of mating activities of mares and stallions; the additional care and supportive treatment that is required for affected horses; and the risk of virus spread by either fresh or frozen semen, artificial insemination, and embryo transfer. Because coital exanthema is not a reportable disease, its true prevalence and economic impact are difficult to assess and are probably underestimated.[33] Affected horses should be isolated and removed from the breeding program for a minimum of 4 weeks. The disease has no known effect on fertility.

Horsepox

Horsepox is a relatively benign viral disease that has become nearly extinct.[34] The virus is transmitted by direct contact with an infected host or with contaminated grooming tools or tack.

Pyrexia and anorexia may be observed early in the course of the disease, and horses of all ages may be affected. The initial skin lesion is an erythematous maculopapular eruption followed by the development of vesicles. This stage is transient and may not be observed. Vesicles develop into umbilicated pustules with a depressed center and a raised erythematous border. When the pustule ruptures a crust develops and the lesion heals, often with scarring. Three clinical presentations (oral, leg, and vulvar) have been described. Oral horsepox (buccal horsepox, contagious pustular stomatitis) is characterized by the development of lesions on the inner lips and buccal mucosa. In severe forms, pox lesions may develop in the pharynx, larynx, and nostrils. Leg pox usually develops on the pasterns and fetlocks and often is confused with "scratches" or "greasy heel." Pain and lameness are common. Vulvar pox (genital horsepox) is uncommon and occurs predominantly in severely affected animals.

Diagnosis is based on history and clinical signs and confirmed by histologic examination. Intracytoplasmic inclusion bodies demonstrated by routine histopathologic examination of tissue or electron microscopy are diagnostic. Other findings include ballooning degeneration of the epidermis (stratum spinosum), reticular degeneration, acantholysis (loss of cohesion of cell in the granular area), intraepidermal microvesicles, a superficial and deep perivascular dermatitis, and intraepidermal microabscesses and pustules.

Treatment is symptomatic. Most horses recover in 2 to 4 weeks. Occasionally the disease is fatal in severely affected young horses. Recovery produces lifelong immunity. This disease also affects humans and cattle.

Fungal Diseases

Dermatophytosis (Ringworm)

Dermatophytosis (ringworm) is the most common fungal disease in the horse. *Trichophyton equinum, T. mentagrophytes, Microsporum gypseum,* and *M. canis* are the most frequent isolates.[1,2] Dermatophyte infections are self-limiting but can become a significant source of frustration, particularly in large stables.

Dermatophytes are transmitted by direct contact with an infected host or by indirect contact with contaminated fomites or the environment. Illness, poor nutrition, overcrowding, age (young or old immunosuppressed individuals), and stress predispose horses to infection. Chronic moisture from sweating or excessive bathing with detergent shampoos damages the protective barrier of the skin and enhances the opportunity for infection. The incubation period is usually several weeks. During this time, fungi invade the epidermal keratin, hair follicles, and the hair shaft itself with the aid of enzymes that are allergenic to the host. Hair shaft integrity is compromised, and hairs fall out or are fractured easily, resulting in areas of alopecia with variable crusting and scaling that are characteristic of the disease (Figs. 18.18 and 18.19). Although rare, pruritus can be severe. Secondary bacterial infections can complicate the clinical picture and diagnosis. Infection is eliminated from a particular hair on shedding or as it enters the telogen stage, or the dermatophyte elicits an inflammatory response.

Lesions are most common in areas in which tack contacts the skin but may be limited to the distal limbs; posterior pasterns; and rarely, coronary bands.

The diagnosis is confirmed by demonstration and identification of the organism. Wood's lamp examinations are generally not useful because the most commonly implicated species do not fluoresce. Commonly used diagnostic tools include direct examination of hair shafts for microconidia and hyphae, skin biopsy, and fungal culture. More recently, polymerase chain

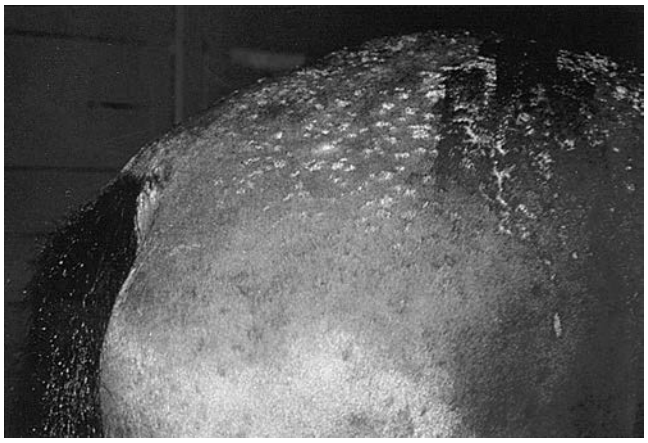

FIG. **18.18** Dermatophytosis. The papular eruption on the advancing edge of the lesions is notable.

FIG. **18.19** Classic signs of dermatophytosis (ringworm).

reaction (PCR) has become available at some laboratories. Hairs are collected for both PCR and culture from the periphery of a newly developing lesion, avoiding areas that have been previously treated. For fungal culture, the area is gently wiped with an alcohol swab to minimize growth of contaminants before collecting hair samples. Hairs should be plucked in the direction of growth and transported to a laboratory in which culturing of equine dermatophytes is routinely performed. Culturing equine dermatophytes can require medium enhancement in some instances. If biopsying, early lesions with crusts are ideal. Care should be taken to protect the crusts during skin preparation, and gently rinsing without wiping with sterile saline is sometimes recommended for this and other crusting lesions. Histologic findings include folliculitis, perifolliculitis, and furunculosis; superficial perivascular dermatitis with orthokeratosis or parakeratosis; and intraepidermal vesicular or pustular dermatitis. Septate fungal hyphae and oval spores may be present in the superficial keratin or hair follicle.[2]

Although most cases of dermatophytosis heal spontaneously within 1 to 6 months, treatment is advised to minimize contagion to other animals and humans. Weekly bathing with antifungal veterinary shampoos (2% miconazole or 1% ketoconazole) or accelerated hydrogen peroxide shampoo and application of 0.2% enilconazole as a leave-on rinse at a 1:50 dilution applied weekly for 6 to 8 weeks (Imaverol; Elanco, Basel, Switzerland) are good choices that often have better client compliance than lime sulfur or dilute bleach (1:10 with water) application; this is likely because they do not produce offensive odor or coat color alterations.

Systemic antifungal drugs, such as griseofulvin (50 mg/kg orally once daily or 100 mg/kg once daily for 7–10 days), itraconazole (5–10 mg/kg orally once daily), and 20% sodium iodine (250 mL per 500-kg horse every 7 days), have been used, but there are no controlled studies demonstrating efficacy, and use of these drugs is contraindicated in pregnant mares.

Elimination of dermatophytosis from a barn requires elimination of the organism from infected hosts and decontamination of the environment including fomites such as brushes, tack, blankets, leg wraps, and riding apparel, particularly the rider's boots. Commercial antifungal vaccines for equine dermatophytosis are not available in the United States.

Piedra

Piedra is a rare superficial fungal disease of horses that causes nodules on the hair shaft. Black or white filamentous nodules consisting of tightly packed hyphae are most commonly visible on the mane and tail. Affected hairs break at the site of infection. A definitive diagnosis is made by fungal culture and microscopic identification of the agent *Piedraia* sp. or *Trichosporon beigelii.* Treatment of affected horses includes clipping the hair and applying topical fungicides.

Sporotrichosis

Sporotrichosis is a zoonotic mycosis caused by *Sporothrix schenckii,* a dimorphic aerobic fungus. The organism lives in soil and decaying vegetation and enters the horse's skin via a traumatic wound. Early lesions begin as papules that may exude a seropurulent material. Nodules are most common on the thigh or proximal foreleg and chest (Figs. 18.20 and 18.21). If the immune system does not eliminate the organism, hard subcutaneous nodules develop along the lymphatics draining the area. The lymphatics become corded and drain thick, brown-to-red exudate. The disease rarely becomes systemic.

The definitive diagnosis is determined by demonstration of the organism via cytologic examination of exudate, culture of tissue or exudate, or skin biopsy. The organism appears as a cigar-shaped yeast in macrophages and neutrophils on Giemsa-stained smears. Histologic examination of tissue reveals nodular to diffuse, suppurative to granulomatous dermatitis. Intraepidermal microabscesses may be visible. The yeast is rarely seen in tissue sections. The number of organisms present in the tissue may vary, and repeat cultures are often necessary.

Ethylene diamine dihydroiodide (EDDI), a feed additive and an organic iodide powder, is the drug of choice because of its cost and ease of administration. It is administered at 1 to 2 mg/kg q 12 h for 7 to 10 days as a loading dose followed by 0.5 to 1.0 mg/kg q 12 h for 1 month past the resolution of clinical signs. The dose of EDDI is based on the active ingredient in the feed additive, which is usually 3.65% or 3.65 mg/g of product. Sodium iodide (20% solution) has also been successful for treating sporotrichosis in horses. A loading dose of 20 to 40 mg/kg is administered IV for 2 to 5 days, followed by once daily oral therapy (20–40 mg/kg) for 1 month after lesions disappear. Both EDDI and sodium iodide may be given orally via syringe or mixed in sweet feed. Iodism may develop and may require temporary discontinuation of therapy. Iodine cause abortion and should not be used in pregnant mares.

Mycetomata

Mycetomata are chronic pyogranulomatous infections of the skin and subcutaneous tissues caused by actinomycetes (actinomycetoma) or fungi (eumycotic mycetoma).[35,36] Mycetomata in horses have been reported in North America, South Africa, and Australia.[37] The most common agents of eumycotic mycetoma in horses belong to the *Scedosporium*/*Pseudallescheria* complex (SPC) and *Madurella* genera (i.e., *M. mycetomatis*); however, *Curvularia verruculosa, Phialophora oxyspora,* and *Aspergillus* spp. have also been occasionally detected.[36,37]

Lesions are characterized by swelling, draining tracts, and tissue granules. Regardless of the causative agent, the organism usually gains entrance to the body through traumatic inoculation. As with other granulomatous reactions the body is able to recognize the intruder and isolate it but not to eliminate it.

Lesions may vary in shape, size, texture, and color, depending on the etiologic agent. Single or multiple nodules of varying size can occur almost anywhere on the body of the horse. The nodules often are pigmented and ulcerated and may discharge tissue grains (small sandlike particles). The tissue grains are masses of hyphae from the causative organism, with dark-brown granules from the *Madurella* genera and white grains generally from SPC.[35,36] Definitive diagnosis can be made with fine-needle aspirate or excisional or wedge biopsy of a lesion. Histologic examination shows diffuse to nodular pyogranulomatous to granulomatous inflammation surrounding septate branching hyphae. Tissue grains are often visible microscopically. The hyphae contained in tissue grains or tissue may be pigmented or nonpigmented. Fungi are cultured best from tissue grains and, occasionally, exudate. Complete surgical excision is curative; if this is not possible, then additional local therapy may be beneficial.[38]

Phaeohyphomycosis

Phaeohyphomycosis (Table 18.2), sometimes known as chromomycosis, is a chronic cutaneous, subcutaneous, mucosal, and occasionally systemic infection caused by pigmented opportunistic fungi. The most commonly implicated organisms are *Alternaria* spp., *Drechslera spicifera,* and *Curvularia* spp., but *Hormodendrum, Phialophora,* and *Cladosporium* species have also been documented. Many of the organisms that cause fungal mycetomata can cause phaeohyphomycosis, but the distinguishing difference is the lack of tissue grains. Pigmented fungi (dematiaceous fungi) causing this disease are soil and vegetative saprophytes that gain entrance into the body via a wound or abrasion. The body is not able to eliminate the organism, which proliferates in tissues. Immunosuppression may be a predisposing factor.

Lesions can appear anywhere on the body but are most often found on the head and neck and may be single or multiple ulcerated cutaneous or subcutaneous nodules.[39] Some lesions are pigmented deeply on gross examination, or pigmentation is only a microscopic feature. Nodules vary in size and are cool, nonpainful, and nonpruritic. Regional granulomatous dermatitis may be present.

Definitive diagnosis is made by histologic examination and fungal culture of an excised nodule. Skin biopsy reveals suppurative to granulomatous dermatitis with pigmented septate hyphae. Observation of pigmented septate hyphae in the skin indicates opportunistic invasion of the tissue.

Complete surgical excision, and the administration of fluconazole when complete excision is not possible, for 10 days (a loading dose of 14 mg/kg given once followed by 5 mg/kg PO daily) and potassium iodide (30 mg/kg PO daily for 30 days) are the current recommended treatments.[38]

TABLE **18.2** **Fungal Diseases of Horses**

Disease	Common Causative Agents	Clinical Signs
SUPERFICIAL INFECTIONS		
Dermatophytosis	*Microsporum* and *Trichophyton* spp.	Circular patches or hair loss, crusting and scaling, urticaria, papules
Piedra	*Piedraia* spp. or *Trichosporon beigelii*	Black or white filamentous nodules on hair shaft
INTERMEDIATE INFECTIONS		
Sporotrichosis	*Sporothrix schenckii*	Papules and nodules occur along lymphatics; nodules may ulcerate, become thickened, and drain a thick brown to red-colored exudate
Phaeohyphomycosis (chronic, subcutaneous fungal infection caused by pigmented opportunistic fungi)	*Hormodendrum, Drechslera, Phialophora, Curvularia, Cladosporium*	Single or multiple nodules; lesions may be grossly or microscopically pigmented, nonpruritic, nonpainful, and cool to the touch
Mycetoma (chronic subcutaneous infection)	Filamentous bacterial organisms and opportunistic fungi	Single or multiple nodular lesions are present; ulcerated, draining tracts are common; mycetomata discharge tissue grains in contrast to phaeohyphomycosis, which does not

Pythiosis

Pythiosis (previously referred to as phycomycosis) is one of the few dermatologic emergencies in equine practice. It is caused by an aquatic fungus called *Pythium insidiosum*.[40] Originally more common in warm wet climates such as the southeastern United States and portions of South America and Australia, the organism has made its way to Michigan, Indiana, Washington State, and other similarly cooler climates. *Pythium* is a plant parasite that normally lives on aquatic vegetation and organic debris. It can live in the soil and grass for prolonged periods of time and becomes infective during periods of extended rain. Infective zoospores gain entrance into the horse via small wounds or through prolonged contact with contaminated water.

The most commonly affected areas include the distal limbs, ventrum, perioral and nasal area, and chest (Fig. 18.22). Early signs of fungal invasion include single or multiple minute foci of necrosis that progress rapidly into circular, ulcerative, and granulation-tissue–like masses with serosanguineous discharges. These masses are intensely pruritic, which is a hallmark of this disease. Lameness, regional lymph node involvement, anemia, and hypoproteinemia are common findings. If left untreated the disease will become systemic, with most horses succumbing to the disease within 6 months. The lesions of pythiosis can be confused with habronemiasis, exuberant granulation tissue, bacterial granuloma, and invasive squamous cell carcinoma (SCC), which may delay appropriate treatment. Lesions are often hemorrhagic from self-trauma and frequently weep thick, serosanguineous material thought to resemble leeches (giving it the colloquial name *Florida horse leeches*). Tracts within the lesions will contain "kunkers" (another hallmark of this disease), which are hard, gritty, and white to yellow masses that can be expressed with moderate pressure. The kunkers can be seen to branch with the naked eye, which can be used to help distinguish them from granules observed in several other skin diseases. Kunkers are composed of fungal hyphae, host exudate, and protein. The diagnosis of *Pythium* infection can be made quickly by kunker evaluation if sent to a laboratory specializing in its diagnosis. A definitive diagnosis can also be made through serology, biopsy, culture, and cytologic examination of exudate. Biopsy of early lesions of equine pythiosis reveals abundant microabscesses with eosinophils and a few neutrophils, lymphocytes, and macrophages. In chronic cases, an eosinophilic granuloma with giant cells is observed with microabscesses and kunkers at the center. With periodic acid-Schiff (PAS) and silver stains *P. insidiosum* appears as sparsely septate hyphae 6 to 10 mm in diameter. An initial diagnosis can be made grossly on lesion appearance, location, and/or the presence of kunkers. Because of the aggressiveness and severity of the disease, treatment should not be delayed while awaiting the results of additional

FIG. **18.22** Horse with bilateral pythiosis on the legs.

FIG. **18.23** Pastern dermatitis.

diagnostic tests. If properly treated early after onset of clinical signs, the outcome is favorable. The fatality rate is 100% if the animal is left untreated. The likelihood of successful resolution of lesions declines with chronicity of disease.

Lesions in horses are best treated with a combination of therapies including radical surgical excision of the lesion, three or more doses of *Pythium* immunotherapy (www.pavlab.com), and topical application of antifungal solutions. Affected horses may also benefit from regional limb perfusion with 50 mg amphotericin B[41] or oral and/or IV iodides. Prognosis for horses affected with cutaneous pythiosis is good if recognized early and immediately and aggressively treated. The disease is not a known zoonosis, but protective latex gloves should be worn when examining patients with suspected lesions.

Stachybotryotoxicosis

Stachybotryotoxicosis is a mycotoxicosis caused by the toxins of the fungus *Stachybotrys atra*.[2] This fungus grows on hay and straw and produces toxins referred to as *macrocytic trichothecenes*. These toxins cause bone marrow suppression, profound neutropenia, thrombocytopenia, and necrotic-ulcerative lesions of the skin and mucous membranes.

Lesions commonly begin at the mucocutaneous junction as focal areas of necrosis and ulceration. Petechiae, ulcers, large areas of necrosis, catarrhal rhinitis, suppurative rhinopharyngitis, and laryngitis follow. Skin lesions occur as early as 24 hours after ingestion of the toxin. Systemic signs include lethargy, anorexia, weight loss, hyperactivity, proprioceptive deficits, colic, muscular stiffness, and second-degree atrioventricular block. Affected animals develop hemorrhagic diathesis, hemorrhagic enteritis, and septicemia and die.

The diagnosis is based on history, clinical signs, and finding the toxin in the feed. If one recognizes toxicosis early in the course of the disease, withdrawal of affected feed has resulted in resolution of signs. Animals with extensive lesions and chronic exposure have a poor prognosis.

Pastern Dermatitis

Pastern dermatitis (scratches, greasy heel, and mud fever) is a descriptive term used for lesions of varied etiologies that appear on the back of the pasterns and/or heel bulbs (Fig. 18.23) and sometimes spread up the legs. Bacterial infection is usually a significant component; *D. congolensis* is frequently a copathogen with two or more other bacterial species. The lesions can be associated with other conditions including photosensitivity in horses with socks or stockings, chorioptic mange in draft horses, or simple staphylococcal bacterial folliculitis. Lesions may be scaly, crusty, oozing, or crusting and can be quite sensitive to the touch. Lameness may be present. Mild cases may resolve with clipping of excess hair from the pasterns to allow them to dry more quickly, gentle cleaning with chlorhexidine followed by thorough drying, and the topical application of water-soluble antibacterial ointments. The horse must be moved to a dry environment until lesions are completely healed. Severe cases of pastern dermatitis require systemic antibiotics, and affected horses frequently benefit from biopsy with culture and sensitivity. Silver stain of the histology specimen to examine for the presence of spirochetes is worthwhile in horses that do not respond to traditional therapy. Severely affected horses may benefit from regional limb perfusion with an antibiotic appropriate to the bacteria isolated.

Parasitic Diseases

Ectoparasites are a common cause of dermatitis in horses and can have a serious impact on the animal's welfare. They are also important vectors in the transmission of a wide variety of infectious agents.

Lice (Pediculosis)

Lice typically cause severe pruritus, which leads to self-traumatic excoriation and patchy alopecia; when left untreated the coat can become dull and scaly. Affected horses can become agitated and have a poor appetite. Foals may develop muscle fasciculations without other symptoms. Heavy infestations of sucking lice may cause anemia or severe debilitation. Infestation has no age, breed, or gender predilection.

Lice are highly host-specific, obligate parasites that spend their entire life cycle (20–40 days) on the host. In ideal environments, lice can live for 2 to 3 weeks off of the host, but less than 7 days is more typical.[42] Lice infestations are transmitted by direct or indirect contact. Grooming instruments and tack serve as fomites for transmission, and adult horses may act as asymptomatic reservoirs that are identified only when foals or other susceptible animals become infested.

Female lice attach their nits to the horse's hairs via a clear adhesive secretion. Two types of lice feed on horses. Biting lice *(Damalinia equi)* feed on epidermal debris and prefer the dorsolateral trunk. Sucking lice *(Haematopinus asini)* feed on blood and tissue fluid, and most commonly infest the mane, tail, and fetlock region.

Lice infestations can occur year round but are more common in the winter in northern climates when the longer hair coat and cooler skin and hair temperatures are more favorable to reproduction.

The diagnosis of lice infestations is made by visualizing adults or eggs or both on the horse's hair. In bright sunlight or in animals with light-colored hair the veterinarian may need to use a fine-toothed comb or brush the coat onto a darker surface to find the lice. Skin biopsies may reveal a nonspecific superficial perivascular eosinophilic dermatitis with or without intraepidermal microabscesses.[2]

When managing a lice infestation, the goal is to treat all animals on the premises. Ivermectin at 200 µg/kg orally every 2 weeks for three treatments is generally effective for treating sucking lice. Controversy exists as to whether biting lice respond as well to oral ivermectin treatment as sucking lice, but the use of topical eprinomectin solution (Eprinex Pour-on; Merial, Manukau City, New Zealand) 500 µg/kg body weight weekly once for four administrations appears to be curative. Both sucking and biting lice will respond to

insecticidal or 1% selenium sulfide shampoos, which kill the adult lice, but the hatching nits will require a second shampooing in 2 weeks. Two applications of insecticidal sprays or powders containing pyrethrins and pyrethroids at 14-day intervals are also efficacious. Older pour-on permethrin products have caused local paresthesia and local hair loss in some horses. A newer permethrin product that also contains pyriproxyfen and dinotefuran (Vecta 3D; Ceva, Lenexa, KS) does not seem to produce these untoward effects (see the section Treatment of Allergic Skin Disease), and one treatment is generally adequate for both adults and nits. Applications of imidacloprid, phoxim, and 0.25% fipronil are also effective.[43,44] Lime sulfur and pyrethrin dips have fewer associated adverse reactions in horses than do other dip treatments. Because these products do not affect lice eggs, two to three repeat applications of the dip are recommended at 2-week intervals. For optimal efficacy, one should treat the whole body of the horse when applying the dips. All products should be used according to label directions. The presence of lice in the nearby environment should be addressed by cleaning and decontaminating all tack and grooming supplies and decontaminating the stabling area using a commercial flea premise spray. Horse trailers are frequently overlooked during treatment but can be the source of infestation. Treating animals returning from shows, breeding farms, or training facilities prophylactically should be considered in high-risk facilities.

Mites (Mange)

A variety of mites may infest horses. *Sarcoptes scabiei* var. *equi* (scabies, head mange), *Chorioptes equi* (leg mange), *Psoroptes equi* (body mange), *Pyemotes tritici* (straw itch mite), and *Trombicula* and *Eutrombicula* species (chiggers) are associated with pruritic equine skin diseases.[42] The pruritus accompanying a mite infestation results from a combination of mechanical irritation and hypersensitivity to the mite and byproducts of the mite (i.e., feces). The primary skin lesion from a mite infestation is a maculopapular eruption. With chronic infestations the skin is markedly inflamed and chronically thickened, and secondary bacterial infections are often present. As of 2006, mite infestations are no longer federally reportable conditions in horses in the United States, although they may remain reportable to some state veterinary agencies. Regardless of the type of mite present on the horse, skin scrapings should be part of the diagnostic investigation. With the exception of lice and trombiculid larvae that can be seen with the naked eye, mite infestations are best confirmed by microscopic examination of skin scraping samples.

Sarcoptes scabiei. *S. scabiei* is highly contagious in horses and transiently infests the humans in contact with them. *S. scabiei* is capable of surviving off the host for up to 3 weeks, and transmission by fomites or environmental sources is possible. Scabies mites burrow in the superficial epidermis in which they lay their eggs. In early infestations, mites are found in highest concentration around the head and neck and seem to prefer the ears on horses. As disease progresses, mites spread over the entire body. Scabies infestation in the horse results in intense pruritus and generalized scaling and crusting with excoriations and lichenification. Secondary bacterial infection may occur. The scabies mite is circular with short legs, a terminal anus, and long unjointed pedicles. Unfortunately, as in other species, the scabies mites can be difficult to find on skin scrapings. Therefore a negative skin scraping does not ensure that the horse does not have scabies.

Ivermectin at a dose of 200 µg/kg orally is effective for treating horses with scabies. As in other species, the practitioner should repeat ivermectin treatment at 2-week intervals for a total of two to three treatments because the eggs hatch and new adult mites are present at that time. Alternatively, topical treatments such as lime sulfur dip, lindane, coumaphos, diazinon, malathion, or toxaphene also have been used. Affected horses and those in contact with it should be dipped every 7 to 10 days for three to six treatments. Fomites should be decontaminated (e.g., tack, brushes) as well as the environment.

Chorioptes equi. *C. equi* mites are host specific and do not parasitize humans (Fig. 18.24). They spend their entire 3-week life cycle on the host but can live off the horse for 70 days. The mite tends to be more common in the winter months. *Chorioptes* feed on epidermal debris at preferred sites, which include the distal limbs and perineum. Infested horses exhibit intense pruritus with chewing, licking, stomping of the feet, and rubbing of the tail and perineal area. In some horses only the hindlimbs are affected. Skin lesions include papules, alopecia, erythema, scabs and crusting of the pasterns, fetlocks, or perineum. Diagnosis can sometimes be made by deep skin scrapings often onto clear packing tape or a drop of oil placed on a glass slide so that the mites do not escape. If the clinical picture fits *C. equi* infestation but no mites are recovered, then the response to treatment may be used for diagnosis. Although infested horses can have a large number of easily recoverable mites, there appears to be a population of horses that has few to no recoverable mites; clinical signs on these horses may be caused by hypersensitivity. Draft-breed hors-

FIG. **18.24** *Chorioptes* mite.

es or other horses with feathered fetlocks are predisposed to *C. equi* where they may contribute to the lesions of chronic progressive lymphedema (CPL; Fig. 18.25).

C. equi should be included in the list of differential diagnoses for horses with pastern dermatitis or greasy heel. When a *C. equi* infestation is diagnosed, all horses on the property should be treated. Because *C. equi* does not cause severe clinical signs in every infested horse, chorioptic mange is often overlooked as a diagnosis when one horse in a group of horses is affected.

Treatment with topical eprinomectin solution (Eprinex Pour-on; Merial, Manukau City, New Zealand) at the manufacturer's recommended therapeutic dose for cattle of 500 µg/kg body weight weekly once for four administrations is recommended.[45] The appropriate dose volume for each horse is administered along the back line, from the withers to the proximal tail. Topical fipronil (Frontline; Merial, Iselin, NJ) is also useful, although some horses seem to become agitated when the fipronil is applied, potentially from increased activity of the mites. Both ivermectin and moxidectin have been advocated for treatment of *C. equi* in horses; however, resistance to the products may be developing. Topical dip therapy may be indicated in some horses. If a topical medication is used, clipping the hair around the fetlocks and pasterns to ensure optimal contact of the dip with the skin and mites is advisable. The premises should be decontaminated with a commercial premise spray for fleas.

Psoroptes equi. *P. equi* mites are highly contagious to other horses but do not infest humans. They are biting mites that live on the skin surface and feed on serum and cellular components. Transmission of *P. equi* mites is by direct contact and exposure to fomites. Mite infestations tend to begin on the forelock, mane, and tail and spread to the trunk. These mites have been known to infest the ear canal and cause otitis externa. Affected horses typically show headshaking or rubbing. As with many other mites, pruritus results in alopecia, papules, oozing crusts, excoriations, and ulcers on the skin. The intensity of pruritus varies. History and clinical signs suggest the diagnosis of *P. equi* mange. Skin scrapings are required to confirm a diagnosis. *P. equi* has an oval body with segmented pedicles. Treatment for *P. equi* infection is similar to that described for all mites.

Trombiculiasis. Trombiculiasis (chiggers, red bugs, and harvest mites) is caused by an infestation with larvae of free-living adult mites (genus *Eutrombicula* or *Neotrombicula*). Larvae are most prevalent in grasses, forests, or swamps in late summer and fall. Small rodents are the natural host. Pathognomonic skin lesions are papules or wheals with a small orange or red dot (trombiculid larvae) in the center. Lesions occur most commonly on the face, muzzle, distal limbs, ventral thorax, and abdomen. Trombiculiasis is seasonal, but the seasonality varies with genus and species. *E. alfreddugesi* is active in the late spring and peaks midsummer, whereas *Neotrombicula autumnalis* is most active from the late summer to midautumn.[46] Larvae feed on the host in the late afternoon and early evening. Diagnosis is based on observation of the distinctive lesion with the larvae approximately 0.2 to 0.4 mm in size, oval in shape with six legs, in the center of the skin lesion. Trombiculiasis is a self-limiting disease. Some horses are uncomfortable with this mite infestation and should be treated. Recommended treatments include lime sulfur dip, permethrin, pyrethrin, cypermethrin, and phoxim sprays or dips as a one-time treatment in association with prednisolone at a dosage of 0.5 mg/kg orally for 3 to 5 days.

FIG. **18.25** A 10-year-old draft horse with chronic progressive lymphedema. Before (A) and after (B) clipping the feathers on a horse with chronic *Chorioptes equi* and a secondary mixed bacterial infection demonstrating that feathers can hide serious skin lesions. The horse had previously been treated with ivermectin multiple times with no resolution of the pruritus or skin lesions. Eprinomectin solution applied to the horse's topline and topical wound care with systemic antibiotics were able to control disease progression.

Pyemotes tritici. *P. tritici* (straw itch mite) normally parasitizes the larvae of grain insects. Occasionally this mite parasitizes humans and horses.[15] Infestation in horses occurs from contaminated hay fed in overhead racks. The mite produces a maculopapular crusted eruption on the head, neck, and trunk that is only occasionally pruritic. The diagnosis is based on history and clinical examination. This disease is self-limiting, and the owner should remove contaminated forage or feed the horse from the ground until all contaminated forage has been consumed. Infestations from fomites or hay fed on the ground have not been reported.

Dermanyssus gallinae. The nymphs and adults of the poultry mite, *Dermanyssus gallinae,* will occasionally parasitize the horse. This mite feeds at night. The adults are oval and 0.6 to 1 mm long with eight long legs. The color of the mite is white, gray, or black. After poultry mites consume a blood meal they take on a red appearance.

This mite causes pruritic papules and crusts of the head and legs of horses. Skin scrapings and tape preparations at night yield the best chance of obtaining the mite from the horse. Mites may be more easily identified on poultry from the horse's environment. Cleaning the environment and routine mite treatments as described previously are beneficial for treatment of this mite. If it is not possible to eliminate the horse's contact with poultry, recurrence of dermatitis can be prevented by regularly applying permethrin to the horse and biannual decontamination of the horse's stable.[47]

Demodicosis. Demodectic mites are normal skin residents in horses; therefore, the rare animal that manifests clinical signs of demodicosis is likely to be immunocompromised. Two species of *Demodex* can infest horses, *D. equi* and *D. caballi,* and each affects different areas of the body. *D. caballi* prefers the eyelids and muzzle, whereas the lesions of *D. equi* are more generalized. Clinically these horses have one or more alopecic or scaling areas. The most common areas of the body affected in horses with *Demodex* are the face, neck, and sometimes shoulders. The mite is easily identified on skin scrapings of affected areas. Because the infestation is usually asymptomatic and will likely regress once the underlying cause for immunosuppression is addressed, most horses are not treated. Treatment with 2% trichlorfon topically every other day or ivermectin orally for 15 days has shown some success. Amitraz is contraindicated because it can cause colic in horses. Regardless, the veterinarian should identify and treat the underlying cause for the demodicosis, which is most commonly equine Cushing's disease (PPID).[1,2,46]

Ticks

Ticks not only harm their host locally through bite injuries, but they can also play a significant role in transmission of a variety of viral, protozoal, rickettsial, and bacterial infections. In addition, horses suffer tick paralysis similar to dogs. Tick infestations are most common in the spring and summer.

Soft (argasid) ticks lay eggs in protected areas in the environment, and newly hatched ticks suck blood and lymph from the horse and then drop off to develop into adults (one-host ticks). Soft ticks infest barns, sheds, and other areas in which animals are housed. In horses, the soft tick *Otobius megnini* (spinose ear tick) tends to infest the ears and ear canal. Clinical signs of infestation include otitis externa, head tilt, headshaking, ear rubbing, and occasionally aural hematomas. Hard (ixodid) ticks such as *Dermacentor, Ixodes,* and *Amblyomma* species are the most common ticks found on horses. They also lay their eggs in sheltered outdoor areas, but hard ticks are three-host ticks, which means they must feed on three separate hosts to complete their life cycle.

The severity of clinical signs from tick feeding depends on the density of the infestation and whether the horse develops a hypersensitivity reaction to the bites. Infestations occur most commonly on the ears, face, neck, groin, distal limbs, and tail. Early lesions consist of papular to pustular eruptions that rapidly develop into crusts, erosions, ulcers, and hair loss. Hypersensitivity reactions may be local or general. Local responses appear as nodules that develop at the site of the tick bite. Systemic reactions are characterized by whole-body urticaria or multifocal urticarial plaques. In Australia, a hypersensitivity reaction to *Boophilus microplus* has been observed in sensitized horses. Intense pruritus, papules, and wheals develop as soon as 30 minutes after ticks begin to feed.

A definitive diagnosis is made by observation of ticks attached to the horse or in the ear canal. Treatment aims at killing ticks on the horse, and knowledge of the parasiticidal resistance of the local tick population will greatly help direct treatment. Pyrethrin or pyrethroid sponge-on dips can be applied to the body of the horse, taking extra care to soak skinfold areas. Soft ticks will generally require two to three treatments. Treatment for hard ticks must be repeated throughout the tick season because of their three-host life cycle. Infestations of *O. megnini* require mechanical removal of as many ticks as possible. One part rotenone and three parts mineral oil applied twice weekly is an effective otic parasiticide for horses as are commercially available pyrethrin otic preparations (Otomite Plus; Virbac, Fort Worth, TX). Ivermectin and fipronil have also shown efficacy. A drop or spray of fipronil can be applied to the ear pinnae on a monthly basis for tick prevention.

Helminths

Onchocerciasis. Lesions of *Onchocerca cervicalis* infection begin as a simple thinning of the hair coat, often around the eyes, muzzle, neck, chest and ventral abdomen.[1,2] As the disease progresses, lesions vary from focal to generalized areas of alopecia, scales, crusts, and plaques (Figs. 18.26 and 18.27) and may become severely excoriated, ulcerated, oozing, and lichenified. Leukoderma can develop at the site of the lesion but is generally reversible. Ocular diseases associated with *O. cervicalis* include equine recurrent uveitis (which is the most common cause of blindness in horses worldwide), sclerosing keratitis, vitiligo of the bulbar conjunctiva, and conjunctival nodules.[48]

The nematode lives in the ligamentum nuchae and produces microfilariae that migrate through the skin and are ingested by the intermediate host, the *Culicoides* species. Microfilarial populations vary seasonally and are highest in the spring and summer, which are also peak season for the *Culicoides* vector. Clinical signs of onchocerciasis are believed to be caused by an idiosyncratic hypersensitivity reaction to one or more microfilarial antigens because many horses that have circulating microfilariae do not have lesions.[49]

Onchocerciasis is an important disease of horses worldwide, has no breed or gender predilection, and usually affects horses 4 years of age and older. Diagnosis of onchocerciasis is most reliably made with a mince preparation or via histologic examination of skin from a biopsy specimen. Mince preparations require a 4-mm or 6-mm punch specimen of tissue. The tissue specimen is placed in a Petri dish with a small amount of physiologic saline, minced with a scalpel blade or razor,

FIG. **18.26** Ventral midline dermatitis caused by onchocerciasis.

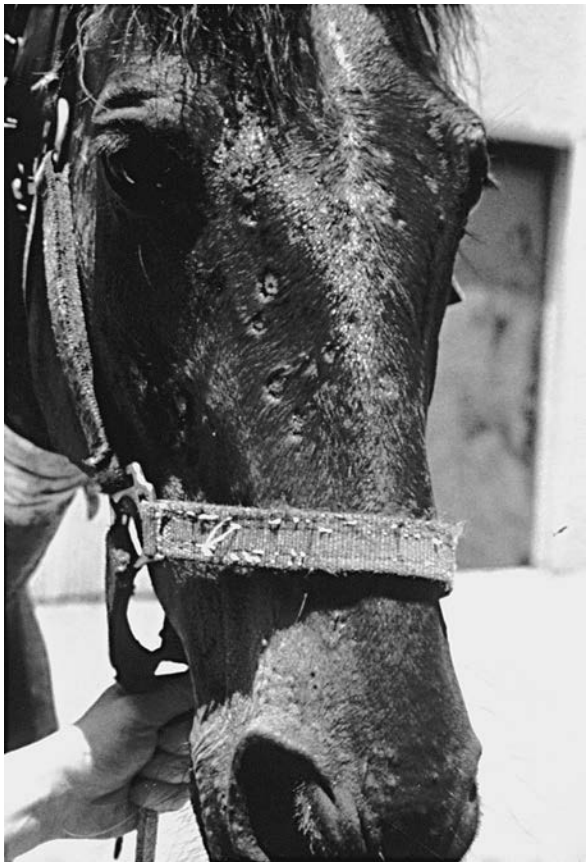

FIG. **18.27** Equine onchocercosis.

and incubated at room temperature for 30 to 60 minutes. The specimen is then examined microscopically for evidence of the rapid motion of the microfilariae. Skin biopsies reveal a superficial perivascular eosinophilic dermatitis. Often, microfilariae are visible in the superficial dermis.

Treatment with either ivermectin or moxidectin is effective for the microfilaria at the standard dosage. Some horses require two to three monthly treatments before clinical signs resolve. Approximately 25% of horses with severe disease have an adverse reaction, such as ventral midline edema or pruritus, which occurs 1 to 10 days after treatment. This reaction is believed to be caused by dying and dead microfilariae. In rare cases, severe umbilical and eyelid edema and fever may occur. Anecdotal reports suggest treatment may also precipitate an episode of uveitis.

FIG. **18.28** Recurrent *Habronema* infection on the penis of a Lusitano gelding.

Some practitioners pretreat horses with known cases of equine recurrent uveitis with nonsteroidal antiinflammatory agents. Alternatively, prednisolone at a dose of 0.5 mg/kg orally may be given, but this is not routinely recommended. None of the currently available anthelmintics kills adult parasites in the ligamentum nuchae, and affected individuals require periodic retreatment with ivermectin when clinical signs recur. The prevalence of cutaneous onchocerciasis has decreased significantly over the years with routine deworming protocols using ivermectin. The more recent use of deworming by fecal egg counts appears to have increased the incidence of *Onchocerca*-related dermatitis.

Habronemiasis. Cutaneous habronemiasis is a common nodular skin disease caused by three species of nematodes: *Habronema muscae, H. majus (H. microstoma),* and *Draschia megastoma (H. megastoma).* The housefly is an intermediate host for *H. muscae* and *D. megastoma,* whereas the stable fly is the intermediate host for *H. microstoma.* Adult nematodes live in the stomach and produce larvae, which are passed in the feces and ingested by maggots of the previously mentioned intermediate hosts. The intermediate host deposits infective larvae near the horse's mouth, which the horse then swallows to complete the cycle. Cutaneous habronemiasis occurs when the intermediate host deposits infective larvae on skin, open wounds, or chronically moist areas.

Horses with cutaneous habronemiasis have ulcerative nodules in the spring and summer that partially or completely regress in the winter. Arabians, gray horses, and horses with color dilutions (i.e., palomino, buckskin, dun) may be predisposed to developing cutaneous habronemiasis. Thoroughbred horses appear to be underrepresented. No breed, gender, or age predilection exists. Individual horses may be predisposed to cutaneous habronemiasis, exhibiting clinical signs each year, whereas other horses on the same premises never develop this condition.

Lesions commonly occur on the limbs, urethral process of the penis, prepuce, or any area with trauma to the skin (Fig. 18.28). Common periocular sites include the medial canthus, conjunctival sac, lacrimal duct, and third eyelid. Single or multiple nodules may be present. In most cases, pruritus is present, presumably caused by a hypersensitivity reaction to the parasite. The intensity of pruritus may vary from mild to severe. In severe cases in which ocular lesions are present the horse can suffer from photophobia, epiphora,

and chemosis. Dysuria can occur when lesions affect the urethral process.

Lesions often are ulcerated and appear similar to exuberant granulation tissue. Yellow granules ("sulfur granules") approximately 1 mm in diameter may be present. Microscopic examination of these granules does not reveal branching hyphae such as one frequently observes with granules from pythiosis or zygomycosis lesions.

Differential diagnoses for cutaneous habronemiasis include bacterial granuloma, fungal granuloma, pythiosis, exuberant granulation tissue, eosinophilic keratitis, SCC, and equine sarcoid. *Habronema* spp. are often present concurrently with other dermatologic conditions, and biopsy is important for a complete and definitive diagnosis.

The diagnosis is based on history, physical examination, cytologic examination, and biopsy of lesions. Occasionally the parasite itself may be directly seen and cytologic examination of exudate sometimes reveals the presence of nematode larvae. These larvae are large (3 mm × 60 μm), with a spiny tail, and are usually motile. Skin biopsies reveal a nodular to diffuse granulomatous dermatitis with large numbers of mast cells and eosinophils, and foci of coagulation necrosis are characteristic. Sometimes this area of necrosis contains cross-sections of larvae.[1,2]

Treatment of cutaneous habronemiasis should include control of the associated hypersensitivity reaction and elimination of the parasite. The routine use of macrocyclic lactones (ivermectin or moxidectin) should remove the adults from the stomach and minimize continued transmission. For horses that have ongoing lesions, repetitive ivermectin treatments spaced 2 weeks apart in addition to topical wound care is recommended. Topical wound care often includes a mixture of glucocorticoids and dimethyl sulfoxide (DMSO) to which ivermectin or moxidectin and fenthion, thiabendazole, ronnel, or trichlorfon is added. Systemic corticosteroids may be required in some horses; a common dosage of prednisolone is 0.05 to 1 mg/kg once daily for 10 to 14 days with a gradual decrease over an additional 2-week period. The addition of diethylcarbamazine (3 mg/kg PO q 24 hours) to kill the microfilaria is useful in some horses; these horses may require concurrent corticosteroid treatment to manage pruritus from dying microfilaria.

Severely affected horses will require surgical excision of lesions with follow-up topical and systemic treatment. Although cryosurgery has been recommended for cutaneous habronemiasis, the delay in healing compared with surgical removal makes the horse susceptible to reinfection for a longer period of time. In all cases of cutaneous habronemiasis, protecting the lesion from fly contact is necessary to break the reinfestation cycle.

Conjunctival habronemiasis is treatable with topical echothiophate drops instilled three times a day to kill larvae in combination with an ophthalmic ointment that contains dexamethasone and an antibiotic. Other ocular treatments include neomycin, polymyxin B, and dexamethasone applied topically three to four times daily until healed. If corneal ulcers are present, ophthalmic antibiotics without steroids are used until the ulcer is healed. After the corneal ulcer is healed, an ophthalmic dexamethasone ointment is added. Most ocular lesions heal within 5 to 18 days, with a mean of 8.2 days.[50]

Fly control is an essential part of treatment with different recommended control methods (Box 18.4).

Prognosis for horses with habronemiasis is good with appropriate and timely treatment. The veterinarian should warn the owner that habronemiasis may recur in subsequent years. Fly control is essential to preventing recurrence. Regular collection and composting of manure away from where the horse lives will also help with preventing recurrence. Placing a humidifier in the barn as a fly attractant during outbreaks of habronemiasis in drought conditions may decrease the incidence of equine infections.

BOX 18.4 Primary Management Strategies for Common Equine Pests

Stabling
- Tabanids: Diurnal and crepuscular periods
- Black flies: Diurnal and crepuscular periods
- Biting midges: Under fans; nocturnal and crepuscular periods

Exclusion devices
- Black flies: Ear nets
- Houseflies: Face masks
- Face flies: Face masks

Hay and manure management
- Stable flies: Particularly hay in pastures
- Houseflies: General sanitation

Cattle management
- Horn flies: Control pest on natural host
- Face flies: Undisturbed cattle manure requisite for larval development

Water management
- Mosquitoes: Only certain species
- Biting midges: Only certain species

Source identification and removal
- Straw itch: Normally infested hay
- Blister beetle: Normally products containing alfalfa

Restricted grazing or movement
- Chiggers: Erratic distribution in spring or fall
- Ticks: Mowing and understory control also helpful
- Tabanids: Allow horses to escape from wooded areas
- Poultry pests (sticktight fleas and lice): Separate horses from poultry

From Robinson NE, ed. *Current therapy in equine medicine.* 6th ed. St. Louis, MO: Saunders; 2009.

Pinworms. Pinworms *(Oxyuris equi)* are a common cause of tail rubbing in horses and are small white worms with a pointed tail that resembles a pin. Adult pinworms are found in the colon; the female worm migrates down the gastrointestinal tract and deposits eggs around the anus. These eggs are cemented to the skin with a thick, sticky, yellow-gray substance that can cause intense pruritus. In severe infestations, horses may also develop vague abdominal discomfort.

Eggs develop to the infective stage within a 4- to 5-day period. At this time the cement substance cracks and dries and then detaches from the skin as flakes. These flakes contain a large number of eggs that adhere to walls, buckets, and other objects in the environment.

Because ova of *O. equi* are not often observed on routine fecal flotation, a diagnosis of pinworms is based on clinical signs and identification of pinworm eggs on cellophane tape preparations. A piece of clear adhesive tape is pressed to the skin around the anus. The tape is removed and placed on a slide for microscopic examination for oval ova with an operculum or plug at one end.

Treatment is accomplished through routine deworming with ivermectin, moxidectin, pyrantel pamoate, or benzimidazoles. There are anecdotal reports of occasional resistance to ivermectin and pyrantel dewormers, but resistance must be differentiated from rapid reinfestation. If true resistance exists, fenbendazole is the treatment of choice. To avoid reinfestation the perineal area should be cleaned well at the time of deworming. Application of a light coating of oil for a few minutes followed by scrubbing with mild soap should be adequate. Infestation of pasture areas can be minimized by harrowing in midsummer. Pinworm eggs are unable to survive exposure to high temperatures, but in ideal conditions they can survive in the environment for up to 1 month.

Warbles

Warbles occasionally occur in horses and are caused by a larval stage of *Hypoderma bovis* and *H. lineatum*. Horses that develop infestation are usually pastured with cattle. Adult flies lay eggs on the hairs, and larvae migrate toward the skin surface and eventually penetrate the skin. Once in the body of the host, the larvae migrate to reach the subcutaneous tissues of the neck and trunk. A swelling develops at the site of the larvae, which eventually becomes perforated as a breathing pore is formed. Nodules are visible most often over the withers, and almost all develop a breathing pore. The nodules are often painful. Spontaneous rupture may cause anaphylaxis. Occasionally, aberrant migration causes neurologic signs.

The presence of dorsal swelling or a nodule with a breathing pore is diagnostic. The major differential consideration is collagenolytic granuloma; however, these nodules lack a breathing pore. Hypodermiasis is treated by gently enlarging the breathing pore surgically and removing the grub, removing the entire nodule surgically, or allowing the grub to fall out spontaneously. In areas of high occurrence, one may use pour-on insecticides as a preventative. Horses should be treated at the same time of year as affected cattle are treated in the area.

NUTRITIONAL AND TOXIC SKIN DISORDERS

Protein Malnutrition

Protein malnutrition in horses usually occurs from inadequate intake associated with poor quality hay or forage. Horses with long-standing systemic illness, poor dentition, significant parasitism, dysphagia, burns, proteinuria, liver disease, gastrointestinal diseases, or any other disease in which metabolic demand increases and availability of protein decreases may also suffer protein malnutrition. These horses can develop dry, dull, and brittle hair coats (Fig. 18.29). Although poor coat density has been reported in some animals, a longer hair coat with prolonged shedding may also be observed.

Iodine Toxicity

Iodine toxicity or iodism is uncommon in the horse and is generally iatrogenic in nature. Iodine is used in the treatment of infectious agents such as *P. insidiosum, S. schenckii,* and conidiobolomycosis. Even when administered at appropriate doses the prolonged treatment sometimes required can result in the classic signs of iodine toxicity, including severe dry seborrhea of the mane and tail. Some horses exhibit signs throughout their hair coat. Noncutaneous signs include cough, excessive lacrimation, salivation, nasal discharge, and joint pain. No specific therapy is indicated because horses recover spontaneously on removal of the source of excess iodine.

FIG. **18.29** Long, dry, dull hair coat in Quarter Horse and Paint yearlings with chronic protein malnutrition and parasitism. Horses also failed to shed appropriately. Dietary changes and deworming improved hair coat and overall growth. (Photograph courtesy of Dr. Judy Marteniuk.)

Selenium Toxicity

Selenium toxicosis is most common when horses eat selenium-concentrated plants that grow in soils with high selenium concentration, such as those in the Great Plains and Rocky Mountain areas of the United States. At toxic levels selenium is substituted for sulfur in sulfur-containing amino acids and alters keratinization of the hoof and hair. Toxicity occurs in any age, breed, or gender. The hair coat becomes rough, and there is a dramatic loss of mane and tail hairs. Generalized alopecia may also be visible. Lameness can be severe as the coronary band and hoof develop cracks and separate, and some hooves eventually slough (Fig. 18.30A–B).

A definitive diagnosis is made by history, clinical signs, and tissue analysis for selenium levels. Selenium in excess of 1 to 4 parts per million (ppm) from blood, 11 to 45 ppm for hair, and 8 to 20 ppm for the hoof indicates chronic toxicity. Horses should be moved from the selenium source as quickly as possible, but recovery is often prolonged and the prognosis for severely affected animals is poor. A high-protein diet rich in sulfa-containing amino acids and 2 to 3 mg orally per day of DL-methionine may be beneficial. The administration of inorganic arsenic and copper has been suggested as treatment.

Arsenic Toxicity

Clinical signs of chronic arsenic toxicity include a long hair coat, thinning of the mane and tail, and severe dry seborrhea. Horses also develop poor body condition and weight loss. At one time small doses of arsenic were commonly used in equine practice to improve hair coat and body condition, and this therapy may still be used by some veterinarians for this purpose.

Diagnosis is based on history of ingestion or treatment with arsenic or an arsenic-containing compound with the presence of compatible clinical signs. Definitive diagnosis is by measurement of arsenic levels in the kidney or liver (>10 ppm).[2] Reported treatments for chronic arsenic toxicity include sodium thiosulfate and dimercaprol.[2]

FIG. **18.30** Selenium toxicosis in a mare. Note the abnormal growth at the coronary band (A) and dramatic loss of main and tail hairs (B). (Photographs courtesy of Skip Aaroe.)

Mercury Toxicity

Mercury toxicity is rare in horses but can occur when the horse ingests feed contaminated with fungicide or ingests mercury from counterirritants. Mercury counterirritants can cause significant inflammation to the skin at the site of application and ulceration of the tongue and lips if the horse attempts to lick the substance. Systemically affected horses may have gastrointestinal disorders, depression, anorexia, and weight loss followed by generalized alopecia with subsequent loss of mane and tail hair. The diagnosis is confirmed by assaying kidney tissue in which mercury is concentrated. In addition to treatment with sodium thiosulfate and dimercaprol, orally administered potassium iodide at 4 g/day for 14 days may be beneficial.

Cutaneous Drug Reactions

Cutaneous drug reactions in horses are rare and represent an adverse reaction of the skin to any chemical compound that gains access to the skin by ingestion, injection, inhalation, or topical absorption. These reactions can occur on the first exposure to the drug, but the reaction itself may be delayed for weeks or months. It is most common, however, that the onset of the reaction occurs within 24 to 48 hours of drug administration. Drugs most likely to be involved in these eruptions include antibacterial agents (especially penicillin and sulfonamides), phenothiazine-based tranquilizers, nonsteroidal antiinflammatory agents, diuretics, and local anesthetic agents. Drug reactions are believed to involve type I, II, III, or IV hypersensitivity reactions. Urticaria is the most commonly observed sign and can be accompanied by intense pruritus, angioedema, diffuse erythema, bilateral symmetry of lesions, papular eruptions, sharply demarcated erosions and ulcerations, vesicular and bullous eruptions, photosensitization, and noninflammatory acquired alopecia. Once the drug's use is discontinued, signs may persist for varying time intervals ranging from several hours to more than 6 months. Differential diagnoses to consider include other types of hypersensitivities, systemic lupus erythematosus, and PF. Exposure to the causative drug should be carefully avoided in the future.

The diagnosis of a drug reaction depends on an accurate medication history. Skin biopsies may be helpful in supporting a clinical diagnosis. The most commonly reported patterns of inflammation are perivascular dermatitis and intraepidermal or subepidermal vesicular dermatitis.[1,2] The diagnosis may be confirmed by provocative challenge, but, as this may lead to anaphylaxis or death, it is not recommended.

Treatment requires removal of the offending drug, symptomatic therapy, and avoiding related compounds. Drug reactions usually subsides within 2 to 3 weeks but may persist for months.

Irritant Contact Dermatitis

Irritant contact dermatitis is fairly common in horses and, unlike allergic contact dermatitis, the offending substance invariably causes a reaction if left in direct contact with the skin; prior sensitization is not needed. The mechanism of irritant contact reaction depends on the causative chemical, but moisture and tissue maceration are important predisposing factors. Common irritating substances include feces, urine, wound secretions, caustic substances, crude oil, diesel oil, turpentine, blisters, leg sweats, improperly used insecticides, fly wipes, concentrated disinfectants, irritating plants, and soiled bedding.

No age, gender, or breed predilection exists for irritant contact dermatitis. Acute lesions are often erythematous, vesiculated, erosive or ulcerated, and painful. As the condition continues, necrosis, crusting, scaling, and hair loss occur. Leukoderma and leukotrichia are common and may be permanent. Pruritus and pain vary.

The diagnosis is determined from the history, clinical signs, and inspection of the horse's environment. Provocative testing is useful in identifying and confirming the causative agent, as long as the risk is minimal to the horse. Histologic examination of skin reveals necrosis, spongiotic vesicles, and ulceration.

Treatment requires identification and removal of the offending substance. One should wash affected areas daily with copious amounts of water and mild shampoo. Secondary bacterial infections should be addressed. Healing is usually rapid once the irritant is removed.

Irritant and Toxic Causes of Mucocutaneous Vesicles

Irritant reactions, toxic chemicals, or allergic reaction to drugs may result in oral mucocutaneous vesicles. One should

suspect these causes when lesions develop acutely in the absence of signs of systemic illness, in single animals within a herd, or in horses receiving medications or counterirritants. Some formulations of ivermectin dewormers, orally administered fluoroquinolone antibiotics, and NSAIDs are among the most common veterinary products to cause mucocutaneous vesicles. Mercurial compounds (commonly used in counterirritants) can also cause generalized hair loss, lameness, and emaciation in chronically intoxicated animals. Creosol and cantharidin beetles are common causes of oral ulcers. Foreign bodies such as grass awns may cause mucocutaneous ulceration and vesicles.

Envenomation

Many species of snakes, spiders, and insects have venomous bites and stings. Except for snakebites, these animals lack sufficient quantity of venom to cause more than transient pain or local inflammation. Venoms contain a variety of substances, including enzymes, peptides, polypeptides, amines, and glycosides, which act locally by causing tissue necrosis and vascular thrombosis and hemorrhage or systemically by causing widespread hemolysis and neurotoxicity.

Snake Bites

Of the poisonous snakes in the United States, bites from rattlesnakes, water moccasins, and copperheads are most common in horses.[51,52] The venom from snakes can be hemotoxic and proteolytic and produces extreme local swelling with significant tissue and red blood cell destruction.

Most bites occur in the spring and summer. Horses are most often bitten on the nose, head, neck, and legs. Snakebites may or may not involve envenomation. Bites in which no venom is injected swell minimally and are only slightly painful (dry bite). When envenomation occurs (wet bite), rapid swelling, pain, and local hemorrhage develop, usually within 60 minutes of the bite. Fang marks are often difficult to find because of tissue swelling. Edema, erythema, and tissue necrosis develop over days, and the skin may slough (Fig. 18.31). Bites occurring on the face or head are serious because of the risk of respiratory and nasal edema. If respiratory distress is severe, the horse will need a tracheotomy.

Snakebites should be treated symptomatically. The wound should be cleaned and hydrotherapy with cold water provided to minimize swelling. If swelling is already present, warm hydrotherapy may stimulate circulation and removal of tissue edema. Whether hydrotherapy increases the absorption of venom in the early stages of the bite is unknown. Broad-spectrum antibiotics are indicated to prevent secondary infection. The use of glucocorticoids is controversial but may be beneficial in decreasing inflammation and pain. Nonsteroidal antiinflammatory agents also may be beneficial. Surgical debridement and wound closure may be necessary if severe necrosis and sloughing occur. Although specific antivenoms are available, they are of limited use. Maximal benefit is attained only when they are administered within hours of the bite. The volume of antivenom necessary to treat snakebites in horses may be cost prohibitive.

Fire Ant Bites

Fire ants, *Solenopsis* spp., are common in the southern United States. Single or small numbers of stings are acutely painful, and pustules or crusts develop rapidly at the site. Horses are bitten most commonly on the legs, nose, and ventrum, but massive exposure can occur if the horse is bitten by hundreds or thousands of ants. Fortunately, horses that live in the southern regions quickly learn to avoid fire ant hills, and massive exposure is uncommon. Complications of massive exposure include infection, anaphylactic shock, bronchospasms, and sloughing of the epidermis. Single or multiple small numbers of solitary stings usually require little or no treatment. Applying an antibiotic ointment to minimize the chance of myiasis is prudent; otherwise, wounds heal without complication. If massive exposure has occurred, one may need to use systemic antibiotics and NSAIDs to decrease pain and swelling.

FIG. **18.31** Face of a horse after being bitten by an Eastern diamondback rattlesnake.

Spider Bites

Black, brown, and red widow spiders (*Latrodectus* spp.) and the brown recluse *(Loxosceles reclusa)* spider are common in America, whereas in Australia it is the black house spider *(Ixeuticus)* that causes painful, inflamed bite lesions. Spider bites are characterized by hot, edematous, painful swellings in the area of the bite. The brown recluse spider has a dermal necrotoxin that can cause significant dermal necrosis.

Treatment is symptomatic. Cold ice packs applied to the area, and systemic glucocorticoids or antihistamines, or both, may be helpful. Spraying the horse's environment with a parasiticide is important. Owners should clean the premises and remove materials that create areas for venomous spiders to hide.

IMMUNE MEDIATED SKIN DISORDERS

Hypersensitivity Reactions

Allergic dermatitis is common in equine practice and most often presents as urticaria and/or pruritus. Horses are frequently sensitive to multiple allergens, each of which contributes to the total antigen load and pruritic threshold, making it necessary to identify and correct as many factors as possible to obtain long-term control.

Urticaria (Hives)

Urticarial lesions (Fig. 18.32) are caused by dermal mast cell degranulation and release of active compounds, including histamine, platelet-activating factor, and prostaglandins. Relaxation of vascular smooth muscle cells and retraction of endothelial cells occurs and allows plasma to extravasate and form wheals. Nonimmunologic (physical) urticaria can be caused by heat, cold, pressure, and exercise. The surface of the lesions can appear normal, but with severe dermal edema serum will ooze to the skin surface, causing focal crusting and matting of the hair coat with focal hair loss. Lesions may manifest as singular eruptions, intermittent eruptions, or chronic recurrent urticaria. Wheal formations vary from 2 to 3 mm up to 20 to 40 cm. Papular wheals (3–6 mm) are often linked to biting insects. Giant wheal formation or polycyclic urticaria is often related to drug reactions. Annular wheals have a ring of edema surrounding a central, nonedematous depression. Angioedema is diffuse edema of the dermis and subcutis and is a significantly rarer manifestation of allergy than urticaria. Urticarial and angioedema lesions frequently resolve within 24 to 48 hours but may recur.

Insect bites are the most common cause of urticaria in the horse. Salivary antigens provoke an IgE-mediated inflammatory response that results in pruritus. Degranulation of mast cells and basophils causes the release of histamines, interleukins (ILs), prostaglandins, and kinins.

Treatment of acute urticaria usually includes glucocorticoid therapy. Specific treatment recommendations for acute and chronic urticaria are described in detail in the next section.

FIG. **18.32** Urticaria in a horse following the administration of penicillin.

Insect Bite Hypersensitivity

Insect bite hypersensitivity (IBH) is the most common allergic skin disease of horses[53] and ordinarily manifests as a chronic relapsing seasonal allergic dermatitis. In contrast to what the name implies, IBH is not simply a response to salivary antigens in the actual bite; rather, transcutaneous absorption and inhalation of desiccated insect parts can also incite the allergic response. Lesions are most common on the dorsal and ventral body. Affected horses may have crusted papules and evidence of self-trauma including ulcers and erosions, hair loss, lichenification, and pigmentary alterations. Chronic pruritic or nonpruritic recurrent urticaria may also be present. Some horses are so severely affected that they completely denude their entire mane and/or tail. Secondary bacterial infections and behavioral changes are common, and the disease can be a significant animal welfare issue in severely affected equids. Traditionally, IBH has been associated with insects of the genus *Culicoides;* biting midges, also known as no-see-ums; midgies; punkies; and sandflies, which belong to the Ceratopogonidae family. *Culicoides* are closely related to Simuliidae (black flies or buffalo gnats), which have also been implicated in IBH. *Haematobia* (horn flies), *Stomoxys calcitrans* (stable flies), mosquitos (Culicidae) and less commonly *Chrysops* (deer flies), *Musca* (houseflies), *Tabanus* (horse flies), bees, and wasps may also trigger IBH. Some horses have hypersensitivities to multiple biting insects.[54]

Insect hypersensitivity reactions are seasonal in colder climates but can be nonseasonal in warmer climates in which insects persist year around. Most horses with IBH begin to show clinical signs between 3 and 4 years of age; the hypersensitivity commonly exacerbates as the animal ages. There is no gender, breed, or color predisposition. Certain breeds appear to be at increased risk including Icelandic, Friesian, Arabian, and Quarter Horses. There is a demonstrated heritable component to IBH as well as an immunotolerance component, which has been demonstrated in Icelandic horses imported from Iceland in which *Culicoides* spp. are absent. Age at time of importation is positively correlated with the likelihood of development of IBH later in life. Of horses that were imported before they were 10 months old, only 6% developed IBH, whereas of those imported at 12 years of age 80% developed the disease.[55]

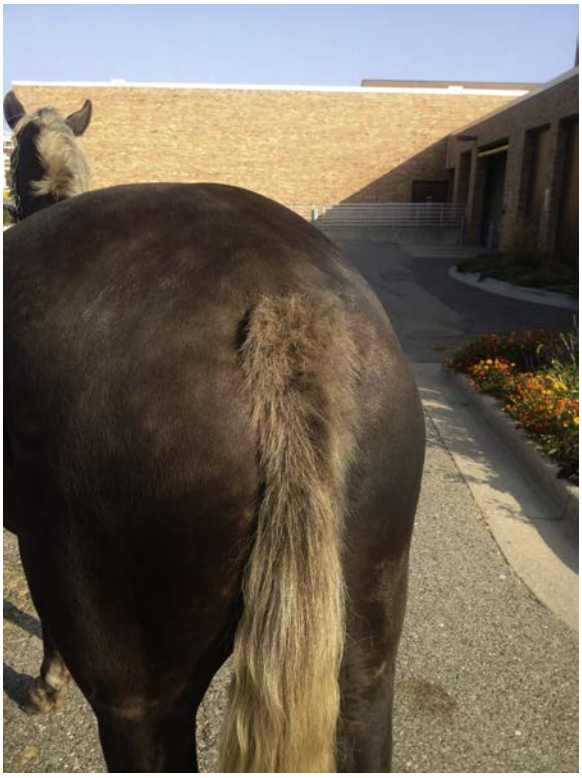

FIG. **18.33** A horse with *Culicoides* hypersensitivity. This horse has evidence of mane and tail rubbing and ventral midline dermatitis typical of this disease. Intradermal skin testing confirmed hypersensitivity to a number of additional antigens.

The distribution of IBH skin lesions varies and depends on the feeding preferences of the insect involved. Some *Culicoides* spp. commonly feed on the mane, tail, dorsum (Fig. 18.33), and ventral midline of the horse, but the face, ears, croup,

FIG. **18.34** Alopecia with some crusting around the umbilicus on a horse with horn fly infestation.

distal limbs, ventral trunk, and neck can be frequent feeding spots for other *Culicoides* spp. Black flies tend to feed on the head, ears, and ventral abdomen and may produce a generalized pattern of ventral midline edema. Horn flies typically feed around the umbilicus (Fig. 18.34). Mosquitoes prefer feeding on the lateral aspects of the body, but lesions associated with their bites may be more of a generalized papular urticaria or true hives. Stable flies prefer feeding on the lower legs but have also been known to feed on the ventral abdomen, chest, and back. The lesions in any given IBH horse may change over weeks to months as the specific population of *Culicoides* spp. or other insects present in the environment changes.

Some insects require a specific environment to propagate. Knowledge of these requirements may be helpful in establishing insect control programs. *Culicoides* spp. and mosquitoes prefer freestanding stagnant water for propagation, whereas black flies prefer moving water such as a stream, brook, or river. Horn flies are obligate parasites of cattle that require fresh cattle feces for reproduction. Several species of insects, including stable flies and houseflies, prefer decaying vegetation or manure for reproduction. They tend to be a bigger problem when sanitation practices at the stabling facility are problematic.

The time of day that an insect prefers to feed also differs among species. *Culicoides* spp. are often more active at night, and black flies are more active in the morning and late afternoon. Mosquitoes are most active at dusk and the first 2 hours after sunset. Horseflies, stable flies, black flies, and horn flies are usually active during the daylight hours. If the time of feeding is known for the potential offending insect, then the horse may be stalled during peak feeding hours to limit exposure.

The diagnosis of insect hypersensitivity is based on a compatible history, physical findings, and elimination of other causes of pruritus in the horse. Skin biopsies may reveal the presence of a superficial or deep perivascular eosinophilic dermatitis with epidermal spongiosis (intercellular edema of the epidermis), necrosis, and collagen degeneration. Although intradermal skin testing has been used to diagnose hypersensitivity, it is best used to confirm the allergens necessary for hyposensitization (see the section Treatment). The most important aspect of treatment for IBH is insect control. Fortunately, control measures are similar for most biting and flying insects (see Boxes 18.4 and 18.5). Additional treatment strategies are described in the next section.

Atopic Dermatitis

Atopy is the second most common form of skin allergy in the horse. It is an inherited hyperreactivity to environmental allergens that produce skin disease and, less commonly, respiratory disease. Atopy may also be associated with headshaking. Horses with atopy form sensitizing antibodies against a variety of antigens including grasses, pollens, dust mites, molds, trees, and fabrics. One or more of these allergens may be involved in any individual horse.[37]

A preliminary study on the skin barrier of atopic horses indicates that it is different from that of normal horses.[56] Similar abnormalities in the skin barrier in atopic dogs and humans are known to allow absorption of allergenic proteins, which are then carried to the lymph nodes. Naive T lymphocytes are activated, and IgE production is induced.[54] A variety of cytokines, including IL-4, IL-5, IL-6, IL-13, and IL-31, are released, and some stimulate itch.[54] Allergen-specific IgE binds to mast cells, basophils, Langerhans cells, and other cells within the skin and mucous membranes, and further allergens are captured. Subsequent exposure to the allergen results in amplification of the allergic response.[54]

Intradermal skin testing can be used to confirm that a horse has atopy and identify the allergens needed for hyposensitization treatment. Although serum allergy testing has also been recommended for this purpose, the sensitivity and reliability of the current tests are poor.[57] Additional strategies for treatment of atopy are provided later in this chapter.

Food Hypersensitivity

Food hypersensitivity is an immune-mediated adverse reaction to a feedstuff unrelated to any physiologic effect of the feed. Food can cause hypersensitivity by contact or ingestion. Food allergy might be suspected when a horse is presented with nonseasonal pruritic disease or urticarial signs. Pruritus and urticaria may be observed in areas less likely to be affected by an insect hypersensitivity; generalized or multifocal pruritus and urticaria are common ("grain bumps"). Pruritus limited to the base of the tail and anus would also increase the consideration of an adverse food reaction. Flaking, lichenification, and gastrointestinal signs may occur concomitantly.

There is no accurate in vitro or in vivo diagnostic test for food allergies in horses,[58] and allergen-specific immunotherapy (ASIT) for diagnosis of food allergy remains controversial. Lesions observed in skin biopsy specimens from affected horses are nonspecific (perivascular dermatitis with eosinophilia) and identical to those seen in specimens from horses with any other allergic skin disease.

Food allergies are classically considered to result from ingestion of specific feed types. In horses, however, allergic reactions to food may also occur through inhalation, or transdermal exposure. Dusty foodstuffs should be removed from the diet in case there is an inhalant allergen present. Hay and other feed storage should be investigated. Housing of the affected horse should be modified to avoid overhead storage of feed or exposure to the diets of other horses.

BOX 18.5 Parasite Control Strategies for Insect Bite Hypersensitivity

Medical treatments of insect bite hypersensitivity with corticosteroids, antihistamines, and topical shampoos or sprays is only palliative and must be coupled with practices aimed at reducing a horse's exposure to biting insects. These practices include but are not limited to the following management strategies.

USE OF INSECTICIDES AND PHARMACOLOGIC AGENTS

- Apply long-acting insect repellents twice daily, especially in the evening and early morning hours. Modern pyrethroids such as cypermethrin in combination with piperonyl butoxide to enhance potency are among the best choices. Long-acting fly repellents can also be applied to fly sheets.
- Long-acting "spot treatments" such as Vectra 3D (Ceva Animal Health, LLC, Lenexa, Kansas), which contains dinotefuran, pyriproxyfen (an insect growth regulator), and permethrin can be used. Three tubes of the "dog over 95 lb" size are used: one applied to the mane and face, one to the back and rump, and one to the ventral abdomen.
- Treatment with concentrated (44%–64%) permethrin products may result in hair loss and/or paresthesia at the site of application in the horse. Application of vitamin E oil to the application site prior to product use may mitigate this effect (Freedom 45 Spot-On [Star Horse Products NV, Carson City, Nevada].
- Insecticidal impregnated fly sheets are available and may be washed multiple times without a decrease in efficacy (Amigo Bug Blaster Fly Sheet).
- Place permethrin-impregnated tags in the mane, tail, and forelock.
- For those clients interested in natural fly repellents, Eco-Vet (Snohomish, Washington), a fatty acid-based fly repellent, is recommended.

OTHER MANAGEMENT STRATEGIES

- Use a fly sheet, fly mask with ear protection, and fly leg guards when the horse is turned out.
- Keep the horse stabled at times of day when biting insects are abundant.
- Use a good quality fan (industrial, appropriate for barn use) on the horse when the horse is stalled (many of the biting insects are poor flyers).
- Use automated fly sprayers in the affected horse's stall or throughout the stabling area.
- Use a Mosquito Magnet (Woodstream Corporation, Lititz, Pennsylvania) or similar system, which attracts and kills mosquitoes, black flies, *Culicoides,* sand flies, and other biting insects with carbon dioxide. An area the size of one acre can be controlled with the mosquito population collapsing in 6 to 8 weeks as egg-laying females are destroyed.
- Avoid turnout near insect havens such as bodies of water, manure piles, or cattle.
- Manage wet areas around the farm and routinely clean or treat water troughs.
- Use larvicidal feed supplements (SimpliFly, Farnam Corporation, Phoenix, Arizona).
- Place fly predator wasps (Spalding Laboratories, Reno, Nevada) in areas where manure accumulates.

The diagnosis of food allergy is most accurately made by eliminating the causative feed from the diet of affected horses through a food elimination trial. A complete dietary history is essential, and all components of the diet (concentrate, forage, and supplements) should be considered. A practical approach to a food elimination trial is to begin by eliminating any supplements and concentrates from the diet for 4 to 6 weeks. Major changes in diet (hay and grain) should be made gradually to prevent colic. The hay should be switched from grass hay to alfalfa or vice versa. After clinical signs disappear, feedstuffs are reintroduced to confirm that the pruritus is caused by a food allergy and that improvement was not coincidental. The offending substance is identified by reintroducing one dietary item at a time each week and observing the horse for recurrence of clinical signs, usually within 24 to 72 hours. The hypoallergenic diet is reinstituted until clinical signs subside.

Management of horses with food allergy consists of permanent dietary and pasture restrictions along with the administration of glucocorticoids and antihistamines on an as-needed basis. Omega fatty acid supplementation may be beneficial. Colloidal oatmeal shampoos can be used to minimize transdermal allergen exposure to feedstuffs. Additional information regarding treatment strategies is provided in the following section.

Contact Hypersensitivity

True contact allergies are rare in horses, perhaps in part because the hair coat acts as a protective barrier but may result from exposure to pasture plants, bedding, tack, and topical agents. Parasiticides and bath oils applied as insect repellents are some of the most commonly identified causes of contact allergy. Contact allergies, when they occur, are type IV hypersensitivity reactions. Potential allergens are usually small molecules that penetrate the skin, bind to dermal collagen or carrier proteins, and are taken up by antigen-presenting cells (Langerhans cells) in the dermis. On reexposure, an inflammatory response occurs that results in skin disease. Development of allergic contact reactions can takes months to years; a horse may suddenly develop clinical signs of a hypersensitivity reaction to a substance to which it has been exposed for years without prior incident.

Clinical signs of contact allergy vary and depend on the duration of the allergic reaction. Erythema, swelling, vesicles, papules, oozing, pain, or pruritus develops within 2 to 3 days of application of the offending substance. If untreated, lesions often progress over weeks or months to alopecia, lichenification, and crusting. The distribution of the lesions may suggest the cause: legs (plants and bedding); face and muzzle (plants and bedding); face and trunk (tack); and face, ear, neck, and trunk (insect repellents).

A definitive diagnosis of contact allergy is based on provocative exposure or patch testing. Provocative exposure requires avoiding the suspect substance for 10 days or until lesions resolve, reexposing the horse to the substance, and noting recurrence of lesions or clinical signs over the next 7 to 10 days. Provocative testing does not distinguish between an

irritant reaction and an allergic reaction but does identify the offending substance.

Patch testing requires the application of the suspect substance to an area of the skin for 48 to 72 hours. Plant material, bedding, or other particulate matter does not adhere well to the skin and is tested best under an occlusive dressing (closed patch test). For each test substance, a 3-cm^2 area of hair on the thorax or dorsum is clipped, a small amount of the suspect substance is applied to the skin, and the site is covered with a gauze sponge bandage for 48 to 72 hours. A control site should also be bandaged. On removing the bandages, the area is assessed for erythema, swelling, induration, pain, and exudation. Biopsies of the control should be obtained and the site or sites tested for histologic confirmation of the diagnosis. Liquid substances may be applied to the skin daily without using an occlusive bandage.

The suspected material should be removed from the horse's environment for a minimum of 10 days. After clinical signs regress the substance can be reintroduced. Signs of recurrence within 1 to 3 days provide a definitive diagnosis. If the causative agent cannot be identified, oral or topical glucocorticoids, mild cleansing shampoos, and omega fatty acid supplementation are used to reduce inflammation as described in the following section.

Treatment of Allergic Skin Disease

Elimination or reduction of allergen exposure is the optimum treatment for equine allergies, but unfortunately it can be impractical for many horses. Most affected horses are treated with some combination of management changes, ASIT, pharmacologic therapy, dietary supplementation, and medicated shampoos.

Pharmacologic Therapy. Corticosteroids have long been the preferred drug for pharmacologic management of allergy treatment despite their association with a variety of adverse effects. Laminitis is the most concerning potential adverse effect of corticosteroid therapy in horses, but polyuria, polydipsia, increased susceptibility to infection, mood changes, and increases in liver enzymes may also occur. The most commonly used corticosteroids for the short-term control of equine allergic reactions are prednisolone and dexamethasone. Precise treatment recommendations should be individualized for each patient and adjusted according to patient response. A suggested regimen for prednisolone is 0.5 to 1.5 mg/kg PO daily as an induction dose for 7 to 14 days and then tapered to 0.2 to 0.5 mg/kg every 48 hours for 2 to 5 weeks for maintenance. Administration of prednisolone in the morning before 9 a.m. may lessen the likelihood of the development of laminitis, possibly because it is consistent with the natural diurnal rhythm of cortisol production in the horse.[59] A recommended loading dosage for dexamethasone is 0.05 to 0.1 mg/kg, PO, IM, or IV, every 24 hours for 4 to 7 days, decreasing to a maintenance dose of 0.01 to 0.02 mg/kg every 48 to 72 hours. The injectable dexamethasone formulation can also be administered orally, but the bioavailability is only 60% to 70%. The decrease in bioavailability observed with oral dosing should be considered when developing a tapering dosage regimen for a patient.

Long-term glucocorticoid use is not recommended if it can be avoided. Antihistamines and tricyclic antidepressants may be used to reduce the dosage and length of glucocorticoid treatment. Commonly used agents include cetirizine at 0.2 to 0.4 mg/kg PO every 12 hours and hydroxyzine hydrochloride or pamoate 0.5 to 1 mg/kg, PO, every 8 to 12 hours. Alternatives include doxepin (0.5–0.75 mg/kg, PO, every 12 hours), chlorpheniramine (0.25–0.5 mg/kg, PO, every 12 hours), diphenhydramine (1–2 mg/kg, PO, every 8–12 hours), and pyrilamine maleate (0.8–1.32 mg/kg IV, IM, or subcutaneously; may be repeated in 6–12 hours if needed). Generally, oral dosing of antihistamines is preferred because of the potential for adverse reactions with IV administration. Because there can be significant variation in the response to these agents, it may be necessary to try drugs from different classes at 2-week intervals to find an effective treatment. Adverse effects associated with antihistamines include sedation and behavior changes.

Pentoxifylline (8–10 mg/kg, PO, every 8–12 hours) is a phosphodiesterase inhibitor with steroid-sparing, immunomodulating effects that can further improve the clinical signs in allergic horses. It alters T- and B-cell activation and proliferation, decreases leukocyte adhesion and aggregation, and lessens the response to inflammatory cytokines. Pentoxifylline also has rheologic effects that may minimize laminitis risk with corticosteroid therapy.

Allergen Specific Immunotherapy. The goal of ASIT or hyposensitization is to redirect the immune response to an allergen to reduce the hypersensitivity reaction. The precise mechanism(s) of action for ASIT is unknown, but several theories have been proposed. These include the production of blocking antibodies by shifting the immune response from one dominated by IgE to one dominated by IgG, altering the proportion of type 1 and type 2 T-helper cells, and induction of regulatory T cells. The percentage of horses that respond to ASIT varies between 60% and 85% and may be related to antigen preparation. ASIT may take 1 to 24 months (average 3–6 months) before effects are recognized. Because ASIT therapy is not prohibited for competition horses, it is a potentially useful therapy for this population. Unlike other treatments, ASIT may result in remission of the allergy. ASIT has been recommended for long-term control of insect hypersensitivity, recurrent urticaria, and atopy. Other therapies such as corticosteroids, antihistamines, and fatty acids may be used concurrently with ASIT to treat allergic skin disease.

Dietary Supplementation. Omega fatty acids can act synergistically with steroids and antihistamines to decrease inflammation. Fresh ground brown flax by itself has an antiinflammatory effect in the skin of allergic horses.[60] Whole flaxseed is chemically stable but will pass through the equine gastrointestinal tract intact, and ground flaxseed can become rancid at room temperature within 7 to 10 days. Whole flaxseed can be ground to an appropriate form using a small coffee grinder and fed to horses at a rate of 0.5 to 1 lb daily for a 500-kg horse. A large variety of fatty acid supplements are commercially available in capsule, powder, pellet, or oil formulations.

Medicated Shampoos. The major route of allergen delivery in humans and dogs is transcutaneous. It is unknown whether this is true for horses, but topical therapy with appropriate shampoos does appear to significantly increase comfort level and decrease the need for systemic medications presumably by removing surface irritants, bacteria, allergens, and the pruritic load. Rehydration of the skin improves the integrity of the epidermal barrier.

Horses should be bathed in cool water, which will constrict surface vessels and minimize the release of histamine and delivery of other inflammatory mediators to the skin. Surface cleaning of the skin with a nonirritating cleanser such as diluted Ivory dish soap before the use of

the medicated shampoo may be necessary for the extremely dirty horse; however, shampoos with a strong detergent component may strip the skin of ceramides and other fats important in maintaining the skin's natural barrier to allergens. Contact time (generally 10–15 minutes) is an important consideration in medicated shampoo use. Moisturizing hypoallergenic shampoos and/or colloidal oatmeal shampoos are available from a variety of manufacturers and suppliers. These shampoos help raise the pruritic threshold by cooling and moisturizing dry skin. Products that contain local anesthetics, such as pramoxine, can provide relief at least for short periods. Shampoo, sprays, and mousses containing chlorhexidine, ketoconazole, and benzoyl peroxide can help reduce secondary infections of the skin. Antibacterial shampoos can be used to reduce secondary infections and do not require the lengthy contact time of the moisturizing and colloidal oatmeal shampoos; leaving antibacterial shampoos on the horse for long periods of time has resulted in skin irritation in some horses.

Other Therapies. Anecdotal reports suggest possible benefits from a wide variety of other therapies for allergic horses. Methylsulfonylmethane (MSM), a DMSO derivative with antioxidant properties, may be effective as an aid to relieve pruritus associated with equine insect hypersensitivity. MSM is administered at 10 to 12 g/500 kg PO q 12 h initially and then tapered to q 24 h. Preliminary studies in tissue culture of equine fibroblasts indicate that avocado-soybean unsaponifiables are effective antiinflammatory agents for skin when administered at the high end of label directions.

Anecdotal reports also suggest that oclacitinib (Apoquel; Zoetis, Parsippany, NJ), a Janus kinase inhibitor that has been successful in the control of allergic dermatitis in dogs, has a positive effect in horses when administered at 0.25 mg/kg PO q 12 h for 14 days.

Pemphigus Foliaceus

PF is an uncommon but potentially life-threatening autoimmune disease of the skin. Affected horses produce autoantibodies directed against the surface proteins of keratinocytes that mediate intercellular adherence. Autoantibodies against desmoglein-1 and desmoglein-3 (DSG-1 and DSG-3) destroy the bonds that maintain cell-to-cell adhesion.[59] The cells separate from one another, leaving a space that fills with fluid, resulting in a blister or pustule close to the horse's skin surface. Although these early lesions are the preferred biopsy sites, they are quite fragile and rupture quickly after being formed. This leads to oozing, crusting, scaling, and erosions of the horse's skin (Fig. 18.35), which are the most common signs of PF.[61] Some horses may develop acute, recurrent, or chronic hives before progressing to fulminant PF. A number of horses with PF develop significant alopecia. Lesions commonly begin on the face, legs, or abdomen and spread quickly over the next 1 to 3 months. Occasionally horses have lesions that localize to the face or coronary band for prolonged periods. A number of horses with PF have considerable swelling of their distal limbs and ventral abdomen with or without pain or pruritus and in the absence of hypoproteinemia. Many horses are in so much pain they are reluctant to move and can exhibit systemic signs such as fever, depression, lethargy, anorexia, and weight loss.

Although Appaloosas, Quarter Horses, and Thoroughbreds have been implicated as being predisposed, any breed can develop PF, and there is no reported age or gender predisposition.[62] Some studies indicate a seasonality to PF (between September and February),[63] which suggests that

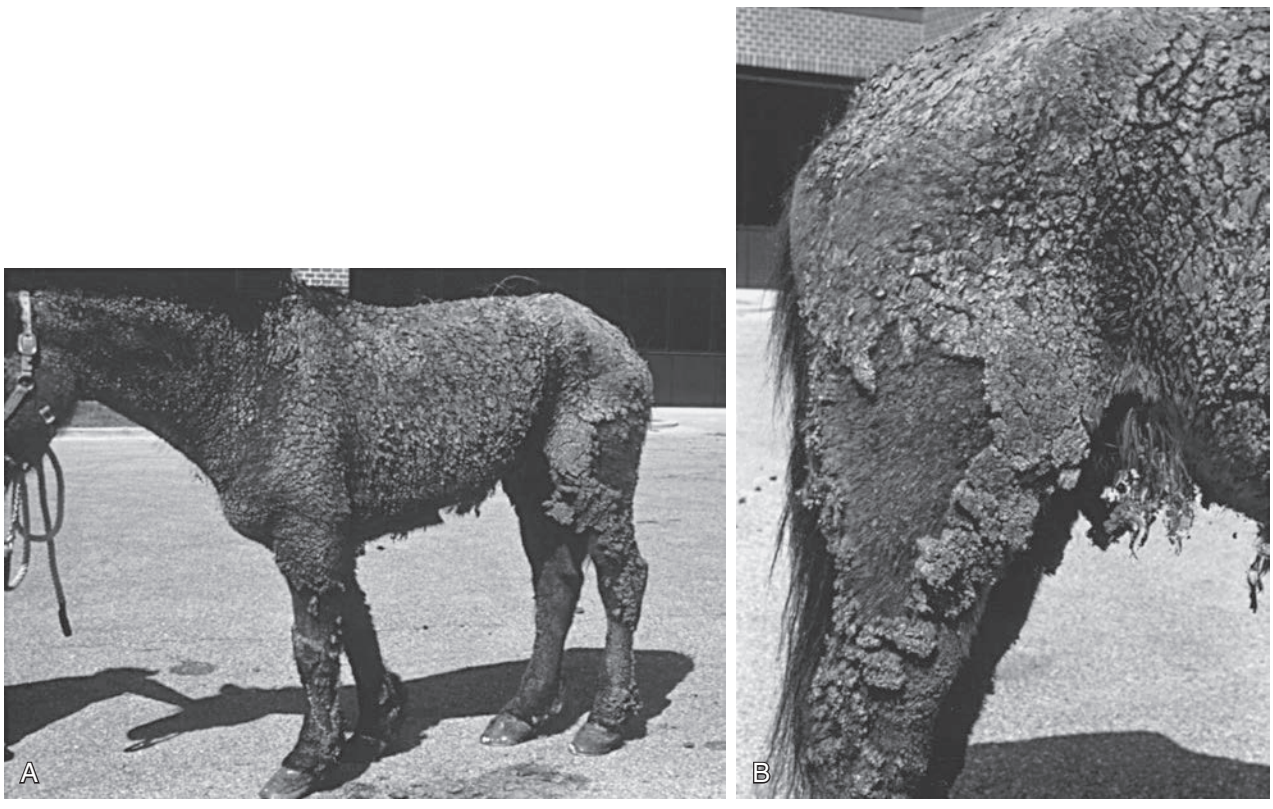

FIG. **18.35** (A) Pemphigus foliaceus in a horse. (B) Skin with significant crusting.

insect hypersensitivity, seasonal allergens such as pollens, and ultraviolet light may be predisposing or initiating factors in some horses. Drugs often used during this time frame such as antibiotics, dewormers, vaccines, and some supplements may also be involved.

It can be challenging to confirm a diagnosis of PF in horses. Early stages may be confused with allergic reactions such as drug or insect allergies, dermatophytosis, dermatophilosis, lymphoma, and defects in keratinization such as cannon keratosis. Other diseases should be ruled out with appropriate tests (special stains, fungal cultures, etc.). A tentative diagnosis of PF may be made based on impression smears of the content of intact pustules or the underside of exudative crusts (Fig. 18.36). Rafts of deeply basophilic acantholytic cells and nondegenerate neutrophils are highly suggestive of this disease.

Definitive diagnosis is made by routine histologic examination of a skin biopsy specimen. Submitting a skin biopsy with intact crusts attached to the underlying skin or hairs is critical. Histologically, PF is characterized by intragranular to subcorneal acantholysis. Layered rafts of acantholytic cells within crusts interspersed among neutrophils may be observed. A minority of horses with PF will have a predominance of eosinophils in the inflammatory infiltrate.[64] Direct immunofluorescence is unreliable for diagnosis but, if positive, reveals diffuse intercellular fluorescence.

The mainstay of treatment is high doses of glucocorticoids such as prednisolone at 1.0 to 2.5 mg/kg orally in the morning every 12 hours until no new lesions develop, which usually occurs within 7 to 10 days, at which time tapering over several weeks is indicated.[59] A maintenance dose of 0.5 mg/kg to 1 mg/kg every 48 hours is administered indefinitely. Alternatively, an immunosuppressive dose of dexamethasone can be administered at 0.02 to 0.1 mg/kg per day for 7 to 10 days and subsequently tapered to 0.01 to 0.02 q 48–72 h.

Chrysotherapy (gold salts) has also been used successfully in horses with PF. Unfortunately, aurothioglucose (Solganal; Schering Corporation, Kenilworth, NJ) is no longer available, but aurothiomalate (Myochrysine; Merck and Co., White House Station, NJ) can be used. Test doses of 20 and 50 mg are given at weekly intervals to evaluate for potential adverse effects (eosinophilia and cutaneous reactions). If no adverse reactions occur, an induction dose is given at 1 mg/kg IM weekly with a long lag phase of 6 to 12 weeks before a positive response is noted. Monitoring for stomatitis, urticaria, skin sloughing, blood dyscrasias, and proteinuria is recommended. If no adverse effects are observed, weekly therapy is continued at 1 mg/kg IM until control is achieved (6–12 weeks). Maintenance therapy is tailored to the individual animal, which may involve biweekly or monthly therapy. Complete remission of clinical signs may not be possible to achieve even with combination therapy. Weekly monitoring of a complete blood count and urinalysis is recommended for the first month and then monthly if no abnormalities are observed. Azathioprine has been administered as a steroid-sparing drug to treat equine PF. The recommended dosage for azathioprine is 1 mg/kg per day orally for 14 days then every other day or 2.2 mg/kg every other day orally. The use of omega fatty acid supplements such as fresh ground flax and bathing horses with PF in cool water may make them more comfortable.

Spontaneous regression has been reported in rare cases of young horses with PF, but most horses will require long-term if not lifelong treatment. Generally, younger horses are more likely to achieve remission than older horses and tend to have less severe disease and respond better to treatment. Unfortunately, regardless of age approximately 50% of horses that initially respond to treatment relapse and become progressively less responsive to treatment with each relapse. Horses are frequently euthanized because of the disease or because they develop laminitis possibly related to glucocorticoid treatment. Some horses die acutely when treatments fail.

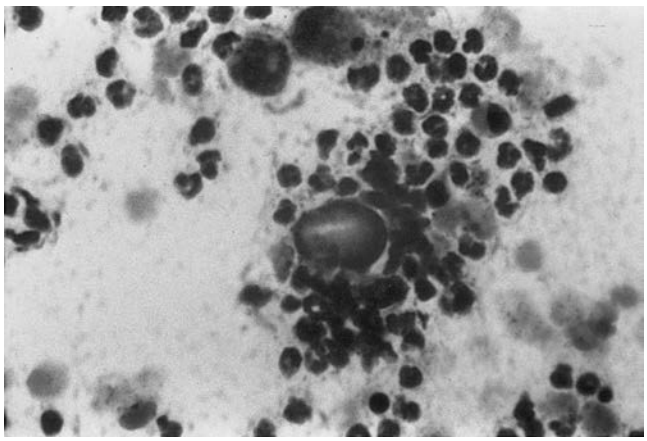

FIG. **18.36** Cytologic appearance of a touch preparation from a pemphigus lesion. Rounded cells (acanthocytes) are notable.

Pemphigus Vulgaris

Pemphigus vulgaris (PV) and bullous pemphigoid are less common than PF in horses and have a poorer prognosis.[61] Lesions of PV occur in the mouth and at other mucocutaneous junctions where vesicles, bullae, and painful ulcers are common. The immune reaction occurs at the basement membrane in which immunofluorescence has identified circulating anti-DSG-3 IgG in affected horses. Similar to PF, lesions can also occur in the mane and tail and on the coronary bands. Despite aggressive therapy the prognosis remains grave. On necropsy, horses with PV may have ulcerations in the esophagus and stomach.

Bullous Pemphigoid

Of the autoimmune diseases that make up the pemphigus complex, bullous pemphigoid is the rarest and has the poorest prognosis.[61] Similar to pemphigus vulgaris, crusts and ulcers are common, and ulcers can extend throughout the gastrointestinal tract.[61] Skin lesions occur in the axilla and groin. Vesicles and bullae rupture easily and are often crusted; secondary bacterial infections may occur. Pain, pruritus, anorexia, fever, and salivation are common.

The immune reaction in bullous pemphigoid occurs when antibody binds to the basement membrane zone and complement fixation occurs, resulting in production of inflammatory mediators chemotactic for neutrophils and eosinophils. These cells release proteolytic enzymes that disrupt the dermal-epidermal cohesion, resulting in subepidermal cleft and vesicle formation. Acantholysis is absent in this disease. A definitive diagnosis is made by eliminating other causes of vesicular lesions and by skin biopsy. Biopsy of a vesicle or intact bullae is essential; biopsy of crusted or ulcerative lesions will be nondiagnostic. Bullous pemphigoid is characterized by subepidermal vacuolar alterations and subepidermal clefts and vesicles.[1] Neutrophilic and eosinophilic

infiltration of the superficial epidermis is common. Immunohistochemistry and immunoserology are becoming increasingly helpful in the diagnosis of autoimmune blistering diseases. There are few reports of the treatment of bullous pemphigoid in horses.[1,2] Treatment is the same as that for PF but is generally less successful.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a multisystemic autoimmune disease that is rare in horses.[61] Clinical signs of SLE include weight loss, bilaterally symmetric alopecia, seborrhea, oral ulceration, and lymphadenopathy. Necropsy findings may demonstrate membranous glomerulonephritis and fibrous synovium. Some horses have concurrent Coombs test-positive hemolytic anemia and positive antinuclear antibody test results. Histologic evaluation reveals interface dermatitis with linear deposition of IgG at the basement membrane zones of the epidermis and hair follicles. In some horses with systemic lupus, profound lymphedema of the lower limbs may be the only clinical sign. The disease is treated with immunosuppressive doses of glucocorticoids similar to those of PF. The prognosis for horses with SLE is poor.

Discoid Lupus Erythematosus

Discoid lupus erythematosus is a rare skin disease in horses that is believed to be a variant of SLE. Affected horses develop areas of patchy erythema, crusting alopecia, and scaling on the face, ears, and neck. The disease can be limited to the coronary bands with or without involvement of the chestnuts and ergots in some horses. The affected coronary bands can become crumbly and exudative. Pain and lameness may occur; however, some horses with significant coronary band lesions remain surprisingly sound. Leukoderma and leukotrichia may be present.

The diagnostic test of choice is a skin biopsy. Because full-thickness biopsy of the coronary band will result in permanent abnormality of the hoof wall, biopsy of the chestnut is preferred when lesions also occur at that site. The skin biopsy reveals an interface dermatitis (hydropic or lichenoid or both). Focal hydropic degeneration of basal epidermal cells, pigmentary incontinence (pigment granules in the dermis or in dermal macrophages), and focal thickening of the basement membrane are important histologic features. Direct immunofluorescence testing may show a linear deposition of immunoglobulins at the basement membrane zone. This test is not reliable and is not recommended as a substitute for a routine histopathologic study.

Discoid lupus erythematosus is treated on an individual basis. Ideally the owner should stable the horse during daylight because sunlight aggravates the disease. Topical sunscreens and topical glucocorticoids, for example, 0.1% betamethasone 17-valerate, may be beneficial. Severe or refractory cases of discoid lupus erythematosus may require immunosuppressive doses of oral prednisolone.

Immune-Mediated Vasculitis

Vasculitis is an inflammatory reaction occurring in the wall of the blood vessel (Fig. 18.37). Vasculitides are classified by inflammatory cell type. Neutrophilic vasculitides are subdivided further into leukocytoclastic (neutrophil nuclei undergo karyorrhexis) or nonleukocytoclastic.

The immunologic mechanisms involved are typically type I and type II hypersensitivity reactions. Equine viral arteritis, equine influenza, *C. pseudotuberculosis,* and *Streptococcus* spp. (especially *S. zooepidemicus* subsp. *equi*) infections have been postulated to be precipitating factors for immune-mediated vasculitis.[65] Vasculitis also may occur following *Rhodococcus equi* pneumonia, cholangiohepatitis, and some antibiotic treatments. Often the underlying cause is not identified.

Idiopathic vasculitis has no known breed, gender, or age predilection. The most common locations for lesions are the distal limbs, ears, lips, and periocular areas.[2] Oral ulcers and bullae may be present. Skin lesions consist of purpura, edema, and erythema. Systemic signs may include pyrexia, depression, anorexia, weight loss, and lameness.

Purpura hemorrhagica is an acute noncontagious disease of horses characterized by extensive edema and hemorrhage of the subcutaneous tissue. Hemorrhage in the mucosae and viscera are common. Clinical signs usually develop within 2 to 4 weeks of a respiratory tract infection, frequently strangles or influenza. Urticaria followed by pitting edema of the distal limbs, head, and ventral abdomen is common. Severe edema of the head may compromise breathing. Tissue exudation and sloughing may occur. Pain and pruritus are rare. Affected horses usually are depressed, reluctant to move, and often anorectic.

Diagnosis of vasculitis is by skin biopsy. Obtaining skin biopsy specimens from lesions 8 to 24 hours of age is important because these lesions tend to have the most diagnostic changes. Lesions more than 24 hours old may be nondiagnostic because of intense secondary cellular infiltrates or necrosis. Skin biopsy reveals neutrophilic, eosinophilic, lymphocytic, or mixed cellular infiltrates in the vessel wall. Fibrinoid degeneration and hemorrhage are common. Direct immunofluorescence testing is occasionally useful as an adjunct diagnostic aid.

FIG. **18.37** Horse with vasculitis resulting from strangles.

Prognosis for horses with vasculitis is unpredictable. Therapy for vasculitis is discussed in Chapter 15.

NECROTIZING SKIN DISORDERS

Necrotizing skin diseases develop from a wide range of causes. The unifying characteristic is that each of these diseases may cause local or widespread full-thickness death of the skin, sloughing of tissue, ulceration, and exudation. A definitive diagnosis of the underlying cause may be difficult in some cases.

Decubital Ulcers

Decubital ulcers (pressure sores, saddle galls, and saddle sores) are caused by prolonged pressure to the skin, usually over a bony prominence. Thin and emaciated animals that spend a significant time in recumbency are at greatest risk for development of decubital ulcers. Decubital ulcers may develop from poorly fitting tack on the back, neck, or girth of the horse; from recumbency during surgery; improperly applied or maintained casts; leg wraps; or elastic bandages. The amount of pressure required to create a decubital ulcer is not great if the pressure occurs for an extended period of time. Tack and saddles may cause lesions over bony prominences or other areas subjected to prolonged pressure. Capillary circulation is stopped or severely limited, resulting in tissue anoxia and retention of metabolic wastes with tissue damage and death. Most lesions begin as small areas of tissue necrosis and progress to areas of ulceration. Secondary infections are common.[2]

Clinically, early lesions begin with hair loss, swelling, and erythema. A red-purple area of tissue discoloration may be visible. Within a few days, oozing, necrosis, and ulceration become visible. In severe cases the skin loses its elasticity, subcutaneous tissues slough, and the skin may harden. Strands of living tissue may be attached to necrotic tissue. Lesions are often malodorous. Healed lesions tend to scar, and leukotrichia or leukoderma are common sequelae.

The diagnosis is based on history and clinical examination. Areas of skin that have lost sensation or have a parchment-like feel should be suspect.

Treatment can be difficult if the horse remains recumbent. Because of the significant capillary and venous congestion, systemic antibiotics are often not effective. Wounds are managed best topically. Wounds should be cleaned daily with copious amounts of water to remove tissue debris and stimulate circulation, and topical antibiotic creams or ointments (i.e., iodine and chlorhexidine) should be applied to prevent secondary infection and to prevent the wound from becoming desiccated. Reepithelialization and wound healing greatly improve with the use of surgical dressings, but bandaging some lesions may be a challenge, such as those that occur over the wing of the ilium. In these instances, using super glue to build a frame around the lesion, which can be used to anchor elastic tape covering a donut type of padding, may be useful. Surgical debridement and skin grafting may be indicated in some cases.

Gangrene

Gangrene is a clinical term used to describe wet or dry tissue necrosis. Gangrene may result from external pressure, severe edema, burns, frostbite, snakebites, vasculitis, ergotism, fescue toxicosis, bacterial sepsis, or viral infections.[2] The characteristic lesion results from occlusion of the venous or arterial blood supply.

Dry gangrene occurs when the arterial blood supply to an area is occluded but the venous or lymphatic drainage is intact. Wet or moist gangrene is caused by occlusion or impairment of lymphatic and venous drainage plus putrefaction caused by a bacterial infection. Lesions of dry gangrene are dry, leathery, discolored, sunken, and cold to the touch. The skin may take a long time to slough. Lesions of wet gangrene are swollen, discolored, and malodorous.

The diagnosis is most often made by clinical examination and confirmed by biopsy. The primary cause of gangrene must be identified and treated.

Thermal Injuries

Burns

Excessive heat (burns) can occur from barn fires, brush fires, hot solutions, lightning, electrocution, rope burns, counterirritants, or radiation. Barn fires are the most common cause of severe burns in horses.

Large thermal injuries in horses are difficult to manage.[66] The large surface area of the burn dramatically increases the potential for fluid, electrolyte, and caloric losses. Depending on the depth of the burn, burns that cover 50% or more of the body are usually fatal.[66] Wound contamination is difficult to prevent because of the lack of a sterile environment. Horses may require long-term restraint to prevent continued trauma; wounds are often pruritic, and self-mutilation is common. Badly burned horses are frequently disfigured and have poor quality scar tissue preventing them from returning to full function.[66]

Burns are classified by the depth of the injury.[66] First-degree burns involve only the most superficial layers of the epidermis. These burns are characterized by erythema, edema, desquamation of superficial layers of the skin, and pain. The germinal layer of the epidermis is spared, and these burns heal without complication. Second-degree burns involve the entire epidermis and may be superficial or deep. Superficial second-degree burns involve the stratum corneum, stratum granulosum, and a few cells of the basal layer. Deep second-degree burns involve all layers of the epidermis. Clinically, these burns are characterized by erythema, edema at the epidermal-dermal junction, necrosis of the epidermis, accumulation of white blood cells at the basal layer of the burn, eschar (slough produced by a thermal burn) formation, and minimal pain. The only germinal cells spared are those within the ducts of sweat glands and hair follicles. Second-degree burns generally heal well with appropriate wound care. Third-degree burns are characterized by loss of epidermal and dermal components. Fluid loss occurs, along with significant cellular response at the margins and deeper tissue, eschar formation, lack of pain, shock, wound infection, and possible bacteremia and septicemia. Healing is by contraction and epithelization and occurs only from the wound margins. Infection and problems with wound healing frequently complicate these burns. Fourth-degree burns involve all the skin and underlying muscle, bone, and ligaments.

Burns cause local and systemic effects.[66] Local tissue damage results from massive protein coagulation and cellular death. In the immediate area of the burn, arteries and venules constrict and capillary beds dilate. Capillary wall permeability increases in response to vasoactive amines released as a result of tissue damage and inflammation.[66] These vascular responses result in fluid, protein, and

inflammatory cells accumulating in the wound. Vascular sludging, thrombosis, and dermal ischemia occur, resulting in further tissue damage. The tissue ischemia continues for 24 to 48 hours after the injury and is believed to be caused by the local release of thromboxane A_2. Lipid layers in the skin are destroyed, and a fourfold increase in the loss of fluid occurs. Fluid losses result in increased heat loss from evaporation and an increased metabolic rate. The full extent and depth of the burn may not be evident for several days. Neutrophil function and chemotaxis greatly decrease, predisposing the wound to local infection, bacteremia, and septicemia. The following microorganisms frequently colonize burns: *P. aeruginosa, Staphylococcus, E. coli, Klebsiella* spp., nonhemolytic *Streptococcus* spp., *Proteus* spp., *Clostridium* spp., and *Candida* spp.[13,67,68] Systemic effects are life-threatening and include hypovolemia, fluid and electrolyte losses, protein loss, pulmonary edema, anemia, increased basal metabolic rate, increased caloric needs, and depressed cell-mediated and humoral immune responses. Hypovolemia exacerbates a decrease in cardiac output after a circulating myocardial-depressant factor.

First-degree burns and superficial second-degree burns should be treated immediately with cold water to prevent further tissue necrosis. A water-soluble antibacterial cream should be applied to the wound to prevent infection. Nonsteroidal analgesics should be administered to alleviate pain and to help reduce dermal ischemia. Aspirin at 10 to 20 mg/kg orally once or twice daily decreases thromboxane production, may halt further dermal ischemia, and may be the initial drug of choice if pain is otherwise controlled.

Full-thickness burns (third and fourth degree) are treated by occlusive dressing (closed technique), eschar production (exposure technique), continuous wet dressings (semiopen technique), or excision and grafting techniques. The most practical therapy for large burns in horses is the semiopen method, leaving the eschar intact with continuous application of moist bandages and antibacterial agents. The moist dressings help prevent heat and moisture loss from the eschar, provide protection of the eschar, and help prevent bacterial invasion in the wound.

Systemic antibiotics should be used with caution, and in the absence of sepsis systemic antibiotics are contraindicated. Topical medications should be a broad-spectrum, nonirritating water-based cream such as silver sulfadiazine, which is effective against gram-negative bacteria, causes no discomfort to the horse, penetrates eschar, and has a 24-hour duration of action. Aloe vera is reported to relieve pain, decrease inflammation, stimulate cell growth, and kill bacteria and fungi. Aloe vera is most useful in the early treatment of mild burns. Horses with severe burns often succumb to respiratory disease secondary to smoke inhalation. Damage to the corneas is also common. Several excellent references for further information on long-term medical and surgical management of horses with large thermal burns are available.[66]

Frostbite

Frostbite occurs when tissue is exposed to extreme cold. Sick, debilitated, and neonatal animals are at increased risk. Cold temperatures inhibit cell metabolism and cause tissue dehydration, cell disruption by ice crystals, ischemia, and vascular damage. The most commonly affected areas are the glans penis, ear tips, coronary bands, and heels.[1,2] The initial lesion of frostbite is paleness of the skin. Erythema, scaling, and hair loss follow. Pigment loss may occur. In severe cases, necrosis and dry gangrene occur.

Mild cases of frostbite do not require treatment. More severe cases require rewarming and the application of antibiotic ointments without steroids to the area. In severe cases with necrosis and sloughing, topical wet soaks and symptomatic therapy with antibiotics may be needed to prevent sepsis. Surgical debridement should not be attempted until an obvious demarcation is present between viable and nonviable tissue. Previously frostbitten areas may be more susceptible to cold injury in the future.

Photosensitization

Photosensitization occurs when skin is exposed to ultraviolet light after being sensitized by photodynamic agents. It is an uncommon cause of dermatitis but a potentially serious problem in horses. The spectrum of disease associated with photosensitization ranges from being a simple nuisance to a life-threatening crisis.[69]

Pathogenesis

Photodynamic agents responsible for photosensitization can be phototoxic or photoallergic. Phototoxic agents produce a photosensitivity reaction in almost all animals under suitable conditions. Photoallergic agents require the animal to be sensitized to the compound. Both types of photodynamic agents reach the skin via the bloodstream or by direct contact in which they absorb wavelengths of ultraviolet or visible light that exceeds the UV-B range and become activated, ultimately damaging the epidermis and superficial blood vessels.

Four types of photosensitization are recognized in animals: primary photosensitivity (type 1 photosensitivity), hepatogenous photosensitivity (type 2 photosensitivity), photosensitivity from aberrant pigment synthesis (porphyria), and photosensitivity of uncertain etiology.

Primary photosensitization results when the photodynamic agent is ingested, systemically administered (certain antibiotics), or absorbed through the skin. Ingestion is typical of plants like St. John's wort *(Hypericum perforatum),* buckwheat (*Fagopyrum* spp.), spring parsley *(Cymopterus watsonii),* and *Ammi* spp. St. John's wort contains a red fluorescent pigment called *hypericin*. It is present in the plant's leaves as clear small dots. Clinical signs appear within 21 days. Primary photosensitization from other plants is uncommon in the horse.[69]

Contact photosensitization is associated with pastures that contain legumes like clovers. Horses with signs of contact photosensitization should be evaluated for liver disease, because some clovers can cause both contact and hepatic photosensitization. Many drugs and chemicals cause primary photosensitization through various mechanisms (see Table 18.3). Fly sprays, antimicrobial soaps, and tetracycline antibiotics are common sources.

Hepatogenous photosensitivity develops secondary to hepatic injury. When liver function is compromised, the liver cannot excrete phylloerythrin (a degradation product of chlorophyll), and it accumulates. Phylloerythrin is a photodynamic agent, and high levels render the animal photosensitive. Clinical signs develop when phylloerythrin concentrations are greater than 8.0 μg/dL. Hepatogenous photosensitization may develop secondary to liver damage and cholestasis, but it is often caused by ingestion of toxic plants and mycotoxins (see Table 18.4).

TABLE **18.3 Causes of Primary Photosensitization**

Substance	Photodynamic Agent
PLANTS	Hypericin (ingested)
Hypericum perforatum (St. John's wort, goat weed, Klamath weed), *H. pseudomaculatum* (large St. John's wort), *H. punctatum* (spotted St. John's wort)	
Fagopyrum esculentum, F. sagittatum, F. tatoricum (buckwheat)	Fagopyrin, photofagopyrin, pseudohypericin (ingested)
Cymopterus watsonii (spring parsley)	Furocoumarins
Ammi majus (Bishop's weed)	Furocoumarins
Thamnosma texana (Dutchman's breeches)	Furocoumarins (ingested)
Lolium perenne (perennial rye grass)	Perloline (ingested)
Froelichia humboldtiana	Naphthodianthrone derivative
Medicago denticulate (burr trefoil)	Aphids
Trifolium hybridum (alsike clover), *T. pretense*	Ingested and possibly contact with unknown photo and hepatotoxin
Medicago spp. (alfalfa)	Unidentified
Sphenociadium capitellatum (whiteheads, ranger's buttons)	Ingested—unidentified agent
Heracleum mantegazzlanum (giant hogweed)	Furanocoumarin (contact)
Cooperia pedunculata (rain lily)	Unidentified agent
Avena sativa (oats)	Unidentified agent
Brassica napus (rape)	Unidentified agent
Brassica rapa (mustard)	Unidentified agent
Vicia spp. (vetches)	Unidentified agent
MYCOTOXINS	
Fungi on celery and parsnips	Phytoalexins (xanthotoxin, tripsoralen)
DRUGS AND CHEMICALS	
Phenothiazine	Phenothiazine sulfoxide
Thiazides	Unidentified agent
Retinoids, therapeutic photoagents	Tazarotene (surface application)
Promazines	Unidentified agent
Acriflavines	Unidentified agent
Rose bengal	Unidentified agent
Methylene blue	Unidentified agent
Sulfonamides	Unidentified agent
Tetracyclines	Unidentified agent
Chlorpromazine	Unidentified agent
Quinidine	Unidentified agent
Coal tar derivatives	Unidentified agent
Furosemide	Unidentified agent
Some antimicrobial soaps	Unidentified agent
ENDOGENOUS METABOLITES	
Porphyrins	Genetic abnormality (porphyrin)
Phylloerythrin	Hepatic failure (ingested)
Bilirubin	Liver, blood disorders (endogenous)

Adapted from Scott DW, Miller WH, eds. *Equine dermatology*. 2nd ed. Maryland Heights, MO: Elsevier Saunders, 2011.

Pyrrolizidine alkaloids, one of the most common toxic causes of hepatogenous photosensitization, are found in plants throughout the world. Pyrrolizidine alkaloids are transported to the liver and metabolized to pyrroles. Metabolites have an antimitotic effect that prevents cells from dividing. Eventually, fibrosis and liver failure ensue. In addition to photosensitization, significant neurologic disease can develop (hepatic encephalopathy). Horses will reject plants containing pyrrolizidine alkaloids unless there is nothing else to graze. Animals more readily eat the plants when they are processed in hay or silage. Pyrrolizidine alkaloid toxicosis develops in late winter and early spring and manifests as chronic hepatitis in early summer when ultraviolet light levels increase.

Alsike clover *(Trifolium hybridum)* is unique because it causes both primary and secondary photosensitivity.[70,71]

TABLE **18.4 Causes of Hepatogenous Photosensitization**

Substance	Hepatotoxin
Diseases	
Common bile duct occlusion; inflammation, cholelithiasis, parasite migration	
Theiler's disease, serum hepatitis immunologic disease	
Chronic active hepatitis	
Cholangiohepatitis	
Ascending bacterial infection	
PLANTS	
Senecio jacobaea (tansy ragwort), *S. riddellii* (Riddell's groundsel), *S. douglasii* (woolly groundsel), *S. vulgaris* (common groundsel)	Pyrrolizidine alkaloids (retrorsine)
Amsinckia spp. (tarweed, fiddleneck)	Pyrrolizidine alkaloids
Crotalaria spp. (rattleweed)	Pyrrolizidine alkaloids
Echium plantagineum (Salvation Jane, Patterson curse)	Pyrrolizidine alkaloids
Heliotropicum europeaum (common heliotrope)	Pyrrolizidine alkaloids (lasiocarpine, heliotrine)
Cynoglossum officinale (hound tongue)	Pyrrolizidine alkaloids
Kochia scoparia (fireweed, burning bush)	Unidentified agent
Myoporum laetum (ngaio tree)	Ngaione
Lantana camara (lantana)	Lantadenes
Tribulus terrestris (goathead, puncture vine)	Unidentified agent
Nolina texana (bunchgrass, sacahuiste)	Unidentified agent
Narthecium ossifragum (bog asphodel)	Unidentified agent
Tetradymia canescens (horsebrush, rabbitbrush), *T. glabrata* (spineless horsebrush, coal-oil brush)	Unidentified agent
Trifolium hybridum (alsike clover)	Unidentified agent
Medicago spp. (Bermuda grass)	Unidentified agent
Holocalyx glaziovii (Alecrim)	Unidentified agent
Lippia spp. (whitebrush)	Unidentified agent
Panicum antidotale (blue panicum), *P. coloratum* (klein grass), *P. dichotomiflorum* (smooth witchgrass), *P. maximum* (guinea grass), *P. miliaceam* (millet), *P. virgathum* (switch grass)	Saponins (diosgenin, tamagenin, epismilagenin)
Agave lecheguilla (lecheguilla)	Saponins
Brachiaria brizantha (Australia grass), *B. decumbens* (signalgrass), *B. humidicola, Brassica rapa* (cabbage, kale)	Saponins
MYCOTOXINS	
Microcystis spp. (blue-green algae in water)	Cyclic peptide
Phomopsis leptostromiformis (on lupins)	Phomopsins
Pithomyces chartarum (facial eczema, perennial ryegrass staggers, sporodesmin)	Unidentified agent
Lupinus spp. (lupinosis, lupine)	Unidentified agent
Medicago sativa (moldy alfalfa)	Unidentified agent
Fusarium spp. (moldy corn)	T-2 toxins
Aspergillus spp.	Aflatoxin
TOXINS AND CHEMICALS	
Carbon tetrachloride	
Carbon disulfide	
Phenanthridium	
Copper	
Phosphorus	
Iron	
MISCELLANEOUS	
Serum, antiserum	Immune complex disease
Liver diseases (abscess, neoplasia, parasite migration, cholelithiasis, inflammation)	Chemical mediators

Adapted from Scott DW, Miller WH, eds. *Equine dermatology*. 2nd ed. Maryland Heights, MO: Elsevier Saunders, 2011.

Primary photosensitization occurs as an acute reaction and is not linked to liver disease. Chronic alsike clover poisoning is associated with hepatic necrosis, fibrosis, and cirrhosis. It leads to clinical signs similar to those of pyrrolizidine alkaloid toxicosis. Pastures with less than 25% alsike clover density are believed to be safe for equine grazing.

Other causes of hepatic photosensitization (Table 18.4) include crystalline hepatopathy, pharmaceutical-related hepatopathy, and hepatic disease associated with the administration of equine-origin biologics or iron-containing supplements.

Porphyria is a rare congenital form of photosensitivity arising from aberrant pigment synthesis and has not been reported in horses. In cattle, swine, and cats it is caused by a metabolic defect in uroporphyrinogen III cosynthetase, which is an enzyme required for hemoglobin synthesis. Affected cattle have discoloration of their teeth, bones, and urine that vary from shades of pink to reddish-brown. Dermal lesions occur in unpigmented areas when affected animals are subjected to sunlight.

Diagnosis

Clinical signs of photosensitization traditionally occur in poorly haired, white, or unpigmented areas, and such signs provide a presumptive diagnosis of the disorder (Fig. 18.38). Initially, erythema, edema, and pruritus may occur. Serum transudation, erosion, or ulceration of the skin may result in a secondary bacterial invasion. Jaundice is often seen with hepatogenous photosensitization caused by alterations in the liver's ability to process bilirubin. Generalized lesions suggest liver involvement and liver function should be assessed, whereas localized lesions affecting the lips and distal limbs suggest primary photosensitivity. Biopsy reveals superficial dermal blood vessel degeneration and thrombosis with perivascular inflammation. Chronic lesions may show a lymphocytic perivascular dermatitis, epidermal hyperplasia, and hyperkeratosis, with serous crust formation. Apoptotic keratinocytes, or "sunburn cells," may be present.

FIG. **18.38** Photosensitization on the muzzle of a horse. Note the distribution limited to white areas of skin that were in contact with the offending agent. (Photograph courtesy of Dr. Judy Marteniuk.)

Treatment

The goal of treatment is to prevent further damage. Treatment focuses on stall confinement away from sunlight and removing photodynamic agents. Ointments, astringents, or antiseptics can be applied. Corticosteroids may reduce inflammation and pruritus. Antibiotics may treat secondary bacterial infections. Liver disease should be treated immediately.

Photosensitivity secondary to hepatopathy produces vague, nonspecific signs including poor appetite, weight loss, icterus, fever, mild colic, and affected skin. Neurologic abnormalities are associated with advanced liver dysfunction. Other signs of liver disease may include colitis, polydipsia, and cranial nerve abnormalities such as dysphagia and inspiratory stridor.

Differential diagnoses include sunburn, contact dermatitis, dermatophilosis, photoactivated vasculitis, PF, and bacterial and fungal infections.[69]

Treatment of contact photosensitization includes removing sensitizing agents and stall confinement. Nighttime pasture access is permitted. Fly sheets, masks, boots, and the application of 30 to 55 SPF sunscreens may be sufficient in mild cases. Systemic glucocorticoids or nonsteroidal antiinflammatory agents, topical corticosteroids, pramoxine, and control of myiasis may be beneficial.

Horses with hepatogenous photosensitization may respond to appropriate medical treatment and management (Chapter 13). Any delay in diagnosis and treatment increases complications and mortality rates. The horse should be restricted from sunlight, and offending agents should be removed. Mild to moderate dermatitis is best treated with topical, water-soluble antimicrobial agents like silver sulfadiazine. Corticosteroids may calm inflammation. Cold water hydrotherapy rids the skin surface of debris, decreases inflammation, and prevents myiasis. Bandage swollen, exudative limbs with clean, nonadhesive materials and sheet cotton. Severe dermatitis and cellulitis is associated with swelling, heat, pain, lameness, and low-grade fevers (102°F to 104°F). Horses with severe infections become inappetent and show signs of discomfort. Systemic antimicrobial treatment is indicated with cellulitis. β-Lactam antimicrobials are indicated for clostridial diseases and other anaerobic bacterial infections. Standard dosing of ceftiofur sodium (2.2 mg/kg, IV or IM, q 6–8 h), procaine penicillin G (22,000 IU/kg, IM), or penicillin G potassium (22,000 IU/kg, IV, q 6 h), combined with an aminoglycoside and oral metronidazole (20–25 mg/kg, PO or per rectum, q 6–8 h) offers coverage for most bacterial organisms. Antimicrobial treatment for cellulitis should continue for at least 10 to 14 days.

Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis or photoaggravated vasculitis is relatively common in horses with a significant amount of white hair and pink skin on their lower limbs. Immune deposits (IgG or complement component 3, or both) around the vessel walls have been detected in early skin lesions using direct immunofluorescence. The fact that unpigmented skin appears to be affected suggests a role of ultraviolet light in the development of this dermatologic problem. Drug reactions and

FIG. **18.39** Horse with leukocytoclastic vasculitis.

Staphylococcus spp. bacterial infection may serve as underlying causes. This dermatologic condition generally affects mature horses. Lesions are confined to the lower limb (Fig. 18.39). A lack of pigment in the affected area is believed to be the major risk factor, but pigmented skin has also been reportedly diagnosed with this condition. Lesions are usually multiple and well marked. Initially, erythema and exudation occur, which progresses to crusting and open sores or ulcerated areas. The affected area may ooze, and swelling is present. Chronic cases may develop a rough-appearing surface. This condition is more painful than pruritic. The diagnosis is confirmed with histopathologic findings of leukocytoclastic skin lesions with perivascular inflammation, blood vessel degeneration, and clots involving the small vessels in the superficial dermis. Treatment consists of systemic corticosteroids at relatively high doses for 1 week and reduced doses for another 4 to 6 weeks. A reduction in ultraviolet light exposure by bandaging the affected leg or stabling the horse indoors during daylight hours is recommended. Application of sun block (minimal SPF of 20) may be beneficial. Secondary bacterial infections should be treated.

NEOPLASTIC SKIN DISORDERS

Sarcoid

Sarcoids are the most common neoplasm in horses worldwide, with reported prevalence rates ranging from 12.9% to 67% of all equine tumors. Sarcoids consist of cutaneous accumulations of transformed fibroblasts, which are locally invasive, nonmetastatic, and rarely regress spontaneously. They can occur on any part of the body either singly or in clusters; the ventral abdomen, limbs, and head, especially around the eyes, pinnae, and commissures of the lips are the most commonly affected sites. Lesions frequently occur in areas that have experienced trauma. Early detection and responsible treatment provide the best possible outcome for affected horses.

Sarcoids have been causally associated with bovine papillomaviruses (BPV) types 1 and 2[72-74] and potentially type BR-UEL-4. Recent studies provide further support that latent BPV infections result in neoplastic transformation in genetically susceptible individuals.[75,76] This may explain the high incidence of tumor recurrence after excision alone; surgical trauma may induce proliferation and expression of latent virus, resulting in regrowth of the tumor. Viral burden has been associated with sarcoid severity, with higher viral burdens present in more aggressive tumors. Biting flies may be the route of transmission. In addition to evidence for genetic susceptibility to sarcoids, familial tendency has been identified.[77]

Sarcoid tumors commonly present with linear or focal dermal thickening. The epidermis varies from thick, rough, and hyperkeratotic to ulcerated. Tumors can also occur in the subcutaneous tissue as firm, moveable masses with an intact covering of skin. There are several forms of sarcoids that are recognized with varying treatment recommendations and prognosis. Regardless of the treatment modality used, small sarcoids are more likely to resolve than large sarcoids. Relatively small, benign sarcoid lesions may transition to more aggressive types of sarcoids if treated inappropriately. Tumor location is also an important factor when considering treatment modality. For example, periorbital tumors will require a treatment plan that will not threaten future vision. Generally, tumor duration is inversely correlated to resolution irrespective of tumor size.

Occult sarcoids are most common in the skin around the mouth, eyes, neck, and other relatively hairless areas of the body including the medial aspects of the forearm and thigh. These lesions manifest as a slightly thickened area of skin with a mildly roughened surface that is devoid of hair. They are commonly mistaken for ringworm infection or simple trauma. Occult sarcoids can stay dormant for extended periods of time before spontaneously enlarging or converting to more aggressive types (Fig. 18.40). Any sarcoid undergoing a more aggressive transformation should be treated immediately.

Verrucous (warty) sarcoids show a predilection for the face, body, groin, and sheath areas. Lesions are generally small, rarely exceeding 6 cm in diameter, with a dry, horny surface and a cauliflower-like appearance. These tumors can grow slowly over years and occasionally become quite large, sometimes covering an 8-inch-diameter or larger area. Like large occult sarcoids, large verrucous sarcoids can undergo malignant transformation.

Nodular sarcoids consist of firm and generally round masses that can vary widely in size. Nodular sarcoids are classified based on tissue involvement.[1] In type A1 the masses have no cutaneous involvement, are located subcutaneously. and are easily moveable. Type A2 masses also have no cutaneous involvement but are locally invasive with a "bound down" character; these types are very common around the eye. In type B nodules, the overlying skin cannot be moved over the nodule and is frequently abnormally thin, hyperkeratotic, or ulcerated. Type B nodules tend to be more aggressive than

FIG. **18.40** Large occult sarcoid beginning to show characteristics of a verrucous sarcoid.

FIG. **18.41** Fibroblastic (proliferative) sarcoid.

type A nodules and can be particularly problematic around the eyes and mouth. Type B1 nodules lack deep tissue invasion, whereas type B2 nodules are attached to deeper and surrounding structures. Nodular sarcoids can be easily confused with other nodular masses such as melanomas, lymphosarcomas, round cell tumors, and dermoid cysts. General predilection sites for nodular sarcoids include the groin, sheath, or eyelid areas. As with occult and verrucous sarcoids, nodular sarcoids can quickly progress to more aggressive forms, especially if the area is traumatized.

Fibroblastic sarcoids are variable in appearance and usually found on the groin, eyelid, lower limbs, previous wound sites, and sites of other sarcoid types subjected to insult. Some are well-circumscribed fibrous nodules in the dermis covered by intact epidermis (Fig. 18.41), but most have ulcerated surfaces that hemorrhage easily and may be covered by necrotic debris. These lesions often have an aggressive nature and will spread locally in the dermis. The fibroblastic sarcoid will often resemble exuberant granulation tissue. Type 1 fibroblastic sarcoids are pedunculated, with or without a discernible root, whereas type 2 have a broad base (sessile). Type 2 tumors frequently extend beneath the visible lesion a significant distance. Because fibroblastic sarcoids can be so similar in appearance to granulation tissue it is often difficult to differentiate between sarcoid regrowth and normal healing after fibroblastic sarcoids are debulked and treated. Prolonged healing and/or excessive granulation tissue postoperatively at the site of any sarcoid removal are cause for concern. Until the wound is totally healed with normal epidermal covering, sarcoid regrowth should be considered. Any wound that fails to heal may contain sarcoid tissue mixed with granulation tissue. Fibroblastic sarcoids can also be confused with pythiosis lesions. Unlike pythiosis, sarcoids are generally neither painful nor pruritic and grow more slowly.

Mixed sarcoids are composed of a variety of sarcoid types. The term *mixed* is used when no one type predominates. This type likely represents the progression of occult or verrucous types to more aggressive forms of sarcoid. Mixed sarcoids are a common consequence of biopsy or trauma (Fig. 18.42).

Malignant or malevolent sarcoids have also been described. Malignant sarcoids are "locally malignant" but, like all other forms of sarcoids, do not metastasize to other areas. A history of repeated surgeries and failed treatments of another form of sarcoid is common. Malignant sarcoids may track along or infiltrate lymphatic or other vessels and invade underlying structures (Fig. 18.43).

Differential diagnoses that must be considered when any form of sarcoid is suspected vary widely depending on the physical appearance of the lesion and may include excessive granulation tissue (proud flesh), dermatophytosis, linear hyperkeratosis, blisters, burns, rub marks, papillomatosis, hyperkeratosis, SCC, fibromas, neurofibromas, equine eosinophilic granulomas, melanoma, pythiosis, fibrosarcoma, and lymphosarcoma.

Although biopsy of occult, nodular, and small verrucous tumors is often not recommended to avoid altering the morphology and behavior of the lesion, definitive diagnosis is based on histologic examination of the affected tissue. When possible an en bloc resection of the entire tumor should be considered. If closure of the biopsy site is to be attempted, changing all surgical instrumentation and gloves is imperative to avoid accidental recontamination of the area. When either

FIG. **18.42** Originally a verrucous sarcoid, this lesion has developed a more aggressive appearance several months after biopsy.

FIG. **18.43** A large malevolent sarcoid in a Quarter Horse mare. The tumor tracks both proximally and distally from the large, ulcerated, fibroblastic mass. Several ulcerated areas are present.

an en bloc resection or punch biopsy is performed it should be followed by some additional form of treatment. Biopsy alone may cause a sarcoid to become more aggressive. When treatment of small sarcoids is considered, it may be prudent to simply treat the lesion as a tumor without a biopsy.

Histopathologically, equine sarcoids appear as a fibroblastic proliferation of cells that form whorls or interlacing bundles.[1,2] The usual overall orientation of this proliferation is perpendicular to the basement membrane, but exceptions exist. The epidermis, when present, is hyperplastic with characteristic elongated rete ridges, but normal or even atrophic epidermis with significant hyperkeratosis can occur (flat sarcoids). The best time to biopsy a sarcoid is before initial treatment; subsequent biopsies can be more difficult for the dermatopathologist to interpret. Sarcoid tumors can be difficult to differentiate from schwannomas based on histopathology alone.[78]

The presence of sarcoid lesions at prepurchase examination should be noted and the purchaser warned. Equine sarcoids can have a noticeable impact on equine health and welfare and become a significant financial burden for potential owners.

There is a wide range of treatments available for equine sarcoids. The treatment modality selected is determined by location, size, and aggressiveness of the tumor as well as by clinical experience, client commitment, and the availability of services, equipment, and facilities.

Conventional surgical excision of equine sarcoid is simple, but the recurrence rate varies between 15% and 82%, with most tumors recurring, often more aggressively, within 6 months. Surgical excision is better used to reduce tumor volume and improve therapeutic efficiency of other treatment modalities. Any time surgical excision is used in the treatment of sarcoid, a 0.5- to 1-cm margin of normal tissue is recommended. Adequate margins are not always possible, however, when the tumor is located near the orbit or similarly important structures. Primary closure is preferred when margins can be achieved. Presuturing and/or releasing incisions can be helpful to achieve primary closure. When closing en bloc sarcoid resections, particularly if releasing incisions are performed, new scalpel blades, instruments, and gloves should be used to minimize the chances of tumor spread. Adjunctive therapy is recommended any time a sarcoid is surgically removed.

Carbon dioxide laser excision of equine sarcoid may, in select cases, provide some additional benefit over conventional surgical excision. Because laser energy is absorbed by surrounding tissues, tumor cells are killed up to 0.2 mm beyond the wound margins. In addition, the CO_2 laser can be used to debulk tumors by vaporization. Reported recurrence rates for laser excision range from 17% to 33%.[79,80] Laser excision may be combined with other treatment modalities to further avoid tumor regrowth.

Cryotherapy with liquid nitrogen is cost-effective in the treatment of equine sarcoid, but recurrence rates vary widely for this procedure; case selection and method of freezing are likely to play a role in the observed variability in outcome. When using cryotherapy on large tumors they must be debulked before the standard three freeze/thaw cycles. The tumor should be rechecked at 2- to 4-week intervals and another set of freeze/thaw cycles implemented if the sarcoid appears to be recurring. Healing is by second intention or delayed closure, which will result in scarring and hair depigmentation. Because of the significant tissue destruction associated with cryotherapy, this treatment modality may be inappropriate for tumors near the eye, nostrils, or similarly significant structures. In all cases, the

client should be warned about posttreatment swelling, hyperemia, hemorrhage, necrosis, and local edema and permanent leukotrichia that will occur after treatment.

Intratumoral hyperthermia has been successful in treating equine sarcoids and can readily be combined with intralesional chemotherapy. Hyperthermia units have recently become more readily available, and their use appears to be on the rise. When used in conjunction with intralesional chemotherapy the tumor is first injected and then heated. Heating tumors to temperatures between 38°C and 43°C boosts the delivery of oxygen to the lesion, improves the distribution of chemotherapy inside the tumor, and significantly increases the uptake of the chemotherapeutic agent.

The intralesional use of platinum-based antineoplastic agents, cisplatin (injectable suspension or absorbable beads) and carboplatin (injectable suspension) consistently provides long-term control of equine sarcoids and most often offers a cosmetic end result. In one of the largest studies of sarcoid treatments ever performed, therapy with cisplatin suspension had a 96.4% resolution rate (3.7% recurrence rate) after 4 years in 573 horses.[81] Cisplatin is purchased as a compounded emulsion in sterilized sesame oil to affect a slow release allowing an elevated tumor-to-plasma drug concentration ratio. Tumors are injected a minimum of three to five times at 2-week intervals with 1 mg of cisplatin for each cubic centimeter of tumor bed and margin of normal tissue. When using carboplatin, the dosage is increased to a minimum of 1.3 mg/cm^3. Tumor volume should be accurately estimated for appropriate dosing, and this can be accomplished in a variety of ways (http://www.calculator.net/volume-calculator.html).

Small sarcoids and those with softer textures are injected with 22- to 25-gauge 1- to 1.5-inch needles. With denser sarcoid tumors, injecting cisplatin solution into the tumor may be difficult and may require a larger needle (19- to 21-gauge 1.5-inch), which is inserted through the tumor, and the chemotherapeutic agent is injected as the needle is slowly withdrawn. Injecting the tumor at a number of injection sites is usually required; the exact number of sites depends on the size and configuration of the tumor. The space between each line of injection should be 6 to 8 mm to ensure adequate diffusion of the chemotherapeutic agent. The process is repeated until the tumor is fully injected in one plane. Then the injections are rotated 90 degrees and the tumor is fully reinjected along this plane, forming a cross-hatched pattern. Because this may take some time, a three-way stopcock should be available to ensure that the oil and water emersion do not separate from one another. The tumor is reinjected every 2 weeks until resolution. Large tumors should be debulked and treated immediately regardless of whether primary closure has been achieved. Appropriate human precautions should be taken when handling any hazardous drug including these chemotherapy agents. Precautions include using a Luer-Lok syringe to help minimize potential human exposure and wearing personal protective equipment including nitrile gloves, face shield, and protective clothing. All contaminated or potentially contaminated material must be discarded into a biohazard container after use.

Bioresorbable cisplatin beads are easily implanted, are less likely to result in human contamination with the agent, and have demonstrated similarly excellent tumor resolution (9% recurrence rate). The 1.6-mg cisplatin beads release cisplatin over 30 days. Tumors should be debulked if they are >1.5 cm in size. Beads are then placed 1.5 cm apart through subcutaneous stab incisions throughout the tumor and margin. Repeating the bead implantation is recommended in 1 month if tumor remains. The beads are available from specialized equine compounding pharmacies.

Recent descriptions of treatment of equine sarcoids with cisplatin electrochemotherapy indicate a 99.5% success rate in 194 tumors[82] and 92.3% in a study of 52 tumors with one recurrence 60 months after treatment.[83] When surgical resection was combined with electrochemotherapy the success rate was 100% in 18 tumors with one recurrence 14 months later.[83] Electrochemotherapy works via a combination of a physical effect, cell membrane poration, and cytotoxic drug administration. Cell membrane poration is achieved by applying short intense electric field pulses. Pore formation on the cell membrane allows the cisplatin to enter the cell and significantly increases its local toxicity. Horses require repeat anesthesia and treatment every 4 weeks, which significantly adds to the cost of treatment and potential for adverse events. The number of recommended treatments ranges from one to five sessions.

Mitomycin-C, a DNA cross-linking agent similar to carboplatin and cisplatin, has also shown promise in the treatment of equine sarcoids. Sarcoids are injected with a 0.04% solution of mitomycin-C, at 0.5 to 1.0 mL/cm^3 of tumor every 8 weeks until resolution is achieved. In one study of 59 sarcoids, 9 of 9 periocular sarcoids resolved with an average of 1.9 injections.[84] Of the other 50 sarcoids, 48 (96%) resolved after an average of 2.4 injections. Adverse effects included the development of leukotrichia and infrequent swelling and discharge from the necrosing tumor. Recurrence rates at 6 to 30 months were zero for periocular sarcoids and 3 of 48 (6%) for other types. Additional injections were effective in horses with tumor recurrence.[84]

Electrosurgical excision of equine sarcoids had a reported treatment success rate of 86.8% in 319 tumors. Tumors were excised under general anesthesia. Direct tumor contact was avoided during the skin preparation protocol to avoid tumor spread. Margins of a ≥12-mm tumor-free zone were obtained, and the electrosurgical instrument was used with a nontouching technique to avoid iatrogenic spread of tumor cells. All wounds were closed with a new set of instruments and gloves. Unfortunately, the size of the sarcoids being treated was not described, making a comparison with other forms of treatment more difficult.[85]

A topical ointment, AW-3-LUDES, has shown success in the treatment of severe sarcoids. It contains a variety of heavy metals and the antimitotic compounds 5-fluorouracil and thiouracil. The ointment is administered on successive or alternate days for three to five treatments. A response should be evident in the following 5 to 10 weeks and will be noticed as preferential necrosis and sloughing of the sarcoid tissues.

The successful treatment of equine sarcoids by topical acyclovir application has also been reported[86] and can be a cost-effective and safe alternative or adjunct to cisplatin treatment and surgical therapy. All 47 (100%) of the sarcoids responded to acyclovir application by shrinking, with complete tumor regression observed in 68% of the lesions. Incomplete resolution was observed in 32% of the lesions, which is likely caused by acyclovir's inability to penetrate thicker areas. Acyclovir is proposed to be routinely used for the treatment of flat and mild-type sarcoids or as a relatively economical way to shrink tumors before the use of cisplatin. The drug is applied daily for a minimum of 2 months for thinner tumors, and thicker tumors will take longer to resolve and may require debulking

before treatment. The advantage of acyclovir is that it does not cause an inflammatory reaction like many other topical agents.

Imiquimod 5% (Aldara; 3M Pharmaceuticals, St. Paul, MN), an immunomodulator that stimulates macrophages, Langerhans cells, natural killer cells, and B lymphocytes, has shown efficacy in the treatment of equine sarcoid with an overall 60% resolution of nondebulked tumors.[87] In 80% of treated tumors there was a significant reduction in tumor size (75% reduction). Debulking tumors before the use of imiquimod appears to provide even better success, which is likely caused by better penetration of the product. Imiquimod is applied to the sarcoid three times a week on alternating days for 32 weeks or until the lesion resolves. Treatment can result in local inflammation, exudation, depigmentation, alopecia, and behavioral issues (if the horse does not appreciate being touched in the area of application). The use of tazarotene cream in conjunction with imiquimod has improved the overall resolution rate of sarcoids but also appears to increase pain and inflammation associated with treatment.[88]

Other forms of immunotherapy are relatively common in the treatment of equine sarcoid with bacillus Calmette-Guérin (BCG), an attenuated strain of *Mycobacterium bovis,* historically being used most often. Mycobacterial antigens are thought to stimulate host lymphocytes and also may stimulate an increase in natural killer cells. Success rates for treatment of periocular sarcoids with BCG range from 83% to 100%; sarcoids elsewhere on the body have much lower reported success rates (48%). Severe inflammatory reactions can occur with the use of this drug and can result in fever, necrosis, and extensive swelling. Anaphylaxis has also been reported, and pretreatment with flunixin meglumine or corticosteroids is recommended. The tumor is injected with BCG vaccine every 2 to 3 weeks for four treatments. A commercial BCG product for horses is not currently available in the United States.

Nonviable *Propionibacterium acnes* in ethanol (EqStim; Neogen Corporation, Lexington, KY), has shown variable results for sarcoid treatment. Protocols differ widely and include intralesional and/or IV injections given once weekly for 6 to 8 weeks. Susceptible lesions generally show improvement after two to three treatments and eventually necrose and slough.

Autogenous vaccines have been described to have some success in a limited number of horses.[89] This technique involves the horse-side removal, freezing, and reimplantation of a sarcoid into the same horse. The transfer of sarcoid tissue, tumor homogenates, and cell-free tumor extracts from one horse to another has been proposed to stimulate production of new tumors or regression of existing tumors. Because other less invasive treatments frequently work well and tumor transplantation bears risks, such as tumor production and transmission of other diseases, this procedure should only be attempted in the most refractory of cases and with individuals known to be negative for infectious diseases such as equine infectious anemia.

Several products containing bloodroot extracts *(Sanguinaria canadensis)* and zinc chloride have been used in the treatment of various types of skin lesions including sarcoids. The bloodroot is made into an escharotic salve, which penetrates the lesion, killing the affected cells. These preparations do not always spare the surrounding healthy tissue and are thought to work by changing the antigenicity of the sarcoids so that the body recognizes these cells as foreign and produces antibodies against them. Alternatively, the concentrated zinc chloride in these products may be adequately caustic to result in the treatment outcomes. The bloodroot extract is applied while wearing gloves to the sarcoid lesion, and a bandage is placed over the area for 4 days. If the sarcoid has not sloughed by 4 days, the treatment is repeated. A rapid response to the salve is usually noticed, with the lesion sloughing in 7 to 10 days. Repetition of the treatment is sometimes required. In one study of 125 sarcoids in 49 horses complete resolution was obtained for 65.6% of tumors, partial resolution for 23.2%, no response for 5.6%, and 5.6% worsened.[90] Size of tumor in this study was highly significant; tumors that were less than 2 cm had a 14% tumor recurrence rate. Bloodroot is a reasonable and inexpensive treatment option for small sarcoids that can be easily bandaged and for larger sarcoids in horses where significant financial constraints are present.

Various radioisotopes have been used for interstitial brachytherapy of equine sarcoids. Permanently implanted seeds of radon-222 or gold-198 and removable needles of radium-226, cobalt-60, or iridium-192 have been used. Although expensive, for recurrent, aggressive, and surgically inaccessible sarcoids, this modality should be strongly considered.

Squamous Cell Carcinoma

SCC is the second most common tumor diagnosed in horses, accounting for 20% of equine neoplasms. It is the most commonly diagnosed neoplasm of the eye, conjunctiva, ocular adnexal structures, and external genitalia but can also affect the stomach, esophagus, nasal passages, paranasal sinuses, hard palate, pharynx, larynx, perianal tissue, ear canal, tongue, hoof, and guttural pouches. Older horses are at higher risk for the development of SCC as are breeds of horses with unpigmented skin or hair surrounding their mucocutaneous junctions such as Appaloosas, American Paint horses, and Pintos.

Halflingers are also at increased risk for the development of limbal and/or third eyelid SCC despite their pigmented skin and hair.[91] A DNA marker identifies Haflingers at higher risk to develop this type of SCC, and a genetic test is commercially available. Halflingers homozygous for the risk factor (R/R) are 5.5 times more likely to develop ocular SCC than those with one copy (R/N) or no copies (N/N) of the risk factor. The increased incidence of SCC in draft breeds is also thought to be genetic.

The pathogenesis of SCC is related to ultraviolet light exposure coupled with the lack of pigmentation in sparsely haired areas. EcPV2 has been implicated as a positive etiologic agent in equine genital, ocular, and nasal SCC.[92,93] The presence of smegma, persistent phimosis, or repeated trauma may predispose stallions and geldings to developing lesions of the external genitalia.

Early clinical signs of SCC include thickening and mild exfoliation and ulceration of the skin. Mature lesions can be erosive or productive in nature. Reported tumor metastasis rate varies among SCCs, and they are generally slow to metastasize, with metastasis rates reported to vary between 2% and 18.6% of cases.[94] Poorly differentiated tumors are more likely to metastasize. Local lymph nodes are most commonly affected by the metastasis, but in rare instances, SCC may also spread to the lungs. Differential diagnoses include sarcoids, melanoma, exuberant granulation tissue, and pythiosis.

In SCC of the male genitalia, tumors usually arise from the glans penis or the inner lining of the penile sheath and spread

to the corpus cavernosum (Fig. 18.44). Early clinical signs include preputial edema and an odoriferous discharge. Intermittent hemorrhage, dysuria, pollakiuria, weight loss, and urinary incontinence may also develop. The regional lymph nodes should be assessed for metastasis by inguinal and rectal palpation. Regular examination and washing of the prepuce and penis will aid in early detection of SCC and may assist in preventing its development. SCC affecting female genitalia typically originates at the clitoris and progresses toward the vaginal vestibule and mammary glands. Hypertrophy of the clitoris and surrounding tissue and roughening of the ventral commissure may be noticed early in the disease. Ulcerative lesions of the lateral labia are also relatively common; when these are treated early they generally carry an excellent prognosis.

Lesions affecting the eyelid frequently begin as white or pink raised plaques at the edge of the eyelid and proceed to extensive ulceration and destruction of the eyelid, rapidly invading the periorbital tissues (Fig. 18.45). The earliest stages may present with bloodstaining of the tears, which progresses rapidly to a granulomatous and ulcerated lesion. Further information regarding ophthalmic SCC is available elsewhere in this text (Chapter 17).

Diagnosis of SCC can be accomplished by cytologic or histologic examination. Depending on the site and size of the lesion, excisional, wedge, punch, or elliptical biopsy can be performed. Other diagnostic methods include fine-needle aspiration of nodular lesions, cytologic examination of superficial scrapings from ulcerated lesions using a dull blade, and impression smears.

FIG. **18.44** Early squamous cell carcinoma on the penis of a 23-year-old Morgan gelding. This tumor would likely respond well to several applications of topical 5-fluorouracil.

Treatment of SCC is most successful when the lesion is recognized and therapy is initiated early in the course of the disease. Even so, recurrence of SCC is not uncommon. Debulking the tumor may be accompanied by cryosurgery, injection or implantation with cisplatin or mitomycin-C, or radiation therapy as previously described to treat sarcoids. Similarly, bloodroot extract and other topical medications can be useful.

Compared with equine sarcoid, wide surgical excision alone for treatment of early cases of SCC typically carries a more favorable prognosis; however, recurrence is always possible and the lesion characteristics may be altered with recurrence, making the tumor less likely to be recognized. When the third eyelid is removed in its entirety, care should be taken to check for extension of the tumor into nearby conjunctiva, and, for added insurance, mitomycin-C or 5-fluorouracil ophthalmic drops should be added to the treatment regimen. When using surgical excision alone in the treatment of SCC, a 0.5- to 1-cm-diameter margin of normal tissue has been recommended. This can be difficult to achieve with periocular SCC. In a study of nine horses with ocular SCC, 80% experienced tumor resolution when debulked and treated with mitomycin-C.[95] Ophthalmic 5-fluorouracil drops may provide similar or better control. The ophthalmic drops of either mitomycin-C or 5-fluorouracil are administered in a pulsed fashion. For mitomycin-C, 0.2 mL of a 0.04% solution of mitomycin-C is instilled into the conjunctival sac of the affected eye every 6 hours for 7 days. The treatment is then discontinued for 7 days, and the cycle is repeated until the tumor has resolved. For 5-fluorouracil treatment, ophthalmic drops or ointment is instilled in the affected eye q 6 to 8 h for 3 to 4 days, and then treatment is discontinued until the following month. The cycle is repeated monthly until resolution occurs. With the more recent evidence of EcPV2 playing a role in the etiology of SCC, it may be time to rethink treatment by surgical excision alone.

FIG. **18.45** Squamous cell carcinoma of the lower palpebrum in an aged Paint Horse.

There are many topical treatments available for the treatment of genital SCC. Tumors that are thick or nodular should be debulked before topical therapy. Topical 5% 5-fluorouracil cream is reported to have a 90% success rate for treatment of superficial SCC of the penis and prepuce.[96] The penis and prepuce should be cleansed and dried before rubbing a small amount (the size of a pea is adequate for most SCC if caught early) of cream into all affected tissue. The process is repeated every 2 weeks until resolution because 5-fluorouracil is retained in the prepuce for 10 to 14 days. A 40-g tube is usually sufficient for treatment of all but the most extensive disease. Application to the urethra is appropriate if necessary. The most common errors are applying too much (more inflammation than needed) and not sticking with the 2-week interval for an adequate length of time. The penis should be reevaluated every 3 months for the first year after resolution of the tumor and then every 6 months. For tumors on the external sheath, perineum, or vaginal wall, application is performed daily until the area is inflamed. The area is allowed to recover, and any residual tumor is retreated in the same fashion.

Beta irradiation (strontium-90) has been used successfully to treat SCC and is particularly good for ocular lesions because the orbit and adnexa can be preserved. Course-fractionated cobalt-60 radiotherapy has provided good to excellent long-term results in several cases with severe involvement of the paranasal sinuses.[97]

Piroxicam (80 mg/1000 lb PO once daily), a nonspecific cyclooxygenase-2 (COX-2) inhibitor, has been reported to be an effective adjunctive therapy for some horses with SCC.[98] Piroxicam is proposed to induce apoptosis and angiogenesis and stimulate the immune system through inhibition of PGE_2 production in epithelial tumors. There are conflicting reports on the production of COX-2 by SCCs in the horse[99-101] and no reported controlled studies of its use in the treatment of epithelial tumors in horses.

Melanoma

Melanomas are common tumors that arise from the malignant transformation of melanocytes. They can occur in horses and mules of any coat color, but incidence is much greater in gray and white horses. Arabians, Thoroughbreds, and Percherons may be at increased risk for developing this disease. In one study of 264 gray-skinned Camargue-type horses, the prevalence of melanomas in the overall population was 31.4%.[102] The incidence, size, and number of melanomas was significantly correlated with age, giving a prevalence of 67% at ages >15 years. Other sources indicate that approximately 80% of all gray horses will develop one or more melanomas at some location by the age of 15.[103] There appears to be no gender predilection for these tumors. The most common areas of the skin affected are underneath the tail and external genitalia (Figs. 18.46 and 18.47). Other regions less commonly affected include the ear, eyelid, neck, parotid salivary gland, guttural pouches, lips, and limbs. When melanomas do occur in horses of other colors, they may be at greater risk for becoming malignant.

The etiology of melanomas in the horse has not been clearly defined but is believed to be secondary to genetic mutations in the melanin metabolism molecular pathway. Controversy exists as to whether or not exposure to increased levels of ultraviolet radiation may also play a role in the pathogenesis. Ninety-five percent of melanomas are of little

FIG. **18.46** Multiple melanomas on the penis of a 12-year-old grey pony gelding.

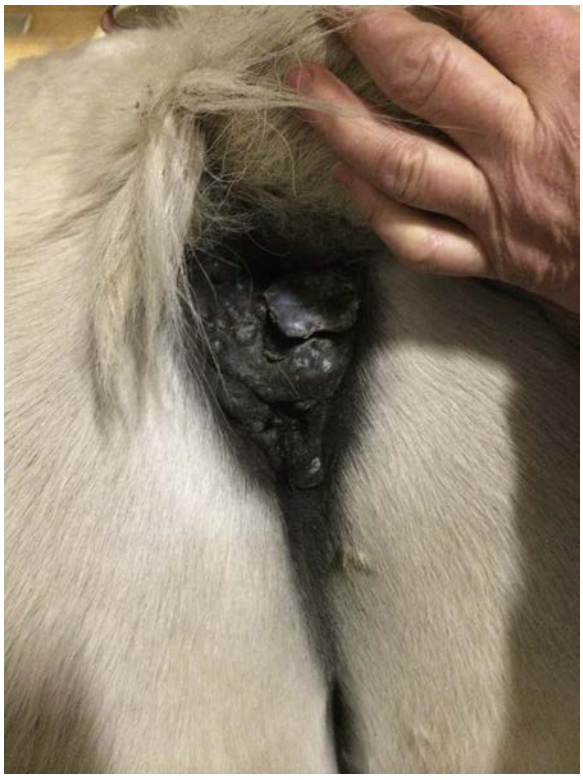

FIG. **18.47** Dermal melanomatosis in an aged pony gelding.

clinical significance except when they inhibit the use of riding tack or interfere with urination, defecation, and coitus. As horses age, however, these tumors can progress and demonstrate overt malignant behavior including local invasion and metastasis. Metastasis may occur by either hematogenous or lymphatic spread to any region in the body including lymph nodes, spleen, liver, and lungs. In rare instances melanomas exhibit rapid growth and malignant properties from the onset. Diagnosis of equine melanomas is generally based on their black gross appearance but can be confirmed using histology (Fig. 18.48).

The term *equine melanoma* or *melanocytic tumor* encompasses all histologic and clinical variants from the benign to the most anaplastic malignant variants, and in gray horses there appears to be a continuum between the two. Four distinctive manifestations of equine melanocytic tumors have been defined based on clinical presentation, histologic examination, tendency to become malignant, and response to surgical excision. *Benign melanocytic nevi (benign melanocytoma)* are characterized by their origination in the superficial dermis or at the dermoepidermal junction. Involvement of the epithelium is common. Histologically, the tumor appears as nests of large pleomorphic epithelioid cells, which contain variable amounts of pigment mixed with melanophages. Mitotic cells, binucleate cells, and euchromatic nuclei are occasionally seen. Surgical excision is largely curative. *Dermal melanomas* are located in the deep dermis and appear histologically as small, homogeneous, indistinct round or dendritic tumor cells containing condensed chromatin and dense cytoplasmic pigmentation. They demonstrate minimal malignant criteria. *Dermal melanomatosis* refers to many dermal melanomas that have coalesced. *Malignant melanomas* are characterized by pleomorphic epithelioid cells with vascular, lymphoid, and/or dermal invasion; variable pigmentation; and a moderate to high number of mitotic figures. Differential diagnosis includes habronemiasis, cutaneous collagen necrosis, mast cell tumors, and sarcoid.

Melanomas commonly appear as black or gray, solitary, discrete, firm, spherical, or flat nodules in the skin or subcutis and may have a pedicle. Tumors frequently coalesce, and hundreds of variable-sized nodules may be present without affecting the well-being of the horse. Many small tumors may be present, producing a cobblestone appearance. The overlying skin may be intact or slightly alopecic, with some tumors developing ulcers at the surface.

FIG. **18.48** Cut surface of a melanocytic tumor demonstrating dark pigment and well-encapsulated margin.

Treatment is often not necessary for small melanocytic tumors located in uncompromising locations. Large masses or masses located in areas in which they can be a nuisance are treated with surgical excision. When possible a wide margin should be attained with surgical excision. Cryosurgery can be used in conjunction with surgical excision. However, tumor regrowth is possible.

Intralesional injection or implantation of cisplatin has been very effective in the treatment of tumors less than 3 cm in diameter. The use of microwave energy (Thermofield System; Parmenides Inc., Franklin, TN) has been reported and allows for treatment of larger tumors. It is even more effective when combined with intratumoral cisplatin. Similarly, the use of cisplatin and hyperthermia improves the effect of cisplatin intratumoral therapy even in more advanced disease.[104] The few reports of electrochemotherapy in the treatment of large melanomas has been less promising.

Studies evaluating the use of cimetidine in the treatment of melanomas have shown varying results[105,106]; regression of tumors should be evident within 3 months of initiating treatment, or treatment should be discontinued. Cimetidine is administered at 2.5 mg/kg q 8 h and continued for 2 to 3 weeks following resolution of tumor growth. Some horses may require treatment their entire life. Liver enzymes should be monitored semiannually in horses receiving this medication. Similar to the treatment of SCCs, adding piroxicam (80 mg/1000 lb PO once daily) to melanoma therapy may be beneficial, but there are currently no controlled studies.

Techniques to prepare monoclonal antibodies and DNA vectors encoding eqIL12 and eqIL18 to promote immunologic recognition and tumor rejection of melanomas have been developed but are not currently available for clinical use.[107]

A canine melanoma vaccine (Oncept; Merial) is currently undergoing equine clinical trials. It contains the human DNA sequence that encodes a specific protein (tyrosinase) that is only found within melanocytes. Tyrosinase is an enzyme that is crucial to the melanocyte's ability to produce melanin and also to the survival of the melanocyte itself. The human tyrosinase protein appears similar to that of the horse. Ideally the vaccine will result in the destruction of the tyrosinase in the cancerous melanoma cells, and ultimately, the inability of the tumor cells to survive. Early results appear promising, with most horses demonstrating tumor shrinkage following vaccination and some horses demonstrating dramatic tumor shrinkage. The vaccine is given four times in 2-week intervals and then every 6 months for the remainder of the horse's life.

Mast Cell Tumor

Mast cell tumors are uncommon in horses and appear to occur more often in Arabian Horses than any other breed.[1,29] Mast cell tumors are benign and most commonly occur as a single cutaneous nodule, often located on the head (Fig. 18.49). Nodules range in size from 2 to 20 cm in diameter. The surface of the nodules may be normal, hairless, or ulcerated. Alternatively, mast cell tumors may cause diffuse swelling on a lower extremity, usually below the carpus or hock. The swelling is firm, and the overlying skin is normal in appearance. Radiographs of the limb commonly show multifocal areas of soft tissue mineralization.[64]

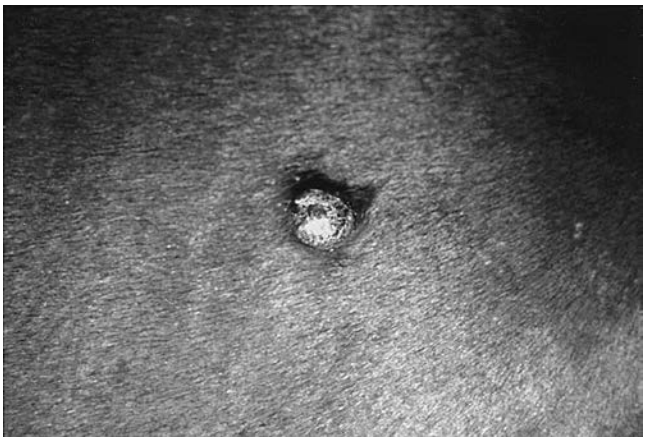

FIG. **18.49** Hyperplastic mast cell tumor in a horse.

The diagnosis of a mast cell tumor is determined by biopsy. Diffuse to nodular proliferations of mast cells occur in the dermis. Tumor cells may be well differentiated or more atypical. Tissue eosinophilia, collagen degeneration, and dystrophic mineralization are common.

Surgical excision is curative, but the tumors also respond well to sublesional triamcinolone acetonide (5–10 mg per lesion), cryosurgery, and carboplatin. Spontaneous remission may occur after incomplete excision or in young horses. Metastasis has not been reported.[29]

Cutaneous Lymphoma

Systemic lymphoma is discussed in detail in Chapter 15. Cutaneous lymphoma is rare in horses. The breed most often affected is the Quarter Horse followed by Thoroughbreds and Standardbreds. Equine cutaneous lymphomas can be classified as one of two types.[108] Cutaneous T-cell lymphoma is an epitheliotropic scaling disease widely disseminated throughout the skin. T-cell–rich, large B-cell cutaneous lymphoma or nonepitheliotropic lymphoma is a nodular disease. A definitive diagnosis is made by histologic examination of a skin biopsy with several representative tissue samples for examination. Epitheliotropic lymphoma carries a poor prognosis. Treatment strategies include prednisolone at 1 mg/kg orally once daily for 7 days and then every other day. PEG-l-asparaginase at 10,000 IU/m^2 once weekly may also be beneficial. Low-dose cyclophosphamide and immunization with *vaccinia* virus–infected autologous tumor cells were successful in inducing a 19-month remission in a 13-year-old horse.[109] Nonepitheliotropic lymphoma carries a much better prognosis. Affected horses can have one or many nodules, with some horses having a single nodule for years without showing any other effects of the tumor. The presence of underlying diseases including *Borrelia* infection and EHV-5 should be ruled out in horses with nonepitheliotropic lymphoma. When the nodules are removed in horses with one or a few nodules, they tend to recur, but many horses can live near normal life expectancies. In addition to surgical resection, the use of corticosteroids and cisplatin intralesional injections has proven to be useful in some horses.

Pseudolymphoma

Pseudolymphomata are common in horses compared with lymphomata.[2] Differentiating the two diseases is important because the prognosis for pseudolymphoma is excellent.

FIG. **18.50** Hemangioma on the dorsal surface of the hock in a yearling. (Photo courtesy of Karl Frees.)

Pseudolymphomata are nodular to papular lesions that develop in the skin as a result of chronic antigenic stimulation. The most common antigenic stimuli are believed to be insect bites and drug reactions. Lesions are most common in late summer and fall and are usually solitary but may be multiple. Pseudolymphomata usually occur on the head and trunk. Individual lesions are firm, raised, and haired.

A definitive diagnosis is made by a skin biopsy. Histologic examination of tissue shows dense dermal and subcutaneous infiltration of lymphocytes, histiocytes, plasma cells, and eosinophils. Lymphoid nodules and eosinophils are present and are an important aid in the differentiation of pseudolymphoma from lymphoma.

Pseudolymphomata often spontaneously regress but may be excised surgically or injected sublesionally with triamcinolone acetonide at 3 to 5 mg per lesion, not to exceed a total dose of 15 to 20 mg.

Hemangioma

Hemangiomas (vascular hamartoma and verrucous hemangioma) are benign tumors of the endothelial cells of blood vessels. Lesions are most common in horses less than 1 year of age, and some horses are born with them. Hemangiomas tend to be solitary tumors occurring on the distal limbs (Fig. 18.50). The clinical appearance varies and may be circumscribed, nodular, firm to fluctuant, blue to black in color, dermal or subcutaneous, hyperkeratotic, or verrucous. Ulceration and bleeding are common.

Confirmation of the diagnosis is made by skin biopsy, which reveals proliferation of blood-filled vascular spaces lined by single layers of well-differentiated endothelial cells. Equine hemangiomata are characterized by a multinodular

capillary hemangioma with hyperplasia and hyperkeratosis of the overlying epidermis.

Bloodroot extract has been used to treat these tumors as has cryosurgery, surgical excision alone, and cisplatin electrochemotherapy. Complete removal is generally curative, and there are reports of spontaneous regression. Recurrence rates are unknown.

Dermoid Cysts

A dermoid cyst is a tumor of developmental origin consisting of a wall of fibrous tissue lined with stratified epithelium containing hair follicles, sweat glands, sebaceous glands, nerves, or any combination of these. Dermoid cysts may be congenital or hereditary, have been reported in horses 6 months to 9 years of age, and are more common in Thoroughbreds. They occur frequently on the dorsal midline between the rump and withers. The cysts appear as soft, fluctuant swellings with normal overlying skin. The diagnosis is made by histologic examination after excision.

Atheroma

An atheroma is a cyst in the false nostril. These lesions are believed to develop from hair follicle retention cysts or from displaced germ material. Atheromata are present at birth, are usually unilateral, and enlarge with time. They are not usually noticeable until they enlarge to greater than 2 cm. The tumor is firm on palpation but is rarely painful.

Diagnosis is based on clinical signs. Treatment is not necessary unless the atheroma negatively impacts airflow or the owner is disturbed by the lesion. Surgical excision is the treatment of choice, but one must take care to remove the entire cyst, or recurrence or chronic drainage occur.

MISCELLANEOUS AND IDIOPATHIC SKIN DISORDERS

Anhydrosis

Anhidrosis is characterized by the inability to sweat appropriately in response to an adequate stimulus.[110] The result is exercise intolerance and dermatologic problems, and in extreme cases, collapse and death may occur. This disease is primarily a problem in hot, humid climates, such as that found in the Gulf Coast states. Symptoms are exhibited during the hottest months of the year when daytime highs can exceed 100°F, and the lows remain in the 70°F range. During the cooler months of the year, the condition tends to resolve. Cases are uncommon in temperate climates. Anhidrosis can affect up to 20% of horses in some geographic areas. The disease does not have a breed, gender, age, or coat color predisposition. Horses that were born and raised in the northern United States have been known to develop anhidrosis shortly after arriving in the southern region of the country. Horses that were born and raised in the southern regions have been known to develop the condition at age 12 or later. Native and imported horses tend to be equally affected.

The pathogenesis of anhidrosis is not clearly understood. It is believed that the condition results from a conditioned insensitivity of sweat glands to epinephrine. Studies of the sweat glands of anhidrotic horses revealed that there was a reduced number of cytoplasmic vesicles, compacted intercellular spaces, lack of evidence of myoepithelial cell contraction, and evidence of contracted ductal lumina that appeared occluded by cellular debris. These findings suggest that a failure or impairment of sweat production had occurred. The cause of these findings is not known, but hypothyroidism, hypochloremia, and downregulation and exhaustion of β-adrenergic receptors in apocrine sweat glands have been proposed.

Horses affected with anhidrosis may be presented for evaluation of respiratory disease, skin disease, exercise intolerance, and failure to sweat. These horses may exhibit exercise intolerance, tachypnea, flaring of the nostrils at rest, elevated rectal temperature, and partial or complete lack of sweating. Any sweating that is noted will most likely be restricted to the mane, axilla, and groin regions. In long-term cases, patchy alopecia of the head and neck along with seborrhea may be present, which are associated with reduced hair follicle function. Other clinical signs that may be evident include pruritus, polydipsia, polyuria, a poor appetite, and a loss of body condition.

Diagnosis of anhidrosis is accomplished by observing a lack of localized sweating in response to intradermal injections of epinephrine or terbutaline. The epinephrine or terbutaline is injected intradermally at a dose of 0.5 mL at concentrations of 1:1000, 1:10,000, 1:100,000, and 1:1,000,000. In normal horses, sweating will be evident over the injection sites within 30 minutes, at all dilutions. Anhidrotic horses will only respond to the 1:1000 dilution, and even this response may take 5 hours or more. Differential diagnoses include PF, sarcoidosis, and dermatophilosis.

The most successful remedy for anhidrosis is to move the horse to a more temperate climate. If this is not possible, the horse should be kept in a stall that is supplied with a flow of cooling air. The horse should also be trained during the coolest part of the day, and the training regimen should be modified in intensity. A variety of other treatments including electrolytes, nutritional supplements, clenbuterol, vitamin E, and iodinated casein have been reported anecdotally to help some affected horses. For some horses, reduced stress and rest for an extended period may help decrease the severity of clinical signs.

Chronic Progressive Lymphedema

CPL of draft horses is characterized by progressive swelling, hyperkeratosis, and fibrosis of the distal limbs.[111,112] The disease is seen in Shires, Clydesdales, Belgian Draft horses, and Gypsy Vanners. Clinical signs appear at an early age and progress throughout the life of the horse. Initial clinical signs mimic those of common pastern dermatitis but progress to skin thickening and folding with crusting lesions in the pastern area. Because of the heavy feathering present in affected breeds, the lesions may go unnoticed until they are extensive. Chorioptic mange and/or secondary bacterial infections are not uncommon. Chronic inflammation results in lymphedema, and lower leg enlargement becomes permanent. Treatment includes clipping the feathers, addressing the underlying skin infections, exercise, bandaging, and cold water hydrotherapy. Euthanasia is common in severely affected horses.

Dermal Panniculitis and Fat Necrosis

Panniculitis refers to inflammation of the subcutaneous fat. This condition is rare in horses and results from widespread death of lipocytes.[113] Fat cells are vulnerable to trauma, ischemia, and neighboring inflammation. When lipocytes are damaged, lipid is released and undergoes hydrolysis into glycerol

and fatty acids. Fatty acids are potent inflammatory agents that elicit further inflammatory reactions.

Dermal panniculitis is rare and may be precipitated by a wide range of causes including trauma, infections, autoimmune disease, pancreatic disease, glucocorticoid therapy, vasculitis, vitamin E deficiency, and idiopathic causes. In the horse, few cases have been reported, and their causes were obscure. Although vitamin E deficiency was suspected in a few horses, treatment with vitamin E has failed to resolve the disease in multiple cases.

Clinically, horses with panniculitis show deep-seated nodules and plaques. Lesions may be single or multiple and vary in size. They may be hard and well defined or soft and ill defined. Initially, lesions are not fixed to the overlying skin, but as the disease progresses, nodules become cystic and rupture onto the skin surface. The ulcerating nodules drain a yellow to brown to bloody oily material. Pain varies. Healed lesions may leave depressed scars. Affected animals may be febrile, depressed, lethargic, and anorectic.

A definitive diagnosis is made by skin biopsy. Samples should be obtained for histopathologic evaluation by deep excisional biopsy using a scalpel blade because skin biopsy punches do not obtain sufficiently deep samples to be diagnostic. One should request special stains (i.e., PAS, Gomori's methenamine silver, Brown and Brenn) for causative agent. Skin biopsy reveals lobular to diffuse pyogranulomatous inflammation in the panniculitis.

The practitioner should identify and treat underlying causes appropriately. Idiopathic panniculitis may respond to prednisolone at 1 to 2 mg/kg orally once daily for 7 to 14 days or to a single treatment of dexamethasone at 20 to 30 mg IM. Clinical improvement may occur within 7 to 14 days. Relapses occur, and the horse may require lifelong therapy.

Equine Axillary Nodular Necrosis

Equine axillary nodular necrosis is similar to equine eosinophilic granuloma with collagen degeneration, except that the lesions are localized to the axillary region.

The condition has no known age, gender, or breed predilection. Clinically, single or multiple nodules develop unilaterally in the axillae. The nodules are painless, nonpruritic, haired, well-circumscribed firm masses that vary in size from 0.5 to 4.0 cm or greater in diameter. Multiple lesions tend to be arranged in a row.

Skin biopsy is diagnostic. Biopsy findings include pyogranulomatous, eosinophilic dermatitis with foci of coagulation necrosis. Collagen degeneration is not a common finding. Treatment is the same as that for equine eosinophilic granuloma.

Eosinophilic Granuloma

Eosinophilic granulomas (nodular necrobiosis) are probably the most common nodular skin disease of the horse. Lesions appear as firm dermal nodules that are associated with degenerative collagen. No breed, gender, or age predisposition has been identified for this disease. Nodules usually arise in the warmer months of the year. Sites most commonly affected are the withers, back, and sides of the neck. Other areas of the body that can potentially be affected include the girth area, mane, rump, and face. Most commonly horses are brought for examination of eosinophilic granuloma because the owner is concerned that the lesion is neoplastic or the lesion occurs in an area in which it is irritated by tack.

The etiology of eosinophilic granulomas is not known. It has been suggested that a hypersensitivity reaction might play a role in the pathogenesis. Insect bites, especially those of mosquitoes, have been implicated as the cause of this disease, although the evidence for this is weak. Because lesions are common in the saddle region, it is possible that trauma is the factor in lesion development. Atopic horses may be predisposed to developing the nodules. Nodules occur as single or multiple lesions ranging from 0.5 to 10 cm in diameter, with small lesions being significantly more common (Fig. 18.51). The lesions are typically rounded, well circumscribed, and firm, with no alopecia or ulceration present. There is usually no pain or pruritus associated with the nodules. In areas in which collagenolysis is extensive and involves the superficial dermis, transepidermal elimination may occur, resulting in ulcerated lesions containing a central grayish white caseous core. The skin and coat overlying the nodules are generally normal unless traumatized. In some cases, hundreds of pea-sized nodules have been seen.

Diagnosis of eosinophilic granulomas is usually based on history and physical appearance but cannot be definitively made without a biopsy of a nodule. Culture results for bacteria and fungi will be negative. Histologic observation of a biopsy specimen shows several foci of collagenolysis, with the collagen fibers exhibiting a hyaline or granular appearance. Free hair shafts are sometimes observed within the lesions. In these horses there is usually a history of body clipping before the development of the nodules, which may suggest an association. Older nodules tend to exhibit marked dystrophic mineralization and may be mistaken as calcinosis circumscripta lesions.

FIG. **18.51** Horse with multiple eosinophilic granuloma.

Differential diagnosis includes axillary nodular necrosis, hypodermiasis, amyloidosis, and cutaneous lymphosarcoma.

Treatment of eosinophilic granuloma can be accomplished by surgical excision, intralesional corticosteroids, or systemic corticosteroids. The method of therapy used depends on the number and size of nodules. A single small lesion can be left untreated because it is asymptomatic, or if it is undesirable to the owner it can be surgically removed. If just a small number of lesions are present, intralesional corticosteroids may be the best method of treatment. Triamcinolone acetonide (3–5 mg per site, total dose not to exceed 20 mg/1000-lb horse) or methylprednisolone acetate (20 mg per site) can be injected into and under the nodule using a Luer-Lok syringe and a ⅜-inch, 23-gauge needle. Injections can be repeated at 2-week intervals if necessary. Any lesions remaining after multiple injections will probably not be susceptible to the steroids and can be surgically removed. Because of the risk of inducing laminitis, no more than 20 mg of triamcinolone should be administered at one time. If multiple lesions are present, the administration of prednisolone orally at 1 mg/kg once daily for 2 to 3 weeks is recommended. After lesions have resolved, the dosage of prednisolone should be tapered and discontinued over a 5- to 10-day period. Horses with seasonal recurrences in which insect hypersensitivity is involved and documented via intradermal skin testing might benefit from ASIT to insects. Older, mineralized lesions may be unresponsive to glucocorticoid therapy and can be surgically excised. Nodules often respond well to corticosteroid treatments, but relapses are common. Retreatment is often successful in these cases.

Multisystemic Eosinophilic Epitheliotropic Disease

Multisystemic eosinophilic epitheliotropic disease is a rare idiopathic disease of horses characterized by nodules or masses in numerous organs, ulcerative stomatitis, severe wasting, significant exfoliation, and eosinophil infiltration of the skin.[1,2,114] No gender or breed predilection exists, but lesions tend to be more common in younger horses. Early lesions begin as scaling, crusting, exudation, and fissuring at the coronary band. Oral ulcers are usually present at this stage. Over several weeks a generalized exfoliative dermatosis develops. Hairs are epilated easily, and alopecia with multifocal areas of ulceration and exudation develops. The horse may be pruritic. Affected horses without ulcerative stomatitis have a good appetite but exhibit rapid, severe weight loss. Some horses have concurrent protein-losing enteropathy or malabsorption syndrome or respiratory signs including nasal and ocular discharge, swollen submandibular lymph nodes, chronic cough, and respiratory distress.

The definitive diagnosis is based on the history, physical examination, rectal examination, and skin biopsy. Ruling out PF and bullous pemphigoid is important. The chronic wasting nature of the disease and multisystemic signs are key to making a diagnosis. Laboratory features include hypoalbuminemia, hypoproteinemia, impaired small intestinal carbohydrate absorption, and increased activities of γ-glutamyl transferase, serum alkaline phosphatase, and bile duct isoenzymes. A superficial and deep eosinophilic and lymphoplasmacytic dermatitis with irregular epidermal hyperplasia is present. Exocytosis of eosinophils and lymphocytes and necrosis of keratinocytes occurs. Perivascular collagen degeneration, lymphoid nodules, and a lichenoid inflammatory infiltrate may be present. Eosinophilic infiltrates of the pancreas, salivary glands, oral cavity, and gastrointestinal tract are common. Peripheral eosinophilia is usually absent. Abdominal ultrasound may show an enlarged liver, thickened intestine, and enlarged mesenteric and intestinal lymph nodes. In some cases thoracic radiographs may be abnormal with the presence of an interstitial pattern and nodules.

Treatment is symptomatic and includes anthelmintics, antibiotics, azathioprine, and corticosteroids. Two horses have responded to dexamethasone at 0.2 mg/kg IM for the first 5 days, followed by prednisolone at 0.5 mg/kg orally every 12 hours for 7 days and then 1.0 mg/kg every 24 hours for a week, followed by alternate-day therapy. Most horses, however, respond poorly to systemic glucocorticoids, and the prognosis is grave. A single horse with this disease showed a partial response to hydroxyurea and dexamethasone therapy.[115]

Sarcoidosis

Equine sarcoidosis (ES), also known as equine idiopathic granulomatous disease, can occur as a localized, partially generalized, or generalized condition. Although all forms are rare, it appears that they are becoming more frequently encountered in equine practice. The localized form of the disease tends to remain focused within the skin, most commonly in the lower limbs. The partially generalized and generalized forms are characterized by extensive exfoliation, severe wasting, and granulomatous inflammation of multiple organ systems.

Multiple breeds have been affected, with the most affected horses being greater than 3 years old. Mares appear to suffer a greater prevalence for this condition.[116] The skin disease begins as scaling, crusting, and alopecia on the face, limbs, and/or trunk (Fig. 18.52). Clinical signs may progress rapidly or slowly. Peripheral lymphadenopathy may develop concurrently with weight loss, muscle wasting, anorexia, exercise intolerance, and fever.

The definitive diagnosis is made by skin biopsy where multifocal nodular to diffuse lymphogranulomatous dermatitis with multinucleated giant cells are present with or without vasculitis. Granulomatous infiltrates also occur in other organs, including the lymph nodes, lung, gastrointestinal organs, liver, and spleen. A complete blood count reveals leukocytosis, increased fibrinogen, and hyperglobulinemia. Anemia caused by chronic infection may be present.

FIG. **18.52** Horse with generalized granulomatous dermatitis. (Courtesy A. A. Stannard, University of California at Davis.)

The recommended treatment includes a large loading dose of prednisolone (1–2 mg/kg orally q 24 h, given in the morning) followed by 0.2 to 1.0 mg/kg orally q 24 h for several weeks or longer. Alternatively, dexamethasone can be used for the loading dose at 0.04 to 0.08 mg/kg IM q 24 h for 7 to 14 days followed by the lower prednisolone dose. Pentoxifylline at 10 mg/kg PO q 12 h and omega fatty acids may be useful adjunctive therapies. The prognosis for both generalized and partially generalized ES is poor. The prognosis for localized ES is good for survival, but the majority of horses will need low-dose prednisolone for life for lesion control, although spontaneous remission may occur.[116,117]

CHAPTER 19

Disorders of the Reproductive Tract

Maria R. Schnobrich*

This chapter will review the normal anatomy and physiology of the mare and stallion with a discussion of pathology and common clinical presentation of reproductive disorders. There will also be a discussion of breeding management and advanced reproductive techniques for fertility enhancement and diagnosis of reproductive dysfunction.

Reproductive Anatomy and Physiology of the Nonpregnant Mare

Maria R. Schnobrich

INTRODUCTION

Equine reproductive anatomy and physiology deviate from those of other domestic animals in several notable ways, requiring an in-depth understanding for appropriate reproductive management and treatment. This section will serve as a review of reproductive anatomy and physiology of the nonpregnant mare, focusing on the clinically important features and highlighting where the mare differs from other species.

REPRODUCTIVE ANATOMY

The reproductive anatomy of the mare includes structures intrinsic to the reproductive tract (tubular tract and ovaries) and structures that are remote from the reproductive tract that play a role in regulating reproductive function (hypothalamus, anterior pituitary, retina, and the pineal gland) or are linked to reproductive function (mammary gland). This section will review the embryonic origin and key features of the relevant anatomic structures.

Internal Reproductive Tract

The mare's reproductive tract includes the ovaries (gonads), the tubular tract (oviducts, uterus, cervix, vagina, and vestibule), and the external genitalia (vulva and clitoris).

*The editors and authors acknowledge and appreciate the contributions of Daniel C. Sharp, Michael B. Porter, Nigel R. Perkins, John B. Chopin, Carlos R. F. Pinto, Dale L. Paccamonti, Elizabeth Metcalf, Grant S. Frazer, Michelle M. LeBlanc, Elaine M. Carnevale, Marco A. Coutinho da Silva, and Juan C. Samper as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

Ovaries

The paired ovaries are composed of tissue derived from mesoderm (ovarian parenchyma and vasculature) and the primordial germ cells (oocytes).[1] The ovaries are shaped like kidney beans and are approximately 2 to 4 cm in height and 8 to 10 cm in length.[2] They are usually located at the most cranial aspect of the reproductive tract, approximately 15 cm caudal to the corresponding kidney, suspended in the mesovarium.[3,4] The ovaries are generally positioned with the long axis of the ovary parallel to the mare's spine, and the ovulation fossa (the concave portion of the ovary) directed ventrally.[4]

Resting on the abdominal viscera, the position of the ovaries is somewhat variable within the sublumbar region between the 10 and 2 o'clock position, ventral to the fourth or fifth lumbar vertebrae, approximately 4 to 8 cm craniolateral from the tip of the uterine horn.[5] Ovarian size varies with hormonal environment and follicular activity. The ovaries are usually small and inactive during anestrus (3–4 cm in length) or can be quite large (10–12 cm in length) when multiple follicles are present in estrus, in vernal or autumnal transition, or under the influence of gestational hormones. The preovulatory follicle of the mare is usually larger (≥35 mm) than that in most other domestic species and can be appreciated on transrectal palpation as a toned, fluid-filled vesicle that has a characteristic difference in consistency compared with the surrounding ovarian tissue.[3-6]

The mare's ovary is unique compared with other domestic species in two ways: (1) the cortex (containing the follicles and oocytes) is internal to the ovarian medulla (ovarian vasculature), which lies on the exterior of the ovary, and (2) ovulation occurs internally, releasing the oocyte through the ovulation fossa, whereas ovulation occurs over the entire exterior surface of the ovary in other species.[4,6] This unique anatomy of the mare's ovary makes transrectal palpation and identification of corpora lutea not practical or accurate.[4,6] In addition, pathology of the ovulation fossa can result in infertility, because the ovulated oocytes may be prevented from reaching the oviduct for fertilization.

Oviduct

The oviducts (uterine tubes) originate from the most anterior segment of the paramesonephric or müllerian ducts.[1] The concentric tissue layers of the oviduct from the external surface to the oviductal lumen consist of serosal surface, muscularis (longitudinal and circular muscular layers), submucosa, and mucosa. In the 500-kg mare they are approximately 20 to 30 cm in length and travel a tortuous path in the mesosalpinx from the ovary to the tip of the uterine horn.[4]

The oviduct is divided anatomically into three sections: the infundibulum, the ampulla, and the isthmus.[1-4] The infundibulum is a funnel-shaped dilation covering the ovulation fossa that transports the oocyte from the ovary to the ampullary region of the oviduct where fertilization occurs.[1] Following fertilization, the conceptus passes through the isthmus (the narrowest portion of the oviduct that enters the uterus at the uterotubal junction) to the uterine lumen. The uterotubal junction has a muscular sphincter that selectively allows embryos (which produce prostaglandin E_2 [PGE_2]), but not unfertilized oocytes, to pass into the uterus at approximately 5.6 to 6 days post ovulation (Fig. 19.1).[7,8] In addition, the unique anatomy and physiology of the uterotubal junction make salpingitis rare in the mare compared with other species such as cattle and swine.[6,9]

Uterus

The mare's uterus consists of two uterine horns and a uterine body that are derived from the partial fusion of the paramesonephric ducts.[1,3,5] The mare's uterine tissue layers are as follows from external to internal lumen: serosa (perimetrium), the myometrium (outer longitudinal smooth muscle fibers and inner circular fibers separated by a vascular layer), and the endometrium. The endometrium is divided histologically into three layers from deep to superficial lumen: (1) the stratum spongiosum (loose connective tissue, submucosa, and glands), (2) the stratum compactum (1-mm region beneath luminal epithelium with a high density of stellate stromal cells), and (3) the luminal epithelium (consisting of simple columnar epithelium).[4,5] The uterus, ovaries, and oviducts are suspended in the abdomen by the broad ligament in a T-shape or Y-shape when viewed from above.[3,4] The broad ligament originates from the sublumbar region, and the fibers converge over the uterine body and cervix, causing the mare's uterus to have a less distinct tubular feel when palpated transrectally compared with cattle.[6] The endometrium of the mare's uterus has 5 to 10 longitudinal folds that extend from the tips of the uterine horns through the uterine body and are continued through the cervix where they become the cervical folds seen on vaginoscopy (Fig. 19.2).[4,10] The function of the endometrial folds has been theorized to aid in sperm transport to the oviduct and to provide channels for removal of fluid and debris following breeding.[4]

The uterus is the site of semen deposition during breeding and where the developing fetus is nurtured during pregnancy. It is a dynamic and changing environment influenced by circulating and local hormones that dramatically alter uterine size, contractility, tone, secretory activity of glands, immune competence, and overall character and function.

FIG. **19.1** Oviductal papilla or uterotubal junction as viewed from hysteroscopic evaluation of the uterine lumen.

Cervix

The mare has a muscular cervix (approximately 6–7 cm in length) derived from ectodermal tissue and the fusion of the paramesonephric ducts.[1,4] The cervix of the mare differs from some other farm species in that it lacks prominent cervical rings and can easily be dilated by digital manipulation.[6] The luminal epithelium is a secretory, stratified squamous epithelium, surrounded by an internal circular and longitudinal outer muscular layer. The longitudinal folds of the uterus are continuous with the cervical folds and give the scalloped appearance of the external cervical os during estrus.[4] The external cervical os is located in the vaginal fornix (anterior vagina) and has two bands of tissue that extend from the dorsal and ventral margins to the vaginal wall (dorsal and ventral frenulum) that are often confused with adhesions (Fig. 19.3).[2,4,9]

The cervix can be appreciated with transrectal palpation as a tubular structure with variable tone, located in the anterior pelvic inlet in the region of the bladder. The cervix of the mare differs from the cow in that it is less prominent and tubular on palpation due to a more dorsal insertion of the broad ligaments and the lack of fibrocartilaginous rings. The mare's cervix cannot be grasped and used to retract the reproductive tract as in a cow.[6] The cervical length of most mares is approximately 5 to 7 cm, and the width increases during estrus to approximately 2 to 4 cm. Cervical size, tone, and character will vary with breed, age, prior trauma, and reproductive status.[2,4] The cervix is a versatile structure that in estrus provides lubrication and accommodates the stallion's penis during intromission. It then maintains tone and serves as a protective barrier to the uterine environment in diestrus and pregnancy, and finally during parturition it dilates to allow expulsion of the fetus. These dynamic changes are under the control of reproductive hormones, allowing veterinarians to use the cervix clinically as a barometer of the mare's hormonal milieu (Fig. 19.4).

Vagina

The vagina originates from the fusion of the paramesonephric ducts cranially (mesodermal origin) and the urogenital sinus

FIG. **19.2** Excised uterus postmortem with the uterine lumen exposed to show endometrial folds.

caudally (ectodermal origin).[1] It consists of a collapsed potential space extending from the cranial vaginal fornix caudally to the transverse fold.[1,11] Some authors consider the vestibule as part of the vagina, and others define the caudal border at the transverse fold.[4,11,12] The vaginal epithelium is aglandular, stratified squamous tissue and is surrounded by a thin wall of fibroelastic tissue and scant smooth muscle.[11] The cranial portion of the vagina lies in the peritoneal cavity and is covered by serosa, without a distinguishable muscular layer. The caudal vagina lies in the retroperitoneal space and is not covered with serosa. This has clinical implications, because cranial vaginal lacerations can result in peritonitis. The lumen of the vagina is normally collapsed, and the vestibulovaginal fold (or hymen) in normal mares prevents aspiration of air and fecal material into the vagina. The mucosa of the vagina should be pale pink, and fluid should only be present at certain times (lochia post foaling or small amounts of translucent fluid during estrus). Otherwise, pathology should be suspected.

The vestibulovaginal fold (transverse fold or "hymen") is a fold of tissue derived from the fusion of the paramesonephric ducts cranially and the urogenital sinus caudally.[1] This fold of tissue provides a barrier against external contamination of the cranial vagina and uterus. It is easily visualized as a sheet of pink tissue at the cranial aspect of the vestibule when one parts the vulvar lips (Fig. 19.5).[13] When a vaginal or speculum examination is performed on a maiden mare this tissue may need to be broken down manually (causing minimal discomfort). It is usually thin, occasionally fenestrated, and easily torn. The function of this tissue as a barrier can be assessed by parting the labia, and if air is aspirated into the vagina (as diagnosed by an audible noise or on visual evidence of pneumovagina on transrectal ultrasound) then it is determined that the vestibulovaginal seal is incompetent.[13] Clinically, failure of this seal may be less of a concern if the mare has an adequate vulvar seal.

FIG. **19.3** Cranial vaginal fornix demonstrating the dorsal and ventral frenulum of the cervix.

Vestibule

The vestibule, originating from the caudal urogenital sinus (ectoderm), is the region of the reproductive tract that extends from the vestibulovaginal fold to the vulvar lips.[1] The vestibule of the mare is lined by stratified squamous epithelium, and a series of branched vestibular glands are present with openings visible in the ventral and lateral vestibular walls.[11] The lateral walls of the vestibule contain erectile tissue that form the left and right vestibular bulbs, which associate abaxially with the constrictor vestibuli muscle.[4] The external urethral orifice lies beneath the vestibulovaginal fold, and the position of the urethral opening relative to the pelvis and this fold may predispose the mare to urovagina or urometra (Figs. 19.6 and 19.7).[4]

Vulva

The paired vulvar labia arise from the ectodermal tissue of the urogenital sinus and provide the first and arguably the most important external barrier to the internal reproductive tract.[1,4] The vulvar labia of normal mares appose completely, with no mucosal surface visible. The ventral commissure is rounded and houses a prominent clitoris (approximately 2 cm in diameter), lying in the clitoral fossa, which can be seen rhythmically everted during estrus ("winking"). The dorsal commissure of the vulva is pointed, and its location and degree of cranial inclination are often critically evaluated during a reproductive examination, because poor vulvar conformation has been associated with contamination and pathology (Fig. 19.8).[12,13] Mares with an increased cranial angle to the vulva, sunken anus, or poor labial apposition are predisposed to fecal contamination of the reproductive tract and may require corrective surgery (Caslick or episioplasty and Gadd or perineal body reconstruction).[5,13]

Clitoris

The mare's clitoris arises from ectodermal tissue and consists of a body and glans clitoris.[1,12] The clitoral body (5 cm in length) is formed from the crura of the ischium.[12] The mare's glans clitoris is more prominent than in most domestic species (2–3 cm in diameter), and, similar to the male homolog, the glans penis contains erectile tissue.[1,12] The clitoris lies within the clitoral

fossa (fossa clitoridis) and has three sinuses present in the skin overlying the clitoris (Fig. 19.9).[2,3] There are two smaller lateral sinuses and a larger median sinus that can accumulate debris and provide an environment that promotes growth of certain pathogenic bacteria *(Taylorella equigenitalis)*.[4,12,14]

Nonreproductive Tract Anatomy

Mammary Gland

The mammary glands are derived from ectodermal tissue and lie in the inguinal region, often inconspicuous even during lactation.[1] The mare's udder consists of left and right laterally compressed halves with its respective teat.[2] Each teat has two (sometimes three) separate lactiferous duct systems that empty into a single ostium.[2] There may be two or three ostia per teat, with each opening representing a separate duct system. During lactation the glands are soft and should not be firm and distended if the foal is nursing adequately. When not lactating, the glands involute and become soft and flaccid.

Hypothalamus and Pituitary Gland

The hypothalamus (part of the diencephalon) is located below the thalamus in the rostral aspect of the brainstem.[2,3] The hypothalamic nerve cell bodies (hypothalamic nuclei) that influence reproductive function are grouped into "tonic" and "surge" centers.[1] Neurons in these regions have axons that either terminate into a capillary system that perfuses the anterior pituitary or that terminate in the posterior pituitary to release hormones into systemic circulation.[1,2] The hypothalamohypophyseal portal system carries gonadotropin-releasing hormone (GnRH) from hypothalamic nerve endings in undiluted small concentrations to target cells in the anterior pituitary.[1,2,4]

The pituitary is divided into the posterior lobe (neurohypophysis) and the anterior lobe (adenohypophysis), which is further divided into anterior and intermediate lobes.[3,12] The anterior pituitary cells under stimulation from GnRH release their hormones into the systemic circulation. The primary hormones released from the anterior pituitary's gonadotroph cells include follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin (PRL). Neurons from hypothalamic nuclei such as the paraventricular nuclei (PVN) in the hypothalamus extend directly into the posterior pituitary, where upon stimulation of the cell body, hormones (oxytocin and vasopressin) are directly released into circulation.[1,2,4]

REPRODUCTIVE PHYSIOLOGY OF THE NONPREGNANT MARE

Reproductive Hormones

Environmental factors (daylight length, pheromones, and nutrition) transmit information through neural signaling and the pineal gland to the hypothalamus to regulate the release of GnRH.[1,4-6] The pulse frequency of release is regulated by positive and negative feedback from other reproductive hormones (inhibin, estrogens, and progestogens) secreted by the reproductive tract. The reproductive tract undergoes changes as a result of this hormonal milieu, which is dictated by the interplay of the hypothalamic-pituitary-gonadal (HPG) axis. Table 19.1 summarizes the major reproductive hormones and their primary targets and effects. Fig. 19.10 is a simplified summary of this hormonal axis and the reproductive tract illustrating the hormones, their targets, and effects.

Reproductive Phases of the Nonpregnant Mare

The mare is a seasonally polyestrous, long-day breeder with regular estrous cycles repeated when daylight is long and resources for the dam and foal are optimal.[4-6] The mare's annual reproductive rhythm (in the Northern Hemisphere) can be divided into four phases: (1) winter anestrus, (2) vernal transition, (3) ovulatory/breeding season, and (4) autumnal transition. The transition into these different phases is mediated through environmental clues, most notably length of exposure to light or photoperiod.[4,5,15]

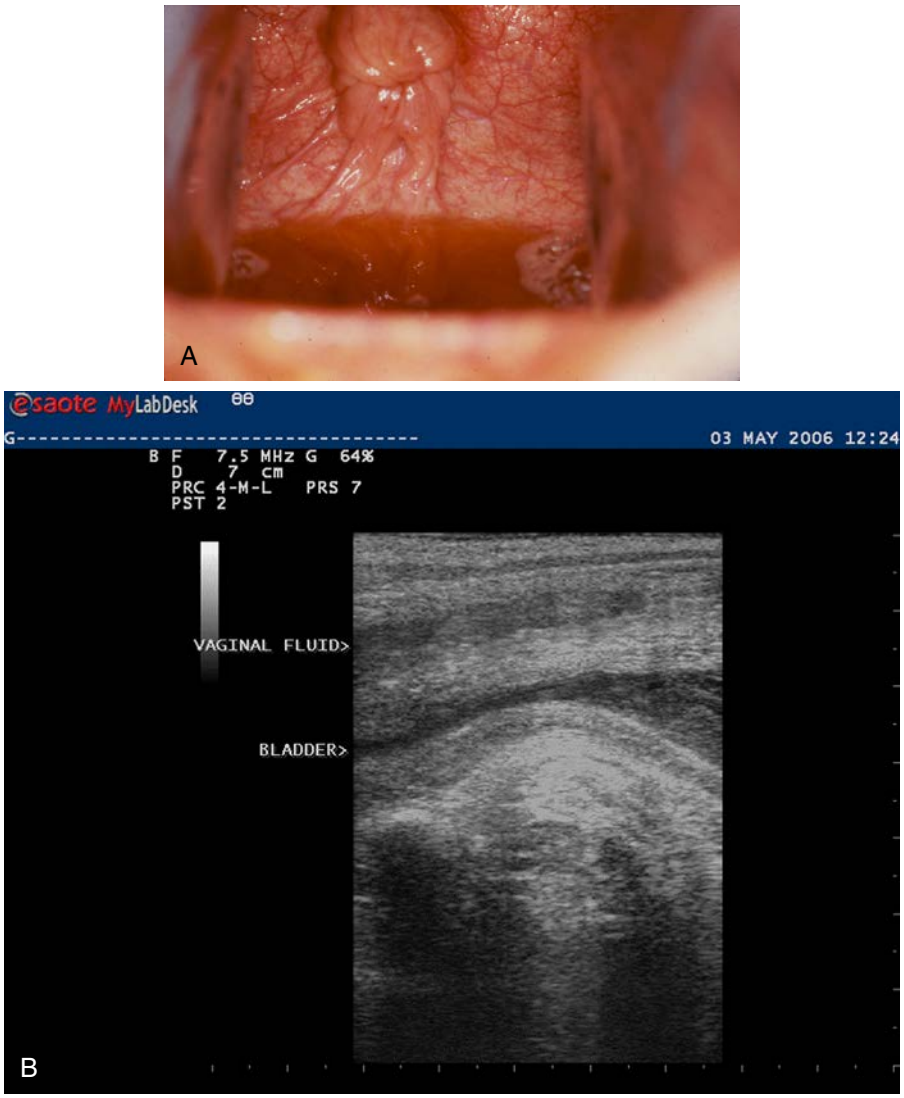

FIG. **19.7** (A) Urovagina as viewed on vaginoscopy with hyperemic vaginal mucosa and (B) as viewed on transrectal ultrasound with hypoechoic fluid present in the vagina. (Courtesy Dr. Patricia Sertich).

It is believed that this change in photoperiod is conveyed by the retina through a multineuronal pathway that modulates melatonin secretion, which then regulates hypothalamic secretion of GnRH.[4,5] Under increasing daylight, melatonin secretion is reduced (the majority of melatonin is secreted during night/dark), and melatonin's inhibitory influence on GnRH synthesis and secretion is removed, resulting in increased GnRH secretion. Increasing concentrations of GnRH stimulate follicular development and the start of the vernal transition.[4]

Winter Anestrous/Anovulatory Season

Generally the incidence of mares undergoing a period of reproductive quiescence or anestrus varies in relation to increasing distance from the equator. The incidence of anestrus at latitudes between 30° and 50° is approximately 70%, whereas at latitudes between 10° and 30°, less than 50% of mares experienced anestrus.[15-18] During anestrus the mare's production of GnRH is reduced, resulting in a decrease in pituitary secretion of FSH and LH. Consequently there is little follicular development and no corpora lutea formation, and thus circulating concentrations of estradiol and progesterone are low.

Palpation and ultrasonography of the reproductive tract during anestrous reveal small inactive ovaries (largest follicle <10 mm), a flaccid uterus, and a cervix that may have tone but will relax and give way to digital pressure or dilation. No uterine edema or intraluminal uterine fluid should be present, and the cervix is often pale pink and appears closed on vaginoscopy. Reproductive behavior is considered ambivalent, with neither strong aversion to the stallion nor demonstrative teasing. Occasionally breeding will be permitted by the anestrous mare and can be mistaken as a sign of true fertile estrus and follicular development. This is confusing because the term *anestrus* means lack of estrus or receptivity to the stallion, and as previously mentioned mares in this period have been known to allow breeding and even demonstrate receptive sexual behavior. This highlights another difference in mare reproductive physiology compared with most domestic species.

FIG. **19.9** Clitoris with smegma in the clitoral fossa.

Vernal Transition/Anovulatory Receptivity

As the length of daylight increases, hypothalamic GnRH production and secretion increases, resulting in an increase in circulating FSH and eventually LH concentrations.[4,19] Several waves (average of 3.7) of follicular growth and regression occur without ovulation before the first ovulation of the season.[20,21] The first ovulation marks the end of vernal transition and the beginning of regular interovulatory intervals or the "breeding season." FSH levels are variable during transition, whereas LH concentrations remain low, resulting in prolonged periods of estrus for approximately 1 to 2 months before ovulation.[22] Early follicular waves have decreased steroidogenesis, so estradiol elevates only in the later follicular waves that result in ovulation.[23] These transient infertile estrus periods may cause the inexperienced owner or practitioner to waste time inappropriately breeding a mare that will not ovulate, generating unnecessary costs and possibly contaminating the mare. It should be noted that not all mares have a defined transitional phase, and some remain in deep anestrus and only develop one follicular wave prior to ovulation.[24]

Reproductive evaluation of the mare during this time usually reveals large ovaries with multiple medium (>20 mm) to large follicles and no corpora lutea. Endometrial edema may vary from nonexistent to prominent, and there is a palpable increase in uterine thickness and tone. Small amounts of intrauterine fluid may be present coinciding with increased uterine edema. The mare's cervix relaxes under an environment of increasing estradiol and minimal to no progesterone. The mare's behavior is often characterized as persistent, intermittent, or irregular intervals of estrus in which the mare is receptive to mating but because of lack of ovulation will not conceive.[5,6,15] This can be a very frustrating time for owners with horses in training because they often complain of persistent estrus, which some feel interferes with performance.

Ovulatory Receptivity/Breeding Season

Following the first ovulation of transition, the mare begins to have regular interovulatory intervals (estrous cycles). The time the first ovulation occurs may vary based on individual, latitude, management, and breed. In the Northern Hemisphere, the first ovulation of the year usually occurs naturally around late April to May.[4] The average estrous cycle duration in the mare is 21 days (range 18–24), with estrus (follicular growth with sexual receptivity) lasting 4 to 7 days on average, and diestrus (active corpus luteum [CL] and nonreceptivity) lasting 14 to 15 days.[4-6]

Estrus. Estrus is defined as the behavior of sexual receptivity to the stallion but also refers to the phase in the estrous cycle when the mare is approaching ovulation and is sexually receptive.[21,22,25] Estrus in the mare, as stated previously, is typically around 7 days, lasting longer at the beginning of the breeding season and growing shorter toward the end.[4,5] During early estrus, follicles are recruited to grow under increasing FSH and LH secretion, and progesterone is low (<1 ng/mL).[1,4,5] As the cohort of follicles grow (3–5 mm/day) they secrete estradiol, which has a positive feedback on the anterior pituitary, inducing an increase in LH secretion and thus follicular maturation.[1,4,22] Inhibin, produced from the growing dominant follicles, inhibits FSH secretion, and one or two dominant follicles continue to develop (>30 mm) under stimulation from LH alone. This single follicle or occasionally two or more dominant follicles continue to grow, and when preovulatory estradiol levels are reached, an increased LH (an

TABLE **19.1 Summary of Reproductive Hormones***

Name of Hormone	Biochemical Classification	Source	Target Tissue	Main Action
GnRH	Neuropeptide (decapeptide)	Hypothalamic surge and tonic centers	Anterior lobe of the pituitary (gonadotroph cells)	Release of FSH and LH from the anterior pituitary
FSH	Glycoprotein	Anterior lobe of the pituitary (gonadotroph cells)	Ovary (granulosa cells)	Stimulates follicular development
LH	Glycoprotein	Anterior lobe of the pituitary (gonadotroph cells)	Ovary (cells of theca interna and luteal cells)	Induction of ovulation, follicular maturation Luteal tissue support
Prolactin	Protein	Anterior lobe of the pituitary (lactotroph cells)	Mammary cells	Induces maternal behavior, induction of lactation
Oxytocin	Neuropeptide (octapeptide)	Synthesized in the hypothalamus, stored and released from the posterior pituitary Evidence of production in the endometrium	Myometrium and endometrium, myoepithelial cells in the mammary gland	Induces uterine contractions and milk ejection, induces prostaglandin release and promotes maternal behavior
E_2	Steroid	Granulosa cells of the follicle, placenta	Hypothalamus, entire reproductive tract	Facilitates receptive sexual behavior, regulates GnRH secretion, enhances secretory activity of the reproductive tract, and enhances uterine motility
P4	Steroid	Corpus luteum and placenta	Uterine endometrium, myometrium, mammary gland, and hypothalamus	Inhibits sexual receptivity, alters endometrial gland secretion, promotes maintenance of pregnancy, and inhibits GnRH release
Testosterone	Steroid	Cells of the theca interna of the follicle	Brain, skeletal muscle, and granulosa cells	Substrate for E_2 synthesis, abnormal masculinization
Inhibin	Glycoprotein	Granulosa cells of the follicle	Gonadotrophs of the anterior pituitary	Inhibits FSH secretion
Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)	Prostaglandin (C-20 chain fatty acid)	Endometrium and follicle	Corpus luteum, uterine myometrium, and ovulatory follicles	Luteolysis, promotes uterine contraction, role in ovulation induction
Melatonin	Neuropeptide	Pineal gland	Hypothalamus	Inhibits GnRH secretion

E_2, Estradiol; *FSH,* follicle-stimulating hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone; *P4,* progesterone; *$PGF_{2\alpha}$,* prostaglandin $F_{2\alpha}$. LH surge) is induced, causing ovulation.[24,26,27] The process of ovulation is thought to take approximately 2 to 7 minutes and results in the oocyte being released from the follicle through the ovulation fossa. Ovulation generally occurs 1 to 2 days after the initial rise in LH, with LH concentrations reaching peak levels usually 1 day after ovulation has occurred.[1,4,26] Remarkable tissue remodeling occurs so that the oocyte can be released, and it is suggested that this process is mediated by prostaglandins (PGE_2 and $PGF_{2\alpha}$) and tissue-remodeling enzymes (MMP-1 and MMP-2).[1,23,28]

During estrus, the reproductive tract prepares for mating. There is increased lubrication of the tract as uterine and cervical glands increase mucus and glandular secretion. Ultrasonography of the ovaries reveals multiple follicles (>20 mm) that grow 3 to 5 mm/day, often with one or two dominant preovulatory follicles reaching preovulatory sizes of 35 to 50 mm.[4,5] Immediately before ovulation the follicular wall may thicken, the follicle softens, and often the mare is sensitive to palpation in the periovulatory window.[4,5,25] Endometrial edema is maximal 3 to 4 days before ovulation and then decreases approximately 1 to 2 days before ovulation.[3,26] The mare's uterus becomes more edematous and "doughy" on transrectal palpation, with the cervix relaxing significantly as ovulation approaches.[1,5,26] During estrus, scant hypoechoic intraluminal fluid can often be visualized on transrectal ultrasound in the normal mare, but it is widely believed that greater than 2 cm of fluid—or echogenic fluid at any time—is associated with decreased pregnancy rates and possible pathogy.[30,31] The cervix relaxes as ovulation nears, becoming edematous, pliable, and well lubricated. These changes serve as a tool for the clinician to evaluate the mare's hormonal environment and thus accurately time breeding (see Fig. 19.4). The behavioral signs observed during estrus include elevation of the tail in the presence of the stallion; eversion of the vulvar lips to expose the clitoris or "winking"; squatting with rotation of the pelvis, urination, and leaning toward the stallion; turning the head back toward the stallion; and moving toward the stallion.[32] Monitoring sexual

behavior of the mare is an essential part of good broodmare management because it helps to identify the current stage of the cycle and to determine the optimal time to breed or when a mare is returning to estrus.

Diestrus. Diestrus is characterized by the elevation in circulating progesterone from the CL that rises shortly after ovulation.[1,4] Progesterone levels in the blood rise from <1 ng/mL during estrus to peak levels (8–16 ng/mL) at approximately 6 days post ovulation, and progesterone levels above 4 ng/mL persist until luteolysis occurs.[4,5] Clinically this is useful if one is unsure of the mare's current stage of the estrous cycle, because a serum progesterone can determine whether there is active luteal tissue present (>1 ng/mL). FSH levels rise and fall during diestrus, inducing follicular development and estradiol secretion, but because of the inhibitory action of progesterone on LH secretion, these diestrus follicles rarely ovulate.[33] Luteolysis occurs when episodic bursts of $PGF_{2\alpha}$ from the mare's endometrium are released at 13 to 16 days post ovulation in the absence of maternal recognition of pregnancy. Luteolysis is rapid, and progesterone concentrations plummet to <1 ng/mL within 2 days of initial prostaglandin release.[4]

During diestrus, the reproductive tract functions to support an early pregnancy. The uterus becomes toned, and uterine contractions change to facilitate establishment of pregnancy.[34,35] The cervix elongates and closes, protecting the uterine environment from caudal reproductive tract contamination.[4,5] The signature feature of ovarian morphology in diestrus is the presence of an active CL, and it is important to note that follicles can be any size during diestrus (from 10–50 mm in normal mares). Because of the inside-out structure of the ovary and the restriction of ovulation to the ovulation fossa, the CL remains almost entirely within the ovary, making identification by transrectal palpation difficult. The advent of transrectal ultrasound imaging has improved diagnostic capabilities by enabling practitioners to visualize the corpora lutea, and with increasing resolution, often aged inactive corpora lutea can be visualized as well. During mid to late diestrus there is normally no uterine edema or intraluminal fluid present. The mare is categorically nonreceptive to the stallion and may kick out, strike, and demonstrate avoidance to precopulatory interactions of a stallion.[32]

Autumnal Transition. During the "autumnal transition" the mare progresses from regular interovulatory intervals to ceasing ovulation and finally into anestrus. Often changes associated with this transition begin to occur shortly after the summer solstice in the Northern Hemisphere. The beginning of this period is marked as following the last ovulation of the season.[36] The transition is characterized by irregular estrous intervals, failure of ovulation, and a prolonged or shortened luteal period. Photoperiod and environmental stressors (nutrition, temperature, and stress) are all believed to have some role in the decrease in gonadotropins during this period.[4,36] During this approximately 60-day window, GnRH, FSH, and LH production and secretion decrease, and consequently, systemic estradiol and progesterone concentrations eventually wane to basal levels.[4,36]

Reproductive tract examination at this time often reveals multiple large anovulatory follicles in early transition to minimal ovarian activity late in transition, with occasionally the last CL still visible with transrectal ultrasound. The uterus under the decreasing estradiol and progesterone becomes increasingly flaccid with minimal to no edema. The cervix often remains toned and closed because of the dwindling progesterone from the last ovulation. Mares often demonstrate erratic estrus duration and frequency, similar to the vernal transition, again making their behavior a source of frustration for owners.

Postpartum Period

Immediately after expulsion of the fetus, the equine uterus begins the rapid process of involution. The mare's placentation (diffuse and epitheliochorial) requires less endometrial repair following parturition compared with other domestic species (bovine, caprine, and ovine), enabling a mare to conceive and carry another pregnancy again shortly after foaling.[1,4,5] Histologic return of the endometrium to the pregravid size is reported to occur by 10 to 14 days, and the uterine size is reported to return to the pregravid state over a period of 23 to 32 days.[4,37,38] "Foal heat" is defined as the first period of sexual receptivity and ability to conceive after parturition and usually begins 7 to 9 days after foaling.[4] The first ovulation post foaling occurs on average at 9 days post parturition.[4] Depending on the efficiency of uterine involution, the fertility of this foal heat varies. There are many different opinions on the fertility of "foal heat" breeding, and it is likely that breed and management may have an influence. If significant fluid (>3) cm is present within the uterus at foal heat, then breeding the mare is not recommended.[38] In addition, studies regarding the effect of season on first postpartum ovulation suggest that mares that foal in January and February tend to have longer intervals from foaling to the first fertile ovulation than mares that foal in late spring. After the foal heat most mares have a second 30-day heat that occurs approximately 14 days after the end of the foal heat and may represent a more reasonable time to breed. It has been suggested based on several studies that increased pregnancy rates and decreased embryonic loss occurs when mares are bred at least 10 to 20 days postpartum. Some authors suggest an even longer period is needed following parturition to return to prepartum per cycle pregnancy rates.[38-40]

During the postpartum window in hospitalized patients, it is important to monitor daily rectal temperatures, uterine fluid accumulation, and the attitude of the mare, because significant endometritis can develop into metritis in mares not given the opportunity to ambulate and expel lochia. Although fluid within the uterine lumen by ultrasound is not abnormal, lavage and ecbolic agents may be helpful to assist with involution. In healthy mares the uterine fluid (lochia) and debris usually dissipate 7 to 10 days after parturition.[4,30,31]

Lactational Anestrus

Lactational anestrus, or inhibition of follicular development because of nursing, is not as well defined in the mare as it is in other species.[6] Because of the prevalence of foal heat and normal cyclicity in the majority of mares nursing foals, most believe it does not exist at all but is a consequence of stress from the puerperal period and perhaps increased metabolic demands. Limited studies have been performed in which foals were removed from mares at varying time points after parturition. One study indicated that removal of the foal hastens the onset of estrus.[41] Foal removal has been associated with elevated LH concentrations and increased ovarian follicle diameter in some studies and conflicting results in others.[40,41]

Mare Breeding Soundness Examination

Maria R. Schnobrich

This section will describe the reproductive evaluation of the mare (also known as a breeding soundness examination [BSE]), the procedures involved, and the common pathologies identified. A BSE of the mare may be performed for a variety of reasons including prepurchase or prebreeding examination to confirm normal reproductive tract findings, the evaluation of subfertile mares, or identification and treatment of reproductive tract pathology. Procedures that should be performed in all BSEs include proper identification of the individual, review of signalment and pertinent medical and reproductive history, general physical examination, perineal examination, transrectal palpation and ultrasonography of the reproductive tract, vaginoscopy, and digital cervical and vaginal examination. Additional procedures that may be considered depending on the purpose of the BSE and preliminary findings include uterine culture and cytology, uterine biopsy, and hysteroscopy. Next is a stepwise description of the procedures performed when conducting a thorough BSE.

TABLE **19.2 Details of Information to Be Gathered During History Taking**

History	Comments
General health	Vaccination, deworming, foot care, dental care, nutritional history, systemic diseases, and management
Athletic	Level of activity, age at which athletic career ended, any known drug usage
Cycling	Length of estrus, expression of estrus, interovulatory interval
Breeding	Number of cycles bred, breeds per cycle, natural or artificial insemination, fertility of stallion, age at which the mare was last bred
Pregnancies	Number of diagnosed pregnancies and outcomes
Foaling	Any history of dystocia, type of management
Prior reproductive examinations	Diagnoses, treatment, management
Prior reproductive surgeries	Nature of surgery, date performed, and outcome
Drug use during breeding season	Ovulation induction, estrous cycle manipulation

IDENTIFICATION

Detailed identification of the mare is of utmost importance for legal and ethical reasons. The recording of acquired brands, tattoos, and detection of a microchip should all be considered to supplement the physical description or photographs. In the worst-case scenario, improper identification can lead to erroneous conclusions and recommendations being made or to procedures being performed on the incorrect mare, which could compromise a pregnancy.

SIGNALMENT AND HISTORY

History and signalment may suggest possible problems and guide the diagnostic approach (Table 19.2). The administration of certain medications (anabolic steroids, progestogens, and GnRH vaccine) during an athletic career can affect the horse's future fertility, and the possibility of previous administration should be investigated. The use of anabolic steroids can cause masculine behavior and changes to the external

genitalia. There might also be a downregulating effect on the HPG axis, causing reproductive senescence that has to reverse over time. The use of an anti-GnRH vaccine (Equity; Pfizer Animal Health, West Ryde, Australia) is used as a reportedly effective way to inhibit estrus in fillies. Unfortunately, a number of fillies have had prolonged ovarian inactivity in their breeding career caused by this vaccination.[42-44] Several cases have been described of cytogenetically normal mares that have prolonged (four seasons or more) ovarian inactivity after the use of the GnRH vaccine. The age when the vaccine was administered may also have an effect because peripubertal fillies receiving the vaccine appear to have more prolonged periods of ovarian inactivity.

Breeding history should include detailed information from the immediate past, including information on the standard of current or previous breeding management and facilities. It is also valuable, although more difficult, to obtain historical information on the mare's entire breeding career. Particular attention should be paid to the specific details of the time and cause of any pregnancy loss; any dystocia and follow-up reproductive function; or known trauma, hemorrhage, or pathology associated with breeding, pregnancy, or foaling, because these may highlight particular regions that should be evaluated more critically during examination. Often a detailed breeding history of an infertile mare will help direct the evaluation and diagnostics used, because a mare that has never had an early pregnancy diagnosed has a different differential list compared with a mare with repeated early pregnancy loss.

In addition to breeding history, the mare's medical history and current management should be evaluated to identify areas (nutrition, hoof care, pain management, deworming and vaccination) that may need to be addressed to optimize the chances of conceiving and carrying a pregnancy to term. Any previous or current medical issue should be evaluated to determine whether it is still having any adverse effects on the mare's systemic health, and appropriate management and treatment should be initiated to optimize the overall health of the animal.

BEHAVIOR

The season of the year should be considered when assessing reproductive behavior in the mare, because transitional anestrous mares and mares in estrus can demonstrate similar behavior despite being at different reproductive phases.[45] The behavior expected for each phase of the reproductive cycle is described in the previous section. Assessing the mare's response to a stallion while in estrus is important and can help time appropriate breeding and determine whether additional steps must be taken to safely achieve live cover. If a foal is present with the mare, then estrus may not be demonstrated as readily to the stallion until the foal is taken away. In addition, shy or aggressive behavior toward the teaser by the mare while in true physiologic estrus might require additional training and management in a live-cover breeding situation. Overly aggressive, stallion-like behavior when presented with a teaser may also help confirm the presence of a hormone imbalance or reproductive pathology.

GENERAL PHYSICAL EXAMINATION

General observation of the mare while loose and being led to the stocks will allow assessment of behavior and preliminary assessment of comfort, condition, and conformation and may highlight musculoskeletal issues. A brief general physical examination should be performed to ensure that the mare has no detectable condition that could interfere with the ability to conceive or carry a foal to term. The practitioner should inspect the mammary glands visually and with palpation for evidence of abnormalities such as spurious lactation, mastitis, fibrosis, and neoplasia. Excessive body condition and abnormal fat deposits (cresty neck) or hair coat may suggest endocrine disorders such as metabolic syndrome or pituitary pars intermedia dysfunction (PPID), which may have negative effects on the mare's fertility.[45-48] Poor body condition has been associated with decreased fertility, and an underlying cause should be identified and addressed. The mare's hair coat should also be evaluated, as a poor hair coat may suggest systemic health concerns.

RESTRAINT

The mare must be adequately restrained before further examination. What constitutes adequate restraint will depend on the mare's disposition, the skill and experience of the handler and veterinarian, the procedures being performed, and the facilities available. Particular care must be exercised when performing a BSE on mares with little prior exposure to transrectal palpation or vaginal speculum placement. Stocks are generally recommended for a BSE, although adequate restraint (chemical and/or twitch or lip chain) with the mare backed out of a stall door will suffice for practitioners comfortable working under these conditions. If hysteroscopy is to be performed, then it is recommended that the mare be sedated and restrained in stocks. The stocks minimize the mare's movement during the examination and protect the veterinarian and equipment.

Chemical restraint facilitates a safe and efficient examination for certain BSE procedures that are less well tolerated or more prolonged. Chemical restraint may cause some degree of relaxation of the perineum, and therefore it is recommended to assess perineal conformation prior to sedation. In addition α_2-agonists cause increased uterine tone. The dose of sedation is based on the behavior and excitability of the mare. In general detomidine HCl (0.01–0.02 mg/kg) and butorphanol tartrate (0.01–0.02 mg/kg) administered intravenously (IV) often provide adequate sedation for most procedures. Xylazine (0.2–1.0 mg/kg) or detomidine HCl (0.006–0.01 mg/kg) is administered again if sedation is not adequate or if the procedure length dictates additional redosing.

EXAMINATION OF EXTERNAL GENITALIA

The perineal region is inspected for indications of vulvar discharge and gross abnormalities of the anogenital region. Vulvar discharge or urine scalding of the inner thighs may suggest infection, urine pooling, or urinary incontinence. Fluid and dried secretions in the tail may give evidence of vulvar discharge as well. Clitoral enlargement or abnormal anogenital distance may indicate prior exposure to androgens or progestogens or an intersex condition (Fig. 19.11). Normal vulvar lips are vertical, have good tone, and are in close apposition.

Vulvar integrity is important in forming an effective seal against contamination of the genital tract with air, urine, feces, and potential pathogens.[13,49] Vulvar conformation is assessed by digital palpation adjacent to the vulvar lips to locate the

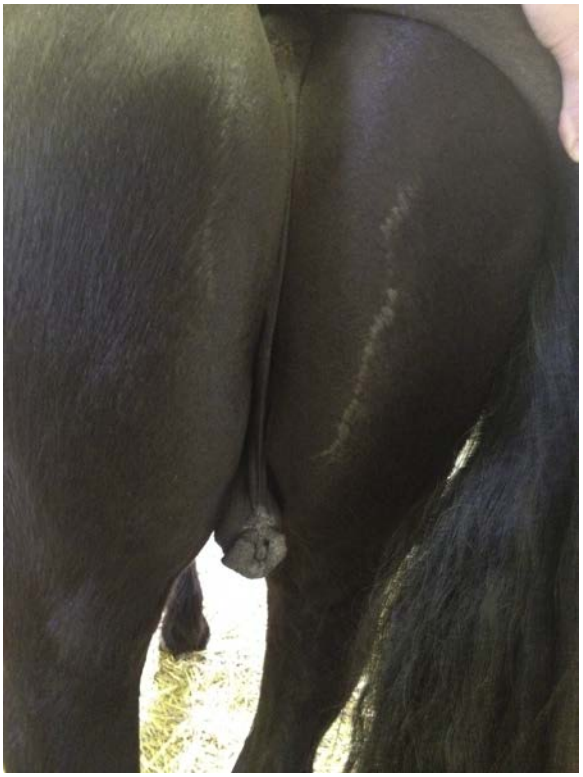

FIG. **19.11** Abnormal anogenital distance in a Friesian male pseudohermaphrodite.

position of the caudal bony pelvic brim (tuber ischii) relative to the dorsal commissure of the vulva. Pascoe's description of Caslick index has been modified to produce a simple assessment technique for vulvar conformation.[49] Generally the dorsal commissure should be level to less than 4 cm above the brim of the pelvis with well-apposed labia and minimal cranial tilt of the vulva, and the anus should be in the same vertical plane as the vulvar lips. Sunken anus, thin vulvar lips, poor labial apposition, and cranial tilt to the vulva all predispose to fecal contamination and have been associated with decreased pregnancy rates.[13,49] To determine the competency of the vulvar seal and the vestibulovaginal fold, transrectal ultrasound can be performed, and the vagina and vestibule can be evaluated for air contamination. Traditionally this evaluation has been performed by gently parting the vulvar lips to determine whether air is readily aspirated into the vagina.[13] If there is poor labial apposition or aspiration of air, then the mare may be prone to pneumovagina and at increased risk of ascending vaginitis and subsequently endometritis.[13]

- Vulvar conformation (VC) good: No Caslick is required. Dorsal commissure of the vulva is less than 4 cm above the bony pelvic brim, and vulvar lips are within 10 degrees of vertical and form an effective seal.
- VC marginal: Caslick may be required. Dorsal commissure of the vulva is 4 to 7 cm above the bony pelvic brim, vulvar lips are within 10 to 20 degrees of vertical, and vulvar lips still form an effective seal.
- VC poor: Caslick or some other corrective procedure is definitely required. Dorsal commissure of the vulva is 5 to 9 cm or more above the bony pelvic brim, vulvar lips are 30 degrees or more in front of vertical, and the vulvar seal is not effective.
- It should be noted that in certain breeds (Thoroughbreds) the Caslick's is recommended in almost every mare, as even those mares that appear to have normal vulvar conformation are predisposed to contamination, and ascending placentitis is a more common occurrence.

TRANSRECTAL PALPATION AND ULTRASOUND EXAMINATION OF THE REPRODUCTIVE TRACT

It is essential that the nonpregnant status of the mare is confirmed before any procedure is performed that could compromise a pregnancy. Transrectal palpation of the genital tract is generally considered safe and appropriate but does carry some risk of rectal mucosal trauma and potentially laceration. The risk increases if excessive force is used, if palpation continues in the presence of pneumorectum, and if the mare strains excessively. Mild sedation to minimize anxiety and reactivity may be accomplished with an α_2-agonist as described previously, with or without an opioid (e.g., butorphanol). Administration of *N*-butylscopolamine (0.3 mg/kg) by IV injection several minutes before the examination may also help prevent straining and relax the rectum, but it may interfere with accurate assessment of uterine tone.[50] As noted previously, α_2-agonists increase uterine tone, and *N*-butylscopolamine will decrease uterine tone.

Transrectal palpation of the reproductive tract should proceed with an organized, methodical approach. For example, one author, after removing all fecal material, palpates the left ovary, left uterine horn, right uterine horn, right ovary, right uterine horn, uterine body, and finally the cervix. It is important to note the ovarian position, follicular activity, size, texture, and presence of the ovulation fossa. The loss of a palpable ovulation fossa can be an early indicator of distortion of the normal ovarian shape secondary to neoplasia or other pathology.[51,52] The position of the uterus relative to the brim of the pelvis; the size, tone, sacculations, or differences in texture of the horns; and the presence and character of endometrial folds should be assessed. The general tone of the uterus should be evaluated and compared with the stage of the cycle; for example, one would expect a toned uterus in diestrus, and conflicting findings may suggest pathology. The cervical size (approximate length and width), tone, and consistency are assessed by pressing the cervix down against the pelvic floor. Cervical relaxation can most effectively be measured on a sliding scale that spans from the closed toned cervix, 0% relaxed (i.e., tightly closed, tubular cervix) to 100% relaxed (i.e., indistinguishable from adjacent uterus), and should be critically evaluated if appropriate tone is present for the stage of estrous cycle.

It is important to purposefully assess anatomic structures other than the reproductive tract as part of the palpation examination, including the pelvic inlet, caudal aorta, broad ligaments, bladder, intestines, and lymph nodes. Note the presence of soft tissue or bony changes that may narrow the diameter of the pelvic inlet, suggest pathology (aortic aneurysm, neoplasia), or potentially interfere with foaling. For example, firm swellings in the broad ligaments may suggest previous hemorrhage, neoplasia, or an abscess. Structures that may narrow the pelvic inlet and cause a potential problem for foaling include abscesses, lacerations, hematomas, neoplasia, vascular aneurysms, bladder stones, and pelvic fracture.

TABLE **19.3 Application of Transrectal Palpation and Ultrasound of the Genital Tract for Assessing Various Parameters**

Organ	Structure	Detail of Assessment	Technique
Ovary	Ovary	Size, shape, presence of ovulation fossa	P, US

Vagina and vestibule		Fluid accumulation, gas (air) accumulation	P, US

P, Transrectal palpation; *US,* ultrasound.

Transrectal ultrasound examination should be considered a routine part of a reproductive tract examination. It allows the use of electronic calipers for measuring structures and facilitates the assessment of tissue and fluid characteristics as well as subtle pathology that may not be detected by palpation. Table 19.3 presents comparative information on the application of palpation and ultrasound for assessing various genital tract structures.

The basic approach as described previously for rectal examination is used for transrectal ultrasound examination. Most practitioners use a 5- to 10-MHz linear rectal probe, and focal distance is set at a depth of 5 to 10 cm for initial evaluation. While holding a linear transducer, the practitioner extends the fingers beyond the end of the probe to assist in locating genital tract structures and prevent the probe from penetrating the rectal wall. The uterine body is initially identified as a landmark by sweeping the probe from side to side in the anterior pelvis. The uterine body is then followed cranially to the bifurcation, and the probe is swept out toward one uterine horn and ovary. Structures are examined in the same order as for palpation alone: left ovary, left horn, right horn, right ovary, uterine body, cervix, bladder, and finally vagina and vestibule. The orientation of the probe is adjusted to attempt to get a clear cross-sectional image of the uterine horns, and in the longitudinal plane the uterine body, cervix, and vagina are visualized by moving side to side while moving the transducer caudally (Figs. 19.12 and 19.13).

A simple recording system should be used with defined abbreviations. This ensures that records can be understood at a later date and facilitates an efficient communication between multiple attending veterinarians. Ovarian size, follicles, and the presence of any corpora lutea should be recorded along with any suspected cysts or abnormal structures. Uterine horn diameter should be measured about one third of the distance from the bifurcation, and the presence of endometrial edema and depth and character of any intraluminal fluid (in the dorsoventral plane) should be recorded. Uterine and cervical tone as assessed by palpation should be recorded. All follicles larger than 15 mm in diameter are recorded individually, and smaller follicles are recorded as multiple small follicles or may be measured and recorded in some cases. The tone of the follicles present should also be recorded, because often there is a loss of turgidity in preovulatory follicles.

DIAGNOSIS OF OVARIAN PATHOLOGY

Abnormal ovarian enlargement should be suspected if an ovary is greater than 10 cm in diameter and the increased size cannot be attributed to recent ovulation or a follicle and persists for more than a month.[51-53] Large ovaries may be associated with physiologic causes (e.g., persistent follicles, hematoma, multiple corpora lutea in midgestation) or pathologic processes (e.g., neoplasia, hematoma, abscess).

Neoplasia more commonly affects one ovary, although it can affect both, and typically results in an alteration in ovarian size, shape, and consistency. There appears to be no consistent pattern in the change affecting a neoplastic ovary with the exception of teratomas in which the diagnosis may be based on the detection of germ tissues, including cartilage, hair, and bone. Other neoplasias may present as single large cystic or multicystic structures or even solid tissue, and in rare cases no ultrasonographic evidence of ovarian abnormality is present. In many cases the diagnosis of ovarian neoplasia is based on persistent unilateral ovarian enlargement with obliteration of the ovulation fossa and an inactive or normally functioning contralateral ovary.[54,55] There might be a history of aberrant ovarian activity before the development of the tumor.[54] A granulosa cell tumor (GCT), the most common ovarian neoplasia, may produce varying levels of testosterone, estrogen, inhibin, and anti-müllerian hormone (AMH) but rarely produce progesterone.[56-58]

Functional ovarian tumors, such as the granulosa-theca cell tumor (GTCT) or granulosa cell tumor (GCT), may manifest as masculinization of appearance. Increased plasma

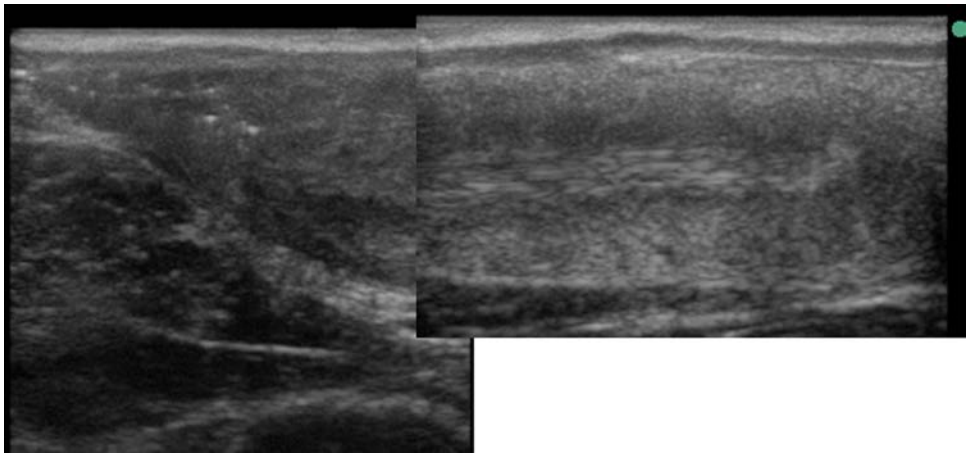

FIG. **19.12** Longitudinal image of the cervix with air in the vagina. Orientation in this image is cranial to the right and caudal to the left. This image was made by combining two images taken as the probe was positioned caudally.

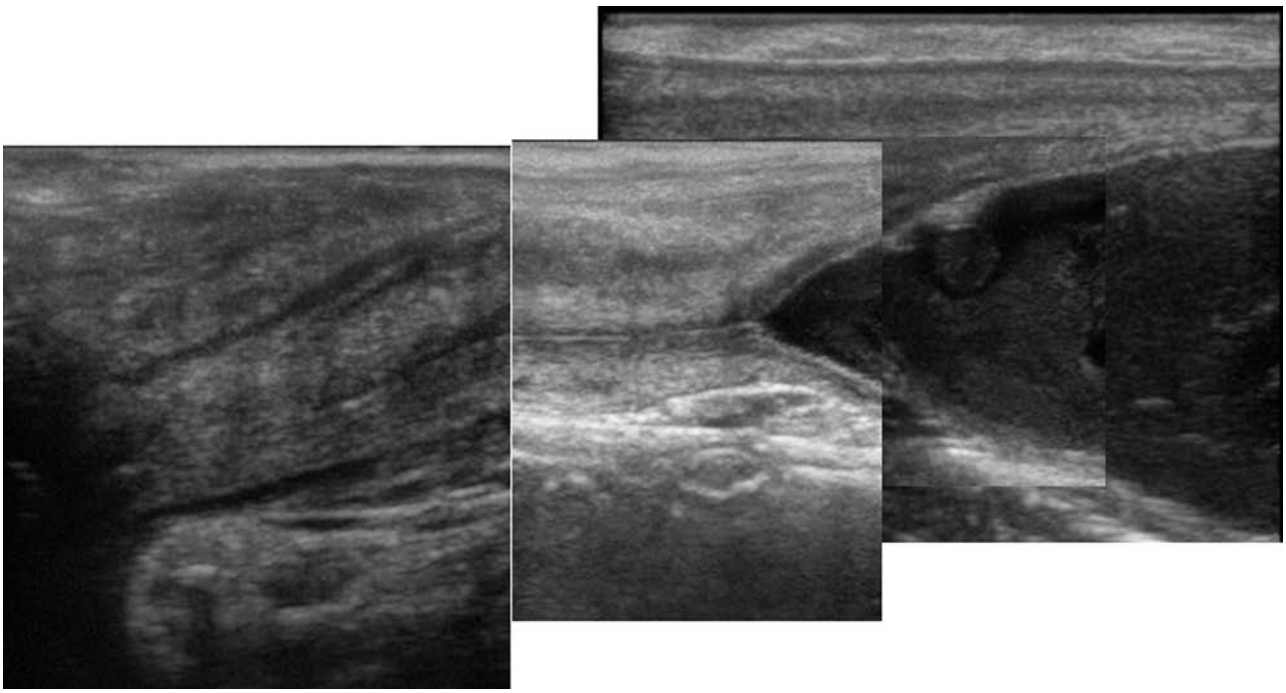

FIG. **19.13** Longitudinal image of the bladder, pelvic urethra, and opening of the ureter in the dorsal bladder wall. This image was made by combining serial images of the tract obtained with a standard linear rectal probe.

concentration of AMH, inhibin, or testosterone in conjunction with clinical signs (abnormal ovarian parenchyma or abnormal behavior) is considered diagnostic of GTCT.[57,59] The ultrasonographic appearance of most GTCT is characteristic, varying from uniformly dense multiloculated to cystic (Fig. 19.14), although it should be noted that some GTCT tumors present with no detectable abnormalities on transrectal palpation or ultrasound and are confirmed at the time of histologic tissue analysis with the only presenting complaint being abnormal behavior.[59,60]

Anovulatory follicles often grow to an unusually large size (50 mm or greater) and fill with blood, organizing into a structure with the ultrasonographic appearance of a hematoma that gradually recedes over time. Some of these structures appear to develop a thick rim of tissue resembling luteal tissue, with the mare entering a diestrus state, with progesterone concentrations greater than 4 ng/mL. Other mares do not develop a thick rim of tissue, and the structure may appear to be inert. There is a lack of consensus regarding terminology, with some authors distinguishing anovulatory hemorrhagic follicles (AHFs; no luteinization) from luteinized unruptured follicles (development of luteal rim). Others suggest that the two structures are variations of the same condition.[61,62] The condition appears to be more common in mares approaching winter anestrus and in pregnant mares under the influence of equine chorionic gonadotropin (eCG), and there is some

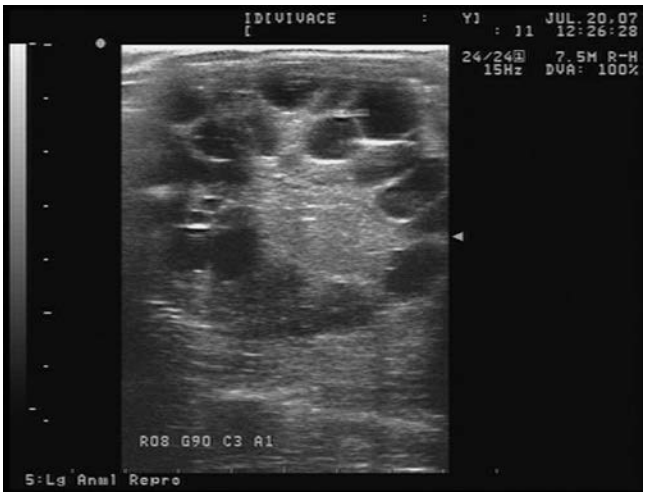

FIG. **19.14** Transrectal image of a granulosa-theca cell tumor with multiloculated "honeycomb" appearance.

evidence to suggest an increased incidence in mares administered a luteolytic agent.[61] Anovulatory follicles occur in 8% of all estrous cycles[63] but in 5% of estrous cycles in the early ovulatory season and 20% of estrous cycles in the late ovulatory season.[63] The ultrasonographic appearances of ovulatory and anovulatory follicles are largely the same. Rarely is the ovulation process normal in these structures, so mares that develop these processes may have a history of infertility and irregular estrous cycles.

Failure of the normal process of luteolysis may result in prolonged luteal maintenance. Diagnosis depends on confirmation of nonpregnant status and the presence of a CL for a period longer than the normal diestrus length (approximately 14 days)[64]. This condition, termed *pseudopregnancy,* must be differentiated from cases in which a mare is ovulating between examinations and exhibiting an apparently persistent CL. Luteolysis depends on $PGF_{2\alpha}$ release from the uterus,[65-67] which relies on the timely (approximately 12-14 days after ovulation) mechanism for endometrial $PGF_{2\alpha}$ release to be functional. An ovulation during diestrus will prolong diestrus, and the resultant CL can last for more than 2 months.[65,67] Other reasons for failure of luteolysis include the release of $PGF_{2\alpha}$ when the CL is still immature and unable to optimally respond to $PGF_{2\alpha}$ (traditionally thought to be 5 days post ovulation), the failure of $PGF_{2\alpha}$ to be released at the proper time, and low-level chronic release $PGF_{2\alpha}$ from the endometrium (which has been described in mares with endometritis).[68]

Small cystic structures may be palpated or visualized with transrectal ultrasound adjacent to the ovary. These structures often have an ovoid or serpentine shape, contain anechoic fluid, are outside the ovarian parenchyma, and are usually less than 2 cm in diameter. The structures (paraovarian cyst or epoöphoron) are typically incidental findings assumed to be cystic remnants of the mesonephric tubules and ducts.[1] It is possible that these structures could interfere with gamete transport if they obstruct normal function of the ovarian bursa and infundibulum but are almost always functionally insignificant.

Very small and inactive ovaries may be secondary to seasonal anestrus, reproductive senescence in old mares, pituitary gland dysfunction, severe malnutrition, administration of anabolic steroids, administration of anti-GnRH vaccine, or congenital infertility resulting from sex chromosome abnormalities.[45,69-71] Sex chromosome abnormalities are often associated with hypoplasia or segmental aplasia of the tubular tract. Karyotyping may be used to further investigate such mares. Chromosomal abnormalities have also been reported from subfertile mares that have foaled previously and have no detectable abnormalities of the genital tract. In light of this fact, karyotyping may be considered in mares in which routine diagnostic procedures fail to explain subfertility.[72-77]

Individuals with 63,X0 karyotype tend to be small in stature and phenotypically female, with a small uterus and ovaries.[71,74,78] These mares demonstrate irregular estrus or ambivalence in the presence of a stallion, and the uterus palpably and histologically can be within normal limits.[71,74] Plasma estrogen levels are low, and plasma LH levels are normal to high.[71] Sex reversal is a disorder that occurs in horses and most commonly results in an infertile animal.[72,76,77] The two most common forms of sex reversals are a female phenotype with male karyotype 64,XY, and a male phenotype with female karyotype 64,XX. There can be a wide phenotype variation with both conditions.[72,79]

The X trisomy is relatively rare in the horse. The XXX mare is infertile, often demonstrates erratic estrus, has normal external genitalia, and is phenotypically female with a small, thin-walled uterus and small hypoplastic ovaries. Some of these mares have been known to develop follicles and undergo what appears to be ovulation.[79-82]

Mosaics and chimeras occur when the individual has more than one cell line with different chromosomal makeups. 63,X/64,XX mosaics are phenotypically female; the uterus varies in development, but ovaries may be small and nonfunctional. These horses may show estrus and have an enlarged clitoris. Endometrial biopsy often reveals glandular hypoplasia.[70,72,73]

DIAGNOSIS OF UTERINE PATHOLOGY

Endometritis

Endometritis refers to infectious or noninfectious inflammation of the endometrium, which is a major cause of infertility in the mare. It is critical to differentiate this from metritis, in which inflammation extends to the myometrium and can cause life-threatening sequelae such as sepsis or laminitis. While endometritis compromises a mare's fertility, the mare with endometritis is generally not systemically compromised from the condition and can live a normal life if untreated. A later section in this chapter discusses diagnosis and treatment of endometritis in detail because of its importance in successful mare breeding management. This section of the text will review diagnosis of endometritis for the purpose of the BSE.

Transrectal ultrasonography is very useful for evaluating presence, quantity, and echotexture of uterine luminal fluid. Increased echogenicity of uterine fluid is positively correlated with the amount of debris or white blood cell infiltration into the fluid and is more common in older mares.[83,84] Table 19.4 presents a grading system for recording uterine fluid echotexture.[85] The presence of grade I, II, or III fluid during any stage of the cycle likely indicates endometritis. The presence of fluid in diestrus has been associated with a lower pregnancy rate and a higher embryo loss rate,[86] presumably caused by high levels of $PGF_2\alpha$ in the fluid from the neutrophils.[87] The

TABLE **19.4 Classification System for Recording Uterine Fluid Echotexture**

Grade	Ultrasound Appearance	Gross Appearance
I	White (hyperechoic)	Thick and creamy
II	Light gray	Milky
III	Black with white specks	Obvious sediment in fluid
IV	Black (anechoic)	Clear fluid

TABLE **19.5 Grading System for Recording Volume of Intrauterine Fluid**

Classification	Maximum Fluid Depth (mm)	Gross Description
VS	1–2	Barely detectable
S	1–5	Often focal
M	5–20	Obvious fluid
L	>20	Immediately apparent

L, Large; *M,* moderate; *S,* small; *VS,* very small.

presence of more than 2 cm of intraluminal fluid in the dorsoventral plane during estrus, the presence of fluid during diestrus, and fluid present 72 hours after insemination are strong indicators of mares' increased susceptibility to endometritis.[31] Table 19.5 presents a grading system for recording the volume of intrauterine fluid.

Complete absence of detectable intraluminal fluid during estrus is associated with the absence of cytologic inflammation in most cases.[31,88] The significance of anechoic (grade IV) luminal fluid is less clear. Small or very small volumes of clear fluid during estrus are likely to be normal, particularly if present during early estrus before complete cervical relaxation and maximal uterine drainage. Large volumes of clear fluid during estrus, fluid that persists into late estrus, or smaller volumes during early diestrus suggest an increased predisposition to endometritis and reduced pregnancy rates compared with mares without fluid.[88-90] Luminal fluid visible more than 12 to 20 hours after breeding indicates mating-induced endometritis.[31,90,91] This condition has been reported in 10% to 15% of mares being bred by live cover on a commercial Thoroughbred stud farm.[91] A more thorough discussion of endometritis and the significance and character of intraluminal fluid is included later in this chapter.

Discrete hyperechoic reflections present in the uterine lumen on ultrasonographic examination may indicate air, urine crystals, mucoid debris, and foreign material. Pneumouterus may be seen in normal mares soon after uterine culture, intrauterine treatment, artificial insemination (AI), or natural breeding but should not be seen more than 24 hours after breeding or treatment. The presence of pneumouterus at times other than after breeding or uterine therapy indicates loss of integrity of physical barriers to contamination (vulva, vestibulovaginal sphincter, and cervix), and the cause of this should be identified.

Endometrial Cysts

Circumscribed, discrete collections of fluid within the uterine lumen may indicate endometrial cysts, intraluminal fluid accumulation, or a conceptus. Endometrial cysts are usually classified as lymphatic or glandular. Lymphatic cysts are generally larger, anechoic, intraluminal cysts visualized by transrectal ultrasonography, whereas the glandular cysts remain small and surrounded by fibrocytes and are not easily identified with transrectal ultrasound. Cysts may protrude into the uterine lumen or remain intramural. Cysts may be single, discrete structures closely resembling a conceptus or complex, compartmentalized structures with irregular borders. Cysts that protrude into or occlude the uterine lumen may reduce fertility by interfering with embryo mobility and maternal recognition of pregnancy.[92,93] Cysts within the endometrium may interfere with gland function, and an increased number of cysts is likely an indication of a compromised endometrium.[94]

Properties of an early conceptus that can be used to distinguish it from an endometrial cyst include movement through the uterine lumen between days 10 and 16 post ovulation; spherical, symmetric appearance with specular reflection visible on ultrasound; rate of growth (cysts are assumed to grow little if at all); and appearance of the embryo proper after about day 20, or presence of heartbeat after day 25. In addition, there are palpable changes in the tract that are consistent with early pregnancy (e.g., increased uterine tone and closed, elongated cervix persisting after day 14 post ovulation), and general failure to return to estrus that would not be expected in the nonpregnant mare. The association between cysts and reduced fertility is debated, and the incidence of endometrial cysts increases with age and parity.[94,95] Large cysts or large numbers of cysts may interfere with uterine clearance, embryonic movement, maternal recognition of pregnancy, and early placentation. Extensive glandular cystic change may also adversely affect uterine gland function and compromise establishment or normal development of pregnancy. To determine whether a cyst is intraluminal and assess its location better, the uterus can be distended with sterile saline or lactated Ringer's solution (LRS), and the outline of the cyst relative to the lumen can be evaluated with transrectal ultrasound. Hysteroscopy is also helpful for identifying the degree of interference a cyst has with the uterine lumen (Fig. 19.15). Biopsy of cysts and removal by laser or manual rupture have been described. To minimize inflammation and prevent recurrence, cyst removal with a diode laser has been reported to be very effective and safe and to have improved the fertility of previously barren mares.[95]

Pyometra

Pyometra is a chronic condition with accumulation of mucoid or mucopurulent material within the uterine lumen with or without cervical occlusion. The condition may occur in the presence or absence of a CL and usually does not result in systemic signs of illness. Pyometra may be mistaken for pregnancy on palpation as a result of fluid distention of the uterus but can be diagnosed effectively with transrectal ultrasound.[96] Treatment of pyometra usually involves dilation of the cervix to allow drainage and uterine lavage with or without antibiotic use.

Adhesions

Adhesions and scarring of the endometrium may result from infusion of irritating solutions into the uterus, cesarean section, and trauma associated with foaling or dystocia. Occasionally, redundant tissue from failure of normal uterine development or the absence of one uterine horn can be seen.[97] Adhesions involving the cervix have similar initiating causes and can impair cervical function. The role of chronic endometritis or

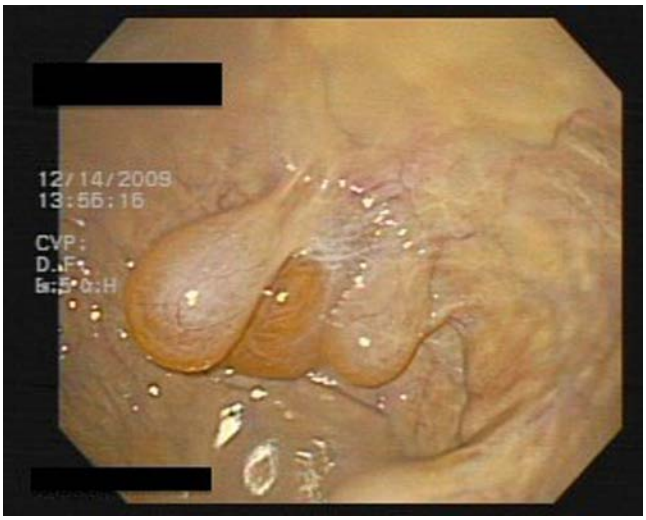

FIG. **19.15** Hysteroscopic image of a cluster of intraluminal lymphatic cysts in the uterine horn.

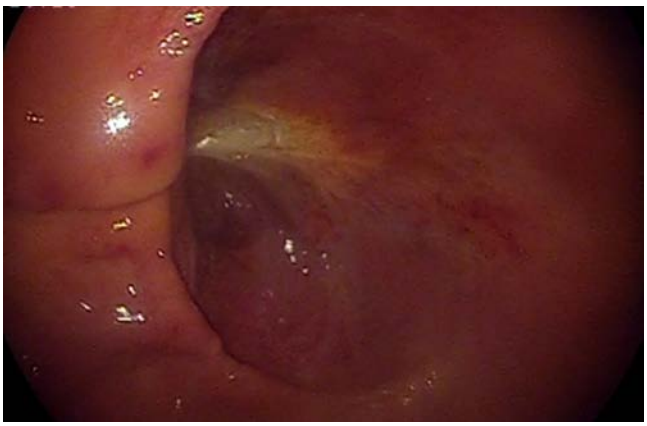

FIG. **19.16** Luminal adhesions diagnosed on hysteroscopic evaluation of a mare with chronic endometritis.

iatrogenic causes such as mechanical curettage in uterine or cervical adhesions is less clear. Adhesions may reduce fertility by interfering with function of the uterotubal junction, uterine clearance, embryo movement, maternal recognition of pregnancy, and normal placentation.[98,99]

Occlusive adhesions may result in the accumulation of fluid in the proximal portions of the tubular tract, and this may be detected on palpation or ultrasound examination of the tract. More commonly, adhesions are detected during hysteroscopy (Fig. 19.16). Occasionally these adhesions can cause a pyometra that can progress to systemic illness if infection is established without drainage.

Focal uterine lesions may respond well to surgical removal using a biopsy instrument or laser surgical equipment guided by hysteroscopy.[98] If the lesions are extensive or affecting the deeper layers of the endometrium, then the prognosis may be poor and treatment not warranted. Cervical adhesions are commonly managed by manual disruption and then repeated application of topical ointment containing an antimicrobial and steroid in an attempt to prevent recurrence. In many horses, cervical adhesions tend to recur once treatment stops.

Ventral Uterine Sacculation

Ventral sacculation is associated with a loss of normal muscle contractility in the uterine wall, with the uterine sacculations occurring most often at the ventral base of one or both uterine horns. The condition is more common in older, multiparous mares and may result in an increased risk of endometritis due to loss of the normal contractile mechanisms responsible for expelling uterine luminal fluid. This may also be linked to mares that have a more pendulous uterus. When the uterocervical angle is more ventral than horizontal, the mare is more prone to fluid accumulation because of a reduced mechanical ability to expel fluid.[99]

Vaginal and Cervical Examination

Good hygienic practice is essential in performing any vaginal procedure, particularly those that involve penetration of the cervix, to avoid inoculating the uterus. Cleanliness is perhaps the simplest and most fundamental principle of good reproductive practice. The practitioner should wrap the proximal portion of the tail at a minimum, or enclose the tail in a plastic sleeve and tie it to the mare's neck with a quick-release knot. Alternatively, an assistant may hold it out of the way. The perineal region should then be washed with water and mild detergent or povidone–iodine scrub and rinsed thoroughly. The practitioner should then wipe just inside the vulvar lips with damp cotton and clean smegma from the clitoral fossa and sinuses. This is particularly important for mares with sloping vulvar lips or if a rectal examination has just been performed. The presence of fecal matter in the vestibule without a history of any invasive procedure indicates a failure of the vulvovestibular seal.

Use of sterile, plastic sleeves for vaginal procedures is ideal. A practical alternative used by one author is to keep in a dust-free area a zipper storage bag (e.g., Ziploc) containing clean plastic sleeves to be used for vaginal procedures only. A new sleeve is taken out carefully by grasping it only at the open end, or each sleeve is turned inside out immediately before putting it on to minimize the risk of contamination. Tearing off the fingers from a plastic sleeve and putting on a sterile, surgical glove can increase sensitivity and also facilitate cleanliness. Sterile lubricant and equipment should be used. The practitioner should be meticulous to prevent contamination of either equipment or sleeves and gloves during any procedure.

Vaginal Speculum Examination

A sterile, lubricated speculum is inserted into the vestibule in a slightly dorsal direction to avoid the urethral opening and pushed through the vulvovestibular sphincter, with sphincter integrity assessed as the speculum is inserted. Because they reduce the risk of iatrogenic infection, single-use, sterile, disposable specula are preferred over metal Caslick specula for routine examinations. In some cases, a self-retaining metal Caslick speculum may provide better visualization of the vagina and vestibule.

Vaginoscopy is useful for the detection of vaginal hyperemia, fecal contamination, suppurative exudate, persistent hymen, urine pooling, varicose veins, vaginal trauma, rectovaginal defects, and cervical defects. Although examination with a vaginal speculum may be performed at any stage of the cycle, evaluation of mares suspected of urovagina is best performed during estrus, because estrogenic relaxation of the genital tract and perineal region is maximal at this time.[100] Vaginal speculum examination is an important component of

the BSE and often highlights abnormalities not identified by transrectal palpation and ultrasonography.

The timing of the vaginal examination in relation to the rectal examination is also important. If the rectal examination is performed first, then fecal contamination of the perineum and vulva is often increased. This slight disadvantage is offset by the advantage of doing the rectal ultrasound examination first to assess pneumovagina and pneumouterus. The presence of air in the vagina and uterus is difficult to interpret after a vaginal examination. However, if air is present before a vaginal examination, then it may indicate dysfunction of the vulvovestibular fold. Repeated vaginoscopy may be associated with an increased risk of iatrogenic vaginitis and persistent infection. As a result, one author prefers to perform routine assessment of cervical relaxation by transrectal palpation.

The vestibule and vestibular mucosa are evaluated by parting the vulvar lips and by continuing to look in the speculum as it is withdrawn following vaginoscopy. Varicosities of the vestibulovaginal fold are best recognized and evaluated in this manner.

Manual Examination of the Vagina and Cervix

Examination of the genital tract is incomplete without manual exploration of the vagina and cervix. The major benefit in this procedure is the detection of cervical defects. Once the hand is inserted into the anterior vagina, the forefinger is placed into the cervical lumen and the thumb in the vaginal fornix. The hand is then rotated and the entire circumference of the cervix is palpated between finger and thumb to feel for disruption in the cervical musculature. Abnormalities in the musculature or damage to submucosal layers might interfere with the ability of the cervix to close effectively. The cervical canal should be evaluated for any defects, tortuosity, or diverticula in which debris can accumulate. Cervical abnormalities (adhesions, muscular defects, and diverticula) are considered significant if they prevent the cervix from relaxing during estrus to facilitate uterine clearance, disrupt the ability to form an effective seal during diestrus and pregnancy, or serve as a nidus of infection. The examiner should also consider the length and diameter of the cervical canal in relation to the estrous stage of the mare. A partial tear involving the external os of the cervix may not require treatment if the cervix can still maintain an effective seal during diestrus. For this reason, assessment of the severity of cervical disruption should be performed when the mare is in diestrus. Alternatively, the diestrus tone can be replicated by the administration of progesterone for a few days to close the cervix.

Care should be taken while performing a manual examination of the vagina and cervix to take time to palpate the vaginal surface for pathology such as rectovaginal fistulas, vaginal lacerations and scar tissue, varicosities, urine crystals, perivaginal hematoma or abscesses, and any abnormal mass or structure that may suggest pathology. In cases in which the mare is suspected of urovagina, the integrity of the urethral sphincter should also be assessed.

Endometrial Culture and Cytology

Endometrial culture and cytology are performed as diagnostic tools for identification of endometritis, assessment of its severity, and determination of etiology. A variety of instruments and techniques have been described for sampling the mare's endometrium for cytologic analysis, microbial culture, and DNA isolation, and there is much debate regarding the methodology and interpretation of these diagnostics. At this time the gold standard based on sensitivity and specificity of correctly identifying a bacterial or fungal infection is believed to be culture of a biopsy sample obtained with a guarded technique and histologic evaluation of the sample. This is not always practical, so at a minimum a culture (double-guarded swab or guarded small-volume lavage) and cytology (double-guarded swab, swab cap, small-volume lavage, or guarded brush technique) should be performed.[101-104] Table 19.6 summarizes the sensitivity and specificity of each method for diagnosing endometritis. Generally, it is believed that a negative aerobic culture with no inflammation on cytology is reflective of no or subclinical endometritis; a negative culture with inflammation on cytology (>2 neutrophils per 400–1000× field) is a false-negative and the offending agent has likely not been identified; and a positive culture with inflammatory cytology is considered positive for endometritis.[105,106] There is debate regarding what constitutes inflammation as well as what is truly a uterine pathogen, but the reader is referred to the section on endometritis later in this chapter for a more in-depth discussion of this topic.

TABLE **19.6 Clinicopathologic Techniques Available for Diagnosing Endometritis in Broodmares**

Methodology	Test	Relative Sensitivities (Number of Disease-Positive Animals That Test Positive)	Relative Specificities (Number of Disease-Negative Animals That Test Negative)

	Cytology	Moderate	High
Double-guarded swab	Culture	Low	High
	Cytology	Not performed	Not performed
Low-volume lavage	Culture	Moderate	High
	Cytology	High	Moderate
Biopsy	Culture	Moderate	High
	Cytology	Moderate	High
Cytology brush	Culture	Low	High
	Cytology	High	High

Adapted from LeBlanc MM, Causey RC. Clinical and subclinical endometritis: both threats to fertility. *Reprod Domest Anim*. 2009;44:10; Nielsen JM. Endometritis in the mare: a diagnostic study comparing cultures from swab and biopsy. *Theriogenology*. 2005;64:510; and Overbeck W, Witte TS, Heuwieser W. Comparison of three diagnostic methods to identify subclinical endometritis in mares. *Theriogenology*. 2011;75:1311.

If endometritis persists despite appropriate treatment, cultures are often obtained from multiple sites in the genital tract, including endometrium, cervix, vagina, clitoral fossa, and clitoral sinuses. For the majority of mares a double-guarded endometrial swab or fluid sample is often the only sample submitted for aerobic culture, although anaerobic and fungal cultures may be useful in some cases. There is an increasing body of evidence to suggest the presence of commensal bacterial in the mare's vaginal and caudal reproductive tract, as well as possibly dormant bacteria in the endometrium, which may confuse the results of culture.[107-109] Endometrial culture should be performed before any other invasive procedure in a BSE to reduce the risk of inadvertent contamination of the uterine lumen before culture samples are obtained.

A guarded culture rod or small-volume lavage set should be used to minimize the risk of contamination with material from sites other than the uterine lumen. There is a lack of consensus on the optimal time of the cycle for obtaining endometrial culture and cytology samples. Some experts recommend performing endometrial cultures on the first or second day of estrus, when uterine secretions are increasing and the flushing action of the uterus is just beginning.[110-112] Mares with endometritis have been reported to accumulate free luminal fluid in late diestrus, and this represents an alternative time for endometrial culture, although it can result in contamination.[86] Often culture and cytology samples are obtained regardless of where the mare is in her cycle, because there is a limited period available for evaluation. If the mare's endometrium is cultured, biopsied, or the cervical barrier breached in diestrus, then it is recommended to induce luteolysis ($PGF_{2\alpha}$ administration) after the evaluation to help the mare resolve any contamination or iatrogenic inflammation.

To perform a double-guarded swab culture of the endometrium, the practitioner should carry the guarded culture rod into the vagina and through the cervix which can be accomplished through a speculum or manually. The capped rod is then passed through the cervix and the culture tip pushed through the guard and rolled against the endometrial surface for 30 to 60 seconds. The culture tip is withdrawn into the rod, and the outer sheath is rotated three times to collect endometrial cells in the cap for cytologic analysis. The guard and swab are removed gently, avoiding contamination of the cap with vaginal or vestibular secretions. The rod is then extracted without contacting the sheath and placed into a transport culture medium (Amies medium is an example). The cap's contents are tapped onto a glass slide for cytologic evaluation.[106]

The sample should ideally be transferred onto the final growing medium (e.g., trypticase soy agar (TSA), 5% sheep blood and eosin methylene blue (EMB), and a thioglycolate broth) as quickly as possible after the sample is obtained to allow quantification of colony numbers as an indication of severity of infection. When possible, quantification of colony growth should be performed, because heavy growth after 24 to 48 hours' incubation is more meaningful than a few scattered colonies. If immediate plating is not possible, then transfer the culture tip in a sterile manner into appropriate transport medium. Use of transport medium allows proliferation of some species and possibly reduced growth of others, so colony counts are not interpretable.

A wide range of organisms have been isolated from horses with acute endometritis. A combination of positive culture and evidence of inflammation on endometrial cytology is sufficient to diagnose endometritis and identify major pathogens. A positive bacterial culture in the absence of any cytologic evidence of inflammation or clinical signs is considered likely to be caused by contamination during the culture procedure and does not indicate endometritis, although *Escherichia coli* has been an agent associated with minimal inflammation and should considered if heavy growth is identified.[105,106]

In the absence of cytologic evidence, it is particularly difficult to interpret culture results. Recovery of relatively pure or heavy cultures of the following organisms may be considered indicative of endometritis: β-hemolytic streptococci, *E. coli, Pseudomonas* spp., *Klebsiella* spp., and *Candida* spp.[113-116] Recovery of other organisms without concurrent cytologic information should be viewed with more suspicion.

Endometrial cytology is used by some practitioners as a rapid screening test for detection of endometrial inflammation in mares at the beginning of the breeding season or before they are bred. When it was first described in the mare, the detection of neutrophils was correlated with positive bacteriologic findings. When no or low numbers of neutrophils were detected, bacteriologic findings were more often negative.[117] Mares with cytologic evidence of inflammation had lower 28-day pregnancy rates than mares with normal cytologic results, irrespective of culture results. Day 28 pregnancy rates were also lower in mares that had bacteria isolated from their uterus, even if cytologic results were normal.[118]

Numerous techniques have been described for collecting cytologic samples.[117-119] The approach used by the author is simple, rapid, and feasible in busy clinical practice. As previously described, a guarded culture rod (Kalayjian Industries Inc., Long Beach, CA) can be used to obtain both endometrial culture and cytology samples. The swab tip is withdrawn back into the sheath and the rod rolled against the endometrium to collect fluid and cells in the cap. After the rod is withdrawn from the mare, the cap can be cut off and tapped against a slide to make the smear from the small drop of fluid. The smear is dried and stained using any commercial Romanowsky-type staining kit (e.g., Diff-Quik; American Scientific Products, McGaw Park, IL). If no endometrial cells are seen on an initial inspection of the slide, then the sample may not have been collected from the uterus, and another sample should be taken. The presence of polymorphonucleocytes (PMNs) is generally believed to indicate infectious endometritis, but the most appropriate methodology for quantifying PMNs remains subject to debate.[120- 122] Suggestions for criteria to diagnose endometrial inflammation include observation of more than two PMNs in five high-power microscope fields (400×–1000×) or more than one PMN per 10 endometrial cells in more than one area of the slide.[121,122] In most mares with clinical endometritis, there are large numbers of PMNs evident on cytologic evaluation, and occasionally intracellular phagocytized bacteria may be seen.

Endometrial Biopsy

Preparation for endometrial biopsy is the same as for culture or cytology. There is debate as to the best time in the cycle to obtain an endometrial biopsy. Diestral samples have been recommended over estral samples because physiologic changes in the endometrium during estrus make the slides more difficult to interpret.[119,122,123] However, samples may be taken at any stage of the cycle as long as the information on the stage of cycle is provided and the person reading the slide has experience in evaluating equine endometrial biopsies. In the absence of clinically detectable pathology involving the

FIG. **19.17** Rigid endometrial biopsy rod with alligator forceps.

uterus, a single endometrial biopsy sample is representative of the entire endometrium.[124,125] However, another study found that even in clinically normal mares endometrial biopsy scores varied with the site selected; thus it may be prudent to collect more than one sample.[124,126-128]

The sterile biopsy instrument is used to recover a sample containing at least 2.5 cm of luminal epithelium. The most commonly used instrument is a rigid alligator forceps (Fig. 19.17). The hand covers the basket as the instrument is guided (with jaws closed) through the cervix and into the uterine lumen. The tip of the biopsy forceps is guided manually through the cervix. Once the instrument's tip has been passed into the uterine lumen, the guiding hand is withdrawn and inserted into the rectum to guide the closed tip to the site desired for sampling (most commonly the base of a uterine horn). The instrument is then turned on its side and the jaws gently opened. A portion of endometrium is pressed between the jaws using the index finger within the rectum, and the jaws are closed and the instrument retracted in a quick tug to remove the tissue sample.

A simpler vaginal technique is useful for collecting biopsy samples when there is no need to sample from a specific site. The instrument is introduced into the uterine lumen, and the hand is left in the vagina with the index finger in the cervical lumen. The tip of the instrument is advanced about 2 to 3 cm into the uterine lumen with the jaws closed. The jaws are opened and the instrument advanced an additional 1 to 2 cm. The instrument can then be deviated slightly to one side and the jaws closed to collect a sample. The sample is taken from the cranial uterine body close to the bifurcation. This approach has the advantage of being quick and simple. It allows the operator to return for a second sample immediately if the first sample is too small, whereas the rectovaginal technique often results in gross contamination of the instrument and vulva during the procedure, making a second sample impossible unless the mare is cleaned again and a second sterile instrument is available.

The specimen is removed from the biopsy basket using a small-gauge needle and transferred to fixative solution, preferably Bouin fixative or 10% buffered formalin. Samples placed into Bouin fixative should be transferred to 10% formalin or 80% ethanol after 12 to 24 hours for optimal retention of cell detail and tissue integrity.[119,123]

There is a strong case to be made for clinicians to read slides from their own cases or to involve a reproductive specialist familiar with biopsy interpretation. Although expert assessment by a trained pathologist may better reflect histologic tissue changes, it is vital to interpret histologic change in light of clinical and historical information about the mare. Training and practice will allow the clinician to detect most of the common pathologic changes seen in biopsy samples. An endometrial biopsy report should include the histologic evaluation and an epicrisis, which provides a biopsy grade (I, IIA, IIB, or III); prognosis for carrying a foal to term and treatment/management recommendations based on the histologic character of the endometrium; and the results of reproductive examination, endometrial culture and cytology results, and patient history.

The method of biopsy evaluation differs but should be a repeatable sequence that allows one to determine the pathology present in the endometrium. The clinician must first ensure that cellular characteristics are consistent with the stage of estrous cycle. Pathologic changes include inflammation, fibrosis, cystic glandular distention, and lymphatic stasis.[10,119,122,123,127] Generally, inflammation is evaluated by characterizing the cell type frequency, distribution, and character. The uterine luminal contents, the epithelium, the superficial endometrium (stratum compactum), and the deeper endometrium (stratus spongiosum) are all described based on the cellular infiltrate present (neutrophils, eosinophils, lymphocytes, plasma cells, and hemosiderophages), the frequency (mild, moderate, or severe), and for the endometrium, the distribution (diffuse, multifocal, perivascular, or periglandular). Acute inflammation is associated with PMNs and an increased likelihood of positive endometrial culture.[119] Increasing numbers of PMNs and their presence in deeper layers of the lamina propria indicate more severe inflammation. Chronic inflammatory change includes lymphocytes, plasma cells, eosinophils, and mast cells. Eosinophils have been associated with urometra, pneumouterus or pneumovagina, and yeast. Hemosiderophages are often associated with parturition or abortion.[119,122-126,128]

Endometrial fibrosis is believed to be a permanent degenerative change seen as increased fibrocytes surrounding the endometrial glands; when this is severe it causes the clustering of glands (fibrotic nests) or gland branches. Fibrosis can also be seen adjacent to the basement membrane of the luminal epithelium. Fibrosis often forms in concentric layers around gland branches or glands, and the number of layers of fibrosis is related to the severity of the degenerative change.[127,128] Fibrosis may be localized or diffuse, and the more widespread or severe the change, the more adverse the effect on gland function and fertility. These degenerative changes appear to be closely associated with age rather than parity.[10,127,129-132] Severe degenerative endometrial fibrosis can occur in the older maiden mare that has not had the challenges of pregnancy and exposure to semen.[127,131,132]

Cystic glandular distention may be seen in normal mares during anestrus. When diagnosed in mares during the breeding season, it is considered a pathologic change and is associated with reduced fertility. Glandular fibrosis may also be associated with cystic distention of the affected glands. Extensive fibrosis interferes with uterine gland function and may result in early embryonic death.[10,128]

Persistent endometrial atrophy is associated with an extremely poor breeding prognosis.[10,123,126,128] Large empty spaces on the biopsy slide must be interpreted with caution, because they may be artifacts associated with sample processing. If the spaces appear to be lined with an endothelial cell layer, then it indicates lymphatic stasis. Widespread lymphatic stasis may be associated with reduced contractile capability within the uterus, a doughy feel to the uterus on transrectal palpation, and reduced fertility.[119]

Assessment of severity and distribution of pathologic changes allows the sample to be classified into one of four diagnostic and prognostic levels based on a modified version of the original three-level system proposed by Kenney.[10,119,128]

Category I: No significant changes in the endometrium and no treatment required; predicted foaling rate following conception is 80% to 90%.

Category IIA: Slight to moderate inflammatory change. Scattered fibrotic change may consist of either fibrosis around individual gland branches or fewer than two fibrotic nests per high-power field. There is moderate cystic glandular distention or extensive lymphatic stasis. If two or more of these changes are present in the same sample, then the sample is classified as IIB. Expected foaling rate following conception ranges from 50% to 80%.

Category IIB: Inflammatory change is widespread and moderately severe. There is widespread fibrotic change or up to four fibrotic nests per high-power microscope field. Widespread, severe cystic glandular distention or lymphatic stasis is evident. If two or more of these changes are present, then the sample is classified as III. Expected foaling rates following conception are 10% to 50%.

Category III: The mare exhibits widespread severe changes that may include fibrosis or severe inflammation or both. The expected foaling rate following conception is less than 10%.

Use of paired biopsy samples taken at the initial diagnostic workup and again 4 weeks after completion of treatment appears to improve the usefulness of the biopsy as a prognostic indicator of a mare's fertility.[129] Mares that were classified as grade III pretreatment and that improved to grade II after treatment achieved a foaling rate of 40%, whereas mares that were still grade III after treatment had a 0% foaling rate. This is likely a result of improvement in reversible pathologic changes.[129,130,132] This approach allows effective use of the grade III categorization on the follow-up biopsy to justify recommending that such mares be culled from the breeding program or consider other alternatives (embryo transfer, oocyte transfer, or intracytoplasmic sperm injection [ICSI]).

The epicrisis of the biopsy report summarizes the histologic findings and interprets the significance of these changes in light of culture and cytology results, reproductive examination findings, and patient history. Ideally the epicrisis identifies the significant pathology and severity and guides appropriate treatment and future reproductive management.

Uterine Endoscopic Examination: Hysteroscopy

Hysteroscopy allows direct visual inspection of the uterine lumen through a flexible fiberoptic endoscope. It is indicated when other diagnostic procedures do not detect a cause for subfertility, a mare has persistent endometritis despite appropriate treatment, or to further examine a mare with suspected uterine pathology.[4-6]

Hysteroscopy is most commonly performed when the mare is in diestrus, or the cervix can remain closed enough to allow insufflations/dilation of the uterus for evaluation.[133-135] Sedation is usually required because the procedure is associated with mild discomfort. The perineum is aseptically prepared as for other vaginal or uterine procedures, and a sterilized endoscope is inserted in the vagina and guided digitally through the cervix and into the uterus. The cervical lumen is then occluded, either by insertion of one or two fingers into the cervix alongside the endoscope or by gently holding the external os of the cervix around the endoscope. The uterine lumen is distended with saline or water infused through a flexible catheter held adjacent to the endoscope or with air delivered through the endoscope. Endometrial folds should be assessed while the uterus is being distended, because they flatten out and become difficult to distinguish in the fully distended uterus. The endoscope is then manipulated through the uterine lumen, allowing visualization of the entire endometrial surface, including the tips of the uterine horns and the two oviductal papillae. Hysteroscopy allows direct visualization of a variety of abnormal changes, including inflammation, polyps or neoplasia, cysts, retained endometrial cups, bacterial or fungal plaques, adhesions, and severe scarring or fibrotic change. It can also aid in various procedures, including guided retrieval of foreign bodies, laser surgical management of conditions such as endometrial cysts or adhesions, biopsy of pathologic sections of endometrium, or hysteroscopic hydrotubation of the oviducts.

Excessive distention (>100 mm Hg) of the uterus may cause discomfort and an elevated heart rate and should be avoided.[133] Mares subjected to hysteroscopy appear to be at risk of developing subsequent endometritis caused by the inflammation associated with the procedure. It is often helpful to administer an antiinflammatory agent before the procedure (flunixin meglumine 1.1 mg/kg IV or dexamethasone 0.04 mg/kg IV) and perform a uterine lavage (1–5 L sterile saline or LRS) with oxytocin (10–20 IU intramuscularly [IM]) following the procedure. If hysteroscopy was performed when the mare was in diestrus, then administering a luteolytic agent is recommended to return the mare to estrus and facilitate recovery from the procedure. In addition, evaluating and culturing the mare's endometrium on the subsequent estrus is recommended to address any residual inflammation or infection associated with the procedure.

HORMONAL ASSAYS

In the nonpregnant mare, serum or plasma samples may be collected for measurement of a variety of reproductive hormone concentrations, including progesterone, estrogens, testosterone, inhibin, AMH, and gonadotropins. Other systemic conditions that may have effects on cyclicity and fertility include equine metabolic syndrome, PPID, and general systemic illness. The reader is referred to Chapter 16 for a discussion on appropriate testing for endocrine disorders.

Progesterone is produced by ovarian luteal tissue. Serum progesterone concentrations are low during estrus and begin to rise 12 to 24 hours after ovulation, peaking between days 5 and 10 after ovulation.[4,5,136,137] Progesterone assays in nonpregnant mares can be used to assist in determining the stage of the cycle and to confirm that ovulation has occurred. They are also used as an indirect method of pregnancy diagnosis, but false-positive results are common.[1,6]

Progesterone is necessary for early pregnancy maintenance, and primary luteal insufficiency has been linked to pregnancy loss.[138,139] Low levels of progesterone are associated with increased early pregnancy loss, and higher levels of progesterone are associated with double ovulations.[140-142] Older mares appear to require a higher level of progesterone to maintain pregnancy.[138,139] Progesterone levels on day 7 were significantly lower in mares with periovulatory intrauterine fluid

accumulation and significantly lower in mares that underwent embryonic loss.[88,139] The presence of luminal fluid in diestrus was associated with a lower progesterone level and increased embryonic loss, indicating endometritis as a cause for lower progesterone levels.[31,86,138,139]

Some researchers recommend that progesterone concentration in the peripheral blood of pregnant mares should be above 2.5 to 4 ng/mL for normal pregnancy maintenance; this will be discussed in more detail later.[142] Single samples of peripheral blood concentrations are difficult to interpret because repeated sampling of normal pregnant mares has shown that blood levels vary widely over short periods.[137,138] It is clear that in the mare the serum progesterone taken at a single time point must be critically compared with normal values for stage of cycle and pregnancy, because these change significantly as a part of normal physiology.

Thyroid gland dysfunction has been discussed as a cause of subfertility in mares with recommendations to measure total serum thyroxine (T4) or thyroxine response to administration of thyroid-stimulating hormone (TSH). Endogenous thyroxine is significantly affected by season and reproductive status.[16,143] Thyroxine is seasonally regulated when mares are kept on a constant energy balance out of the breeding season.[143,144] Although thyroidectomy of pony mares did not have any adverse effect on reproductive performance,[144] mares that continued to cycle out of season had higher levels of thyroxine than anestrous mares, which has led some clinicians to supplement subfertile mares with thyroxine.[16,143,145,146] Mares with low thyroxine levels were more likely to enter anestrus after parturition.[16] Research has demonstrated that the horse is rarely truly hypothyroid as is seen with other domestic species, and a study evaluating the effect of thyroxine supplementation of mares with low T4 (<16 µg/dL) found no benefit of supplementation on early pregnancy rates.[146] Several other studies have shown there was no association between thyroxine level and pregnancy rate 15 to 16 days after ovulation.[144,146]

Ovarian neoplasia, particularly GCTs, may be associated with increased production of testosterone, inhibin, and AMH by the affected ovary. Serum inhibin concentration is elevated in approximately 80% of mares with a GCT, and testosterone is elevated in about 50% to 60% of cases.[147-149] Recent work suggests that an increase in AMH, a hormone expressed in granulosa cells of preantral and small antral follicles, is elevated in mares with GCT tumors. It is believed that an elevated concentration of serum AMH is the most sensitive test for GCT at this time, with a sensitivity of 98%.[148-150] A study in 2013 demonstrated that the sensitivity of elevated blood AMH (95%) for the detection of histologically confirmed GCTs was significantly greater than that of either an elevation in inhibin (85%) or testosterone (55%) alone or the combination of inhibin and testosterone (89%).[149,150] Generally normal concentrations in nonpregnant mares for inhibin, testosterone, and AMH are less than 0.7 ng/mL, less than 45 pg/mL, and less than 4 ng/mL, respectively, but these values should be compared with the laboratory normal in which samples are being processed.[149,150]

Horses with PPID often exhibit variable degrees of hirsutism with a range of other systemic signs. The direct effect on the reproductive tract and fertility is currently a subject of much debate. Anecdotally, mares with PPID can have reproductive changes such as increased incidence of anovulatory follicles, loss of uterine tone, increased fluid accumulation, decreased cervical relaxation, and decreased resistance to bacterial or fungal endometritis. Diagnosis and treatment of this disorder are discussed in the later section Endometritis and Uterine Therapy.

The measurement of estrogen concentration in blood, urine, feces, milk, and saliva has been used for monitoring the estrous cycle, determining pregnancy status,[92-94] and monitoring fetal-placental viability. Peripheral blood estrogens may be either unconjugated or conjugated (bound to sulfates), and different forms of estrogens are found in the mare, particularly during pregnancy. Estrogen production in the pregnant mare will be reviewed more thoroughly later, but generally conjugated estrogens exist in the circulation at much higher concentrations than the unconjugated forms, and measuring either estrone sulfate or total conjugated estrogens has historically been used to assess pregnancy status and viability. Often a dramatic increase in peripheral blood estrone sulfate concentrations occurs in pregnant mares after day 60 of pregnancy, whereas in fecal assays this increase may take up to 150 days to occur.[153,156,157] A rapid decline of estrone sulfate concentration in a pregnant mare may indicate loss of fetal viability.[155-158] One of the difficulties of measuring specific estrogens is the cross-reactivity on most commercially available immunoassays and interpreting findings relative to normal changes in concentration.

Equine chorionic gonadotropin (eCG, formerly known as pregnant mare serum gonadotropin [PMSG]) is a hormone produced from the trophoblast cells derived from the chorionic girdle that invade the endometrium, forming "endometrial cups" at around day 35 of gestation.[1,4,6,158,159] This hormone has both FSH and LH effects on the ovary, inducing the formation of accessory CLs to help maintain pregnancy until the placenta develops and produces hormones that support the pregnancy in later gestation. The accessory or secondary CLs form from follicles that often luteinize without ovulating.[159] Pregnancy loss after day 35 can sometimes be associated with undetectable eCG concentrations in blood and the failure of endometrial cup formation, which is presumed to play an essential role in pregnancy maintenance. Pregnancy loss after day 35 may be associated with a positive or elevated eCG blood concentration following pregnancy loss, and affected mares often do not cycle properly because follicles fail to ovulate normally and luteinize. When ovulation does occur, the pregnancy rate is low, presumably because of a low-grade endometritis resulting from the presence of endometrial cups,[160-162] which have a life span of about 100 days and are therefore nonfunctional after about 150 days' gestation.[160] However, there have been reports of the prolonged survival of endometrial cups after abortion and even normal foaling.[161,162] The abnormal persistence of endometrial cups lasts an average of 18 months but could last up to 30 months. This has implications into the next breeding season, and mares showing aberrant ovarian activity should be investigated for the possibility of persistent endometrial cups (Fig. 19.18). Peak elevation of eCG occurs naturally between days 50 and 85 of gestation (15–125 IU/mL) and should be gone from the serum after 150 days' gestation.[162] Mares have been observed clinically to have abnormal, accessory CLs, retained endometrial cup tissue, and erratic cycles with eCG levels of 2 IU/mL, highlighting the importance of testing eCG in appropriate cases.

The measurement of serum or plasma concentrations of GnRH, gonadotropins (FSH and LH), and steroids appears to offer promise in the diagnostic assessment of the hypothalamic-pituitary-ovarian axis. The anterior pituitary gland produces FSH in response to GnRH release.[1,4,163,164] FSH is

FIG. **19.18** Hysteroscopic image of retained endometrial cups present in the base of what was the pregnant horn.

released in a bimodal pattern with peaks (35 ng/mL) in early and late diestrus. There are two major waves of follicular growth coincident with the two surges of FSH.[4,164-166] FSH starts to rise 4 to 5 days before an ovarian follicular wave. The peak of FSH is 3 days before the emergence of the wave, which then plateaus for 5 days. Sampling of circulating blood FSH would be performed in mares with inactive ovaries or erratic follicular waves to determine the cause.

GnRH release from the hypothalamus stimulates LH release from the anterior pituitary gland,[4,166] although there is an association between releases of oxytocin in estrous mares and LH release, which suggests that repeated sexual stimulation might also increase LH and advance ovulation.[167] LH concentrations are low during the midluteal phase (5 ng/mL) but rise a few days before estrus after progesterone decreases (<1 ng/mL) because of luteolysis. LH peaks (45 ng/mL) during estrus after ovulation and returns to midluteal levels over a few days.[166]

Little information is available regarding the existence of abnormalities in the hypothalamic-pituitary-ovarian axis and either their relationship with subfertility or their detection by measurement of hormone concentrations. Assessment of the production and release of either GnRH or FSH and LH presents practical difficulties, because this may require cannulation of the pituitary venous sinuses.[168] In addition, these hormones are released in a pulsatile manner, with pulse frequency and amplitude influencing function.[4,169] Finally, there are varying isoforms with differing bioactivity that may be difficult to distinguish on enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (RIA).[169,170]

Leptin is a protein synthesized by adipose (fat) tissue.[171,172] It acts as negative feedback to brain centers to control obesity (satiety centers) in times of nutritional abundance.[171-176] During starvation, reduced leptin levels cause changes in reproductive endocrinology that limit reproductive activity.[173] Short-term feed restriction (for 24 hours) significantly decreases leptin levels in mares but does not affect reproductive hormones.[176] There might be a seasonal influence on leptin levels because mares in good body condition experience a general decline in leptin concentrations during winter. The decline is not as great as that observed in mares in poor body condition, and the mares in good body condition continue to have estrous cycles through winter.[177]

Currently, the measurement of these and other hormones of the central nervous system appears to be restricted to research applications. Measuring these products may offer considerable benefits in the future, but additional research and development are required before it can be of use to field practitioners.

CONCLUSION

Following evaluation, interpretation of test results, and a review of the mare's history, a summary of the BSE findings should be made with the goal of identifying any abnormalities, providing a possible treatment plan, and discussing with the owner/client the prognosis for future reproductive health. There are conditions that may not have a treatment option (karyotype abnormalities, severe adhesions, and chronic incurable endometritis), but for all mares, regardless of the pathology, several options such as specific treatment plans, surgical correction (cervix, urethra, perineal body, and vulva), and advanced reproductive options (embryo transfer and ICSI) should be discussed. For some clients the BSE serves to ensure that an investment in the mare's prospective breeding career is not in vain, and a BSE with no abnormalities can provide useful information. It should be emphasized, based on the findings from that one examination, that a mare's prospective breeding status cannot definitively be labeled as fertile or infertile but that the mare meets or does not meet the normal parameters that one would expect for a satisfactory potential breeding animal. It is also important to recognize the legal implications of a BSE, and if the examiner is not comfortable or experienced enough to make a conclusion, then it is best to consult with an experienced practitioner or trained reproductive specialist.

Mare Reproductive Pathology

Maria R. Schnobrich

This section is a review of specific reproductive pathology in the nonpregnant mare. Some of this has been discussed as part of the findings of a BSE in the previous section, but this section will provide more details regarding pathogenesis, diagnosis, and treatment options.

VULVAR PATHOLOGY

The integrity of the vulvar lips and their anatomic relationship to the perineal area and anus are essential components of a mare's reproductive health, because they are the first barrier against uterine contamination from the external environment. The endocrine patterns associated with each stage of the estrous cycle and pregnancy can influence the disposition of the vulva, with increased estrogen relaxing vulvar tone and increasing vulvar length. Generally the vulva should have at least two thirds of its length below the pelvic brim, the slope of the vulva in relation to the vertical axis should not be greater than 10 degrees, and the vulvar lips should have an even and firm apposition. Absence (natural or acquired) of a normal perineal conformation can facilitate the entry of air (pneumovagina), feces, and potential pathogens into the reproductive tract, which jeopardizes the fertility of the mare as mentioned previously.[4,6,13]

Body Weight

Severe loss of body condition, as experienced by some pregnant mares not adequately supplemented during the winter or

during lactation, results in a sunken anus, an increased slope of the vulva, and loss of fat that maintains adequate conformation. An apparently normal perineal conformation noted in mares in good body condition may become less than adequate if loss of body weight is extreme. With weight loss the caudal barriers to the reproductive tract become less efficient and pneumovagina and contamination of the reproductive tract can occur. Contamination of the vagina with feces during mid to late gestation may lead to ascending bacterial placentitis, which is one of the leading causes of abortion and neonatal septicemia in the United States.[178]

Parity and Age

Aging of the mare associated with repeated foaling can cause stretching and loss of tone of the perineal muscles that allow the vulva to form an effective barrier. Injury to the mare during foaling aggravates this condition, resulting in loss of vulvar tone and apposition of the labia. Mares undergoing repeated episiotomies also may have permanent damage to vulvar structures.

Caslick Vulvoplasty

Surgical closure of the dorsal part of the vulvar labia is intended to correct poor perineal conformation. The Caslick procedure removes the vulvar mucosal surface at the mucocutaneous junction of the labia from the dorsal commissure to a level approximately level or below the brim of the pelvis. The vulvar opening is reduced significantly, and the opposing debrided labia are sutured together. Decreasing the length of the vulvar cleft, one decreases entry of air and potential pathogens into the vestibule and vagina in a mare otherwise susceptible to pneumovagina, fecal contamination, and associated complications. It has been reported that Caslick-operated mares with poor perineal conformation that successfully foal should be resutured immediately after parturition to minimize the chances of uterine contamination and consequent endometritis. This preventive measure is believed to contribute to adequate pregnancy rates and maintenance of pregnancy until term.[4,49,178-181]

This procedure, however, is overused in mares in which such intervention is not warranted. Paradoxically, a mare with successive Caslick surgeries may experience considerable loss of vulvar tissue, generating an abnormal perineal conformation. Another indirect complication associated with the Caslick vulvoplasty is the increased incidence of vulvar lacerations and dystocias in mares in which the vulva was not opened before foaling. Regardless of the originating cause, the Caslick operation is used to correct first-degree perineal laceration affecting only the perineal skin and vulvar mucosa. Second-degree (laceration of deeper tissues of the perineal body) and third-degree (a defect resulting in communication of the ventral rectum with the dorsal vagina) lacerations require more elaborate reconstructive surgery to correct.[180] As a rule, any corrective surgery of the perineal body and vulva should be delayed until inflammation and edema of the involved tissues have resolved. Mares with third-degree rectovestibular laceration invariably develop endometritis, but endometrial biopsy of mares affected with third-degree laceration have shown a rapid endometrial response to surgical repair of the laceration. Mares can be artificially inseminated by 2 weeks after surgery.[181]

Equine Coital Exanthema

Equine coital exanthema is a venereal disease caused by equine herpesvirus type 3 (EHV-3). Mares infected with equine coital exanthema develop pustules and ulcers in the vulvar mucosa and perineal area. Once the lesions start to heal (usually by 14 days after the onset of clinical signs), characteristic depigmented small circular areas (usually <1 cm) in the vulvar labia and perineal skin are visible.[182] Similarly to other herpesvirus-induced diseases, lifelong infection is the rule. Recrudescence may occur after stimuli such as stress, systemic disease, or trauma to the genital area. No specific treatment is recommended other than disinfection of pustules and ulcers to prevent secondary bacterial infections during the acute phase. Natural service should be avoided while active lesions are present to prevent transmission of the disease. One can artificially inseminate affected mares during the symptomatic stage of the disease or wait until 6 weeks after complete healing of equine coital exanthema–associated lesions before natural service.

Neoplasia

Melanoma is the most common disease of the vulva and perineum, affecting 80% to 100% of adult gray horses and, less frequently, aging horses of other colors. Common sites for melanoma include the anus, perineum, and vulva. No effective treatment is available for melanomas, but oral treatment with cimetidine (a histamine $_{H2}$ antagonist) has been reported with variable success, resulting in partial or complete regression of melanocytic nodules.[183] In addition, recent research has suggested autologous vaccination or other types of vaccines for melanomas may be effective.[184] Squamous cell carcinomas are less common than melanomas, and hemangiosarcomas have been reported.[185]

CLITORIS

The clitoris in the mare is an important reservoir for the bacterium *Taylorella equigenitalis,* which is the causative agent in mares affected with contagious equine metritis (CEM). The disease is highly contagious, and the organism can be harbored in the clitoral fossa and sinuses (especially the median sinuses) for prolonged periods. To test a mare for CEM, the practitioner should swab the median clitoral sinuses and then seed an Amies charcoal medium to be transported (preferably kept at 4°C) to a diagnostic laboratory.

Even in CEM-free areas, it is important to remember that the clitoral sinuses may function as nidi for uterine infection, especially infection that was iatrogenically induced during diagnostic procedures of the reproductive tract or AI. Careful asepsis of the perineal and vulvar area (including the clitoral fossa) with a mild disinfectant before any invasive procedures are performed minimizes the risk of introducing potential pathogens into the uterus. In rare cases, clitorectomy may be performed to eliminate this nidus of infection.

Congenital anomalies of the external genitalia occur in intersex animals that may have underdeveloped vulvar labia associated with an abnormally enlarged clitoris. Treating prepubertal mares or pregnant mares with anabolic steroids may lead to enlargement of the clitoris in the mare or foal exposed to androgens in utero, resulting in a partially and permanently exteriorized clitoris.

VAGINA

The vestibule is the area that separates the vulva and clitoris from the vagina proper. At the cranial border of the vestibule,

where it meets the vagina, lies the vaginovestibular fold. This folded mucous membrane acts as the second physical barrier between the uterus and the external environment. In young horses the hymen is usually a weak membranous extension of the vaginovestibular fold. Occasionally, a persistent hymen may be present in a maiden mare. A manual examination of the vagina is usually sufficient to rupture the persistent hymen. Some mares with a persistent hymen may accumulate fluid in the vagina proper and uterus (mucometra). Once the persistent hymen is disrupted, evacuation of the fluid is uneventful.

Pneumovagina

Listening for an inrush of air into the vagina when one gently parts the vulvar labia, or evidence of air in the vagina on transrectal ultrasound, can test the adequacy of the vaginovestibular fold as a physical barrier to external contaminants. A positive test (noticeable sound of air rushing in to the vagina, or air visualized in the vagina on transrectal ultrasound) indicates that the vestibular fold is not properly restricting the vagina proper from the outside environment.

Improper functioning of the first barrier (vulva) and second barrier (vaginovestibular fold) may lead to the constant or frequent entry of air into the vagina. The condition may be exacerbated during estrus, when the perineal body is more relaxed than in other stages of the estrous cycle. Accumulation of small amounts of a frothy fluid in the cranial vagina may indicate pneumovagina. Fecal staining and debris may also suggest this condition as well as the presence of air in the vagina and occasionally the uterus (pneumouterus), which is visible as hyperechoic particles seen in these areas during transrectal ultrasonographic examination.

In mares with severe alteration of the perineal conformation, vulvar closure using Caslick vulvoplasty may not correct the problem, and surgical reconstruction of the perineal body (perineoplasty) is recommended. In addition, in mares with poor body condition, weight gain may also be beneficial.

Urovagina

Urovagina, also known as *vesicovaginal reflux* or *urine pooling,* refers to the presence of urine in the cranial vagina and possibly in the uterus. As with pneumovagina, mares with marginal perineal conformation may be predisposed to accumulate urine in the vagina during estrus, when reproductive organs and the perineal body are relaxed. In older mares with splanchnoptosis, the reflux of urine into the genital tract may be permanent. Urovagina can cause vaginitis, cervicitis, endometritis, and placentitis, which ultimately result in infertility. Perineoplasty and urethral extension are common surgical procedures to correct this condition. In some cases fluid may only be appreciated in the uterus, and the fluid can be sampled and a creatinine concentration evaluated to determine whether urine is present. Generally values >2 mg/dL are considered consistent with urine contamination.

Varicose Veins

During estrus and especially during pregnancy, varicose veins may develop in older mares. Varicose veins can be present in any part of the vagina; however, they often are found in the vaginovestibular area. Bleeding may occur after natural service or spontaneously during mid to late gestation. Occasionally, persistent hemorrhage results in considerable blood loss, but the condition usually subsides with the end of pregnancy. Cautery or ligation of varicose veins is warranted if hemorrhage is persistent or frequent. There is anecdotal evidence of success with topical application of commercially available hemorrhoid creams containing phenylephrine HCl 0.25% for less severe cases.

Neoplasia

Vaginal neoplasms are not common in mares, but leiomyomas, squamous cell carcinoma, and melanomas have been reported.

Vaginitis

Minor tears, lacerations, and hematomas are common findings in the vaginas of mares after foaling. Medical treatment generally is not needed, and most mares do not show complications in the postpartum period. If more serious trauma occurs, then the mare may develop vaginitis. Mares with extensive vaginitis or a large hematoma may show signs of pain and refuse to stand quietly to nurse the foal. Vaginal abscesses can develop when a vaginal laceration becomes infected with local flora or fecal contamination.[108] Clinical signs caused by swelling from a hematoma or abscess include vulvar discharge, stranguria, and straining to defecate. Treatment with antibiotics and antiinflammatory drugs is warranted when extensive vaginitis or abscesses are found in the vagina. An abscess impinging on the urethra or interfering with defecation may require drainage. Occasionally, vaginal trauma may result in adhesions that can interfere with uterine drainage.

Rectovaginal Fistulas

During parturition the foot of the foal may be directed toward the dorsal vagina or ventral rectum and if unattended may cause a third-degree perineal laceration. However, if the dystocia is corrected in time, then the damage may be limited to a first- or second-degree rectovaginal tear or rectovaginal fistula. Surgical correction of the anatomic defect is necessary to restore fertility if the defect allows vaginal contamination to occur. Generally in the case of the complete loss of barrier between the rectum and vagina, the mare is evaluated 3 to 4 weeks after injury to allow the tissue to heal before surgical repair to prevent failure of corrective surgery.

Breeding Trauma

Vaginal lacerations may occur during natural service when the stallion's penis is disproportionately large compared with the mare's reproductive tract, or restraint of the mare prohibits appropriate coupling during mating. Depending on the location of the tear in relationship to the peritoneal reflection, a vaginal tear may communicate with the peritoneal cavity, likely resulting in peritonitis, or may be retroperitoneal. Treatment includes broad-spectrum antibiotics, antiinflammatory drugs, and tetanus prophylaxis. Peritoneal lavage may be beneficial if the tear communicates with the peritoneal cavity. A breeding roll positioned under the tail of the mare and dorsal to the penis of the stallion prevents the stallion from inserting the full length of its penis into the vagina and may help prevent mating-induced trauma. Some tears are large enough to require surgical correction, and any mare with excessive bleeding or discomfort after live cover should be evaluated.

CERVIX

The cervix is the last of the three physical barriers protecting the uterus from the external environment. Cyclic hormonal

changes dictate the tone of the cervix. During estrus the cervix is relaxed and open. High concentrations of progesterone during diestrus or pregnancy cause the cervix to be elongated, tubular, firm, and tightly closed. These changes are readily appreciated with transrectal palpation. Moreover, a vaginal examination during estrus reveals the cervix positioned low in the cranial vagina and relaxed, well lubricated, and easily dilated, allowing access to the uterus. During diestrus or pregnancy, a vaginal examination reveals a tightly closed cervical os that is pale and positioned high off the floor of the vagina.

Cervicitis

Inflammation of the cervix often accompanies vaginitis or endometritis. Cervicitis usually occurs in the postpartum period, especially after a dystocia. Severe cervicitis associated with metritis also may occur in mares infected with organisms, such as *T. equigenitalis,* that cause copious purulent discharge.[186] Infusion of certain chemicals (e.g., chlorhexidine, strong iodine solutions) into the uterus to treat endometritis may irritate not only the endometrium but also the cervix and vaginal mucosa. If the practitioner intends to use such solutions, care must be taken so that adhesions and fibrosis do not result as a sequela.

Trauma

Although cervical lacerations can occur during natural service, these lesions are usually small and resolve without major consequences. Occasionally, maiden mares are found in estrus with a tightly closed cervix that might suffer laceration during natural service, especially if the stallion is much larger than the mare. However, these tears are usually small and heal without further treatment. Most serious lacerations occur during parturition. They may result from normal parturition, or they may be iatrogenic, occurring during intervention to correct a dystocia by mutation or fetotomy.

Although one should examine the cervix digitally after a difficult foaling or dystocia (especially if a fetotomy is performed), the extent and severity of a cervical laceration are best evaluated once the cervical lesion has healed. The competency of the cervix should be evaluated during diestrus or when the mare is under the influence of exogenous progestogens so that the competency of the cervical canal can be accurately assessed. Diagnosis of cervical transluminal adhesions and anatomic defects is best performed by digital examination of the cervix rather than by vaginoscopy. Transrectal ultrasound and hysteroscopy can also be useful in detecting cervical defects. Because surgical correction is difficult and not always rewarding, the practitioner should take a biopsy sample of the uterus to assess the mare's ability to maintain a pregnancy before attempting surgical correction of a cervical laceration.

Generally any cervical defect that impairs cervical function should be addressed. In a retrospective study evaluating mares that had surgical repair of a cervical defect within 24 months, the postoperative pregnancy rate (67.24%) was greater than mares that did not undergo repair or waited longer than 24 months for repair (41.78%).[187]

Polyps or Cysts

Occasionally, pedunculated cystic structures are apparent on transrectal ultrasound, vaginoscopic, or digital examination of the cervix. These structures are often attached to the cervical os or emanate from the cervical lumen and protrude into the vagina or uterine body. Although their cause is unknown, they do appear to be associated with infertility, and removal by laser or ligation is recommended.

UTERUS

Ventral Sacculations

Aside from changes associated with pregnancy, other pathologic conditions cause focal enlargements in the ventral portion of the uterus. These uterine changes usually are associated with increased age and parity and invariably are found at the base of one or both of the uterine horns. Inexperienced veterinarians may mistake these enlargements for a pregnancy, especially if they do not use ultrasonography to confirm their palpation findings. Mechanisms contributing to formation of ventral uterine enlargements have been identified, including but not limited to endometrial atrophy, focal myometrial atonia, and lymphatic lacunae.[92] Furthermore, in older and multiparous mares the uterus may tilt ventrally in relation to the pelvic brim (uterine splanchnoptosis). Mares with ventral sacculations and uterine splanchnoptosis have a higher incidence of delayed uterine clearance than normal mares.[99]

Endometriosis

Endometriosis was once known as *chronic infiltrative endometritis* and currently refers to the presence of fibrosis in the stromal and periglandular compartments. The degree of endometriosis is associated closely with the ability of a mare to establish and maintain a healthy pregnancy until term. Parity and age contribute to degenerative changes occurring in the endometria of mares.[10,130]

Fibrotic changes may occur around the endometrial glands and in association with the basement membrane in the stratum compactum. The amount and pattern of distribution of the fibrotic tissue has been classified descriptively as slight (one to three layers of periglandular fibrosis), moderate (4 to 10 layers), and severe (more than 10 layers).[10] Cystic glandular dilation is another manifestation of endometriosis. Periglandular fibrosis, glandular epithelial hypertrophy, or inadequate lymphatic drainage may lead to dilation of the endometrial glands.

Other degenerative alterations in the endometrium that lead to endometriosis include lymphatic lacunae and angiosis.[130,188] Lymphatic lacunae are histopathologic indications of lymphangiectasia. Angiosis (a vascular pathologic condition) is associated with aging and parity, especially in uteri with ventral sacculations and associated venous congestion, which are pathogenic factors for angiosis.[188] No treatments exist for these anatomic and vascular degenerative changes in the uterus. Mares with lymphatic lacunae and disseminated uterine angiosis are at risk for infertility caused by delayed uterine clearance and persistent mating-induced endometritis.[130,188]

Pregnancy loss attributed to endometrial fibrosis more commonly manifests during the embryonic period. The secretion of histotroph by the endometrium is critical for proper embryonic development. The area of the endometrium in immediate contact with the conceptus has been shown to undergo specific changes in glandular density on days 16 through 30 of gestation; this is a period during which embryonic loss is commonly diagnosed in mares with endometrosis.[189] If pregnancy continues to progress beyond the initial 30 days of gestation, then abortion during the early fetal period may still occur if uterine fibrosis interferes with implantation of

the placenta. Microcotyledonary attachments begin to develop by 80 to 120 days' gestation.[190] Ultrastructural evaluation of the placenta in mares with chronic degenerative endometritis (CDE; endometriosis) has shown a delay in microcotyledon development and a reduction in the number of microcotyledons and villi per surface area. Endometrial atrophy may not result in abortion but can influence fetal growth. Fetal weights in mares with degenerative endometritis were lower than in normal mares.[191] Endometrial atrophy may be evident on inspection of the placenta after delivery.[192]

Endometritis

Whereas endometriosis reflects chronic structural changes associated with age and parity, endometritis encompasses endometrial changes associated with acute or chronic inflammation. The changes associated with endometritis are modulated by the action of a local immune system and influenced by the hormonal milieu. A transient endometritis normally occurs in all mares that were mated naturally or artificially inseminated. Mares mount an inflammatory reaction in response to the presence of semen in the uterus, but this apparently normal inflammatory response subsides (histologically) within 2 to 3 days.[193,194] Detection of intrauterine fluid by ultrasonography per rectum 24 hours after mating suggests delayed clearance. Persistent mating-induced endometritis is a clinical entity that has been recognized as a major cause of infertility in mares. A more detailed discussion on endometritis is found in later sections of this chapter.

Endometrial Biopsy

An endometrial biopsy, as covered in the section on BSE, is often considered a routine part of a complete BSE. Because an endometrial biopsy can aid in predicting the chances of a mare carrying a foal to term, one should consider the information provided by a biopsy before purchasing the horse or undertaking reproductive surgery such as repair of a cervical tear. Biopsies sometimes provide information that is useful in the diagnosis of infertility and may provide a basis for treatment. One must realize, however, that an endometrial biopsy alone is often not the most significant part of a BSE but must be considered in light of other information obtained from the history and reproductive examination.

Generally a biopsy specimen is taken from a site at the base of one of the uterine horns. When procuring a biopsy, the practitioner should take care not to obtain tissue from a site near the internal cervical os. Glands are less dense near the cervix, making a biopsy obtained from that area less representative of the uterus and more difficult to interpret. Moreover, accidentally taking a biopsy sample from the cervix can result in adhesions.

A single biopsy has been considered to be representative of the entire uterus, but studies have shown that variation by as much as an entire category may exist among sites.[125] Therefore one first should perform a thorough examination by palpation and ultrasonography to determine whether any areas of the uterus appear to be abnormal and also to rule out pregnancy before taking a biopsy. If one detects an abnormal area, then biopsy samples should be obtained from the abnormal and the normal areas. Repeated or multiple biopsies do not significantly affect fertility. A mare may become pregnant when bred just a few days after a biopsy specimen is taken.[195]

One must relay all pertinent history, including the estrous stage during which the biopsy sample was obtained, to the pathologist reading the sample. Periglandular fibrosis may appear worse in biopsy samples taken during anestrus because of the sparseness of glands. In addition, biopsy samples taken during anestrus or transition may have evidence of increased inflammation because the cervix has been in a relaxed state for a prolonged period as a result of the absence of progesterone.

Endometrial biopsies are classified into four categories as previously described (I, IIA, IIB, and III). A mare with a category I biopsy has an essentially normal endometrium. The likelihood of the mare becoming pregnant and carrying a foal to term, estimated at 80% to 90%, depends more on broodmare management than on the inherent fertility of the mare. Mares with a category III biopsy have severe pathologic changes in the endometrium and an estimated 10% chance of carrying a foal to term, even with good breeding management. Most mares are classified as a category IIA or IIB with an estimated 50% to 80% and 10% to 50% chance, respectively, of carrying a foal to term, reflecting a combination of management practices and the inherent fertility of the mare.

The clinician's primary concerns are the severity and distribution of inflammation and the presence of degenerative changes such as periglandular fibrosis, angiosis, and lymphatic lacunae (enlarged and dilated lymphatics). Degenerative changes carry a worse prognosis than inflammatory changes because they are considered permanent and progressive. No effective treatment for these conditions has been identified. The origin of such degenerative conditions is not known but widely presumed to be caused by repeated insults to the uterus. These conditions are more common in older mares.[130] Dilated lymphatics often indicate a uterine clearance problem. However, the practitioner can diagnose delayed clearance more reliably by ultrasonographic examination in the post-breeding period.

Although biopsy can reveal the presence of an inflammatory condition, other methods (e.g., examination of perineal conformation) are necessary to reveal the reason that the condition is present, and an endometrial culture is needed to identify the particular pathogen. A repeat biopsy after appropriate therapy may provide insight regarding the extent to which treatment was successful and aid in determining a prognosis for future fertility.[129]

Endometrial Cysts

Endometrial cysts often are cited as a cause of infertility, but a clear cause-and-effect relationship has not been established. The proportion of mares with endometrial cysts increases with age. Mares older than 11 years of age are more than four times as likely to have endometrial cysts compared to younger mares, and most mares older than 17 years of age have endometrial cysts. Reports that associate endometrial cysts with a lower pregnancy rate or increased embryonic loss often fail to account for the effect of advancing age. When one controls for confounding effects, such as parity and age, the assumption that cysts are causing infertility is not supportable. When confounding factors were accounted for in the analysis of nearly 300 mares, endometrial cysts did not have a statistically significant effect on establishing or maintaining pregnancy, although the time of initial pregnancy diagnosis was not controlled strictly.[94] Another report by a different group of researchers who did control the time of pregnancy diagnosis similarly found no difference in pregnancy loss between mares with cysts and those without, although mares with endometrial cysts tended to have a lower day-40 pregnancy rate. The effect of cysts on fertility appeared to be quantitative because

an effect was not evident until a mare had numerous cysts or the cysts were large. However, even then the effect of endometrial cysts on fertility was much less than that with delayed uterine clearance or intrauterine fluid accumulation. A quantitative effect of endometrial cysts could be caused by interference with embryonic mobility. It is well known that the equine embryo undergoes a period of mobility after entering the uterus and finally becoming fixed in place at approximately 16 or 17 days of gestation. If mobility is restricted during this period and the embryo is not permitted to come in contact with a sufficient portion of the endometrium, then maternal recognition of pregnancy may not occur, resulting in luteolysis and embryonic loss.

Rather than viewing endometrial cysts as a cause of infertility, one should consider them as an indication of underlying pathologic changes in the uterus. Large endometrial cysts are usually of lymphatic origin, and their occurrence may be associated with a disruption of lymphatic function.

Endometrial cysts are best diagnosed with ultrasonography. Cysts are identified as hypoechoic, immoveable structures, with a clear border, as opposed to intraluminal fluid, which is movable and has a less distinct shape or border. Endometrial cysts are usually multiple and most commonly found at the base of the uterine horns. Cysts may change in size and number between estrus, diestrus, and pregnancy.

Endometrial cysts can complicate a diagnosis of early pregnancy. They are often similar in size and appearance to an early conceptus. Cysts that appear spherical often are shown to have a more irregular shape if the ultrasound probe can be reoriented in relation to the cyst. To make the diagnosis of early pregnancy easier and more reliable, the practitioner should record the size and location of endometrial cysts using a diagram or by storing ultrasonographic images during a prebreeding examination. Even so, it may be necessary to repeat the pregnancy examination or delay confirmation in some mares with endometrial cysts. In most cases of endometrial cysts, no treatment is necessary other than recording their size and location for future reference during pregnancy examination. However, if the cysts are sufficient in size or number such that they pose a potential threat to embryonic migration, treatment can be aimed at facilitating the establishment of pregnancy by providing exogenous progestogen.

Progestogens, usually in the form of altrenogest (0.044 mg/kg/day, administered orally), can maintain pregnancy even when the signal for maternal recognition of pregnancy is lacking. Numerous studies have shown the ability of altrenogest to maintain pregnancy after luteolysis or in ovariectomized mares. It is important to note that if progestogen therapy is deemed necessary, then the correct dose and frequency of administration are required or the effort is wasted. For example, once-a-month administration of medroxyprogesterone is insufficient to maintain pregnancy. Therefore it would not be beneficial in mares with large or numerous endometrial cysts.

Alternatively, endometrial cysts may be removed surgically. Laser surgery is an ideal method if the equipment is available. Ligation and transection of the stalk of pedunculated cysts is an alternative. Merely puncturing and draining the cyst or incising its wall does not usually provide long-term remission.

Transluminal Adhesions

Trauma or severe infectious or chemically induced (e.g., after intrauterine infusion of irritating chemicals) endometritis may induce the formation of transluminal adhesions in the uterus. These lesions are usually asymptomatic and found during hysteroscopy. Uterine adhesions may cause the retention of endometrial secretions, resulting in mucometra or pyometra. Early embryonic motility, a phenomenon paramount for maternal recognition in horses, may be impaired by intraluminal adhesions. Treatment modalities include manual disruption of intraluminal adhesions or ablation by way of laser surgery.

Pyometra

Pyometra is an accumulation of purulent exudate in the uterus. Unlike cows, mares with pyometra do not necessarily have a persistent CL, and many may cycle normally. A cervical anatomic defect or persistent "hymen" that prevents the clearance of fluid from the uterus may predispose mares to pyometra. However, this condition also can affect mares without an apparent anatomic defect in the reproductive tract. One can diagnose pyometra readily by transrectal ultrasonography when intraluminal fluid with moderate echogenicity is visible in the uterus. Because most mares with pyometra are brought to the veterinarian's attention at an advanced stage, degenerative changes such as endometrial atrophy may preclude mares from returning to normal fertility after treatment. A biopsy sample of the uterus should be examined before treatment to determine the prognosis for potential fertility. Although medical evacuation of the uterus may be attempted, hysterectomy is an option for mares refractory to treatment or with advanced degeneration of the endometrium (severe endometriosis).

Neoplasia

Uterine neoplasms are uncommon in mares. Leiomyomas, often referred to as *fibroids,* are benign mesenchymal neoplasms derived from smooth muscle and often are associated with the presence of fibrous tissue. Leiomyoma is the most common neoplasm affecting the uteri of mares; small neoplasms do not necessarily result in reproductive failure. Leiomyosarcoma, lymphosarcoma, and adenocarcinoma are rare malignant neoplasms affecting mares.

Neoplasms affecting the equine uterus are usually discovered during rectal palpation and transrectal ultrasonography in broodmares during the breeding season. If a uterine neoplasm is suspected, then the clinician should perform uterine endoscopy and take a biopsy sample of the tissue for final diagnosis. Surgical excision of neoplasms is indicated when extensive hemorrhage and endometritis are present or when the presence of the neoplasia would be incompatible with establishing a pregnancy. Prognosis for future fertility is reduced, but pregnancy has been reported in mares with partial hysterectomy.[196]

Uterine Lacerations

Uterine lacerations can occur during unattended or assisted parturition. Rectal and vaginal palpation and abdominocentesis aid in diagnosis.[197] Uterine lacerations historically have been thought to occur most frequently in the dorsal wall of the uterine body, but more recent work has suggested an increased frequency in the uterine horn with the right side affected (73%) more often than the left.[198,199] Uterine lacerations, once confirmed, are surgically repaired because they can cause life-threatening peritonitis or persistent infertility. Adhesions involving the serosal surface of the uterus may occur after cesarean section or uterine tears. No effective treatment, other than attempted surgical excision, exists once the

adhesions form. Therefore some recommend daily palpation of the uterus to avoid adhesion formation following cesarean section.

Uterine Artery Rupture

There is conflicting evidence about what the predisposing factors are for uterine artery rupture. Age (>15 years) and parity have been shown to be contributing factors for mares at risk for uterine artery rupture.[5,200-202] Periparturient artery rupture can occur before foaling but most often occurs during or immediately after parturition. The mare may appear to have colic post foaling, or the hemorrhage may occur after uterine lavage or transrectal palpation several days later. In one study, mares with periparturient arterial rupture represented 1.5% of the total equine necropsy cases; there was no predilection for the left or right sides, and the uterine artery was the most commonly ruptured vessel.[201] Uterine vessels undergo extensive dynamic remodeling during pregnancy and the postpartum period, and this is thought to contribute to progressive degenerative vascular changes. If a mare is believed to be hemorrhaging, then the most common treatment regimen includes sedation and hemostatic support (aminocaproic acid and Yunnan Baiyao). Although many different treatments have proven to be effective, the most important goal is keeping the mare quiet and comfortable.[202,203] If a mare survives an acute episode of rupture of the uterine artery, then antimicrobial therapy is indicated to prevent the hematoma from becoming an abscess. Monitoring the mucous membranes and pulse for 30 minutes after foaling is indicated if the parturition was induced or assisted by a veterinarian and especially when an intervention to correct a dystocia is performed.[204] In mares that survive a ruptured uterine artery, fertility is usually not altered, but mares may be at increased risk for repeated fatal hemorrhage during the subsequent parturition. Further discussion of this condition can be found in the pregnant mare section.

UTERINE TUBES

As mentioned previously, mares are unique in that unfertilized oocytes are retained in the uterine tubes or oviducts and are not transported to the uterus. The mechanism accounting for this phenomenon (selective transport of fertilized versus unfertilized oocytes) has been demonstrated to involve embryo secretion of PGE_2.[8] A healthy oviduct responds to embryonic signals, resulting in proper timing of tubal transport. Diagnosis of pathologic conditions in the uterine tubes is difficult, but laparoscopic evaluation and patency tests have been described.

Postmortem examination of reproductive tracts revealed that salpingitis was common in mares: 37% had infundibulitis, 21% had ampullitis, and 9% had isthmitis. In that study 50% of mares were more than 15 years old, and 85% were older than 11 years of age. The infundibulum generally was found adhered to the uterus, mesovarium, or ovary. The incidence of adhesions on the right side was significantly higher than that on the left side.[205]

Postmortem analysis of uterine tubes has suggested that tubal patency is not a major problem in mares. Oviductal obstructions are less common in the mare than in the cow, although masses of collagen have been found in the oviducts of young maiden mares and pregnant mares and were observed more often in mares that are more than 7 years old.[206] An examination of 700 postmortem specimens, primarily from mares older than 11 years of age, found that almost all oviducts were patent, although more than 40% had adhesions involving the infundibula.[205] Only one uterine tube was found to be occluded among 1248 pairs of uterine tubes that were flushed postmortem.[205,206] Despite this research, there is evidence that oviductal treatment with PGE_2 topically through a laparoscopic approach and oviductal flushing have increased fertility in a certain population of mares that have unexplained infertility that includes a history of no early pregnancy seen despite what appears to be a normal reproductive tract.[207-211]

OVARY

The presence of an enlarged ovary in a mare may be normal or an indication of a pathologic ovarian condition. Consideration of the various possibilities and careful diagnostic procedures are necessary so that normal ovaries are not surgically removed. A thorough history review, including changes in behavior, estrous cycle characteristics, sexual behavior, and the last observed estrus, is important. Ultrasonography, palpation, and hormonal assays are helpful in reaching an accurate diagnosis. In some mares, sequential examinations are beneficial in determining changes in the size of ovaries or various structures on an ovary.

Discovery of an enlarged ovary may be an incidental finding during a normal reproductive examination or may be stimulated by specific clinical signs. Behavioral changes or signs of colic in a mare warrant examination of the reproductive tract, with special attention to the ovaries. Mares with a history of infertility often are suspected of having abnormalities of the ovaries and deserve a thorough examination before surgical removal of an enlarged ovary. The clinician must consider various factors, such as season and pregnancy status, when interpreting a finding of ovarian enlargement. Large ovaries may be normal during the transitional periods in the spring and fall and are expected during certain stages of gestation.

Neoplasia

Granulosa cell tumors (GCTs) or granulosa-theca cell tumors (GCTCs) are the most common tumors of the reproductive tract in mares. They are benign sex cord tumors that can occur in mares of any age; they also have been reported in foals and pregnant mares. Although the granulosa and the theca interna cell layers may be involved, the granulosa cell layer most commonly is affected.

Behavioral changes are common in mares with GCTs that secrete steroid hormones. Behavior may be stallion-like, or persistent estrus or anestrus may occur, depending on the steroid production of the tumor. In other cases of GCTs, behavior may be unchanged yet the mare may be showing signs of abdominal discomfort, lameness, anemia, or other signs seemingly unrelated to the reproductive system. Stallion-like behavior is the most commonly reported behavioral change observed. This is possibly because the change from previous behavior is obvious to the owner and causes an increased challenge in handling the mare. In one report of 63 mares diagnosed with GCTs, 20 exhibited anestrus, 14 were in persistent estrus, and 29 showed stallion-like behavior, which is usually associated with elevated serum testosterone (>45 pg/mL). However, persistent estrus has not been correlated with elevated estrogen.[147,212-214]

On rectal palpation the affected ovary is often enlarged, whereas the contralateral ovary is typically small and inactive. Atrophy of the contralateral ovary can be misleading during winter anestrus, when ovaries are small and minimal follicular growth occurs. Atrophy of the contralateral ovary is not absolute. Although unusual, GCTs have been reported in pregnant mares and in cyclic mares with a functional contralateral ovary and even in both ovaries.[212,213] The enlarged ovary may be smooth or knobby, hard or soft, and may feel as if multiple follicles are present as described previously. Typically, one cannot palpate the ovulation fossa on the affected ovary, although with any greatly enlarged ovary the fossa may be difficult or impossible to palpate. In one report a mare developed a GCT in the contralateral ovary 4.5 years after the initially affected ovary was surgically removed.[213] Ultrasonographic evaluation often shows the classic multiloculated appearance, with cystic structures having sharp rather than rounded borders. However, sometimes the tumor may appear solid or with a single larger cystlike hypoechoic area.[147,214] Although ultrasonography is a useful adjunct, it may not yield a definitive diagnosis as mentioned previously. The ultrasonographic image of GCTs can be similar to that of other ovarian abnormalities, especially ovarian hematomas. A variety of reported appearances makes diagnosis based solely on ultrasonography impossible in many instances.

Mares with GCTs have changes in the circulating hormone concentrations as previously described. Although testosterone often is elevated in mares with GCTs exhibiting stallion-like behavior, testosterone is within normal limits in 10% to 50% of cases. Testosterone in normal cycling mares is less than approximately 45 pg/mL and often is greater than 100 pg/mL in mares with stallion-like behavior. McCue reported that only 54% of mares with GCTs had elevated testosterone, yet 87% had elevated inhibin, leading to the conclusion that inhibin is a better indicator of the disease.[147,214] Inhibin suppresses FSH, leading to a decline in follicular growth, which explains the profound negative feedback effect on the contralateral ovary. Recent work, as mentioned in the previous section, has highlighted the increased sensitivity (98%) of an elevated AMH concentration for detecting the presence of a GCT.[149] At this time most practitioners will have the hormones AMH, inhibin, and testosterone tested, and an abnormal elevation in these concentrations, in conjunction with behavioral signs and abnormal ovarian architecture that persists >30 days, is considered sufficient evidence for the presence of a GCT and the recommendation for unilateral ovariectomy.[149,215]

Overall, the prognosis for life and reproductive function in a mare with a GCT is good. Depending on the time of year when the ovary is removed, the individual mare, and the length of time the tumor has been present, resumption of ovarian activity usually occurs 83 to 392 days after surgery, with a mean of 209 days. If the intended use of the mare is solely as a broodmare, then a reproductive examination, including a uterine biopsy, is recommended before surgery.

Teratomas, although uncommon, are the second most common ovarian tumors. They contain at least two, if not all three, germinal layers. Most teratomas found in mares are benign. They usually contain hair and also may contain bone, teeth, and neural tissue. Teratomas are usually an incidental finding because most are small and do not often cause significant ovarian enlargement. However, on occasion, large teratomas develop that result in ovarian enlargement. Teratomas do not affect the estrous cycle and, therefore, lack obvious outward clinical signs.

Serous cystadenomas are neoplasms of epithelial origin usually found in older mares. These tumors do not metastasize. Although they have been found in mares with high plasma testosterone,[216] behavioral changes are not characteristic. The contralateral ovary is not affected, continues to have normal activity, and does not atrophy; and affected mares usually continue to cycle. On the affected ovary the ovulation fossa is not obliterated and is palpable.

Dysgerminomas are highly malignant tumors that are also of germ cell origin. They metastasize rapidly to the abdominal and thoracic cavities and are considered the counterpart of the testicular seminoma. Because of their nature, dysgerminomas can affect other organ systems, and cases have been reported of associated hypertrophic pulmonary osteoarthropathy.[217] Clinical signs on presentation, therefore, often are unrelated to the reproductive system. These tumors carry a poor prognosis.

Ovarian Abscess

Ovarian abscesses often are attributed to procedures involving puncture of the ovary, such as biopsy or follicle aspiration. As assisted reproductive techniques became more successful and therefore more popular, the incidence of ovarian abscesses was thought likely to increase. However, this has not proved to be the case. Moreover, not all ovarian abscesses can be attributed to iatrogenic causes. Ovarian abscesses have been reported in mares that have had no such procedures performed on them. In these cases, abscesses are likely caused by the hematogenous spread of bacteria or may be associated with strongyle migration.

Affected mares may be febrile and anorectic with an elevated white blood cell count. On ultrasonographic examination the enlarged ovary typically has a thick-walled, fluid-filled structure. The fluid is usually heterogeneous and hyperechoic. Medical management with long-term antibiotic therapy has been successful in treating these cases. Surgical removal of the affected ovary is an alternative treatment, but one must take care that the abscess does not rupture in the abdominal cavity.

Ovarian Torsion

Ovarian torsion, a condition not uncommon in women, has been reported in a mare with a large GTCT that was showing signs of abdominal discomfort.[218] It might be suspected in mares with known ovarian enlargement if sudden signs of abdominal pain develop.

Non-neoplastic Ovarian Enlargement

An ovarian hematoma can form after follicular aspiration or as hemorrhage occurs into the follicular lumen after ovulation. On occasion this hemorrhage can be excessive, possibly because of an anticoagulant present in follicular fluid. Hematomas can be large, up to 20 cm in diameter or more. Although the ovulation fossa is still present, palpating it can be difficult if the hematoma is large. The ultrasonographic appearance varies, causing confusion with a GCT. Large fluid-filled cavities may be observed, or the hematoma may have a more solid appearance, sometimes with fibrin strands. A trait that is sometimes useful in differentiating a hematoma from a GCT is the responsiveness to administration of $PGF_{2\alpha}$. Hematomas that are at least 5 or 6 days old often respond to $PGF_{2\alpha}$ by decreasing in size because of the luteolytic effect. GCTs do not respond to $PGF_{2\alpha}$ treatment with any change in size, shape, or ultrasonographic appearance. Because the follicle wall still undergoes luteinization despite the presence of the hematoma, progesterone concentrations in blood may rise, and cyclicity

usually remains unaltered. Unless the hematoma obstructs the ovulation fossa, fertility is usually not compromised. However, because of the presence of a hematoma, the enlargement of the ovary may persist for several estrous cycles even though the life span of the luteal tissue is normal. Because this structure is a postovulatory phenomenon, the oocyte has been released and the mare may become pregnant if she is mated.

Anovulatory follicles are most common in mares near the end of the breeding season as they go through the autumn transition. These follicles grow to an unusually large size (70–100 mm) yet fail to ovulate. Instead, they fill with blood and develop a gelatinous consistency. A thick (compared with a normal follicle) wall commonly forms. The follicles become firmer and then regress over time, usually disappearing within a month. Free-floating echogenic spots are evident in the antrum of the follicle on ultrasonography, and these increase in number as the follicle grows. When the follicle stops growing, the contents become organized with an echogenic appearance and fibrin strands. Formation of luteal tissue around the periphery of the anovulatory follicle is usually minimal in a true autumnal follicle that occurs at the end of the season. The cause of anovulatory follicles is unknown, although they have been hypothesized to be caused by changes in the hormonal status of the mare that occur with autumn transition. This hypothesis does not explain the occasional occurrence of anovulatory follicles during the breeding season, however. Luteinized anovulatory follicles, although unusual during the ovulatory season, most often occur in older mares, mares with endometritis and mares administered luteolytic agents. Their response to induced luteolysis varies.

During gestation, ovarian enlargement is normal and should be expected when eCG levels are elevated and accessory CLs are present. Ovarian enlargement is associated with increased follicular activity and subsequent ovulation (secondary CLs) or anovulatory luteinization (accessory CLs). An increase in follicular growth begins before day 20 of gestation. New CLs form at approximately day 40 of gestation. Corpora hemorrhagica and hemorrhagic follicles are most common from day 40 to 60. Mares bred early in the season have greater follicular activity during the first 4 months of gestation than mares bred after July.

As described previously, mares undergo transition from winter anestrus to the normal ovulatory season during the spring. The spring transition is characterized by the development and regression of several follicular waves without ovulation, and the ovaries can be quite large, with multiple follicles on each ovary. This transitional period until ovulation occurs lasts for a variable time depending on the mare, photoperiod, and other undetermined factors. The ovaries can be large during the spring transition and may be mistakenly called *cystic*. No treatment is necessary, although a combination of progesterone and estrogen often is used to suppress follicular activity in an attempt to hasten the onset of ovulation and normal cyclicity.

Small and inactive ovaries normally are found in mares in deep anestrus, prepubertal mares, and pregnant mares in the last third of gestation when, curiously, the fetal gonads are larger than the ovaries of the dam. Mares subject to severe malnutrition, of advanced age, treated with anabolic steroids, and with chromosomal alterations leading to gonadal dysgenesis may have abnormally small and inactive ovaries. Mares administered GnRH vaccines have also been demonstrated to have prolonged periods of ovarian inactivity.[42,44]

This section has provided the basic approach to the most common pathologies associated with the reproductive tract of the nonpregnant mare. The following section serves as an in-depth discussion of endometritis, which is arguably one of the most important topics in reproductive management of the horse because it is the most common problem associated with establishing pregnancy in the mare.

Endometritis and Uterine Therapy

Charles F. Scoggin, Kirsten E. Scoggin

Endometritis is the leading cause of subfertility in broodmares. Identification of the cause(s), targeted therapy, and periodic monitoring are important components of successful management. In addition, some causes (e.g., sexually transmitted diseases [STDs]) have important regulatory considerations and can affect international trade and transport. This section will provide an overview of the pathophysiology, methods of diagnosis, and treatment strategies for endometritis.

INTRODUCTION

Inflammation of the uterus following breeding is considered a normal yet transient physiologic response in mares.[219] Most mares (~90%) are capable of managing this inflammation with little to no intervention; these individuals are considered reproductively normal or *resistant* mares. The other 10% either have or are prone to endometritis and are considered *susceptible* mares.[220,221] Causes of susceptibility include infiltration of pathogenic organisms, anatomic and functional defects, aberrant local immune response, and method of breeding.

PATHOPHYSIOLOGY OF ENDOMETRITIS

In clinical broodmare practice, the most important causes of endometritis are (1) infectious endometritis (IE), (2) post-mating-induced endometritis, (3) CDE, and (4) STDs. These diseases are not mutually exclusive and can occur in tandem.

Infectious Endometritis

Infectious endometritis occurs following colonization of the uterus with opportunistic bacteria. The most frequently encountered pathogens in mares are β-hemolytic streptococci (*Streptococcus equi* ssp. *zooepidemicus;* β-strep) and *E. coli*.[222,223] Less common but no less pathogenic are the bacteria *Pseudomonas aeruginosa* and *Klebsiella* spp. and the yeast *Candida* spp. and *Aspergillus* spp. As will be discussed later, these microbes are identified by microbiologic techniques, cytologic evaluations, and histologic studies of the endometrium.

Persistent Mating–Induced Endometritis

Equally as significant as IE is persistent mating–induced endometritis (PMIE). This condition occurs when mares have anatomic or physiologic abnormalities that lead to excessive intraluminal fluid accumulation and/or impairment of the uterine clearance mechanisms. Normal or resistant mares should typically have only a trace amount (e.g., <1 cm in depth) of anechoic fluid seen on transrectal ultrasound 24 to 36 hours after breeding.[224] In contrast, susceptible mares will

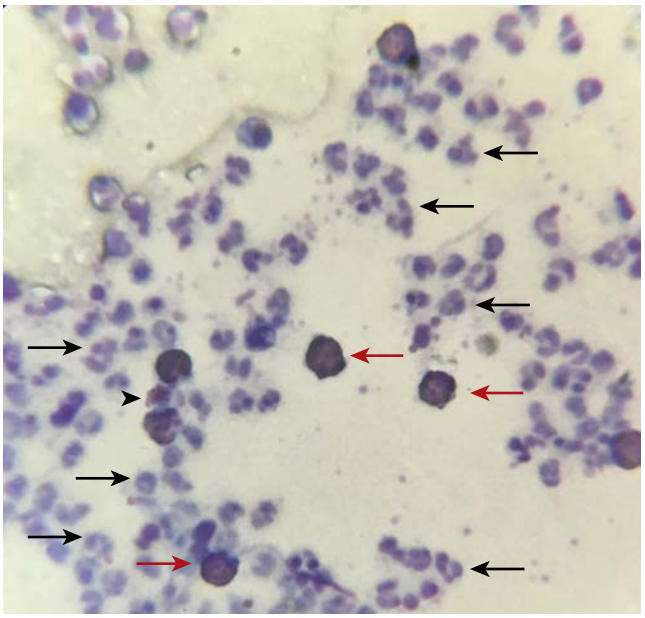

FIG. **19.19** Light micrograph of an endometrial cytology from a mare with persistent mating–induced endometritis (PMIE). Numerous neutrophils and eosinophils are present in this sample. Bacterial colonies are also evident.

FIG. **19.20** Cross-sectional transrectal ultrasonographic image of the uterus from a mare with persistent mating–induced endometritis (PMIE). Note the edema pattern present within the endometrium that is associated with the echogenic intraluminal fluid. (Courtesy P.M. McCue).

have a significant amount of echogenic fluid measuring several centimeters within the uterine lumen. This fluid is usually an accumulation of inflammatory cells, uterine secretions, and semen (Fig. 19.19). Endometrial edema is often present and excessive, indicating an exaggerated local inflammatory response (Fig. 19.20).

Chronic Degenerative Endometritis

Chronic degenerative endometritis is typically considered an age-related phenomenon.[225] Changes within the reproductive tract associated with CDE occur regardless of parity or past reproductive history. A recent review on this subject evaluated data from three different regions of the world with large Thoroughbred breeding programs.[226] On average, reproductive efficiency in broodmares increased steadily until ~10 years of age and remained relatively steady until ~14 years of age. Reproductive performance slowly but steadily declines thereafter and goes into a downward spiral by the late teens. Mares with CDE are readily diagnosed by endometrial biopsy. Common findings include increased fibrosis, cystic glandular distention, and lymphangiectasia (Figs. 19.21 and 19.22). Clinically, these changes put mares at risk for either IE or PMIE. In addition, age-related changes occur to other important parts of the reproductive system, such as the cervix and perineum.[227,228] The clinician is thus reminded to evaluate all structures of the reproductive tract when managing endometritis or other causes of subfertility.

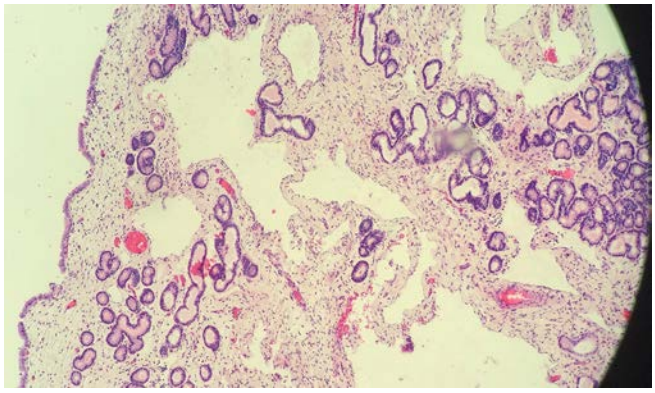

FIG. **19.21** Light micrograph of an endometrial biopsy showing age-related changes in the stratum compactum consistent with chronic degenerative endometritis (CDE). Note denuded epithelium, sparsity of glands, and foci of inflammatory cells. (Courtesy C.F. Scoggin).

Molecular and Gene Expression Studies

Recent studies have shown there are multiple and complex signaling pathways involved in both experimental and clinical cases of endometritis. Included in these events is release of proinflammatory and antiinflammatory cytokines. The interleukin (IL)-1 cytokine family (IL-1α, IL-1β, and IL-receptor antagonist [IL-1Ra]) plays an important role in immune regulation and inflammatory processes.[229] Several recent studies have focused on characterizing this cytokine signaling pathway in the mare reproductive tract in response to bacterial or breeding-induced endometritis (reviewed in Woodward and Troedsson[230]). Current experimental models use either bacteria (such as β-strep or *E. coli*) or spermatozoa to induce an inflammatory response. In these models, upregulation of proinflammatory cytokines—such as tumor necrosis factor-α (TNF-α), IL-1β, and IL-8 (a neutrophil chemoattractant), as well as the antiinflammatory cytokine IL-10—was observed within 3 hours after challenge.[231] This same group also found a systemic increase in serum amyloid A (SAA) expression up to 12 hours after inoculation. A follow-up study comparing mares classified as resistant or susceptible to persistent endometritis found that both groups exhibited an immune response after

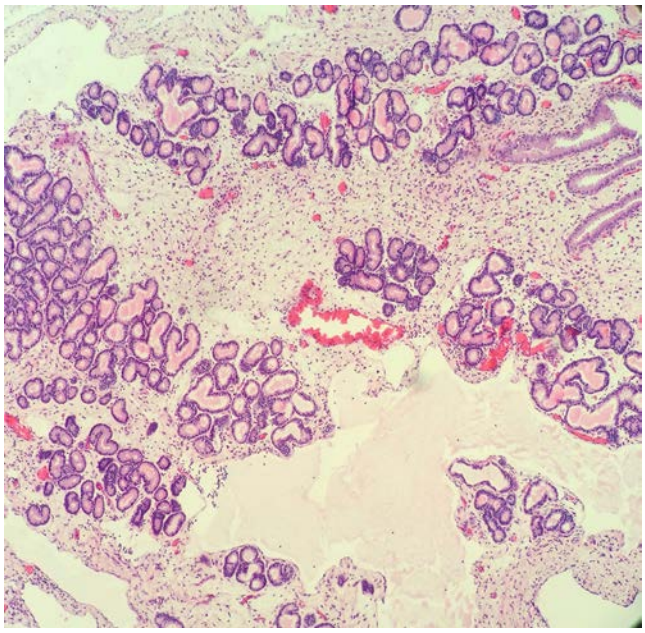

FIG. **19.22** Light micrograph of an endometrial biopsy of the stratum spongiosum. Age-related changes are evident and consistent with chronic degenerative endometritis. (Courtesy C.F. Scoggin).

E. coli infusion, but the susceptible mares showed a sustained cellular immune response (up to 72 hours).[232] The susceptible mares showed an increase in IL-1β and IL-8 expression at 24 hours, and IL-1β at 72 hours compared with resistant ones. In addition, susceptible mares had a decrease in IL-6 and TNF-α expression compared with resistant mares at 3 hours post infusion. In this study, there was no upregulation or downregulation observed for the inflammatory-modulating cytokine IL-10, but this may be caused by a lower dose of *E. coli* used for the bacterial challenge.

Endometrial cytokine gene expression was also analyzed in mares resistant and susceptible to persistent post-breeding endometritis. Fumuso et al.[233] examined the expression of IL-1β, IL-6, and TNF-α in resistant and susceptible mares 24 hours after AI and found that both groups detected an increase in these proinflammatory cytokines, but the susceptible mares had overall higher basal levels of these cytokines. The same research group subsequently found that susceptible mares had an increased expression of IL-8 (which mediates recruitment and leukocyte activation at sites of inflammation) and lower expression of the antiinflammatory mediator IL-10 compared with resistant mares 24 hours after insemination.[233,234] The cytokine response to killed spermatozoa was also compared between resistant and susceptible mares at multiple time points after insemination (0, 2, 6, 12, and 24 hours).[235] Both groups exhibited changes in cytokine expression, but significant differences between groups were only observed at the 6-hour time point. Six hours after insemination, susceptible mares had a lower expression of the antiinflammatory cytokines IL-1Ra and IL-10 and the proinflammatory cytokine IL-6 (which can stimulate the immune response and also has antiinflammatory properties[236] compared with resistant mares). Thus the inflammatory gene response may differ in mares with persistent breeding-induced endometritis. A better understanding of the molecular causes and pathways involved in the disease could lead to new treatments aimed at targeting these particular pathways. These include treatment with immune-modulating substances either locally or systemically and will be discussed in a later section pertaining to therapeutic options for endometritis.

Biofilm Infections

Over the past decade biofilm infections have received a great deal of attention as a cause of mare subfertility. Bacteria can exist in one of two states: The first is the free-floating or planktonic state, and the second is the biofilm state. This biofilm state contains a community of bacteria, and together they create an added barrier of protection against the host's immune system and antibiotic agents above and beyond the capability of planktonic bacteria. These biofilms are proposed as a cause for persistent and chronic endometrial infection, and research is actively being pursued on this topic.

Biofilm is made up of an exopolysaccharide matrix (EPS) that is produced by the bacterial community within the biofilm.[237] This EPS contains plasmids that can be shared among this community to confer resistance to outside stresses or an adverse environment. The EPS also allows for chemical signal transduction, allowing bacteria to coordinate their activities to increase efficiency and resiliency of the biofilm. The presence of biofilm has been found in various areas, including the bladder and skin wounds, and can lead to persistent infections, making treatment and resolution difficult. The actual presence of biofilm within the mare's uterus has not been confirmed, but research appears to be on the precipice of answering that question.[238,239]

Pathogenic bacteria implicated in biofilm formation in the mare are *E. coli, K. pneumoniae, P. aeruginosa,* and β-strep. A presumptive diagnosis of uterine biofilm infection can be made in mares that fail to respond to conventional treatments as determined by repeated "dirty" cultures and inflammatory cytologies. Current therapies are aimed at disrupting biofilm formation and will be discussed in a subsequent section.

Sexually Transmitted Diseases

There are several equine STDs that are of relevance from both clinical and regulatory standpoints. Readers are strongly encouraged to contact their local U.S. Department of Agriculture-Animal and Plant Health Inspection Service (USDA-APHIS) official for updated information or whenever a reportable or foreign animal disease (FAD) is suspected. Questions pertaining to the handling of potentially infected gametes (e.g., spermatozoa and embryos) should be directed to these and other regulatory officials.

Contagious Equine Metritis

As the name implies, CEM is a contagious disease affecting the uterus of the mare. It is of increased significance because of its impacts on international transport of livestock. A true venereal disease, CEM is caused by the bacterium *Taylorella equigenitalis,* a gram-negative coccobacillus that is considered highly contagious.[240] Transmission via fomites also appears to be likely and was implicated as a cause for an outbreak in the United States from 2008 to 2009. Clinical signs vary from relatively unapparent to copious vulvar discharge originating from the uterus.[241] The majority of CEM-affected mares are otherwise clinically normal and will resolve the infection within 2 to 4 weeks. Unfortunately, by the time clinical signs are observed, at least one cycle is lost to endometritis, and spread of the disease is rapid to other mares and stallions. Inapparent or "silent" carrier stallions are the most common

source for disease transmission among horses. What ensues is a significant drop in productivity (as measured by per cycle pregnancy rates) and increased costs associated with management and veterinary care. As will be described later, treatment for *T. equigenitalis* is fairly straightforward and consists of careful cleansing of the internal and external genitalia and application of local antiinfective agents. Systemic antibiotics may be needed in severe cases. To the authors' knowledge, no vaccine exists for this disease. Because of the fairly recent outbreak of CEM, the United States has undergone a reclassification in its status as a CEM-free country. As this chapter goes to press, international transport of horses to and from the United States is permissible by most agricultural ministries provided proper screening and required treatments are performed prior to introduction of the animal into the country's breeding population.

Equine Viral Arteritis

Equine viral arteritis (EVA) is another disease that has important regulatory implications. It occurs following infection with equine arteritis virus (EAV), an enveloped, single-stranded virus.[242] Clinical signs vary in degree and intensity and include vasculitis, distal limb edema, pyrexia, rhinitis, conjunctivitis, and anorexia. Most important, it can cause abortion outbreaks and severe neonatal pneumonia in naive herds, causing significant economic damage and lost productivity. Modes of transmission include respiratory secretions and other body secretions, including semen, fetal fluids/tissues, and fomites. Most mares mount a significant immune response to the disease and are generally considered immune for several years following clinical infection. Current estimates suggest that 30% to 70% of exposed stallions will become persistently infected with the virus and are referred to as "shedder" stallions.[243] For a more complete review of EVA in stallions, the reader is referred to Chapter 8 and the section of this chapter related to diseases of the stallion. In mares, disease is usually self-limiting, and treatment consists primarily of supportive care and isolation strategies. A modified live virus vaccine is commercially available in the United States (Arvac; Zoetis, Inc., Parsippany-Troy Hills, NJ 07054) and has been approved for use in nonpregnant breeding stock. The authors have used it safely in mares at various stages of gestation. Control of disease is best accomplished by screening, isolation, and vaccination. Breeding with EAV-infected semen is permissible with proper documentation of the mare's vaccination status. Certain breed registries and state agricultural departments have restrictions regarding vaccination of breeding stock and use of EAV-infected semen. The reader is encouraged to compile and organize this information before vaccination or use of semen from a shedder stallion.

Equine Herpesvirus Type 3

EHV-3 is the causative agent of equine coital exanthema. It is not currently considered a reportable disease in the United States. This virus is transmitted primarily via coitus, but transmission can also occur via fomites, including shared examination gloves and vaginal specula. Clinical disease is primarily manifested as vesicular and painful lesions on the external genitalia of both mares and stallions. These lesions cause discomfort during reproductive evaluations and during live-cover matings, but aside from transient and often self-limiting pyrexia, infection typically has no lasting or impressionable effects on fertility.[244] Lesions will take 4 to 6 weeks to heal and are characterized by focal areas of depigmentation. Gentle cleansing of active lesions may soothe and reduce inflammation. Reports of antiviral treatments are sparse, and treatment is usually tincture of time. Mares can resume breeding once the lesions have healed. Recrudescence of this particular herpesvirus is unknown.[245] Control is aimed at early detection and temporarily removing infected animals from breeding until lesions have subsided. There is no commercially available vaccine against EHV-3 in the United States.

Dourine

Dourine is a serious STD of equids because of its high morbidity and mortality. The etiologic agent is the protozoa *Trypanosoma equiperdum*. Infection affects several body systems, and clinical signs include intermittent fever, swelling of and discharge from the genitalia, cutaneous plaques, and neurologic signs.[246] It is generally considered a chronic and progressive disease; the onset of recumbency usually indicates terminal disease. This disease has been eradicated in several developed countries, including the United States. It is still seen in Africa, the Middle East, South America, and Central America, but sporadic outbreaks have been reported in Asia and Germany.[240] Diagnosis is made via compatible clinical signs and a complement fixation (CF) test, which is prone to false-positives from other species of *Trypanosoma*. Newer methods of diagnostics, including ELISA and polymerase chain reaction (PCR) technologies, are currently being explored for both testing and screening purposes. If found in a particular area, then infected animals should be identified, and breeding activity should cease until positive animals have been removed, usually via culling. Treatment with antiprotozoal drugs has been performed in some endemic areas, but they are unproven and even discouraged because of the concern of generating inapparent shedding animals.

Piroplasmosis

Piroplasmosis is a disease that became prevalent in the United States earlier this decade after a fairly long period of absence. It is considered an FAD in the United States, but it is endemic in many other parts of the world. This disease is caused by the protozoa *Babesia caballi* and *Theileria equi* (formerly *Babesia equi*). Transmission occurs either via a vector (e.g., ticks) or mechanically (e.g., improperly sanitized instruments). It also has the potential to be transmitted venereally in cases of hemospermia. Piroplasmosis creates disturbances to the circulatory, musculoskeletal, abdominal, and nervous systems. Clinical signs can be nonspecific and may vary based on the severity of disease and degree of chronicity. Horses surviving the acute phase of the disease can become carriers. Diagnosis can be made based on observation of the organism on blood smears and serologic testing. Treatment with antiprotozoan medications is unproven, and recrudescence is a concern.[240] Similar to other reportable diseases, concerns about a potential FAD should be directed to the local USDA-APHIS official.

DIAGNOSTICS

History

Evaluation of past reproductive, medical, and management issues is tantamount to an effective workup of susceptible mares. Calculation of per cycle pregnancy, embryonic loss, and live foal rates are useful measures of reproductive

efficiency. Disturbances to other body organs may also factor into susceptibility. Chronic injuries to the musculoskeletal system can be particularly problematic because they can be a source of steady pain and ill-thrift. Metabolic disease can also affect fertility (e.g., PPID). This disease is covered more thoroughly in Chapter 16, but it can affect the reproductive system by leading to chronic infections and erratic cyclicity. Finally, consideration should be given to stallion fertility. Chances of conception are improved by selecting a stallion of known fertility. With respect to the phenomenon of *mare-stallion incompatibility,* it has never been proven in horses; nevertheless, the potential exists as suggested by numerous anecdotal reports of switching stallions and improving fertility rates in problem mares.

Reproductive Evaluations

The importance of a thorough physical examination cannot be overstated. As mentioned previously, abnormalities in other body systems can adversely affect reproductive efficiency in broodmares. These should be noted and incorporated into the future plan. Screening for infectious and metabolic disease should also be performed when indicated.

Reproductive evaluations consist of inspection of both the external and internal genitalia, including the mammary glands. Perineal conformation is judged by evaluating the declination and location of the vulva with respect to the anus and ischium. A more objective measure is calculating the Caslick index described by Pascoe.[49] In normal mares, the anus, vulva, and ischium lie in a relatively similar vertical plane, with about two thirds of the vulva lying dorsal to the ischium. The vulvar lips should form a tight seal enclosing the vestibule, urethral orifice, and clitoris. Abnormal findings include a forward-tilting pelvis, sunken-in anus, and more of the vulva lying dorsal to the ischium than ventral. Clinically, these abnormalities can lead to pneumovagina and urovagina, as well as fecal contamination of the vestibule and vagina.

Palpation per rectum should reveal two ovaries that are kidney-bean shaped with readily distinguishable ovulation fossae. The uterine horns, uterine body, and cervix should also be identified and felt for tone, relative turgidity, and location of the uterus relative to the pelvis. Sweeping these structures in a continuous motion can help identify adhesions and/or intramural masses. Susceptible mares often have a pendulous uterus, which can restrict uterine clearance. Rectal ultrasonography is a key component of mare reproductive examinations and allows for further characterization of the ovaries, uterus, cervix, and vagina. Archetypal findings of endometritis are echogenic, intraluminal uterine fluid exceeding 2 cm high by 2 cm wide, exaggerated endometrial edema using a subjective scoring system, and pneumovagina as evidenced by hyperechoic flecks within the vaginal vault.

Moving caudal to cranial, the three important barriers to the uterus are the vulva, the vestibulovaginal fold, and the cervix. Breakdowns in any of these barriers can lead to acute or chronic inflammation and/or contamination with pathogenic organisms. A vaginal examination can identify sources of vulvar discharge, the relative seal of the vestibulovaginal fold, character of the vagina, and integrity of the cervix. Most theriogenologists prefer to do both speculum and manual examinations because some abnormalities are best visualized, whereas other abnormalities are best palpated.

Finally, evaluation of the udder is recommended. Abnormalities are rare but can affect rearing and mothering ability, and they suggest endocrine disorders. Congenital defects, previous trauma, and infections can occur within the mammae. Admittedly, it is unusual for abnormalities of the mammae to be associated with endometritis. However, it is worthy to mention that milk production can be adversely affected in severe cases of endometritis that progress to metritis.

Assessment of the Endometrium

The past two decades have brought forth significant advancements in diagnostics used for identifying endometritis. This particular section will include both time-honored techniques (e.g., culture, cytology, and biopsy) that comprise a minimum database expected for evaluating mares with endometritis as well as discussion of new techniques that may aid in the diagnosis and management of endometritis. Table 19.6 provides a list of various clinicopathologic techniques available and their relative merit for diagnosing endometritis in the mare.

When samples are procured from the internal reproductive tract, the mare should be adequately restrained with her tail held or tied out of the way. Her rectum should be evacuated and her perineum thoroughly cleansed to remove feces, smegma, and other debris. The clinician should use sterile gloves, rods, sleeves, speculums, and swabs to maintain cleanliness.

Endometrial Culture

With respect to endometrial cultures, several means are available for acquiring samples. The most common method consists of using either a Kalayjian or double-guarded swab. The penetrating portion of the swab is protected within the palm or fingers of the clinician before entering the vaginal vault. The external os of the cervix is located, and the swab is fed through the cervix and into the lumen of the uterus. After contacting the endometrium, the swab is popped through the protective cap or sheath and gently rolled along the endometrium. Care must be taken to turn the swab in the same direction to prevent it from snapping off within the endometrium. The swab is then retracted back into its sheath(s) and placed in holding media, properly labeled, and submitted to the laboratory for culture and sensitivity. Aerobic cultures are most commonly submitted. In cases of suspected anaerobic or fungal infections, the clinician should communicate directly with the laboratory when preparing these cultures and attempting to identify the agent(s) involved. The major advantage of the swabbing technique is the relative ease by which it can be collected. Some clinicians prefer this method when using a speculum for accessing the vaginal cavity. The major downside of this method is that it involves sampling only a small portion of the endometrium. Focal infections can thus be missed, leading to a false-negative result.

Other means of obtaining uterine cultures are low-volume lavage (LVL), direct aspiration of intraluminal fluid, and biopsy specimens. The LVL is a popular method for evaluating cases of acute and chronic endometritis, especially in susceptible mares. It consists of feeding a Bivona catheter into the uterus and instilling a predetermined amount of physiologic saline or LRS. The uterus is gently massaged per rectum, and the effluent is collected via gravity. The retrieved fluid is first evaluated for its relative clarity and amount of mucus. Although subjective, visual assessment appears important because a cloudy efflux is highly correlated with the presence of bacteria.[247] This fluid is then transferred into sterile 50-mL conical vials and subsequently centrifuged at 400*g* for 10 minutes. The supernatant is poured off, and two sterile cotton swabs are placed

in the pellet: one for culture and one for cytology (see later). The primary advantage of the LVL is that it provides a more representative sample of the entire endometrium. The main disadvantage is that it is prone to false-positive bacteriologic results caused by potential contamination from the vagina.

Direct aspiration of intraluminal fluid entails collection of fluid already present (as diagnosed by ultrasound) within the lumen of the uterus. It can be accomplished by feeding a flexible insemination pipette into the uterus, attaching a syringe to the other end of the pipette, and under ultrasound guidance, gently aspirating fluid from the uterus. This fluid is submitted to the laboratory for both culture and cytology. Advantages to this method are that it does not require the addition of fluid into the uterus, and the recovered fluid has a high probability of containing inflammatory debris and/or pathogenic microbes. Disadvantages include the need for increased technical expertise and, in cases in which mares do not have a great deal of intraluminal fluid, unsuccessful retrieval.

A final means of obtaining an endometrial culture is the collection of an endometrial biopsy. A more thorough discussion of the technique and histologic evaluation was provided in an earlier section. Biopsy samples can also be used to obtain both microbiologic and cytologic samples. For bacteriology, the sample itself can be smeared on a blood agar plate, or a Culturette can be run over the specimen and placed into transport media before immersion into a fixative. Impression smears can also be made and evaluated with common staining techniques. The major benefits of this technique are improved sensitivity of bacteriology findings relative to the guarded swabs and cytologic evaluation, a high positive predictive value, and the potential to identify infectious organisms deeper within the stratum compactum.[222] Drawbacks of this method include an increased technical skill in obtaining the sample and relatively low negative predictive value.

Endometrial Cytology

As alluded to earlier, endometrial cytology is often performed in tandem with endometrial cultures. They are collected in the same manner as endometrial cultures, with clinician preference representing the deciding factor as to what method to use. When Kalayjian swabs are used, a cytology specimen can be obtained by gently rolling the outer sheath of the rod within the endometrium to allow the cap to collect a sample. It is important that the culture swab has been retracted back into the sheath before the rod is rolled to collect the cytologic specimen. Once collected, the rod can be withdrawn from the mare, the swab placed in transport media, and the cap gently "flicked" onto two separate slides, one for an eosin-nigrosin stain and one for a Gram stain. The specimen is then evaluated for the presence of inflammatory cells using bright-field microscopy. Other examples include the previously described LVL technique, mare cytology brushes, and impression smears from biopsy specimens. Mare cytology brushes are similar to those used in women for Papanicolaou (Pap) smears and attached to a plastic rod in a fashion similar to those of double-guarded swabs, and the procedure is identical. Biopsy specimens collected for histology can be used to make impression smears onto slides before immersion in fixative.

In addition to advancements in sample collection, our understanding and interpretation of results have also evolved. No technique is perfect, and each is prone to both false positives and false negatives, which influences the sensitivity (percent of disease-positive subjects that test positive) and specificity (percent of disease-negative subjects that are negative) of each test. Table 19.6 lists probability measures for each previously described technique used to diagnose endometritis. Uterine biopsy samples are the most consistent and serve as the "gold standard" in comparing the worthiness of other diagnostics for detecting endometritis. At least two studies have shown that bacteriology results obtained from endometrial biopsy samples are superior to guarded-swab techniques for positive identification of bacterial pathogens.[222,248] Additionally, these studies and another[106] demonstrated the importance of collecting both a culture and cytology. Indeed, cytology was at least twice as sensitive as culture in predicting the presence of endometritis.[106] The LVL technique has demonstrated improved sensitivity for detecting bacterial growth relative to the guarded swab but had lower specificities for culture and cytology than the swab method.[220] Consequently, it appears that LVL underestimates inflammation, which may be caused by dilution of retrieval fluid. However, it should be noted that when researchers factored in the character of the efflux, the specificity substantially improved.

Endometrial Biopsy and Histology

Histologic evaluation of biopsies is an invaluable tool and widely agreed to be the gold standard when measuring a mare's future reproductive capacity.[10] The procedure as described previously involves aseptic preparation of the perineum, and 60-cm uterine biopsy forceps are used to obtain the sample. Aside from proper restraint, mares generally do not react to the biopsy, and minimal aftercare is warranted. The instrument is then removed from the vagina, and the sample is immersed in a suitable fixative. The authors prefer Bouin solution over 10% neutral-buffered formalin as histologic architecture and luminal contents are better preserved, but samples must be transferred from Bouin solution into another fixative (e.g., water and alcohol) within 24 hours to avoid tissue disruption. Formalin is a suitable alternative and should be used if samples are not going to be processed immediately. If the sample is intended to be used for concurrent culture and cytology, then these samples should be obtained from the biopsy before immersion into a fixative. Multiple biopsies can be collected from different areas of the uterus, and focal abnormalities detected within the endometrium can be biopsied via ultrasound guidance or hysteroscopy. Samples can be submitted for processing and preparation. Each grade is associated with the likelihood of the mare carrying a pregnancy to term (expressed as a percentage) and has been previously described[249]:

Grade I: Normal endometrium or mild, focal inflammation or fibrosis; >80% of maintaining a pregnancy until term.

Grade IIA: Mild to moderate inflammation and/or multifocal fibrosis with one to three layers of fibroblasts surrounding glands or less than two fibrotic nests per 5-mm linear field; 50% to 80% chance of maintaining a pregnancy to term.

Grade IIB: Moderate inflammation and/or multifocal to diffuse fibrosis with four or more layers of fibroblasts surrounding glands or two to four fibrotic nests per 5-mm linear field; 10% to 50% chance of maintaining a pregnancy to term.

Grade III: Severe inflammation and/or diffuse fibrosis with five or more nests per 5-mm linear field; <10% chance of maintaining a pregnancy to term.

Review and interpretation of the sample by a theriogenologist are recommended to ascribe a grade and offer a treatment plan (i.e., epicrisis).

The above techniques represent a minimum database for evaluation of a subfertile mare. As a summary, these include a thorough history; physical examination; reproductive evaluation; and culture, cytology, and biopsy of the endometrium. Theriogenologists have gained an appreciation of the relative benefits and limitations of each test and how using them in tandem improves the reliability of the results and the inciting cause. However, there are some instances in which either routine diagnostics fail to identify the problem or prescribed treatment fails. The next section discusses advancements in diagnostics that are improving both the accuracy of results and response to therapy.

ADJUNCTIVE TECHNIQUES

Hysteroscopy

Hysteroscopy allows for complete visual assessment of the lumen of the uterus via video endoscopy. This imaging technique can identify transluminal adhesions, congenital abnormalities, persistent endometrial cups, uterine tears, foreign bodies, and focal areas of inflammation/infection. Ideally, this procedure should be performed while the mare is in diestrus so that the cervix is closed, allowing for proper insufflation. Priming with progesterone is an option when preparing a mare for hysteroscopy. The endoscope should be cold sterilized with an appropriate disinfectant and then rinsed thoroughly with sterile saline or LRS. The procedure is usually performed under standing sedation. The perineum is cleansed appropriately, and the distal end of the scope is guided into the vagina. Evaluation of the vaginal vault can be useful for detecting sources of persistent or periodic hemorrhagic discharge (e.g., varicose veins) or cervical abnormalities. The end is then passed through the cervix and into the uterus. Insufflation with air or a balanced polyionic fluid allows for visualization of the entire lumen as the uterus expands. The scope is then maneuvered for a complete evaluation of the body and both horns. Each horn should be examined along its entire length to visualize the papilla representing the uterotubal junction. A normal endometrium is pale pink in color with a mostly homogeneous smoothness. If the examination is performed during estrus, then endometrial edema will be grossly evident, characterized by folds and a glistening surface.[250] Video 19.1 provides an example of a normal endoscopic examination of the mare's reproductive tract. The endoscope was advanced through the cervix, and rapid insufflation distended both horns, allowing for complete visualization of the body and both horns of the uterus.

A hallmark sign of acute endometritis is cloudy, neutrophil-laden fluid. Video 19.2 is an example of an abnormal endoscopic examination with mucopurulent exudate diffusely throughout the endometrium. Subsequent biopsy specimens yielded a heavy growth of β-strep. Signs of chronic endometritis are more variable, but they would include focal changes in texture or color, erosions or ulcerations, and plaques or mucoid debris.[250] After hysteroscopy is completed, the uterus should be lavaged, and a luteolytic dose of $PGF_{2\alpha}$ is recommended to contract the uterus and open the cervix for proper drainage.

Hysteroscopy can also assist with treatment. When used in conjunction with an Nd:YAG laser system, it can be used to remove endometrial cysts, adhesions, and retained endometrial cups.[160] Additionally, it can facilitate ligation of vessels and removal of masses within the uterus or vagina. Other uses for endoscopy of the reproductive tract include low-volume insemination, fetal mummification or membrane extraction, hydrotubation of the oviducts, and foreign body removal.

Serum Amyloid A

Acute phase proteins (APPs), such as haptoglobin and SAA, are produced in the liver and stimulate the innate immune response and assist in the elimination of infection.[251] Their production is stimulated by proinflammatory cytokines, including IL-1, IL-6, and TNF-α, which help to modulate the local and systemic immune response. Studies in horses have measured SAA in monitoring the inflammatory response to various clinical conditions, such as castration,[252] endometritis and placentitis,[253,254] induced arthritis,[255] and neonatal illness.[256]

These proteins are also thought to play a role in the inflammatory cascade of the mare's reproductive tract. Studies in cattle have shown elevations in APPs associated with other clinical and diagnostic signs of endometritis[257,258] and could potentially be useful biomarkers in broodmares. SAA is a major protein that normally has low or undetectable levels in a healthy horse; however, plasma concentrations can increase more than 10-fold in response to injury or trauma.[259] SAA concentrations remain stable at baseline levels during the 4 months before parturition[260] and significantly increase within 36 hours postpartum.[261] Studies of mares experiencing early embryonic loss showed increased levels in peripheral SAA 72 hours after insemination and ovulation,[262] but a field study comparing SAA concentrations at days 0 and 15 between mares with early embryonic loss to matched mares that maintained pregnancy found no correlation between elevated SAA levels and pregnancy loss.[263] A study by Nash et al.[264] found that peripheral SAA levels did not increase at 24 hours post insemination with frozen/thawed semen, but a local response within the uterine was not tested. Recent studies have focused on the SAA response in equine endometritis using the bacterial-induced model to monitor changes in peripheral concentrations of SAA, as well as local changes, by measuring gene expression within in the endometrium. Uterine infusion of high doses of *E. coli* yielded a measurable increase in SAA, which significantly correlated with upregulation of SAA in endometrial biopsies at 3 and 12 hours post infusion.[231] Thus, selected markers of the systemic acute phase reaction were altered in the circulation in response to experimental IE. A subsequent study by the same group evaluated the effect of glucocorticoid therapy on SAA endometrial gene expression in susceptible mares after *E. coli* infusion. Researchers found a decrease in SAA concentrations in treated mares,[265] supporting previous clinical studies demonstrating the efficacy of preemptive steroid treatment in mares prone to PMIE.[266,267] More studies are necessary to further characterize the correlation and clinical usefulness of measuring SAA concentrations in cases of endometritis.

TREATMENT STRATEGIES

Antibiotics

The use of antibiotics in broodmare reproduction has a lengthy history. Local intrauterine infusions have been used for decades to treat or act as a prophylactic measure against

endometritis. Systemic antibiotics have gained popularity over the past few years for use either in conjunction with or as an alternative to intrauterine infusions. Doses, routes, and frequency for systemic antibiotics almost always follow published guidelines for administration of these drugs in horses (please see Chapter 2 for a detailed discussion). However, when choosing a systemic antibiotic, it is important to base the choice on sensitivity results and whether it can attain effective concentrations in the endometrium and other tissues of the urogenital system. These and other indications and options for antibiotic use in broodmares will be discussed next.

Intrauterine Antibiotics

In 1992, Pycock and Newcombe published a report in which they showed a significant association between postmating intrauterine antibiotics and improved pregnancy rates.[268] The authors hypothesized that these results were related to reducing or eliminating bacteria tracked into the uterus following breeding. In other words, because the act of mating, especially live cover, was viewed as an inherently dirty process, the use of intrauterine antibiotics assisted local immune defenses in treating opportunistic bacteria. Interestingly, intrauterine antibiotics used alone yielded pregnancy rates similar to those in mares treated solely with a single dose of oxytocin. However, when these two treatments were combined, pregnancy rates were significantly higher than in other treatment groups. This study gave credence to prophylactic intrauterine antibiotic infusions and popularized their use sufficiently where they have become a routine part of a postmating examination in live-cover operations regardless of other findings (or lack thereof). With concerns over antimicrobial resistance reaching near pandemic levels, this practice is no longer condoned. A more prudent and scrupulous course of action is to use antimicrobial agents when there is clinical and/or diagnostic evidence for treatment. Indeed, a recent review regarding the prophylactic use of intrauterine antibiotics concluded that despite justifiable pressures, use of antimicrobials in this manner was questionable, and the use of alternative treatments such as ecbolics and uterine irrigation may be more beneficial.[269]

When selecting an antimicrobial for intrauterine delivery, factors to consider include:

- Appropriate sensitivity pattern
- Stage of estrous cycle
- If it is relatively nonirritating to the endometrium and genitalia
- Compatibility of different agents if two different drugs are mixed

Although some clinicians discourage empiric therapy, there are instances in which delaying treatment or ignoring one's clinical intuition and other findings may have negative consequences. As such, broad-spectrum antibiotics can be chosen that meet the other requirements given earlier. With respect to the stage of the estrous cycle, past studies suggest that intrauterine treatment should only be performed while the mare is in estrus. Treatment during diestrus may have unintended consequences—namely, iatrogenic contamination and increased risk of fungal endometritis.[270] Selection should also depend on the chemical properties of the antibiotic and its respective diluent. Ideal solutions should be nonirritating, attain proper minimum inhibitory concentration (MIC) concentrations for the targeted microbe, and leave minimal residues. Other characteristics, such as -cidal or -static effects and concentration-dependent or time-dependent doses, can also be factored in. However, most doses are empiric. Dosages for various antibiotics for intrauterine delivery are listed in Table 19.7.

In a recent survey involving more than 200 equine practitioners, Dascanio et al.[271] reported that ceftiofur was the most commonly used antibiotic by a narrow margin over gentamicin (21% vs. 19%, respectively). These two were followed by ticarcillin and clavulanic acid (13%), ampicillin (12%), other (12%), amikacin (5%), procaine penicillin (3%), potassium penicillin (3%), and ticarcillin (3%). It was not specified if these selections were made based on culture and sensitivity. Regarding empiric therapy, one study showed that 100% of clinical isolates of β-strep were susceptible to both ampicillin and penicillin G, whereas 100% of *E. coli* were sensitive to gentamicin.[272]

Frequency and length of treatment are other important considerations. As shown in Table 19.7, most uterine infusions are performed once daily. The exception is ticarcillin and clavulanic acid, which, based on previous studies, indicates that multiple daily infusions may be more appropriate to achieve therapeutic concentrations than the standard once-daily dosing.[273] On the other hand, ceftiofur has been found to reach effective concentrations when delivered either intrauterine or IM.[274,275] A recent report demonstrated the potential benefit of a water-soluble solution of enrofloxacin for treating resistant infections.[276] Therapeutic concentrations were above MICs in half of the test mares, and no long-lasting effects on the endometrium were noted, indicating its relative safety. Studies of other antibacterial agents in the uterus are in need of evaluation to combat recurring infections and address antimicrobial resistance.

Systemic Antibiotics

The use of systemic antimicrobial agents to treat endometritis has gained significant momentum over the past decade. Dosages are listed in Table 19.7. The benefits of systemic antibiotics compared with those given via the intrauterine route are the ability to treat regardless of stage of the estrous cycle and the ability to maintain effective and steady therapeutic concentrations for a prolonged period. Additionally, they are not subject to the adverse environment of the uterine lumen and will not iatrogenically inoculate the reproductive tract, as would occur with repeated vaginal treatments.[220] Disadvantages are increased costs associated with higher volumes used and daily treatments. Less common but no less important risks are antibiotic-induced diarrhea, injection site reactions, thrombophlebitis, and anaphylaxis.

Systemic treatment should either be preceded by or performed concurrently with uterine irrigation to remove luminal inflammatory debris. Irrigation should be performed judiciously to reduce the risk of tracking bacteria into the reproductive tract. Systemic antimicrobials can also be used in conjunction with ecbolics, which are discussed in the following section. To the authors' knowledge, studies comparing the effects of systemic versus intrauterine or other therapies are lacking.

Ecbolics

Ecbolics are used to induce contractions of the uterus to promote uterine drainage. Oxytocin is a neuropeptide produced in the hypothalamus and released by the posterior pituitary. It is frequently given exogenously for its ecbolic effect, and its usefulness for uterine clearance has been previously documented.[268,277] Exogenous treatment is somewhat empiric, but consideration should be given to the stage of estrous

TABLE **19.7 Antibiotic Drugs, Systemic and Intrauterine Doses, and Clinical Considerations for Treatments of Endometritis in the Mare**[a]

Drug	Systemic Dose	Intrauterine Dose	Anticipated Spectrum of Activity	Comments
Amikacin sulfate	10–15 mg/kg, IV, q 24 h	1–2 g, q 24 h	Gram (–)	Buffer with bicarbonate for intrauterine use
Ampicillin	29 mg/kg, IV, q 12 h	1–3 g, q 24 h	Gram (+) and *Escherichia coli*	Dilute in high volumes (~200 mL) to prevent precipitation when using intrauterine dose
Ceftiofur sodium	2 mg/kg, IV or IM, q 12–24 h	1–2 g, q 24 h	Gram (+) and (–)	Dilute with sterile water only for intrauterine use (inactivated in saline)
Ceftiofur crystalline-free acid	6.6 mg/kg, IM, two doses 4 days apart	Not approved or studied for intrauterine use	Gram (+) and (–)	Can be given q 7 days for two more doses and maintain effective endometrial tissue concentrations[b]
Enrofloxacin	5–7.5 mg/kg, IV, q 24 h; 7.5 mg/kg, PO, q 12 h	50 mL of water-based 2.5% suspension, q 24 h[c]	Gram (–)	Only compounded formulations available for PO and intrauterine use
Gentamicin	6.6 mg/kg, IV or IM, q 24 h	1–2 g, q 24 h	Gram (+) and (–)	Buffer with equal volume bicarbonate solution and dilute further in sterile water or saline for intrauterine use
Neomycin	5–15 mg/kg, PO, q 24 h	4 g, q 24 h	Gram (–)	Infrequently used
Polymyxin B	5000 U/kg, IV, q 8–12 h	100,000 IU, q 24 h	Gram (–)	Dilute in 1 L fluids when administering systemically; dilute in 100–200 mL for intrauterine use
Potassium penicillin G	20,000–40,000 U/kg, IV, q 6 h	5 million units, q 24 h	*Streptococcus equi* subsp. *zooepidemicus*	Synergistic with aminoglycosides when given IV; adverse interaction when administered concurrently for intrauterine use[d]
Procaine penicillin G	20,000–40,000 U/kg, IM, q 12 h	5 million units, q 24 h	*S. equi* subsp. *zooepidemicus*	Possible intraluminal residues for intrauterine use
Sulfadiazine and trimethoprim	24 mg/kg, PO, q 12 h	Not approved or available in the United States	Gram (+) and *Nocardioform* species	Emerging resistance of *S. equi* subsp. *zooepidemicus*
Ticarcillin and clavulanic acid	50 mg/kg, IV or IM, q 6–8 h	3–6 g, q 12–24 h	Gram (+) and (–)	Dilute in 60–120 mL sterile water for intrauterine use

cycle when implementing a dosing strategy. For example, IV administration of 30 units to estrous mares was shown to reduce uterine contractions compared with lower doses of 5 to 10 units.[278] Interestingly, the density of oxytocin receptors is highest in late diestrus and decreases during estrus and early diestrus,[279] and the uterine response to oxytocin is inversely related to progesterone concentrations.[280] It thus seems prudent to adjust doses with respect to the stage of the estrous cycle. Current recommended doses are 10 to 20 units during estrus and 25 to 40 units after ovulation.[220] Routes of administration include IV, IM, and intrauterine. Oxytocin is not a "silver bullet," and its effects can be limited by anatomic (e.g., closed cervix, pendulous uterus) and mechanical (e.g., fibrosis aberrant contractions) deficits concurrently involving the reproductive tract. Carbetocin, a synthetic analog, has been available in countries outside the United States. Its plasma half-life is over two times that of oxytocin and may be useful in mares that do not respond to oxytocin.[281]

Oxytocin is directly responsible for the release of $PGF_{2\alpha}$ from the endometrium, as evidenced by a spike in its metabolite (PGFM) in the serum shortly after oxytocin administration.[279] Exogenous administration of $PGF_{2\alpha}$ can thus be used clinically as an ecbolic, and research suggests that the synthetic analog, cloprostenol, produces the best response

TABLE **19.8 Intrauterine Therapies and Lavage Fluid Additives**

Agent	Intrauterine Dose		Indications/Comments
NAC, 20%	30 mL in 150–250 mL saline, q 24 h		Mucolytic
Antimicrobial peptides (Ceragyn)	60 mL		Potential biofilm disruptor
Dimethyl sulfoxide (90%)	50 mL in 1 L saline, q 24 h		Mucolytic
Hydrogen peroxide (3% USP)	20 mL qs to 60 mL with saline	100 mL in 1 L lavage fluids	Potential biofilm disruptor, antiseptic, counterirritant
Kerosene	250–500 mL, once		Counterirritant; used for cases of CDE
Lactated Ringer's solution	1–6 L, q 12–24 h		Used for lavage to assist with uterine drainage and clearance of debris
10% povidone–iodine solution	5–15 mL in 1 L saline, q 24 h		Disinfectant
Saline (0.9%)	1–6 L, q 12–24 h		Lavage and diluent fluid
Tricide (EDTA-tris)	250–500 mL, q 24 h		Synergistic effect with aminoglycosides and clotrimazole, used in cases of chronic IE and suspect biofilm production
Vinegar (5%)	100 mL in 1 L saline, q 24 h		Yeast infections

CDE, Chronic degenerative endometritis; *EDTA,* ethylenediaminetetraacetic acid; *IE,* infectious endometritis; NAC, *N*-acetylcysteine; *qs,* as much as needed.

among the $PGF_{2\alpha}$ preparations studied.[282] The primary difference between oxytocin and $PGF_{2\alpha}$ is that the former produces strong and rapid uterine contractions over a relatively short period (~0 minutes). The latter produces lower amplitude contractions over a longer period (4–6 hours). These varying effects should be considered when implementing treatment. It is relatively unknown how much oxytocin and how many contractions are needed to obtain the ideal clinical effect. Dosing of oxytocin usually involves multiple daily dosing, but $PGF_{2\alpha}$ typically involves a single daily dose. There is some evidence that cloprostenol can interfere with early luteal development, but the clinical significance is unknown because fertility is not compromised in mares treated through the second day after ovulation.[283]

Other drugs potentially affecting uterine contractility are the α_2-agonist sedatives and nonsteroidal antiinflammatory drugs (NSAIDs). Detomidine causes contractions in normal non-pregnant mares, whereas NSAIDs, because of their inhibitory action on inducible prostaglandin release, may inhibit uterine clearance.

Lavage and Nonantibiotic Therapies

Uterine lavage or irrigation is an important component in the treatment and management of endometritis. In mares susceptible to PMIE, lavage can be performed before or after breeding. No detrimental effects on pregnancy rates were seen in mares lavaged with LRS before mating.[284] However, it appears that lavage should be withheld for a minimum of 4 hours after mating.[285] In mares with endometritis secondary to other disease processes (e.g., retained fetal membranes [RFMs], metritis, pyometra), lavage can be performed multiple times a day to evacuate septic uterine contents. Isotonic fluids, such as LRS, are preferred when performing uterine lavage because of the more physiologic pH, but saline can be substituted if needed.

Additives are frequently combined with lavage fluids. Examples are listed in Table 19.8. Both betadine and hydrogen peroxide have antiseptic properties, whereas dimethyl sulfoxide (DMSO) and *N*-acetylcysteine (NAC) are used for their mucolytic and antiinflammatory activities. Vinegar is added to fluids to increase acidity, which is commonly done for treatment of yeast infections. These treatments are followed by regular fluids or fluids without additives. Uterine lavage should be repeated daily until the effluent is clear. One common veterinary disinfectant that has been shown to cause substantial irritation to the uterus and should be avoided is a 2% chlorhexidine gluconate (CHG) solution.[286] Dilution to 0.25% CHG has been shown to be less irritating, but sanitizing properties were not evaluated.

NAC is a mucolytic agent that is useful when treating cases of endometritis. Treatment involves diluting a 20% (200 mg/mL) solution in 150 to 250 mL of saline to achieve a 3.3% solution and instilling it into the uterus.[287] This can be done 24 to 48 hours before or 6 to 24 hours after breeding. Serial uterine lavages are often performed 12 to 24 hours after infusion and repeated until the efflux is clear. In a clinical study, mares treated with NAC before breeding had higher fertility rates than those that were not, and treatment had no adverse effects on the endometrium as judged by uterine biopsy.[288]

Kerosene is a clear liquid formed by fractional distillation of petroleum. Primarily used as a fuel, it can also be used as a solvent for removing grease and tenacious mucilage, as well as a pesticide for killing lice and bed bugs. Intrauterine infusion of kerosene in subfertile mares was first reported by Bracher et al.[289] They reported relatively high early pregnancy (87.5%) and live foal (62.5%) rates in subfertile mares treated with kerosene on the cycle before mating. Despite inducing intense inflammation, no long-term side effects, such as cervical or uterine adhesions, were observed in mares treated with kerosene. Kerosene can be used at any stage of the estrous cycle, including diestrus and up to 48 hours before breeding. The only adverse effect observed was mild scalding on the gaskins of a small proportion (<5%) of mares. Mares who have gone more than 1 year barren, who have not responded favorably during multiple cycles of other intrauterine therapies, or who have severe intrauterine fluid accumulation are candidates for uterine infusion of kerosene. Treatment is thought to perform a chemical curettage of the endometrial epithelium, effectively stripping the epithelium of debris, inspissated material, and microorganisms.[290]

Recommendations for the volume of kerosene to be infused varies among theriogenologists. Some use moderate volumes (e.g., 90 mL), whereas others use much larger volumes (500 mL). Because of this rather wide variation in volume, some postulate that contact time with the endometrium may be just as important as (if not more than) the volume of the infusate. Unfortunately, this observation is purely subjective, because no studies exist comparing these variables. Approximately 12 to 16 hours post infusion, uterine lavage with LRS is performed. Lavage should be repeated daily until the effluent is clear. Effluent character can vary from mostly clear (yet strongly odorous of kerosene) to hemorrhagic with the consistency of curdled milk. Caution should be taken when handling and using kerosene because it is flammable, and it is recommended to turn mares out in the paddock overnight after infusion. The authors have found kerosene to be a reliable and successful treatment option in the management of CDE.

Other fluid additives include those targeting potential biofilm infections. Based on the current understanding of biofilm infections, treatment should target both the EPS and the bacteria within the biofilm community. Purported biofilm disruptors include the previously mentioned hydrogen peroxide, DMSO, chelating agents containing *tris*-EDTA, and Ceragyn (Purishield Life Sciences, LLC, Walnut Creek, CA 94597), which is a proprietary and commercially available antimicrobial peptide mimic. All of these agents have shown varying results in vitro for reducing biofilm mass and/or killing organisms within a biofilm.[239]

Long used as an antiseptic, hydrogen peroxide (H_2O_2) has shown a broad spectrum of activity against various microbes, including bacteria, virus, fungi, yeast, and spores. In mares, the recommended dose is 20 mL of a 3% H_2O_2 solution diluted to 60 mL in LRS.[287] An in vitro study demonstrated that 1% H_2O_2 was effective against most pathogens in both their planktonic and biofilm state, except for *P. aeruginosa,* which was capable of inactivating H_2O_2.[239] Bacterial resistance to H_2O_2 has been documented in human cases, but research is lacking in horses.

Buffered chelator solutions have proven useful in cases of refractory bacterial and fungal infections.[291] *Tris*-EDTA has been shown to potentiate the effects of certain antimicrobial agents, presumably by altering cell-wall permeability.[292] Aminoglycosides are one such example, and the two can be mixed together. β-lactam antimicrobials may precipitate in the presence of Tricide, which is thought to inactivate this class of antibiotics. In vitro studies evaluating the use of a similar buffered chelator solution, *tris*-EDTA, showed it to be highly effective on free-floating bacteria.[239] However, *tris*-EDTA was inconsistent in disrupting biofilm production from clinical isolates of *P. aeruginosa*[239]; thus it is by no means a silver bullet for suspected biofilm infections.

Naturally occurring antimicrobial peptides (AMPs) are produced and used by neutrophils to degrade bacteria. Ceragyn (Purishield Life Sciences, LLC, Walnut Creek, CA) is a commercially available wound-healing medical device that is marketed as an AMP mimic. Anecdotally, AMPs need only come in contact with the cell membrane to exert a bactericidal effect. Other attributes of AMPs include a broad spectrum of activity, less risk of developing resistance to microbial defense mechanisms, and direct activity against biofilm. Ceragyn is also being distributed as a uterine lavage device labeled for use either 4 hours before or 6 to 48 hours after breeding. Preliminary studies evaluating its activity against certain biofilm-producing bacteria have been promising. Ferris[239] showed that Ceragyn was effective in degrading biofilm biomass produced in vitro by *E. coli, K. pneumoniae, P. aeruginosa,* and β-strep, and it was also capable of killing β-strep within a biofilm. More research is necessary on this and other products to further evaluate their clinical efficacy. One thing for certain is that none appears to be a panacea for treating chronically dirty mares.

Adjunctive Therapies

Several other therapies exist for the treatment of endometritis. Most can be used quite effectively in conjunction with other therapies. As will be discussed next, some of these therapies are thought to assist with uterine drainage, whereas others act on the immune system to modulate the response to breeding.

Acupuncture

Acupuncture has its origin in Eastern medicine and has been used for a wide range of conditions affecting the mare's reproductive tract. For endometritis, acupuncture is thought to induce uterine contractions to help with the expulsion of intraluminal fluid. A retrospective study involving 44 broodmares showed a reduction in postmating fluid and improved pregnancy rates in mares with a history of susceptibility.[293] Controlled studies are necessary to compare this modality to more traditional treatments such as oxytocin and uterine lavage. Moreover, current protocols and methods used (e.g., "wet versus dry" needling, electrostimulation) are subject to individual practitioner preferences, and measuring response can be confounded by a lack of control subjects. As stated in a review on the use of acupuncture in equine reproduction: "Although acupuncture physiology and efficacy have yet to be thoroughly defined in a traditional Western medicine sense, current research demonstrates a case for continued use as well as further investigation."[294]

Immunomodulators

Influencing either systemic or local immune defense systems has been investigated in broodmares. Corticosteroids have been used to modulate the immune response of susceptible mares, with the primary benefits thought to be reduction in neutrophil margination into the uterus and countering lymphangiectasia. The clinical benefit of dexamethasone was described in a report by Bucca et al.[267] in which they reported improved pregnancy rates in susceptible mares treated with 50 mg (IM) of dexamethasone before breeding. Prednisolone (0.1 mg/kg, PO, b.i.d.) beginning 2 days before breeding has also been used to manage acute inflammation when breeding with frozen semen.[266] Attention should be paid to patient selection and length of dosing schedule because of potential untoward side effects of steroid administration in equids.

Modulation of local defense mechanisms has been explored as a means to improve fertility rates in susceptible mares. More specifically, improving the phagocytic activity of mononuclear cells and reducing the production of proinflammatory cytokines are possible benefits of altering uterine immune systems. Mares treated with a commercially available *Mycobacterium* cell-wall extract showed a quicker reduction in inflammation compared with controls.[295] A similar product containing *Propionibacterium acnes* was shown to increase pregnancy and live foal rates in barren mares treated with this product when combined with conventional management strategies.[296] Use of these agents for endometritis thus appears to warrant more consideration in the management of endometritis, especially PMIE.

Although commonly used to treat orthopedic conditions, regenerative therapies have been explored for their efficacy in the management of endometritis. Foaling mares treated with a combination intrauterine infusion of autologous plasma and antibiotics had higher pregnancy rates than control mares.[297] The purported benefit was thought to be improved opsonization of bacteria, but this treatment has not garnered wide-scale use. More recently, the use of platelet-rich plasma (PRP) was explored. Preliminary studies showed intrauterine infusion of PRP caused downregulation of inflammatory cytokines and improved pregnancy rates in susceptible mares.[298,299] Researchers at Colorado State University evaluated the use of autologous conditioned serum (ACS) and mesenchymal allogeneic stem cells (MSCs) in reproductively normal mares.[238] Mares treated with ACS 24 hours before a dead-sperm challenge had significantly lower neutrophil counts 6 and 24 hours after this challenge compared with control mares. Those treated with MSCs had significantly lower neutrophil counts 6 hours after sperm challenge relative to controls. More research and clinical studies are necessary to explore further the efficacy and indications for these treatments. Given the current costs, resources necessary, and foresight required to implement these therapies, they currently seem more of a novel or stopgap therapy in cases in which conventional therapies have repeatedly failed.

Exercise

The authors are advocates of providing breeding animals with as much exercise as possible. Farm and ranch management, climate, and overall health of the mare are factors dictating the type and amount of exercise. Farm practices in central Kentucky are such that horses are turned out in large multiacre fields with other broodmares for significant portions of the day. Turnout during inclement weather is at the discretion of the farm, but most horses are much more resilient to adverse environmental conditions than thought. Potential benefits of exercise include toning of the hindquarters to improve perineal conformation and improved uterine clearance associated with locomotion. In addition, exercise and socialization engage horses both mentally and physically. In humans, physical fitness has proven health benefits in staving off the ill effects of advancing age, which is the most significant factor affecting reproductive efficiency in broodmares.[226]

Supplements

A number of nutritional supplements are available to be fed to horses, some of which have either documented or anecdotal evidence supporting their use. Supplementation with omega-3 fatty acids (OM3FAs) has become popular, and a small body of research supports their use. Supplementing the diets of mares and stallions with OM3FAs has improved certain measures of reproductive performance. For example, mares fed a commercially available supplement containing docosahexaenoic acid (DHA)/OM3FA (Releira, Arenus, Fort Collins, CO 80524) was associated with a reduction in endometrial cytokine expression in mares bred with frozen semen as compared to control mares.[300] Supplementation with OM3FAs has also been postulated to improve follicular and luteal health to support a healthy pregnancy, but these assertions are in need of further study. With respect to stallions, those fed a DHA-enriched nutraceutical showed improved seminal quality judged by higher progressive motility after 24 and 48 hours of test cooling as well as significantly higher postthaw motility following freezing, compared with control stallions.[301] Although not yet fully evaluated, the use of OM3FAs may help decrease inflammation and improve the chance of maintaining a viable pregnancy.

Other supplements include antioxidants and hormone mimics. Antioxidant therapy may be beneficial in staving off sperm membrane damage from free radicals in the seminal plasma or uterus. Hormone-mimicking agents are purported to enhance breeding performance by improving libido, increasing sexual arousal, or removing inhibitions. Peer-reviewed and independent studies supporting the use of many of these products are lacking, so further research is necessary to determine the precise value of these products. Furthermore, caution should be exercised in using or mixing supplements because of potential adverse interactions.

FUNGAL ENDOMETRITIS

Endometritis secondary to colonization of the uterus with fungi is an uncommon (1%–5% of cases) but highly frustrating clinical condition in mares.[302,303] Fungal pathogens most commonly identified from uterine cultures are *Candida* spp. and *Aspergillus* spp. However, other organisms have been reported. For example, *Cladophialophora bantiana* was identified in one case report of a 15-year-old Standardbred mare that was subsequently euthanized because of the zoonotic potential of the pathogen.[304] Skin and feces are the most common sources of fungi, but fungal elements have also been found in the urethral fossa and penis of stallions, leading to potential (although unlikely) venereal transmission.[270,305] Factors predisposing mares to fungal endometritis include prolonged intrauterine antibiotic therapy, immunosuppressive therapy, endocrine disease, or foaling trauma.[270] The diagnosis of fungal endometritis is made based on a combination of aerobic culture and cytology, as described in a previous section. The presence of budding yeasts (Fig. 19.23) and/or branching hyphae

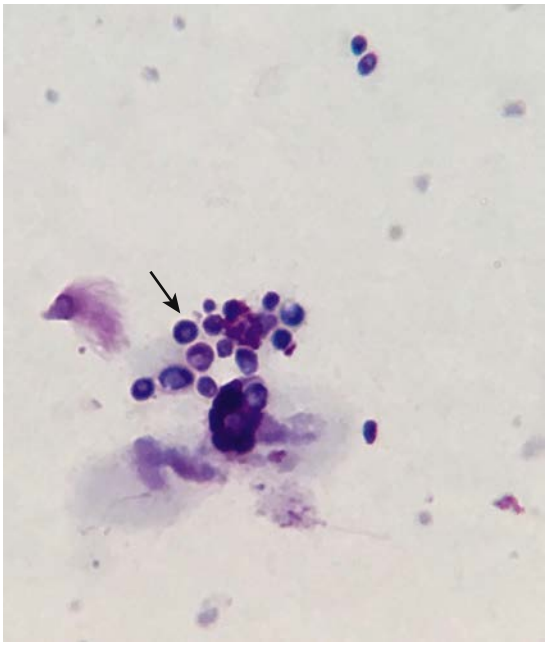

FIG. **19.23** Uterine cytology demonstrating the presence of budding yeast organisms using a modified Wright-Giemsa stain. (Courtesy C.F. Scoggin).

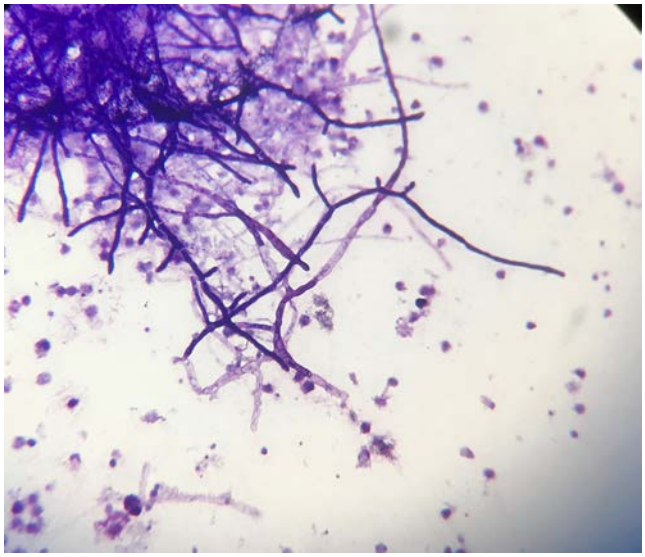

FIG. **19.24** Endometrial cytology from a mare demonstrating numerous and prolific branching fungal hyphae using a modified Wright-Giemsa stain. (Courtesy C.F. Scoggin).

(Fig. 19.24) is diagnostic for fungal endometritis. Endometrial biopsies have also been used to diagnose and/or confirm more invasive forms of fungal endometritis when cytology is inconclusive. Other methods, such as quantitative PCR, have been developed to detect and identify fungal DNA in equine endometrial samples. These can be used in conjunction with cytologic and/or histologic samples to confirm a diagnosis and further quantify the organism(s) present.[306]

Treatment for fungal endometritis has historically been based on individual case studies using empiric dosing schedules. Myriad treatments are available, but none of them appear to be particularly effective or carry a broad spectrum of activity. Various antifungal agents and their dosing regimens are provided in Table 19.9. Antifungal drugs are typically divided into two main categories: polyenes and imidazoles. Polyene antibiotics include amphotericin B, natamycin, and nystatin. The imidazole drugs include clotrimazole, ketoconazole, and miconazole.[307] Triazoles (fluconazole and itraconazole) are another group of synthetic antifungals used to treat yeast infections. Based on a retrospective study by Beltaire et al.,[308] polyenes are the best first choice for treatment of yeast infections (100% in vitro susceptibility), but care must be taken when using these antifungals because of their potential cytotoxicity. Consequently, these drugs are typically used locally as intrauterine infusions. Polyenes were also effective against most molds (69%–100%), whereas the imidazole drugs were only marginally effective (38%–46%) against molds and septated hyphae. All mold isolates were resistant to fluconazole. Reports such as these are beneficial for improving the efficiency and, potentially, the success of treatment. Moreover, although fungal endometritis is an uncommon problem, it is an area of research that could benefit from prospective studies that correlate clinical outcomes with fungal culture and treatment approach.

Another treatment for fungal infections often used in conjunction with antifungal agent(s) is uterine lavage with white wine vinegar. The acetic acid component can decrease the pH of the uterine environment, inhibiting growth of planktonic fungi. Typically used in an in-and-out fashion, regular fluids (e.g., LRS) are used for irrigation until the effluent is clear. The chitin inhibitor, lufenuron, has also been used to treat fungal infections.[309] Instillation of 540 mg of this drug diluted in 60 mL of physiologic saline has been used to resolve colonization of the uterus by both *Candida* spp. and *Aspergillus* spp. Despite these promising results, however, this treatment failed to develop steam as a viable treatment. Currently, treatment of fungal infections is deemed difficult, and resolution usually involves both a lengthy treatment schedule and tincture of time.

CONCLUSION

Endometritis is an important and ongoing issue in broodmare management. Numerous causes of endometritis have been identified, and the disease may manifest itself in many ways. No matter how innovative or novel a treatment is, it cannot replace the importance of first performing a thorough physical and reproductive examination. Careful evaluation of history, stallion fertility, perineal conformation, and reproductive organs will help identify problem areas that may need to be addressed before endometrial treatment. Goals of management include assisting with uterine drainage/clearance, addressing anatomic defects, implementing appropriate antimicrobial therapy, modulating the inflammatory response, and using other means to create a hospitable environment for sperm transport and a developing conceptus.

Hormonal Manipulation of the Mare

Carleigh E. Fedorka, Maria R. Schnobrich

This section will describe how hormonally based therapeutics are used to optimize reproductive efficiency in the mare. The background physiology and underlying targeted response or goal of each treatment will be described. The reader is referred to previous sections in this chapter for a review of the natural hormonal targets and physiology of the nonpregnant and pregnant mare.

VERNAL TRANSITION

Mares are seasonally polyestrous breeders, and during winter or shortened periods of daylight increased melatonin secretion from the pineal gland inhibits the release of GnRH. Because of this, the majority of mares experience a period of reproductive senescence when daylight is abbreviated. As day length increases in the early spring in the Northern Hemisphere, the suppression of the HPG axis is downregulated. The mare then enters the "vernal transition," which is characterized by a marked increase in FSH with low levels of luteinizing hormone (LH) and, therefore, a lack of ovulation as described previously.

Many hormonal regimens have targeted this transitional phase and are aimed at shortening the anovulatory period and hastening the onset of normal cyclicity. Increasing the exposure to light (to 14.5 hours a day, equivalent to a 100-W bulb in a stall, or "enough light to read a newspaper") beginning approximately 60 days before the start of the targeted first ovulation has proven to be the most widely used and effective means of shortening the time to the first ovulation of the season.[310] This

TABLE **19.9 Antimycotic Drugs, Doses, and Clinical Considerations for Treatment of Endometritis in the Mare**

Drugs	Systemic Dose	Intrauterine Dose	Anticipated Spectrum of Activity	Comments
Amphotericin B	0.3–0.9 mg/kg, IV, q 24–48 h	100–200 mg, q 24 h	Broad spectrum	Dilute to 1 mg/mL in 5% dextrose and administer over 1–2 h
Clotrimazole	Not reported	500–700 mg, q 24 h	Broad spectrum	—
Fluconazole	Loading dose of 14 mg/kg then 5 mg/kg, PO or IV, q 24 h	100 mg	Yeast	—
Itraconazole	5 mg/kg, PO or IV, q 12–24 h	Not reported	Yeast, *Aspergillus* spp., and dimorphic fungi	—
Ketoconazole	20 mg/kg (in 0.2 N HCl), NGT, q 12 h	Not reported	*Candida* spp.	Must be given via NGT to avoid irritation from acid
Lufenuron	Not reported	540 mg qs 60 mL with saline	*Candida* spp.	Chitin inhibitor
Miconazole	Not reported	500–700 mg, q 24 h	Broad spectrum	—
Nystatin	Not reported	0.5–2.5 million units, q 24 h	Yeast	Dilute in sterile water to avoid precipitation

HCl, Hydrochloric acid; *IV,* intravenous; *NGT,* nasogastric tube; *PO,* orally; *qs,* as much as needed.

is achieved through the use of outdoor paddock lighting, the stabling of horses for increased periods under lights, or the addition of lighted masks.[311] Along with the use of lights to effect the photoperiod, hormonal manipulations are often used in conjunction to hasten the onset of normal cyclicity.

Dopamine is secreted in synapses between dopaminergic neurons in the median eminence of the hypothalamus and hypothalamic GnRH neurons. Research has shown that inhibition of dopamine (D2 dopamine receptors) increases LH secretion, although the exact mechanism is unclear. It is believed to act by removing the inhibition on PRL secretion and possibly through the reduction on the negative feedback of estradiol on GnRH.[312] Many dopamine antagonists including sulpiride, domperidone, and perphenazine have been tested, but inconsistencies in dosage, treatment onset, and duration of studies have caused high variability in the outcomes of these studies, making comparisons difficult.

Domperidone significantly hastens the time to first ovulation (51 days vs. 129 days for controls).[313] When begun on January 15, and without the addition of a lighting program, treatment with domperidone results in increased LH, estradiol, and PRL concentrations, and six of eight treated mares resumed normal cyclicity after treatment. Perphenazine, another dopamine antagonist, is also able to shorten the anovulatory period by approximately 30 days when administered at a dosage of 0.08 mg/kg daily when used without the addition of a lighting program.[314]

Sulpiride is another commonly used dopamine antagonist. In a study by Mari et al. its effectiveness was compared with that of domperidone.[315] Mares were treated with 1 mg/kg sulpiride (Championyl), 1 mg/kg domperidone (Motilium), or a control daily for 25 days without the addition of a lighting program. Sulpiride significantly decreases the length of time to the first ovulation (36.9 days) compared with both domperidone (74.7 days) and control (81.4 days), and it hastens the establishment of pregnancy by an average of 20 days.[315] In a second study, mares were treated with sulpiride once the presence of a 25-mm follicle was noted. Daily treatment of 1 mg/kg sulpiride results in a hastened follicular development.[316]

Another strategy for manipulating the vernal transition is through the supplemental use of progestogens, in particular altrenogest. The mechanism of action is believed to be caused by negative feedback on the hypothalamic-pituitary axis, which when removed, results in an increase in LH. Daily administration of 27 mg of altrenogest (Regu-Mate) when a 20-mm follicle is present significantly decreases the length of time to ovulation compared with controls.[317]

Additionally, first ovulation can be hastened by use of GnRH analogs. Equine follicle-stimulating hormone (eFSH) at a dose of 12.5 mg IM (Bioniche) twice daily has been shown to hasten the time to first ovulation when administered to transitional mares once the presence of a 25-mm follicle is noted.[318] In addition, recombinant eFSH (reFSH) has been developed, and when it is administered at a dosage of 0.65 mg twice daily, it is able to stimulate follicular development in anestrous mares under lights. Unfortunately, these mares did return to anestrus after treatment and ovulated naturally at a similar time as control mares.[319] It can be difficult to reliably obtain eFSH; therefore this protocol, while effective, is not frequently used. Another protocol using a GnRH agonist consists of administration of 25 μg of buserelin twice daily (SQ) once the mare has developed a 20-mm follicle until ovulation occurs.[320] Ovulation induction is achieved in most GnRH analog protocols with the administration of human chorionic gonadotropin (hCG) at varying dosages of 1500 to 3000 IU, either IV or IM, once a follicle has reached the size of 35 mm or greater.[321]

SYNCHRONIZING THE ESTROUS CYCLE

To optimize breeding efficiency, the ability to predict estrus and ovulation becomes an important tool to successful reproductive management. Although mares show variability in their response to hormonal treatment, the concept of fixed-timed insemination, or "appointment breeding," has been successful in equine reproduction. Common reasons for estrous

synchronization include synchronization of a group of mares (e.g., in an embryo transfer program), manipulation of ovulation timing to best fit a popular stallion, limited show schedule for breeding, and strategic management of insemination with shipped or frozen semen.

To manipulate the estrous cycle of the mare with some precision, one must understand the basic endocrine events of the normal 21- to 22-day cycle of the mare as previously reviewed.[4] The day of ovulation is considered to be day 0 and is preceded by a period of estrus of variable length (5–7 days).

Most hormone regimens used to synchronize estrus are aimed at manipulating and shortening the luteal phase (diestrus) of the cycle. Perhaps the simplest method of synchronizing the cycle of a mare is through the use of synthetic preparations of $PGF_{2\alpha}$, which effectively and reliably shorten diestrus through inducing luteolysis and removal of the source of progesterone production. There was previously a belief that one had to wait until day 5 post ovulation to reliably induce luteolysis with a single dose of $PGF_{2\alpha}$.[322,323] Research has demonstrated that repeated doses of $PGF_{2\alpha}$ administered after ovulation prevented CL formation, and breeding on the subsequent estrus was not associated with a decrease in pregnancy rates.[324] The size of the follicle at the time of prostaglandin administration often dictates the duration to ovulation, with larger follicles ovulating sooner.

It is critical to evaluate the follicles present at the time of $PGF_{2\alpha}$ administration for two reasons: (1) to note if the mare has a large follicle, and therefore reexamination and breeding can be scheduled appropriately, and (2) because inducing estrus and breeding on a large diestral follicle is not optimal and waiting until the follicle regresses may be more ideal. Mares that were administered prostaglandin when follicles were larger than 30 mm had an approximately 20% lower per cycle pregnancy rate than mares bred on a natural estrus.[325] It has also been demonstrated that treatment of mares with a $PGF_{2\alpha}$ analog on day 0 (ovulation) or day 1 has a negative effect on the developing CL. Not only are the size and echogenicity of the CL reduced, but also a transient and significant suppression in progesterone levels occurs. Most important, pregnancy rates may be lower in treated mares.[326-328] Treatment with $PGF2_{\alpha}$ analogs increases the risk of AHFs, and this risk should be taken into consideration, most critically in mares that may be predisposed to developing AHF.[329]

A number of $PGF_{2\alpha}$ preparations have been used successfully for luteolysis in the mare. Side effects associated with $PGF_{2\alpha}$ administration include sweating, anxiety, diarrhea, and signs of colic. The severity of the side effects depends on the dose and preparation of $PGF_{2\alpha}$. A two-dose regimen at a much lower dose (0.5 mg $PGF_{2\alpha}$) is equally effective in inducing luteolysis as a higher single dose (50 mg $PGF_{2\alpha}$) but devoid of adverse effects.[330] Similarly, a single dose of 25-µg cloprostenol (Estrumate; Bayer Corp., Shawnee, KS), that is one tenth of the previously recommended dose, is effective in inducing luteolysis and does not cause adverse side effects.[331] Generally most practitioners use 10 mg of dinoprost (Lutalyse) or 250 µg of cloprostenol 5 days post ovulation. Cloprostenol is associated with fewer side effects and has also been shown to be as effective at inducing luteolysis as dinoprost, although cost may factor into the decision of which drug is used.

Treatment with progestogens with or without estrogens represents one of the oldest and most reliable means of synchronizing estrus in the mare, especially when coupled with appropriate light exposure and $PGF_{2\alpha}$ administration. Exogenous administration of progesterone simulates the diestrus period of the estrous cycle. Repositol progesterone, progesterone in oil (Sigma Chemical Co., St. Louis, MO), or oral progestin compounds (altrenogest [Regu-Mate], Intervet Inc., Millsboro, DE) are effective in suppressing estrus but not necessarily effective for inhibiting follicular development or ovulation.

When synchronizing mares, one protocol that is used commonly is to administer progesterone for a minimum of 10 days in cycling mares and 14 days in transitional mares. On the last day of progesterone treatment, a $PGF_{2\alpha}$ injection is administered to induce luteolysis of any remaining CL. As in treatment with prostaglandins alone, the mare should be evaluated at the time of prostaglandin administration because follicle growth may still occur with progestogen administration. Scheduling for breeding and predicting ovulation can be made based on the follicle size at the time of induced luteolysis. Generally it is believed that most mares come into heat 3 to 5 days after the last treatment of progesterone and ovulate an average of 7 days after treatment, but this depends on the size of the follicles present on the ovary at the time of luteolysis.

Addition of estradiol to a synchronization protocol inhibits follicular growth and allows better synchrony of ovarian structures at the time of luteolysis. Often referred to as "P and E" or "programming," this is done by administering daily injections (IM) of 10 mg of estradiol-17β and 150 mg of progesterone once the presence of a 20-mm follicle is noted. On the tenth day, the mare is administered $PGF_{2\alpha}$ and is evaluated at this time with transrectal ultrasound. Breeding is recommended once a dominant follicle is greater than 35 mm, and this tends to coincide with day 19 from the start of treatment. This protocol is considered superior by some because the addition of estradiol inhibits follicular activity; thus, at the time of prostaglandin administration all mares on this protocol should have minimal follicular activity and ovulate in a similar time period.

The oral progestogen preparation altrenogest is perhaps still the most popular progestin compound for use in mares. Altrenogest is easy to administer, not painful, and has few adverse effects. Although most commonly used for estrus suppression, it does not inhibit follicular development; therefore, it is rarely used when attempting to synchronize a mare's follicular growth. Injectable preparations of repositol altrenogest may be effective in suppressing estrus from a behavior standpoint, but they have not been thoroughly investigated for their ability to effectively synchronize follicular growth and ovulation.

For several reasons, all progestogen preparations should be used with caution in mares that are susceptible to delayed uterine clearance or uterine infections. Progesterone increases the tone of the cervix, and its use may inhibit the physical clearance of fluid. Progesterone has also been associated with lower immunoglobulin levels (especially IgG) in the uterus.[332] Thus the combination of adverse effects of most progestogens can lead to delayed uterine clearance, endometritis, pyometra, and other undesirable reproductive conditions.

SUPPRESSION OF ESTRUS

Although most hormonal regimens act to hasten the interval to estrus and ovulation, there are commonly requested behavioral and managerial reasons to suppress estrus. Altrenogest was designed to prevent show mares from exhibiting unwanted

estrus during performance, and it has proved to be effective in this regard, suppressing signs of estrus in 95% of mares that were given a daily dose of 0.044 mg/kg for 3 days. In an attempt to find a more economic and less time-consuming means of suppressing estrus in mares, progestin-estradiol implants (Synovex; Syntex Animal Health, Des Moines, IA) licensed for food animals have been investigated in mares. Although some mare owners report an improvement in the behavior of the mare, scientific reports have been less supportive of their use. McCue et al. found that mares treated with these implants did not show suppression of estrous behavior and cyclicity, even at 20 times the usual dose.[333] Vanderwall et al. have examined the effect of oxytocin administration during diestrus on prolonging time to luteolysis.[334] Mares that received oxytocin (60 IU twice daily IM) on days 7 through 14 after ovulation demonstrated prolonged luteal function up to 30 days after ovulation, suggesting that oxytocin administration may offer a means of long-term suppression of estrus. Medroxyprogesterone has also been suggested anecdotally to suppress estrus, but this has not been substantiated by any research. It was found to have no suppressive effects on follicular activity, although anecdotally many trainers claim benefits.[335]

Immunization against GnRH is another effective means of suppression of follicular development in the mare. When considering this treatment, it should be noted that a subset of mares may show estrus or sexual receptivity despite the absence of follicular activity. Mares vaccinated twice, 4 weeks apart, with a GnRH vaccine (Equity; Pfizer Animal Health, Sydney, Australia) did not return to follicular estrus during that breeding season but returned to cyclicity the next year. Foaling rates were not significantly different from control mares.[336] The vaccine is not commercially available worldwide, and there are reports of long-term infertility following vaccination.[337] Another form of immunization as a means for inhibiting fertile estrus is through immunocontraception. Joone et al. demonstrated that vaccinating pony mares with porcine zone pellucida (pZP) causes an extended anestrus in 86% (six out of seven) of mares and inhibited pregnancy in all vaccinated animals.[338] In addition to its suppression of follicular development, it was determined that this treatment was reversible, because all mares returned to normal cyclicity within 10 months post treatment. Unfortunately, the pZP vaccine is not available commercially, and these results should be critically reviewed due to small study size.

Another option for suppression of estrus is the BioRelease formulated progesterone or altrenogest (BET Pharm, Lexington, KY). These injectable drugs have been effective for estrus suppression using either a vehicle with a delayed release of hormone or microparticle formulation (used in absorbable sutures). A study by Storer et al. showed that altrenogest suspended in either the sustained-release vehicle at a dosage of 225 mg or 500 mg altrenogest suspended in the lactide-glycolide microparticle significantly increases the interovulatory interval (3.9 days from Lutalyse to ovulation compared with 33.5 days when the microparticle formulation was administered).[339]

Theoretically, if the LH surge has not yet occurred, then oral progestogen treatment should inhibit LH release and delay ovulation. Altrenogest at label dose or double the label dose is effective in delaying ovulation compared with control mares if an ovulation induction agent has not been administered.[340] Intraluminal fluid retention, possibly caused by decreased uterine contractility, has been observed in some treated mares.

Delaying the interval to first ovulation of postfoaling mares results in higher pregnancy rates for the first heat cycle. Although some breed on this "foal heat," it has been consistently demonstrated that delaying breeding until the second estrus, or "30-day heat," post foaling is associated with higher pregnancy rates and decreased pregnancy loss.[39] Breeding on foal heat or before 10 days post foaling is associated with an increase in pregnancy loss, which is likely because of a more hostile uterine environment, though this may be breed dependent.[39,341,342] To optimize the maintenance of those early pregnancies yet still increase the reproductive efficiency of the mare by breeding her back as soon as possible, delay of the first postpartum interval to ovulation has been attempted. Due to some of the adverse effects of progestogen administration this can be accomplished by delaying administration of an ovulation-inducing agent. The combination of 150 mg of progesterone and 10 mg of estradiol-17β (E2-17β; Sigma) has been suggested to prolong ovulation until at least day 10 post foaling.[343] Most experienced practitioners will evaluate the mare critically post foaling to determine whether a foal heat breeding is appropriate (additional time needed for involution, breed practice, availability of stud, pregnancy to carry, or embryo transfer), and this protocol is rarely used.

INDUCING OVULATION

Induction of ovulation is useful for assuring timely ovulation relative to insemination, to synchronize mares, and to shorten estrus length. Limitations of semen availability and longevity include stallions that are available only one day for live cover, semen being limited to a strict shipment schedule for cooled shipped semen, and the small time window of semen viability when using a single dose of frozen semen. A number of ovulation-inducing agents have been investigated and are used in practice. The most effective agents possess LH activity with varying degrees of FSH activity. The hCG (Chorulon; Intervet, Millsboro, DE), with its potent LH-like activity, is currently the least expensive and perhaps the most popular agent used for the induction of ovulation. Given IM, IV, or subcutaneously, hCG reliably induces ovulation within 48 hours in mares with a 35-mm or larger follicle, and it is effective at doses ranging between 1000 and 5000 IU.

Use of hCG in the mare has some limitations. First, with its repeated use, antibody development may occur.[344,345] Second, mare owners often complain about the apparent pain associated with administration of some hCG products, although this is a rare occurrence. Finally, the reliability of hCG in its ability to hasten the interval to ovulation, especially in the older or compromised mare, has been questioned. Regardless of its potential disadvantages, hCG remains a popular, inexpensive, and effective means of inducing ovulation in most mares.

Synthetic GnRH analogs also have proven to be effective in inducing ovulation because they cause endogenous release of LH, prompting ovulation.[346] Examples of synthetic GnRH analogs are deslorelin acetate (Ovuplant; Fort Dodge, Canada), buserelin (Intervet; Millsboro, DE), and Cystorelin (BET Pharm, Lexington, KY).[327-348] The use of Ovuplant, when left in place, has been associated with delayed return to estrus and in some cases may inhibit follicular activity for prolonged periods (anecdotally up to 3 months), but removal of the implant a few days after insertion can ameliorate this delay. Injectable deslorelin is available through compounding companies in the United States. One option that is approved in the United States

by the Food and Drug Administration is the injectable SucroMate, which contains 1.8 mg/mL deslorelin acetate. SucroMate has been shown to effectively induce ovulation within 48 hours when 1 mL is injected IM once the mare has developed a follicle larger than 30 mm. In a large clinical study done by Ferris et al., a higher number of mares ovulated when treated with SucroMate compared with hCG, and there was no difference in the interval of time between injection and ovulation for either treatment.[349] The general impression of practitioners is that the GnRH analogs are more reliable in inducing ovulation, especially in mares that are prone to ovulation failure (e.g., older mares, mares in vernal transition, mares concomitantly treated with prostaglandin-inhibiting agents such as many antiinflammatory drugs).

Ovulation-induction agents are reliable and effective only if given at the appropriate time during estrus. If endometrial edema and a large dominant softening follicle (>35 mm in diameter) are present, then hCG, deslorelin acetate, and buserelin are expected to induce ovulation in an average of 36, 41 to 48 hours,[344] and 24 to 48[348] hours, respectively, after administration. Samper reported that 98% of mares with maximal endometrial edema given hCG or deslorelin consistently ovulated within 48 hours of administration.[350] Most remarkably, most mares to which Ovuplant had been administered at the proper time ovulate 36 to 40 hours later, facilitating timely ovulation relative to a scheduled breeding.[351]

SUPEROVULATION

In an effort to increase the number of offspring produced in the lifetime of an animal or in any given season, researchers have investigated numerous means of superovulating to enhance the number of oocytes available for fertilization. Overall, attempts at reliable superovulation in mares have not been as successful as those in the food animal industry, and increasing the number of ovulations and the gain regarding embryos recovered have been minimal. Unlike the swine and bovine models, the administration of porcine FSH preparations is ineffective in mares.[352] Stimulation of endogenous FSH secretion by indirect and direct immunization against inhibin has not resulted in a superovulatory response in mares.[353] The administration of equine pituitary extract preparations in research trials increases the number of embryos recovered from 0.5 per cycle to 2.2 per cycle but with high variability among mares.[354,355]

Promising results have been achieved with the use of eFSH (Box 19.1). Treatment of cycling mares with eFSH in early diestrus (12.5 mg, administered twice daily) increased the pregnancy rate compared with untreated control mares (1.8 vs. 0.6, respectively).[356] In another study, in which Welsh et al. incorporated a "coast" period into the previously described experimental design, the ovulation and embryo recovery rate were 3.8 ± 1.2 ovulations and 1.7 ± 1.4 embryos, respectively.[357]

Because of the inability to obtain eFSH on the commercial market, investigators began examining recombinant proteins. The combination of recombinant LH (reLH) and reFSH proved efficient at stimulating numerous ovulations.[358] Although the protocol is intensive, it appears to be the most efficient in stimulating numerous ovulations. Treatment commences when a 22- to 25-mm follicle is noted, with IM injections occurring twice daily (1.3 mg reLH/0.65 mg reFSH). Luteal regression is stimulated by $PGF2_{\alpha}$ administration on the second day of reFSH treatment. Three days after the onset of treatment, reFSH dosage was reduced to once daily injections until a follicle of greater than 29 mm was present. This was followed by 1.3 mg reLH being administered three times daily until the majority of the follicles reached 35 to 38 mm, at which time hCG was administered to induce ovulation. Compared with only reFSH treatment, this dual treatment of reFSH/reLH significantly increased the number of ovulations and number of embryos retrieved but did not increase the number of anovulatory follicles observed.[358] The incidence of anovulatory follicles has been a concern in the majority of other superovulation protocols. Unfortunately, neither of the recombinant proteins is available commercially.

BOX 19.1 Recommended Protocol for Superovulation in Mares Using Equine Follicle-Stimulating Hormone

1. Determine the day of ovulation.
2. Monitor follicular development in early diestrus.
3. Begin eFSH therapy (12.5 mg IM twice daily) when the largest follicle is 22 to 25 mm in diameter.
4. Administer cloprostenol (259 μg IM) on the second day of eFSH therapy.
5. Discontinue eFSH treatment when follicle(s) are greater than 32 to 35 mm in diameter.
6. Administer hCG (2500 IU) to induce ovulation.
7. Breed or inseminate according to standard procedure.

eFSH, Equine follicle-stimulating hormone; *hCG,* human chorionic gonadotropin; *IM,* intramuscular.

CERVICAL DILATION

One of the more challenging conditions encountered when breeding mares is failure of the cervix to relax during estrus. Although not objectively studied, this condition is more common in older maiden mares and certain breeds. However, even normal maiden mares may not have the same degree of cervical relaxation during estrus that is typical of multiparous mares. This condition is also seen in mares with cervical trauma, adhesions, and fibrosis, which prevent normal relaxation. On transrectal palpation, the cervix may feel toned instead of soft in estrus, and transrectal ultrasound of the cervix may show increased echogenicity of the cervix, which can be evidence of fibrosis. Often it is not clear until the periovulatory period that this pathology exists, and it frequently results in fluid accumulation and increased incidence of PMIE.

Although this condition does not prevent breeding, it can prevent dilation of the cervix by the penis of the stallion in natural cover and the normal evacuation of fluid in the hours after breeding, setting the stage for delayed uterine clearance and persistent endometritis. A synthetic PGE_1 analog, misoprostol (Cytotec; Searle Corp., Chicago, IL), has been used successfully in women for cervical dilation. For years, clinicians have used this therapeutic to stimulate cervical relaxation in the horse and gotten promising results, but a controlled study by McNaughten et al. demonstrated that the application of misoprostol directly to the external cervical os had no effect on the tone, length, height, or degree of relaxation.[359] This treatment is still being used clinically, both to stimulate

cervical relaxation for breeding and during the induction of parturition, with successful anecdotal results. In addition, *N*-butylscopolammonium bromide combined with sterile gel and applied to the cervix has anecdotally resulted in cervical relaxation. In addition to relaxing the cervix around the time of breeding, these agents have also been used to soften the cervices of pregnant mares in preparation for induced parturition at various stages and may help prevent cervical trauma.[360]

OVIDUCTAL CONTRACTION

The early embryo secretes PGE_2, which is believed to play a role in the contractility of smooth muscle of the oviduct and allow selective transport of the embryo into the uterine lumen.[8] PGE_2 is also secreted during the high-mobility phase of the embryo within the uterus and is suspected to stimulate uterine contraction and enhance uterine tone.[361] Laparoscopic application of PGE_2 along the serosal surface of the oviduct can modify embryo transport. Interestingly, not only is embryo transport hastened, but also the unfertilized oocytes that are rarely recovered in the mare are released. Laparoscopic-guided PGE_2 application on the mare's oviduct has been reported to assist in clearing oviductal debris and improve the fertility in a small subset of mares suspected of having oviductal pathology.[362]

UTERINE CONTRACTILITY

One of the most common hormones used to induce uterine contractility is oxytocin. Naturally produced by the hypothalamus and stored in the posterior pituitary, it induces uterine contractions after sexual intercourse and during labor, aids in involution of the uterus, and promotes social bonding. Synthetic oxytocin increases intrauterine pressure in a dose-dependent manner from 2.5 to 10 IU in reproductively normal mares and mares suffering from delayed uterine clearance.[194] This is affected by the day of the cycle in which oxytocin is administered, with the periovulatory phase being more influenced by exogenous oxytocin than the postovulation phase.[280] This appears to be affected by season, because anestrous mares that have been primed with progesterone show minimal contractile response when oxytocin is administered, although uterine tone increases. Clinically, oxytocin is used to facilitate uterine clearance in mares suspected of experiencing abnormal fluid accumulation. When administered at a dosage of 10 to 20 IU IM two to four times daily in the periovulatory period, it is shown to be effective in promoting uterine clearance. It is recommended that exogenous oxytocin not be administered before 4 hours after breeding—and not immediately before breeding—to avoid any negative effect it may have on sperm transport to the oviduct.

The combination of PGE_2 and oxytocin is also used to induce parturition in the late-gestation mare. Mares pretreated with 2.0 mg of intracervical PGE_2 6 hours before IV administration of 15 IU oxytocin have increased cervical diameter, a decreased necessity for repeated oxytocin injections, and a hastened time to parturition compared with mares lacking PGE_2.[360] Mares pretreated with PGE_2 before oxytocin injection also produce foals that stand and nurse more swiftly than mares that are induced solely by oxytocin. Clinically, the addition of PGE_2 to the protocol has shown anecdotal evidence of hastening parturition as well as reducing the necessary dosage of oxytocin required to stimulate parturition.[363]

Prostaglandins have also been shown to induce uterine contractions, and the administration of the synthetic $PGF_{2\alpha}$ analog cloprostenol at a dosage of 250 µg has been shown to be effective at inducing more coordinated, longer effects than oxytocin (>6 hours compared with 20 minutes, respectively). The use of cloprostenol was also shown to be more effective at improving uterine clearance in a subset of mares.[282]

HORMONAL SUPPORT OF PREGNANCY

The equine pregnancy differs from other species in that progesterone is almost undetectable in the serum of pregnant mares in the latter half of pregnancy. Instead, in the second and third trimesters, the fetal-placental unit produces high concentrations of metabolites of progesterone, deemed progestogens, which inhibit uterine contractions and maintain cervical closure, promoting the optimum uterine environment for pregnancy. Despite conflicting evidence regarding the benefits of progestogen supplementation, progestogen supplementation throughout gestation is common. Recent studies have further elucidated the hormonal regulation of pregnancy and the proper supplementation protocols and should be reviewed by practitioners and breeders alike. This will also be discussed in more detail in the following sections describing management of the pregnant mare.

In the horse, the initial source of hormonal support for pregnancy is the progesterone derived from luteal cells of the primary CL. Progesterone secretion is sustained for nearly 30 days post ovulation because of the poorly understood mechanism of maternal recognition of pregnancy and subsequent suppression of luteolysis. A secondary surge of progesterone occurs roughly 35 days into gestation in response to the formation of endometrial cups, which actively synthesize eCG. Because of its dual LH and FSH functionality, it stimulates follicular growth and development in addition to ovulation and/or luteinization.[364] It is because of this dual functionality that accessory CLs are able to form and continue the luteal synthesis and secretion of progesterone. This increase in progesterone lasts until approximately 120 days of gestation, when the endometrial cups are destroyed by an endometrial lymphocytic immune response.

At approximately 120 days of gestation, the steroidal regulation of pregnancy transfers from ovarian to fetoplacental. At this time, uterine quiescence is thought to be maintained by metabolites of progesterone and pregnenolone, commonly referred to as the progestogens, and specifically 5α-pregnane-3,20-dione (5α-DHP) and 20α-hydroxy-5α-pregnane-3-one (20α-5P).[365-368] This hormonal support of pregnancy is made possible through synchrony of the fetal gonads, fetal adrenals, and the placenta functioning as complementary endocrine organs. Although these progestogens increase in concentration in maternal serum later in gestation, progesterone rapidly declines and remains at basal concentrations until the abrupt rise immediately before parturition.

In addition, the fetoplacental unit produces large quantities of dehydroepiandrosterone (DHEA) in late gestation, which rapidly are aromatized within the placenta into estrogens. In addition to estrone sulfate and estradiol, the equine-unique estrogens equilin and equilenin are also produced in high concentrations throughout late gestation.[368] Total estrogen concentrations rapidly rise starting at approximately 100 days'

gestation into thousands of nanograms per milliliters, peak roughly 2 weeks before parturition, and then promptly decline. Estrone sulfate has been used as a marker of fetal well-being in early pregnancy, because it represents the effective process of a conversion of the fetal gonadal production of estrogen.[155] Fetal estrogens are enzymatically converted to soluble estrone sulfate by the placenta. When estrone sulfate declines, it suggests that this conversion process has been disrupted, either from fetal demise or placental dysfunction.[155] Some have argued that estrogen supplementation in mares with low total estrogens during gestation may help, and there is a growing body of knowledge suggesting beneficial effects.[369] In contrast to other species, the horse has a rapid decline in total estrogen concentration before parturition, the exact reasoning for which has not been clearly determined. Esteller-Vico et al. did a study in which Letrozole, a potent aromatase inhibitor, was used to significantly suppress estrone sulfate in circulation in late-gestation mares.[369] Although estrone sulfate concentrations were suppressed to basal levels, gestational length was not affected, further indicating the lack of sufficient data and indicating the necessity for further work exploring estrogen supplementation in late gestation.

Poor uterine tone, the presence of abnormal uterine edema, low serum progesterone, and a small-for-age embryo are all indicators of a compromised pregnancy, which often lead to hormonal supplementation. Unfortunately, none of these conditions is well characterized, and their diagnosis and interpretation vary considerably among practitioners. In addition, low serum progesterone concentrations have been shown to correlate poorly with early embryonic loss.[370] Still, many practitioners supplement with progestogens throughout pregnancy. The two most common types of exogenous progestogens are oral altrenogest (Regu-Mate) or daily IM injections of progesterone in oil. In a study done by McKinnon et al., five different synthetic progestogens were evaluated for maintenance of pregnancy.[371] Only altrenogest, administered at the recommended dosage of 0.044 mg/kg daily, provided sufficient support for maintenance of pregnancy after luteolysis was induced using $PGF_{2\alpha}$. In addition to Regu-Mate, a long-acting progesterone formulation is currently available on the market (BioRelease P4 LA 150) that has been shown to be effective when administered once every 7 days (BioPharm). In addition, BioRelease also produces sufficient levels of progesterone for pregnancy maintenance in the absence of luteal tissue.[372] Although both provide adequate embryonic support in the absence of luteal functionality, the BioRelease formulation is less labor intensive, requiring weekly injections instead of daily.

Although it has been well documented that progesterone concentrations in serum are negligible in late gestation, supplemental progestogens are routinely administered. In cases of suspected placentitis, placental separation, placental insufficiency, inflammatory conditions, and supplemental progestogens are used to promote uterine quiescence and for their antiinflammatory properties. Altrenogest is recommended for the treatment of placentitis in addition to antimicrobials and antiinflammatories, which when combined significantly decrease the risk of abortion caused by experimentally induced placentitis.[373] Routine supplementation with altrenogest in late gestation is associated with clitoral enlargement in female offspring and an increase in serum LH in prepubertal fillies produced by mares that underwent treatment.[374] Foals born to mares that have received altrenogest in late gestation have been found to be immunocompromised, with a lower neutrophil/lymphocyte ratio than normal foals.[375] Although this may be caused by dysmaturity at birth, these results were contradicted by a second study, which found that supplemental altrenogest in late gestation has no antiinflammatory effects on the endometrium of mares post parturition.[376] A more comprehensive discussion of this topic will be covered in a later section.

INDUCTION OF LACTATION IN THE BARREN MARE

When the foal's dam has died, cannot lactate appropriately, or a suitable nurse mare or foster dam is unavailable, lactation-induction protocols are used to provide a lactating mare for the foal. Lactation can be induced in the barren mare, which can alleviate the need for producing an orphan foal from a nurse mare. Chavatte-Palmer et al. demonstrated that a hormonal manipulation of the mare, beginning at any time in her cycle, could induce lactation within days of treatment.[377] This protocol involves placement of an intravaginal sponge containing 500 mg altrenogest and 50 mg estradiol benzoate, and it has proved effective. A week after the onset of treatment, a second sponge is placed, containing 100 mg estradiol benzoate in addition to 50 mg/100 kg body weight sulpiride. In a second study, domperidone (1.1 mg/kg) was evaluated in replacement of sulpiride. Both treatments induce lactation within 7 to 12 days after the beginning of treatment, including the production of colostrum.

A second study found that routine IM injections of sulpiride (twice a day at a dose of 0.5 mg/kg) beginning during diestrus and continuing for 9 to 14 days effectively induced lactation.[378] Large mare-to-mare variability was seen when considering daily milk output. It has been noted that mares were only responsive to sulpiride when the ovaries were functionally performing steroidogenesis and producing estrogen and progesterone. Neither anestrous nor ovariectomized mares responded to treatment. Clinically, induction of lactation is assisted by daily milking and repeated oxytocin injections.

A follow-up study done by Korosue et al. demonstrated that foal size is not affected by the use of a lactationally induced surrogate mare.[379] Hormonal stimulation of lactation had no effect on subsequent reproductive performance, indicating that these foster mares may still achieve pregnancy.

Breeding Management to Optimize Pregnancy Rates

E. Bradecamp

There are several components of breeding management that can be manipulated and controlled in an attempt to optimize pregnancy rates. Fertility can be measured by per cycle pregnancy rate, which is the number of estrous cycles required to establish a pregnancy. The more concise the breeding management is, the more likely pregnancy rates will be maximized and the more efficient, both economically and timely, the breeding program will be.

It is imperative to recognize that breeding management can be divided into two categories, the mare factors and the

stallion factors. Additionally the human factor—the management of the mare and stallion that is directly affected by human decisions—cannot be overlooked as an important element in the success of a breeding program. Regardless of how fertile a mare or stallion may be, human factors that result in less than optimal management may yield decreased pregnancy rates.

STALLION MANAGEMENT TO OPTIMIZE PREGNANCY RATES

The gold standard for the measurement of stallion fertility is per cycle pregnancy rate. Semen analysis can provide a plethora of information and values regarding the quality of spermatozoa in an ejaculate. While a single in vitro test cannot reliably predict fertility, ejaculates with higher percentages of morphologically normal, progressively motile sperm yield higher pregnancy rates than ejaculates that exhibit poorer quality morphology and motility. Second, even if a stallion has excellent fertility, poor management of that stallion can result in poor pregnancy rates; therefore proper management is essential to optimize fertility. Depending on the breeding program and the method by which the mares are bred (live cover or AI with fresh, cooled shipped semen or frozen semen), there are important conditions that must be met to maximize pregnancy rates.

OPTIMIZING PREGNANCY RATES WITH FIELD BREEDING

Although less reported in scientific research and literature, field breeding remains the primary method of breeding for many stud farm operations around the world. In North America, many large ranches and pregnant mare urine (PMU) farms (farms that establish pregnancy in mares to recover estrogens from urine for commercial use) continue to rely on pasture breeding to achieve pregnancy or "settle" mares. It is important to realize that even with the many management techniques used in programs that utilize hand breeding or AI, higher pregnancy rates are not guaranteed and often are not achieved above those yielded by pasture breeding. At the same time, pasture breeding does have its limitations; mature stallions are often restricted to 20 to 35 mares with which they can breed live cover in a pasture setting. Placing a stallion with a herd of mares that is too large may have a negative effect on his ability to achieve optimal pregnancy rates, and it may be detrimental to the stallion's health. In breeding programs in which stallions are booked to greater than 100 mares per season, other methods of breeding must be used to optimize pregnancy rates.

When using field breeding, it is ideal to have a closed herd of mares that has had time to establish its order of dominance before introducing the stallion. The stallions are typically left with the mares for a period of time that allows every mare to pass through two consecutive heat cycles (45–60 days). The stallion is then removed from the herd, and pregnancy examinations are performed 21 or more days later. If a mare is bred on the day that the stallion is removed and does not ovulate for several days, this allows for every mare to be a minimum of 14 days pregnant at the time the pregnancy examinations are performed.

Ideally, once the herd is established and the stallion has been added, more mares should not be added to the herd because a new hierarchy will need to be established, and the stallion may not accept the new mare, even if she is in estrus. Injuries are more likely to occur when new horses are added to the herd. If a new mare must be added, then the stallion should be removed for a couple of days to allow the mares to reestablish their hierarchy, and then the stallion can be added back in the herd. If the mare is an outside mare (not native to the farm), then it is imperative that she has been appropriately quarantined before being added to the herd to prevent disease transmission that would negatively affect the herd health and fertility.

Pastures need to be maintained with safe fencing and ideally without direct contact with other horses across fence lines. The fields need to be large enough to allow horses to get away from more aggressive pasture mates. All horses should be unshod and have their feet trimmed to minimize injuries and lameness.

BSEs should be performed on both the mares and the stallion before the beginning of the breeding season to identify any need for treatment or management changes. An entire breeding season can be lost when mares that have been housed with a stallion for 45 to 60 days are not checked for pregnancy until several weeks after the stallion has been removed, and then reproductive pathology is discovered.

Several factors aid in maximization of pregnancy rates when using field breeding, including:

- For fertile stallions, a BSE should be performed before the breeding season, and ideally the stallion has a history of successful field breeding.
- Each fertile mare should have a BSE performed before the breeding season.
- Do not overextend a stallion and house him with more mares than he can breed successfully. A young, inexperienced stallion may not be able to breed as many mares as an older, more mature stallion.
- Maintain a closed herd to reduce the possibility of stress and introduction of diseases that could negatively impact pregnancy rates.
- Maintain good herd health practices, such as vaccination, deworming, hoof care, dental treatments, and an adequate plan of nutrition. These should all be addressed, in place, and up-to-date before the breeding window to minimize stress during this period.

OPTIMIZING PREGNANCY RATES WITH LIVE COVER IN HAND BREEDING

Many small stud farms rely on breeding mares live cover, and all Thoroughbreds bred to be registered with the Jockey Club are required to be bred live cover. The key factors affecting pregnancy rates in live-cover situations are ensuring that the stallion's book size is appropriate, based on the stallion's history and daily sperm production, and that the mares bred are suitable for mating and ovulate in a timely manner after breeding. Ovulation should occur within 48 hours of breeding or the mare should be bred again. Ideally the mare should be administered an ovulation-inducing agent to ensure ovulation occurs within 24 hours following breeding.

A more thorough discussion of how to calculate an appropriate book size based on the stallion's testes size and seminal parameters can be found in later sections. Briefly, Love et al.

described how to estimate a stallion's book size based on testes size and predicted or known daily sperm output (DSO).[380] If a stallion is booked to more mares than is appropriate for his DSO, then he may fail to meet an acceptable per cycle pregnancy rate, resulting in more mares needing to be rebred on subsequent cycles and compounding an already overestimated book size. Monitoring a stallion's ongoing per cycle pregnancy rate as the breeding season progresses aids in identification of any pathology and mismanagement or fertility issues and allows for necessary evaluations and adjustments to stallion management to be made to optimize fertility.

Research has also shown that for approximately 60% of stallions "reinforcement breeding" after the stallion has covered the mare results in improved pregnancy rates by approximately 10%.[381] Reinforcement breeding involves collecting the postejaculate semen that drips from the urethra following dismount, which is combined with an appropriate semen extender to be inseminated into the mare's uterus. Reinforcement breeding has been most beneficial to stallions that routinely dismount before completing ejaculation. One stallion the author worked with had a 30% increase in per cycle pregnancy rates when reinforced breeding was added to stallion management.

OPTIMIZING PREGNANCY RATES WITH ARTIFICIAL INSEMINATION WITH FRESH SEMEN

If the stallion and mare reside on the same farm, then instead of breeding via live cover, the stallion's semen may be collected and the mare bred with the fresh semen by AI. As with live cover, the mare should be programmed to ovulate within 24 to 48 hours post breeding. To optimize pregnancy rates, when the ejaculate is going to be used to breed more than one mare on a given day, each mare should be inseminated with a minimum of 500 million progressively motile sperm or 250 million progressively motile, morphologically normal sperm. Although some stallions can achieve acceptable per cycle pregnancy rates with fewer sperm per insemination dose, until a stallion's minimum sperm/dose threshold is determined, 500 million progressively motile sperm are considered an appropriate dose for fresh semen. To improve pregnancy rates with a subfertile stallion, one can increase the number of sperm per dose or perform deep-uterine-horn or hysteroscopic insemination techniques to deposit the semen closer to or on the oviductal papilla ipsilateral to the dominant follicle.

OPTIMIZING PREGNANCY RATES WITH ARTIFICIAL INSEMINATION WITH COOLED SHIPPED SEMEN

When one is breeding with cooled shipped semen, proper preparation of the semen is paramount to obtaining maximum pregnancy rates. In this program the semen is collected from the stallion, processed according to known standards of semen preparation, and placed in a cooling device (Equitainer or disposable shipper) to be maintained at 5°C until it arrives at the location for insemination. Generally most semen is shipped in this program overnight for arrival the next day, although this may vary depending on shipping options available. Once the semen arrives, the mare is artificially inseminated and ideally will ovulate within 24 hours post insemination. Human error in the preparation of the semen for shipment and delayed time from insemination to ovulation or missed ovulation are the most common detriments to establishing successful pregnancies.

Before the start of the breeding season a BSE should be performed on every stallion and mare considered for use in this program to identify pathology, establish ideal semen-processing techniques to optimize pregnancy rates, and minimize costs associated with multiple breedings. Regarding the stallion, a longevity analysis of sperm motility using different semen extenders and different conditions should be conducted to identify processing and packaging that optimally maintains sperm motility for 24 to 48 hours under cooled conditions. Generally semen processing for cooled shipped semen involves the following:

1. Immediately after the semen is collected it is extended to a minimum of 1:3 ratio of semen to extender (ideally 1:4 or greater), and kept at room temperature out of direct light until analysis and packaging are complete. The extender should be warmed to 37°C before collection and then allowed to passively cool to room temperature at the same rate as the semen to prevent any temperature shock of the semen when the two are combined.
2. The final concentration of the extended semen should be between 25 and 50 million spermatozoa per milliliter.
3. Industry standards have established that a minimum of 1 billion progressively motile sperm should be included in each dose of cooled shipped semen to optimize pregnancy rates.

The mare that is to be bred should be administered an ovulation-inducing agent 24 hours before breeding to ensure that she ovulates within 24 hours after breeding. When two doses of semen are available, reports conflict as to whether better pregnancy rates are achieved if both doses are inseminated at the same time or if the mare should be bred twice approximately 24 hours apart.[382,383] Unfortunately, both studies contained a limited number of stallions, and more research needs to be conducted in this area to answer this question. The fertility of the stallion and reproductive health of the mare and how well an individual stallion's spermatozoa tolerate cooling also factor into what management options are best.

OPTIMIZING PREGNANCY RATES WITH ARTIFICIAL INSEMINATION OF FROZEN SEMEN

When frozen semen is used for breeding, accurate timing of breeding in relationship to ovulation is imperative to achieve maximum pregnancy rates. Frozen-thawed semen does not remain viable in the mare (estimated 12 hours on average) as long as fresh or cooled semen (approximately 48 hours), potentially because of capacitation-like changes that occur during the cryopreservation process.[384] Recent studies have shown that similar pregnancy rates can be obtained with frozen and cooled shipped semen, and Loomis et al. reported first cycle pregnancy rates of 60% and 63%, respectively, in a study of three farms with a combined total of 36 stallions shipping either cooled or frozen semen to a total of 648 mares.[385] The number of doses available for insemination on a given cycle dictates whether the mare can be bred with two doses using a timed insemination protocol or if the mare is bred with one

dose once ovulation is detected. Similar pregnancy rates can be achieved with either method as long as insemination occurs no more than 12 hours before and 6 hours after ovulation. If two doses of semen are available, then the mare is administered an ovulation-inducing agent once a 35-mm follicle and maximal uterine edema are observed. Insemination occurs at 24 and 41 hours later, with ovulation being confirmed within 12 hours of the second ovulation. If only one dose of semen is available, then the ovulation-inducing agent is administered as described earlier, and starting 24 hours later transrectal ultrasonography is performed approximately every 6 hours until ovulation is detected, at which time the mare is bred. Frozen semen causes a more severe inflammatory reaction in the endometrium than fresh or cooled shipped semen because of the removal of seminal plasma and its antiinflammatory properties. Because of this, the decision to breed with one dose versus two is made based on the mare's reproductive health and history.

Proper handling of frozen semen is also important to ensure that maximal pregnancy rates are achieved. Frozen semen must be maintained in appropriate liquid nitrogen storage units until immediately before thawing and should not be exposed to ambient temperature air at any time for more than a couple of seconds. Exposure to ambient air will result in thawing and then refreezing when returned to the liquid nitrogen, resulting in damage to the spermatozoa. Frozen semen should be thawed according to instructions that are included with the semen when it is shipped to ensure that maximum viability is maintained. If no instructions are included then it is safest to thaw at 37°C for 30 seconds for 0.5-mL straws, with larger straws requiring a longer thawing time. Once thawed, the semen should be inseminated into the mare immediately. Although there is no set industry standard for the number of total or progressively motile sperm required for a dose of frozen semen, there are some guidelines. In a study of more than 30,000 mare inseminations in the French National Stud, it was concluded that when mares were inseminated with doses containing less than 750×10^6 total frozen-thawed sperm, the resulting per cycle pregnancy rates were lower.[386] Based on these results, the World Breeding Federation of Sport Horses currently recommends this as the accepted minimum number of sperm per dose of frozen semen. Additionally, Volkmann and van Zyl showed that per cycle pregnancy rates were significantly higher when the insemination dose of frozen-thawed semen was increased from 137 to 210×10^6 to 222 to 333×10^6 progressively motile sperm (44% vs. 73%, respectively).[387] Based on these studies, it has become industry standard that a commercial dose of frozen semen should contain 200 million progressively motile sperm and possess greater than 30% progressive motility on thawing. It should be remembered that, unlike in the bull, fertility varies greatly from stallion to stallion and may not always be highly correlated to motility.

OTHER FACTORS AFFECTING PREGNANCY RATES

In addition to proper management of the stallion and mare, there are other variables that affect pregnancy rates. Understanding, controlling, or adjusting management of the mare to address these variables when possible will ensure that optimal pregnancy rates will be achieved. In addition, it is important to understand how these factors, listed below, will affect expected pregnancy rates and allow the clinician to provide the owner with a realistic prognosis for reproductive success:

- Reproductive status of the mare (barren, foaling, or maiden)
- Age of the mare or stallion
- Time of year of breeding
- Presence of endometritis
- The effects of inflammatory cytology and positive culture on pregnancy rates
- Uterine and systemic treatments that can aid in improving pregnancy rates in mares with endometritis
  - Corticosteroids
  - Ecbolics
  - Uterine lavage
  - Intrauterine and systemic antibiotics
  - Antiinflammatories and mucolytics

Although these factors will not be discussed in this section, they are covered in detail in other sections. It is important to remember that appropriate management of these variables can aid in obtaining optimal pregnancy rates. Regarding the reproductive status of the mare, the highest per cycle pregnancy rates of age-matched mares under 9 years of age is in the maiden > foaling > barren mares, although exceptions can occur. Generally the highest pregnancy rates are achieved with young fertile animals using fresh or cooled semen. Per cycle pregnancy rates decrease, and increases in pregnancy loss occur when mares age.[388,389] Breeding outside of the natural breeding season, when daylight is short, can be associated with a decrease in fertility in both mares and stallions, with animals farther from the equator demonstrating a more dramatic, longer period of reproductive quiescence. Although it has been shown that endometritis, associated with the presence of fluid in the uterus, inflammatory cytology, and positive cultures all result in decreased pregnancy rates, it has also been shown that appropriate treatment of these pathologies can result in improvement in pregnancy rates.[390]

There exists a population of mares for which these traditional breeding programs do not meet acceptable expectations because of poor uterine health, repeated pregnancy loss, or inability to deliver a viable foal at term or the desire for more than one offspring per season. For these mares, assisted reproductive techniques such as embryo transfer and oocyte aspiration for ICSI are options that should be considered when consulting with the client.

Equine Embryo Transfer

E. Bradecamp

Embryo transfer as a means to produce offspring is used for several different reasons in the equine industry. As mentioned previously, it is the next option for mares that cannot generate viable offspring because of reproductive tract limitations (cervical damage, persistent endometritis, fibrosis, and repeated pregnancy loss), systemic issues (laminitis, pelvic fracture, and lameness), when the client would like to have multiple offspring in one season, or in a healthy performance mare that cannot carry a pregnancy because of competition. Briefly, equine embryo transfer involves breeding a "donor" mare with the desired genetics, monitoring ovulation, and recovering the embryo through a uterine flush 7 to 8 days post ovulation. The embryo is then transferred into a synchronized "recipient"

mare that will carry the pregnancy to term and raise the foal. A multitude of factors play a role in the success of an embryo transfer program, and a comprehensive understanding of the effects of donor mare fertility, recipient mare management, and embryo procurement and processing techniques is imperative to maximize the chances of obtaining a pregnancy. This section will provide an overview of the factors involved in managing donor and recipient mares and the techniques for flushing, transporting, and transferring equine embryos.

The first live foal produced by embryo transfer was reported by Oguri and Tsutsumi in Japan in 1974.[391] Initially, embryo transfers were performed surgically by using a standing flank laparotomy, by which the embryo was deposited into the uterine lumen through a small incision in an exteriorized uterine horn. The incision was then closed, the uterine horn returned to the abdomen, and the flank laparotomy site closed. By the late 1990s, with advancements in the technique of transcervical transfer, Foss et al. reported that pregnancy rates from nonsurgical embryo transfer could be achieved that were comparable or superior to surgical transfer.[392] Since that time, nonsurgical embryo transfer has become the industry standard of care.

Initially, it was hoped that embryo transfer would provide a modality by which to obtain foals from mares with various causes of infertility. Although successful in some of these cases, embryo transfer success depends on the cause of infertility and may not improve pregnancy rates for some infertile mares. The procedure has proven to be more successful in mares that become pregnant but fail to maintain their pregnancies than in mares in which no pregnancy has ever been diagnosed. Embryo transfer allows foals to be produced from show or race mares that the owner desires to keep in competition; mares that cannot carry a pregnancy because of systemic, musculoskeletal, or reproductive disease; 2-year-old mares; and mares that have foaled late in the breeding season. This allows them to remain open so that they can be bred back early the following year. Embryo transfer also allows embryos to be cryopreserved and stored for later use.

The success of an embryo transfer program is dependent on multiple factors, including donor mare fertility, recipient fertility and synchrony, semen quality, and expertise of the veterinarians managing the mares and performing the procedures. An extensive review of the factors affecting embryo transfer rates will be provided later in this section. The majority of embryos are shipped to recipient herds with proper synchronization and selection, but owner-provided recipient mares may also be used. Although a majority of breed registries (with the Jockey Club being one exception) now permit registration of foals produced by embryo transfer, mare owners need to check with their specific breed registry to familiarize themselves with the regulations of that organization. Some registries allow an unlimited number of foals to be produced from a mare in a given year, whereas some registries, such as the United States Trotting Association, only permit one foal per mare per year to be registered.

DONOR MARE

Factors Affecting Fertility

The fertility and age of the donor mare has a significant effect on the success of an embryo transfer program. The chances of obtaining an embryo is highest in young (less than 10 years of age), fertile mares, with Foss et al. reporting embryo recovery rates as high as 84.2% in show mares; 59.7% in multiparous, nonbarren mares; and as low as 30% in mares with a history of infertility.[392] McCue et al. reported that one or more embryos were recovered from 144 of 252 flushes (57.1%) from mares 15 years of age and younger and 93 of 236 flushes (39.4%) from mares older than age 15.[393] Marione et al. also showed that mare age had a significant effect on embryo recovery rate. When mares were divided into three age groups—fillies (3 and 4 years old), middle-aged mares (aged 5–10 years), and old mares (aged 13–25 years)—the embryo recovery rates were 171/244 (70.1%), 774/1081 (71.6%), and 385/701 (54.9%), respectively, with significantly fewer embryos recovered from the old mares.[394]

The type of semen used to breed the donor mare also has an effect on pregnancy rates and embryo recovery rate. Squires et al. reported that pregnancy rates were highest when fresh semen was used (60%–77%) and were significantly lower when chilled (44%) or frozen semen (46%) was used.[389] The quality of the sire's semen should be taken into careful consideration in an embryo transfer program. Stallions with poor per cycle pregnancy rates will subsequently yield poorer embryo recovery rates.

Both exercise and heat have the potential to negatively affect embryo recovery rates. This should be taken into consideration when attempts are being made to obtain embryos from mares that are concurrently in active training and/or competition. A study performed by Kelley et al. demonstrated that exercised mares had lower peak LH concentrations, higher cortisol levels, and altered follicular dynamics compared with nonexercised mares.[395] The exercised mares had longer interovulatory intervals, fewer 6- to 10-mm follicles, and more follicles 20 mm or greater on the day of deviation, suggesting delayed deviation. Additionally, when embryo transfer was performed on the exercised and control mares, significantly fewer embryos were recovered from the exercised mares. Mares were divided into three groups: nonexercised controls, mares that were exercised moderately for 30 minutes a day during the periovulatory period but rested after ovulation for 7 days, and mares that were exercised for 30 minutes daily from the periovulatory period until day 7 post ovulation. Embryo recovery rates were significantly higher in the controls (67%) than the partially exercised (44%) or fully exercised (43%) groups. Vascular perfusion of the periovulatory follicular wall was significantly decreased on the day before ovulation in both groups of exercised mares, and vascular perfusion of the follicular wall was correlated with the likelihood of recovering an embryo.[395] Mortensen et al. also demonstrated that when mares were exercised for 30 minutes daily under ambient conditions of over 30°C and over 50% humidity, an increase in rectal temperatures from 38°C to 39.9°C occurred. Embryo recovery rates in the exercised mares decreased by 50% compared with the control mares, and 50% fewer grade I embryos were recovered from the exercised mares.[396] Conversely, there have been studies that did not show any effect from exercise in hot, humid conditions on embryo recovery rates, but the mares in these studies experienced less elevation in rectal temperatures and may have been at a higher fitness level than the mares in other studies.

Managing the Donor Mare for Embryo Transfer

Management of the donor mare for embryo transfer is very similar to managing any mare that is being bred. The mare

should be in good body condition and health, and any health-related problems should be addressed and every attempt made to keep the mare pain and stress free. Mares should be bred to minimize and modulate the inflammatory process that naturally occurs in the reproductive tract with breeding, and the treatments required to do this may vary greatly from mare to mare. Young, healthy mares usually require minimal treatment, whereas older, subfertile mares may require more aggressive treatment modalities that aid in the evacuation of fluid from the uterus and minimize the development of postbreeding endometritis. It is imperative that the exact day of ovulation is documented to ensure that the embryo flush is performed on the correct day post ovulation. Embryo flushes are performed 7 to 8 days post ovulation. If the mare is less than 10 years of age and was bred with fresh or cooled shipped semen, then the flush may be performed on day 7 or day 8, depending on the clinician's preference. Embryo flushes are typically performed on day 8 in older mares and mares bred with frozen semen. The embryo appears to be slightly delayed in its early development and transport in older mares and when frozen semen is used, so recovery 1 day later allows an increased likelihood of recovering an optimally developed embryo.[355]

When multiple embryo flushes are going to be performed on a donor mare within one breeding season, it is imperative to be cognizant of the inflammation that is incited with each breeding and flush cycle. Research has shown that these inflammatory episodes are additive, and mares that have had multiple embryo flushes performed during a season have higher levels of inflammation and fibrosis observed on uterine biopsies compared with control mares. Carnevale et al. showed a positive correlation between repeated embryo recovery attempts and chronic inflammatory changes in the uterus.[397] Additionally, although there is anecdotal evidence that repeated embryo flushes over several years have a negative effect on the fertility of some mares, there are studies that do not show an alteration in embryo recovery rates with an increasing number of successive embryo collections.

RECIPIENT MARE

The ideal recipient mare should be 3 to 10 years of age, of good body size (15.2–16.2 hands) or as close to the same size of the donor mare as possible, systemically healthy, easy to handle, and reproductively sound. Standardbred and Quarter Horse–type mares have historically shown to be well suited as recipient mares, but the predominant type of mare within any individual recipient herd is often dictated by the types of mares available as recipients within that geographic region, and potentially the predominant types of donor mares are flushed. Although it has been well demonstrated that the size of the mare's uterus controls the size of the fetus, allowing the transfer of draft horse embryos into ponies to produce live foals without resulting in severe dystocia, it has been demonstrated that when there is a gross disparity (draft to pony) the fetus may not reach its full potential size as its siblings that are transferred into recipients of similar size to the donor. It should be noted that these studies examined the extremes of embryo transfer, and it is because of the mares' ability to control fetal size that embryo transfer can be performed so readily in mares and the offspring produced are able to mature to their genetic potential when light horse breeds are transferred into light horse breeds. Intrauterine growth restriction (IUGR), a potential for increased incidence of osteochondritis dessicans lesions, and changes in conformation have been attributed to large differences in the recipient and donor mares, and every effort should be made to best match the recipient to the size of the donor mare.

Detailed descriptions of the specific surgical and nonsurgical procedures involved in the collection, shipping, and transfer of equine embryos is beyond the scope of this text, and the reader is referred to other recent texts and publications for such information.

The Pregnant Mare

Igor F. Canisso, Maria R. Schnobrich

This section will review the physiology and relevant anatomic considerations for clinical management of the pregnant mare. In addition, management, treatment, and pathology associated with the pregnant mare and periparturient period will be discussed.

PHYSIOLOGY OF GESTATION

Maternal Recognition of Pregnancy

Once the oocyte is fertilized, the zygote begins its journey down the oviduct, reaching the uterine horn by days 6 to 7.[398-401] Older mares and mares bred post ovulation or with frozen semen are thought to have delayed embryonic vesicle transport through the uterine tubes by 1 or 2 days. It has been suggested that the early equine embryonic vesicle must be viable and signal its presence in the uterotubal junction to allow its passage into the uterine lumen.[4,402] This mechanism is thought to be mediated by embryonic production of PGE_2,[401] which is supported because PGE_2 administered in the oviduct hastens embryonic transport through the uterine tube.[8] Nonfertilized oocytes are thus retained in the mare's uterine tubes until complete degeneration occurs.[4] Detailed descriptions of the early development of the equine embryo are outside the scope of this text, and the reader is referred to elegant reviews published elsewhere.[4,401-403] Early embryonic development in the horse is characterized by the formation of a tough, elastic, unusual acellular mucin-like glycoprotein "capsule" covering the trophectoderm and the overlying zona pellucida.[400,403] This structure is first detected by day 7 post ovulation and completely envelops the spherical conceptus until as late as days 23 to 25 of gestation.[400,403] Although the term *embryo* is used routinely to describe the early conceptus, it is important to understand that what is generally being discussed is the embryonic vesicle as well as the embryo proper. These two structures will ultimately develop into the fetal membranes and fetus, respectively. Embryonic development has progressed sufficiently by day 40 of gestation, and the term *fetus* is used thereafter.[4]

The longitudinal arrangement of the endometrial folds is suggested to favor mobility of the spherical equine embryo.[4] After entering the tip of the uterine horn by days 6 to 7, the embryo moves down toward the uterine body by day 8.[404,405] The intrauterine mobility phase continues until days 15 to 17 post ovulation, and during this period the embryo may move between the horns 10 to 20 times each day.[399,401,404-406] An embryo-derived factor is suspected to signal the suppression of the uterine luteolysin ($PGF_{2\alpha}$) release, which interrupts the oxytocin-$PGF_{2\alpha}$ interaction in mares and allows early

pregnancy maintenance.[279,407-409] The mobility of the spherical equine conceptus is critical for this proposed blockage of luteolysis,[398,399,401] which is why large uterine cysts are thought to cause pregnancy loss.[135,410,411] If the enlarging vesicle cannot pass by a large lymphatic uterine cyst, then it may be unable to come into contact with all endometrial surfaces and inhibit $PGF_{2\alpha}$ production.[93] Historically, it has been suggested that maternal recognition of pregnancy starts by 10 days post ovulation in mares,[412] but a recent study reported successful establishment of pregnancies when day 10 embryos were transferred to recipient mares ovulating within 2 to 6 days of the donor mare.[413] This suggests that the luteolytic cascade does not begin until day 12 and that the critical window for maternal recognition of pregnancy in mares likely occurs between days 12 and 14 post ovulation.

If maternal recognition of pregnancy does not occur or the mare is not pregnant, luteolysis begins with release of $PGF_{2\alpha}$ by endometrial cells into the systemic circulation. This is in contrast to ruminants, in which $PGF_{2\alpha}$ is delivered directly to the ovary via the countercurrent exchange between the ovarian artery and uteroovarian vein.[414,415] If the mare is not pregnant or embryonic migration is impaired by day 15 of the cycle, then there is increased expression of cyclooxygenase-2 (COX-2) by endometrial epithelial cells compared with pregnant mares.[416,417] Therefore inhibition of the COX-2 enzyme is considered a key factor for maternal recognition of pregnancy in mares.[412,417] Interestingly, although this release of $PGF_{2\alpha}$ is stimulated by oxytocin produced by luteal cells in ruminants, there is no such luteal production of oxytocin in the mare, with the endometrium being its primary source.[4,418]

The embryonic vesicle typically becomes fixed at the base of one of the uterine horns with the embryonic pole of the vesicle opposite to the mesometrial attachment (antimesometrial).[419] This fixation is a result of the increasing embryonic vesicle diameter, uterine tone, and its arrival at the uterine bifurcation, which presumably has the smallest lumen diameter. An early vascular indicator of the future position of the embryo proper consists of a colored spot seen on Doppler imaging of the endometrium close to the wall of the embryonic pole. This finding may prove useful when differentiating between a cyst and a vesicle before the embryo proper becomes visible on the ultrasound image.[420,421] In postpartum mares, the embryo usually becomes fixed in the more involuted horn,[421-424] with higher pregnancy losses being associated with those embryonic vesicles that fix in the previously gravid horn by an unknown mechanism.[424]

Placentation

The trophoblast cells of the early embryo are programmed to form the absorptive placental contact with the endometrium.[4] The mare has a nondeciduate, epitheliochorial, diffuse, microcotyledonary placenta.[4,402,403,425-430] The entire maternal surface of the fetal membranes becomes covered with delicate, diffuse microvilli that interdigitate with the proliferating luminal epithelial cells to form intricately branched microcotyledons.[425-430] The interdigitation tends to be deeper at the tip of the nongravid horn, which may help explain the higher incidence of fetal membrane retention in that horn.[431-433] In a normal pregnancy the noninvasive allantochorion extends slowly to fill the uterus by days 80 to 85 of gestation, and its microcotyledonary architecture, which provides both hemotrophic and histotrophic nutrition for the growing fetus, is not fully established until days 120 to 140 of gestation.[4,161] During the second half of gestation, most of the mitotic activity is confined to the periphery of the microcotyledons, which are still growing.[434,435]

Vascular endothelial growth factor, a potent vasculogenic and angiogenic factor, and its two main receptors, Flt-l and KDR, are expressed on both the endometrium (i.e., maternal) and chorioallantois (i.e., fetal) throughout gestation in the mare.[436] These molecules are presumed to facilitate the continuing development of the prominent fetal and maternal capillary networks within the microplacentomes of the equine placenta.[436-438]

Degenerative changes (endometriosis) in the endometrium can adversely affect the ability of the microcotyledonary placenta to facilitate optimal hemotrophic nutrition and exchange of waste products.[437] If the pregnancy is maintained, dysfunctional placental attachment can lead to the birth of dysmature, weak foals through intrauterine growth restriction (IUGR), which may have detrimental consequences on the health and athletic performance of the mature horse.[437,439,440]

Failure of microcotyledon development results in the characteristic white, avillous portions on the maternal surface of aborted twin fetal membranes.[441,442] Although histotrophic nutrition (i.e., through secretions from endometrial glands and absorption by the chorionic cells) is likely to remain important throughout gestation, adequate hemotrophic nutrition is essential to support the rapid fetal growth that occurs during the latter part of gestation.[4] The morphology of endometrial blood vessels observed on uterine biopsy can vary considerably, depending on the age and reproductive status of the mare.[443] Mild to severe degenerative lesions may be observed in smaller and larger arterial and venous vessels in as many as 20.5% of the endometrial specimens examined.[188] Unaltered vessels were detected only in maiden mares.[188]

The incidence and severity of angiopathy increase with the number of previous pregnancies and with advancing age.[188,443] Changes in the endometrial vasculature of multiparous mares have been compared with the so-called pregnancy sclerosis of other species, with fraying and disruption of the elastic internal membrane, medial and adventitial elastosis and fibrosis, and calcification processes within the media.[188,443]

In multiparous mares, cycles of vascular growth during pregnancy and subsequent involution postpartum are thought to result in progressive degenerative vascular changes in the endometrium. Aging processes, chronic inflammation, and short foaling intervals have been implicated as additional detrimental factors.[188,437,438,443] Severe angiopathy is frequently combined with phlebectasia and lymphangiectasia, possibly indicating a reduced ability of the vessels to adapt to the varying demands of uterine circulation, with a decrease of uterine perfusion and lymph drainage.[188,443] In addition, mares with a grade III biopsy score, consistent with severe endometrial degenerative changes (Kenney and Doig classification[249]) had lower vascular perfusion during early pregnancy than mares with grades I and II (no or minimal endometrial fibrosis).[444] Angiosis in older, multiparous mares might therefore be intimately related to infertility, possibly because of detrimental effects on early embryo nourishment and subsequent placentation. Controlled studies have demonstrated the impact that uterine capacity and placental area can have on the size and birth weight of the foal and postnatal development.[445-448] In one study, pony embryos were transferred into draft mare recipients, and then the genetic dams were bred and allowed to carry a full sibling to term.[445] The embryo-transfer foals

were all larger than their siblings at birth, presumably due to the larger uterus in the draft mare recipients.[445] Although the increased milk production of the draft mares may have explained the subsequent faster growth rates, it was noted that all three draft-gestated foals were still heavier at 4 years of age.[445]

Recently a similar study demonstrated that pony foals born from draft recipient mares (i.e., a model for enhanced uterine environment) had insulin resistance postnatally, whereas Saddlebred foals born from pony mares (i.e., model for restricted uterine environment) had increased sensitivity to insulin and were considerably lighter.[447] A similar embryo transfer experiment used a Thoroughbred-in-Pony (Tb-P) and Pony-in-Thoroughbred (P-Tb) comparison, with Thoroughbred-Thoroughbred and Pony-Pony transfers acting as controls.[449] The Tb-P foals were lighter than the P-Tb foals and had lower placental weight, volume, and surface area and reduced postnatal adaptive responsive and hypercortisolemia.[448,449] Altogether, these studies were consistent with an earlier study in which a Shetland pony mare was inseminated with Shire semen and a Shire mare was bred with Shetland pony semen. The foal out of the pony mare was 50% of the weight of the half-sibling that was gestated in the Shire mare, with the marked size discrepancy remaining after maturity.[448] On the practical side, as mentioned in the discussion on embryo transfer, these studies demonstrated the importance in embryo transfer programs of having embryo recipients compatible with the body frame of the embryo donor to avoid effects of an enhanced or restricted uterine environment. It is worth noting that sudden weight loss may mimic the situation of a restricted uterine environment, which may result in deficient fetal growth and a weak newborn foal. This has been observed in clinical practice and demonstrated experimentally in Thoroughbred primiparous mares using a *Streptococcus equi* subsp. *equi* infection-mediating nutritional insults.[450]

Endocrinology of Pregnancy

Endocrinology of equine pregnancy has been elegantly reviewed elsewhere, and the reader is referred to those publications for more detailed description of all endocrinologic events that occur during pregnancy.[4,451] Regardless of whether the mare is pregnant or not, there is a rapid organization and vascularization of the corpus hemorrhagicum, which culminates in the formation of a CL and increased progesterone production.[4] There is controversy as to whether large (i.e., granulosa cells origin) and small luteal cells (i.e., internal theca origin) are steroidogenically active as in other domestic mammals. The lack of progesterone receptors and steroidogenic enzymes in small luteal cells substantiates the hypothesis that small luteal cells do not secrete progesterone.[452] It is interesting to note that after undergoing artificial insemination, mares that became pregnant had significantly higher progesterone concentrations as early as 5 days post ovulation when compared with mares that did not become pregnant.[453] Additionally mares experiencing pregnancy loss or premature luteolysis may have decreased progesterone concentrations by 10 to 15 days post ovulation.[454,455] This finding highlights the importance of checking progesterone concentrations in mares with recurrent embryonic death by 10 days post ovulation and at pregnancy diagnosis on day 15 for mares exhibiting signs of premature luteal regression (e.g., poor uterine/cervical tone, endometrial edema, absent/small CL, presence of a smaller than expected embryonic vesicle).[455]

After day 15 post ovulation, nonpregnant mares normally start undergoing luteolysis and return to estrus and ovulate at 20 to 22 days on average from the previous primary ovulation.[4] However, some normal mares (bred and nonbred) may experience prolonged luteal function caused by diestrual ovulation, endometrial lesions, or for unknown reasons.[4,66]

In pregnant mares, the chorionic girdle is a distinct and specialized structure that can be seen surrounding the top third of the embryonic vesicle by day 25 post ovulation.[398,399] At around 35 days post ovulation, invasive trophoblast cells originating from the chorionic girdle detach from the embryonic vesicle and successfully invade the endometrium.[4,456-460] The invasive cells aggregate to form the endometrial cups, which are endocrinologically active tissue that secrete large quantities of eCG.[456-460]

Endometrial cups become visible by day 38 to 40 as a ring of small, pale plaques in the endometrium that surround the developing conceptus.[4,401-403] Because fetal cells are provided by the sire and thus differ genotypically from the maternal cells, the fetal antigens invoke a cell-mediated immune response.[461,462] This influx of lymphocytes creates a pronounced, localized immunologic reaction, and by day 120 of gestation, the endometrial cups are sloughed.[461-463] The subsequent necrotic tissue and inspissated secretions form invaginations into the chorioallantois and may still be seen on the allantoic surface at delivery as allantoic pouches.[464]

Equine chorionic gonadotropin, a large-molecular-weight glycoprotein, has both FSH-like and LH-like activity, as previously described.[465] During early pregnancy, periodic surges (10–12 days apart) of pituitary FSH trigger the waves of ovarian follicular development.[466] The eCG also promotes luteinization and ovulation of ovarian follicles, forming accessory (secondary) CLs that augment the progesterone production from the primary CLs that developed at the time of conception.[4,401,402] This process is critical to ensuring pregnancy maintenance before the placenta is fully capable of supporting pregnancy at ~100 days' gestation.[4,401,402]

High concentrations of eCG may be detected in the blood of pregnant mares from 40 to 120 days' gestation.[4,401] Interestingly, mares losing pregnancies during this interval of gestation may have a prolonged and persistent presence of active endometrial cups that secrete eCG, causing erratic estrous behavior, unreliable follicular development, luteinization of immature follicles, and unpredictable ovulation. Anecdotally, the treatment of persistent endometrial cups can be attained through laser therapy, intrauterine infusion of kerosene, lavage of the uterus with hypertonic saline, and endoscopic removal of cysts, but these have not been critically evaluated.

The equine embryonic vesicle is capable of producing large quantities of estrogen.[451] Estrogen concentrations increase significantly in the yolk sac and uterine lumen by day 12 post ovulation, with estradiol becoming the predominant estrogen in the yolk sac by 18 to 20 days post ovulation.[467] Another unique feature of early gestation in the mare is that the corpora lutea produce increasing concentrations of conjugated estrogen (e.g., estrone sulfate) and testosterone in response to eCG.[468-471] Starting by 70 days post ovulation, there is a progressive increase in estrogen concentration (presumably of fetoplacental origin), peaking by 210 to 240 days post ovulation and progressively declining toward parturition.[451]

Fetoplacental estrogens are synthesized from androgens produced by the enlarged fetal gonads.[472] Bilateral fetal gonadectomy performed between days 197 and 253 of gestation

causes a precipitous drop in plasma estrogen levels that then remains basal until small foals are spontaneously delivered in 70 to 97 days.[473] After day 220 the enlarged gonads gradually shrink into an insignificant size by birth.[471] Two groups of estrogens can be found in pregnant mares: classic phenolic estrogens (estradiol, estrone, and their conjugated forms) and equine-specific steroid ring B unsaturated estrogens (equilin and equilenin).[472] DHEA and 7-dehydro DHEA serve as precursors for classic estrogens and for ring B unsaturated estrogens (equilin and equilenin), respectively.

Four separate components combine to produce the progesterone and biologically active 5α-reduced pregnanes needed to maintain pregnancy in the mare.[4,451,474] The primary CL is prolonged beyond its cyclical life span by the downregulation of endometrial oxytocin receptors to prevent activation of the luteolytic pathway. Its waning progesterone production is supplemented from day 40 of gestation by the formation of accessory CLs that develop in the maternal ovaries as a result of the gonadotropic actions of pituitary FSH and endometrial eCG.[4] The equine fetoplacental unit produces significant quantities of progesterone and C-21 progestogens.[4,474] The placenta (chorioallantois and endometrium) initially uses maternally derived cholesterol to metabolize into pregnenolone and then progesterone. A significant amount of progesterone originates from this source, starting from approximately day 70 of gestation.[4,474]

In normal pregnant mares, peripheral progesterone concentration starts to decline by 4 months of gestation, reaching baseline levels by days 150 to 180.[473-475] Progesterone may be undetectable in the serum by this time (<1 ng/mL), depending on the type of assay used, and is no longer indicative of what is happening at the uterine level, because the placenta secretes progesterone and progestogens directly to the endometrium and underlying myometrium. In the second half of gestation, most of the placental-derived progesterone is further metabolized into 5α-reduced pregnanes (5α-dihydroprogesterone or 5α-pregnane-3,20-dione, and 20α-5P or 20α-hydroxy-5α-pregnane-3-one, together with other 5α-reduced metabolites of progesterone and pregnenolone).[4,367,474] Even later in gestation, it has been suggested that another steroid, perhaps 5α-pregnane-3,20-dione (5α-DHP) and not progesterone, is an important precursor for the other progestin metabolites found in circulating plasma.[4,367,474] A recent study demonstrated that 5α-DHP binds to the progesterone receptor with at least the same affinity to progesterone and is thought to be responsible for pregnancy maintenance in the mare for the second and third trimester of pregnancy.[451,474] In the final months of gestation, the enlarging fetal adrenal gland secretes appreciable quantities of pregnenolone, which is then used by the placenta to synthesize progestogens.[4] Even at this late stage in equine gestation, there is insufficient adrenal 17α-hydroxylase activity to convert the pregnenolone into fetal cortisol, so it passes out in the umbilical vessels and is converted to 5α-reduced pregnanes in the placenta. Thus, unlike with ruminants, there is a significant increase in the mare's plasma progestogen concentrations during the last 4 to 6 weeks of gestation followed by a precipitous drop in concentrations at the time of parturition.[4,473] A premature rise in progestins has been observed in mares with chronic placentitis, and this phenomenon is thought to be associated with fetal stress and premature maturation of the pituitary adrenocortical axis and more progesterone escaping placental metabolization.[476] When pony mares were subjected to intrafetal injections of adrenocorticotropic hormone (ACTH) at day 300 of gestation, maternal plasma progestogen concentrations increased significantly.[477]

Physiology of parturition in the mare is not as well documented as in ruminants. The precise mechanism that couples the fetal hypothalamic-pituitary-adrenal axis in the foal that is carried to term remains to be determined.[451,478] Across species, under normal conditions parturition is triggered when the fetus becomes fully mature.[478-481] In the mare, the fetal cortisol concentrations remain basal until the last 2 days' gestation, when a marked rise culminates in parturition,[4,481] and enhanced adrenocortical activity in the fetus is also associated with onset of parturition in many species.[479,482] Final maturation of the fetus results in increased ACTH release from the pituitary and subsequent stimulation of the fetal adrenal cortex. However, it is not until the maturing adrenal gland attains 17α-hydroxylase capacity that the high levels of pregnenolone are metabolized into fetal cortisol.[4,483,484] Disruptions of these fetal maturational processes, with suppression of fetal adrenocortical activity, have been suggested to be key events in the pathophysiology of fescue toxicosis.[485] The normal fetal maturational change (pregnenolone conversion into fetal cortisol) causes the maternal progestogen levels to plummet, resulting in a rising estrogen-to-progestogen ratio, and in the final hours, estrogen ultimately becomes dominant in the prepartu-rient mare.[4,451,486]

Intrafetal injections of ACTH result in precocious maturation of the equine fetus and reduction in gestational length mediated through adrenal regulation of fetal maturation and production of maternal progestogens.[481] Further work is required to establish the optimal gestational age and dosage for maternal ACTH administration before clinical recommendations can be given for this therapy.[485]

Previously it was thought that transplacental transfer of cortisol was very minimal because of the presence of the enzyme 11α-hydroxysteroid dehydrogenase, which inactivates cortisol, converting it into cortisone.[487] However, work out of the United Kingdom demonstrated that healthy Thoroughbred mares receiving 100 mg of dexamethasone at days 315, 316, and 317 of gestation could deliver live foals.[488] This demonstrated that practitioners managing high-risk pregnancies may be able to rescue the foal or improve the likelihood of a viable foal being delivered alive if the above protocol is applied.

Relaxin is produced by the placental trophoblast cells and is speculated to be involved in softening the pelvic ligaments to facilitate fetal passage and to promote uterine quiescence until parturition is imminent.[4] The myometrium becomes more responsive to oxytocin and PG, and eventually the high concentrations of oxytocin and PGs may overcome the inhibitory effects of relaxin.[4,483,489] The sudden dominance of estrogen is thought to promote cervical production of PGE_2. $PGF_{2\alpha}$ promotes myometrial contractility by acting on intracellular calcium, but PGE_2 promotes cervical relaxation.[486]

Endocrinology of Parturition

The third trimester of pregnancy is characterized by increasing concentrations in $PGF_{2\alpha}$, promoted by estrogen.[490] Estrogen also increases expression of oxytocin receptors and myometrial gap junctions, facilitating the ability of the uterus to have coordinated contractions. Interestingly, pregnant mares experience an increase in estrogen and $PGF_{2\alpha}$ concentrations during the night,[473,491] which may explain the phenomenon of the majority of foalings occurring at night.[492] Together this

results in increased myometrial contractility, which facilitates normal parturition.[493] During stage I of parturition, the contracting myometrium forces positional changes in the fetus to prepare for expulsion, and the chorioallantoic sac begins to be pushed against the softening cervix, eventually resulting in rupture of the chorioallantois, which defines the onset of stage II of parturition. Once the foal is engaged in the birth canal, expulsive efforts during vaginal passage of the foal are driven by rising oxytocin and prostaglandin concentrations, which will reach peak concentrations during stage II of parturition. Contraction of the abdominal muscles (maternal straining) is almost always associated with large sustained uterine contractions. Mares with severe debilitating conditions (e.g., chronic diarrhea, neoplasia), advanced age with poor body condition score, and mares with abdominal bandage (e.g., following colic surgery, body wall rupture, hydrops) may be unable to have adequate abdominal contractions, resulting in a delayed second stage of parturition and dystocia. Such mares need assistance delivering their foals and may progress to a dystocia due to uterine inertia if not assisted.

Concentration of PRL increases in the last week before parturition; this increase is responsible for mammary development and the initiation of lactation.[4] Prolactin release from lactotrophs in the anterior pituitary is regulated by hypothalamic secretion of PRL-releasing factor. The PRL-inhibiting factor is thought to be dopamine.[4] Oxytocin is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. Milk is produced in the alveoli and expelled into the lactiferous ducts and teat cisterns when oxytocin causes contraction of the myoepithelial cells. It is assumed that nursing by the foal stimulates the release of oxytocin from the neurohypophysis.

Myometrial Activity

The myometrium of the uterus is composed of an inner circular and an outer longitudinal smooth muscle layer. This arrangement of muscle fibers permits regulation of luminal size (circular) and uterine length (longitudinal).[4] The uterus is palpably flaccid during and immediately after estrus and then increases in tone and becomes turgid if the mare is pregnant.[4,494] Myometrial activity is vitally important to uterine clearance following breeding.[494-496] Uterine contractions also play an integral role during the embryo mobility phase of early gestation.[496] Between at least days 9 and 16 post ovulation, the spherical equine conceptus migrates continuously throughout the uterine lumen, propelled by peristaltic myometrial contractions.[4,402] This unusually long period of intrauterine movement ensures that the conceptus delivers its antiluteolytic signal to the entire endometrium. Conceptus mobility is high between days 10 and 14 after ovulation but can be reduced immediately and markedly by an IV injection of flunixin meglumine.

This suggests that prostaglandins are the primary stimulus for the myometrial contractions that drive migration of the conceptus.[407] The embryo produces prostaglandins that act as myometrial stimulants, and then subsequent uterine contractions result in embryo mobility.[404] The conceptus produces estrogens by day 12, and these, along with embryonic production of PGE_2, are thought to play a role in stimulating uterine contractions and increasing uterine tone during the mobility phase.[4] Progesterone is vital for embryonic development, and it plays a role in the mobility, fixation, orientation, and maintenance of the equine conceptus.[497]

Because there is little, if any, progesterone in the maternal circulation during late gestation, the quiescence of the uterus is thought to be maintained by progestogens, which are uteroplacental metabolites of pregnenolone and progesterone.[367,498] These hormones are thought to play a significant role through a paracrine action within the fetus and uteroplacental tissues.[498] Administration of a progestogen (altrenogest) will prevent PG-induced abortion in the first trimester of pregnancy.[115] There is considerable controversy and confusion surrounding the use of progestogen supplementation in the later trimesters, which will be discussed later.

The cellular mechanisms involved in myometrial contractility have not been well characterized in the pregnant mare, and it may not be appropriate to extrapolate from studies in nonpregnant mares. The classic theory in many species is that myometrial excitation and uterine contractility are suppressed by the so-called progesterone block.[499] Progesterone and progestogens were once assumed to be necessary for myometrial quiescence in the pregnant mare, and it was also thought that binding of 5α-dihydroprogesterone to endometrial progesterone receptors controlled uterine prostaglandin production and inhibited myometrial activity.[500] It is now known that 5α-dihydroprogesterone binds to the progesterone receptor with equal affinity.[474] The oxytocin-neurophysin I gene is transcribed into mRNA in the endometrium of mares, and mRNA levels are negatively correlated with serum progesterone concentrations.[501] However, progestogens were ineffective at controlling myometrial contractility in vitro and did not inhibit the effects of oxytocin, raising questions about the accuracy of the progesterone block theory in the mare.[502]

A reduction in circulating progestogen levels by experimental blockade with the 3β-hydroxysteroid dehydrogenase inhibitor (epostane) did not increase myometrial activity (labor) in late-gestation pony mares as it does in other species of domestic animals.[368,503] However, despite a paucity of evidence that a deficiency of fetoplacental progestogen production is a cause of pregnancy loss in the mare, exogenous progestogen therapy is widely used as a form of preventive insurance in pregnant mares, in the belief that it will promote uterine quiescence and guard against the possibility of pregnancy failure. The progestogens may enhance the activity of the endometrial enzyme 15-hydroxyprostaglandin dehydrogenase, promoting rapid metabolism of prostaglandins into inactive metabolites.[368] Early cases of premature luteal regression can only survive if the mare is treated with progestogens, and this has been used as a reason to justify progestogen supplementation.[455]

Electromyographic activity in the uterus of pregnant mares increases during the last week before foaling, even though the circulating progestogen levels are still quite high.[451,493,504] There is a progressive, reversible rise in myoelectrical activity at night in the last 6 days preceding parturition.[505] The endocrine profile of the periparturient mare is characterized by increasing concentrations of progestogens and decreasing estrogens.[369] Despite this decline, estrogens are essential for normal parturition in the mare. Recent work suggests that nightly elevations in estradiol-17β levels may bring about changes in the uteroplacental tissues, which facilitate the PG and oxytocin release that promotes the onset of myometrial contractions.[369] Pashen and Allen demonstrated that if the fetal gonads are removed, then the pregnancy would continue, but there were weak ineffective myometrial contractions and significantly reduced prostaglandin production during labor.[490] However, a recent study failed to demonstrate the importance of estrogen in late-term pregnant mares; peripheral estrogen concentrations were reduced by 90% with letrozole (aromatase inhibitor), and

mares still delivered foals normally and no changes in vascular perfusion were observed.[369]

The high levels of relaxin in the preparturient mare may act by inhibiting myometrial contractions until rising oxytocin and PG concentrations become overwhelming.[479] The number of oxytocin receptors and myometrial gap junctions may not increase until just before parturition in the mare.[493] At that time the myometrium becomes remarkably sensitive to even low doses of oxytocin.[369] A rapid membrane depolarization will result in the onset of strong, coordinated uterine contractions that characterize the first stage of labor. In the last 6 hours before rupture of the chorioallantois, a significant increase in $PGF_{2\alpha}$ concentrations occurs before there is a significant increase in oxytocin concentration.[506] Even if the $PGF_{2\alpha}$ concentrations are reduced by the COX inhibitor flunixin meglumine (1.1 mg/kg), oxytocin administration can still facilitate an expedient delivery.[506,507]

Teratogenesis

Little is known about the embryotoxic, and possible teratogenic, effects of chemicals, drugs, and other agents that may be administered to pregnant mares. Goiters have been reported in two newborn Arabian foals after the mares had been supplemented with excess iodine during the final 24 weeks of pregnancy.[508] Phenothiazines, thiabendazole, and organophosphate anthelmintics have been reported to cause pregnancy loss.[6] Likewise, Sudan grass or sorghum pastures have been reported to be toxic to the fetus.[6,509] In recent years more definitive documentation has become available with respect to the toxic effects of some medications. When griseofulvin was used to treat dermatomycosis in a mare during the second month of pregnancy, the mare carried a male foal to 331 days' gestation.[510] The foal showed bilateral microphthalmia, severe brachygnathia superior, and palatocheiloschisis. The lesions were incompatible with life, and the animal was euthanized. Griseofulvin administration during pregnancy has been associated with similar lesions in other species. Given that the development of the eyes and facial bones in the horse occurs in the second month of pregnancy, the lesions described in this case most likely can be attributed to griseofulvin administration.

Three weak, recumbent neonatal foals with skin lesions, including a thin, wooly coat, were born to mares being treated for equine protozoal myeloencephalitis.[511] The foals were anemic, leukopenic, azotemic, hyponatremic, and hyperkalemic. The pregnant mares had received sulfadiazine or sulfamethoxazole-trimethoprim, pyrimethamine, folic acid, and vitamin E orally. Serum folate concentrations in the three foals and two mares were lower than those reported in the literature for clinically normal broodmares. At necropsy each foal had lobulated kidneys with thin cortices and a pale medulla. The spleen and thymus were small. Histologic examination revealed marked epidermal necrosis without inflammatory cells, thin renal cortices, renal tubular nephrosis, lymphoid aplasia, and bone marrow aplasia and hypoplasia. These observations indicated that oral administration of 2,4-diaminopyrimidines (pyrimethamine with or without trimethoprim), sulfonamides, and folic acid to mares during pregnancy is related to congenital defects in newborn foals. Further investigations are warranted to ascertain the toxic agent and to determine at what stage of gestation the fetus is most vulnerable. In general there is a paucity of research on known teratogens in the pregnant mare, but research into the known effects in the mare and effects in other species and the potential risk and necessity of the given treatment should always be considered prior to administration of any medication to a pregnant mare.

PREGNANCY DIAGNOSIS

Standard transrectal imaging technique will permit an experienced practitioner (using a 5-MHz ultrasound transducer under optimal lighting conditions) to detect up to 98% of embryos as early as day 11 after confirmation of ovulation.[512] However, the first pregnancy check is not usually performed prior to 14 days post ovulation, as asynchronous twins are more likely to be diagnosed and the increased vesicle size makes pregnancy confirmation easier. The black (anechoic) spherical vesicle is characteristic of the ultrasonographic appearance of the equine pregnancy at this stage. Novices should realize that bright white (echoic) lines at the upper and lower margins of the vesicle are the normal ultrasound artifact (referred to as "specular reflection") generated by the ultrasound waves penetrating and reflecting through a perfectly round fluid structure.[513] It also must be appreciated that the equine embryonic vesicle can be anywhere in the uterine lumen before fixation on day 16.

Diagnostic errors can easily be made unless the entire length of both horns and the uterine body down to the cervix are meticulously searched during an ultrasonographic examination. Confirmation of mobility, as well as the presence of the specular reflection, is useful in differentiating an embryonic vesicle from a cyst. At the time of fixation at the base of a uterine horn, the yolk sac has three germ layers (ectoderm, mesoderm, and endoderm) near the embryonic pole, and only two layers (ectoderm and endoderm) at the opposite pole.[4] The difference in rigidity between the three-layered ventral wall and the two-layered dorsal wall explains the characteristic guitar pick–shaped image on ultrasound by day 18. The thickest portion of the yolk sac wall (embryonic pole) rotates to a ventral position. The change from the previous spherical shape is caused by uterine turgidity and thickening of the dorsal uterine wall. The increased uterine tone is responsible for the failure of the embryonic vesicle's diameter to enlarge between days 18 and 26, thus creating the classic growth profile that plateaus during this period.[4]

By day 21 post ovulation, the amniotic cavity has completely formed, and the embryo can often be detected by ultrasound. As the allantoic sac enlarges, the embryo proper can be seen to be raised off the ventral floor by day 24. The embryo can be seen suspended on a thin echoic line that delineates the apposition of allantois and yolk sac.[513] This separating membrane tends to be horizontal, and thus it is a useful means for differentiating a singleton from twin embryonic vesicles. In the latter case the adjacent walls of the two vesicles tend to form a vertical separation. The primitive heartbeat can be detected between 22 and 25 days and is a useful indicator of embryonic viability. By day 40 the embryo (now called a fetus) has been elevated to the dorsal pole because the allantoic cavity has almost completely displaced the vestigial yolk sac. The membranes and blood vessels that separate the allantois and yolk sac give rise to the umbilical cord. The increasing size of the fetus causes the fetus and amniotic sac to gradually descend back to the floor of the chorioallantoic vesicle by day 48. The remnant of the yolk sac is incorporated into the umbilical cord. The site in which the umbilical cord attaches to the chorioallantois identifies the horn and site in which embryo

fixation originally occurred. The dorsal attachment ensures that the developing fetus will not compress this vital area.[402]

These gestational developments can be used by the practitioner to determine whether the pregnancy is developing normally. Generally each practitioner will have set gestational ages that pregnancy evaluations are performed to ensure normal development of the pregnancy. Most practitioners will perform ultrasound evaluations at the following times: 14 to 16 days to ensure normal size and identify the presence of twins, 28 to 30 days to confirm normal development, heartbeat and no twin before the formation of endometrial cups, 42 to 60 days to assess development and potential sex of the fetus, and later checks vary more after this period with either one or monthly evaluations thereafter. Generally mares with a history of pregnancy loss or abnormal ultrasound findings are evaluated and monitored more frequently to determine appropriate management and treatment.

Although ultrasonographic examinations have become standard practice for confirmation of pregnancy in mares, it is still essential that the veterinarian be competent at manual diagnosis. By 18 days after breeding, an experienced clinician may be able to perceive changes in uterine tone and consistency that, coupled with palpation of a narrow elongated cervix, are consistent with early pregnancy. However, it should be remembered that it is not uncommon for a persistent CL to provide a prolonged progesterone environment in a nonpregnant mare. It is important not to mistake the curvature at the base of the uterine horn for an embryonic vesicle.[4] An ultrasound image of the embryonic vesicle is required to definitively confirm pregnancy at this early stage. However, the gradually enlarging embryonic vesicle will eventually create a discernible ventral bulge that has been described as being the size of a hen's egg (day 30), goose's egg (day 35), and orange (days 40–45). Because there is minimal dorsal distention at this stage of pregnancy, it is essential that the ventral aspect of each uterine horn be examined. Errors can be made if the fingers are not passed far enough around the cranial aspect of the uterine horn to reach well under the uterine body and horns. A ventral bulge that is consistent with a 35- to 45-day pregnancy can be identified by the distinct margins that are palpable when the fingers are moved along the ventral aspect of the uterus. The conceptus becomes more oval as it expands during the third month of pregnancy. At 90 days, the chorionic vesicle is comparable in size and shape to a football. The mare's age and the number of previous foals will affect the rate of descent of the gravid uterus over the pelvic brim. Positive pregnancy diagnosis becomes progressively more difficult as the large, heavy uterus descends into the abdominal cavity. Normal pregnant mares should have a thin, pliable uterine wall, whereas pyometra cases have a thickened uterine wall and viscous purulent fluid in the uterus. The fetus itself is not always palpable before day 120 of gestation, but gentle ballottement will usually reveal the fetus after that time. Palpation of some part of the fetus should be able to confirm pregnancy status between 5 months and term.

Blood tests for pregnancy are sometimes indicated, especially in Miniature breeds.[514] Measurement of eCG levels verifies that the mare has endometrial cups but does not guarantee that a viable fetus is still present.[4] With this caveat in mind, eCG is suitable for determining pregnancy status in Miniature mares between 40 and 100 days after mating.[515] However, mares that have been diagnosed as pregnant should undergo a blood estrone sulfate test 100 or more days after mating to eliminate the possibility of a false-positive diagnosis. Determination of eCG concentration is used to confirm suspicious retention of endometrial cups in mares with history of losing a pregnancy in the first 100 days.

The fetoplacental unit secretes large quantities of estrogen.[4,451] Measuring blood estrone sulfate levels is recommended as the method of choice for determining pregnancy status in Miniature mares 100 or more days after mating.[515] Fecal estrone sulfate measurements provide a noninvasive alternative to blood testing from 150 days after mating. However, the discrimination between pregnant and nonpregnant estrone sulfate concentration is not as great in feces as it is in blood.[515] Determination of estrone sulfate and eCG concentrations can be used in some cases as confirmatory pregnancy diagnosis tests. For example, Miniature mares presented for pregnancy diagnosis are initially screened with an abdominal ultrasound. If signs of pregnancy are detected (fetal fluids, fetal heartbeat, and movements) then the mare is confirmed pregnant, but if one fails to identify these findings with ultrasound, then blood can be collected for eCG and/or estrone sulfate determination. Nonpregnant mares will have baseline concentrations for both hormones.

MANAGEMENT OF TWINS

In the mare it is assumed that most twin pregnancies arise from double ovulations, but occurrence of monozygotic and triplet pregnancies has been reported.[516-519] Presumably, monozygotic twin pregnancies may occur more often in mares following the transfer of a single embryo for unknown reasons.[516] There is a higher incidence of double ovulations in Thoroughbred and Warmblood mares, but mares of any breed may consistently double ovulate.[520-524]

In a large retrospective study involving more than 3000 cycles in 1581 Thoroughbred mares, multiple ovulation occurred in 29.3% of cycles.[523] Incidence of multiple ovulation increased with age (20.7% in 2- to 4-year-olds; 35.6% in 17- to 19-year-olds). Multiple ovulations may occur synchronously (same day or <2 days apart) or asynchronously (>2 days apart).[4,523] Asynchronous ovulation is termed *diestrous ovulation* because more than 2 days after the first ovulation the concentrations of progesterone will rise and the mare is in diestrus. Both synchronous and asynchronous ovulation may result in twin pregnancies, particularly if semen from a fertile stallion was used for breeding. This emphasizes the importance of counting the number of CLs present at the first (13–16 days) and second (23–28 days) pregnancy diagnosis, as well as meticulous ultrasound evaluation looking for the presence of a second embryonic vesicle, even if only one ovulation was detected. Epidemiologically, mares ovulating from different ovaries are more likely to have twin pregnancies than mares ovulating in the same ovaries. In addition, asynchronous ovulations within the same ovary are less likely to result in twin pregnancies compared with synchronous ovulations in the same ovary.[4,525] In a large study with Thoroughbred mares in the United Kingdom, 25.2% of multiple ovulations were apparent as multiple pregnancies and 37.8% as single pregnancies at 13 to 14 days post ovulation.[523] In a previous study of Thoroughbred mares in the United Kingdom, the rate of twin vesicles present at days 13 through 16 after ovulation was reported to be between 10.3% and 13.1%.[526] This was similar to a Swedish study (n = 430) in which the frequency of twin vesicles at days 14 through 15 was 10.5%.[527]

In the past, veterinarians often discouraged breeding of a mare when two large (>30 mm) follicles were palpated or to recheck the second follicle 10 to 12 hours after the first detected ovulation.[528] Because an ovulated oocyte is less likely to result in a viable embryo after this time, a delayed breeding could be performed in anticipation of the second ovulation. Today it is recommended to breed all eligible mares irrespective of the number of preovulatory follicles and perform a thorough pregnancy diagnosis between 13 and 16 days. The widespread adoption of early ultrasonographic pregnancy examinations has permitted the focus to be placed on embryonic vesicle reduction after the presence of a twin pregnancy is confirmed.

Manual Reduction

The increasing size of the embryonic vesicle, coupled with the increasing tone of the early pregnant uterus, will lead to the fixation of the conceptus at the base of one uterine horn by day 16.[4] When performing pregnancy diagnosis in mares, particularly during the first 100 days of pregnancy, it is essential that the ultrasonographic examination of the uterus is thorough, ensuring a complete evaluation of both uterine horns and the uterine body extending back to the cervix. This is especially important before day 16, because the vesicle moves freely within the lumen of both horns and the uterine body.[525] If twin vesicles are detected, then manually separating them before day 16 will be easier. Successful elimination of one vesicle is more likely at that time because the uterine walls are thin and minimal pressure is required to crush a vesicle.[529] A definite *pop* can often be felt when the vesicle ruptures, but success always should be confirmed by ultrasound. This sensation is attributable to the rupture of the embryonic capsule.[4,530]

The downside to this approach is that an early embryonic vesicle can easily be confused with an endometrial cyst. The embryo itself does not become readily identifiable until the fourth week of pregnancy (i.e., embryo proper and beating heart). Thus it is good practice to note the size and location of any cysts at the time the mare is being examined for breeding. Uterine cyst mapping is more easily performed post ovulation when the uterine horn becomes more toned because of the increasing progesterone concentrations. Interestingly, some cysts change shape according to the uterine tone. The printing of high quality pictures of the cysts or the ability to record them in a flash drive connected with the ultrasound machine has proven particularly useful in mares with excessive lymphatic cysts. If there is no record of cyst size and location, then it is virtually impossible to distinguish early twin vesicles from a singleton and a cyst with a single examination. This is especially true because asynchronous ovulations are likely to result in considerable size discrepancy between the two vesicles.[4]

If the clinician evaluates a mare at first pregnancy diagnosis and there is a suspicion of twins but no lymphatic uterine cysts mapped, it is recommended that the clinician record the size and location of each structure and reevaluate the mare in 1 or 2 days. In the next reproductive ultrasound, there will be little change in format of lymphatic uterine cysts, but embryonic vesicles should grow approximately 4 mm per day and are likely to move.[530] Early diagnosis of twin pregnancies is paramount for the best odds to successfully reduce one of the embryonic vesicles before fixation because delays may make separation of unilaterally fixed vesicles more difficult because of their ongoing growth and the increased uterine tone.

Manual reduction of bilaterally fixed vesicles requires less manipulation than with unilateral twins. It is a relatively easy procedure, and success rates exceeding 90% are not uncommon if the vesicle is crushed before day 16.[529,531] After fixation a success rate of 75% is still possible if the bilateral twin is crushed before day 30.[529] If the vesicles are unilaterally fixed, then the clinician should attempt to move the more proximal vesicle toward the tip of the uterine horn. At this location the manual reduction procedure is less likely to disrupt the remaining vesicle. The vesicle can be crushed by pinching it between the thumb and fingers. Alternatively, the vesicle is squeezed against the mare's pelvis using the ultrasound probe or fingers until it ruptures. If the twins can be separated before crushing, then the success rate may be similar to that for reduction of bilateral twins. If the unilateral twins cannot be separated or are greater than 20 days' gestation, then the success rate is lower.[532] After fixation and with unilaterally fixed vesicles (<20 days), it is the authors' preference to reduce twin pregnancies using the "snowflake" method, which consists of applying pressure with the transducer until hyperechoic spots (resembling snowflakes) are observed within the embryonic vesicle. A perceived advantage of this method is that there is less manipulation of the uterus and therefore less possibility of trauma to the other vesicle. Potentially the damaged vesicle that presented the snowflake appearance will release the fluid from the yolk sac slowly, which will be less likely to dislodge the viable vesicle and cause the loss of both embryonic vesicles.

Because squeezing an embryonic vesicle results in increased concentrations of 15-ketodihydro-PGF($_{2\alpha}$) and cortisol,[533] most clinicians commonly administer a combination of antiinflammatories (flunixin meglumine 1.1 mg/kg q 24 for 3 days) and progesterone (150–300 mg/day per mare) or altrenogest (0.044 mg/kg) until pregnancy diagnosis at 25 days post ovulation.

Transrectal ultrasound should be used to identify twin pregnancies and to maneuver the embryonic vesicle toward the tip of the uterine horn or against the cervix in exceptional cases. For a large majority of twin reductions, the authors recommend using the transducer of the ultrasound to identify, manipulate, and squeeze the embryonic vesicle to be reduced. In certain mares, one of the authors (IC) recommends moving the embryonic vesicle toward the tip of the uterine horn with ultrasound and then squeeze one vesicle with the hand without the transducer. This seems to be particularly useful for small embryonic vesicles (~10–12 mm). If the practitioner is not able to comfortably separate vesicles that are next to each other, then it is recommended to recheck the mare within 1 hour or during the next day if the embryonic vesicles are not likely to be fixed the next day. Rechecking the mare the next day may enable the practitioner to reduce one pregnancy manually because the embryonic vesicles have grown in diameter and might be located in an easier location to perform manipulation and manual reduction.

The likelihood of success improves with experience.[529,530] If the unilateral vesicles are not detected until after day 20, then manipulations can easily result in the disruption of both vesicles. If the practitioner is not experienced in performing manual twin reduction, then the unilaterally fixed vesicles should not be the ones used to gain experience. The best option in these cases may be to wait and see whether natural reduction occurs or refer to a more experienced colleague.

Natural Reduction

There is negligible natural reduction of twins before day 15, when the vesicles are close to the end of their mobility phase.[4]

Thus manual reduction is the treatment of choice if twins are diagnosed before fixation. Almost three quarters (70%) of twin embryonic vesicles become fixed unilaterally, with only 30% of twin vesicles becoming fixed bilaterally.[534,535] When twin vesicles are dissimilar in size, there appears to be a much higher incidence of unilateral fixation. The larger vesicle is thought to serve as an impediment to the continued mobility of the smaller vesicle.[402] Fortunately, natural reduction to a singleton is far more likely with unilaterally fixed vesicles. More than 80% of unilaterally fixed twins are likely to naturally reduce to a singleton, with over half of these occurring between days 16 and 20.[6,158,159] On the other hand, the majority of bilaterally fixed vesicles will continue to develop. The proposed mechanism for reduction has to do with loss of apposition between the embryo's trophoblastic surface and the endometrium, especially if the embryo proper is adjacent to another vesicle.[402,534-537]

Pregnancy Termination with Prostaglandin

The probability of natural reduction occurring decreases significantly by day 40.[534,536] If natural reduction does not occur, termination of the early pregnancy with a PG injection may be considered. This should lyse the CLs that resulted from the double ovulation, and the precipitous decline in progesterone will bring the mare back into estrus. However, treatment failures have been reported, and successful termination of the pregnancy should be confirmed by ultrasound.[538] This treatment must be given before day 35 because once the endometrial cups begin to form, repeated PG injections may be necessary to terminate the pregnancy.[498] Owners should be aware that the mare is unlikely to return to normal ovulatory cycles until the cups are sloughed. In the interim, they secrete eCG, a hormone that causes the development of accessory CLs. As mentioned previously, mares with elevated eCG demonstrate erratic estrous behavior, unreliable follicular development, and unpredictable ovulation.

If a mare carries twins into the latter half of gestation, then it is quite likely that abortion will occur between 7 and 9 months. Induced abortion is not without risk, and owners should be aware of the potential for dystocia, cervical lacerations, and fetal membrane retention.[529] Although several researchers have investigated induction of parturition at term, few protocols for early termination of an advanced pregnancy have been published. The natural PG analog cloprostenol has been used at various doses and frequencies, but results are inconsistent with respect to efficacy and duration to fetal expulsion. Daels et al. administered cloprostenol (250 µg) daily until fetal expulsion or for up to 5 days in mares that were 98 to 153 days pregnant. Fetal expulsion occurred after two to three cloprostenol administrations.[498] The addition of intracervical PGE_1 on the second day may help dilate the cervix and hasten delivery.

In Argentina, polo pony breeders do not want male colts; thus a large number of embryo-recipient mares undergo induced abortion to terminate pregnancies of male fetuses following fetal gender determination by 60 days post ovulation. Recently, a new technique was introduced that consists of administering one dose of 500 µg of cloprostenol diluted in 10 mL of saline intracervically; this technique resulted in 100% of the 104 mares aborted within 48 hours. A follow-up study reported that 84.4% (27 of 32) of mares aborted in 48 hours following a single uterine infusion with cloprostenol.[539] The same study reported that most mares underwent 1 to 2 anovulatory cycles (57.2%), whereas about 37.5% apparently ovulated normally and 6.2% progressed to anestrus. Following abortion, 18 mares were reused as an embryo recipient and became pregnant after embryo transfer (mean 58 ± 4.4 days).[539]

Transvaginal Ultrasound-Guided Twin Reduction

Even though the advent of transrectal ultrasonography has dramatically improved the ability of veterinarians to make an early diagnosis of twin pregnancies, diagnostic errors still occur. This could be caused by an early pregnancy diagnosis when the second vesicle was too small to detect, incomplete examination of the entire uterus, poor image quality, or an inability of the clinician to differentiate two embryonic vesicles that are closely apposed to each other. If natural reduction does not occur or the diagnosis of twins is not confirmed until after 30 days, then transvaginal aspiration of one vesicle is an option.[529,532,540] The results are best if the procedure is performed before day 35 and preferably before day 25. Although spontaneous reduction of twin pregnancies can occur even after day 40, the probability of this occurring is low. Natural twin reduction is more likely to occur if an obvious size discrepancy between the two vesicles is present at this time.

If a transvaginal reduction is to be attempted, the mare should be treated with flunixin meglumine. Many clinicians will also administer oral altrenogest. Because sedation causes significant uterine relaxation, most clinicians use a lidocaine enema to reduce straining.[541] The transvaginal aspiration technique uses a 5.0-MHz or 7.5-MHz endovaginal curvilinear transducer. The transducer and casing should be cold disinfected or sterilized before use. The assembled unit is then placed in a sterile transducer cover that has been filled with sterile lubricating gel. The transducer is advanced aseptically until its footplate contacts the cranial vaginal wall, lateral to the cervix. The clinician grasps the pregnancy rectally and advances a sterile, 60-cm, 18-gauge spinal needle with an echogenic tip along the needle guide in the transducer casing. A dotted line on the ultrasound screen can be used to select a path for the needle entry into the embryonic vesicle. A sharp jab of the needle penetrates the vaginal wall, peritoneal lining, uterus, and ultimately the allantoic or yolk sac. A 60-mL syringe is attached to the needle, and the embryonic fluid is aspirated. Aspiration should be stopped when there is a danger of damaging the adjacent vesicle of unilateral adjacent twins. If a bilateral twin is being eliminated, then the needle can be moved within the vesicle until all detectable fluid has been aspirated. The success rate is better for bicornuate twin reductions.[529] Death of the remaining twin is most likely to occur within 2 weeks of the procedure. A recent retrospective study compared two techniques for reducing twin pregnancies by 35 to 45 days post ovulation. Both techniques used the transvaginal ultrasound-guided approach to either stab one of the embryos/fetuses or to aspirate the yolk sac or allantoic sac, and no difference in the results was found between the two techniques.[541] Experienced operators may achieve a live singleton birth in about one third of cases.

Craniocervical Dislocation

Results of postfixation twin reduction techniques have been inconsistent regarding the production of a single healthy foal. A craniocervical dislocation method entails dislocating the first cervical vertebra from the cranium, disrupting the ligamentous

attachments, and severing the spinal cord either through a flank incision or transrectally.[529] A transrectal approach may be performed on a sedated mare between 60 and 90 days, but the mare's body frame and operator's arm length may limit the ability to perform the procedure safely. For the transrectal approach, propantheline bromide (30 mg IV) is recommended to relax the smooth muscles of the uterus and rectum, and flunixin meglumine (1.1 mg/kg) is administered to inhibit PG release. Daily altrenogest (0.044–0.088 mg/kg) is recommended for 3 to 4 weeks following the procedure or until the beating heart from only one fetus is present. A surgical procedure has been used most frequently on twin pregnancies of between 2 to 4 months' duration, and the twin closest to the tip of the horn is selected for elimination. This technique is performed with uterine and fetal manipulation through a flank incision, which enables one twin to be reduced before complete placenta formation has occurred. This allows the remaining fetus to use the entire endometrial surface and to grow to its full potential. Interestingly, a fetus was reported as having a beating heart for as long as 7 weeks following craniocervical dislocation.[529]

Transcutaneous (Abdominal) Ultrasound-Guided Fetal Puncture

In advanced twin pregnancies (up to approximately 5.5 months), it is possible to attempt reduction by a transabdominal approach.[532] Fetal intracardiac injection of potassium chloride (KCl) is effective but requires accurate placement of the KCl into the fetal heart. Best results are obtained when the pregnancy is between 115 and 130 days. At this stage experienced operators can achieve a 50% success rate.[532] Procaine penicillin G can cause fetal death when injected into either the fetal thorax or abdomen, but the effect is not instantaneous. The advantage of the latter treatment is that it does not require precise placement of the injection into the fetal heart. Procaine penicillin G also reduces the likelihood of bacterial infection, and the injection can be visualized on the ultrasound screen. Mares should be started on oral altrenogest, systemic antibiotics, and flunixin meglumine on the day of the procedure. The antibiotic coverage and antiinflammatory medication should be continued for 3 days in uncomplicated cases.

A 3.0-mHz transducer can be used to image the 90- to 130-day fetus in the caudal abdomen, just cranial to the udder, and best results may be obtained after day 115.[532,542] Once the mare has been sedated, the uterus will relax, and the location of the fetuses will shift cranially. A sedative–analgesic combination that works well for this procedure is acepromazine (10 mg), xylazine (100 mg), and butorphanol (10 mg). The smallest or most easily accessible fetus is selected for reduction. The ventral abdomen should be surgically prepared and local anesthetic infiltrated at the puncture site. An 18-gauge, 8-inch spinal needle with stylet can be used for most fetal injections, but the length of the needle is determined by the depth of the fetus from the abdominal wall. Specialized needles with echogenic tips are available to provide better visualization via ultrasound.[529] Once the location of the selected twin's thorax is confirmed, the needle is introduced through the aseptically prepared skin, abdominal wall, and uterus. If procaine penicillin G is to be injected, then the needle may puncture either the fetal thorax or abdomen. Up to 20 mL is typically injected into the fetus. Fetal death should be confirmed the next day.[529,532]

Although the benefits of supplemental progestin therapy are debatable, many clinicians suggest that the mare be medicated for at least 2 weeks if the initial twin reduction has been successful. It is essential that fetal viability is checked regularly because supplemental progestogen therapy may interfere with normal pathways that facilitate elimination of the dead fetuses if both die. Most abortions occur within 1 to 2 months after the reduction procedure.[532] If the operator is experienced in the technique, between 40% and 60% of cases reported have resulted in delivery of a live foal, although it should be noted that conservative estimates in clinical practice are more likely and often the remaining twin experiences some degree of IUGR.[529,532] The eliminated twin in these cases can be seen as a mummified remnant contained within an invaginated pouch that protrudes into the allantoic space of the viable foal's fetal membranes. One theory for the loss of both twins after an intrafetal injection has to do with the presence of vascular anastomoses between the two fetoplacental units.[532] It has been suggested that circulation of either the injected solution or other tissue degradation products could result in the death of the adjoining twin fetus. Small anastomosing vessels are present between twin vesicles as early as 40 to 60 days' gestation.

EARLY PREGNANCY LOSS AND ABORTION

Embryonic Loss

Pregnancy losses occurring prior to day 40 of gestation are defined as embryonic losses, whereas losses beyond this point are considered fetal losses or abortions (Table 19.10).[4] According to the stage of occurrence, pregnancy wastage may also be classified as stillbirth (delivery of a dead foal ≥300 days of gestation), abortions (losses from 40 to 300 days of gestation), and neonatal losses (deaths during the first week or 60 days of life).

Between 10% and 15% of mares undergo embryonic loss or abortion at some time in gestation, and most of these losses occur during the first 40 days' gestation, when the primary CL is the sole source of progesterone.[526,543] However, current evidence suggests that untoward luteolysis is not common in this period as suspected, and the losses that do occur have other underlying causes. Luteal insufficiency/premature luteal regression has been documented, however, in mares as described above.[453,454]

In a study of 376 Thoroughbred pregnancies, 12.2% experienced embryonic loss within 45 days after ovulation,[544] whereas a much larger study (n = 3373 mares) reported a loss of 7.2% to 8.0% by day 42.[526] Three quarters of the losses in the smaller study occurred between 16 and 25 days, and the loss was highest in previously barren mares, followed by aged mares (>15 years) and mares of more than 10 parities. These results were similar to those reported by Swedish investigators.[527] Increasing mare age was the single biggest limiting factor to an otherwise high rate of fertility in the larger study of well-managed Thoroughbreds in the UK.[526] Higher embryonic losses may be expected in mares that are bred during the first postpartum estrus and in those with cysts in the uterus.

It is not easy to differentiate between fertilization failure and embryonic loss before day 10 because this is the earliest stage of development in which ultrasonographic detection is possible under ideal research conditions. Fertilization failure rates and embryonic losses are higher in aged mares.[545-549] Fertilization rates in young, well-managed mares may exceed 90%

TABLE **19.10 Causes of Embryonic Losses in Mares**

Intrinsic	Endometrial disease	Endometritis will have deleterious effects on the embryo, which may result in prostaglandin production and early return to estrus Endometrial fibrosis causes improper embryonic nutrition because the horse is highly dependent on uterine milk secretions for survival during the embryonary period Large lymphatic uterine cysts in the uterine lumen may result in improper endometrial signaling resulting in failure of maternal recognition of pregnancy Large cysts present at the base of the uterine horn may result in embryonary death caused by improper embryo nutrition from endometrial glands
	Progesterone insufficiency	Premature luteal regression or improper CL formation is thought to cause early return to estrus, and low progesterone concentrations in plasma affect secretions of proteins in the uterine milk and, consequently, embryonic growth
	Maternal age	Older mares have defective oocytes, advanced stage of endometrial fibrosis, more lymphatic and endometrial gland uterine cysts, and endometrial fibrosis, which are associated with higher pregnancy losses
	Lactation	Lactating mares experience higher rates of pregnancy loss, particularly if under poor nutrition
	Foal-heat breeding	Mares bred in the foal heat have higher rates of embryonic losses, particularly if the mare ovulates before day 9 postpartum, resulting in arrival of the embryo in utero while the endometrium has not been completely regenerated
	Postovulation breeding	Breeding post ovulation results in higher pregnancy losses, probably related to oocyte aging
	Site of intrauterine fixation of the embryonic vesicle	Embryonic vesicles fixed at the uterine body, particularly the caudal body, present higher incidence of pregnancy loss; this condition is known as "body pregnancy"
	Maternal chromosomal abnormality	Mares carrying chromosome abnormalities are prone to producing defective embryos, which result in embryonic or early fetal loss
	Embryonic defects	Embryos presenting with morphologic abnormalities and underdeveloped for the stage of development result in higher embryonic losses
Extrinsic	Stress	Stress will result in an increase in cortisol concentration and potentially reduction of LH and luteal function, or it may result in ovulation failure
Nutrition		Poor nutrition is associated with reduced progesterone and higher rates of embryonic losses
Season/climate		Anecdotally severe weather (heat/cold) is thought to result in higher pregnancy loss Under experimental conditions mares exercised under intensive Texas weather had a reduced embryo recovery rate compared with mares without exercise, and they tended to present more grade II embryos
Embryo manipulation		Embryo transfer, in vitro–produced embryos, or embryos resulting from ICSI are thought to result in higher pregnancy rates

CL, Corpus luteum; *ICSI,* intracytoplasmic sperm injection; *LH,* luteinizing hormone.

and appear to be over 80% in aged mares.[547,550] Oocytes from aged mares may be more likely to result in nonviable embryos because of inherent morphologic defects.[547,551] Carnevale transferred oocytes from young and aged mares into young recipients so that fertilization and early embryonic development occurred in an optimal oviductal environment. The day-12 pregnancy rate in the recipients that received the oocytes from aged mares was significantly less than that achieved with the younger mares' oocytes.[552] Research has shown that embryo recovery rates are considerably lower in aged mares and that there are significant losses occurring before day 14 of pregnancy.[545,553-555]

The uterine environment may not be the only reason for subfertility in some mares. Embryos collected from normal mares resulted in similar pregnancy rates in both fertile and subfertile recipients (advanced stages of endometrial pathology) at day 28.[556] In a reversal of study design, embryos were collected from the oviducts of normal and subfertile mares 4 days after ovulation and then transferred into normal recipients. Pregnancy rates were lower in those normal mares that received embryos from the subfertile donors.[553] Thus, although the uterine environment may have a delayed effect on embryonic and fetal loss, it appears that oocyte quality and oviductal influences play a significant role in the problem of subfertility and early embryonic loss in mares.[557] In practice, embryonic losses that may be detected between days 14 and 40 can range between 8% and 15% in young, well-managed mares to 25% or 30% in aged mares.[526,550,558] The presence of endometrial inflammation and uterine fluid accumulation will have a detrimental effect on early embryo survival and can markedly increase the likelihood of early pregnancy loss.[83,85,544]

Early Fetal Loss

In one study of Thoroughbred mares, only 4% to 6% of pregnancy losses occurred between day 40 and day 150 gestation, and only a further 2% to 3% occurred before term.[526]

Formation of the endometrial cups is a defining moment related to early pregnancy loss in mares. If the embryo dies before day 35, the chorionic girdle cells do not invade the endometrium, and the endometrial cups do not form. These mares should return to normal estrous cycle activity and may be successfully bred again during the same breeding season. However, if the fetus is lost after day 40, the endometrial cups are irreversibly established.[4] Thus, mares that lose the pregnancy after day 40 following endometrial cup formation will have elevated eCG concentrations until those endometrial cups slough between days 120 and 140 of gestation. This will result in a false-positive blood test for pregnancy using an assay for eCG. Retention of the endometrial cups after fetal loss results in erratic estrous behavior, unreliable follicular development, and unpredictable ovulation.[161] Thus this unique physiologic mechanism typically prevents mares suffering fetal loss after endometrial cup formation from being bred back during the current breeding season.[160]

Pregnancy losses in mares may be multifactorial and difficult to determine. Beyond day 40 of gestation the secondary corpora lutea receive powerful luteotropic support from eCG, which results in increased progesterone concentrations. This makes the corpora lutea resistant to luteolysis as multiple exogenous doses of prostaglandin may be required to induce abortion. From day 80 to 100 until term the supply organ (placenta) and target tissues (endometrium and myometrium) are in direct contact with one another over their entire surfaces. Little evidence suggests that a deficiency of progesterone production is a cause of pregnancy loss in the mare.[543] Certainly, fetal death may follow uteroplacental insufficiency or an overwhelming sepsis.[559] In recent years there has been a general consensus that the inflammatory mediator $PGF_{2\alpha}$ may play an integral role in many cases of pregnancy loss. It is well known that PGs are luteolytic and increase uterine contractility. Thus, in the first 70 to 80 days, when the pregnancy depends on progesterone production by the corpora lutea (primary and accessory), the mare is especially susceptible to the luteolytic effects of PGs. It is important to remember, however, that repeated exogenous PG injections may be required to electively terminate a pregnancy once the endometrial cups have formed. This is because some of the immature accessory CLs may not be sufficiently developed to respond to the first PG injection. Another probable abortigenic feature of PGs may be myometrial hypermotility. This may be associated with placental inflammation or high systemic levels of PG.

An early pregnancy may be lost subsequent to PG-induced luteal deficiency associated with endotoxemia.[560,561] The detrimental effect of the endotoxin could be prevented only if a COX inhibitor (flunixin meglumine) was administered before clinical signs of endotoxemia were evident.[498,562,563] Thus, although gram-negative septicemia and endotoxemia associated with many gastrointestinal crises are known to result in elevated levels of inflammatory mediators, any pregnancy-sparing effect of PG inhibitors is likely to be effective only if antiinflammatory agents such as flunixin meglumine are administered in the acute phase of the disease.[559] Because a healthy fetoplacental unit can produce enough progesterone to sustain the pregnancy after 80 days' gestation, the concept of prophylactic altrenogest past 3 months of gestation is controversial.[371,498,543,563]

Although recent in vitro studies suggest that progesterone may not be the primary regulator of myometrial quiescence, in situations in which elevated PG levels are likely, there appears to be adequate clinical justification at present to provide exogenous progestogen support for high-risk pregnant mares.[502,564] Based on current knowledge, the administration of a double dose (0.088 mg/kg/day) of altrenogest is suggested during the acute phase of a medical or surgical condition when PG levels are likely to be elevated.[565] If oral medication is not possible, then short-term use of progesterone in oil (300 mg/day IV) is warranted. An IM injection of a compounded long-acting progesterone formulation (BioRelease P4 LA 150 mg/mL) every 7 days may also be an efficacious and suitable alternative to currently available progesterone formulations that require daily administration.[372] In the author's practice, LA P4 is used in situations where daily dosing is not possible or not reliable. Mares at high risk for imminent abortion should preferably receive short-acting progestogens.

Administration of supplemental progesterone is based on further work by Daels et al. demonstrating that progestin treatment could prevent PG-induced abortion at 3 to 5 months of gestation if a higher dose of progestin (0.088 mg/kg altrenogest) was administered.[498,563] Abortion did not occur in five of eight progesterone-treated mares and eight of eight altrenogest-treated mares, and endogenous $PGF_{2\alpha}$ secretion was inhibited, compared with values in aborting mares. It was concluded that circulating progestogen concentrations may play a role in the outcome of pregnancy during PG-induced abortion, which may occur after exposure to endotoxin.

It seems logical that separation of the chorioallantois from the endometrium will disrupt local endocrine function. The fetoplacental unit does attempt to compensate for this placental dysfunction by increasing progesterone production.[564,566] However, endotoxemia may harm placental circulation and disrupt vital steroid metabolism within the fetoplacental unit. Thus administration of flunixin meglumine to pregnant mares is indicated early in the course of any condition in which endotoxemia is possible.[567-569] If a mare develops a surgical colic condition during late pregnancy, then the fetus is at risk not only from the maternal endotoxemia that can be associated with gastrointestinal crises but also from any maternal hypoxic episodes that may occur during anesthesia.[568,570-572] Acute enteritis or colitis in a pregnant mare can also result in abortion caused by the effects of endotoxemia.[570,572] Because maternal hypoxia is a risk factor for abortion, intraoperative hypoxia must be avoided if a pregnant mare requires surgery. Approximately 16% to 20% of mares can be expected to abort after colic surgery, but superior intraoperative ventilation and oxygenation techniques may reduce this risk.[570,572] Stage of gestation and duration of anesthesia are less critical factors if maternal oxygenation is adequate. Apparently, aberrations in the cardiovascular and metabolic status of the mare and fetus are more detrimental to pregnancy maintenance than the actual medical or surgical condition.

Mare Reproductive Loss Syndrome

In the spring of 2001, an epidemic reproductive crisis affected the equine breeding industry in central Kentucky, southern Ohio, West Virginia, and Tennessee and ultimately cost hundreds of millions of dollars. Mares foaled prematurely with premature separation of the chorioallantois (late-term "red bag" abortions). Many mares that were approximately 45 to 80 days pregnant suffered acute fetal loss, and most affected mares failed to resume normal cyclic activity until after the official breeding season had closed because endometrial cups had been formed before the occurrence of mare reproductive

loss syndrome (MRLS).[573] The Appalachian region to the north also reported a high number of similar cases. Reports of weather patterns and an unusually high emergence of eastern tent caterpillars (ETCs; *Malacosoma americanum*) were identical in both the central Kentucky and southeast Ohio regions.[574] The epidemic that affected the horse industry in the Ohio Valley in late April and early May of 2001 and 2002 became known as MRLS.

During the initial outbreak, the state diagnostic laboratory was inundated with late-term aborted fetuses, and practitioners identified approximately 2000 early fetal losses.[575] Many of these were detected during what should have been a routine fetal gender determination. Fortunately no contagious infectious cause was identified, and this newly recognized disease became self-limiting as the breeding season progressed. Veterinarians and scientists involved in the epidemic considered the possibility of mycotoxins, ergot alkaloids, phytoestrogens, and even cyanide from wild cherry tree foliage.[576-578] A temporal correlation was established between MRLS and the presence of ETCs.[573,576,579-590] Mares inadvertently ingest ETCs when large numbers are present on pasture, hay, or in the water supply. Abortions consistent with MRLS can be induced by oral administration of whole ETCs or their exoskeletons, which contain hairs (setae). Ingested setae embed into the submucosa of the gastrointestinal tract. Fetal loss occurs when bacteria from the alimentary tract *(Streptococci, Actinobacilli)* establish infection in which the local immune system is compromised (the fetoplacental unit). Management strategies for controlling ETC have been proposed to reduce the risk of MRLS.[575,583] A similar abortion syndrome in Australia is associated with ingestion of hairy processionary caterpillars *(Ochrogaster lunifer)*.[590]

Placentitis

Placentitis is a major cause of pregnancy loss in late-term pregnant mares.[178,591,592] Inflammation of the placenta can affect the interchange of gases, nutrients, and waste products along with disruption of both fetal metabolic and endocrinologic pathways.[593] In recent years, controlled studies and clinical observations from various laboratories and practices across the world have contributed to major advancements in the recognition and treatment of equine placentitis. The reader is referred to recent comprehensive reviews for additional, more detailed, information.[594,595] Four types of placentitis are described based on macroscopic lesions: ascending (focal extensive), nocardioform (focal mucoid), diffuse (hematogenous), and multifocal.[594]

The disease tends to be a sporadic, individual mare problem that seldom has any lasting effect on mare fertility. Both bacterial (*Streptococcus zooepidemicus, S. equisimilis, E. coli, Enterobacter agglomerans, P. aeruginosa,* and *K. pneumoniae*) and fungal (*Aspergillus* spp.) organisms may be the cause. Overall, ascending placentitis is the most common type observed worldwide. [594] Ascending infection results in necrotizing and suppurative inflammation of the chorioallantois that may lead to detachment of the placenta in the area surrounding the cervical star and ventrally toward the uterine body. [594] At the time of diagnosis, the cervix is usually soft, and purulent exudate may be found draining into the vagina. Because the cervical star is the most common site of placentitis in mares, this part of the fetal membranes should be thoroughly and closely examined after abortion and at any foaling. The vestibular sphincter, cervix, and vulvar lips are important barriers to prevent ascending infections. Many aged mares require a Caslick procedure and cervical reconstruction to prevent the likelihood of ascending infection. Young mares, however, with apparently appropriate vulvar conformation and intact cervix may also develop ascending placentitis. The most commonly isolated bacteria are beta hemolytic streptococci (*Streptococcus equi* subsp. *zooepidemicus* or *equi*), *E. coli,* and *Enterococcus* spp., although a broad range of other bacteria have also been isolated from affected mares. In some horses, mixed bacterial and fungal infections occur; it has been suggested that the fungal infection occurs secondary to a primary bacterial infection.[594]

Focal mucoid placentitis is characterized by lesions located in the base of the uterine horns and uterine body.[596] It is commonly associated with nocardioform placentitis in which the fetal lungs are also affected with suppurative lesions, but other microorganisms (e.g., *Cellulosimicrobium cellulans*) can cause similar lesions.[597] Nocardioform placentitis was first diagnosed in mares in central Kentucky in 1986 as a sporadic cause of abortion and weak foals. Since that time, it has been described in mares in Florida, Italy, South Africa, and Australia.[594,596] The number of confirmed cases of nocardioform placentitis has varied widely from year to year, with more than 400 cases in central Kentucky in 2011.

Nocardioform placentitis is associated with gram-positive branching actinomycetes including *Crossiella equi* and *Amycolatopsis* spp. It has been suggested that these microorganisms may gain access to the uterus at breeding, but this unusual form of equine placentitis does not become apparent until the latter part of gestation.[598] The initial lesion is localized on the most dependent aspect of the chorion in the cranioventral aspect of the uterine body and subsequently extends cranially into the base of the horns and circumferentially around the placenta.[596] Outcomes vary from abortion to birth of a normal foal. Some foals are born prematurely, whereas others are delivered at term but may be stillborn or weak with an emaciated appearance.[594,596, 598] Vaginal discharge is not a feature of this condition because the region of the placenta including the cervical star is not involved. After the fetus has been expelled, affected mares rapidly clear the infection and usually experience no adverse effects on subsequent fertility.[594,596,598] When the fetal membranes are examined, there is an obvious line of demarcation between pathologic and normal tissue, with the affected area being covered by a characteristic thick, brownish, mucoid, viscous material.[594,596,598] The underlying chorionic villi are reduced in size, and in the central portion of the lesion, the chorionic surface may be completely denuded.[594,596,598]

Leptospira spp., the most common cause of hematogenous placentitis,[594] causes diffuse lesions with large numbers of spirochetes in the affected placental tissues.[596] Its occurrence is rather sporadic, but outbreaks have been described.[594,596] Late-term mares may abort with no premonitory clinical signs, and occasionally an infected premature or full-term weak, icteric foal may be delivered. The placenta is edematous, with a necrotic chorion covered with a mucoid exudate.[178,596,599] The gross placental lesions are associated with thrombosis, vasculitis, and inflammatory cell infiltrates. The spirochetes tend to be numerous and are readily demonstrated in the stroma and villi of the placenta.[596,599] A microscopic agglutination test (MAT) on fetal fluids (heart and body cavities) or maternal serum is likely to reveal a high titer (1:6400-1:819,200 or greater).[600] Leptospires may be detected in the fetus by the fluorescent antibody test (FAT), silver staining, or darkfield

microscopy.[600] Immunohistochemistry is more sensitive than silver staining and more specific than serology (MAT).[601,602] The fetal kidney should be submitted for a FAT because this tissue yields the highest percentage of positive results and is also the best tissue for culture.[596,603] If urine is to be submitted from an infected mare (FAT or darkfield analysis), it is important to obtain collection instructions and an appropriate transport medium from the diagnostic laboratory. The specimen must be obtained before any antimicrobial therapy has been administered. A recent retrospective study demonstrated that PCR is the most sensitive method in diagnosing *Leptospira* spp. in abortion cases.[600]

In the genus *Leptospira,* the species *L. interrogans* contains several pathogenic serogroups (common antigens) and serovars (specific strain). Serogroups consist of closely related serovars. The predominant serovar affecting horses varies with country and region. The *Bratislava* serovar is most commonly isolated from aborted fetuses in Northern Ireland, but in central Kentucky most leptospiral abortions have been associated with the *Pomona* serogroup, occasionally the *Grippotyphosa* serogroup, and rarely the *Hardjo* serogroup.[600,604] Equine leptospiral infections previously reported as being *L. pomona* are now thought to be more correctly identified as *L. interrogans* serogroup *Pomona* serovar *Kennewicki* and *L. kirschneri* serogroup *Grippotyphosa* serovar *Grippotyphosa*.[600,604] In North America pregnant mares are considered to be incidental hosts that become infected after exposure from maintenance hosts (i.e., wildlife such as skunks and raccoons for *Kennewicki* and *Grippotyphosa* and cattle for *Hardjo*).[600,604] Infected mares may shed leptospires in the urine for up to 14 weeks.[604] Thus therapy is aimed at prevention of urinary shedding and possibly prophylactic treatment of pregnant in-contact mares that have high titers. A combination of penicillin (10,000 to 15,000 IU/kg, administered intramuscularly) and streptomycin (10 mg/kg administered intramuscularly) every 12 hours for a period of 1 week has been recommended, but streptomycin is no longer widely used in equine practice. High doses of potassium penicillin G (20 million units IV every 12 hours) may be effective in preventing infection of a fetus if the mare has a high titer, but this recommendation has not been validated in controlled studies. The dosage and duration of treatment appear to be important. Oxytetracycline (5 to 10 mg/kg) has also been suggested, but it was less effective at preventing urinary shedding of leptospires in all cases tested (5 of 7 infected mares).[605] Anecdotally, doxycycline and enrofloxacin have been used in clinical practice as tools to prevent abortion in mares exposed to other mares aborting with leptospiral infections, but it is important to note that to date neither drug has been proven to be safe to the fetus or efficacious at treating and preventing placentitis in mares.

An approved vaccine for leptospirosis recently became available for horses in the United States, but its efficacy for prevention of abortion has not been assessed. Attempts should be made to prevent direct contact between maintenance hosts and pregnant mares and also to prevent exposure to urine infected by these species (e.g., contaminated water and feed).[594] It may be prudent to vaccinate mares with the equine vaccine if they reside on the same property as pregnant mares with confirmed leptospiral abortion and to isolate aborting mares.[594,596]

Rhodococcus equi has been incriminated as the cause of placentitis and abortion in mares.[606] *Mycoplasma* spp. have been associated with infertility, endometritis, vulvitis, and abortion in mares.[607] *Nocardia* spp. have been described as a cause of placentitis in two mares in Florida. Lesions were similar to nocardioform placentitis, but foals were born with suppurative lung lesions.[608] Cases of mycobacterial abortion and placentitis were confirmed by microbiologic techniques, PCR, and immunohistochemistry.[609] The atypical mycobacteria were within the nontuberculous group and classified as saprophytic and opportunistic microorganisms acquired from the environment (soil, water, and decaying vegetation).[609,610] Gross lesions observed within the submitted cases varied from none to those of a "nocardioform-like" placentitis. Affected fetuses exhibited varying degrees of malnourishment and chronic placentitis. Several fetuses had granulomatous to pyogranulomatous pneumonia, and one fetus without pneumonia contained disseminated granulomas in various organs.[609,610]

Cellulosimicrobium cellulans is a gram-positive branching bacillus that is an opportunistic microorganism found in the soil.[597] The nine described cases of equine abortion and placentitis resulting from *C. cellulans* had nocardioform-like placentitis lesions as well as granulomatous pneumonia. Because atypical *Mycobacteria* and *C. cellulans* organisms can cause similar gross and histologic lesions within the fetus and placenta, they should be considered as differential diagnoses when gross placental lesions suggestive of nocardioform placentitis are encountered.[597,609,610]

Protozoal Abortion

There is limited information available on the association between equine *Neospora* infections and abortions.[611-616] However, the apicomplexan protozoan parasite *Neospora caninum* has been recognized as a major cause of abortion in cattle.[616] Antibodies against *Neospora* spp. have been described in mares that recently aborted.[614] Using an agglutination test, researchers found that the number of animals with elevated (>80) anti-*Neospora* spp. antibody titer was higher in a group of 54 aborted mares than in a randomly chosen group of 121 mares ($P < 0.001$). *N. caninum* DNA was found in 3 of 91 fetal brains, 2 of 77 fetal hearts, and 1 of 1 placenta and was present in both brains and hearts of two fetuses. The mere presence of the organism in an aborted fetus does not necessarily implicate it as being the cause of the abortion.[616] Antibodies to *Neospora* spp. were detected in the sera from 11.9% of 800 asymptomatic horses in Israel and from 37.5% of mares that aborted.[617] Antibodies to *Neospora* spp. have also been detected in mares in Brazil.[612] Further investigations will be needed to determine whether there is an association between equine reproductive failure and *Neospora* spp. infection.[612,615]

Viral Abortion

Equine arteritis virus (EAV) and equine herpesvirus 1 (EHV-1) are the most important causes of viral abortion in horses in the world. Both viruses are associated with acute respiratory tract infection and are discussed in detail in Chapter 8.

EAV is transmitted through inhalation or venereally in the semen of asymptomatic (shedder) stallions.[618-623] Abortion may occur if pregnant mares become infected in the later stage of gestation (5–10 months).[619,622,624,625] Clinical signs are variable but may include fever, conjunctivitis, nasal discharge, and dependent edema that is associated with vasculitis.[618,620,626] Clinical signs are mild or subclinical in many horses and may be clinically indistinguishable from other respiratory infections. Viral myometritis with degeneration of myocytes and infiltration of mononuclear cells leads to transplacental

infection of the fetus.[627] Affected placentae are edematous, and degenerated fibroblasts may be observed in the subvillous layers. Lesions in the fetal tissue include an atrophy of the lymphoid follicles in the spleen and lymph nodes with degenerated lymphocytes. Immunofluorescence can detect EAV antigen in the myometrium and the endometrial glands in the dams, in the subvillous layer of the placentae, and in the aborted fetuses. The virus may be recovered from the uterus and fetus, but the placenta is likely to yield the greatest amount of the virus. The disease may be controlled by an effective vaccination program and screening tests.[618]

Most abortions associated with herpesvirus are caused by EHV-1, but occasional abortions are associated with other equine herpesviruses.[592,628] The number of abortions resulting from EHV-1 infection has declined over the past 20 years, and isolated abortions, rather than abortion storms, are now a more common feature of this disease.[629] This is due to the widespread adoption of stringent vaccination programs in combination with improved management practices on broodmare farms.[630,631] Pregnant mares should be vaccinated with an approved vaccine at 5, 7, and 9 months of gestation. Many farms also vaccinate at 3 months. New arrivals should be isolated for 3 weeks, and groups of pregnant mares should be isolated by stage of gestation. It is especially important to segregate pregnant mares from weanlings and other horses.[632]

EHV-1 can infect the fetus if a mare is viremic during pregnancy. The virus causes abortion as a result of the rapid detachment of the placenta.[633,634] Endothelial cells in the endometrium and allantochorion are often infected by the virus, with accompanying vascular lesions. The fetus can be infected by way of the chorionic vasculature or by inhalation of infected amniotic fluid.[635-637] Abortion may occur soon after the mare is infected or several weeks have elapsed. Therefore maternal serology is of little diagnostic value.[638] The aborted fetus will be fresh, with copious amounts of pleural and peritoneal fluid. The trachea may contain a fibrin clot. Small necrotic foci may be discernible on the swollen liver. A hyperplastic, necrotizing bronchiolitis may be seen in lung sections, and large intranuclear eosinophilic inclusion bodies are a characteristic histologic lesion. Although vaccination is widely practiced, owners should be aware that the protection is not absolute. If a pregnant mare is exposed to infected animals that have recently been to a show or that are returning from a training facility, then it is possible that any protective immunity conferred by the vaccine will be overwhelmed. Abortions have been associated with reactivation of latent virus that was induced by transport stress.[639] Therefore a history of regular vaccination of an aborting mare does not eliminate the possibility of a herpesvirus-related abortion. Neutralization and indirect immunofluorescence tests, as well as PCR and virus isolation, are used for EHV-1 diagnostics. Antigen detection, in combination with virus isolation and PCR from fetal lungs, gives reliable results. More detailed reviews have been published, and the reader is referred to these for a more in-depth discussion.[640,641]

A number of other acute viral infections have been associated with abortion in horses, especially if the horse suffers severe systemic illness at the time of initial infection. For example, mares may abort as a result of the systemic effects of acute infection with equine infectious anemia virus (EIAV), although it is not generally considered an abortigenic virus.[642] When widespread vaccination against West Nile virus was adopted in the United States, some suggested that the killed virus vaccine that was used might result in abortions, stillbirths, and deformities in foals. However, subsequent critical review clearly demonstrates that vaccination of pregnant mares during any period of gestation is not associated with an increased incidence of pregnancy loss.[643]

Treatment of Placentitis

Under field conditions, placentitis is diagnosed in mares presenting with compatible clinical signs of premature mammary gland development and vulvar discharge (with ascending placentitis). These clinical signs should prompt the practitioner to perform a transrectal palpation and ultrasonographic examination. Typically mares presenting with signs of placentitis will have demonstrable placental thickening and separation of the placenta from the endometrium.[594]

Placentitis is detrimental to the pregnancy not only because it disrupts nutrient exchange but also because of the inflammatory mediators (proinflammatory cytokines) that are released. The exact cause of fetal expulsion is not known, but ensuring myometrial quiescence is central to most therapeutic regimens.[505,644] Placentitis cases have substantially increased concentrations of $PGF_{2\alpha}$ and PGE_2 in the fetal fluids.[645,646] Thus antiinflammatory medication (flunixin meglumine at 1.1 mg/kg; phenylbutazone at 4 mg/kg, every 12 hours) is generally recommended,[647] although there are no controlled studies to specifically demonstrate their efficacy. [594] Placentitis associated with early abortions tends to be acute, with the fetus succumbing to bacteremia with no to minimal placental lesions.[648]

Broad-spectrum antibiotics that have been recommended for treatment of equine placentitis include trimethoprim-sulfadiazine (15–30 mg/kg PO every 12 hours), procaine penicillin (30,000 IU/kg/day) and gentamicin (6 mg/kg/day), and ceftiofur (1–5 mg/kg, every 12 hours).[647,649-651] Ceftiofur has been used for treatment of placentitis, but a recent study demonstrated that this drug does not cross the placenta and was ineffective for treatment of experimentally induced placentitis. [652] Gentamicin was undetectable in the plasma of newborn foals after mares were treated with the antibiotic (6.6 mg/kg) an hour before parturition, and it was initially believed that gentamicin does not cross the placenta of mares at term.[653] Murchie et al. monitored drug concentrations in the allantoic fluid of pregnant pony mares using in vivo microdialysis to determine whether this method could detect allantoic concentrations of drugs in normal mares and those with placentitis.[654] Pharmacokinetic comparisons indicated that potassium penicillin G (22,000 IU/kg q.i.d.) persists much longer in allantoic fluid than blood, whereas gentamicin (6.6 mg/kg/day) exhibited similar profiles in the two compartments. Flunixin meglumine (1 mg/kg b.i.d.) was not detected in allantoic fluid. In infected mares penicillin G achieved a similar peak concentration in allantoic fluid, whereas peak gentamicin concentration appeared to be reduced relative to drug concentrations in noninfected mares. Thus penicillin G and gentamicin appear to undergo effective placental transfer in pregnant mares, but transplacental drug transfer may be altered selectively if active placental infection is present.

If the localized production of high concentrations of prostaglandins stimulates the formation of gap junctions, then the subsequent myometrial hypermotility may impede placental blood flow as the uterus contracts.[505,644,655] This will reduce fetal oxygenation and increase fetal stress. Because it is known that progesterone inhibits gap junction formation,

it has been suggested that progestin supplementation may be beneficial when uteroplacental inflammation is suspected.[594] This is the rationale behind the current recommendation to treat suspected placentitis cases with a double dose of altrenogest (0.088 mg/kg/day).[594,647] Delaying premature labor long enough to allow accelerated fetal maturation may improve foal survival rates.[656]

A primary goal in the treatment of placentitis is to delay premature labor long enough to allow accelerated fetal maturation to occur, with the goal of improving foal survival rates.[594] The progestogens may enhance the activity of the endometrial enzyme 15-hydroxyprostaglandin dehydrogenase and thus promote rapid metabolism of PGs into inactive metabolites.[368,564] Although altrenogest is not metabolized to 5α-pregnanes, both 5α-DHP and 3β-5P levels may be increased as a result of supplementation.[657] However, Ousey and others have suggested that progesterone supplementation may be contraindicated because high levels could inhibit the placental enzyme 3β-hydroxysteroid dehydrogenase.[368,564,658] This enzyme produces progesterone from pregnenolone; thus inhibition could interfere with the normal fetoplacental steroidogenic pathway. At present this widely used therapy remains controversial, and even if it does no harm, the expense of long-term progestin supplementation may not be warranted in many cases. Essentially, the use of hormone therapies is subjective and to a large extent reflects lack of understanding about the endocrine relationships among the mare, placenta, and fetus.

The rationale for other treatment regimens is based on extrapolations from the human medical literature and application of sound reasoning for the potential efficacy of a particular drug. Scientific investigation in this area is crucial. Previously, an oral β_2-sympathomimetic drug (clenbuterol) has been suggested to suppress uterine motility in mares with placentitis.[647,659] In the United States the product is marketed as an oral formulation to treat chronic reactive airway obstruction. Research is needed to determine what oral dose of this bronchodilatory compound, if any, is actually effective on the gravid uterus. In countries in which an intravenous formulation is available, a 300-μg IV dose of clenbuterol will reduce uterine tone for approximately 2 hours.[660,661] However, daily IV administration of clenbuterol to mares showing maximal milk calcium levels was not effective in preventing the onset of myometrial contractions and delivery in normal foaling mares at term.[662]

The administration of pentoxifylline (8.5 mg/kg PO b.i.d.) is questionable. While it does not seem to improve perfusion in the mare reproductive tract,[663,664] some clinicians advocate it because it is used in humans to treat tissue ischemia, because of its ability to modulate the inflammatory process by downregulating proinflammatory cytokines, and because of its possible effect on erythrocyte deformability.[647,649,656] Pentoxifylline appears to have good uterine penetration and has been detected in the allantoic fluid of mares.[650,651] Despite these conflicting studies, a multipronged approach (i.e., antibiotics, antiinflammatory agents, altrenogest) to long-term therapy for placentitis may improve fetal survival and foal viability.

Noninfectious Causes of Abortion

Twins

In North America the incidence of twin abortions has decreased significantly because of early intervention after ultrasonographic diagnosis of a multiple pregnancy.[178,529,532] Before the widespread adoption of this technology, twin abortions were a major cause of fetal loss.[441,442] A large European study (n = 12,648 pregnancies) of Thoroughbred mares revealed a twinning rate of 3.5%, with 443 twins and only two triplets.[665] The type of placentation in the mare (diffuse, microcotyledonary) makes it highly unlikely that a twin pregnancy will be carried to term. Obviously there is a finite endometrial surface area available for allantochorion attachment. The more common unicornuate twin vesicles are a problem, because one conceptus is inevitably restricted to the proximal aspect of the gravid horn.[421] Thus the two conceptuses are literally in a deadly competition for adequate nourishment and subsequent placentation. If the twin pregnancy is maintained until the latter part of gestation, the nutrient demands of the rapidly growing fetuses outstrip the placental attachments. Fetal growth is such that nutrient demands may be met until the latter half of gestation, when the marked fetal development in the last trimester usually requires more exchange capability than the smaller placenta provides. The fetus becomes stressed as it becomes progressively emaciated and ultimately dies.[529,666] Death of one fetus or both fetuses is followed by abortion, with the characteristic avillous areas on the fetal membranes confirming the amount of placental disruption.[178,442,522] Affected mares develop premature mammary enlargement and may "run" milk before aborting. Transabdominal ultrasonographic evaluation may be useful to confirm the diagnosis at this late stage. Although the area of apposition of the two chorioallantoic membranes (twin membrane) may be seen, measurement of fetal thoracic diameters and heart rates can confirm the diagnosis of twins.[666] Twin abortions in the last few months of gestation are likely to cause a dystocia. Bicornuate twins are more likely to survive, because each membrane can attach to an entire horn and one side of the uterine body, but the resulting foals are likely to be stunted as a result of IUGR.[402,442,529] The live birth of twin foals is extremely uncommon, and many of these neonates do not survive, with as few as 14% of surviving foals reaching the second week of neonatal life.[442,531] The mares are prone to fetal membrane retention and may be difficult to rebreed. Thus it is not surprising that the equine breeding industry has always tried to prevent twin pregnancies. After such a diagnosis the owner is faced with three choices: attempt elimination of one fetus in utero, manage the pregnancy to term in the remote hope of two viable foals, or induce abortion. Management of a twin pregnancy was discussed in more detail in a previous section.

Umbilical Cord Compromise

On rare occasions, a large ossified remnant of the yolk sac may compromise blood flow through the umbilical cord and result in abortion.[667] The pathologic condition referred to as *umbilical cord torsion* may be defined as excessive twisting of the cord such that there is complete or partial occlusion of the umbilical vessels or urachus.[668] The two umbilical veins that return oxygenated blood from the placenta fuse within the distal aspect of the amniotic portion of the cord, and a single vein enters the fetal abdomen.[669] Strangulation may occur if the cord becomes tightly wrapped around a portion of the fetus. Pressure sites on or around fetal parts may be caused by the effects of constriction by prolonged tension on a strangulated umbilical cord.[670] Affected fetuses are not usually expelled immediately after death, so some degree of tissue autolysis should be expected.[671]

The length of the equine umbilical cord in normal gestation can be quite variable, and factors that affect cord length and the number of twists present are unknown. Lethal umbilical torsion appears to be a sporadic condition with no apparent increased risk for future problems in mares that abort as a result of fetal complications.[672] Whitwell has shown that some mares have three or more foals with abnormally long cords.[441] A study of 93 Standardbreds did not demonstrate an effect of sire on cord length, and much larger studies will be required to ascertain whether genetics are involved.[429] Although the possibility of a heritable component for cord length cannot be discounted, a more plausible explanation may be that abnormally long cords are associated with the amount of fetal movement.[669]

Ultrasonographic studies of fetal mobility have helped explain the characteristic twisting feature of the normal equine umbilical cord.[402,673-675] Differing from ruminants, the equine amnion floats freely within the allantoic fluid. Fetal rotation within the amniotic cavity and amniotic sac rotation within the allantoic cavity result in the characteristic twisting of the equine umbilical cord.[676,677] The lumen of both uterine horns becomes constricted (presumably by localized circular muscle contractions) between 5 and 7 months, and the allantoic fluid along with the fetus is contained within the confines of the uterine body.[402,673-676] Ginther has described that as the noncord horn remains closed, the cord horn gradually permits the entry of the hindlimbs between 7 and 9 months.[675] The limbs can enter the horn only when the fetus is in dorsal recumbency because the angle between the horn and body is so acute by this stage of gestation. Thereafter, the hindlimbs remain enclosed within the cord horn, and the hooves extend to the horn tip by the tenth month. It is interesting that the peak incidence of abortions due to umbilical torsions occurs when the hindlimbs can become permanently enclosed in the uterine horn. In some instances this may prevent the unraveling of those critical few rotations that can lead to circulatory compromise. There is no doubt that a longer umbilical cord predisposes the fetus to this condition.

Reports from the United Kingdom suggest that with the decline in twin abortions, excessive twisting of the umbilical cord has become the most frequently made diagnosis in some laboratories. These abortions were associated with excessively long cords, with many over 80 cm in length.[592,678] Because spiraling of the equine cord (four to five times over its length) is a normal feature, it is important to ensure that the fetal demise was caused by vascular compromise.[669,677] Evidence of pathologic twisting with tension and compressive forces on the affected portion of the cord may include aneurysms, tearing of the intima of vessels, hemorrhage, thrombosis of vessels, blanched constricted areas, local edema, and urachal dilations of varying sizes. Inadequate perfusion can cause intravascular thrombosis in the peripheral tissues of the chorioallantois and possible necrosis of the aspect of the placenta that is most distant from the attachment of the cord (the cervical pole of the body segment).[669,671] These findings are by no means definitive, and there may be variability in interpretation among laboratories. Other considerations should include general agonal changes and the potential effects of cord tension when a live fetus is expelled. Whitwell's morphologic studies have established normal metrics for equine fetal membranes. The average length of the umbilical cord in a Thoroughbred is 55 cm (95% confidence interval; 36–83 cm; $n = 143$).[679]

Williams reviewed 168 cases of umbilical cord torsion from the University of Kentucky Veterinary Diagnostic Laboratory, representing 6% of equine fetus submissions over a 5-year period.[672] The gestational age ranged between 5 and 10 months, with a mean of 7.5 months. Umbilical cord length varied between 62 and 125 cm, with an average length of 96 cm. The cords tended to be highly twisted, with areas of constriction, edema, hemorrhage, and fluid-filled sacculations. The fetuses were slightly to moderately autolyzed in a manner consistent with fetal death before abortion. Urinary bladder dilation was observed in some cases. The most consistent histopathologic finding was evidence of necrotic changes with secondary deposition of calcified material in the blood vessels of the chorioallantois.[591,672] A less common cause of abortion resulting from cord obstruction is when an excessively long amniotic portion of the cord becomes tightly wrapped around a portion of the fetus.[670,679,680] Although it may be more common for a fetal extremity to be involved, the author managed a case in a pony mare in which the tightly wrapped cord left a deep groove around the lumbar region, with evidence of local edema.[670]

GENDER DETERMINATION (FETAL SEXING)

The advent of fetal sexing has permitted early gender determination to influence the value of the pregnant mare. Factors that may vary depending on the predicted sex of the foal include choice of state for foaling, appraisals and insurance coverage, sales reserves, bookings for stallion service the next season, and retention or sale of the mare.[681] Accurate determination of the sex of the equine fetus can be made using either transrectal or transabdominal ultrasonography.[78,681-683] Fetal gender should be certified only when the identifying structures have been clearly delineated and the accuracy of the determination is guaranteed. Accurate determination of fetal sex may be difficult or impossible in some cases because of excessive mare or fetal movement or because the fetus is located too ventrally to permit adequate imaging. Although tranquilization (e.g., xylazine and butorphanol tartrate) is sometimes used, it may cause the uterus to relax and drop away from the examiner.[681] A 5.0-MHz linear array transducer is adequate for transrectal gender determination, but a 3.5-MHz transducer will ensure the depth of penetration that is required to obtain transabdominal images.

Gender determination is based on ultrasonographic assessment of the relative location of the genital tubercle, an embryologic structure that is initially located between the rear limbs in both sexes. The genital tubercle differentiates into either a clitoris or a penis and has an ultrasonographically distinctive, hyperechoic, bilobulated appearance in both sexes. Curran reported that the optimal time for gender determination is between days 59 and 68, and Holder concurs that a window between days 60 and 70 is ideal.[681,682] A second ideal period for gender determination may be between days 110 and 120, because the genitalia are now well developed and the fetus tends to be more accessible again. After this time the increasing depth of the uterus means that a diagnosis may not be possible if the fetus is in an anterior (cranial) presentation at the time of the examination.[681] If the transabdominal approach is used, then the optimal window of time in both sexes is between 100 and 220 days' gestation.[78,681,682] Thereafter, it may become increasingly difficult to identify the anatomic structures required to make an accurate gender determination.

Detailed instructions for fetal sexing by ultrasonography have been described.[78,681,682] Transabdominal gender identifications based on the presence of the penis or prepuce (or both) in males and mammary glands and teats or fetal gonads in females can be quite accurate.[78]

MONITORING PREGNANT MARES

Placentitis should be suspected in mares that develop premature mammary enlargement (with or without vulvar discharge). Varying blood markers have been recommended to monitor late-term pregnant mares.[594] Relaxin is a protein hormone produced by the placenta. Low concentration of peripheral relaxin has been associated with various causes of placental dysfunction including fescue toxicosis, oligohydramnios, and placentitis.[684,685] Currently, however, there is not a commercially available assay, and normal concentrations of relaxin are highly variable among mares.

Serum amyloid A and haptoglobin have been suggested to be useful diagnostic and prognostic markers for ascending placentitis.[253,261] Similarly, alpha-fetoprotein and estradiol 17β[472] have been shown to be useful markers for experimentally induced ascending placentitis. It remains to be determined, however, if these molecules are useful for diagnosis of naturally occurring placentitis.

Measurement of an equine fetal protein and estrone sulfate levels in maternal plasma has not proved useful for early detection of fetal stress associated with medical and surgical colics.[514,686] In central Kentucky, a commercial laboratory offers a test to measure "total estrogens" that purportedly measures different fractions of nonconjugated classic phenolic estrogens present in late-term pregnant mares. Mares with lower concentrations of total estrogen are supposedly prone to abortion.[687] Before day 310 of gestation, total estrogen levels of less than 1000 ng/mL may be indicative of fetal stress, and mares with levels of less than 500 ng/mL are likely to have a severely compromised or dead fetus. This assay has not been tested under controlled conditions.

It is important to remember that the circulating concentrations of hormones in maternal plasma represent a small percentage of the levels that are being metabolized by the fetoplacental unit.[368,564,688] The definitive studies on mare progestogens (progestins) were performed using gas chromatography-mass spectrometry (GC-MS) or liquid chromatography.[368,475,688] It is imperative that clinicians understand that common commercially available assays (e.g., RIA, ELISA) using an antibody raised against progesterone or estrogen usually cross-react with several other steroids present in plasma of pregnant mares. Thus the results typically reported by the laboratories as being progesterone, estradiol, or estrone represent a mix of different progestogens and estrogens, respectively. In clinical practice this might be of particular relevance when the practitioner tries to compare results from an assay presented by one laboratory to the results obtained from another laboratory. Assay results may not be readily comparable.

Although placental pathology has been associated with increased plasma progestin concentrations in some reports, others failed to detect differences in plasma progestin concentrations in mares with impending abortion and mares with normal pregnancies when monthly blood sampling was performed.[368,439,475,476,688] Therefore it is recommended that whenever possible, serial samples (e.g., daily for 3 days, then weekly) be obtained from a mare in which the condition is suspected; doing so may help the clinician identify a clinically useful trend in progestogen concentrations.[688] Unfortunately, in practical settings this might not be feasible, making progesterone measurement not applicable to all situations.

Plasma progestogen concentrations increase in normal mares as gestation progresses, and concentrations in the maternal plasma may range between 5 and 50 ng/mL or even higher as mares approach term. It is thought that chronic fetal stress may cause the increased progesterone and pregnenolone concentrations (as well as those of several metabolites) that have been observed in mares with placentitis.[688,689]

Ousey has described three abnormal progestogen patterns that may be clinically useful: a rapid decline, precocious elevation, and failure to increase at term.[368,688] A rapid decline is consistent with fetal death or imminent fetal expulsion and may be seen after a uterine torsion or colic.[367,688] Pregnant mares that have experienced colic or uterine torsion and have plasma progestogen concentrations below 2 ng/mL are at high risk for fetal loss.[686] Prolonged increase of progestogens for several weeks before delivery (especially if earlier than 305 days' gestation) is consistent with metabolic activity in the fetus and uteroplacental tissues despite the presence of placental pathology.[476,646,688-692] Although typically small with poor skeletal development, foals born after being exposed to chronic fetal stress (placentitis) tend to exhibit precocious maturation, even when delivered several weeks early.[693]

Transrectal ultrasonography provides an excellent assessment of the current status of the caudal allantochorion, and as such it is an invaluable aid when examining a mare in late pregnancy that exhibits signs of placentitis.[694,695] An image of the ventral placental tissues in the area adjacent to the cervical star provides the ability to accurately diagnose the early stages of ascending placentitis.[694,695] Experienced clinicians are able to observe abnormal tissue thickness and even evidence of placental separation with an associated pocket of inflammatory exudate. Early therapeutic intervention may provide the best chance for a successful outcome. In a normal placenta the chorioallantoic membrane and endometrium are intimately connected, making them ultrasonographically indistinguishable from each other. Thus a combined tissue measurement is used, and normal values for the combined thickness of the uterus and placenta (CTUP) have been established.[696] The amniotic membrane should not be included, and this should be remembered if the fetal limbs are active at the time of the examination. The area 1 to 2 inches cranial and ventral to the cervix provides the most consistent CTUP measurement in normal mares, and this is the recommended site for any measurements. The ultrasound image should be frozen once the landmark vessel (a branch of the uterine artery) in the ventral uterine wall is located, and caliper measurements are taken from the inner dorsal surface of the ventral uterine vessel to the edge of the allantoic fluid.[694] It is recommended that three individual measurements be recorded.

An increased CTUP at any point from midgestation until term may indicate placental disruption and pending abortion.[697] Transrectal CTUP measurements that are considered abnormal would be greater than 8 mm (between days 271 and 300), greater than 10 mm (between days 301 and 330), and greater than 12 mm after day 330.[694,696,698]

An increased CTUP measurement in the absence of other clinical signs constitutes only weak evidence of placentitis. While examining a mare suspected to have placentitis, the practitioner must be looking for further signs of placentitis,

such as placental separation, intracervical fluid accumulation, vulvar discharge, or premature mammary gland development.[594] Placental folds, amnion, and at times individual mare variation may be responsible for apparent increased CTUP in the absence of placentitis.

Most practitioners do not recommend vaginal examination of pregnant mares unless the mare is presenting with purulent vulvar discharge or has other clinical indications for performing the exam. If such an examination is warranted, however, it is important to employ strict hygienic procedures when performing a vaginal speculum examination on a mare with a high-risk pregnancy, because the first two barriers to the pregnant uterus will be breached (i.e., vulvar lips, vestibular sphincter). Mares at risk for abortion often have a moist, hyperemic, relaxed cervix. Even if vaginal discharge has not been reported, many of these cases have a purulent cervical discharge if placentitis is present. Whereas cervical softening and vaginal discharge may be present if the infection is localized around the cervical star, in the case of nocardioform placentitis, the lesion does not involve the cervical star, and vaginal discharge is conspicuously absent.[596,699,700] Although transrectal ultrasound is an extremely useful aid in diagnosing ascending placentitis, the site of the nocardioform lesion makes it of limited diagnostic value in these cases.[659] Transabdominal examination of the ventral uterus may reveal separation of the chorioallantoic membrane from the endometrium, often with evidence of hyperechoic fluid accumulation between the two surfaces. Placentitis and associated placental edema will result in a thickened uteroplacental image. The CTUP on a transabdominal ultrasound image should be between 7 and 12 mm.

Transabdominal ultrasonography has become a routine diagnostic aid for evaluating mid- to late-term mares. Although the 5.0-MHz linear array transducer is ideal for transrectal reproductive ultrasonography, some probes have shallow depth of penetration (approximately 10 cm) that limits their usefulness for transabdominal examinations in mares in late pregnancy. The author recommends use of a transducer that achieves 15- to 20-cm depth for optimal transabdominal examination. If the mare does not have a pronounced plaque of ventral edema, most modern ultrasound units with a 5.0-MHz transducer will be sufficient to image the uteroplacental unit and some of the fetal fluids and allow assessment of the fetal heart rate.

Either a 3.5- or 2.5-MHz curved linear array or sector scanner transducer is best for transabdominal examinations because these can penetrate to a depth of 20 or 30 cm, respectively. Although the 70- to 90-day fetus may be imaged from the ventral abdomen, just cranial to the mammary gland, the late-gestation gravid uterus extends along the ventral abdomen to the xiphoid.[694,701-704] By the ninth month of gestation, the fetus should be in anterior (cranial) presentation and dorsopubic or dorsolateral position[402,675,702]; thus in late gestation the fetal head should be positioned near the mare's pelvis. An abnormal presentation or the presence of twins is possible if a fetal head is detected along the ventral abdomen during late gestation. A more detailed examination is indicated in such cases. The posture of the extremities varies with fetal movement.[702]

A standardized methodology must be followed when scanning the uterus from the ventral abdomen, starting just cranial to the mare's mammary gland and moving cranially to locate the fetal thorax. The ribs cause multiple acoustic shadows that delineate the thoracic cavity. A complete examination of the fetus and uterus involves scanning cranially to the xiphoid in multiple parasagittal planes and then scanning from the left to right sides of the abdomen in multiple transverse planes.[704] Transabdominal ultrasound examination is an important diagnostic tool when attempting to identify the presence of twin fetuses during late gestation. Identification of the nongravid horn can be useful to help rule out the possibility of twins. Obvious size discrepancy often serves as confirmation that twins are present. In other cases one thoracic cavity does not contain a beating heart, confirming that one of the twins has already died.

In a normal pregnancy the majority of the fetal fluids are within the allantoic cavity. The amnion is imaged as a thin membrane that surrounds the fetus and lies in close contact with the fetus over much of its body. The amniotic membrane divides the imaged fetal fluid into two distinct cavities. It is most easily seen around the fetal neck, shoulder, thorax, and foreleg. The largest pocket of amniotic fluid is usually imaged at the point where the forelimb and neck meet the thorax.[704] The maximum vertical depth of amniotic and allantoic fluid and the echogenicity and character of amniotic and allantoic fluid are useful guides to fetal well-being. Any measurements of fluid depth should be made as perpendicular to the uteroplacental surface as possible. In the normal equine pregnancy, the maximum ventral fetal fluid pocket depth for amniotic fluid is 8 cm, and it is 13 cm for allantoic fluid.[694,703,704] Extremes in either direction are not normal. Obviously deficient amounts of fetal fluid indicate placental dysfunction, and excessive amounts suggest a hydrops condition. Fetal fluid quantities should be considered excessive if the maximal vertical amniotic fluid depth exceeds 14.9 cm or the maximum vertical allantoic fluid depth exceeds 22.1 cm. The quality of the fetal fluid is scored from 0 (clear) to 3 (echogenic fluid with numerous particles).[702] It is not unusual for echogenic particles to be noted in the fetal fluids, especially during periods of fetal activity. These represent sloughed cells and proteinaceous debris. The fetal skin releases vernix as the pregnancy advances, and these free-floating particles can increase the cloudiness of the amniotic fluid. Thus an increase in the number of echogenic particles in late gestation may not be abnormal.[702] However, if a high-risk pregnancy is being regularly monitored and a sudden increase in fluid turbidity (grade 3) is observed, the prognosis is not good.[702] The clinician should consider the possibility of inflammatory exudates, meconium passage by a compromised fetus, or even hemorrhage. It should be remembered that hippomanes (allantoic calculi) are a normal feature of the equine pregnancy. These structures may often be observed as free-floating echogenic accumulations on the ventral aspect of the allantoic cavity.[704]

An equine biophysical profile has been proposed as a guide to assessing fetal well-being and predicting perinatal morbidity and mortality.[694,702,705] Although a low score is definitely indicative of a negative outcome, higher scores do not guarantee the birth of a viable neonate. While establishing the biophysical profile of fetuses during pregnancy is an interesting concept, some clinicians question its validity for clinical practice as it is a time-consuming technique, and results are not necessarily useful in determining interventions. Fetal breathing, heart rate and rhythm, fetal tone, and general activity are useful guides when evaluating fetal health and well-being. Therefore chemical sedation of the mare is not recommended because commonly used drugs are likely to induce fetal bradycardia and suppress normal fetal activity.[706] Fetal breathing

is characterized by movement of the diaphragm between the thorax and abdomen in conjunction with rib cage expansion without any other movement by the fetus. Fetal breathing patterns should be monitored for at least 30 seconds.[694,704]

When fetal heart rate and rhythm are monitored, it is not appropriate to scan for only 10 to 15 seconds and then multiply by a correction factor to obtain the number of beats per minute. Beat-to-beat variations and observation of periodic accelerations are important. It is normal for the heart rate accelerations to occur in association with fetal activity. Multiple measurements of fetal heart rate and assessments of fetal heart rhythm should be made over a 30-minute period while evaluating the fetus, fetal fluids, and placenta. Ideally, three measurements should be obtained with the fetus at rest and another three after periods of activity. It is difficult to accurately monitor the heart rate during periods of fetal activity, unless M-mode echocardiography equipment is available. Fetal heart rates vary with the stage of gestation and the amount of fetal activity at the time of the examination.[694,707-709] The fetal heartbeat is normally regular and will decrease from greater than 120 beats/min in midgestation to between 60 and 90 beats/min in late gestation. Cardiac accelerations (20–40 beats/min above baseline) are normal if they are associated with fetal movement, but persistent tachycardia in the absence of fetal activity indicates fetal stress. A resting heart rate in excess of 104 beats/min indicates fetal stress in a late-gestation fetus.[702,704] A heart rate of less than 57 beats/min in a fetus that is less than 330 days' gestation and a rate of less than 50 beats/min in a fetus older than 329 days' gestation should be considered abnormal. A fetus suffering from hypoxia will have a slow heart rate, with minimal limb activity or fetal breathing, indicative of central nervous system depression. However, if the condition is chronic and ischemic conditions are developing, then the fetus will become tachycardic despite a lack of fetal activity. This is a prelude to fetal demise. In terminal cases extreme bradycardia ensues just before fetal death. Although failure to observe fetal activity may be caused by the stage of the normal rest-activity cycle, confirmation of a regularly beating heart at least verifies that the fetus is alive. This is a major advantage over transrectal fetal ballottement, in which failure to detect movement can raise unnecessary concerns about fetal health.

If Doppler ultrasound equipment is available, then the Doppler transducer is placed directly over the site in which the best image was detected by the ultrasound scan. Tracings of fetal heart rate and rhythm can be recorded over time (usually at intervals of 5 to 10 minutes). This makes analysis easier and serves as a permanent record of the fetal status at the time of the recording. If there is some question about the presence of twins after a transabdominal ultrasound examination, then fetal electrocardiogram (ECG) tracings may show two distinct fetal patterns.[708,709] Features of the ECG tracing that should be noted include fetal heart rate and rhythm, accelerations and decelerations, complex polarity changes, and beat-to-beat variation. In the last weeks of pregnancy fetal foals usually have a baseline heart rate in the range of 60 to 75 beats/min. Transient low heart rates of less than 60 beats/min are not uncommon. These troughs warrant concern only if they are not interspersed with accelerations. Likewise, transiently elevated rates in the order of 120 beats/min (occasionally >200 beats/min) are not abnormal, provided they return to baseline. If the fetal heart rate is found to be less than 60 beats/min or greater than 120 beats/min during an observation period, then more frequent monitoring is justified to determine whether the fetus is distressed. Beat-to-beat variations are normal, and a finding of no variability is an ominous sign. Maternal medications such as alpha-2 agonists (e.g., detomidine, xylazine) or opioids (e.g., butorphanol) will reduce fetal heart rate variability transiently.

The fetus is noted to have tone if it is observed to flex and extend the limbs, torso, or neck. Tone is poor or absent if the fetus appears flaccid. Fetal movements include partial to full rotation around the long axis of the fetus as well as less marked activity such as extension and flexion of the extremities. Fetal activity is rated on a scale from 0 to 3, with 3 being a very active fetus. A score of 0 indicates that no fetal movement was noted during the examination period. Long periods without noticeable fetal activity are cause for concern and should be evaluated in conjunction with information about the fetal heart rate and rhythm. The fetus may be distressed, suffering from advanced hypoxia and central nervous system depression.

Fetal aortic diameter is correlated with the weight of the pregnant mare and the final neonatal foal weight.[694,702,703] Thus the pregnant mare's weight can be used to estimate what the fetal aortic diameter should be, using the regression equation ($Y = 0.00912 \times$ pregnant mare's weight in pounds + 12.46), where Y is the predicted fetal aortic diameter (in millimeters).[702,703] The actual diameter of the fetal aorta should then be measured in the thoracic cavity as close to the fetal heart as possible. A smaller-than-predicted aortic diameter may indicate a dysmature or growth-retarded fetus (IUGR) or twins. The maximal thoracic diameter is measured from the spine to the sternum over the caudal part of the thorax, and in a late-gestation fetus it should be 18.4 ± 1.2 cm. It has been correlated with fetal aortic diameter and neonatal foal weight in high-risk pregnancies.[702, 703] Foal girth measurements and hip height are also correlated with fetal aortic diameter measurements.[704,710] Fetal biparietal measurements and orbital diameters have also been used to estimate fetal size.[694,710] Eye length (sclera to sclera) is a useful predictor of days before parturition in small ponies.[711] Decreased blood flow to the placental unit inhibits fetal growth, and some form of chronic placental insufficiency should be suspected when small fetal size is detected.

It is important to monitor fetal viability if a high-risk pregnancy is being maintained on altrenogest supplementation. Although most nonviable fetuses will be aborted, there is a report of a mummified fetus being retained when the mare was receiving long-term progestogen supplementation.[712]

COMPLICATIONS IN LATE GESTATION

Once confirmed to be at least 45 to 60 days pregnant, most mares can be expected to carry the fetus to term. The incidence of fetal loss after 100 to 120 days' gestation is low and accounts for only a small percentage of total pregnancy wastage. Fetal death and maceration are very uncommon in the mare. A set of macerated twins were seen by one of the authors (GF) in a draft breed mare that suffered no ill effects systemically. The mare was evaluated only after the owner noticed a foul-smelling vaginal discharge.[713]

Ventral body wall ruptures and uterine torsions are uncommon, and hydrops of the fetal membranes is an especially rare condition. Accurate diagnosis and appropriate management of these clinical cases can prevent the development of a life-threatening condition. If a ventral body

wall rupture or uterine torsion is present, then the birth of a viable foal may still be possible provided that the case is properly managed.[714] In referral hospitals, mares with body wall defects tend to be presented in advanced stage, making management more challenging. Outcomes for several diseases of the late-term pregnant mare can be improved by training farm personnel and horse owners to identify clinical problems. Owners should be trained to check late-term pregnant mares daily or weekly for signs of placentitis (e.g., vulvar discharge, premature mammary gland development) and areas of focal ventral edema. As described elsewhere in this text, ventral edema may be observed in some normal periparturient mares. Mares with expanding areas of edema in the ventral abdomen should be examined immediately by palpation and ultrasonography of the area and surrounding body wall. Muscle failure can frequently be felt and observed, and medical treatment, rather than surgical, may provide a better outcome for dam and fetus.[715]

Hydrops of the Fetal Membranes

Hydrops is a condition of the last trimester, with the pregnancy developing normally until somewhere between 7.5 months and term. Hydrallantois and hydramnios are rare conditions of pluriparous mares that involve a pathologic accumulation of fluid within the allantoic and amniotic compartments, respectively. Normal volumes of allantoic fluid in mares vary from 8 to 18 L at term. In documented cases of hydrops, the allantoic fluid volume ranged from 110 to 230 L. Just as with cows, hydrallantois accounts for most dropsical conditions in the mare.[716-719] The pathophysiology of hydrallantois in the cow has been related to a placental abnormality, whereas hydrops amnion has been associated with a fetal head anomaly that precludes swallowing.[200] Dysfunctional placentation may cause an increased production of transudate or disruption of transplacental fluid absorption. There does not appear to be any consistent abnormality of the fetus or fetal membranes that is characteristic of the condition in the mare. A mare with confirmed hydramnion delivered a viable foal.[720] A mild diffuse placentitis or endometrial vasculitis has been incriminated in some cases. A potential correlation between hydrallantois and *Leptospira* infection has been suggested, but causation has not been established.[720]

Generally there is a sudden onset of abdominal distention, and walking becomes difficult. The mare may exhibit variable degrees of colic. There is a progressive loss of appetite, and the mare may experience some difficulty in defecation. The increasing pressure on the diaphragm causes dyspnea, and the mucous membranes may appear cyanotic, especially when the mare is recumbent. On physical examination the rectal temperature is normal, but the heart rate will be increased. Transrectal palpation reveals characteristic findings. Copious lubrication and extreme caution should be used because passage of the forearm will be impeded by pressure from the large fluid-filled uterus. In advanced stages, the feces tend to be covered with mucus as a result of the prolonged passage through the lower gastrointestinal tract. The gross distention of the uterus means that the fetus is usually not palpable. Failure to detect the fetus by external ballottement further supports the diagnosis, but some mares may not tolerate ballottement. Transabdominal ultrasound may confirm the presence of excessive amounts of hyperechoic fluid. A thorough examination from both sides of the abdomen should be performed to rule out the possibility of twins.

Owners should be advised that this is a progressive condition, and it is extremely unlikely that the mare will be able to sustain the pregnancy and deliver a viable foal. Despite this, a recent report documented a case that was successfully managed until a viable foal was delivered at 321 days' gestation.[720] In that case the mare was provided with close monitoring of maternal and fetal health, in combination with care that included a supportive belly wrap, antiinflammatory medication, and altrenogest. A partial drainage technique is sometimes used in an attempt to manage cases that were diagnosed within 2 to 4 weeks of term. Affected mares receive abdominal support (belly band), IV fluids, broad-spectrum antibiotics, and antiinflammatory medication. The technique of slow, repeated drainage requires a major time commitment and would not be cost effective in many cases. Fetal death may occur as a result of placental separation. There also appears to be a considerable risk for iatrogenic fetal infection after contamination of the fetal fluids, despite attempts to perform the drainage technique in an aseptic manner. Despite heroic attempts in valuable mares, the fetus is likely to be lost in cases of hydrallantois. The prognosis for mare and foal survival may not be favorable, particularly when the mare is <300 days' gestation. Owners may opt to euthanize a mare without further effort, for economic reasons, if the foal has little chance of survival.

In most cases induction of parturition may be advisable before the mare's condition deteriorates further. Continued abdominal enlargement will predispose the mare to body wall tears or prepubic tendon rupture, and uterine rupture has also been reported.[721] Induction of parturition is not without risk (shock and dystocia), but the prognosis for survival of the mare is good provided appropriate supportive therapy is instituted, particularly at an early stage of disease. The prognosis for the mare's reproductive future may also be favorable if there are no untoward sequelae (cervical lacerations, retained fetal membranes, and metritis) or severe dystocia.

Application of PGE_1 to the cervix before induction may facilitate atraumatic fetal extraction.[360] Six of eight mares that had previously developed a hydrops pregnancy subsequently became pregnant and delivered normal healthy foals at term.

Before a therapeutic induction of parturition, the tail should be wrapped, the perineal area cleansed, and an indwelling IV catheter inserted. Large-volume IV fluid therapy may become necessary if hypovolemic shock develops as the allantoic fluid is discharged.[714] In some cases controlled drainage may be beneficial before inducing delivery. An added complication in hydrops cases is that the thickened, edematous chorioallantoic membrane may be difficult to rupture.[716] If digital pressure alone is unsuccessful, then an endometrial biopsy forceps can be used to create an opening in the chorioallantois. Some authors report that the lack of pressure from the atonic uterine wall will result in minimal release of fetal fluid from the punctured chorioallantoic sac, but in most cases there is a massive release of fluid once the chorioallantoic membrane is ruptured. If insufficient fluid release occurs, a sterile nasogastric tube can be introduced into the uterus to begin controlled siphoning of fluid. The authors recommend detaching the caudal pole of the chorioallantois and introducing a nasogastric tube through the cervix and the chorioallantois. An alternative technique is to introduce a thoracic trocar catheter through the cervix and employ a sharp puncture of the chorioallantois. This approach permits the excess fluid to be removed by controlled drainage. Administration of IV fluids with gradual

removal of the excess allantoic fluid will permit the mare's cardiovascular system to adapt.

Oxytocin and $PGF_{2\alpha}$ injections have been used in an attempt to abort these cases.[716-718] Although oxytocin is widely considered to be the most efficacious method for routine induction of parturition, in mares with hydrops conditions the distended uterine musculature may not contract effectively.[716,722] This primary uterine inertia is common, and gentle manual dilation of the cervix, or perhaps prior topical application of PGE_1, may be warranted.[360] A smooth induction and manual extraction of the foal was reported for one mare after two doses of cloprostenol administered 30 minutes apart.[723] Efficacy of ecbolics is likely more favorable in mares with mild to moderate distention of the uterus.

The abdominal musculature may be weakened by stretching, and thus the typical stage II abdominal contractions may be compromised. If an abdominal bandage is in place, many mares will not have abdominal contractions, and classic stage II of labor will not occur without intervention to manually extract the foal. Malpositioning and malpostures are not uncommon. The fetus may need to be extracted by assisted vaginal delivery, but care should be taken not to traumatize the cervix by overzealous traction. The expelled fetus will generally be alive, and humane euthanasia is usually warranted.

After delivery of the foal, oxytocin administered as a continuous rate infusion at 1.0 IU/min or as an intermittent intramuscular bolus at 5 to 10 units q 30 min should be included in the treatment plan to promote uterine involution and facilitate fetal membrane expulsion. Retention of the fetal membranes should be expected, and appropriate treatment for removal of these membranes and prevention of the metritis-laminitis complex is indicated. Uterine involution should be monitored by transrectal palpation and ultrasonography.

Ventral Body Wall Hernias and Prepubic Tendon Rupture

Apart from those with pathologic pregnancies, mares with ventral body wall defects are generally close to term.[715,724,725] Damage to the abdominal sling of the pregnant mare may involve rupture of the transverse abdominis and oblique muscles, the rectus abdominis muscles, and the prepubic tendon. In extreme cases the rupture may lead to hemorrhage, shock, and death. The prepubic tendon attaches to the cranial border of the pubis, and lordosis occurs if the tendon is ruptured. Although breed (draft breed and Standardbred mares) and age (older mares) may predispose a mare to development of the condition, in most cases there is no apparent predisposing cause. The extreme abdominal distention associated with the hydrops condition may cause rupture of the ventral musculotendinous support. Defects in the ventrolateral abdominal wall are more common than complete prepubic tendon rupture, and bilateral involvement of the abdominal wall seems to be most common.[9] In a retrospective study of 13 cases, only three were categorized as being caudal midline (prepubic tendon lesions), and all three had additional involvement of the body wall musculature.[715]

The most obvious clinical sign of an impending ventral body wall rupture is a thick plaque of ventral edema extending a variable distance cranial to the udder. However, ventral edema may be a normal consequence of late pregnancy, and it can indicate external trauma. A large ventral swelling may also occur with hematomas from external trauma and should be considered as a differential diagnosis. Mares in late pregnancy often develop a thick plaque of ventral edema that can extend from the udder to between the forelimbs. This is associated with the compressive weight of the gravid uterus on the venous and lymphatic drainage of the ventral abdomen. The presence of a hemorrhagic secretion in the mammary gland supports a diagnosis of tissue trauma rather than pregnancy edema. Unilateral edema is more indicative of damage to the ventrolateral body wall, but it may be associated with partial rupture of the prepubic tendon. The extreme pain associated with progressive enlargement of a ventral body wall rupture causes a marked tachycardia that may not be responsive to analgesics.

Pregnant mares with a ruptured prepubic tendon or abdominal wall may show signs of colic and generally are reluctant to move. If the prepubic tendon is completely ruptured, then the pelvis will be tilted such that the tailhead and tuber ischii are elevated and a lordosis will be present.[714,715,724,725] The mammary gland is often displaced cranially and ventrally because of the loss of the caudal attachment to the pelvis, and bloody secretion is usually present. A rent in the abdominal musculature may be complicated by bowel incarceration.

Confirmation of the tentative diagnosis is sometimes difficult. Because it is not always possible to be certain that a rupture has already occurred, mares with severe ventral edema should be confined to a stall with exercise restricted to hand walking. Rectal palpation of the defect is usually not possible because of the advanced stage of the pregnancy. External palpation is generally unrewarding because of the thickness of the edema, although some crepitation of the ventral abdominal wall may be noted. The mare is generally extremely sensitive and resists palpation of the area. Ultrasonographic examination of the posterior aspect of the ventral abdomen may be useful in some cases and can detect the presence of a bowel segment.[204,704,714,715] Rupture of the prepubic tendon can be identified as disruption of the tendon fibers immediately cranial to the pubis, whereas abdominal wall muscle tears are seen to be discrete tears within muscle fibers, often associated with hematomas.[715] An accurate assessment of the dimensions of the defect often cannot be made until the fetus and fetal fluids are expelled and the ventral edema has subsided. Often body wall tears can be found in the flank as well, and transcutaneous ultrasound in the flank region may be beneficial.

Depending on the degree of discomfort and stage of pregnancy, termination of the pregnancy may be the most humane treatment for the mare, given that further tissue damage is likely to occur to some degree until parturition. The possibility of a segment of intestine becoming incarcerated in the defect also should be considered. In extreme cases the mare may eventually become recumbent, especially if there is a rapidly expanding body wall defect. Owners should be aware that unless parturition is imminent, the prognosis for the foal is not good because fetal readiness for birth is difficult to predict. If it is determined that the goal for the owner is to save the fetus, the management plan should focus on supportive care to facilitate maintenance of the pregnancy to term. In these mares the treatment is essentially supportive, and the prognosis for the foal is good. Antiinflammatory drugs will help alleviate the mare's discomfort. An abdominal sling (belly band) made of canvas or padded leather or a snug abdominal bandage help provide support for the ventral abdominal wall. If a sling is used, the area over the back must be well padded to prevent pressure necrosis because the purpose of this support

is to transfer the weight of the gravid uterus to the vertebral column. Reducing the bulk of the ration and feeding a mild laxative may help reduce the degree of abdominal exertion associated with defecation.

Assistance with parturition should be available because the mare may experience difficulty in mounting sufficient abdominal pressure to expel the fetus, especially if the mare has an abdominal bandage.[715,725] However, one report suggests that some mares can position the foal and complete delivery unassisted.[715,724] Arrangements for an alternate source of colostrum should be made because ventral edema may prevent the foal from suckling. The owner should be informed that although in some cases surgical repair of the defect may be possible by mesh herniorrhaphy, rebreeding the mare with an expectation of carrying the foal to term is usually not advisable. Some mares with small, unrepaired defects may subsequently foal without assistance, but the possibility that future pregnancies may exacerbate the condition should be considered. Embryo transfer offers a viable alternative if this procedure is condoned by the relevant breed society.

Uterine Torsion

Uterine torsion accounts for 5% to 10% of all complicated obstetric conditions in the mare.[726,727] Neither mare age nor parity appears to be a significant risk factor.[728,729] The causes of uterine torsion in the mare are not well defined. The condition is much more common in cattle, and in that species a large term fetus has been implicated as a major risk factor. Most uterine torsions in cows occur at term and are thought to be a direct result of fetal positional changes during late first-stage and early second-stage labor. A striking difference between the mare and the cow is that more than 50% of uterine torsions in mares occur before the end of gestation.[730] It seems that most equine uterine torsions occur before term, and cases may be seen as early as 8 months of gestation.[714] One report documented a mare affected as early as 126 days' gestation.[731] A multicenter retrospective study of 63 cases reported that 59% of the mares were at less than 320 days of gestation.[728] Although Ginther et al. have shown that the fetus is locked in a dorsopubic position during the final months of gestation, it is still possible for the entire pregnancy (uterus and fetus) to rotate approximately 90 degrees on the lower maternal abdominal wall.[402] This occurs because any rotational movement of the caudal half of the fetus (pelvis and hindlimbs) by necessity will involve the close-fitting uterus. It seems likely that in extreme cases this rotating action can lead to a clinical uterine torsion. Owners who work closely with their mares may observe excessive fetal movements in the flank area 1 or 2 days before. In a recent study, 80% of term fetuses were in a dorsosacral position when the uterine torsion was corrected. This suggests that fetal righting reflexes may have played a role in creating the torsion.[726] Vigorous fetal movements during the latter stages of gestation are likely to be a significant factor in the etiology of this condition in the mare.

The clinical signs that attract the owner's attention are the result of abdominal pain and may include restlessness, sweating, anorexia, frequent urination, sawhorse stance, looking at flanks, and kicking at the abdomen. When the veterinarian is first contacted, the signs may have been present for a period ranging between 2 hours and 3 days or more, especially if signs are intermittent and moderate. In mares that are close to term, the owner may assume that the signs indicate impending parturition. In more extreme cases the signs are more severe and may be associated with concurrent involvement of the small or large colon. Veterinarians should always consider the possibility of uterine torsion when a mare in the last trimester of gestation exhibits a mild, persistent colic. Delay in making a definitive diagnosis increases the likelihood of fetal compromise. In one study of 63 cases, the mean time to admission was more than 20 hours.[728] Occasionally the condition may remain undiagnosed for several weeks.[732] In these instances an owner may have attempted treatment with analgesics that were prescribed for previous mild colic episodes.

Transrectal palpation is essential to determine whether a uterine torsion is present. All late-pregnant mares that display signs of mild to moderate colic warrant a thorough transrectal examination to rule out the possibility of uterine torsion. Although vaginal involvement in torsion is very common in the cow, uterine torsions in the mare seldom cause detectable changes in the vagina.[714,733,734] Thus vaginal examination is generally not diagnostically useful in mares.

On transrectal palpation the clinician should aim to carefully advance the forearm while palpating for a taut band on either side of the rectum. The broad ligament on the side of the torsion tends to be more caudal and is palpable as a tight vertical band. As the arm is advanced further, the opposite ligament will be palpable because it is pulled horizontally across the top of the uterus before being displaced ventrally. An accurate examination of the broad ligaments will confirm the diagnosis, determine the direction of the torsion, and give some idea of the severity of the torsion. One retrospective of 54 mares reported that 79% of referred cases were rotated no more than 180 degrees, and 59% of cases involved clockwise torsion.[728]

A transrectal ultrasound examination is useful to evaluate the condition of the fetal fluids and to note whether any placental detachment has occurred. The degree of uterine compromise can be gauged by noting the thickened uterine wall and distended vasculature. Compression of the veins and lymphatics occurs before occlusion of the arterial blood supply; thus the initial changes will be associated with pooling of fluid within the uterine wall. The compressive forces of the displaced broad ligaments may cause variable amounts of constriction of the small colon.[734,735]

Transabdominal ultrasonographic imaging may be used to assess fetal viability (heart rate and rhythm) and to evaluate the character of the fetal fluid. Compression of the uterine blood supply can cause fetal hypoxia and a fetal stress response, especially in more advanced pregnancies. Abdominocentesis may provide prognostic information and guide the clinician in choosing a mode of correction.[197] Because it may be difficult to obtain peritoneal fluid from a mare in late gestation, transabdominal ultrasonography is sometimes useful in locating a pocket of fluid.

Uterine rupture can be a complication of uterine torsion in the mare.[734,736] Mild uterine torsions, or those of short duration, do not alter the color, cellularity, or total protein content of the peritoneal fluid.[197] Mares with severe or chronic uterine torsion may develop significant uterine compromise that results in changes in the composition of the peritoneal fluid. Any alterations in the composition of the peritoneal fluid may indicate the presence of a compromised or ruptured uterine wall or concurrent gastrointestinal involvement.[3] A flank laparoscopic examination can confirm the condition of the uterine wall.[737] This information will facilitate an informed choice of surgical approach or perhaps support a decision for euthanasia if economic considerations preclude surgical intervention.

The stage of gestation and the mare's heart rate are important prognostic indicators for mare survival. A recent study reported that mares that died had significantly higher heart rates (mean 74 beats/min) at admission than survivors (mean 59 beats/min).[728] Increased fetal size and the weight of the gravid uterus make correction closer to term (>320 days) more difficult, and this may explain the poor mare survival rate (65%) compared with cases in less advanced pregnancies (<320 days), in which survival rates are excellent (97%). Owners should be advised that fetal survival rates are not as good, but a similar effect of stage of gestation applies. The chances of the foal surviving exceed 70% if the mare is at less than 320 days' gestation, but only about 30% survive when mares are closer to term.

If the mare is presented in stage I of labor and the cervix is sufficiently dilated to permit passage of a well-lubricated arm into the uterine body, then it may be possible to reach the fetus. It should be grasped ventrolaterally and then rocked back and forth until sufficient momentum is achieved to continue up in an arc. This reproductive maneuver may not be possible in mares with reproductive tract swelling because of a chronic, undiagnosed torsion. This manipulation should roll both fetus and uterus back into a normal position. More than 80% of term torsions may be corrected in this manner.[716,727] Options for management of a preterm uterine torsion are rolling the mare, flank laparotomy, or a ventral midline celiotomy.

In the controlled referral hospital environment, the method of correction is not associated with mare survival, but both rolling and midline celiotomy require general anesthesia and thus entail those additional risks.[728] There is a significant effect on foal survival if the mare is at less than 320 days' gestation, and using the standing laparotomy approach should provide a significantly better prognosis compared with the ventral midline approach. However, the final decision must be based on several factors, including the severity of pain being exhibited by the mare, client financial constraints, and surgeon preference. It should also be noted that a ventral midline celiotomy permits better assessment of uterine viability and evaluation of the gastrointestinal tract compared to a flank incision.

The anesthetized mare may be rolled in an attempt to rotate the mare's body around the stationary gravid uterus.[738] It is essential that the mare be positioned in lateral recumbency and rolled in the direction of the torsion. The aim of the procedure is to roll the mare such that the pelvis "catches up" with the displaced uterus. Correction by rolling the mare is controversial. Citations in the literature report on a limited number of cases.[730,738,739] Concerns with this approach include the following: Unsuccessful attempts to correct the torsion will prolong its adverse effects, misdiagnosis of the direction of the torsion means that rolling the mare may make the condition worse, the condition of the uterus cannot be evaluated, and displacement of the colon may result.[714] In addition, a higher risk of placental detachment and uterine rupture has been reported.[204,739,740] Another concern is that if general anesthesia is induced under less than ideal conditions, maternal hypoxia may cause fatal complications in the already compromised fetus.

In the standing flank approach, a grid incision is made on the same side as the direction of the torsion.[734] The torsion is corrected by placing the forearm under the uterus. The uterus and contents are rocked back and forth to gain momentum. A combination of lifting and rotating movements generally results in easy correction of the torsion. The presence of a live fetus greatly facilitates the detorsion manipulations. More difficulty may be experienced in mares that are close to term, and this may justify the more expensive ventral midline celiotomy approach. If the standing procedure is attempted, then an incision in the opposite flank will permit a second surgeon to assist by gently pulling across the top of the uterus as it is elevated from below. If the fetus is dead, then the mare should abort naturally once the uterine torsion has been corrected, removing the need for hysterotomy and any associated complications.[571,714] However, the mare should be closely monitored, and obstetric assistance must be available to correct any malposition or malposture. Mares experiencing intractable pain should receive general anesthesia during the operation. A ventral midline celiotomy is also indicated when significant uterine compromise is a concern or another problem coexisting in the abdomen is suspected.

The prognosis for mares with uterine torsion depends on the degree of vascular compromise. The severity and duration of the condition affect placental circulation and subsequent fetal viability.[714] In chronic cases in which there is significant uterine compromise, it is feasible to perform an ovariohysterectomy to salvage the mare for nonbreeding purposes.[732,741] If the fetus is alive and the uterine wall is not severely congested and edematous, then the prognosis for both the mare's survival and for the birth of a live foal at term is good. Progestogen supplementation for 3 to 5 days after the manipulations involved in correcting a uterine torsion may be indicated to promote myometrial quiescence and maintenance of the placental attachment. Although supplementation after a uterine torsion would be in the last 2 to 3 months of gestation, there are reports of mares retaining a nonviable fetus (one that died at 3–5 months' gestation) while receiving progestins.[712] Thus if progestin supplementation is administered to a mare after correction of a uterine torsion, then it is prudent to monitor fetal viability at regular intervals. There is probably little merit in continuing the supplementation once the mare has been discharged from the hospital. In one study 28 of 30 mares that were pregnant at the time of discharge subsequently delivered a live foal, and future fertility was good (24 of 29 were successfully rebred).[728]

Vaginal Hemorrhage

Visible blood on the tail hairs or hindlimbs of a pregnant mare warrants careful examination.[742] The integrity of placental attachment immediately cranial to the cervix should be evaluated using transrectal ultrasonography. A pocket of fluid may be evident if placental separation has occurred, and measurements of the CTUP should be made.[697] An increased CTUP measurement is indicative of placentitis.[594] Because two of the three barriers protecting the fetus (vulvar lips, vestibular sphincter, and cervix) will be entered when performing a vaginal speculum examination, it is essential to ensure stringent hygiene. Often, blood clots can be seen in the vestibule when the vulvar lips are parted. A sterile speculum should be covered with sterile lubricant and then gently inserted into the vagina. Some mares with bloody vulvar discharge may have experienced trauma inflicted by herdmates.[743]

In some mares there may be evidence of a serosanguineous discharge from the cervical os. Mares that are aborting a twin pregnancy may also develop a bloody vaginal discharge. However, the practitioner should be aware that the most common source of vaginal hemorrhage in pregnant mares is from varicose veins in the vestibulovaginal fold (hymen), not from an

impending abortion. In many cases no blood is visible in the cranial vagina. If the cervix is closed, pale, and covered with tenacious mucus, then it is unlikely that the blood is associated with the fetoplacental unit. Although the blood could be associated with cystitis or urolithiasis, the source of the hemorrhage usually is varicose vessels in the remnants of the hymen at the level of the vestibular sphincter or cranial vagina. It is not unusual to miss these as the speculum is inserted; thus particular attention should be paid to this area as the speculum is withdrawn.[742]

Vaginal varicosities are most likely to occur in older, multiparous mares during the latter months of gestation.[742,744] A large plexus of dilated veins can develop in the pedunculated mucosa at the level of the vestibulovaginal junction or less commonly in the cranial vagina. The veins can become engorged from 1 to 2 cm during late gestation. If the vessels are ulcerated, there may be intermittent, mild episodes of bleeding from the ventral commissure of the vulva. An owner may report seeing large blood clots in the bedding when the mare is fed in the morning. Although this quantity may be alarming to an owner, it can be explained as merely representing the discharge of pooled blood while the mare was recumbent during the night. Another explanation is that the pull of the rectal attachments when standing creates sufficient tension in the vaginal wall to control hemorrhage, whereas blood loss can occur when the mare is recumbent. In more severe cases there may be dried blood on the perineum, tail hairs, and hindlimbs. Overt vaginal hemorrhage may be sufficient to cause anemia.[744]

The etiology of vaginal varicosities in mares is unknown. The condition is not an uncommon complication of pregnancy in pluriparous women, and it has been proposed that a similar obstruction of venous return is responsible for the development of vaginal varicosities in the mare. Poor vulvar conformation with cranial displacement of the perineum may be involved in some cases.[49,742,744] It is possible that repeated stretching of the vestibulovaginal tissues and changes in the vulvar conformation of pluriparous mares create a physical impairment of venous return from the vestibular and vaginal components of the internal pudendal vein. The dilated veins are generally located on the cranial aspect of the vestibular fold and on the dorsal aspect of the caudal vaginal wall. Thus vaginal varicosities can be easily missed when a tubular speculum is introduced, and they may not be evident during withdrawal. In some cases a tri-valve metal Caslick speculum may provide better exposure so that the tissues of the vestibulovaginal fold can be everted and fully explored. If the diagnosis is still inconclusive, then the next logical step in the physical examination is ultrasound and endoscopic visualization of the vagina and cranial vestibulovaginal fold. The clinician should first advance the flexible scope toward the cervix and then angle the lens back to better evaluate the cranial aspect of the vestibulovaginal fold. If vaginal varicosities are present, usually no treatment is necessary, because the vessels will regress spontaneously after foaling (benign neglect).[742] However, if there is persistent or excessive hemorrhage or the owner is distressed, then the offending vessels can be cauterized (diathermy) or ligated.[742,745] Locating the source of the bleeding can be difficult. Traction on the adjacent vaginal mucosa may arrest the bleeding and help identify the site in such cases. Submucosal resection of a pedunculated plexus of varicose veins has been reported to be successful.[742,744] Some authors have had success with topical application of a human hemorrhoid cream to prominent or suspected vessels. Treatment is generally successful, and no recurrence has been reported.

It is important to consider bleeding from the urinary tract when vaginal hemorrhage is the presenting complaint. If an owner reports having seen bloody urine on the stall floor, then it should be remembered that normal equine urine contains pyrocatechin. This oxidizing agent can cause urine to turn red-brown after exposure to air.[742] Hematuria can result from several disorders of the urinary tract.[746] If blood is present throughout urination, then the lesion is likely to be in the kidneys, ureters, or bladder. If the endoscopic examination has not identified vaginal varicosities as the source of the hemorrhage, then the endoscope should be advanced down the urethra to visualize the bladder lumen (cystoscopy). Although uroliths are more common in geldings and stallions than in mares, a urolith may cause mucosal irritation and hemorrhage, resulting in hematuria.[747,748] Rectal palpation may reveal a firm mass in the bladder that can be imaged by ultrasonography. The pelvic portion of the urethra should also be palpated.[742] Although neoplasia of the urinary bladder is rare, mares are reported to be twice as likely as male horses to develop primary bladder tumors.[746] Squamous cell carcinoma is the most commonly reported bladder tumor, but transitional cell carcinomas can also occur. The condition has been reported as a cause of hematuria, often with blood clots.[749] A more detailed discussion of hematuria may be found in Chapter 14.

Fescue Toxicity and Agalactia

A wide range of reproductive problems (e.g., thickened placenta, abortion, prolonged gestation, dystocia, dead or weak foals, agalactia) have been attributed to the effects of the fungal endophyte (*Acremonium coenophialum,* now known as *Neotyphodium coenophialum*).[750-752] The endophyte produces a dopaminergic, vasoactive ergopeptine alkaloid (ergovaline). This alkaloid disrupts the fetoplacental production of progestogens, but the precise mechanism has not been established.[753, 754] Umbilical vein progestogen levels suggest that the disruption is not at the level of placental steroidogenesis, which is a remarkable observation when the fetal membranes are so edematous. Premature chorioallantoic separation and the failure of the membrane to rupture (red bag) are attributable to the edematous splanchnic mesoderm.[750] ACTH, T4, triiodothyronine, progestogen, and cortisol concentrations are lower in foals born to endophyte-exposed mares, suggesting that the effects are actually at the level of the fetal hypothalamic-pituitary axis, thyroid, and adrenal cortex.[753] This is likely to be the basis for the prolonged gestation and fetal dysmaturity that are associated with fescue toxicosis.

Ergovaline also inhibits prolactin secretion in affected mares by acting as a dopamine agonist at the maternal pituitary level.[754] Prolactin secretion can be inhibited experimentally by administering dopamine agonists such as bromocriptine.[755] Such prolactin-inhibiting treatment of pregnant mares results in agalactia and also mimics the other symptoms of fescue toxicosis (thickened placenta, prolonged gestation, and dystocia). An effect of fescue toxicosis in pregnant mares is a lowering of the circulating relaxin levels.[756] Clinical observations suggest that a one-time injection with fluphenazine improved pregnancy outcome by reducing the adverse effects of fescue toxicosis concomitant with a stabilization of plasma relaxin concentrations. (Caution should be exercised with the administration of fluphenazine to horses because this drug may cause severe extrapyramidal neurologic signs.) These data support

the hypothesis that systemic relaxin may be a useful biochemical means of monitoring placental function and treatment efficacy in the mare.[756]

Because mares in late pregnancy are so susceptible to the toxic effects of ergopeptine alkaloids, they should not be permitted to graze in endophyte-infected tall fescue pastures or ingest hay derived from such pastures. Short-term exposure by mares at 300 days' gestation results in a significant decline in both PRL and total progestogen concentrations within 48 hours. Fortunately, removal of pregnant mares (300 days' gestation) from infected pasture results in a significant increase in prolactin and progestogen levels within 3 days. This will prevent the development of the typical symptoms associated with fescue toxicosis.[753] Even when alternate feed sources are limited, every attempt should be made to remove pregnant mares from endophyte-infected fescue by 30 to 60 days before the expected foaling date. When this is not possible, prophylactic administration of the dopamine receptor antagonist domperidone (Equidone) at 1.1 mg/kg or sulpiride administered orally in the last month of gestation can prevent the negative effects of fescue toxicosis.[314,751,757-759]

FOALING MANAGEMENT

Gestation length is notoriously unpredictable in mares, and the greatest predictor of gestation length may be the mare herself.[760,761] Although the frequently recommended minimum gestation length for successful induction is 330 days, it must be remembered that many mares will carry a foal past 340 days and occasionally to 360 days and beyond. Some mares may carry and deliver a normal foal by 320 days of gestation. Light exposure affects gestation length in mares, particularly early in the foaling season when mares tend to have longer gestation lengths.[762] Mares foaling early in the season should be kept under lights for normal cyclicity postpartum and for normal gestation length. Mares bred in the fall will foal during the summer and will tend to have shorter gestation periods.

There also appears to be some breed variability in gestation length, with the mean for Friesians reported at 332 days, Lipizzaners reported at 334 days, Andalusians reported at 337 days, and Arabians reported at 340 days.[761,763,764] In a retrospective study of Standardbred mares, the mean duration of gestation was 343.3 days, and it was significantly greater for colt fetuses (344.4 days) than for filly fetuses (342.2 days).[765] An average gestation length of 344.1 ± 0.49 days was reported in a recent Thoroughbred study (n = 344 mares). Colt foal pregnancies were significantly longer (346.2 ± 0.72) than fillies (342.4 ± 0.65).[766] Colts were carried 1.5 days longer in a study of 495 Friesian mares.[763] The sire has been associated with duration of gestation, and gestation after mating with certain sires was consistently less than 340 days in duration, whereas duration after mating with other sires was consistently more than 350 days.[763,765] In Andalusians and Arabians, a delay of 1 month in breeding corresponded to a decrease of 3 days in the gestation length.[761]

Because gestation length is highly unpredictable in mares, several other methods have been recommended for use in routine foaling management. Every periparturient mare should be watched closely so that assistance is available at parturition to maximize chances of mare and foal survival. Assisted parturition allows early intervention and correction of simple to more complicated dystocias, allows the clinician to determine if the foal requires immediate veterinary attention, and allows intervention in cases of a "red bag" delivery (i.e., premature placental separation).

Although mammary development is a somewhat useful sign of approaching parturition in normal mares, monitoring changes in mammary secretion electrolyte concentrations and pH are useful tools to monitor time of imminent parturition.[767-769] An inversion in the sodium:potassium ratio followed by a rapid rise in calcium (Ca) concentrations in the last 24 to 48 hours has been correlated with fetal maturity in both mares and jennies.[767] Exact values may vary with the type of chemistry analyzer used by the diagnostic laboratory.

In a normal term pregnancy, the combined mammary secretion levels of Ca (>40 mg/dL), potassium (>30 mEq/mL), and sodium (<30 mEq/mL) are indicative of fetal maturity.[767] Serial assessment of these concentrations is most useful because of daily fluctuations that may occur. Calcium concentration of 10 mmol/L (40 mg/dL, 400 ppm) in mammary secretions is a reliable indicator of fetal "readiness for birth."[760,767,768]

Several stallside tests can measure the Ca ion (Ca^{2+}) concentration in mammary secretions based on a colorimetric change of pads on a test strip. Water hardness kits are also useful for determining the concentration of Ca in mammary secretions.[770-774] These involve titration of a diluted sample until an indicator dye changes color, and although they are more labor intensive than the test strips, they are reported to provide a more reliable guide for predicting the onset of parturition within the next 24 hours. However, it is important to ensure that the water hardness kit is measuring only Ca concentrations if it is being used to determine the safest time to induce parturition.[760] Many kits merely test for divalent cations, which include magnesium as well as Ca. Because magnesium levels peak earlier than Ca concentrations, misleading information about fetal maturity may be obtained.[768,771] If the intent is merely to predict the onset of spontaneous parturition, the type of test is not as critical.

A study has questioned the interpretation of calcium carbonate ($CaCO_3$) test kit data that has formed the basis of recommendations that 200 ppm or 250 ppm $CaCO_3$ should be used as the benchmark for readiness for birth. Paccamonti contends that because Ca in milk is not in the form of $CaCO_3$, any test that measures $CaCO_3$ levels in solution must be adjusted to account for this fact.[760] Because the molecular weight of $CaCO_3$ is 100 and that of Ca is only 40, the conversion factor is 2.5 (i.e., divide the $CaCO_3$ ppm by 2.5 to obtain the Ca ppm). Furthermore, because mammary secretions usually must be diluted before a water hardness test can be used to measure Ca, Paccamonti recommends that 1 mL of secretion be diluted in 4 mL of distilled water. Thus the final reading should be corrected by a factor of 5.[760] The division by 2.5 to convert $CaCO_3$ to Ca and the multiplication by 5 to correct for the dilution mean need only be doubled to provide an accurate level of Ca ppm. Using this logic, Paccamonti contends that the reports using 200 to 250 ppm $CaCO_3$ as an indication of readiness for birth are actually using Ca values of only 80 to 100 ppm. However, if these values are corrected for the reported test dilution (1:6) factor, then the $CaCO_3$ level being reported would have been 1400 to 1750 ppm (560–700 ppm Ca; 14–17.5 mmol/L). These corrected values are thus in excess of the 400 ppm (10 mmol/L) Ca concentrations reported by other researchers. It is obviously important to keep these calculations in mind because water hardness kits may vary and technicians may use different dilutions. Inappropriate application of the math could lead to an erroneous conclusion about fetal maturity and subsequent induction of a premature foal.[760]

Generally mammary secretion Ca concentrations are more reliable for predicting when a mare is unlikely to

spontaneously foal rather than for determining when she is likely to foal. Ley used a water hardness kit and reported that $CaCO_3$ levels greater than 200 ppm (see preceding discussion) indicated a 54% probability of spontaneous foaling within 24 hours, 84% probability of spontaneous foaling within 2 days, and 97% probability of spontaneous foaling within 3 days. A small percentage of mares foaled within 24 hours despite a $CaCO_3$ level below 200 ppm.[769] However, using Paccamonti's logic, this equates to a corrected value of less than 560 ppm Ca^{2+}. Because a value of 400 ppm Ca^{2+} indicates readiness for birth, it is not surprising that some of these mares foaled.

Although the fetus initiates parturition, the mare appears to be able to regulate the actual timing of delivery[775]; thus any untoward changes in the mare's environment may cause her to postpone the delivery and create discrepancies with predictions based on mammary secretion electrolyte concentrations. Calcium and other electrolyte concentrations can change rapidly during a single day, so testing secretions in the morning and evening may be useful. If a single test is to be performed, it is preferable to check the Ca levels late in the day. Generally the more rapid the rise in milk Ca levels, the more imminent is parturition. Primiparous mares can be especially difficult to monitor because no change in mammary secretion electrolyte composition may be detected until immediately before foaling.[770]

Serial assessment of pH from the mammary gland secretions in periparturient mares may also be useful in prediction of foaling.[776-778] A positive predictive value for foaling within 72 hours and a negative predictive value for foaling within 24 hours were 97.9% and 99.4%, respectively, using a pH strip test.[778] The pH of mammary gland secretions is highly and significantly correlated with electrolyte concentrations (Ca, Na, K) in those secretions. Mares that present a rapid reduction (0.5 to 0.8 pH units) from alkaline (e.g., 7.8) to slightly acidic pH (6.8 to 6.4) over 24 hours will typically foal within the next 24 hours.[777] Mares that present with a slow reduction in pH tend to foal when the pH reaches 6.4 to 6.2 and will have an acidic pH for several days prior to foaling. A subset of mares will have only a mild reduction in pH and may foal with an alkaline pH (7.4 to 7.8). These mares will not have a sodium/potassium inversion and will foal with low calcium concentrations in their mammary secretions.[777]

There are several methods to measure the pH of mare mammary secretions. While pH test strips are cheap and readily available, they may not be sufficiently sensitive to detect clinically relevant changes in pH. A hand-held pH meter that allows more accurate determination may be preferred.

Placentitis and other placental pathology are often associated with precocious mammary gland development and premature changes in mammary secretion electrolyte concentrations. Milk electrolyte changes are unreliable for assessing fetal readiness for birth in abnormal pregnancies (e.g., placentitis, impending twin abortion) or when domperidone for milk production has been administered. In cases of abnormal pregnancies there may be elevated mammary secretion calcium concentrations (>10 mmol/L; >400 ppm; >40 mg/dL) before day 310 of gestation.[476]

INDUCTION OF PARTURITION

Induction of parturition may be indicated as a clinical management procedure for some high-risk pregnancies, including mares with hydrops, ruptured prepubic tendon, and ventral herniation. These mares often require assistance with delivery because the stage II abdominal contractions may be compromised.[714] Induction of parturition should not be practiced for convenience alone but should only occur for reasons associated with the clinical well-being of the mare or foal. Owners should be advised that complications such as dystocia, premature placental separation, fetal hypoxia, and dysmaturity are not uncommon sequelae of the induction procedure.[770,779-781] The aim of a controlled foaling is not only to deliver a viable foal but also to prevent any injury to the mare that may compromise future fertility.

Induced foalings are sometimes indicated to ensure that optimal veterinary assistance is available when complications are expected and to optimize resuscitation attempts when a compromised fetus has been monitored in utero. When fetal stress is detected in a high-risk pregnancy, the clinician is faced with the dilemma of inducing delivery and attempting supportive care in a neonatal intensive unit or leaving the compromised fetus in utero. Owners should be informed that delivery is indicated only if the probability of extrauterine survival exceeds that for continued maternal support.

Experience suggests that an abnormal uterine environment is often more conducive to maintaining a fetal foal's life than a neonatal intensive care unit. A fetus that has been exposed to an adverse uterine environment for some time may be more tolerant of premature delivery.[565] Many clinicians administer a dose of corticosteroids to the mare if premature delivery appears inevitable. This may stimulate surfactant production and promote accelerated maturation of the fetal lung.

The normal physiologic processes in the prepartum mare and fetus were discussed in a previous section. There is clear evidence that the fetal hypothalamic-pituitary-adrenal axis initiates the final stages of fetal maturation, which initiates the hormonal cascade that culminates in parturition.[564] Final maturation of the fetus results in increased ACTH release from the pituitary and subsequent stimulation of the fetal adrenal cortex. It is not until the maturing adrenal gland attains 17α-hydroxylase capacity that the high levels of pregnenolone are metabolized into fetal cortisol. These vital changes lead to a fetal cortisol rise in the last 2 or 3 days before birth; thus the equine fetus is at a substantially increased risk of dysmaturity or prematurity if the induction is not carefully planned.[770] This planning has traditionally involved confirmation of gestation length, monitoring mammary development and milk or colostrum production, and ultimately evaluating the amount of cervical softening.[782] The fetus will usually be in the dorsopubic position, with neck and limbs flexed before induction. The incidence of posterior and transverse presentations is rare, but detection of these abnormalities by rectal palpation before induction would be reason to reevaluate the induction plans. Delivery by cesarean section may be a more prudent course of action, especially with transverse presentations.

The presence of cervical softening has traditionally been suggested as a prerequisite for optimal induction of parturition in the mare, and in a recent study mares with a relaxed cervix before induction had a more rapid delivery.[722] The same study found that foals delivered from mares with a preinduction relaxed cervix stood and nursed sooner and had fewer signs of intrapartum asphyxia (hypercapnia and maladjustment) than foals delivered from mares with a nondilated cervix. Mares that developed parturient complications (premature placental separation and dystocia) all had a closed cervix before induction. The status of the cervix is controversial because earlier reports suggest that inductions may proceed successfully even though the cervix is tightly closed and covered with mucus.[781]

Administration of intracervical PGE_2 (2.5 mg) before induction of parturition may aid in cervical relaxation and inducing parturition, though no difference was apparent in the mean interval from initial oxytocin treatment to rupture of the chorioallantois or to the delivery of the foal in mares pretreated with PGE_2 compared to mares administered oxytocin alone.[360] However, the impact on foal viability was positive in that foals delivered from PGE_2-treated mares suckled sooner. The application of intracervical PGE_2 may have some merit in termination of a pathologic pregnancy (e.g., hydrops) in which the induction is known to be premature and is aimed at salvaging the breeding prospects of the mare. Although there is no correlation between myometrial strip (in vitro) response to oxytocin treatment and gestational age, premature induction with oxytocin can take much longer (1–2 hours) than an induction in mares at term. This is consistent with the belief that a critical sequence of hormonal changes are required before fetal expulsion can occur. Because the aborted fetus will generally be alive and gasping for air, it is advisable to have ready some euthanasia solution to euthanize the nonviable neonate. After delivery, not all fetuses will have easily accessible blood vessels; intracardiac injection of euthanasia solution may be considered if immediate humane euthanasia is required.

Several experimental protocols have been reported for induction of parturition in the term mare, including glucocorticoids,[779,781,783-785] prostaglandins,[779,781,786,787] and oxytocin.[360,507,722,780-782] High (100 mg/day) and repeated doses (administered IM daily for 4 days) are required for glucocorticoid induction because this regimen has limited efficacy in the mare (which is not the case with ruminants).[781] However, a more recent study suggests that multiple injections of dexamethasone given to healthy mares at days 315 through 317 of gestation can induce precocious fetal maturation and delivery of viable foals within 5 to 7 days. The mares remained healthy with no evidence of laminitis.[783] Further studies are needed to determine whether dexamethasone treatment can be used safely in mares with compromised pregnancies. Prostaglandin induction is not very efficient in the mare. The synthetic products (e.g., cloprostenol) are more effective than natural prostaglandin, but results can be quite variable. Oxytocin is the preferred drug for induction of parturition in the mare. A wide range of protocols have been suggested over the years, including a bolus dose (20–75 units), low doses (2.5–20 units) repeated every 15 minutes to effect, and as a slow IV drip of 60 to 120 units total (1–2 units/min).

The choice of oxytocin regimen is less important for foal viability than appropriate case selection and adherence to criteria for induction.[722,770] A low-dose protocol has been recommended because it appears to work only in those mares that have a mature fetus.[507] Mares were diagnosed as being ready for birth by mammary secretion Ca strip test measurements. A single injection of 2.5 IU oxytocin (administered IV) was given between 1700 and 1900 hours and resulted in the delivery of a normal foal within 120 minutes in 95% of mares. In response to the first oxytocin injection, 24 of 38 (63%) treated mares foaled. Another 9 of 38 (24%) foaled the next evening in response to the second injection, and 3 of 38 (8%) foaled in response to the third treatment. It was concluded that the major advantage of injecting a daily low dose of oxytocin appears to be that such a low dose induces delivery in only those mares that are carrying a mature fetus and are ready to foal. It has been proposed that this low-dose, early-evening oxytocin protocol could be used as a reliable method to induce parturition or to predict that the mare would not foal that night, if parturition did not occur within 2 hours of treatment. However, even this promising protocol has limitations because it is still possible to occasionally induce a mare to deliver a premature foal.

Villani and Romano studied the effects of a daily oxytocin treatment (3.5 IU) on 174 full-term Standardbred mares that had mammary secretion Ca levels of ≥200 ppm.[788] In this study 69% of the mares foaled within 2 hours of treatment (51.3% responded to the first oxytocin administration, 14.2% to the second, and 3.4% to the third). No significant difference between treated and control mares was observed in the gestational length (340 ± 8 days vs. 337 ± 7 days), duration of foaling (10 ± 5.6 minutes vs. 11 ± 4.9 minutes), incidence of dystocia (1.4% vs. 1.7%), or failure of rupture of the allantochorion (0% vs. 0.6%). No significant difference was observed in the incidence of placental retention between treated and control groups (8.1% vs. 6.3%). Physical and behavioral characteristics were normal in foals of both groups. The authors concluded that daily injections of low doses of oxytocin in at-term mares showed only moderate efficacy for inducing parturition. However, the easy applicability and safety—for both mare and foal—of this method of foaling induction make it a useful tool to simplify the management of mares in commercial stud farms.

Because most inductions will be performed because complications are expected, the clinician should be well prepared before administration of the induction agent (low-dose oxytocin). Even if the induction is not being performed by an IV drip, it is recommended that an IV catheter be inserted. This will facilitate rapid induction of general anesthesia if obstetric difficulties ensue. A fully stocked obstetric kit and ample volumes of lubricant should be placed outside the stall. Neonatal resuscitation efforts should be anticipated, and appropriate supplies (e.g., oxygen delivery system) should be readily available. Premature separation of the placenta is not an uncommon complication of induced births. The clinician should immediately rupture the exposed chorioallantois and then assist with fetal delivery in conjunction with the mare's expulsive efforts. Overzealous traction at this time may cause a laceration of the cervix if it is not yet fully dilated. If necessary, an oxygen tube can be placed in the foal's nostril during the minute or two that may be required to complete the assisted delivery. Additional discussion of neonatal resuscitation and critical care is included in Chapter 20.

MANAGEMENT OF THE PREGNANT MARE

A series of manuscripts addressing the effects of nutrition on various aspects of equine reproduction have recently been published.[789-792] Copper is an overemphasized factor in the etiopathogenesis of osteochondrosis lesions. Supplementation of pregnant mares with copper had no significant effect on the concentration of copper in the liver of foals at birth or on the frequency or severity of lesions in articular cartilage at 160 days of age.[793] Regular exercise and routine hoof maintenance are important for broodmares. A regular anthelmintic program is essential to ensure the mare's well-being. It will also reduce the exposure of the foal to parasite eggs in the mare's feces and the transmammary transfer of *Strongyloides westeri*

larvae. Pregnant mares should be current for all vaccinations that are recommended for their particular geographic locations. In North America it is especially important to advise owners about the importance of a regular vaccination program for EHV. Owners and farm managers should be aware of the need to isolate pregnant mares from transient horses to reduce the risk of infectious disease, especially respiratory viral infections. A tetanus booster may be indicated 1 month before foaling. The American Association of Equine Practitioners has published a general guideline for vaccination of horses, including pregnant mares. The reader is referred to that publication for current best practices related to vaccination of horses.[794]

Ideally the mare should be transferred to the final foaling environment at least 1 month before the due date. Foals are born essentially agammaglobulinemic, and the neonate depends on passive transfer of colostral immunoglobulins to provide initial protection from environmental pathogens. If a vulvoplasty (Caslick surgery) has been performed, plans should be made to open this approximately 1 week earlier than the expected foaling date. If the mare has a history of a previous hemolytic foal (neonatal isoerythrolysis), plans should be made to prevent the neonate from suckling the mare until all the colostrum has been removed or plans for compatibility testing of the milk and foal blood should be made. The mare may be screened for the presence of antibodies to common equine blood antigens 2 weeks prior to the anticipated foaling date to identify mares at risk for producing incompatible colostrum. At-risk mares should be milked immediately postpartum and the foal not allowed to suckle its dam for 24 hours. Some practitioners recommend administering sulpiride or domperidone for early milk production and milking the mare prepartum to avoid colostrum formation. An alternate source of colostrum from an appropriate donor should be available for the foal and plasma supplementation considered.

Those responsible for monitoring the foaling process should understand that mammary development, followed by distention and waxing of the teats and then relaxation of the perineal area, indicates approaching parturition in the mare. The use of mammary secretion electrolyte concentrations and pH to predict foaling was discussed in a previous section. Although it is accepted that the fetus signals its readiness for birth, the mare can regulate the final timing of delivery. Electronic monitoring systems that can be used to signal the start of parturition are also available.

Inexperienced personnel should be counseled about normal foaling events and instructed in how to recognize when professional assistance is required. Inappropriate intervention by ill-informed individuals can jeopardize the foal's life and potentially cause life-threatening complications in the mare. Separation of the fetal membranes will deprive the fetus of oxygen, and this is the critical factor that must be considered when assessing an obstetric case that involves a live foal. Although most references suggest that fetal survival rates are very low if the foal is not delivered within 30 to 40 minutes of chorioallantoic rupture, one author reports having delivered live foals by cesarean section up to 90 minutes later.[795] Another study reports high foal survival rates in mares referred with dystocia for as long as 1.5 hours post rupture of the chorioallantois. These authors suggest that, because transverse presentation appears to be more common in draft mares, parturition does not progress as expected, mares stop having uterine contractions, and, as a consequence, there is minimal placental detachment. These are cases that were promptly presented to the veterinary hospital and that had minimal, if any, vaginal intervention at the farm. It is likely that limited vaginal intervention is less disruptive to the placental attachment, and these foals are not deprived of their oxygen supply. Keeping the mare on her feet, and walking if necessary, may help to reduce straining while professional assistance is sought. If a mare is located a great distance from a referral facility equipped to provide appropriate care, the mare should be sedated with detomidine, and oral clenbuterol should be administered prior to transport.

Normal Parturition

Terminology

The terms *presentation, position,* and *posture* are used to describe the orientation of the fetus as it enters the vaginal canal. Often a fetus is described as having been malpresented or malpositioned when the only anomaly present is postural, the most common cause of dystocia in the mare.[796] To prevent confusion, the all-encompassing term *fetal maldisposition* may be used to describe the combination of presentational, positional, and postural abnormalities that can contribute to a dystocia. *Presentation* describes the aspect of the fetus that enters the vaginal canal first and the orientation of the fetal spinal axis to that of the mare (anterior or posterior longitudinal; ventral or dorsal transverse). More recently, use of the terms *cranial* and *caudal presentation* has become more common. *Position* describes the relationship of the fetal dorsum (longitudinal) or head (transverse) to the quadrants of the mare's pelvis. The normal position for delivery is dorsosacral. A fetus that is still on its side would be right or left dorsoilial, and a fetus that is upside down would be dorsopubic. The terms *right* and *left cephaloilial* refer to the position of the fetal head relative to the mare's pelvic walls, and they imply that a transverse presentation was present. Posture is purely fetal and describes the relationship of the extremities (head, neck, and limbs) to the foal's body (flexed or extended).[200,796]

Fetal Kinetics

Fetal mobility has been discussed with respect to umbilical cord torsion and abortion. Fetal rotation within the amniotic cavity and amniotic sac rotation within the allantoic cavity result in the characteristic twisting of the umbilical cord.[676,677] A highly efficient mechanism ultimately guides most equine fetuses into a cranial, longitudinal presentation. Ultrasonographic studies have noted the percentage of anterior, posterior, and transverse presentations at 5 to 6 months to be 52%, 29%, and 19%, respectively, but the fetal presentation becomes predominantly anterior between 7 and 11 months.[673,675-677,682] Vandeplassche reported the incidence of anterior, posterior, and transverse presentations in the normal parturient mare population to be 98.9%, 1.0%, and 0.1%, respectively.[797] Ginther observed that muscular contractions close the lumen of both uterine horns between 5 and 7 months; thus the allantoic fluid (with the fetus) is confined to the uterine body.[673,674,676] During this time the fetus positions itself so that its head end points toward the mare's cervix (cranial presentation). It has been proposed that neurologic signals within the fetal inner ear may respond to the slope of the ventral uterine wall and guide the fetus to lie with its head elevated toward the cervix.[673] In most cases the noncord horn remains closed, whereas the cord horn gradually permits the entry of the hindlimbs between 7

and 9 months. The limbs can enter the horn only when the fetus is in dorsal recumbency because the angle between the horn and body is so acute by this stage of gestation. Thereafter the hindlimbs remain enclosed within the cord horn, and the hooves extend to the horn tip by the tenth month. Thus the selective closing and opening of the uterine horns, with subsequent trapping of the hindlimbs, is believed to be a key feature of the mechanism that ultimately directs fetal orientation into cranial presentation.[673,675] Entrapment of the hindlimbs within the uterine horn generally means that the caudal portion of the anteriorly presented fetus will be lying in a dorsopubic, and occasionally dorsoilial, position.[675] Ginther's ultrasonographic investigations substantiated the classic radiographic study demonstrating that the full-term equine fetus is initially lying in a dorsopubic position with the head, neck, and forelimbs flexed.[675,798]

In early pregnancy the mesometrial attachments suspend the uterine horns so that they point cranially and dorsally, but by late gestation the horn containing the hindlimbs comes to rest on the dorsal surface of the uterine body with the tip of the horn directed back toward the cervix.[402,675] The hooves and horn tip may be pushed so far caudally that they actually come to lie over the fetal head, meaning that when a rectal evaluation of a mare that is in late gestation is performed, the fetal hooves that are palpable may be attached to the hindlimbs. In some mares the vigorous, piston-like thrusts of the hindlimbs in association with elevation of the fetal rump may push the hooves past the cervix into the rectogenital pouch. This observation may explain the acute colic episodes that have been previously attributed to uterine dorsoretroflexion. Although the caudal aspect of the fetus is intimately associated with the uterine wall, the cranial portion has room to rotate within the uterine body itself. Ultrasonographic studies on mares close to term (>330 days' gestation) have shown that the cranial half of the fetus was in dorsopubic position approximately 60% of the time and in dorsoilial position about 40% of the time. The forelimbs and head were usually flexed (about 80%), but the remainder of the head or limbs was extended.[673] Postural changes are common; thus rectal palpation before the onset of first-stage labor is not a good predictor of impending dystocia. However, detection of a posterior or transverse presentation at this late stage is cause for concern, and appropriate plans should be made to manage the impending delivery.

Stages of Parturition

Behavioral changes that characterize the first stage of parturition include the mare looking at her flank, frequently lying down and getting up, stretching as if to urinate, and passing small amounts of feces. Patchy sweating may develop, and some mares will leak colostrum.[200,796] The restless behavior is similar to that of mild colic and is associated with the development of coordinated uterine contractions that increase uterine pressure and push the chorioallantoic sac (in the region of the cervical star) into the gradually dilating cervix. The increasing uterine tone during stage I of parturition may stimulate the fetus to extend its head and forelimbs up into the dilating pelvic canal.[402] Once the head and forelimbs are fully extended, they are unlikely to return to a flexed posture unless the foal reacts to manual intervention on the part of a foaling attendant. However, it is possible for the neck or a forelimb to develop a malposture if it is not correctly aligned when the mare begins an expulsive effort. Passage of the urine-like allantoic fluid ("water breaking") concludes the first stage of labor. Rupture of the chorioallantois and passage of the allantoic fluid does not occur until the fetlocks, or sometimes the knees, are at the level of the external cervical opening. If the chorioallantois does not rupture, then further separation from the endometrium can result in a red bag delivery, with the velvety red membrane appearing at the vulvar lips. In a normal delivery the chorioallantois is thought to remain attached to the endometrium until after the foal is delivered.[796]

Failure of the chorioallantois to rupture is a common complication of induced parturition.[722] If this happens, then continued separation from the endometrium will compromise transplacental oxygen exchange, and fetal hypoxia is likely.[796] Premature separation of the placenta, or red bag, is an emergency situation, and foaling attendants should be instructed to break the membrane and provide gentle traction in unison with the mare's expulsive efforts. Although the foal should be delivered as quickly as possible, injudicious traction at this time may cause a laceration in an incompletely dilated cervix.[796] Applying traction only in conjunction with the mare's expulsive efforts will reduce the likelihood of creating cervical trauma.

As parturition progresses, passage of the fetus into the pelvic inlet initiates a reflex release of oxytocin from the posterior pituitary (Ferguson reflex), enhancing uterine contractility.[200] Stage II is characterized by strong abdominal contractions that provide the expulsive force necessary to expel the fetus. Most mares will assume lateral recumbency once active straining commences. Many get up once or twice during stage II labor in what is believed to be a further attempt to correctly position the fetus.[796] Appearance of the translucent fluid-filled amnion at the vulvar lips can be expected to occur within 5 minutes of rupture of the chorioallantois.[799] Any delay in the stage II expulsion process increases the likelihood of fetal asphyxia or neonatal problems associated with hypoxia caused by placental separation. At least one hoof should be visible within the amniotic sac, and the other should be located approximately 2 inches behind it. If everything is progressing normally, then the soles of the hooves should face down toward the mare's hocks, and the foal's head should be resting between the carpi.

By the time the nose has reached the vulva, the cranial half of the torso should have rotated from a dorsopubic to a dorsoilial position. The mare probably assists the fetus to reposition itself by the characteristic side-to-side rolling each time she becomes recumbent. It is likely that some dystocias involving fetal malposition and malposture are caused by the failure of a compromised fetus to actively participate in the foaling process. Less vigorous or absent fetal righting reflexes early in the parturient process have been suggested by many authors as a cause of fetal maldisposition.[200,726,798] The observation that ventral deviation of the head and neck is more likely to be present if the fetus is in a dorsoilial position than in a dorsosacral position further substantiates the hypothesis that the fetal righting reflexes are compromised early in these cases.[726]

The second stage of labor in the mare is rapid, with the most forceful contractions occurring as the chest passes through the pelvic cavity. Most foals are delivered within 20 to 30 minutes after the chorioallantoic membrane ruptures. Primiparous dams generally require more time to expel the fetus than do multiparous dams.[200,799] The amniotic sac usually ruptures during these expulsive efforts. However, the equine amniotic sac is not attached to the chorioallantois, as is the case with a ruminant placenta, and the foal sometimes may be delivered with a portion of the sac wrapped around its head. Foaling

attendants should be instructed to promptly free the foal's head from the amniotic sac to prevent suffocation. Active straining ceases once the foal's hips are delivered, and the mare will rest in lateral recumbency. An active foal will extract the hindlimbs from the vagina as it struggles to stand. Stage III of parturition involves expulsion of the fetal membranes, which typically takes between 30 minutes and 3 hours.[200] Owners should be advised to seek veterinary assistance if passage of the membranes is delayed beyond 4 to 6 hours because life-threatening toxic metritis and laminitis are common sequelae of fetal membrane retention.

Etiology of Dystocia

The incidence of dystocia in the general horse population varies among breeds (Thoroughbreds 4%, Shetland ponies 8%, draft breeds 10%).[800] Dystocia is one of the few true emergencies in equine practice. Literally a matter of minutes can determine a successful outcome (i.e., the birth of a live foal). Perinatal asphyxia associated with dystocia is a major cause of equine reproductive loss.[591,592] The long fetal extremities (limbs and neck) predispose the mare to foaling problems. Alert, informed foaling attendants are essential to ensure that abnormalities are recognized early. Attendants should suspect that the mare is experiencing obstetric problems if either the first or the second stage of parturition is prolonged or not progressive.

Signs that a mare may be in dystocia include the failure of any fetal parts or of the amniotic membrane to appear at the vulvar lips for a prolonged period after rupture of the chorioallantois, appearance of only one hoof at the vulva, hooves upside down at the vulva, hooves and nose in an abnormal relationship, and nose but not hooves at the vulva. The most common impediments to delivery are malpostures of the fetal extremities (head and neck and limbs).[726] An experienced foaling attendant may be able to correct minor problems and facilitate a successful delivery, but inappropriate intervention can have potentially fatal consequences for the mare. Furthermore, obstetric manipulations can easily damage the uterus and cervix to the extent that the mare's reproductive future is jeopardized.

Management of Dystocia

When attending to a mare in dystocia, the veterinarian should make a rapid assessment of the mare's general physical condition, noting in particular mucous membrane color and refill time (hemorrhage, dehydration, and shock). A mare that is aborting in late gestation may experience a dystocia because the dead fetus cannot participate in the delivery process. A malodorous discharge and fetal hair in the hands of the clinician strongly suggest the presence of an emphysematous fetus. The perineal area should be inspected to determine the presence and nature of any vulvar discharge and the presence of fetal membranes and to identify any fetal extremities. Excessive hemorrhage or vulvar swelling may indicate that intervention by inexperienced individuals has caused trauma to the reproductive tract. Occasionally, a foaling mare will present with rectal prolapse, an everted bladder, or intestinal loops protruding from the vulvar lips. The intestines may be of fetal origin if there is incomplete closure of the ventral abdomen, but a ruptured vagina is more likely. In the later scenario the foal's foot may have ruptured the floor of the cranial vagina, but injudicious manipulations by an inexperienced attendant should not be discounted. If a rectal prolapse or the urinary bladder is evident, then an epidural anesthetic should be administered to prevent further straining. Alternately, the mare may be anesthetized to facilitate hoisting the hindquarters. The advantage of this approach is that the straining can be stopped immediately. This is especially important if the prolapse involves an intussuscepted colon (type IV). In these cases a palpable defect may extend several feet into the rectum, and avulsion of the mesentery can be a fatal complication that is not readily amenable to surgical correction.

Due to the unpredictable and potentially violent nature of mares in stage II of labor, the use of stocks for restraint is contraindicated. The initial examination can be performed on a standing mare with no more restraint than a twitch or lip chain if her demeanor permits this to be performed safely. It is important to ensure that the examination area is clean, with good footing. There should be ample space for the mare handler, obstetrician, and assistants to move to safety if necessary. Although most veterinary tranquilizers readily cross the placenta and can compromise the fetus, adequate restraint is essential for the safety of all involved.[801] Sedation with tranquilizers may be necessary for some uncooperative mares, and in extremely intractable cases it may be preferable to anesthetize the mare with a short-acting combination. In these cases a hoist should be available to elevate the hindquarters because manipulating the foal is sometimes difficult when the mare is in lateral recumbency. Although not essential, an initial rectal examination may help the practitioner rule out the presence of a term uterine torsion and determine the condition of the uterine wall (tears and spasm). It also may provide useful information regarding the disposition of the fetus. Before any vaginal examination the mare's tail should be wrapped and the perineal area thoroughly cleansed. The clinician's arms and hands should be scrubbed, and the clinician should wear sterile obstetric sleeves. Cleanliness and lubrication are the cornerstones of obstetrics.

The mare's vagina and cervix are easily traumatized by the friction associated with vaginal manipulations. Once the mucous membranes have been abraded, it is likely that adhesions and fibrosis will follow. Thus copious amounts of lubricant are vital to ensure that the soft tissues of the genital tract are not traumatized to preserve the mare's future fertility.[802] Lubricants include methyl cellulose, polyethylene polymer, white petrolatum combined with 10% boric acid, and mineral oil. Water-soluble lubricants are generally not as desirable, because they rapidly lose their lubricating abilities in the presence of fluids. If a large volume of lubricant is to be pumped around the fetus, then investigating the possibility of a uterine laceration is essential. In a referral situation, abdominocentesis should be performed. Serosanguineous to sanguineous fluid that contains elevated total protein levels and an increased white blood cell count is highly suggestive of a uterine rupture.[197] If a uterine tear is unlikely, obstetric lubricant may be gently instilled into the uterine lumen using a clean stomach tube and pump.[802] This is repeated as often as necessary during the procedure to keep the fetus and reproductive tract coated with lubricant.

The vagina, cervix, and accessible parts of the uterus should be carefully explored to ascertain the source of any hemorrhage. Lacerations should be noted and their presence discussed with owners or the attending personnel before any veterinary manipulations are attempted. Occasionally, the cause of the dystocia is a pelvic deformity (e.g., callus, neoplasia). It is important to determine the degree of cervical

dilation. If the mare has been in labor for some time, then it is possible that the uterus is relatively dry and tightly contracted around the fetus. This will make intrauterine manipulations much more difficult, especially because it becomes difficult to repel the fetus back into the uterus without risking rupture. When the uterus is contracted, warm lubricant tends to induce some uterine relaxation, and the volume expansion creates additional space in which to perform manipulations.[204,802] Myometrial contractions (uterine spasm) can be controlled by tocolytic drugs (isoxsuprine and clenbuterol) if they are available for veterinary use.[800] Some mares never stop having strong uterine contractions; general anesthesia is highly beneficial for these mares and allows the clinician to perform appropriate obstetric interventions.

Although fetopelvic disproportion is less common in the mare than the cow, it can be a factor in some equine dystocias.[445,796,803] The disposition of the fetus should be noted and fetal viability determined. Care should be exercised because active fetal response to manipulations can easily complicate an initially simple dystocia. Placement of a rope snare behind the ears and into the foal's mouth ensures that the clinician always has control of the head. This will facilitate correction of a potentially life-threatening development such as lateral deviation of the head and neck if the fetus pulls away from the clinician's manipulations. If the snare is placed around the mandible, then it is essential that only gentle traction be applied to guide the fetal head through the vaginal canal. Excessive force may cause a fracture of the mandible. When obvious fetal movement is absent, digital withdrawal may be initiated in response to pinching of the coronary band. Slight digital pressure over the eyelid onto the eyeball may arouse a response, as may stimulation of the tongue (swallowing). If the thorax can be reached, then the fetal heartbeat is definitive. In posteriorly presented cases the digital and anal reflexes are useful as indicators of fetal viability. Occasionally, it may be possible to reach the umbilical cord.

The clinician should inform the owner of the various options, costs, and prognosis once the current status of the foal is known and the cause of the dystocia has been determined. Ensuring that the owner is aware of the potential complications that may arise is especially important because postpartum medical care can become quite expensive. If delivery of a live foal is anticipated, then the clinician should consider the potential for fetal cardiovascular compromise before administering any tranquilizers to the mare. Light sedation of the mare with acetylpromazine (2–3 mg/100 kg IV) has minimal effect on the foal and may be useful in some cases.[801] Xylazine is preferable to detomidine if the fetus is viable because its depressant effects are of much shorter duration. However, neither xylazine nor detomidine should be used alone to sedate a dystocia case because some apparently sedated mares can become hypersensitive over the hindquarters.[706,801] The combination of xylazine and acetylpromazine provides good sedation in a quiet mare.[198] The author routinely uses a combination of xylazine (0.3–0.5 mg/kg IV) and butorphanol (0.01–0.02 mg/kg IV) for standing obstetric procedures if more sedation is required (e.g., fetotomy procedure). This provides good sedation and analgesia, and additional doses may be administered as necessary. Attendants are instructed to keep the lip chain loose and to tighten it only when instructed to do so. This will ensure that it retains its effectiveness when required to divert the mare's attention. LeBlanc suggested a xylazine (1.1 mg/kg) and morphine (0.1–0.2 mg/kg) combination for sedation of fetotomy cases but cautions that gastrointestinal stasis is a frequent complication.[801]

Although most dystocias can be resolved at the farm fairly quickly by brief manipulation and assisted vaginal delivery, the practitioner should consider the alternatives if resolution is likely to take more than 10 to 15 minutes. Prolonged, unproductive vaginal manipulations are contraindicated in equine obstetrics. Decisions on the next course of action should be based on the viability of the foal, the clinician's obstetric skills, the availability of equipment and facilities, and the financial constraints imposed by the owner.

An epidural does not prevent the mare's myometrial contractions or the abdominal press, and the time involved in administering an effective epidural anesthetic may make this form of restraint impractical when a live foal is present.[796,801] However, if the foal is dead, epidural anesthesia does reduce vaginal sensitivity and thus the mare's perception of vaginal manipulations (Ferguson reflex). Caudal epidural anesthesia should be used at the clinician's discretion, especially if general anesthesia or referral may become necessary. When an epidural is indicated, the author uses a combination of xylazine (0.17 mg/kg) and lidocaine (2–3 mL) diluted in saline, such that the final volume does not exceed 8 to 10 mL to reduce the likelihood of hindlimb weakness.[801,804] Excess volume can cause the mare to become ataxic. Short-term general anesthesia may be indicated when minor postural abnormalities are present and maternal expulsive efforts make correction difficult. Xylazine (1.1 mg/kg IV) followed by ketamine (2.2 mg/kg IV) provides a general anesthetic with a smooth, short (10–15 minutes) duration. Addition of the central-acting muscle relaxant guaifenesin (1 L of a solution of 5% guaifenesin in 5% dextrose) can provide an additional 10 to 20 minutes for fetal manipulation.[801]

In referral equine hospitals that are located close to well-managed broodmare farms, the fetus is often still alive when the mare arrives. A well-coordinated dystocia team that uses a defined protocol can minimize time spent nonproductively. Intrapartum intratracheal intubation and positive pressure ventilation of the fetus (ex utero intrapartum treatment [EXIT]) during resolution of the dystocia has been shown to improve survival rates. It should be remembered that positive pressure ventilation must be continued once begun because it promotes the conversion from fetal circulatory patterns to neonatal patterns, essentially eliminating the role of the umbilicus.[805] In referral hospitals it is common practice to anesthetize the mare after a brief vaginal intervention and then maintain the mare on halothane-oxygen with controlled ventilation. Because halothane anesthesia has been shown to compromise umbilical circulation, the concentration should be kept to a minimum if the foal is still alive.[806]

Total intravenous anesthesia (the so-called triple drip of ketamine, xylazine, and guaifenesin) may be preferable until the foal has been delivered.[801] The mare should be ventilated with oxygen, and IV fluids should be administered as required. If the hind-end elevation technique is used, almost three quarters of such cases can be resolved by controlled vaginal delivery. However, if the fetus is still alive and has not been delivered within 15 minutes, an immediate cesarean section is performed, with a 30% foal survival rate possible, provided the time from rupture of the chorioallantois to presentation at the veterinary hospital is minimal.[795,807] Fertility after cesarean section is quite good, and adverse reports probably pertain more to the extent of vaginal manipulation after surgery.[808,809]

If a hoist is available in the field, then hobbles can be placed on the hind pasterns and the hindquarters briefly elevated 1 to 2 feet. The combination of a relaxed uterus and the effects of gravity can facilitate fetal repulsion and manipulation. If attempts at mutation are successful, then the mare should be lowered into lateral recumbency to permit extraction of the foal. Prolonged dorsal recumbency results in compression of the aorta and vena cava and reduction in venous return, cardiac output, and blood pressure.[801] Hindlimb paresis may develop after prolonged hindquarter suspension and can complicate the recovery process. The use of pads to support the hindquarters will help take some weight off the limbs while the mare is suspended.

Mutation is an obstetric term that is used to describe manipulation of the fetal extremities, with correction of any positional abnormalities, so that assisted vaginal delivery can proceed.[200] Although extra space is available for manipulations when the fetus has been repelled into the uterus, the clinician should remain cognizant at all times that overzealous obstetric manipulations are a major cause of uterine rupture.[197,198,200,204,735,810-812] Repulsion of the fetus from the maternal pelvis is contraindicated if the uterus is contracted down around the fetus. In countries where they are legal, tocolytic agents are effective in relaxing a contracted uterus. If the fetus is dead, many cases may be amenable to correction by fetotomy provided that the clinician has the appropriate skills and equipment.[813-817] Although poor technique and inappropriate fetotomy cuts often lead to infertility, experienced clinicians can rapidly resolve a dystocia while preserving the mare's future breeding potential. The alternative is cesarean section.

Traction must be applied with careful regard for both maternal and fetal well-being. Often traction applied entirely by hand is all that is necessary. Obstetric straps or chains may provide a better grip, with one loop above the fetlock and a second loop encircling the pastern. In assisted vaginal deliveries, traction should be applied as an adjunct when the mare is exerting expulsive force and should be released when the dam stops straining, permitting rest and recovery. This approach is critical to permit adequate dilation of the caudal reproductive tract. Copious lubrication and slow traction with continuous monitoring of cervical dilation are especially important when a controlled vaginal delivery is performed on an anesthetized mare. Excessive use of force may be associated with fetal fractures (ribs, vertebrae, and limbs), maternal soft tissue trauma, and uterine prolapse.[818] No more than two or three people (depending on size and strength) should apply traction to the fetus.

Cranial (Anterior) Presentation

An anteriorly presented fetus that is in the dorsosacral position with head and forelimbs extended should require minimal traction to complete the delivery, assuming that the vaginal canal is well lubricated. By ensuring that slightly more traction is applied to one limb than the other, the practitioner reduces the width of the fetus across the shoulders and can successfully deliver most cases. If progress is not being made, then all traction should stop and the vaginal canal must be fully explored. There are three likely possibilities: elbow lock (incomplete extension of the forelimb), dog-sitting or hurdling posture, and occasionally a fetus that is too large.

Absolute or relative fetopelvic disproportion is uncommon in the mare even when the foal has been carried several weeks past the expected due date. In fact, some cases of prolonged gestation may involve a smaller than normal, dysmature fetus. In a referral hospital study, fewer than 2% of dystocias were attributed to this condition.[726] It is significant, however, that approximately 30% of referral hospital dystocia cases are in primiparous mares.[726,799] Primiparous mares were disproportionately represented in a report on dystocia and neonatal asphyxia from the central Kentucky area.[178] Although fetopelvic disproportion is not common in the mare, obstetric assistance (traction) is required much more often in primiparous mares.[200,730] Dystocia in these mares is further complicated by a tight vaginovestibular sphincter, which may predispose primiparous mares to lacerations and rectovaginal tears. If copious lubrication and gentle traction do not help, then cesarean section or partial fetotomy are the only alternatives.

Incomplete elbow extension may be unilateral or bilateral and should be suspected if the fetal muzzle lies at the same level as the hooves. In this posture the fetal elbows will be tucked back under the shoulder joint, causing increased depth and width of the fetus within the maternal pelvic inlet. Correction involves repelling the fetal trunk so that the forelimbs can be extended, raising the elbows up over the floor of the pelvic inlet.

In a dog-sitting or hurdling posture, there is either bilateral (dog-sitting posture) or unilateral (hurdling posture) hip flexion. This causes the fetal hooves (or hoof) to push against the pelvic brim during attempts at fetal extraction. The unilateral posture is more common.[726] Severe trauma can be inflicted on the mare if this malposture is not recognized and inappropriate amounts of traction are applied. Thus it is important to stop all traction and repel the fetus enough to sweep the floor of the pelvic inlet. In extreme cases the hindlimb may actually extend under the fetus and up into the vagina.[726] Although the hindlimb may be successfully repelled if the fetus is alive, it is a difficult procedure and is associated with some risk of uterine laceration. Judicious use of a snare or fetotome may facilitate safe repulsion of the hindlimb by looping the pastern and using the instrument to repel the hoof away from the pelvic brim. Repulsion should not be attempted on a standing mare if the fetus is dead, because the hindlimb may not return to its normal position. In such cases the hoof of the flexed hindlimb can puncture the ventral uterine wall as the foal is being extracted. If a dog-sitting or hurdling foal is dead, it is then recommended that general anesthesia and hoisting of the hindquarters be used to reduce the risk of ventral uterine rupture.[819] In experienced hands, partial fetotomy is a viable alternative to cesarean section.[813,814,817] A surgical alternative to a cesarean section involves manipulation of the hindlimb through a ventral midline celiotomy incision. An assistant may be able to extract the fetus through the vagina once the hindlimb has been grasped through the ventral incision. If successful, this technique will reduce the potential for contamination that may be associated with cesarean section. If a cesarean section is performed, some surgeons prefer to remove that portion of the foal that is protruding through the vulvar lips before withdrawing the hind end out through the surgical site.

In a foot-nape posture one or both of the forelimbs is displaced over the foal's head and pushed against the roof of the vagina.[802] To correct this malposture the fetus must be repelled into the uterus by applying pressure to the head. Once the forelimbs have been replaced under the head, fetal extraction can proceed quite uneventfully. If not corrected immediately, then the mare's straining can cause the fetal hoof to
