Preface

This is the fourth edition of *Equine Internal Medicine.* Like its three predecessors, it has been written and edited with the aim of promoting a clearer comprehension of the principles of medical disease and/or problem development by focusing on the basic pathophysiologic mechanisms that underlie the development of various equine diseases. As with previous editions, basic information is presented and then related to the clinical characteristics of each disease and its therapy and management.

Most of the chapters that appeared in the previous three editions have been updated, and a number of them have been extensively revised or rewritten. Although the bulk of the chapters address specific diseases along systems-based lines, we realize that the practitioner is initially confronted with a specific problem that may have its origin in one or more of the body's systems. The first section of the book is therefore devoted to an in-depth discussion of the basic mechanisms by which problems might develop, and the principles underlying the treatment of many of them. The reader can build on this foundation by reading about specific disorders in the second section of the book, which is divided into chapters dealing with problems of a particular body system or of a specific nature.

Many true experts have contributed to this text. Their depth of knowledge about all aspects of equine internal medicine is encyclopedic and daunting. We are grateful for their efforts and diligence in helping us to produce what we hope will continue to be regarded as the definitive text on medical diseases of horses. We are indebted to them for their efforts. We trust that they derive a sense of pride from the part they have played in producing what we hope represents the gold standard in equine medical textbooks.

In these days of progressive globalization of the world's societies and associated growth in the international movement of horses for breeding, recreational, and competitive purposes, there also has been a worldwide increase in expectations relating to the standard of veterinary care and evaluation of sick horses. The sophistication of specialist training programs and the increased number of equine internists also taking advantage of postgraduate doctoral opportunities have resulted in a wealth of new information and the maturing of an increasingly complex and challenging discipline—equine internal medicine. The delivery of superior health care and increased client expectations that have been associated with the growth of this discipline have led to the appearance of extremely well-informed and astute equine general practitioners everywhere, and specialist equine internists on most continents. More than ever before, equine internal medicine now stands as an autonomous specialty in the veterinary profession. We trust that the fourth edition of *Equine Internal Medicine* will prove to have as much universal appeal and application as those editions that preceded it.

Finally, we would be remiss if we did not thank the many people at Elsevier for their persistence and efforts. Penny Rudolph, Lauren Harms, Radhika Sivalingam and Anna Miller in particular deserve our gratitude. They and many others have assisted in manuscript preparation, correspondence, and all the other tasks that must be completed to get a book like this into print. Without them and the generosity of our colleagues, this book would not have been published. We think that everyone's efforts have been worthwhile.

CHAPTER 1

Mechanisms of Disease and Immunity

Robert H. Mealey and Maureen T. Long*

The Microbiome

Maureen T. Long

Dermal and mucosal surfaces provide a life-preserving protective barrier composed of physical, chemical, and microbial defenses.[1] In the past 5 years, the concept of normal flora has been broadened to include the whole of "microbiota" that colonizes skin, gut, and mucosal surfaces. The microbiome is the science of analyzing the total number of organisms in an ecosystem, which in our case are animals. The practical application of this science to the clinician is that the microbiome differs among many niches of the body, varies with individuals, and has an interactive role with actual disease states. Microbiota is the microbial population within the different sites of the body. *Commensal bacteria* are those living on or within a host in a way such that both derive mutual benefit and in which interruption of this association results in abnormal host development or overt disease. These represent that part of the microbiome that has intimately coevolved with the different niches of the body.[1]

Environment is local, such as within different areas of the gut, and also external, and these can have either positive or negative effects on the microbiome. For instance, poor ventilation in animal housing not only is a direct irritant, but changes in pH, metabolism of particulates, and activation of the immune system will dramatically alter the structure of the microbiome.

Age is also an important factor. Colonization of skin and mucosal surfaces occurs at birth and is highly variable in early life. Changes in management from birth to weaning are accompanied by changes in diet and husbandry for horses. They create a highly dynamic environment that eventually can be used to predict best practices once data on the microbiome in healthy horses are obtained in a methodical and scientific manner.

Skin Microbiome

The combination of normal flora and mucosal immunity provides an effective barrier against infectious colonization of nondisrupted skin surfaces. Even though horses inhabit an environment heavily contaminated with fecal flora, normal dermal flora in the horse is surprisingly devoid of members of the Enterobacteriaceae.[2] Normal inhabitants include mixed populations of bacteria of species of *Acinetobacter, Aerococcus, Aeromonas, Bacillus, Corynebacterium, Flavobacterium, Micrococcus, Nocardia,* coagulase-negative *Staphylococcus, Staphylococcus aureus, Streptomyces,* and nonhemolytic *Streptococcus* generae.[3] Certain *Staphylococcus* spp. have been associated with skin disease in the horse, and these include *S. aureus, S. intermedius,* and *S. hyicus,* whereas species such as *S. xylosus* and *S. sciuri* were more associated with normal skin. More than 30 species of fungi can inhabit the skin and *Alternaria, Aspergillus, Candida, Fusarium, Rhizopus,* and *Trichophyton* spp. are commonly present.[2] Until recently the presence of *Malassezia* yeast species has been considered pathogenic. Recent fungal culturing of the skin of normal, healthy horses has confirmed colonization by a species of *Malassezia* yeast that is novel to the horse (tentatively named *M. equi*). Colonized sites include the groin, axilla, and perineal regions.[4] To date there are no studies describing the microbiome of the skin of horses.

Oral Microbiome

The oral and pharyngeal mucosa is richly populated with many bacteria, including obligate aerobes, anaerobes, and facultative anaerobes.[5] By culture, gram-positive and gram-negative anaerobes are the predominant flora in the mouth and pharyngeal tonsils of the normal horse, with *B. fragilis* and *Bacteroides* spp. most commonly found. Genera consisting of *Fusobacterium* spp., *Eubacterium* spp., *Clostridium* spp., *Veillonella* spp., and *Megasphaera* spp. are also cultured. Aerobic and facultative anaerobic populations mostly include *S. zooepidemicus, Pasteurella* spp., *E. coli, Actinomyces* spp., and *Streptococcus* spp. In a 16S metagenomics analysis of the subgingival sites of the horse, although highly diverse, many similarities to human and other species were observed.[6] The most common bacterial phyla included Gammaproteobacteria, Firmicutes, Bacteroidetes, Betaproteobacteria, Fusobacteria, Actinobacteria, Epsilonproteobacteria, TM7, Deltaproteobacteria, Synergistetes, GN02, Tenericutes, Spirochaetes, Chloroflexi, and Alphaproteobacteria. The Gammaproteobacteria had the highest population of species, with *Moraxella* spp. and *Pasteurellaceae* spp. overrepresenting the population. In the former, *Actinobacillus* species and unclassified *Pasteurellaceae* were the most common bacteria.

* The editors and authors acknowledge and appreciate the contributions of J. Lindsay Oaks, Thomas R. Klei, D. Paul Lunn, and David W. Horohov as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

The finding of *Actinobacillus* species is not unexpected; however, by comparison these taxa are relatively absent from cat and dog oral metagenomes. Of the highly abundant Firmicutes, many classes of *Bacilli* were detected; several *Neisseria*-like bacteria were detected. Of particular interest is the population of oral spirochetes that reside in the equine mouth because of its relationship to periodontal disease in humans, and although there were *Treponema,* spirochetes, and leptospires present and abundant, "periodontopathogens" were present in low numbers. When healthy horses were compared with horses with oral disease, *Actinobacillus* (Gammaproteobacteria) and the *Neisseria*-like *Gemella* sp. (Firmicutes) predominated compared with *Prevotella* (Bacteroidetes) and *Veillonella* (Firmicutes).[7]

Pharyngeal and Respiratory Microbiome

Because these same genera are also consistently found in horses with lower respiratory infections, opportunistic colonization by pharyngeal flora is the likely mechanism of disease.[5] Contamination of the trachea of the horse is a frequent occurrence, as evidenced by the fact that transtracheal aspiration yields positive bacterial cultures in approximately 30% of both normal adult horses and foals.[8] As with skin flora, normal horses have multiple fungal species inhabiting conjunctival, nasal, and oral mucosa.[8] Stabling increases the frequency of ocular fungi in normal horses.[9]

Intestinal Microbiome

In animal models and chronic human conditions, the presence of normal flora is considered important for intestinal maturity and containment of disease. Changes in cecal weight, villus:crypt ratio, and volatile fatty acid (VFA) production and the development of gut immunoglobulin A (IgA) responses are all affected by suboptimal cecal colonization in germ-free animals.[10] A relationship between severity of mucosal disease and normal flora has also been demonstrated in models of inflammatory bowel disease of humans.[11]

Bacteria are present in all parts of the intestinal tract of the horse, and the microbial fauna increases in complexity and density aborally.[12] The stomach of the horse is not a sterile environment. A dense population of gram-positive bacterial rods, primarily composed of *Lactobacillus* spp., colonizes the nonsquamous portion of the equine stomach. Substantial colonization of the duodenum is present with a large population of proteolytic bacteria, and this colonization increases by tenfold in the ileum.[13]

Microbial degradation and fermentation of plant material in the large intestine are important components of nutrient acquisition in the equid. The consumption of cellulose and starch results in the production of VFAs.[14] The major cellulolytic bacterial strains in the horse produce arrays of fermentation products that differ from those of cattle.[15] Early genetic techniques also demonstrate that the predominant flora are the low guanine-cytosine (GC)-content bacteria, which include *Cytophaga-Flexibacter-Bacteroides* and *Clostridium* bacteria; the actual species are completely novel.[16] Standard microbiologic techniques specifically demonstrate Enterobacteriaceae, *Butyrivibrio* spp., *Streptococcus* spp., *Bacteroides* spp., *Lactobacillus* spp., *Selenomonas* spp., *Eubacterium* spp., *Propionibacterium* spp., and *Staphylococcus* spp. in residence.[17] In addition, there are completely different compositions of bacteria among the differing segments of the colon, especially between the ascending colon and cecum, indicating highly specialized digestive functions associated within the large intestine itself.[16] Yeasts and fungi of the order Mucorales have been identified in the cecum of normal horses and are capable of digesting cellulose and starch.[18] By deep sequencing, Firmicutes and Bacteroidetes (or in another study, Verruccomicrobia) are the two must abundant phyla.[19] The common bovine rumen bacteria *Ruminococcus flavefaciens* is one of the most predominant cellulolytic bacteria of the equine cecum based on standard microbiologic techniques.[15]

Since 2012 several studies have been published investigating the equine microbiome, and these have been recently reviewed.[17] The techniques employed in each investigation could highly bias study results. Fecal samples or samples from specific gastrointestinal locations have been used. Most studies had a stated goal of attempting to define the flora of the hindgut of the horse.

Routine surveillance demonstrates a relative lack of intestinal pathogens in the flora of normal horses. In the largest study to date, fecal shedding of *Salmonella enteriditis* as detected by fecal culture in normal horses from farms without evidence of salmonellosis was 0.8% in resident horses.[20] Molecular diagnostics, once hoped to provide a tool for understanding the incidence of *Salmonella* spp. in the clinically normal horse, has provided inconsistent information, and polymerase chain reaction (PCR) is most useful for identification of subclinical shedders and environmental contamination during an outbreak.[21,22] On the basis of limited investigations, the carriage rates of *C. difficile* in normal horses and foals appear to be low (less than 1.5%).[23]

Intestinal flora in the horse is an important source for extraintestinal pathogens. In studies examining the carriage rate of *Rhodococcus equi,* all horses cultured carried the bacteria regardless of age.[24,25] If a farm had endemic *R. equi* and respiratory isolates contain the 90-kDa plasmid that is associated with disease, fecal isolates also contained this plasmid. In a recent study, there was little difference in the composition of the phyla of fecal bacteria measured via deep sequencing between normal foals and those with either subclinical or clinical *R. equi.*[26] However, a striking difference in flora was observed over the first few weeks of life among all foals demonstrating the transition from a juvenile gut to that of the adult. Flora transitioned from equal abundance of Firmicutes to Bacteroidetes over this short interval.

The right dorsal colon contains the highest numbers and the most diversity of protozoal species.[17] Four classes of protozoa species, Rhizopoda, Mastigophora, Cliata, and Suctoria, have been described based on relative prevalence in ascending and descending parts of the large colon. The importance of protozoa for normal gastrointestinal function is debated, but these organisms are presumed to play an important role in degradation of plant fiber. Despite this presumption, one investigation demonstrated little effect of protozoa on the digestibility of dry matter with little effect on cellulose digestion.[27]

Urogenital Microbiome

By far, most of the work that characterizes equine normal flora has focused on urogenital flora to address infertility and fetal loss. Although vaginal and vestibular mucosa of mares should be colonized with normal mucosal flora, the uterus

is considered sterile. However, typical culturing techniques result in frequent isolation of what could be considered pathogens, and cytology and bacterial counts are essential supplemental tests for detecting true uterine infection. Counts less than 10 colony-forming units and lack of inflammatory cells indicate uterine or technical contamination.[28]

Many bacteria inhabit the external genitalia of stallions, including bacteria considered to be associated with metritis in mares. The predominant aerobe isolated is coagulase-negative *Staphylococcus* spp., followed by *Corynebacterium* spp., α-hemolytic *Streptococcus* spp., and *Lactobacillus* spp. Pathogens such as β-hemolytic *Streptococcus* spp., *Pseudomonas aeruginosa,* and *Klebsiella* spp. can be frequently found in servicing stallions.[29,30] Pregnancy rates appear to be the same in mares bred to stallions with *P. aeruginosa*–infected semen.[31]

Fungal Microbiome

Essentially the same principles apply regarding normal flora, host immunity, and specific virulence factors for the pathogenesis of fungal infection. Fungal infections can be divided into primary or opportunistic pathogens. True pathogens are less dependent on host status than opportunistic pathogens, although even a true pathogen may require some degree of alteration of normal flora or host immunity to become established. Long-term antibiotic use, immunosuppression, and compromised organ function (especially involving the pulmonary or endocrine system) are three primary host factors highly associated with the establishment of opportunistic fungal infection. Fungi in particular can adapt to the mammalian environment over a relatively short course in order to become established. Establishment usually requires a change in thermal range, oxygen requirements, and resistance to host defenses.

Nosocomial Infections

Development of colitis in the horse has been associated with feed change, antibiotics, surgery, nonsteroidal inflammatory drugs, and transport, all events that disrupt flora.[32,33] Rapid change from a roughage diet to concentrate results in increased anaerobes, decreased cellulolytic bacteria, decreased cecal protozoa diversity, and decreased pH in the equine cecum.[32] Isolation of *Clostridium difficile* is more likely from horses treated with antibiotics, and clinical disease has been associated with ampicillin, erythromycin, penicillin, and potentiated sulfonamide administration in adult horses.[34,35] In ponies infected with *Salmonella* spp., transport and surgery reactivated infection and diarrhea, and antibiotics (oxytetracycline) prolonged shedding but did not induce recrudescence.[33] In a case-control study, use of potentiated sulfonamides was not significantly associated with the development of diarrhea in hospitalized horses; however, overall antibiotic use was highly associated with the occurrence of diarrhea.[36]

Antibiotics disrupt normal gastrointestinal flora and function,[37] and changes in carbohydrate metabolism are a large intestinal event secondary to reduced microbial reduction of carbohydrates to short-chain fatty acids (SCFAs). Because SCFA metabolism and absorption result in fluid and electrolyte absorption, a sudden decrease in SCFA leads to osmotic diarrhea with an intraluminal accumulation of organic acids, cations, and carbohydrates. Erythromycin and amoxicillin directly affect colonic motility.[37] Erythromycin is a motilin receptor agonist resting in contraction of antral and duodenal smooth muscles.[38] In the horse erythromycin results in a dose-dependent increase in ileocecal emptying.[39] Motility-enhancing effects have also been observed in human patients treated with amoxicillin.[37]

Occurrence of infectious lower respiratory disease in adult horses is an example of how contamination of a normally sterile site with several commensal bacteria results in disease. The tonsillar mucosa of the oropharynx is heavily colonized with *S. equi* subsp. *zooepidemicus,* and necrosis of this tissue occurring during viral infection is associated with spread to the lower respiratory tract.[5] Transport of horses (especially for distances greater than 500 miles) is a primary risk factor for pleuropneumonia as demonstrated in a large retrospective study.[40] Elevation of the head for an extended period of time is likely a contributing factor. Horses normally feed from the ground for most of the day, and this posture promotes effective tracheal clearance of inhaled debris and particulate matter. *Pasteurella, Actinobacillus,* and *Streptococcu*s spp. are the most frequent and prolific colonizers of the trachea after prolonged head elevation.[41,42]

Nosocomial infection (health care–associated infections) is defined by the Centers for Disease Control and Prevention as a localized/systemic condition resulting from an adverse reaction to the presence of an infectious agent or its toxin. There must be no evidence that the infection was present or incubating at the time of hospital admission.[43] Nosocomial infections are becoming a major problem for large animal veterinary teaching and private referral hospitals. Infections with *Serratia marcescens, Acinetobacter baumannii, S. aureus,* methicillin-resistant *Staphylococcus* spp., *Enterococcus* spp., and various *Salmonella enteritidis* serovars have all been reported in association with nosocomial infection in equine patients.[44,45] Surgical incision infection, joint sepsis, catheter phlebitis, wounds, and diarrhea represent the common clinical syndromes reported in horses.[44-46] When nosocomial infection involves the acquisition of isolates from the hospital environment, these isolates are more difficult to treat because they frequently undergo high-level antibiotic pressure and attain multiple-drug resistance (MDR). Nosocomially transmitted salmonellosis in equine hospital wards is increasingly reported, with *Salmonella enteritidis* serotypes Krefeld, Saint Paul, DT104, and Anatum all demonstrating attainment of MDR over the course of the outbreak.[47,48] Only one study of a nosocomially transmitted *S. enteritidis* (serotype Heidelberg) did not demonstrate significant acquisition of MDR over time.[49]

Pathogenesis of Bacterial Infections

The ability of bacteria to gain entry and cause disease results from a combination of factors possessed by the agent itself, environmental conditions, and status of host defenses. General mechanisms that are specific to bacteria and enhance disease are virulence factors that enhance the entry, spread, and damage to host tissues (Table 1.1). Major virulence factors are listed for specific equine pathogens. Protein secretion systems (PSSs) are a structurally diverse complex of essential virulence factors for bacteria that allow specialized

interactions among cells.[50] These main systems function to translocate various sized molecules and are important in the formation of adhesins on attachment to host cells. Fibrillar adhesins (FAs) and nonfibrillar adhesins (NFAs) are the most important PSS subgroup not used for bacterial conjugation. They specifically target host cells and biofilms for enhancement of colonization and invasion. There are multiple types of FAs in both gram-positive and gram-negative bacteria, with gram-negative types the most well characterized (Table 1.2).[51,52] Pili or fimbriae are rod-shaped structures composed of an orderly array of a single protein usually arranged in a helical fashion to form a cylinder. The tip of the fimbria mediates attachment to carbohydrate moieties on cell surfaces and is integral to bacterial invasion and colonization. Bacteria can also contain multiple types of pili. Both the bacterial pili themselves and the cellular pathways they use for secretion and formation of pili are targets for pharmacologic intervention, and there are multiple subclasses depending on their configuration.[51]

Afimbrial adhesins are cell proteins that enhance the binding of bacteria to host cells. They are also called *microbial surface components recognizing adhesive matrix molecules.*[53,54] Gram-positive organisms possess afimbrial proteins on their surfaces that presumably aid in binding to host cells. The three most commonly studied afibrillar adhesins are those that bind salivary glycoprotein, bind fibronectin, or are composed of lipoteichoic acid.[53,55] Salivary binding proteins are commonly found in pathogens and commensals of the oral cavity. Both *Streptococcus* spp. and *Actinomyces* spp. possess these proteins. Fibronectin binding protein (FBP) is necessary for *S. aureus* invasion and binds both fibronectin and collagen to form a bridge between the FBP and the host cell integrin (integrin $\alpha_5\beta_1$).[56,57] Heterologs of FBP have been demonstrated in *S. pneumoniae* of humans, *S. equi* subsp. *equi,* and *S. equi* subsp. *zooepidemicus.* Other potential equine pathogens that have FBPs on their surface include *Actinomyces* spp., *E. fecalis,* and *L. monocytogenes.*[55,58] Lipoteichoic acid, a common binding factor found in *Streptococcus* group A bacteria, is important in adhesion of bacteria to cells.[59] This protein is also important in stimulation of cytokine secretion from the cells during infection and has been demonstrated in group B *Streptococcus,* including *S. equi* subsp. *equi.*[60] A less commonly described afibrillar adhesin is composed of surface polypeptide chains in *Corynebacterium* that binds to lectin.[61] Afibrillar adhesins are also present in gram-negative organisms; the most commonly studied are conserved high-molecular-weight adhesion proteins of *Haemophilus influenzae* and *Bordetella pertussis.*[59]

Bacterial ecology has emphasized the importance of biofilm for colonization of both biotic and abiotic surfaces of bacteria.[50] A requirement for biofilm formation is a tight interaction of bacterial adhesins with surface receptors that promote further bacterial aggregation. The most important family of biofilm adherence proteins is that of *Staphylococcus aureus.* These proteins have high molecular mass and repetitive structures whose size and number can be varied during the course of infection, possibly allowing for immune evasion.

The most common virulence proteins of both gram-positive and gram-negative organisms are bacteria lectins.[53-62] Although attachment is thought to be the primary role of these proteins, attachment itself results in an intracellular change, including actin rearrangements, cell signaling regulation, or actual secretion of bacterial substances into the

TABLE **1.1 General Mechanisms of Bacterial Pathogenesis**

Action	Mechanism	Examples
Entry of bacteria	Adhesion Entry	Fibrillar adhesins Nonfibrillar adhesins Curli fimbriae Lipoteichoic acid Biofilm adhesion proteins Membrane ruffling
Enhancement of spread	Immune resistance Host substrate utilization	Capsule Lipopolysaccharide Anticomplement Resistance to phagocytosis Phagolysosomal survival Iron acquisition
Damage to host membranes	Toxins	Exotoxin Endotoxin Apoptosis

TABLE **1.2 Major Types of Bacterial Adhesins**

Adhesin	Definition	Example
Type 1 fimbriae	Cell surface structure primarily on gram-negative bacteria that bind to the terminal mannose of glycoproteins on cells	*Escherichia coli*
Type 4 pili	Cell surface structure primarily on gram-negative bacteria that function in adhesion, twitching, and DNA uptake, which bind on CD46 and other glycolipids	*Pseudomonas aeruginosa*
Curli fimbriae	Coiled aggregative fimbrial structures that bind to fibronectin, laminin, and plasminogen and function in adhesion, aggregation, and biofilm formation	Enterohemorrhagic *Escherichia coli* (EHEC) *Salmonella*
Fibrils and flexible rods	Short, thin rodlike adhesins that bind to fibronectin for adhesion to host tissues	*Streptococcus* species
Lipoteichoic acid	Part of the peptidoglycan layer of cell walls	Gram-positive bacteria
Biofilm	Exopolysaccharide produced by bacteria that allows matrix formation of embedded material	Gram-positive and gram-negative bacteria

host cell. These proteins are highly conserved in bacteria and are important targets for immunoprophylaxis. Membrane transformation for uptake of intracellular bacteria such as *Yersinia* spp., *Listeria monocytogenes, Salmonella* spp., and *Shigella flexneri* can be either zipperlike or triggerlike. Alternatively, *Salmonella* and *Shigella* bacteria adhere and secrete proteins that are translocated into the host cell cytoplasm and trigger actin polymerization.[63] In addition to membrane ruffling, *Mycobacterium avium* and *Salmonella* spp. also rely on activation of intracellular GTPases, leading to phagocytosis.[64,65]

Once colonization occurs, multiplication and spread of bacteria are enhanced through virulence factors. These factors assist bacteria in survival in the hostile host environment and breakdown of tissue barriers. One of the most common and potent strategies for avoidance of phagocytosis is the presence of a capsule. Despite the remarkable diversity of bacteria, capsule assembly and structure are remarkably similar across species. Early studies with *S. equi* subsp. *equi* demonstrated that resistance to phagocytosis was associated with an increase in capsule and M-protein,[66] and in a model of *S. equi* subsp. *zooepidemicus* infection in mice, enhancement of virulence was associated with increased amount of capsule, which increased resistance to phagocytosis.[67] Although colonization of the guttural pouch occurs with nonencapsulated *S. equi* subsp. *equi* strains, induction of lymphadenopathy is associated with capsular strains.[68] In more recent studies of *S. equi* subsp. *equi* infection, rapid colonization in the lingual and pharyngeal tonsil is dependent on genetically associated virulence factors that control colony morphology, with the mucoid strain having enhanced virulence.[69]

Capsules of anaerobic bacteria are unique, and these structures may directly account for the formation of abscesses within the host. The capsule of *B. fragilis* has two distinct polysaccharides composed of repeating subunits with oppositely charged groups (Zwitter ion).[70] This polysaccharide complex injected alone promotes the induction of abscess. Infection of rodents with the encapsulated form of *Bacteroides* and *Fusobacterium* spp. results in the formation of intraperitoneal abscesses, whereas nonencapsulated bacteria do not cause abscessation.[71-73] Synergism of capsular anaerobes with other bacteria occurs; nonencapsulated bacteria have enhanced survival in abscesses and produce capsule when cultured or inoculated with encapsulated bacteria.[72]

Similar to and overlapping with capsule are structural proteins that block complement. The O side chain of lipopolysaccharide (LPS) on gram-negative bacteria is an anticomplement factor.[74] The longer the side chain, the greater the distance between phagocytes and bacteria. The capsular component, sialic acid, interacts with O antigen to prevent the formation of C3 convertase.[75] Bacterial enzymes are formed by *Streptococcus* spp. and other organisms that damage the polymorph chemoattractant, C5a.[76,77] Production of a protein in *Salmonella* spp., encoded by the *rck* gene, prevents insertion of the C9 fragment of complement into the bacterial membrane.[78] The M-protein of *S. equi* subsp. *equi* appears to decrease deposition of complement on the surface of bacteria.[79]

Recent studies of streptococci have shown that when M-protein content is kept constant, the amount of capsule is correlated with resistance to phagocytosis.[68] Resistance to in vitro phagocytosis can be abolished with treatment with hyaluronidase and induction of specific immunity against M-protein of *S. equi* subsp. *equi* and *S. equi* subsp. *zooepidemicus.*[80] The M-proteins of *Streptococcus* spp. are also essential for resistance to phagocytosis blocking complement.[66,81-83] This mechanism for complement resistance appears to be through enhancement of binding of fibrinogen to the bacteria in the presence of M-protein.[79,84,85]

Apoptosis is a distinctive morphologic process that results in cleavage of nuclear material and scavenging of unwarranted cells without immune activation. Apoptosis or programmed cell death is an important pathway for complex organisms to deal with damaged and diseased tissue. Apoptosis avoids the release of the tissue-damaging enzymes and nonspecific elimination of tissue that occurs in cellular necrosis. Several bacteria have modulated the host apoptotic pathways for enhancement of survival.[86] *Shigella flexneri, S. typhimurium,* and toxins of *S. aureus, Pseudomonas* spp., and *C. diphtheriae* have demonstrated programmed cell death as a consequence of cellular infection or exposure.[87,88] The protein of *S. flexneri,* IpaB, induces apoptosis by binding to and activating the cellular enzyme caspase 1, which induces apoptosis of macrophages.[89] *Staphylococcus aureus* α-toxin, which is similar to listeriolysin O, presumably escapes the macrophage after engulfment and induces host cell apoptosis.[90] The TSST toxin of *S. aureus* induces B-cell apoptosis and blocks immunoglobulin production.[91]

Pathogenesis of Fungal Infections

Maureen T. Long

Of the 250,000 species of fungi, fewer than 200 are true pathogens.[1] Superficial mycoses affect the hair shaft and the superficial epidermis. Cutaneous mycoses (dermatophytosis) infect the epidermis, dermis, hair, and nails of animals, and *Microsporum, Trichophyton,* and *Epidermophyton* spp. are the most commonly associated pathogenic genera. Subcutaneous tissues can become infected with *Sporothrix, Conidiobolus, Basidiobolus* spp., and members of the Dematiaceae fungi, including the *Chromoblastomycosis, Mycetoma,* and *Phaeohyphomycosis* spp. infections. Most of these infections are introduced by penetration through skin or opportunistic invasion of damaged skin surfaces. *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis,* and *Paracoccidioides brasiliensis* are the four most important fungal pathogens that can cause systemic infection. The most common opportunistic infections include *Candida albicans, Aspergillus* spp., *Cryptococcus neoformans, Mucor* spp., and *Pneumocystis carinii.*

Fungal virulence factors may be more complex than those of bacteria because of the higher degree of opportunism that occurs with a change in host status. There may be subtle factors that, combined with host status, result in a certain fungus attaining a virulent state. For instance, the typical fungal wall is composed of three major polysaccharides: mannose; β-1,3 and β-1,6 linked glucans; and chitin. Chitin mutants in *C. albicans* are less virulent when tested in rodent models than are wild-type fungi.[92] Further, a mutant *C. albicans* that cannot synthesize complex mannose oligosaccharides does not adhere to other yeast and epithelial cells and has lost virulence

in a guinea pig model.[93] Both of these mutants can proliferate in vitro normally, and whether or not this is an actual virulence factor is unclear.

As with bacteria, cellular adherence is an important prerequisite for infection and colonization of the host. Adhesins have been identified in *C. albicans* and *B. dermatitidis.* Two genes have been associated with adhesion in *C. albicans.* The first is a glycoprotein that has sequences consistent with agglutinating activity. Transformation of this gene into other nonadherent fungal species results in adhesion of the transformed yeast to cells.[94] *Candida albicans* also has integrin-like proteins, the disruption of which results in diminished hyphal growth, adhesion to cells, and loss of virulence in mice.[95,96] The *B. dermatitidis* adhesin mediates binding to human monocyte-macrophages through the CD14 receptor.[97]

Many fungi have polysaccharide capsules that, like bacteria, help resist phagocytosis and immune activation. The capsule of *C. neoformans* inhibits leukocyte accumulation, cytokine secretion, and macrophage phagocytosis.[98] Mutants without capsule are highly infective and avirulent. As indicated earlier, many fungi are engulfed by macrophages, and intracellular survival is mediated by virulence factors. Macrophages are decimating cells for *C. albicans,*[99] *H. capsulatum,*[100] and *B. dermatitidis. Histoplasma capsulatum* is primarily a yeast in vivo, and this form infects macrophages. Phagolysosomal fusion occurs at a normal rate,[101] but blockage of acidification of the phagolysosome occurs.[102]

Exposure to both pathogenic and saprophytic fungi is an everyday occurrence. Respiratory contamination and infection are important for many pulmonary species, but skin penetration and dissemination from necrotic gut are important portals for large animals also. Dissemination after the initial infection is dependent on previous damage to host tissues, deeper mechanical penetration, or actual invasion of new tissues. *C. albicans* can actually grow through and replace cell membranes.[99] True molds invade blood vessels and grow along the intima of the vessels. Fungi secrete many degradative enzymes, including proteinases, phosphatases, and DNAses, to surmount structural barriers.[103] A group of genes called *secreted aspartyl proteinase (SAP)* genes allow more persistent colonization of host surfaces and deeper penetration.[104]

When *C. immitis* invades the host, the fungi form endospores. These endospores secrete a proteinase and a urease that likely aid in the breakdown of pulmonary tissues.[105-107] The two proteinases of *A. fumigatus* break down elastin, a major component of lung tissues.[108,109] Phospholipase activity has been demonstrated in *C. albicans, C. neoformans,* and *A. fumigatus.*[110] Strains of *Candida* spp. with high amounts of this enzyme have higher virulence,[111] and abolishing this activity results in decreased adherence of the organism.[112] Host eicosanoids enhance fungal colonization. Recent evidence demonstrates production of eicosanoids by both dermatophytosis and systemic fungi.[113]

Fungi induce apoptosis, which may be due either to the direct effect of a fungal toxin or secondary to host cell cytoskeleton rearrangements.[114] The gliotoxin of *A. fumigatus* can induce DNA fragmentation and apoptosis in macrophages.[115] This toxin also has many other immunosuppressive qualities, which include inhibition of the neutrophil respiratory burst and T-cell activation.

Pathogenesis of Viral Infections

Viral infections such as equine influenza (Orthomyxoviridae), rhinopneumonitis and abortion (Herpesviridae), African horse sickness (Reoviridae), equine infectious anemia (Retroviridae), and various encephalitides (Alphaviridae and Flaviviridae) are responsible for some of the most medically and economically important diseases of horses. Specific therapy of viral infections remains a significant challenge because antiviral drugs are generally ineffective, impractical, or prohibitively expensive for the treatment of horses. Treatment of most viral infections focuses on supportive care of the affected organ systems and control of secondary complications such as bacterial infection. Currently control of most clinically significant viral diseases in horse populations relies on vaccination, quarantine, or even destruction of infected animals.

Despite the great significance of some viral infections, recognizing that many equine viruses are ubiquitous, weakly pathogenic, or not associated with any known disease under normal circumstances is also important. Some examples include equine adenovirus, respiratory and enteric reoviruses (the term *reo* is derived from the acronym for respiratory enteric orphan, indicating that these isolates have not been associated with disease), and equine herpesvirus (EHV) type 2. Some host-virus relationships may be mutualistic in that virally derived genetic elements are theorized to benefit the host by facilitating genetic variability and evolution.[116] Thus many viruses are of no practical clinical significance, and no control efforts are warranted. For this reason, the veterinarian should never assume that the recovery of a virus from a clinical specimen is significant without proof that the virus can cause the disease in question.

An in-depth discussion of viral structure, taxonomy, and replication is beyond the scope of this chapter, and the reader is referred to textbooks of veterinary or human virology for more detailed information.[117,118] A brief overview is presented to emphasize those features that have clinical relevance.

The fundamental structure of all viruses is a DNA or RNA genome enclosed by a coat of protein called the *capsid* (Fig. 1.1). For viruses that are enveloped, the capsid is enclosed further by a host cell–derived lipid membrane into which viral proteins have been incorporated. In addition to protecting the viral genome, the capsid and other associated structural proteins (e.g., matrix proteins) are important for virus assembly, packaging the viral genome, releasing the genome into a target cell, and for nonenveloped viruses providing receptors that bind to host cells. For enveloped viruses the receptors are incorporated into the lipid membrane. The primary clinical significance of these features is that enveloped viruses, because of their fragile lipid membrane, are highly susceptible to inactivation by heat, desiccation, or detergents, and transmission typically requires direct exchange of body fluids, short distance aerosols, or arthropod vectors. In contrast, nonenveloped viruses (e.g., equine rotavirus) are resistant to physical inactivation, and environmental contamination is more likely to be a significant factor in their transmission.

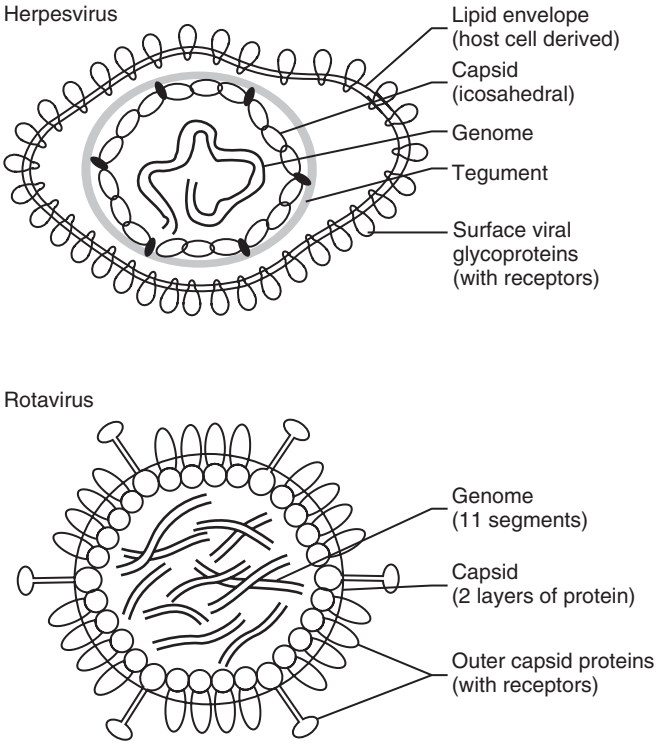

FIG. **1.1** Schematic representations of basic viral structure. The basic structure of an enveloped virus is shown by the drawing of a herpesvirus. The basic structure of a nonenveloped virus is shown by the drawing of a rotavirus.

The composition of the viral genome is an important basis for virus classification (Fig. 1.2). The type of viral genome also determines the strategies required to replicate the genome and transcribe messenger ribonucleic acid (mRNA; Fig. 1.3). Viral genomes may be single-stranded RNA, double-stranded RNA, single-stranded deoxyribonucleic acid (DNA), or double-stranded DNA. The genomes of single-stranded RNA viruses may have positive polarity, in which the genome also serves directly as mRNA for translation of viral proteins. To replicate genomes, these viruses must first synthesize a strand of complementary RNA that can be used as a template to replicate genomes and transcribe new mRNA. Retroviruses are a subset of single-stranded, positive-polarity RNA viruses that use their RNA genomes as templates to produce double-stranded DNA, which in turn is used for the transcription of mRNA and new viral genomes. Single-stranded RNA viruses may also have negative polarity, in which the genome is antisense to mRNA, and synthesis of a complementary RNA strand is required to serve as mRNA and as a template for new genomes. The clinical significance of these types of replication strategies is that they require polymerases and other enzymes not normally found in eukaryotic host cells. These unique viral enzymes are important targets for antiviral drugs because they can be used selectively to inhibit viral replication.

Viral RNA polymerases are low fidelity and lack proofreading functions and thus randomly introduce errors into new RNA at an average rate of about one nucleotide mismatch per 10,000 bases copied.[119] In a population of viruses, therefore, virtually every individual virus differs slightly, and this population is referred to as a *quasi-species.* Although many of these mutations are neutral or even deleterious, in the face of selective pressures such as the host immune response or antiviral drugs, this genetic plasticity allows rapid development of resistant virus populations.[120] Secondary structures or certain sequences in the viral genome may facilitate polymerase errors further at selected regions that are important for immune evasion, such as in sequences that code for neutralizing epitopes.[119] The genome of some viruses, such as influenza, comprise separate segments, which allows reassortment of entire gene segments and sudden and dramatic changes in antigenicity.[121]

All viruses are obligate intracellular parasites. Viral replication can occur only within living cells, and all viruses to some extent depend on the host cell synthetic machinery. The life cycle of all viruses includes the following steps: attachment to the target cell, entry into the cell, uncoating and release of the viral genome, transcription and translation of viral proteins, replication of the viral genome, assembly of new virions, and release of progeny virions[117,118] (Fig. 1.4). Although the biochemistry of these steps is beyond the scope of this discussion, recognizing that they are all specific, energy-requiring interactions between the virus and the host cell is important. The inability of the virus to interact appropriately with a cell at any of these steps prevents replication in that cell type and defines the tropism of the virus. All of these steps are also important potential targets for antiviral drugs and host immune responses.

Once the viral nucleocapsid gains entry to the cytosol of the cell, the viral genome is released through the process of uncoating. After uncoating, the viral genome localizes to the appropriate regions of the cell for replication and mRNA transcription. DNA viruses typically replicate genomes and transcribe mRNA in the nucleus and then transport the mRNA to the cytoplasm for translation. RNA viruses typically replicate, transcribe mRNA, and translate viral proteins in the cytoplasm. These sites of replication account, respectively, for the location of viral inclusion bodies that are diagnostically useful in histopathologic sections.

Cells that replicate virus often are killed as a direct consequence of infection. One mechanism by which viruses kill cells is lysis, often associated with the release of progeny virions. Insertion of viral proteins into cell membranes, budding, direct toxicity of viral proteins, and diversion of normal host cell homeostatic processes to viral replication may result in death of the cell.[117,118,122] Viruses also may activate the cellular self-destruct mechanism of programmed cell death (apoptosis). Although cells may induce apoptosis in an attempt to prevent completion of the virus life cycle, viruses also may use this mechanism to kill the cell and facilitate release of virions.[123]

Viral infection can cause neoplastic transformation of infected cells. The most common examples in horses include warts (equine papillomavirus) and sarcoids (bovine papillomavirus). Virally induced invasive neoplastic diseases such as leukemia or lymphosarcoma have not been recognized in the horse. Viral proteins that activate the cell cycle into the growth and division phases may lead to neoplastic transformation if expressed in a cell that is not killed by the infection. Papillomavirus infections induce epithelial neoplasms (fibropapillomata) using a virally encoded protein (E5 oncoprotein) that induces proliferation of normally quiescent cells and that presumably is needed for viral replication.[124] Oncogenic retroviruses, including leukemia and sarcoma viruses, induce neoplastic transformation by integration into the host cell genome and activation of cellular oncogenes.[125]

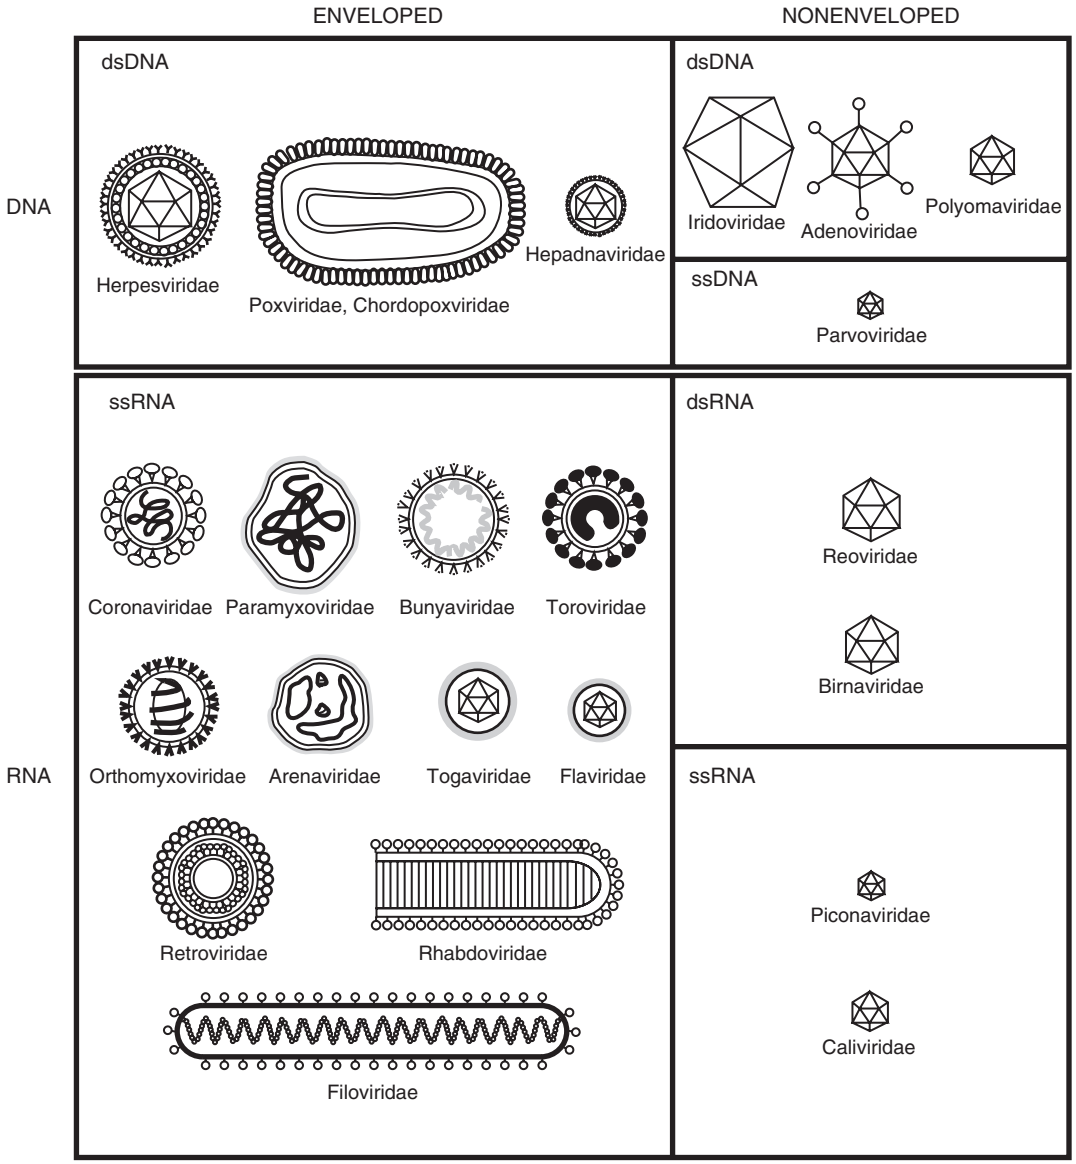

FIG. **1.2** Virus family classification based on genome composition and presence of envelope or absence of envelope. The relative size of the viruses to each other is also shown.

At the host level viruses may use several mechanisms to establish persistent infections and avoid immune clearance. *Virologic latency* is defined as the presence of a viral genome that is not producing infectious virus.[126] The genomes of latent viruses are transcriptionally suppressed and translationally silent so that no viral proteins are expressed that may identify the cell to the immune system as infected. The definition of *latency* also stipulates that on reactivation, viral gene expression and the production of infectious progeny virions can be resumed, differentiating latently infected cells from cells infected with defective viruses. In contrast, some persistent viral infections are characterized by continual replication despite the presence of antiviral immune responses. Even in the absence of recognizable clinical signs, such infections are not truly latent. The classic latent infection is that of the herpesviruses. For the α-herpesviruses, such as EHV1 and EHV4, latent infections are established in the nuclei of sensory neurons and can be maintained indefinitely, and infected animals serve as the reservoir of the virus.[127-129] On reactivation viral nucleic acids are translocated across synapses to epithelial cells of the nasopharynx, which produce infectious virus. The stimuli that induce reactivation are poorly defined, but reactivation can be induced by immunosuppression (e.g., corticosteroids) and presumably by other stressors, such as pregnancy, transport, and social stress.[128,130]

The severity of disease in a virus-infected horse, or whether infection even results in clinical disease at all, is the result of a complex interaction among the triad of virus, host, and environment. Critical factors include viral virulence, viral spread within the animal, the intensity of direct and immune-mediated pathologic response elicited by the virus, and the ability of the virus to avoid clearance by the host. Other than the virulence of the virus, which is strictly a property of the virus, the other virus-host interactions can be influenced by the age and genetics of the host and by environmental factors such as stress and nutrition. These factors account for

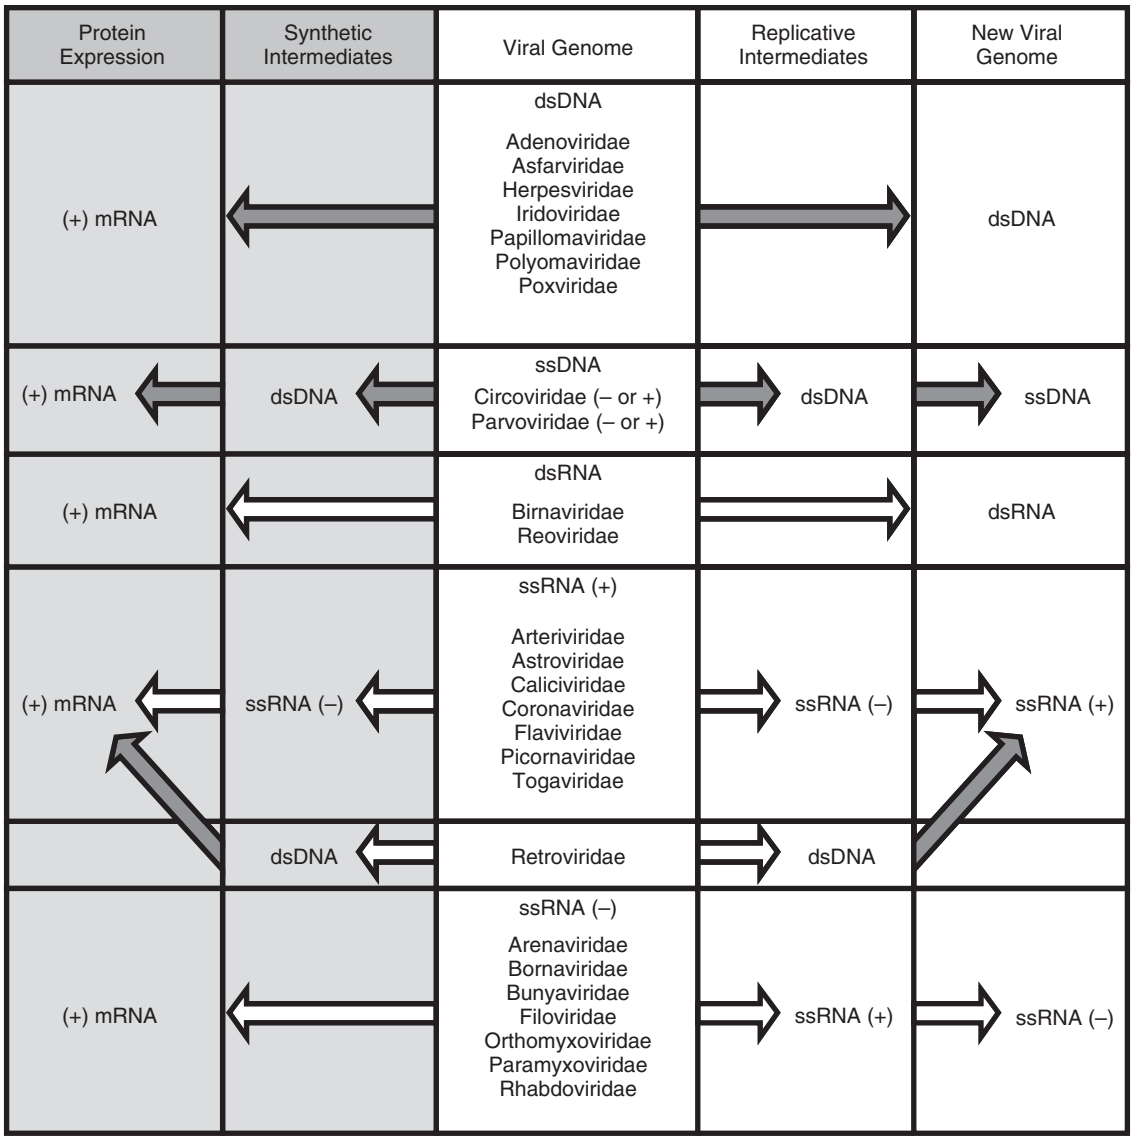

FIG. **1.3** Summary of the main virus families that infect vertebrates and general strategies employed by these viruses to produce mRNA for protein expression and to replicate genomes. Required intermediate molecules are indicated. *White arrows* indicate the need for unique viral polymerases, including RNA-dependent RNA polymerase and RNA-dependent DNA polymerase (reverse transcriptase). *Dark arrows* indicate the use of cellular polymerases or viral homologs of cellular polymerases. *ds,* Double-stranded; *ss,* single-stranded; (+) for RNA = positive polarity, polarity of RNA used for protein translation; (+) for DNA = coding strand, sequence same as for (+) RNA; (– or +) DNA = contains single strands of DNA of both polarities. (Modified from Baltimore D: Expression of animal virus genomes, *Bacteriol Rev*. 35:235-241, 1971.)

the observation that considerable variation in disease signs can occur among a group of animals infected with the same viral strain.

Certain strains of a virus may cause more severe disease than other strains. The main properties of a virus that may affect virulence include host cell tropism and replication rate. A tropism change that leads to involvement of additional tissues or facilitates virus spread generally results in more severe disease. Outbreaks of EHV1 abortion or neurologic disease strongly suggest that EHV1 strains exist that have a tropism for these tissues compared with EHV1 strains that cause respiratory disease. An increase in the viral replication rate is usually associated with an increase in virulence, presumably because of the greater number of infected cells and amount of tissue damage. The virulence of equine infectious anemia virus strains can be correlated directly to plasma virus titers and numbers of infected cells, without any changes in tropism.[131,132] The molecular basis for the increased replication rate is not clear but most likely is caused by variation in viral regulatory sequences and proteins.[133,134]

Viral infections generally are regarded as localized or systemic. Localized viral infections are those that are restricted to a single organ system, often at the site of entry. Because infection of the tissue is direct, the incubation period for localized viral infections is usually short, often only a few

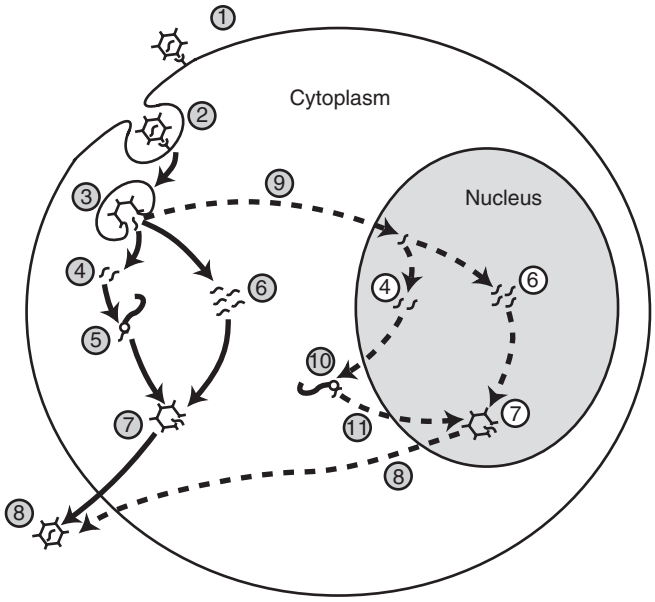

FIG. **1.4** Schematic representation of the general virus life cycle. Both RNA and DNA viruses share the initial steps, including attachment (1); entry/fusion (2); and uncoating and release of viral genome into the cell (3). *Solid arrows* indicate remaining steps for RNA viruses, which all occur in the cytoplasm, including transcription of mRNA (4); translation of viral proteins (5); replication of the viral genome (6); assembly of new virions (7); and release of progeny virions (8). *Dashed arrows* indicate steps for a DNA virus. The life cycle is similar except that the DNA genome is translocated to the nucleus (9) for transcription (4) and replication of viral genomes (6). Viral mRNA is then translocated back to the cytoplasm for translation (10), and newly synthesized viral proteins are translocated back to the nucleus (11) for assembly (7); new virions are then released from both nuclear and cytoplasmic membranes (8).

days. Many infections of the skin or mucosal surfaces are localized, and examples in the horse include infections with enteric rotavirus and influenza. For influenza, virus is inhaled into the nasopharynx and replicates in epithelial cells of the upper respiratory tract and trachea. Virus is not present in the blood or tissues outside of the respiratory tract. In general, viruses remain localized because they lack the receptors to infect cells of other tissues or circulating cells, such as monocytes or lymphocytes, that can disseminate the virus. Some viruses are temperature sensitive and remain localized because they are unable to replicate efficiently at core body temperatures. EHV3, the cause of coital exanthema, is restricted to the surface of the genitalia in horses because of its temperature sensitivity.[135] EHV1 and EHV4 are not temperature sensitive, however, and systemic infection may occur with these viruses. Temperature sensitivity is also a means by which some viruses, such as equine influenza and infectious bovine rhinotracheitis virus, may be attenuated for use as modified-live intranasal vaccines. Infection by the vaccine strain is limited to the cooler mucosal surfaces; the inability to spread systemically prevents sequelae such as abortion and pneumonia.[136,137]

Systemic infections are those in which virus is disseminated to multiple tissues by blood or lymph. This viremia may exist in the form of cell-free virions in the plasma or lymph or may be cell associated in circulating blood cells, usually monocytes or lymphocytes. The classic paradigm for a systemic infection is infection of mice with ectromelia virus[138] (Fig. 1.5). Localized viral replication first occurs at the site of entry and in regional lymph nodes. Depending on the level of replication, clinical disease may be present. The virus then enters the blood or lymphatics and spreads to other tissues, such as spleen and liver, in which clinical disease may occur. Virus is amplified and then released again for a second, usually higher-titered, viremia that further disseminates the virus to other organs. Each viremic episode is associated with a febrile response and is the basis for the biphasic fever response associated with some viral infections. Because systemic infections require multiple steps, the incubation periods are longer than for localized infections, typically 1 to several weeks. Infections in the horse by eastern, western, or Venezuelan equine encephalitis virus closely follow this paradigm. Localized viral replication occurs at the site of entry (mosquito bite) followed by viremia and dissemination to the central nervous system.[139] For most horses, even nonvaccinated horses, dissemination is controlled before infection of the brain, and neurologic disease is a rare outcome of infection. A variation on the theme is infection of horses with EHV1. The most common clinical disease associated with EHV1 infection is rhinopneumonitis caused by a localized infection of the nasopharyngeal mucosa.[140] In almost all cases, a cell-associated viremia also occurs in lymphocytes, but in most infected horses this does not result in disease. However, in some cases, viremia is associated with infection of endothelial cells, and in the pregnant mare vascular damage to the uterus and placenta may lead to abortion.[140,141] Similarly, infection of the vascular endothelium in the central nervous system results in neurologic disease.[142]

Some viruses also may spread in the host through nerves. In the horse rabies is the best-known infection that relies on neural spread. Following local replication in myocytes at the site of entry, usually a bite wound, rabies virus ascends peripheral nerves into the central nervous system, where it replicates in neurons and then egresses by way of cranial nerves to the salivary gland.[143] EHV1 and EHV4 establish latency in the nuclei of sensory neurons that innervate the nasopharynx and reach the nucleus by ascending nerve axons. Similarly, on reactivation these viruses egress back down the axon to infect epithelial cells.[127,144]

Once a virus reaches a target organ, virally mediated cell death is the fundamental source of pathologic response, disease, and clinical signs observed by the veterinarian. Despite the great complexity of virus-host interactions and the many factors that influence the expression of clinical disease, in actuality viruses have a limited number of ways by which to cause pathology. Cells and tissues may be destroyed directly by cytolytic viral infections or by infections that affect the differentiated function of target cells (e.g., neoplasms and immunodeficiencies). Viral infections of organ systems with bacterial flora (e.g., intestinal and respiratory tracts) can disrupt the normal barrier functions of these organs and result in secondary bacterial infections and toxemia that may contribute significantly to the pathologic response. Cell death and pathologic response also may be caused by host immune responses specifically directed against virally infected cells or by indiscriminate inflammatory responses. Virally induced autoimmune diseases have not been described in horses but are another potential source of pathologic response that may be identified in the future.

For most of the clinically important viral diseases of horses, disease manifestation results from some combination of

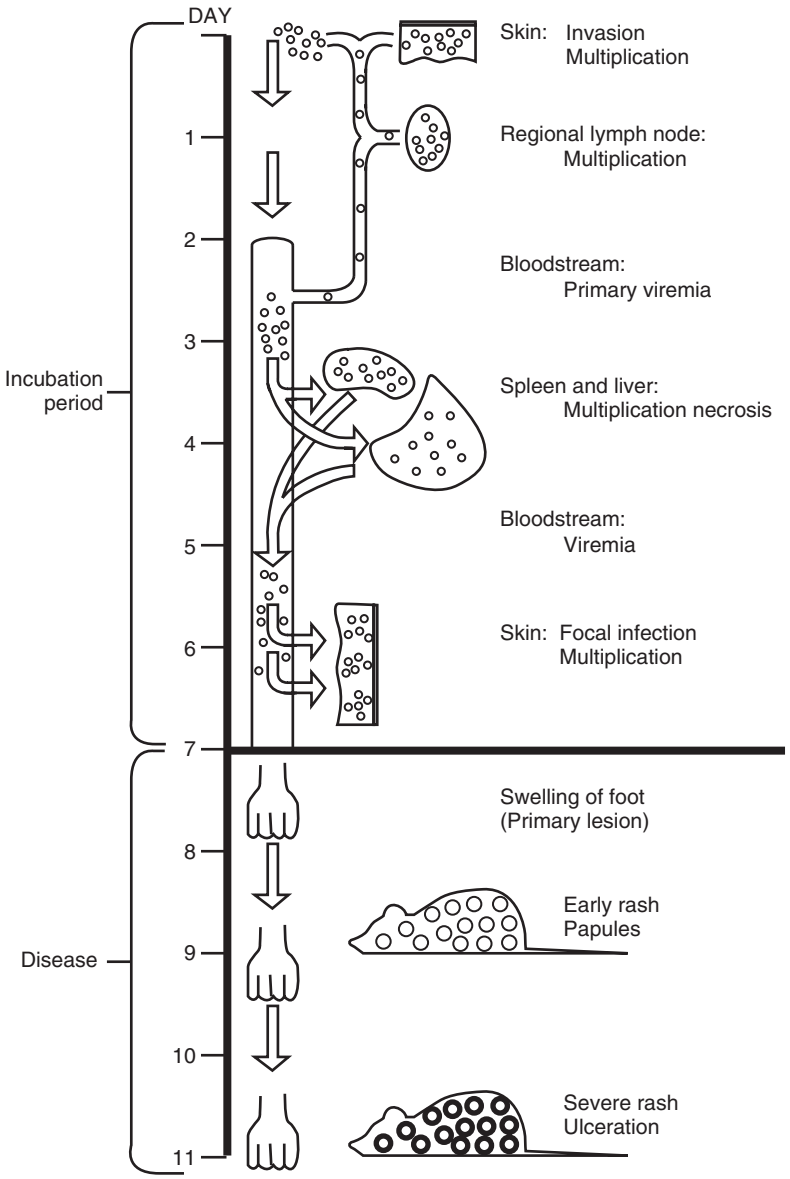

FIG. **1.5** Schematic representation of the pathogenesis of mousepox (ectromelia), illustrating the classic paradigm for the events in a systemic infection. (From Fenner F: The pathogenesis of the acute exanthems, *Lancet*. 252:915, 1948.)

cytolytic infection and immune-mediated tissue destruction. The relative contribution of these mechanisms is primarily a function of viral virulence and host factors that influence the type and intensity of immune responses. The predominant mechanism of pathologic response also can vary with different stages of the same disease, as seen in acute versus chronic equine infectious anemia. In acute disease most of the disease manifestation is caused by direct viral damage and cytokines, whereas in chronic disease immune complex–mediated anemia and glomerulonephritis become more significant.

The disease associated with a given viral infection is related to the affected organ system(s), the number of cells destroyed, and the sensitivity of the affected organ system to dysfunction. If the number of infected cells is not sufficient to lead to clinically significant organ dysfunction, the result is a subclinical infection. When enough cells are infected to lead to overt organ dysfunction, clinical disease becomes apparent. EHV1 infections of the respiratory epithelium, which has a large number of cells with a high turnover rate, produce mild clinical disease even with a high rate of infection. On the other hand, much more significant clinical manifestations of EHV1 infection such as abortion and neurologic disease are caused by infection of a few endothelial cells because minimal vascular damage can lead to thrombosis, ischemic necrosis, and damage to large amounts of tissue. If viral infection results in neoplastic transformation of a cell type, disease may progress according to the characteristics of the neoplasm, whether or not the virus remains associated with the tumor.

In most viral infections immune-mediated pathologic response contributes significantly to disease and in some cases may be the predominant cause of disease manifestation. Equine immune and inflammatory responses are covered elsewhere in this chapter.

Although not described in horses, viral infections in other species can induce immune-mediated responses to host cell antigens and autoimmune diseases. The best documented human autoimmune disease suspected to be initiated by viral infections is Guillain-Barré syndrome, in which infection with cytomegalovirus or Epstein-Barr herpesvirus elicits antinerve ganglioside immune responses and demyelinating disease.[145] Postinfluenza myocarditis is an occasional sequela in horses and human beings and is a potential autoimmune disease. Although no direct evidence supports this theory, influenza virus is not identified consistently in affected heart muscle, and the pathogenesis is not known.[146]

A key requirement for viruses to be maintained in nature is to persist successfully in a reservoir host (if the reservoir is an infected animal) and to be transmitted to another susceptible host. One of the most important obstacles to persistence and transmission is detection and elimination by the host immune system. Within the host rapidly replicating viruses such as influenza may shed and transmit virus before the host can mount specific antiviral immune responses. Herpesviruses avoid detection during latency by not expressing any viral proteins. Immunodeficiency viruses may cripple antiviral immune responses by directly infecting immunoregulatory $CD4^+$ T lymphocytes. One of the most important mechanisms of immunologic avoidance is antigenic variation in which neutralizing viral antigens are altered so that they are no longer recognized or accessible by host immune responses. Antigenic variation is generated by nucleotide errors during transcription or replication, which result in amino acid substitutions in the relevant epitopes. Other mechanisms by which some viruses may modify their antigenicity is through intramolecular recombination/duplication or reassortment of segmented genomes (e.g., influenza and African horse sickness).[120,121] For reassortment, coinfection of a single cell with genetically different virions may result in a progeny virion with segments derived from both virions and a major change in antigenicity. In influenza these are called *antigenic shifts,* and the radical change in the antigenicity of the virus may render preexisting immunity in the host population ineffective at preventing outbreaks of disease with high morbidity and mortality rates.[121]

Genetic differences in susceptibility to disease have been well documented. In an outbred population of animals, the considerable variation in the type or severity of clinical disease is well recognized, even when animals are infected with the same virus strain and have no recognizable differences in other factors such as age, challenge dose, nutrition, and general health status. Conversely, highly inbred populations may be more uniformly susceptible to a viral disease.[147] Thus inbreeding can pose problems for endangered species, such as Przewalski's horse, or other populations with limited genetic variability, which may incur high rates of morbidity or mortality if the animals are infected with a virulent virus. Host genetics may affect the tropism of the virus and influence the type and intensity of immune responses to a viral infection.

Pathogenesis of Parasitic Infections

Horses serve as hosts for numerous parasites, which induce a wide range of pathologic and immunologic responses.[148,149] Many of the latter are of a hypersensitive nature and also result in disease conditions. Immune responses leading to protective resistance against reinfection occur, but the level of this resistance is most often incomplete. Mechanisms associated with these responses have not been investigated extensively in the horse, but information is available from other host-parasite systems that may be relevant to equids. The purpose of this section is to acquaint the reader with contemporary thoughts on host-parasite interactions. Because of their prevalence, major importance to equids, and information available, coverage is limited to helminth parasites that occur in most developed and nontropical countries.

Infection with most metazoan parasites results in inflammation and structural and functional changes of the organs invaded. The outcome of these changes is an alteration of the host's physiologic state. The degree of alteration depends on the existing physiologic condition of the animal, which is dictated to a great degree by its age, nutritional status, and previous immunologic experience with the parasite. The numbers of parasites introduced and the specific parasite also affect the degree of physiologic change that occurs. When these factors favor major alterations, the results are readily identifiable clinical signs of infection. Subclinical infections, although less apparent, are potentially important to the general health of the animal and continued transmission of the agent. The pathophysiologic effects of infection by ectoparasites, helminths, and microorganisms are in many cases similar.[150,151] Abnormalities in weight gain, skeletal growth, reproduction, and lactation may result from infections with any of these agents. These changes are often directly related to parasite-induced anorexia, disruption of metabolic processes, and anemia. An understanding of the morphologic and biochemical lesions produced by specific parasites clarifies the role of these agents in clinical and subclinical conditions associated with the infections. Most detailed studies of the pathophysiology of parasitic infections have been conducted in laboratory animal models and domestic animal species other than the horse.[151] However, the classical pathology of parasitic infections of the horse has been reviewed.[149,152] The following discussion outlines some recent observations on host-parasite interactions that may be of significance to equine medicine. Examples of host-parasite interactions responsible for alterations in host homeostasis are presented as they relate to the gastrointestinal tract, lungs, and skin.

GASTROINTESTINAL TRACT

Internal parasites are most important to equine health as mediators of gastrointestinal problems, including colic and diarrhea. Although almost all internal parasites have been inferentially implicated as causative agents of colic at some time, significant evidence-based experimental or field observations have emerged to support this contention for some parasites. The helminth parasites include large strongyles, principally *Strongylus vulgaris, Parascaris* spp., *Anoplocephala perfoliata,* and as a group the cyathostomins.

The pathogenesis of colic associated with migration of *Strongylus vulgaris* through the mesenteric arteries and the resultant thrombosis, infarctions, and necrosis of the intestine have been described in detail elsewhere.[149,152,153] Large strongyles are easily controlled with currently available macrocyclic lactone anthelmintics and are rare in horses kept on well-managed farms in developed countries. Histologic studies of experimentally infected parasite-free pony foals during the initial stages of infection indicate that the severity of

lesions produced in the intestine cannot be attributed solely to mechanical disruption caused by larval migrations and that these larval stages induce some biologic amplification system within the mucosa, which results in the degree of inflammation observed.[154] Although the mechanisms involved in this response have not been investigated, the histologic nature of the lesion is characteristic of an Arthus reaction, suggesting an involvement of the immune response. Other experimental studies using the parasite-free pony–*S. vulgaris* system have implicated a role for the immune response in the mediation and regulation of the arterial lesions produced by this parasite. Passive transfer of immune serum but not normal serum reduced the severity of arteritis seen and clinical signs associated with experimental infections without reducing the numbers of parasites that develop in these ponies.[155] However, treatment with immune serum also induced an anamnestic eosinophilia and marked perivascular infiltration of eosinophils in the cecum. The reduction in intravascular lesions may have been associated with an inactivation of parasite-secreted inflammatory factors either by antibody or serum enzymes or circulating cytokines. This serum may also have contained nonspecific host-derived antiinflammatory substances. The exacerbation of the eosinophil response may have been associated with the formation of immune complexes. Although the mechanisms are unknown, the results suggest that the immune response may simultaneously modulate and potentiate inflammation. It has been postulated that larvicidal treatment of *S. vulgaris*–infected horses and killing of intravascular larvae may release a bolus of antigenic factors from these larvae within the mesenteric vasculature, resulting in an exacerbation of arterial and intestinal lesions and colic. Experimental testing of this hypothesis indicates that this phenomenon does not occur and further that viable larvae are necessary to maintain the arteritis and eosinophilia seen.[156] Experimental studies using parasite-free ponies that were immunized with crude adult worm antigens and subsequently challenged with *S. vulgaris* larvae showed an exacerbation of the pathologic responses seen in the mesenteric vasculature and including an anamnestic eosinophilia, further suggesting a role for the immune response in the development of these lesions.[157]

Colic associated with *Parascaris* spp. infection in foals has been related to intestinal impaction and rupture and is not considered to be of major significance in adult horses.[158] These conditions in foals may become more important with the widespread identification of *Parascaris* spp. resistance to ivermectin.[159] However, ascarid nematodes are particularly potent sources of allergens, and it is not inconceivable that the hypersensitized mature horse may respond to low-level infections with this parasite. Observations made in the author's laboratory are noteworthy in this regard. Two mature *Parascaris*-free adult horses were inoculated intradermally with less than 90 μg of saline-soluble somatic extract of adult *Parascaris* spp. to test for immediate hypersensitivity to this antigen. Both horses experienced an immediate systemic response and colic. One of the horses died within 3 hours of intradermal inoculation. Necropsy results were consistent with the diagnosis of acute severe colitis. Because of the allergic potential of ascarid nematodes and the sensitivity of the equine gut to immediate hypersensitivity reactions, this potential is worthy of further characterization and consideration.

Clinical observations have maintained an interest and concern over the pathogenic potential of *Anoplocephala perfoliata* infections. Earlier case reports have described cecal ruptures and intussusceptions of the cecum and colon associated with these infections.[160,161] Several case-control studies have documented an association between colics in the ileal region and *A. perfoliata* infection.[162] These parasites inhabit the region of the ileocecal junction and produce ulcerated lesions of the mucosa and submucosal inflammation. Detailed experimental investigations of these infections have not been conducted, and thus specific details on the pathogenesis and relevance of these lesions are lacking. An association between severity of observed lesions and tapeworm burden has been observed.[163,164]

Cyathostomins (cyathostomes or small strongyles) have not generally been considered to be of major importance, particularly as causative agents of colic. In this regard, Uhlinger's field studies are of particular importance.[165,166] In these controlled experiments different anthelmintic treatment regimens were used to test their efficacy in reducing the incidence of colic. The more efficacious treatment programs significantly reduced the incidence of colic by 2 to 13 times that seen in the same herds before implementation of the more efficacious treatment. Because of the management programs used before the initiation of this study and the results of fecal cultures, it can be assumed that the primary parasites present in these horses were cyathostomins. These data strongly implicate a role for cyathostomins in a substantial proportion of colics observed under field conditions. The parasite or host factors involved in these colic cases are unknown but may be the dynamic turnover of parasites during the life cycle in the mucosa and the related inflammatory responses seen that they induce.

Cyathostomins have been implicated in numerous case reports with seasonal diarrhea in adult horses, which is a condition called *larval cyathostominiasis.* These cases are characterized by a sudden onset of diarrhea during the late winter or spring. Horses younger than 5 years of age are particularly at risk, but mature horses can be affected as well, and a case-fatality rate of 50% has been reported.[167] These are difficult to diagnose, and the only consistent signs are weight loss, hypoproteinemia, and diarrhea.[166] Large numbers of larval cyathostomins can be found in the feces or in intestinal contents and within the mucosa of these horses. These symptoms are related to the synchronous emergence of fourth-stage larvae of these parasites from the mucosa. These larvae build to potentially large numbers within the mucosa owing to the arrested development of infective larvae. The seasonality of the occurrence of this condition at present does not appear to vary in different climatic regions as does the analogous bovine condition of type II ostertagiasis. Specific parasite or host factors associated with the regulation of the hypobiotic state of the larvae or the inflammatory response initiated at parasite emergence have not been described. Other clinical reports have suggested that cyathostomin-related diarrhea and weight loss are not related to the seasonal presentation described previously.[168] This is supported by experimental studies demonstrating that pathophysiologic effects occur as large numbers of parasites enter the intestine, as well as when they leave.[169]

In view of the paucity of specific mechanistic information on the pathophysiologic effects of equine gastrointestinal parasites, a synopsis of relevant information gathered from other model systems is warranted, particularly for nematodes.[151,170] Parasitic organisms may induce changes in gastrointestinal function directly by mechanical disruption of tissues and cells

or by the release of factors that directly alter cell function. Induction of the immune response serves as an anamnestic amplification system. The result of these changes is an alteration in function of the smooth muscle and epithelium of the bowel.

A number of helminth parasites, including *Parascaris* spp., stimulate intestinal smooth muscle hyperplasia. This response may be induced by intestinal inflammation or stenosis associated with parasitism. Contractility of these muscles can be induced in a Schultz-Dale reaction by stimulation with parasite antigens. This response is mediated in rats by mast-cell–derived 5-hydroxytryptamine (5-HT) and in guinea pigs by histamine. A regulatory relationship of myenteric neurons to these antigen-induced changes has also been demonstrated in this model system. These latter experiments suggest that antigen-induced stimulation of smooth muscle contractility may be correspondingly blocked by γ-aminobutyric acid similarly stimulated by mast cell products. This complex system may be an adaptation by the host to maintain homeostasis in the face of continued antigenic stimulus. It is noteworthy that strongyle-induced alterations in myoelectric activity of the equine small intestine and colon have been demonstrated in vivo.[171,172] In some of these experiments, dead *S. vulgaris* larvae evoked an alteration of the smooth muscle response in previously exposed ponies, suggesting a role for the immune response in the stimulation of the hyperactivity.[173]

There is a rapidly growing literature on the host-parasite interactions of a number of mouse models of gastrointestinal nematode infections.[174-177] The mouse models include infections of *Trichinella spiralis, Nippostrongylus brasiliensis, Heligmosomoides polygyrus,* and *Trichuris muris.* Because of the use of the mouse the most contemporary of immunologic, genetic, molecular, and cell biologic techniques are available and may provide useful insights into potential explanations of immunologic and pathophysiologic responses of the horse to nematode parasites, particularly the cyathostomins. Although differences in specifics exist among these murine models, it is clear that these worms induce a type 2 T-helper cell cytokine response consisting of interleukins (ILs) IL-4, IL-5, IL-9, and IL-13. IL-4 and IL-13 induction of the Stat6 pathway is central to most of the resulting responses. There is a consistent mastocytosis and eosinophil infiltration of the intestine. The resulting responses also involve goblet cells, the enteric nervous system, epithelial cells, and alternately activated macrophages as effector cells. Cell junctions are disrupted, smooth muscle hypercontractility is stimulated, epithelial cell secretion increased, and goblet cell production of mucus is stimulated. Although these mechanisms are used most often to explain expulsion of the nematodes in question, they could be equally important in the disruption of the homeostasis seen in the parasitized equine intestine.

RESPIRATORY SYSTEM

Several nematode parasites infect the equine lung. These include migrating stages of *Strongyloides westeri* and *Parascaris* spp. en route to the small intestine. Migrating stages of aberrant parasites, such as *Habronema* sp., *Draschia megastoma*, and *Strongylus* spp., which induce granulomatous foci in the lung parenchyma, and adults and larvae of the lungworm *Dictyocalus arnfieldi,* which inhabit the bronchi, also occur. Host responses to two of these are noted.

Parascaris spp. larval migrations in the lungs of yearling horses produce more severe clinical signs and inflammatory responses than in foals that are reared parasite free. These infections in yearlings are accompanied by focal accumulations of lymphoid tissue, indicating an induction of an active local immune response. It is suggested that this is an age-related phenomenon.[178] However, it is likely that more severe reactions could be the result of previous sensitization to *Parascaris* spp. antigens. Increased responses of this nature have been described in the livers of pigs immunized with *Ascaris suum* antigens following challenge infections.

Dictyocalus arnfieldi infections of donkeys rarely produce clinical signs, and it has been suggested that these equids are the natural host for this parasite. Infections of horses produce a more severe and prolonged bronchial inflammatory response similar to *Dictyocalus* sp. infection in other hosts. The mechanisms associated with this differential response have not been defined but are not uncommon in unadapted host-parasite associations. It is possible that the more marked inflammatory reaction of the horse to these parasites is due to the absence of downregulatory mechanisms that are established in the more adapted natural host, the donkey.

SKIN

Whereas *Onchocerca cervicalis* infections in horses are rare where macrocyclic lactone anthelmintics are regularly used, reactions to the filarial nematode illustrate variations seen in responses to chronic parasite infection. Focal, alopecic, depigmented, pruritic lesions are often seen in infected horses. Not all infected horses react to this infection, and the appearance of clinical signs is often seasonal. Detailed studies have not been conducted on the pathogenesis of these lesions in horses. However, similar conditions occur in human onchocerciasis,[179] and it is likely that the host-parasite responses active in humans are also present in the horse. Lesion development is associated with immune-mediated killing of microfilariae in the skin. Parasites appear to be killed in an antibody-dependent cell-mediated reaction. In this response antimicrofilarial surface IgG and IgE antibodies mediated adherence and degranulation of granulocytes, which are predominantly eosinophils. Major basic protein of eosinophils has been demonstrated in the tissues of patients with dermal lesions, and it has been suggested that eosinophil toxic enzymes and proteins are responsible for many of the changes seen. The reason for the absence of these lesions in most horses is unclear. Human onchocerciasis and filariasis are spectral diseases. In these diseases regulation of immune responses has been associated with the lack of pathologic responses to the parasites.[180,181] Immune regulatory mechanisms associated with these infections include immune tolerance, anergy, induction of immune regulation involving Treg cells or macrophages, and the production of IL-10 and transforming growth factor beta (TGF-β)–altering Th-cell subsets and the production of specific cytokines during different phases of the infections. Recent studies have also focused on the role of an intracellular commensal microorganism, *Wolbachia,* which is a parasite of *Onchocerca* and other filarial nematodes. These bacteria have been shown to mediate type 1 inflammatory lesions in humans and mouse models.[180]

The presence of these types of parasite-associated immune regulatory events has yet to be critically studied in the horse. However, the seasonal variability in skin responses to the

Onchocerca microfilariae by horses in some regions has been investigated. In this instance the onset of ventral-midline dermatitis during the summer may be related to a seasonal fluctuation in microfilarial burdens of the skin, which have been demonstrated to correspondingly peak at this time.[182] Not only do total numbers increase, but microfilariae are also found more commonly in the surface layers of the skin. Interestingly, this period of abundant microfilariae corresponds with the seasonal peak in numbers of the vector, *Culicoides varripennis.* Although speculative, correlations in the peak availability of microfilariae and vectors may be an evolutionary adaptation by these parasites to maximize transmission and survival of this parasite species.

PROTECTIVE RESISTANCE

Resistance to infection may be innate or acquired. In some instances innate resistance to equine parasites has been attributed to age, with older individuals being resistant. Most equine helminth parasites develop only in the horse, and conversely the horse exhibits an innate resistance to most nonequine parasites. Exceptions to this rule are parasites with a broader host range that occasionally infect horses, such as larvae of the tapeworm *Echinococcus granulosus* and the liver fluke *Fasciola hepatica. Trichostrongylus axei,* a parasite of ruminants, establishes readily in the equine stomach and produces significant lesions only when present in large numbers. In some cases parasites that develop in the horse induce more severe lesions and clinical signs than in their apparent normal host, as has been described for *D. arnfieldi.*

Age resistance to *Parascaris* spp. and *S. vulgaris* has been described in horses by comparing susceptibility of young and old ponies reared under parasite-free conditions. It is apparent that the reaction of the lung to migrating *Parascaris* larvae is more marked in mature horses and suggests that an immune response occurs in this site.[160,161] Initial reports on age-acquired resistance to *S. vulgaris* infection[183] have not been substantiated, and experimental observations in our laboratory indicate that this does not occur.

The occurrence of acquired resistance to equine parasites can be inferred from the observation that older chronically exposed horses generally have lower burdens of parasites than do similarly exposed young horses. On the basis of these criteria, acquired resistance is apparent to infections of *S. westeri, Parascaris* spp., *Strongylus* spp., and cyathostomin species. Extensive experiments are limited, however, to those on *S. vulgaris* and to some degree cyathostomins.

Although *S. vulgaris* has been largely eliminated from well-managed horse farms, examination of details of the immune response to it illustrates some equine immune mechanisms. Resistance that is acquired to *S. vulgaris* in most cases is partial and of a concomitant type; that is, some stages of the parasite, such as arterial larvae of *S. vulgaris,* may reside within the horse in the face of an active acquired resistance against newly acquired infective stages.

Resistance to infection with *S. westeri* adult parasites is inferred by the short duration of their life cycle within the small intestine and the failure of subsequent exposures to establish patent infections. Mares, however, remain infected with arrested third-stage larvae, which subsequent to foaling are transmitted to the foals in milk starting at 4 days postpartum. Similar phenomena occur in swine strongyloidosis. In these infections there is apparent protective resistance against the migrating L_3, which is effective in preventing reestablishment of the intestinal infection but is ineffective against L_3, which are sequestered in the abdominal fat of the sow.[184] Similar epidemiologic phenomena occur in *S. westeri* infection of horses, and it may be implied that similar immunologic mechanisms are also active.

Immunologic mechanisms associated with protective resistance are presented primarily as they relate to parasites that inhabit the lumen of the gastrointestinal tract and secondarily as those that undergo extraintestinal tissue migration.

Immune responses directed toward gastrointestinal nematodes vary significantly among hosts and against different parasite species within a given host. However, some generalities may serve as a background for understanding these responses in the horse. A phenomenon termed *self-cure* has been described in sheep, in which the ingestion of significant numbers of infective larvae induces the expulsion of existing adult parasites. This expulsion is initiated by a species-specific immediate-type hypersensitivity response that may cause the nonspecific expulsion of other nematode species. Although this phenomenon has not been examined in the horse, experimental infections of naturally parasitized ponies with large numbers of *S. vulgaris* L_3 induced a dramatic decrease in preexisting strongyle fecal egg counts, suggesting that a self-cure–like reaction may occur under some conditions.

More typically, establishment of primary infections results at some time in spontaneous expulsions of these worms as a result either of senility or, as demonstrated in laboratory animal model systems, of active acquired immune responses. This phenomenon occurs experimentally in the absence of reinfection and is thus separate from the self-cure phenomenon. A large number of immune effectors have been identified with this phenomenon in various model systems, and it is likely that some if not all are at some time active in the equine intestine. The mechanisms involved are T-cell dependent. Antibodies may be involved but are not sufficient in themselves to induce expulsion. T-cell–mediated mastocytosis, eosinophilia, and goblet cell hyperplasia have all been demonstrated to be related to expression of expulsion in some systems. These accessory cells are involved in the nonspecific efferent arm of this response. Mediators of inflammation, such as vasoactive amines, prostaglandins, and increased production of mucus, have been linked to immune elimination of primary infections in some but not all model systems. The increased secretion and hyperreactivity of intestinal smooth muscle associated with worm expulsion have been termed *weep and sweep* phenomena. It is likely that a number of specific immunologic events initiate several nonspecific effector mechanisms, resulting in this expulsion. These mechanisms vary with the species of parasite involved. The elimination of adult *S. westeri* and *Parascaris* spp. from maturing horses and the hypothetical seasonal turnover in *Strongylus* spp. and cyathostomin spp. may be mediated by such responses.

In addition to immune responses that occur during tissue migrations, protective resistance to reinfection by gastrointestinal nematodes occurs at the surface of the epithelium. This reaction, termed *rapid expulsion* or *immune exclusion,* is separate from self-cure or immune expulsion of primary infection. Infective larvae are expelled from the intestine in a matter of hours. Again, mechanisms of expulsion described vary between parasite and host species. However, anaphylactic reactions and mucus entrapment have been observed. Some experiments using the *T. spiralis*–rat system suggest

that alterations in the epithelial cells in immune animals are directly involved in the exclusion of these parasites. Although immune-mediated damage of intestinal helminths such as decreased fecundity, reduced size, and morphologic alterations have been noted, infective larvae expelled by rapid expulsion mechanisms remain viable and undamaged. It may be speculated that reactions of this nature are responsible, in part, for resistance to reinfection of equines with cyathostomins.

Some specific observations have been made on the equine acquisition of resistance to reinfection with cyathostomins.[185] This resistance is acquired over time with continued exposure to pasture L3; is incomplete; and, like other parasitic helminth infections, appears to be genetically regulated in that parasite numbers are overdispersed within a given herd of adult animals. The limited number of experimental and field studies completed to date suggests that immunity may be directed toward all stages of the parasite life cycle. Challenge infections of previously exposed and naive ponies with mixed strongyle infections indicate that a nonspecific self-cure–like phenomenon occurs, reducing numbers of adult and fourth-stage larvae (L4) in the lumen as well as within the mucosa.[157] Fecal egg counts are significantly reduced in older animals compared with yearlings even when adult parasite numbers are similar. These observations suggest that immune responses are directed at female fecundity or that the species of cyathostomins present in the older animals are inherently less fecund. Numbers of early L3 (EL3) are reduced following challenge infections of previously exposed adult ponies compared with previously exposed young animals or age-matched naive controls.[186] Other studies have suggested that acquired resistance is important in the induction of hypobiosis.[169,187] Resistance to acquisition of EL3 was not seen when numbers were compared in young previously exposed and age-matched ponies raised under parasite-free conditions. However, these previously exposed young animals demonstrated significantly fewer developing larvae (DL) in the mucosa, suggesting that once the EL3 began to develop, they were susceptible to immune attack.[186] This response is likely driven by cytokines produced by T cells of the Th2 lineage with demonstrated increases in IL-4 and IL-5. This response mimics in some ways the results described in studies of murine nematodes.[177]

A number of intestinal helminths, as well as others, migrate through extraintestinal tissues as part of their life cycle. These include parasites such as *Parascaris* spp., *S. westeri,* and *Strongylus* spp., all of which stimulate an acquired immune response in the horse. During this migration these larvae are vulnerable to attack by immune effectors that may either encapsulate them in an immune-mediated inflammatory response, disrupt their migrations by interfering with important metabolic or invasive processes, or inhibit molting from the L3 to L4 stages. The most studied phenomenon in this regard is antibody-mediated adherence of inflammatory cells, which may result in killing of the larvae. This phenomenon involves many cell types and immunoglobulin isotypes in different host-parasite systems. In vitro studies of this nature have been conducted using *S. vulgaris* third-stage larvae and equine immune effectors.[188] In these experiments an antibody-dependent adherence of cells was demonstrated and shown to be parasite species specific. In vitro killing was mediated by eosinophils and not by neutrophils or monocytes. Activated eosinophils were necessary to mediate this response, and *S. vulgaris* infections have been demonstrated to activate eosinophils and neutrophils in vivo.[189] Although it is not certain that eosinophils are essential in this protective immune response, an anamnestic eosinophilia is characteristic in immune ponies but not nonimmune ponies following experimental *S. vulgaris* challenge.[157] Because of its prominence and compelling in vitro and correlative in vivo data, the eosinophil is considered a major effector in immune-mediated helminth killing. However, recent studies in murine parasite model systems in which eosinophilia was blocked by anti–IL-5 treatment suggest that this type of cell is not essential for protective resistance in some systems.[190] Significant increases in equine IL-5 have been measured in ponies vaccinated against *S. vulgaris.* It is possible, in vivo, that a number of cells function as effectors and may overcome the absence of sufficient eosinophils under some circumstances. Antibody reactivity with parasite-secreted enzymes and molting fluids, factors important in parasite homeostasis, has been demonstrated in vitro; similar reactions may be important in vivo.

T-cell responses are essential for the induction of protective resistance to tissue-migrating helminths in most systems studied, including the experimental *S. vulgaris* pony model. This dependency is likely due to the T-cell dependency of the antibody response and to the mediation of secondary effector cell responses. It is likely that antigenic substances secreted or excreted (ES) by migrating nematodes are important in the induction of these responses. It is probable that a combination of immune responses elicited by a combination of specific parasite antigens, including surface antigens and ES products, is necessary to induce an immune response sufficient to provide protective resistance.

PARASITE-INDUCED REGULATORY RESPONSES

Helminth parasites have evolved elaborate mechanisms to evade the host's immune responses, live in the face of an active specific host response, and yet establish chronic infections. These immune evasion strategies include the production and secretion of molecules such as proteases, protease inhibitors, antioxidants, prostaglandins, and phosphorylcholine-antigens, which disrupt host effector responses.[191,192] Other molecules that mimic host immune regulatory factors, such as TGF-β and (macrophage migration inhibitory factor) MIF, have also been identified in parasitic helminth genomes.[191] These mimics likely down-regulate host-parasite–directed protective response and add to immune evasion.

Helminth parasites can induce a regulatory immune response, which promotes their survival but also has bystander effects on host responses to other infectious agents, vaccines, allergic responses, and autoimmune diseases. These observations have progressed to the point that helminth therapy is being developed for the treatment of human inflammatory bowel disease and ulcerative colitis.[193,194] In this situation infection with the swine whipworm *T. suis* impedes the regulation of type 1 inflammatory responses responsible for these conditions and reduces disease activity. The generally accepted and simple model that has emerged for this type of helminth-induced regulation is that parasite factors stimulate dendritic cells that activate regulatory T cells and alternately activated macrophages. These cells, through the production of TGF-β and IL-10, may suppress both Th1- and Th2-mediated inflammatory responses.[195-197]

Detailed studies of the effects of equine helminths on the regulation of parasite-induced responses or to heterologous immunogens have not been reported. The effects of different levels of gastrointestinal helminth infection on the response of ponies to keyhole limpet hemocyanin immunization was measured.[198] Antibody levels determined by enzyme-linked immunosorbent assay showed that animals with low levels of parasites had a trend toward increased KLH-specific total immunoglobulin, IgG(T), and IgA compared with heavily parasitized ponies. Moderately and heavily parasitized ponies demonstrated a trend toward reduced lymphoproliferative response to KLH that was not restored after the addition of IL-2. Cells from these ponies also produced significantly lower levels of IL-4 compared with lightly parasitized ponies. These data indicate that heavily parasitized animals have uniformly decreased cellular and humoral immune responses to soluble protein immunization. The mechanisms involved are unknown. A recent study evaluated the inflammatory and immunologic response to three different antigens given simultaneously to ponies concurrently dewormed with either ivermectin or pyrantel pamoate or kept as untreated control. This study found no difference in cytokine expression, acute-phase inflammatory markers, or antigen-specific antibody titers between the anthelmintic treatment groups.[199] Taken together, the possible interaction between resident intestinal nematodes and responses to vaccination in horses is in need of further investigation.

Infection and Immunity

Robert H. Mealey

BASIC PRINCIPLES OF INFECTIOUS DISEASE

Equine clinicians devote tremendous effort to the prevention, diagnosis, and treatment of infectious diseases. Detailed and current information on specific infectious diseases in the context of organ systems is provided elsewhere in this book, and in-depth discussions of infectious diseases of horses are provided in a recent text[200] and review.[201] The field of equine infectious disease research is growing rapidly, and modern genomics techniques such as massively parallel deep sequencing have enabled the recent discovery of previously unknown equine pathogens and potential pathogens.[202,203] In addition, continued application of proteomics approaches[204] will lead to a better understanding of infectious disease pathogenesis and the discovery of novel vaccine and therapeutic targets, as well as improved diagnostics.

On a more basic level, the following events occur in all infectious diseases: encounter, entry, spread, multiplication, damage, and outcome.[205] Encounter occurs when the host comes into contact with an infectious agent. The encounter is endogenous when infections are caused by normal microbial flora. An example is pneumonia caused by *Streptococcus zooepidemicus,* a member of the normal flora of the equine nasopharynx. Exogenously acquired infections result from encounter with an infectious agent in the environment or an agent transmitted from other animals or via insect or tick vectors. There are many examples of exogenous infectious diseases, and an important one is pneumonia caused by *Rhodococcus equi.* Entry into the host can occur by ingestion, inhalation, or penetration through epithelial barriers such as the skin or mucosal surfaces. Regarding the entry of organisms, inoculum size is a key factor in determining whether or not disease will develop. Following entry, microorganisms must spread from the entry site to local tissues or disseminate to distant sites in the body. Bacteria such as *Staphylococcus aureus* produce enzymes such coagulase, protease, and hyaluronidase that facilitate their ability to spread through tissues and cause disease. Substances produced by microorganisms that enhance their ability to cause disease, as well as microbial structures that do the same, are collectively referred to as virulence factors. The next step in the development of disease is replication of the infectious agent to levels that result in clinical signs. This period of replication before the development of clinically apparent disease comprises the incubation period. Microorganisms that cause disease by producing toxins, such as botulinum toxin produced by *Clostridium botulinum,* are an exception to this rule. Disease in the host ensues when the infection results in tissue damage. There are many ways in which damage can occur. Cell death caused by replication of the agent, extracellular toxins produced by the agent, and, importantly, the host's inflammatory and adaptive immune responses directed against the agent all result in tissue damage and disease. The systemic inflammatory response elicited by endotoxin during gram-negative bacterial infections is an excellent example of host-mediated damage. The final outcome depends on the interplay between infectious agent factors and host factors, which include the inoculum size and virulence of the agent, as well as the immune status of the host. The host may mount a successful immune response and clear the organism, as occurs with equine influenza virus infection, or the immune response may control replication of the agent such that disease resolves but the agent is not eliminated. This results in persistent inapparent infection as occurs with equine infectious anemia virus infection. Finally, highly virulent agents such as rabies virus and Hendra virus will kill the host, whereas less pathogenic agents may kill hosts that are immunocompromised in some way.

Successful pathogens have developed efficient mechanisms for entry, spread, and replication, all of which enhance their ability to cause disease. Importantly, each one of these steps requires breaching or avoiding host defense mechanisms, which include physical barriers, innate immune responses, and adaptive immune responses. These same immune responses ultimately control most infectious agents but also participate in the pathogenesis of disease. Thus understanding how infectious diseases develop and how they are controlled requires a fundamental knowledge of immunology, which is the primary focus of this chapter.

EQUINE IMMUNOLOGY

Although our modern understanding of the immune system is primarily based on humans and rodent models, the horse has contributed significantly to our understanding of many immunologic processes. These contributions include the earliest work on serotherapy and passive transfer of antibodies, antibody structure and function, immunity to infectious agents, immunodeficiencies, and reproductive

immunology.[206] Work in the horse continues in many of these areas from the standpoint of equine medicine and comparative immunology. With some exceptions, the overall organization and function of the equine immune system is similar to other mammalian species. A number of texts provide excellent in-depth reviews of basic and clinical immunology, and much of the general information provided in this chapter is drawn from these resources.[207-210] This chapter will focus on aspects of the immune system that may be of most interest to equine clinicians and researchers, with pertinent references to equine work provided when possible.

Innate Immunity and the Acute Inflammatory Response

Immune defenses include both innate responses and adaptive responses, each mediated by cellular and soluble components. Although fundamentally different, the innate and adaptive immune systems are intimately related and share many of the same processes and components. Innate immunity is rapid, is nonspecific, results in acute inflammation, and has no memory. In contrast, adaptive immunity takes time to develop, is antigen specific, and has recall capability. It is both the specificity of adaptive responses and the capacity for immunologic memory that allow complete protection against a particular pathogen. However, innate responses play key roles in both triggering the adaptive response and providing valuable time for specific adaptive responses to develop.

The horse, like every other species, is under constant assault from a variety of microbes that share its living space. Although most of these organisms are thought to be harmless, their disease-causing potential is evident when they cause opportunistic infections in individuals with compromised immune systems. In general, mammals have evolved a variety of defensive measures to prevent infections from occurring. The first line of defense includes the physical barriers provided by the skin and the mucosal surfaces of the digestive, respiratory, and urogenital tracts. In addition to providing a barrier to penetration, the surface of the skin contains various enzymes, fatty acids, and oils that inhibit the growth of bacteria, fungi, and viruses. Mucous membranes and mucosal secretions contain bacteriolytic enzymes, bactericidal basic polypeptides, mucopolysaccharides, and antibodies that prevent colonization and penetration of these surfaces. Mucus also provides a physical barrier that entraps invading organisms and leads to their eventual disposal.[211] Particles trapped in the mucus secretions of the respiratory tract, for example, are transported upward through the action of ciliary cells to the trachea where they are swallowed.[212] Once swallowed, the acidic secretions and digestive enzymes of the stomach destroy most organisms. Normal epithelial and tissue architecture is essential for successful exclusion of bacteria, and the disruption of this mechanism makes the host susceptible to infection by bacteria that normally colonize the upper airway.[213,214] The protective role of gastric acidity against gastrointestinal pathogens is supported by the observation that acid-suppressive drugs increase the risk of diarrhea in neonatal foals treated in intensive care units.[215] In humans, administration of proton pump inhibitors in critically ill patients increases the risk of *Clostridium difficile*–associated diarrhea.[216]

Proinflammatory Cytokines, Acute Phase Proteins, and Complement

After physical barriers have been breached, the innate immune system provides a variety of internal defenses to contain and eliminate the invading organisms. Inflammatory responses are initiated either via the activation of plasma protease systems directly, such as by bacterial cell wall components, or by the secretion of toxins or other proteins that can directly activate the inflammatory response.[217] The cell walls and membranes of bacteria contain various proteins and polysaccharides with characteristic, often repeating, molecular structures. These pathogen-associated molecular patterns (PAMPs) include lipopolysaccharides (LPSs), peptidoglycans, lipoteichoic acid, and flagellins.[218] Other PAMPs include viral nucleic acids and unmethylated bacterial cytosine-guanosine dinucleotides (CpG). PAMPs are recognized by pattern recognition receptors found on cells of the immune system, particularly those cells involved in the initial encounter with invading microbes. These "sentinel cells" include macrophages, dendritic cells, and mast cells, with macrophages being the most important for initiating the inflammatory response. Pattern recognition receptors are located on the cell surface, as well as intracellularly, and include toll-like receptors (TLRs), retinoic acid–inducible gene–1 (RIG-1)–like receptors, and nucleotide-binding oligomerization domain–like receptors. The TLRs are particularly important in the induction of inflammation. In addition, binding of PAMPs leads to intracellular signaling events culminating in the expression of costimulatory signals for the developing adaptive immune response. Injured cells release products collectively termed *damage-associated molecular patterns* (DAMPs) that bind TLRs on macrophages and other cells leading to the production of proinflammatory cytokines that augment the inflammatory process. Resident macrophages that encounter the invader initiate the inflammatory response through the production of proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor–alpha (TNF-α).[217] Cytokines are hormone-like proteins that mediate a variety of cellular responses. A vast number of cytokines are involved in the regulation of innate and adaptive immune responses. IL-1, for example, is a pleiotropic mediator of the host response to infections and tissue injury (Table 1.3). Many of the effects of IL-1 are mediated through its capacity to increase the production of other cytokines, such as granulocyte colony-stimulating factor (G-CSF), TNF-α, IL-6, and platelet-derived growth factor (PDGF). IL-6 is responsible for the increased production of acute phase proteins by hepatocytes, including complement proteins, C-reactive protein, and serum amyloid A (SAA).

TABLE **1.3** **Biologic Activities of Interleukin-1**

Activates T cells	Induces fever
Activates B cells	Cytotoxic for some tumor cells
Enhances NK cell killing	Cytostatic for other tumor cells
Fibroblast growth factor	Stimulates collagen production
Stimulates PGE synthesis	Stimulates keratinocyte growth
Stimulates bone resorption	Stimulates mesangial cell growth
Chemotactic for neutrophils	Activates neutrophils
Activates osteoclasts	Induces IL-6 production

Many of these proteins and the cytokines that elicited them are responsible for the characteristic physical signs of inflammation, including increased blood flow and vascular permeability, migration of leukocytes from the peripheral blood into the tissues, accumulation of leukocytes at the inflammatory focus, and activation of leukocytes to destroy any invading organisms.[219]

During viral infections, intracellular pattern recognition receptors (such as RIG-1) bind to viral PAMPs (such as double-stranded viral ribonucleic acid [RNA]) and induce the production of type I interferons (IFNs), including IFN-α and IFN-β. These are produced in virus-infected cells within hours and inhibit viral replication through various mechanisms. In addition, natural killer (NK) cells are capable of lysing virus-infected cells via recognition of different types of receptors on the surface of infected cells, as well as recognizing cells expressing fewer major histocompatibility complex molecules (see later discussion), the expression of which can be down-regulated by viral infection. Finally, NK cells have surface Fc receptors (see later discussion) that can bind the Fc portion of antibodies bound to the surface of infected cells and subsequently kill the infected cell through the process of antibody-dependent cellular cytotoxicity. NK cells are of the lymphocyte lineage but do not possess antigen-specific receptors such as T and B lymphocytes (discussed later) and thus act as innate effector cells.

The complement system consists of over 30 different plasma proteins that are produced primarily in the liver. This complex interacting series of proteases and their substrates results in the production of physiologically active intermediaries that can damage membranes, attract neutrophils and other cells, increase blood flow and vascular permeability, and opsonize bacteria and other particles for phagocytosis.[220] The complement cascade can be activated in three ways. The *lectin pathway* is initiated when soluble carbohydrate-binding proteins (such as mannose-binding lectin) bind to carbohydrate structures on microbial surfaces. Proteases associated with these carbohydrate binding lectins then initiate the cleavage of complement components and activate the pathway. The *classical pathway* involves the binding of C1q to antibodies already bound to the surface of a microbe. Bound C1q is proteolytic and cleaves other complement components activating the pathway. The activation of complement via the *alternate pathway* does not involve antibodies. Instead, certain microbial products stimulate the association of factor D, a proteolytic enzyme, with the complex of factor B and C3b leading to the formation of C3 convertase and its deposition on the microbial surface. All three pathways converge with the generation of C3 convertase and the cleavage of C3. Soluble C3a, produced by the cleavage of C3 by the C3 convertases, can bind to mast cells causing them to degranulate and is thus referred to as an anaphylatoxin, as is C4a. C3b serves as an opsonin for C3b receptor-bearing phagocytic cells. C3b is also required for the formation of the membrane attack complex by the terminal complement components, C5 through C9. In this process C5 is cleaved and C5a is generated, which, along with C3a, is a chemoattractive factor for neutrophils and monocytes.[221] C5b forms a complex with C6, C7, and C8 on cell surfaces. This leads to the insertion and polymerization of C9 that forms a pore in the membrane leading to cell lysis. A summary of the three complement pathways and the resultant effector mechanisms of microbial destruction is provided in Fig. 1.6.

Lipid Mediators. Prostanoids are lipid mediators that regulate the inflammatory response.[222,223] The prostanoids include the prostaglandins (PGs), leukotrienes (LTs), and prostacyclin (PGI_2), and they are the product of cyclooxygenase cleavage of arachidonic acid followed by endoperoxidation. The major sources of prostanoids in acute inflammation are the phagocytes, endothelial cells, and platelets. Although prostanoids, in general, mediate the cardinal effects of pain, fever, and edema characteristic of the acute inflammatory response, their particular roles are somewhat confounding and can be either pro-inflammatory or antiinflammatory.[224] Prostanoid production depends on the activity of the two isoforms of the cyclooxygenase (COX) enzymes within cells: COX-1, which is present in most cells and its expression is generally constitutive, and COX-2, for which expression is low or undetectable in most cells but its expression increases dramatically on stimulation, particularly in cells of the immune system. Increased COX-

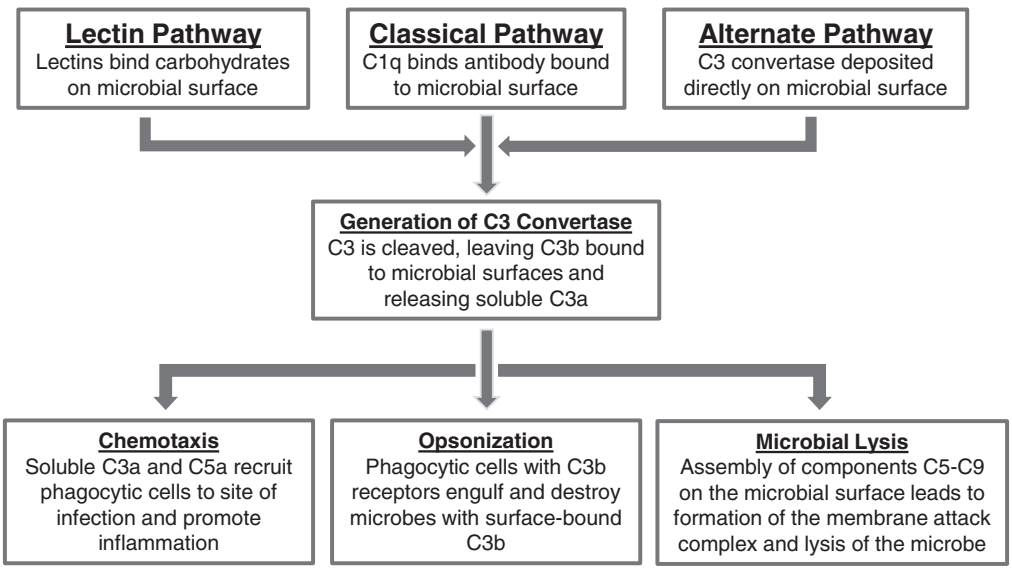

FIG. **1.6** Simplified pathways of complement activation and basic effector mechanisms of microbial destruction. See text for explanation.

2 expression by inflammatory stimuli likely accounts for the high levels of prostanoids found in inflammatory lesions and is the basis for the development of COX-2–selective nonsteroidal antiinflammatory drugs (NSAIDs).[225] Because there are species differences in the pharmacokinetics and COX selectivity of NSAIDs, extrapolation of studies performed in other species should be interpreted with caution with respect to the potential COX selectivity and efficacy in the horse.[226] Meloxicam has COX-2 selectivity and efficacy in the horse[227-229] but at the time of this writing is not approved in the United States for use in horses (but is approved in Europe). Firocoxib is a selective equine COX-2 inhibitor with documented safety and efficacy,[210-236] and it is currently the only COX-2–selective inhibitor approved by the Food and Drug Administration for use in horses in the United States.

Both COX isoforms produce PGH_2, which is the common substrate for a series of specific synthase enzymes that produce PGD_2, PGE_2, PGF_2, PGI_2, and TXA_2. It is the differential expression of these enzymes within cells present at sites of inflammation that determines the profile of prostanoid production. Likewise, the biologic effect of a prostanoid depends on binding to G protein–coupled cell surface receptors. Many cells of the immune system express multiple receptors that couple to apparently opposing pathways. The impact of prostanoids present during an inflammatory response is thus determined by the array of receptors the cells express and the intracellular pathways to which they are coupled. Activation of these receptors, even when coupled to similar pathways, might evoke different responses because of differences in the levels of expression (both constitutive and induced) or in the patterns of desensitization. The role of prostanoids in a given inflammatory response depends not only on the presence of the lipid mediators in the lesion but also the receptor profile on immune cells and the biochemical signaling pathways of these receptors.[237] Thus PGE_2 is considered proinflammatory because it promotes vasodilation by activating receptors on vascular smooth muscle and increases vascular permeability indirectly by enhancing the release of histamine and other mediators from tissue leukocytes such as mast cells. PGE_2 is also the prostanoid responsible for fever production. However, as inflammation progresses, PGE_2 synthesis by macrophages is enhanced as a result of increased expression of COX-2 and PGE-synthase, and the resulting increased levels of PGE_2 inhibit leukocyte activation, inhibit mast cell degranulation, and relax smooth muscle contractions. In the lung, PGE_2 promotes bronchodilation. Thus in these situations PGE_2 may be considered antiinflammatory.

Chemotaxis and Leukocyte Trafficking. One of the initial and most crucial aspects of the acute inflammatory response is the recruitment of leukocytes (primarily neutrophils) to the site of injury. Neutrophils constitute the first line of the cellular defense and are the initial cells involved in an inflammatory response. These phagocytic cells are derived from multipotent stem cells located chiefly in the bone marrow. Under the influence of a variety of signals provided from both within and outside of the bone marrow, these stem cells become committed to developing into cells of the granulocyte lineage. The critical signal is provided by a family of growth factors known as colony-stimulating factors (CSFs) that provide both proliferative and differentiating signals leading to the development of granulocytes and other leukocytes. Once released into the circulation these cells must find their way to the site of the inflammatory response. The production of various chemotactic factors by host cells, bacteria, and other invaders causes various leukocytes to enter the circulation and be carried to the site of the injury.[238] Chemokines are chemotactic cytokines. These are soluble proteins produced by host cells that induce the directional migration and activation of leukocytes, as well as other somatic cell types, and thus play major roles in the inflammatory response.[239] The chemokine CXCL8 (previously known as IL-8) plays a central role in the migration of neutrophils, including equine neutrophils.[240,241] Other chemokines promote humoral and cell-mediated immune reactions; regulate cell adhesion, angiogenesis, leukocyte trafficking, and homing; and contribute to lymphopoiesis and hematopoiesis.[242]

The specific trafficking of leukocytes from the blood to inflammatory sites is dependent on both the production of chemotactic factors and the interaction of specific receptors on the leukocytes with corresponding adhesion molecules on the endothelial surface of the blood vessels. Neutrophil adherence is a two-step process first involving endothelial cell surface molecules known as selectins. Small venular endothelium overlying a site of inflammation and exposed to leukotrienes, platelet activating factor (PAF), IL-1, complement protein C5a, histamine, LPSs, TNF-α, or other mediators released by clotting, platelet activation, or mast-cell activation express P-selectin. P-selectin mediates the process in which neutrophils initially interact with the endothelial surface in a process known as "rolling" in which the circulating neutrophil interacts with the endothelial cell before the actual adherence. P-selectin appears on the endothelial cell surface within minutes of an inflammatory stimulus, followed by E-selectin expression within a few hours. Endothelial selectins function by binding to carbohydrate ligands present on the leukocyte surface. In the case of neutrophils, the ligand is sialyl-Lewis^X, an oligosaccharide present on cell surface glycoproteins. Equine P-selectin binds the sialyl-Lewis^X moiety on equine leukocytes, mediating adhesion and stimulating the production of CXCL8.[243] The second part of the adherence process is the tight binding of integrins on the neutrophil surface to intracellular adhesion molecules on the endothelial cell surface. Leukocyte integrins are heterodimeric proteins and include leukocyte functional antigen–1 (LFA-1, also called CD11a:Cd18) and complement receptor type 3 (CR3, also called CD11b:Cd18). Neutrophils can be activated by a number of soluble proteins present in bacterial but not eukaryotic proteins. Host factors present at the site of inflammation can also activate neutrophils. These include complement proteins (C5a, C3a), the chemokine CXCL8, cytokines (especially TNF-α), and immune complexes.[244] Expression of integrins by the activated neutrophil allows them to become tethered to the endothelial surface. The migration of neutrophils through the vascular wall is less well understood than these initial events leading to firm adhesion. Integrins LFA-1 and CR3, as well as PECAM-1 (CD31), another cell adhesion molecule, appear to play a role in this process. Endothelial cell–produced CXCL8 also has a critical role in this process. Once through the endothelium, the phagocytes will follow chemotactic signals and migrate toward the point of injury. They may adhere to other cells during migration to the site of inflammation, and these interactions also are dependent on integrins.

Neutrophils recruited and activated in this manner will actively phagocytose microscopic invaders and attempt to destroy them using reactive oxygen products generated via a nicotinamide adenine dinucleotide phosphate

(NADPH)-oxidase–dependent respiratory burst. During this process, neutrophils release additional proinflammatory mediators, thus amplifying the response. Among those cells attracted to the area are NK cells, and the production of IFN-α or IFN-β by macrophages and other cells enhances NK cell cytolytic activity. The NK cells themselves can be a source of IFN-γ, another proinflammatory cytokine (discussed in detail later). Depending on the magnitude of the initial insult and the susceptibility of the invader to neutrophil-mediated destruction, the inflammatory response may be either acute or chronic.

Acute inflammation is thus a rapid response to an injury that is characterized by accumulations of fluid, plasma proteins, and neutrophils that rapidly resolves once the initial inflammatory stimulus is removed. Deactivation signals include PGE_2, cortisol, IL-10, and transforming growth factor–β (TGF-β). Some of those chemotactic agents responsible for initiating the response (CXCL8, FMLP, C5a, LTB4, and PAF) also serve to downregulate its intensity by inducing the shedding of IL-1 receptors from neutrophils.[245] The shedding of this decoy receptor may have antiinflammatory effects as it effectively binds and neutralizes this cytokine. Likewise many of the acute phase proteins are thought to have immunomodulatory activity downregulating neutrophil function.[246] Acute inflammatory responses may often be subclinical and resolve without complications. However, if the invader is resistant to neutrophil-mediated destruction or the degree of injury is large, the response may become more chronic with the added recruitment of macrophages, lymphocytes, and fibroblast growth.

The essential characteristic of the innate immune response is that it does not exhibit specificity for the invading organism. Thus the induction of an innate immune response does not require prior exposure to the invading organism nor is it augmented by repeated exposure to the same organism. In most instances these mechanisms are adequate for eliminating casual invaders. However, pathogenic organisms have evolved various methods for avoiding elimination. In response to these organisms, the specialized cells and products of the adaptive immune response are mobilized.

Adaptive Immunity

The adaptive immune response is initiated in response to the encounter with a foreign agent and depends on antigen-specific immune responses mediated by different divisions of the lymphocyte family (Fig. 1.7). In contrast to the nonspecific nature of the innate immune response, an important characteristic of the adaptive immune response is the specificity of this interaction. Thus exposure of the host to a particular microbe or parasite results in the induction of immune responses that are directed against specific components of the invading organism that do not affect unrelated organisms. The specificity of the adaptive immune response is the result of the interaction of specific molecular structures, or *antigens,* of the invader with antigen-specific receptors on lymphocytes. All types of chemical structures can serve as antigens, including proteins, nucleic acids, lipids, and polysaccharides. However, foreign molecules that are large, complex, and stable are the most antigenic. Large antigens, such as proteins, contain multiple *antigenic determinants* or *epitopes* that interact with lymphocytes via their antigen-specific receptors. *Haptens* consist of single antigenic determinants and can effectively combine with the binding site of antibody molecules. However, as they only consist of a single antigenic determinant, they cannot cross-link B-cell receptors (antibody molecules), and they are also unable to stimulate T-cell responses. Therefore haptens cannot stimulate an immune response unless multiple haptens are physically attached to a larger molecule, known as a *carrier.*

Like the innate response, the adaptive immune response to a specific antigen consists of both humoral and cellular effector mechanisms. The humoral component is mediated by immunoglobulins or *antibodies* found in plasma and tissue fluids. Antibodies are produced by B lymphocytes, small lymphoid cells characterized by the cell surface expression of immunoglobulin molecules. B cells represent less than 15% of the circulating peripheral blood mononuclear cells but are present in higher proportions in lymph nodes and the spleen. B cells are derived from the fetal liver and bone marrow of mammals and the bursa of Fabricius of birds. In the bone marrow, B

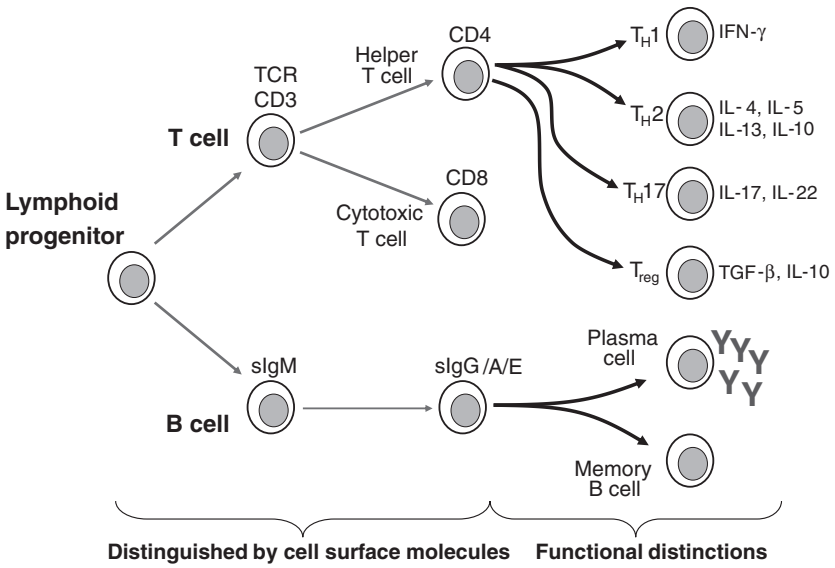

FIG. **1.7** Major divisions of the lymphocyte family. To the left of the diagram different populations of lymphocytes are distinguished by expression of different cell surface molecules. To the right of the diagram the distinctions are functional.

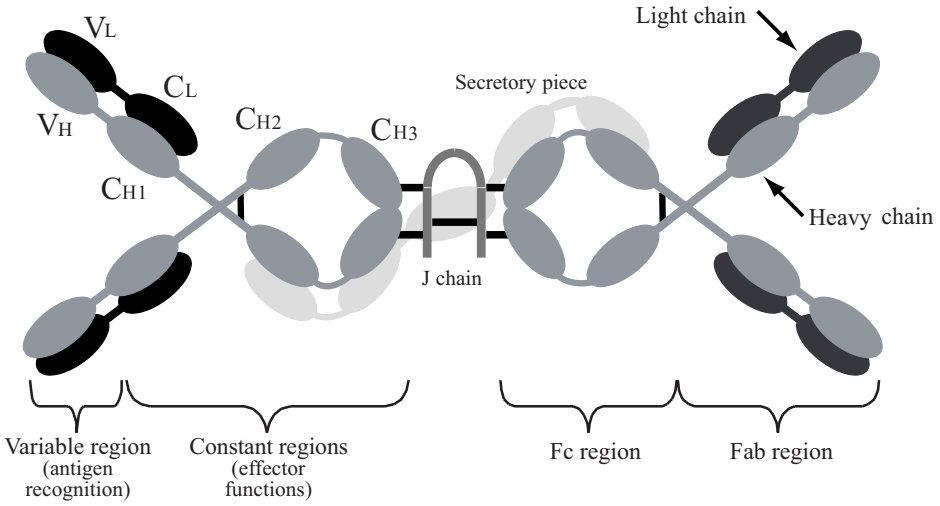

FIG. **1.8** Molecular structure of secretory IgA. This schematic illustrates the major features of immunoglobulin molecules. Whereas the illustrated IgA molecule is dimeric, with the two Ig units joined by a "J chain" and a series of disulphide bonds, IgG molecules are monomeric. Each Ig unit consists of two heavy chains and two light chains. The heavy chains have four subunits and the light chains two. One end of the Ig unit has a highly variable protein structure and is involved in antigen recognition, and the remainder of the Ig unit has a constant structure in each Ig class and subclass and determines the functional characteristics of the molecule, such as binding complement, or recognition by macrophages or neutrophil Fc receptors. This specialized dimeric IgA molecule also has a secretory piece that increases its stability in the harsh mucosal environment. In this diagram, the Fc portion is depicted as a circular structure, consistent with actual x-ray crystal structure determinations.

cells are the products of a putative lymphoid stem cell derived from the pluripotent stem cell. Under the influence of various cytokines produced by bone marrow *stromal* cells, the B-cell precursor undergoes its 3-day development into a mature B cell. On stimulation with a specific antigen, B cells differentiate into *plasma cells* that produce enormous quantities of a specific antibody. The activation, proliferation, and differentiation of B lymphocytes into plasma cells is dependent on other cells, including T lymphocytes, which represent the cellular component of the adaptive immune response. The T lymphocyte is also derived from the multipotent stem cell and lymphoid precursor in the bone marrow, though its subsequent development into the mature T cell occurs in the *thymus*. Within the thymic environment the prothymocyte undergoes a developmental and selective process while emigrating through the cortex into the medullary region of the thymus. Less than 3% of all the immature thymocytes found in the cortex survive to become peripheral T cells.

Though the induction of an antibody response requires the interaction of B and T lymphocytes, these cells recognize different epitopes on the same antigen. Indeed, antigen recognition by B cells and T cells is fundamentally quite different. B cells, and antibodies, recognize antigens in solution or on cell surfaces in their native conformation, whereas T cells only recognize antigen in association with self molecules known as major histocompatibility complex molecules found on most cells surfaces (see later discussion). The adaptive immune response thus differs from innate immunity in that it is antigen driven, and those cells that mediate the adaptive immune responses, T and B lymphocytes, express specific receptors for the antigen. Because the immune system will respond to the antigens of both live and killed pathogens, it is possible to stimulate immunity without causing infection and/or disease (the basis of vaccination). Although this principle appears to be straightforward, vaccination does not always yield the expected result. Why some vaccines work and others fail is a complex issue, a major component of which is the nature of the antigen-specific receptors of lymphocytes.

Immunoglobulin: Antigen-Specific Receptor of B Lymphocytes

The antigen-specific receptor of the B cell is cell surface bound immunoglobulin, also known as antibody. An immunoglobulin molecule is composed of two identical light chains and two identical heavy chains that form a disulfide-linked Y-shaped molecule (Fig. 1.8). The light chain can be divided into two domains, a conserved carboxy-terminal domain and a highly variable amino-terminal domain. Analysis of heavy chains reveals a similar domain structure with the amino-terminal domain being highly variable and the presence of three constant domains. The antigen-binding region of an immunoglobulin molecule is formed by the association of the amino ends of a light and a heavy chain, and the carboxyl end of the heavy chain determines the isotype of the molecule. Similar to most species, five different immunoglobulin *isotypes* (classes) have been identified in the horse: IgM, IgD, IgG, IgE, and IgA (Table 1.4).[247-250] Before the availability of genetic characterization of the equine immunoglobulin heavy chain gene loci, at least four IgG subclasses were identified by physicochemical means and defined serologically by monoclonal antibodies as IgGa, IgGb, IgGc, and IgG(T).[251] More recently, seven IgG subclasses have been defined (IgG1–IgG7) and named based on the designation of the corresponding Ig heavy chain constant region genes.[248,250] The original IgGa corresponds to IgG1, IgGb to both IgG4 and IgG7, IgGc to IgG6, and IgG(T) to both

TABLE **1.4 Immunoglobulin Isotypes**

Isotype	Immunologic Function
IgM	Surface IgM is found on naive, activated, and memory B cells. Secreted IgM is a pentamer and represents the major antibody produced during a primary response. IgM efficiently mediates agglutination, neutralization, opsonization, and complement activation.
IgD	Antigen receptor of naive B lymphocytes. An IgD heavy chain gene has been identified in the horse, and it is expressed.
IgG	The principal immunoglobulin found in plasma representing up to 80% of the total immunoglobulin concentration. Seven subclasses of IgG have been identified (see text). The major functions of IgG include opsonization and neutralization reactions. IgG1, IgG3, and IgG4/7 are effective in fixing complement, and IgG1, IgG4/7, and IgG3/5 bind Fc receptors so they can function as opsonins and mediate antibody-dependent cellular cytotoxicity. IgG6 and IgG5 may play an important role in exotoxin neutralization and immunity to parasites.
IgE	Most IgE is found associated with the surface of mast cells and basophils and only very small amounts are present in the plasma. The cross-linking of two IgE molecules with specific antigen results in the degranulation of the mast cells and basophils. Thus IgE is the primary antibody responsible for type I hypersensitivity reactions and appears to play a central role in immunity to parasites.
IgA	The most abundant antibody in secretions (tears, mucus, saliva, colostrum, etc.) is a dimer composed of two IgA molecules joined by a J chain. IgA in the plasma is predominantly monomeric. IgA antibodies can be neutralizing but do not fix complement efficiently nor do they have efficient opsonization activity.

IgG3 and IgG5.[247,250] All seven IgG subclasses are expressed and functional, with IgG1, IgG3, IgG4, IgG5, and IgG7 able to elicit a respiratory burst in equine peripheral blood leukocytes (predictive of binding to Fc receptors), whereas IgG1, IgG3, IgG4, and IgG7 bind complement C1q and activate the classical complement pathway.[247] Some functional discrepancies exist between the new and original designations. For example, IgG(T) does not fix complement and inhibits complement fixation by IgGa (IgG1) and IgGb (IgG4/7).[252] This is not consistent with the complement fixing properties of IgG3, which, along with IgG5, corresponds to IgG(T).[247] Perhaps new reagents will provide clarification.

Membrane-bound immunoglobulin serves as the antigen-specific receptor for B lymphocytes (B-cell receptor [BCR]). Thus antibodies in serum are secreted soluble forms of BCRs. Each BCR contains a membrane-spanning region near its carboxy end that is inserted into the mRNA during differential splicing of the heavy chain exons. Membrane IgM and IgD comprise the BCRs on the surface of naive B lymphocytes, although the function of IgD is unclear. The IgD isotype is secreted in very small quantities, if at all, and is rarely detectable in the circulation. Once activated, B cells cease to express IgD but continue to express the membrane form of IgM. Early on in an immune response the B cell secretes large amounts of the pentameric form of IgM. As the immune response proceeds, the B cell will switch the isotype of its heavy chain. Isotype switching involves the substitution of one heavy chain constant region in place of another. In the horse, the genes encoding the 11 different constant (C) regions (five primary isotypes including the seven IgG subclasses) of the heavy chain are sequentially arranged on chromosome 24 in the following order: Cμ(M), Cδ(D), Cγ1(G1), Cγ2(G2), Cγ3(G3), Cγ7(G7), Cγ4(G4), Cγ6(G6), Cγ5(G5), Cε(E), Cα(A).[250] Initially, the first two constant region genes encoding the M and D constant regions are used to form the heavy chain. When switching occurs a new constant region segment is selected, and the intervening genes are removed either by splicing or looping out. Isotype switching only affects the heavy chain constant domains and has no effect on the antigen specificity of the immunoglobulin molecule. Isotype switching occurs in lymphoid follicles within the lymph nodes and spleen (and other secondary lymphoid organs) during a primary immune response and requires interaction with T lymphocytes. Cytokines secreted by these interacting helper T cells provide the signals driving class switching. For example, IL-4 and IL-13 induce isotype switching to IgE, and interferon-gamma (IFN-γ) inhibits this induction and augments IgG production. IgA is produced in response to the combination of the cytokines IL-4, IL-5, and transforming growth factor-β (TGF-β).

The antigen specificity of a particular antibody molecule (and the B cell that produces it) is determined by the combination of the variable domains of the light and heavy chains. The association of these two domains results in the formation of an antigen-binding cleft or pocket that contains regions of hypervariability that define the specificity of a particular antibody molecule. It has been estimated that over 10^8 different antibody specificities are possible. The generation of this tremendous amount of diversity in antibody specificity occurs during B-cell ontogeny in the bone marrow. Within a given B cell, the genes encoding the heavy and light chains of an antibody molecule are organized into specific gene segments. Thus the light chain is formed from variable (V_L), joining (J_L), and constant (C_L) gene segments, which together form the variable and constant domains of the light chain. In the germ line of an undifferentiated human cell one finds several hundred different V_L and several dozen J_L gene segments. In the horse, there are 204 V_L genes, 12 J_L genes, and 8 C_L genes.[253] Likewise the heavy chain of a B lymphocyte is composed of V_H, diversity (D), and J_H segments, which form the variable domain, and these join to the constant region genes (discussed earlier) to form the complete heavy chain molecule. Similarly, in the germ line of humans one finds a large number of V_H gene segments and a smaller number of D_H and J_H segments. There are 54 V_H, 40 D_H, and 8 J_H genes in the horse.[253] During the differentiation of a B cell (Fig. 1.9), there is the sequential selection and rearrangement of a V_L segment with a J_L segment and the accompanying deletion of intervening V_L and J_L segments (Fig. 1.10). The VJ segment is joined with a C gene, and the rearranged VJC sequence is then transcribed into mRNA and translated into the light chain. A somewhat similar sequence follows for heavy chains except that two

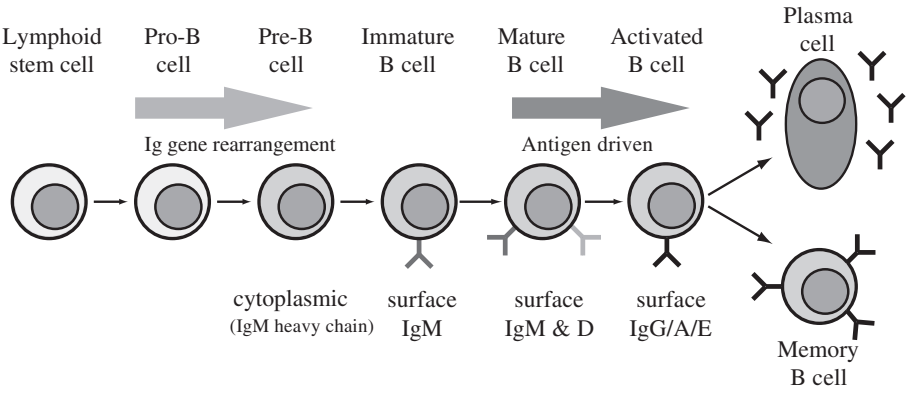

FIG. **1.9** B-cell differentiation. Different stages of B-lymphocyte development can be recognized by expression of immunoglobulin molecules. This maturation requires a series of gene rearrangements to select the genes that will encode the antigen binding part of the immunoglobulin molecule (variable region), and subsequently to select the genes that determine the class or subclass of the antibody molecule. Initially immature B cells express IgM (the majority of peripheral blood B cells), but after antigen exposure the B cell becomes activated and may express any of the immunoglobulin classes or subclasses. This decision depends in large part on cytokine signals from helper T cells. Activated B cells either mature into short-lived antibody-secreting plasma cells or become long-lived memory B cells.

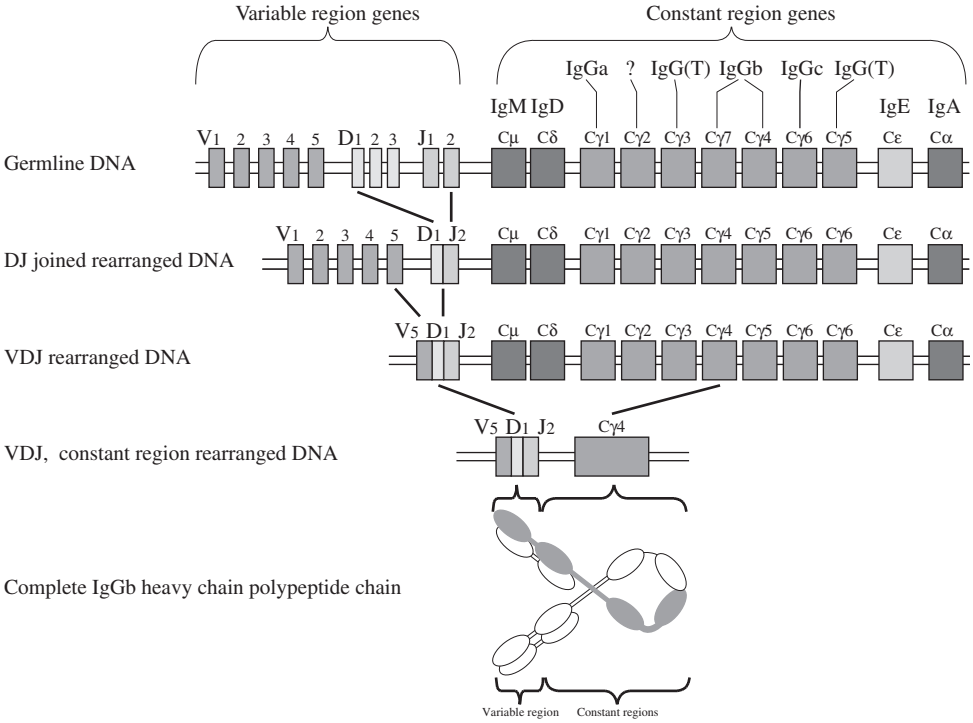

FIG. **1.10** Immunoglobulin gene rearrangement: somatic recombination process for production of an immunoglobulin heavy chain. The figure shows a hypothetical series of V, D, and J variable heavy chain genes, positioned 5′ to the known equine heavy chain constant region gene loci. In the first step in somatic recombination a D and a J gene segment are joined, and in the second step a V gene segment is joined to complete the VDJ recombination and form a gene capable of encoding the variable region. Subsequently one of the seven equine γ heavy chain constant regions, labeled with their corresponding IgG subclass, was selected to complete the gene rearrangement. Because the Cγ4 heavy chain constant region gene was selected, this leads to production of an IgG4 heavy chain.

rearrangements are necessary, a D to J rearrangement followed by a V to DJ rearrangement. Once completed, the VDJ segment is brought into proximity of the appropriate C_H segment and transcribed. During gene rearrangement, intervening deoxyribonucleic acid (DNA) is looped out and excised, which requires V(D)J recombinase. This enzyme is made up of RAG-1 and RAG-2 components, encoded by recombination-activating gene–1 and recombination-activating gene–2. To reconstitute the rearranged gene the cut ends of the DNA must be rejoined, which requires the enzyme DNA-dependent protein kinase (DNA-PK). Not all of the gene segment rearrangements produce functional genes. Because a B cell

has two sets of heavy chain genes, one on each chromosome, and most species have two different sets of light chain genes, including the horse,[253-255] there are several chances to form appropriate heavy and light chains. Once the heavy and light chain gene segments are successfully recombined, the genes on the sister chromosome neither recombine nor are they expressed. This process of allelic exclusion ensures that the B cell produces antibodies of a single specificity. Although this random assortment of gene segments accounts for much of the diversity in antibody specificity, additional mechanisms are also involved, including gene conversion (insertion of pseudogenes), junctional diversity (resulting from the imprecise joining of gene segments), and somatic mutations. Somatic mutations are point mutations in the hypervariable region of either the heavy or light chain that occur during the proliferation of antigen-activated B lymphocytes within germinal centers of lymph nodes and other secondary lymphoid organs and tissues. Such mutations play an important role in increasing antibody affinity for its antigen. Thus fewer than 500 genes can give rise to over 10^8 molecules of the various specificities needed to recognize the vast number of antigens the host may encounter.

T-Cell Receptor and CD3 Complex: Antigen-Specific Receptor of T Cells

T lymphocytes can be differentiated from B lymphocytes in that they do not express surface immunoglobulins but instead express the T-cell receptor (TCR). T cells also express another surface molecule called CD3. (The designation CD stands for cluster of differentiation and is the result of an international workshop to standardize the terminology used to describe leukocyte surface antigens recognized by monoclonal antibodies.) The TCR and CD3 form a multimeric complex on the T-cell surface, and this complex is involved in antigen-specific recognition. The TCR was originally described as a heterodimer comprised of an α chain and a β chain. Peptide mapping studies of the α and β chains from many different T-cell lines demonstrated that they contained variable and constant domains reminiscent of immunoglobulin structure. Further analysis indicated that, like immunoglobulin genes, TCR genes undergo gene rearrangements during T-cell development to generate tremendous diversity in antigen specificity. Subsequently, two additional TCR genes were identified, the γ chain and δ genes corresponding to a second heterodimer. Thus two types of TCRs exist, an αβ heterodimer and a γδ heterodimer. Although the percentages of T cells expressing the γδ receptor vary among mammalian species (ruminants and pigs have higher percentages of γδ T cells than other species), most T cells are αβ T cells with fewer than 5% of all T cells expressing the γδ receptor. The function of γδ T cells is poorly understood. In general, γδ T cells generate less diversity in their TCRs, can recognize nonpeptide antigens such as lipids, do not require major histocompatibility complex presentation for antigen recognition (see later discussion), and participate in inflammatory responses. They secrete cytokines and can have cytotoxic activity and may be important for recognizing antigens frequently encountered at mucosal surfaces and epithelial boundaries, at the interface between the host and the external environment.[207] As such they are thought to play an important role in immunologic surveillance. In the horse, $CD8^+$ T cells expressing the γδ TCR have been identified in peripheral blood.[256]

Analysis of the predicted amino acid sequences for the TCR proteins confirmed a structural similarity with antibody molecules. One peculiarity in the structure of the TCR was observed from the amino acid sequence analysis. Although both the α and β chains of the TCR contained a transmembrane region, both proteins had very short cytoplasmic tails. However, the TCR heterodimer is noncovalently associated with the CD3 complex of proteins. The five proteins of the CD3 complex are involved in signal transduction following TCR binding to antigen. Unlike the TCR α and β proteins, the CD3 proteins have large intracellular domains, some of which are phosphorylated in response to stimulation of the TCR (see later discussion). In addition to providing a signaling mechanism for the TCR, the CD3 complex is also required for the expression of the TCR heterodimer on the cell surface.[257]

The generation of diversity in the TCR during T-cell ontogeny employs a mechanism similar to that used to generate immunoglobulin diversity. The TCR α chains resemble immunoglobulin light chains in that they are composed of V, J, and C gene segments. The particular V, J, and C segments used are selected from a germ line configuration containing a few (C region) to several hundred (V region) gene segments. The selection and rearrangement of the gene segments are similar to those employed by the immunoglobulin light chain and appear to involve the same recombinases and DNA-PK. Likewise the β chains resemble heavy chains, each being composed of V, D, J, and C gene segments, and their selection and rearrangement from germ line genes also parallels immunoglobulin heavy chain rearrangement. Thus the generation of diversity is the result of the combination of multiple gene segments and junctional diversity. However, unlike immunoglobulins, the TCR genes do not undergo gene conversion or somatic mutations.

T-Lymphocyte Subsets

Mature T lymphocytes can be further divided into two distinct populations on the basis of their expression of either the CD4 or CD8 molecule.[258] The expression of these surface molecules is directly correlated with the specificity of the T cell (see later discussion). The expression of either CD4 or CD8 also correlates with T-cell function. Thus those cells that express CD8 are typically cytotoxic effector cells (cytotoxic T lymphocytes [CTLs]), whereas those that express CD4 are typically helper cells that produce cytokines that enhance antibody and cell-mediated immune responses. Whereas the T lymphocytes in the periphery express either CD4 or CD8, cortical thymocytes (immature T cells in the thymus) express both antigens. During maturation in the thymus, these cells convert to either $CD4^+$ or $CD8^+$ cells or they are eliminated (Fig. 1.11). Within the cortex of the thymus, thymocytes are exposed to thymic epithelial cells that present self peptides in the context of major histocompatibility complex (MHC) molecules (see later discussion). The thymic selection process involves both positive and negative selection. During positive selection, thymocytes with TCRs that bind self peptide–MHC complexes with low avidity (weakly) are stimulated to survive. This ensures that the developing thymocyte has a functional TCR. During negative selection, thymocytes that bind self peptide–MHC complexes with high avidity (strongly) are deleted. The end result is that mature T lymphocytes leave the thymus with functional TCRs capable of binding self MHC molecules without autoreactivity.

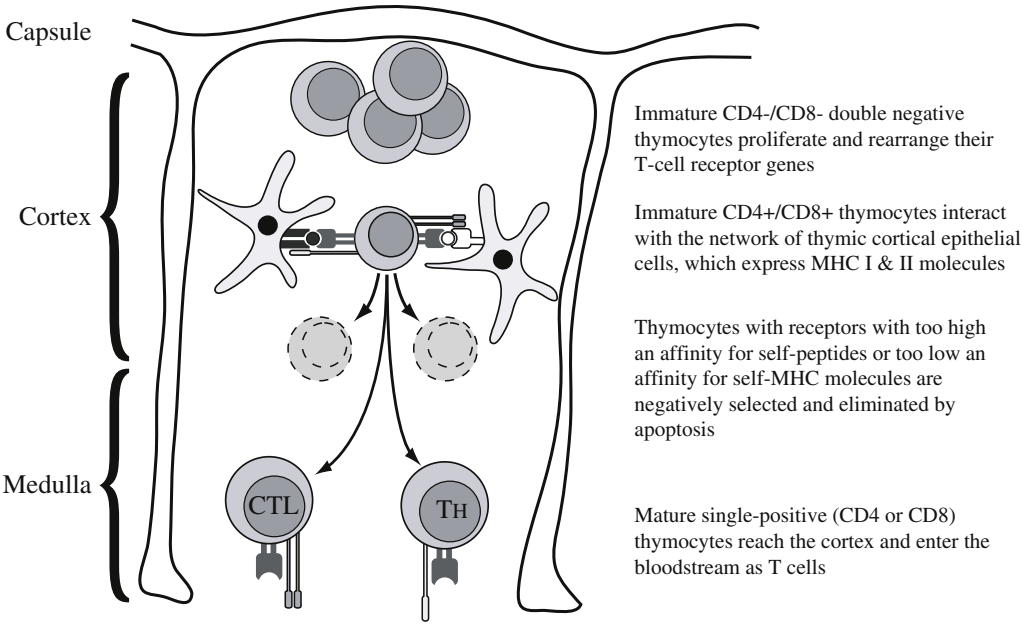

FIG. **1.11** T-cell maturation and selection in the thymus.

Major Histocompatibility Complex Molecules and Antigen Presentation

Unlike B cells and antibodies, which recognize antigens in solution or on cell surfaces in their native conformation, T cells only recognize processed antigen bound by antigen-presenting molecules on the surface of antigen-presenting cells (APCs). These antigen-presenting molecules are glycoproteins encoded by genes within a large gene cluster called the *major histocompatibility complex* (MHC), which also happens to be the most polymorphic gene region known in vertebrates. The MHC was originally defined in terms of its role in allograft rejection. Following the rejection of a primary allograft, antibodies that reacted with the allograft could be found in the recipient's sera. These antibodies could be used to identify or type tissues to determine the suitability of a donor for transplantation. Genetic analysis of the MHC region demonstrated that there were a number of closely linked genes encoding several different, though related, molecules that were involved in allograft rejection. These closely related genes are collectively referred to as MHC class I (MHC I) genes and their products as MHC I molecules. Similar to the anti–donor MHC antibodies found in allograft recipients, it was also demonstrated that multiparous mares had antibodies in their sera as a result of the exposure to paternal MHC antigens on the fetus.[259,260] These sera provided the earliest means to serologically define MHC I haplotypes (the complement of MHC alleles in a given individual) in horses.[259] Equine MHC I haplotypes are designated using the equine leukocyte antigen (ELA) prefix, similar to the nomenclature used in humans and other species (i.e., "HLA" in humans). In addition to the serologically defined MHC I molecules, another group of molecules were identified within the MHC that were involved in the stimulation of mixed lymphocyte responses and the control of immune responsiveness. These MHC class II (MHC II) molecules are structurally and functionally distinct from the MHC I molecules, but both are involved in T-cell recognition of antigen.

MHC I molecules are cell surface glycoproteins consisting of two noncovalently associated proteins, an MHC-encoded α chain (consisting of α1, α2, α3, transmembrane, and cytoplasmic domains) and β_2-microglobulin, a protein encoded outside of the MHC that stabilizes the molecule on the cell surface (Fig. 1.12). The α1 and α2 domains are variable regions encoded by polymorphic genes and form the antigen binding cleft of the molecule. MHC I molecules are expressed on the surface of most nucleated cells, with the highest level of expression on lymphoid cells and lower expression on fibroblasts, muscle cells, and neural cells. MHC I molecules are not detectable on early embryonal cells, placental cells, and some carcinomas. The level of expression of MHC I molecules can be modified by treatment with cytokines or infection with viruses, including equine herpesvirus–1 (EHV-1), which downregulates expression.[261] Interferons and TNF-α augment MHC I expression. This augmented expression is the result of increased production of MHC I mRNA, and the regulatory region of the MHC I genes has been shown to contain interferon and TNF-α–responsive elements that control the transcriptional activity of these genes.

The MHC I region of most species contains a large number of polymorphic genes within several different loci (locations on the chromosome). In humans there are three MHC I loci (A, B, and C) with 2000 to 3000 expressed alleles identified for each locus (Immuno Polymorphism Database; http://www.ebi.ac.uk/ipd). Comparably very few MHC I gene sequences are known in the horse. A recent BLAST query (February 2016) returned approximately 100 equine MHC I sequences, and fewer have been published (approximately 60).[262-264] Although seven loci were identified in MHC I homozygous horses (ELA-A3 haplotype),[264] a more recent study in horses representing 10 different haplotypes revealed that the number of loci differs by haplotype, with 4 confirmed and 3 provisional loci identified.[263] MHC I typing methods in horses include serologic typing,[259] reverse transcriptase polymerase chain reaction (RT-PCR) cloning and sequencing to identify

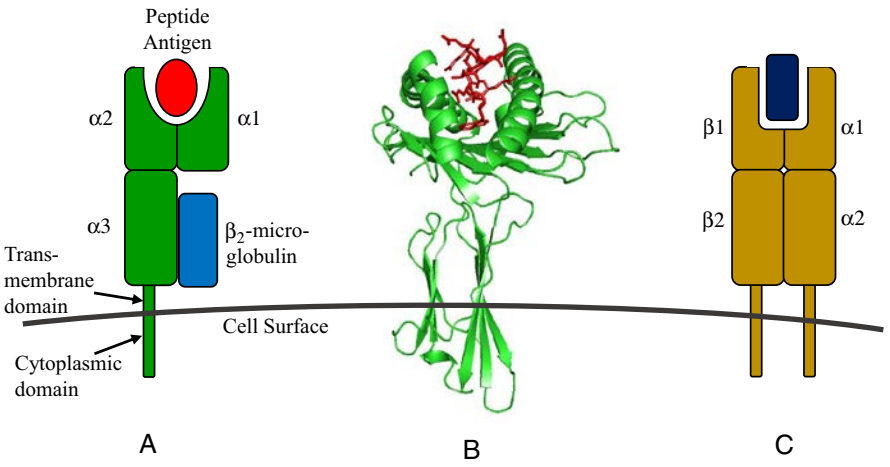

FIG. **1.12** MHC class I and II molecules . (A) Schematic depiction of an MHC molecule expressed on the cell surface, with peptide bound in the cleft formed by the α1 and α2 domains. (B) Molecular model of equine MHC class I molecule 7 to 6 (Eqca-N*00602) presenting the Rev-QW11 peptide, a known CTL epitope within the Rev protein of equine infectious anemia virus. β2 microglobulin not shown. (C) Schematic diagram of an MHC class II molecule expressed on the cell surface, with peptide bound in the cleft formed by the α1 and β1 domains.

specific expressed alleles,[263,265] and DNA microarray.[63] Most recently, MHC haplotypes have been identified using microsatellite markers.[266,267]

MHC I polymorphism is primarily localized in the α_1 and α_2 domains, with the α_3 domain being more conserved. The polymorphism of these two domains is related to their role in presenting antigen to T cells. The physiologic role of MHC I molecules was defined when it was discovered that CTL lysis of virus-infected cells was restricted to target cells expressing the same MHC I molecules as the CTL.[268] This observation led to the realization that T cells recognized the combination of self-MHC and foreign antigen. Furthermore, those T cells that recognized MHC I antigens invariably expressed the CD8 coreceptor. The nature of the association between MHC I and the foreign antigen remained unclear until x-ray crystallographic studies of human MHC I antigen were performed.[269] In addition to revealing the structural organization of the domains of the MHC I antigen, the image also revealed a cleft that lay between the α_1 and α_2 domains. It was proposed that this cleft binds the processed peptide epitopes for presentation to the T-cell receptor. Indeed, the cleft of the crystalized protein used for the x-ray diffraction studies was found to contain a contaminating peptide.[269] Other experiments showed that the incubation of cells with purified viral peptides resulted in the lysis of the cells by virus-specific MHC I–restricted CTL.[270] It is now known that the endogenous processing of viral antigens leads to the association of the viral peptides with MHC I antigens on the surface of the infected cell, and this is recognized by the TCR in association with CD8. How these viral antigens get to the cell surface is the result of a peptide transport system whose function is to transport processed peptides from the cytosol to the endoplasmic reticulum (ER). Foreign and other cytosolic proteins are marked for degradation by covalent linkage to a small polypeptide called ubiquitin. These ubiquinated proteins are targeted for entry into a proteasome, a cylindrical complex that degrades the protein into small peptides. These are then transported into the ER by the transporter associated with antigen processing (TAP). Once in the ER, peptides are handed off to newly formed MHC I molecules and stabilize a trimolecular complex with β2 microglobulin. This complex is then transported to the cell surface, where antigen presentation occurs. Because this is a normal cellular process for eliminating degraded proteins from the cell it is not surprising that MHC I molecules are normally loaded with these self-peptides. Indeed it is this encounter with MHC I loaded with self-peptides in the thymus that is responsible for the deletion of autoreactive clones during T-cell ontogeny. This unique peptide-binding characteristic of MHC I molecules has led to their use as immunologic reagents (tetramers) for the identification and enumeration of antigen-specific $CD8^+$ T cells.[271] In the horse, tetramers based on the equine MHC I molecule 7-6 (Eqca-N*00602), associated with the ELA-A1 haplotype, have been used to identify and quantify equine infectious anemia virus (EIAV)-specific cytotoxic T cells.[272,273] Similar approaches are in development to analyze CTL responses against other viruses and provide important information on the role these cells play in protection from these infections.

Peptides that bind in the MHC I binding cleft are typically 8 to 9 amino acids (aa) in length. Interestingly, three EIAV-specific CTL epitope peptides that bind to two closely related equine MHC I molecules associated with ELA-A1 haplotype are 11 to 12 aa long.[274] The two MHC I molecules, 7-6 (Eqca-N*00602) and 141 (Eqca-N*00601), differ in only one aa in the α2 domain, yet present peptides to CTL differently, resulting in differential CTL recognition. Molecular modeling suggests that these peptides bind in a bulged conformation and provides an explanation for the experimentally observed differential recognition by CTL.[274] Recently an independent group solved the crystal structures of these same MHC I molecules with the bound peptides.[275] This work confirmed the previous molecular modeling conclusions[274] and has provided the first crystal structures of equine MHC I–peptide complexes. In addition, a shorter peptide (9 aa) with similar anchor residues bound the clefts of these molecules in a more typical conformation.[275] Despite MHC I binding, this 9 mer peptide may not

be a CTL epitope. The original study confirmed experimentally that although 1 of the 12 mer peptides bound the Eqca-N*00601 molecule, there was no CTL recognition.[274] Recent work with the Eqca-1*00101 MHC I molecule (associated with the ELA-A3 haplotype) has further defined equine MHC I peptide binding motifs and has demonstrated a narrow peptide binding repertoire.[276] Moreover, $CD8^+$ T-cell recognition of a large panel of EHV-1 peptides that bound this molecule was restricted to a single 9 mer peptide. It will be of interest to determine whether any other equine MHC I molecules share the limited peptide binding and TCR epitope recognition properties of Eqca-1*00101, as this would have implications for the control of intracellular infections in horses with some MHC I haplotypes.

MHC II molecules are heterodimeric, transmembrane glycoproteins composed of an α chain and a β chain (see Fig. 1.12). A third chain, the invariant chain, has been shown to be associated with the MHC II molecule during assembly in the endoplasmic reticulum but is not expressed on the cell surface. Both the α and β polypeptides are encoded within the MHC region. Both polypeptides possess cytoplasmic, transmembrane, and two extracellular domains (α1, α2 and β1, β2). The α1 and β1 domains comprise the peptide binding cleft. The α chain has a single disulfide bond located in its membrane proximal (α2) domain, and the β chain has a disulfide bond in both of its extracellular domains. Structurally, the MHC II molecules resemble MHC I antigens and are also members of the immunoglobulin superfamily, a group of proteins that have structural similarities to immunoglobulin molecules, including conserved domains and variable antigen binding domains.

The MHC II genes are functionally and structurally distinct from the MHC I genes. Unlike MHC I molecules, MHC II molecules are restricted in their expression to certain cells of the immune system: B lymphocytes, dendritic cells, macrophages, and activated T lymphocytes of some species. Other cells may also express MHC II molecules after treatment with various cytokines.[277-279] Interferon-γ, TNF-α, 1,25-dihydroxyvitamin-D3, and granulocyte-macrophage colony-stimulating factor can induce MHC II molecule expression on monocytes and macrophages and other cells. IL-4 enhances MHC II expression on B cells. A number of agents have been shown to downregulate MHC II expression, including glucocorticoids, prostaglandins, and α-fetoprotein. Similar to MHC I, MHC II expression is regulated at the transcriptional level. The regulatory regions are quite different, however, and this probably accounts for the differences in tissue distribution for these two MHC molecules.

Like the MHC I genes, the MHC II region contains polymorphic genes encoding multiple MHC II molecules. There are loci for genes encoding the α chain (including DRA and DQA loci) and β chain (including DRB and DQB loci), with multiple alleles at most loci. In most species there is limited diversity in the α chain genes, with the β chain genes being the most polymorphic. For example, only two expressed alleles occur at a single DRA locus in humans, whereas there are multiple DRB loci containing over 1400 expressed alleles. Although the horse also has a single DRA locus, horses have greater DRA allelic diversity than any other species.[280-282] In addition, there are multiple DQA, DRB, and DQB loci, each with multiple alleles contributing to the level of MHC II diversity in equids.[282-285] Because of the critical role MHC II molecules play in antigen presentation to helper T cells (see later discussion), susceptibility to some diseases is associated with particular MHC II haplotypes. For example, analysis of microsatellite markers and direct sequencing has demonstrated that the MHC II haplotype is a risk factor for insect bite hypersensitivity in defined populations of horses.[286]

Whereas intracellular antigens are processed via the endogenous pathway and are associated with MHC I molecules that present them to $CD8^+$ cytotoxic T cells, extracellular antigens are processed via the exogenous pathway and are associated with MHC II molecules that present them to $CD4^+$ helper T cells (Fig. 1.13). Here endocytosed antigens, such as that phagocytosed by a macrophage, are degraded into peptide fragments within a phagolysosome compartment. Processed peptides then bind within the peptide binding cleft at the junction of the α_1 and β_1 domains of the MHC II molecule. This association of the epitope with the MHC II molecule protects it from further degradation. The MHC II molecule is then transported and expressed on the cell surface for subsequent presentation to the helper T cell. The immune system contains a distinct group of professional antigen-presenting cells called dendritic cells that are specialized to capture antigens and initiate T-cell immunity and move freely from epithelial surfaces to adjoining lymph nodes. Dendritic cells can be found in a variety of locations in the body and are often named based on their microscopic appearance. Thus interdigitating cells found in lymph nodes, veiled cells in lymphatics, and Langerhans cells in skin are all dendritic cells. Immature dendritic cells take up antigens by micropinocytosis using their extensive cellular processes or by receptor-mediated phagocytosis. This results in activation and migration to a regional lymph node where antigen presentation to T lymphocytes occurs. Dendritic cells in the spleen capture blood-borne antigens and similarly become activated, presenting antigens to T cells in the periarteriolar lymphatic sheaths within white pulp. Mature dendritic cells have high levels of MHC II expression on their surface. Although no longer phagocytic, they are extremely efficient stimulators of both MHC I– and MHC II–restricted T-cell responses in the draining lymph node or other secondary lymphatic tissue (Fig. 1.14).

In a complex antigen, certain epitopes are particularly effective at stimulating an antibody response. These *immunodominant* epitopes are often located at exposed areas of the antigen such as in polypeptide loops. These types of structures are often quite mobile and may allow for easier access to the antibody binding site. T-cell epitopes have been shown to possess a particular structural characteristic in that they involve the formation of amphipathic helices. However, structure alone does not determine the immunogenicity of a particular antigen, and T-cell recognition of foreign antigen requires more than just the expression of the processed antigen on the surface of the antigen-presenting cell. Additional signals provided by the antigen-presenting cell are also required for the activation of the T lymphocytes. Among these are signals provided by other accessory molecules found on the antigen presenting cell and various cytokines present in the extracellular environment.

Signaling through Antigen-Specific Receptors

The binding of a specific antigen by either the TCR of a T cell or the BCR of a B cell results in an intracellular signaling

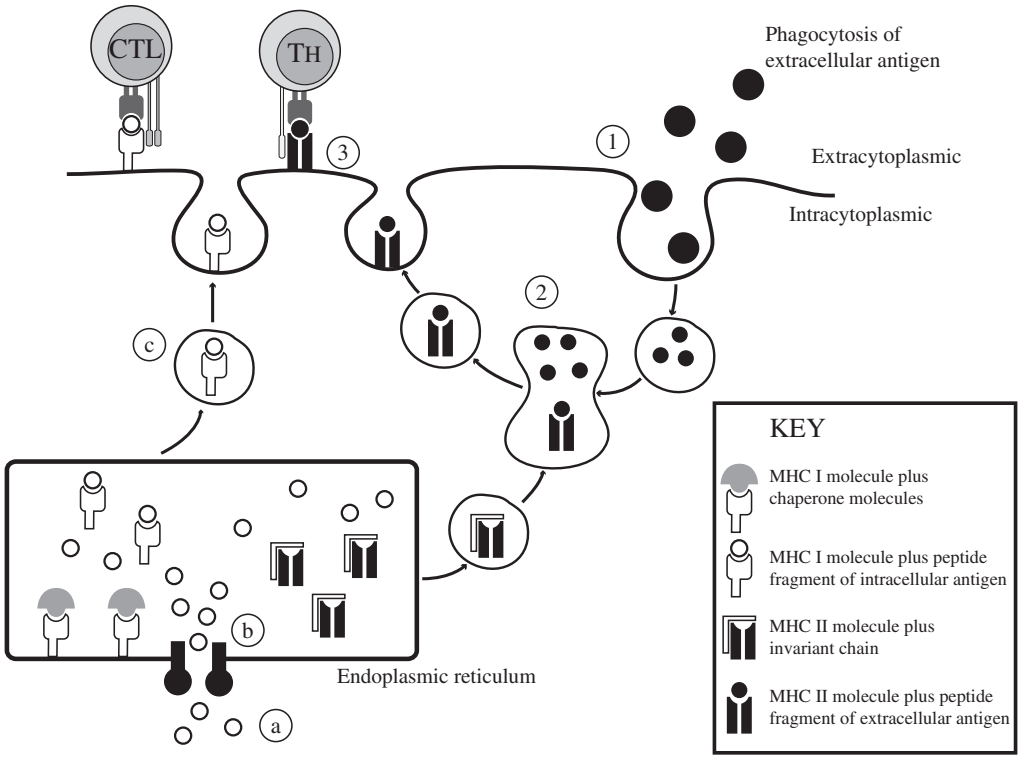

FIG. **1.13** Antigen processing pathways. This figure depicts MHC I antigen presentation to the left of the diagram, and MHC II antigen presentation to the right. In MHC I antigen presentation (a) peptides generated by degradation of proteins in the cytoplasm are transported into the endoplasmic reticulum by TAP (b). In this location, MHC I molecules anchored by calnexin bind the antigenic peptides, which allows release of the MHC I–peptide complex and transport through the Golgi to the cell surface (c). In MHC II antigen presentation, antigen is taken up by phagocytosis (1) into the endosome compartment that fuses with lysosomes for degradation. Vesicles containing MHC II molecules produced in the endoplasmic reticulum fuse with the endosomes (2), and the MHC II molecules bind with the degraded peptides for transport to the cell surface (3). The MHC II molecules are prevented from binding the endogenous peptides in the endoplasmic reticulum by the presence of an invariant chain, which is lost in the acidic endosomal environment.

cascade that eventually leads to the production of various cytokines and the proliferation of the stimulated cell. T-cell recognition of antigen involves the engagement of a TCR-CD4 or TCR-CD8 complex with processed peptide bound by an MHC II or MHC I molecule (Fig. 1.15). The engagement of the TCR with the appropriate MHC-peptide complex also results in the binding of CD4 (or CD8) to a dedicated region of the MHC II (or MHC I). In doing so the lck protein tyrosine kinase associated with the cytoplasmic tail of CD4 (or CD8) phosphorylates the cytoplasmic regions of the CD3 proteins (associated with the TCR) in regions known as immunoreceptor tyrosine–based activation motifs (ITAM). A series of subsequent phosphorylation events ultimately leads to the release of stored Ca from the endoplasmic reticulum. The increase in intracellular Ca levels and the activation of protein kinase C leads to the phosphorylation of various transcriptional factors that regulate the expression of the genes for various cytokines and/or their receptors. The process is subsequently downregulated by various phosphatases that are recruited to and subsequently dephosphorylate the CD3 ITAMs. A similar process occurs in B cells when their surface immunoglobulin receptor is cross-linked on binding to specific antigen. The reader is referred elsewhere for additional information regarding intracellular signaling in lymphocytes.[207,209]

Costimulatory Signals

In addition to the interaction of TCR-CD3, CD4/CD8, and MHC-peptide antigen complexes, other cell surface molecules are involved in signaling pathways. Of greatest importance is the interaction of CD28 on the T cell with B7 (CD80/86) on the antigen-presenting cell (APC). In the absence of CD28-CD80/86 costimulation, T cells are rendered functionally inactive or anergic. On restimulation, anergic T cells fail to proliferate or to produce cytokines such as IL-2 (a cytokine required for T-cell proliferation). The induction of anergy can be prevented by either the addition of exogenous IL-2 or, more important, by interaction of the CD28 cell surface antigen with its ligands (CD80/86). Stimulation of CD28 appears to be necessary for subsequent intracellular signaling events following TCR stimulation as CD28 cross-linking enhances various biochemical events triggered by TCR-mediated signaling. Other molecules, including the TNF-receptor family member CD40, regulate T-cell growth and cell death. The engagement of CD40 on the T cell with its ligand, CD40L (on APC), promotes cell survival and cell cycle progression. The binding of other members of this family, notably TNF-α, to their receptors on activated T cells typically results in the activation of a biochemical cascade of caspases that leads to apoptosis (programmed cell death). The cytocidal activity of these receptors is the result of

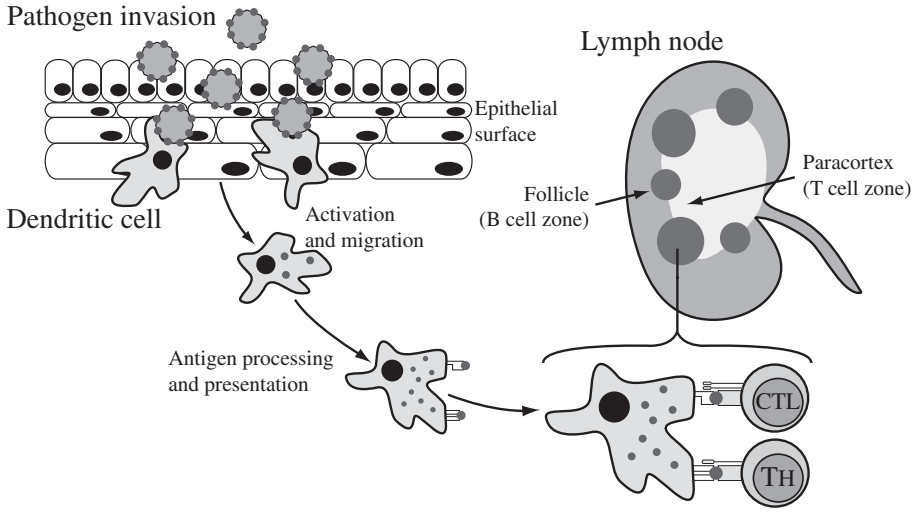

FIG. **1.14** The role of professional antigen-presenting cells (APCs). In this figure pathogen invasion is followed by antigen uptake by a dendritic cell, the most potent of the APC family. The dendritic cells become activated and migrate to a local lymph node where they are extremely effective at stimulating naive T cells in the paracortex, including both T-helper cells and CTLs.

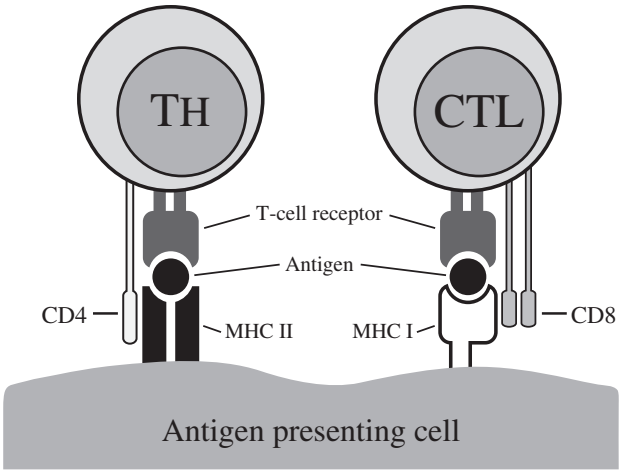

FIG. **1.15** MHC class I and class II restricted T cell recognition: the role of T-cell CD4 and CD8 molecules. T cells use their TCRs to recognize processed antigen presented in combination with either MHC I or MHC II molecules. T cells exclusively express either CD4 (T-helper cells) or CD8 (cytotoxic T lymphocytes [CTLs]). The CD4 molecule is required for interaction with MHC II molecules, and CD8 is required for MHC I interaction. As a result, helper T cells only recognize antigen presented by MHC II molecules, and CTLs only recognize antigen presented by MHC I molecules.

their intracytoplasmic portion of the receptor containing death effector domains. By contrast, CD40 lacks the intracellular death domains and instead has amino acid motifs that promote activation. In addition to their role in promoting T-cell activation and growth, both the CD28-CD80/86 and TNF-receptor pathways may also play a dominant role in the induction of specific T-helper cell subsets (see later discussion).

Cytokines and Cell-Mediated Immunity

As indicated previously, cytokines are hormone-like proteins that mediate a variety of cellular responses. Over 100 different cytokines and chemokines are known, and the reader is referred elsewhere for comprehensive lists of their designations and functions.[207,209] Table 1.5 provides an abbreviated list of cytokines with critical roles in innate and adaptive

TABLE **1.5 Selected Cytokines**

Cytokine	Biologic Activities and Source
IL-1	Multiple proinflammatory effects. Produced by macrophages. See Table 1.3.
TNF-α	Multiple proinflammatory effects. Produced by macrophages.
IL-2	Stimulates growth and proliferation of T cells. Produced by activated $CD4^+$ T cells, T_H1 cells, and some $CD8^+$ cells.
IL-4	Activates B cells and isotype switching to IgE and IgA. Produced by T_H2 cells. Promotes differentiation of T_H2 cells.
IL-5	Activates B cells and isotype switching to IgA. Recruits and stimulates eosinophil growth. Produced by T_H2 cells.
IL-6	Proinflammatory. Induces fever and the production of acute phase proteins by hepatocytes. Produced by macrophages. Also activates B cells and stimulates growth in stromal cells, fibroblasts, and a variety of other cell types.
IL-8	Now called CXCL8. A chemokine that is chemotactic for neutrophils. Produced by macrophages, endothelial cells, and various other cells.
IL-10	Inhibits the production of IL-12 by dendritic cells and IFN-γ by T_H1 cells. Suppresses macrophages and T-cell function. Produced by T_H2 cells and T_{regs}.
TGF-β	Produced by T_{regs} and other cells. Promotes differentiation of T_{regs}. Inhibits cell growth. Antiinflammatory. Inhibits T-cell proliferation and function. Promotes tissue repair. Induces isotype switching in B cells to IgA.
IL-12	Stimulates T_H1 differentiation. Augments NK cell and CTL function. Produced by dendritic cells and macrophages.
IFN-γ	Enhances phagocytosis and killing by macrophages. Produced by T_H1 cells. Enhances MHC expression and antigen presentation by APCs. Suppresses T_H2 responses. Induces isotype switching in B cells to IgG.
IL-13	Produced by T_H2 cells. Activates B cells and isotype switching to IgE. Inhibits T_H1 cells.
IL-17	Proinflammatory. Produced by T_H17 cells. Recruits neutrophils via induction of cytokine and chemokine production by other leukocytes, epithelia, endothelia, and fibroblasts.
IL-21	Produced by T_H17 cells and amplifies T_H17 responses. Promotes B-cell and T-cell responses.
IL-22	Proinflammatory. Produced by T_H17 cells. Induces chemokine production by epithelia and promotes epithelial barrier function. Induces production of defensins.
IL-23	Promotes T_H17 differentiation. Produced by dendritic cells and macrophages.

immune responses. A significant number of equine cytokines have been cloned and sequenced, and specific protocols are available to measure their expression. Numerous studies confirming the role of cytokines in equine sepsis, joint disease, airway diseases, and a variety of viral and bacterial diseases emphasize the similarities between equine and human immune systems.[206] As such, the potential for manipulating these responses using recombinant cytokines or anticytokine reagents is as applicable to equine medicine as it is for human medicine. The reader is referred to the U.S. Veterinary Immune Reagent Network (http://www.umass.edu/vetimm/equine) for information and links regarding cloned equine cytokines and other equine immune reagents currently available or in development.

Cell-mediated immunity is the component of adaptive immune defense mediated by T lymphocytes. Helper T cells are critical in these responses because depending on the cytokines they produce, they can activate macrophages to kill phagocytosed microbes, promote $CD8^+$ CTL responses, provide help for B cells in the production of antibodies, and, conversely, inhibit any of these responses. Helper T cells can be divided into distinct effector subsets based on the cytokines they produce. These subsets include T_H1, T_H2, and T_H17 cells, as well as a regulatory T-cell subset (T_{reg}), which has suppressive functions (see Fig. 1.7).

T_H1 $CD4^+$ Effector T Cells

The predominant cytokine produced by T_H1 cells is IFN-γ, but they also secrete IL-2 and TNF-α.[287] Although classically considered a T_H1 cytokine, IL-2 is produced transiently by $CD4^+$ T cells in general, within hours after their initial interaction with the APC during recognition of antigen and costimulators. IL-2 supports the stimulation, proliferation, and differentiation of all antigen-activated T cells very early in the immune response. Thus it is IFN-γ production that best characterizes T_H1 cells. The primary function of T_H1 cells is to activate macrophages to phagocytose and kill invading pathogens and to support the activation of CTL responses. Thus T_H1 cells are critical for controlling intracellular infections. In addition to its primary effect on activating macrophages to destroy microbes, IFN-γ produced by T_H1 cells enhances MHC antigen presentation and costimulation by APC, promotes activation of $CD8^+$ CTL, promotes further differentiation of T_H1 cells, inhibits the differentiation of T_H2 and T_H17 cells, and acts on B cells to promote isotype switching to IgG subclasses while it inhibits switching to T_H2-type isotypes such as IgE (Fig. 1.16). During antigen activation, $CD4^+$ T cells differentiate into T_H1 cells primarily during intracellular infections under the influence of IL-12 produced by dendritic cells and macrophages, as well as IFN-γ produced by other T_H1 cells and by NK cells.

T_H2 $CD4^+$ Effector T Cells

In contrast to T_H1 cells, T_H2 cells promote phagocyte-independent immune responses, including those mediated by eosinophils and mast cells, and they provide help to B cells for the induction of antibody responses. These responses are important for the elimination of extracellular infections, including parasitic infections and microbes infecting mucosal tissues. Detrimentally, T_H2 responses are involved in the development of allergic diseases. Antigen-activated $CD4^+$ T cells differentiate into T_H2 cells in the absence of IL-12 and IFN-γ, under the influence of IL-4 produced by other T_H2 cells, and perhaps by mast cells or even the $CD4^+$ T cell itself during initial activation. Regardless, T_H2 cells are best known

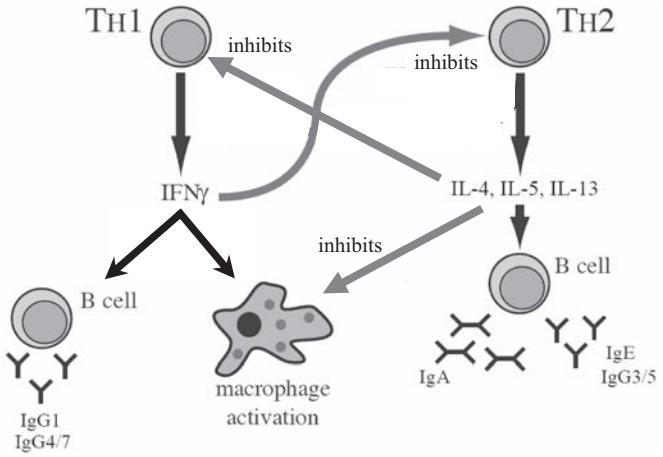

FIG. **1.16** T_H1 and T_H2 regulation. T_H1 lymphocytes provide help for macrophage activation, cytolytic activity, and production of a subset of IgG subclasses. T_H2 lymphocytes promote antibody responses, including IgA, IgE, and the remainder of the IgG subclasses. This is mediated by production of cytokines, which have a regulatory effect on each other.

for their production of IL-4, IL-5, and IL-13.[287] The combined effects of these cytokines include stimulation of isotype switching in B cells to produce IgE (IL-4 and IL-13), IgA (IL-4 and IL-5), and some IgG subclasses; further differentiation of T_H2 cells and suppression of T_H1 development (IL-4); recruitment of eosinophils and increased production of mucus in the gastrointestinal tract and airways (IL-4 and IL-13); and suppression of IFN-γ activation of macrophages and stimulation of alternative activation of macrophages with an antiinflammatory phenotype that promotes collagen synthesis and fibrosis (IL-4 and IL-13).

T-Helper Paradigms

The role of helper T-cell subsets and the cytokines they produce in promoting cell-mediated immune responses can best be illustrated in two scenarios, the first involving the induction of a T_H1 immune response in response to viral infection, and the second an allergic response to biting insect salivary antigens. In the first scenario, viral antigen present at the site of an ongoing infection in the lungs is processed by resident dendritic cells via the endogenous pathway (cytosolic viral proteins associated with intracellular infection), as well as the exogenous pathway (endocytosed virus and/or viral particles released by dead and dying infected cells). The exogenously processed epitope is presented on the surface of the dendritic cell in the context of an MHC II molecule to a naive $CD4^+$ T cell in a regional lymph node. The APC produces IL-12, which induces NK cells attracted to the site of the infection to produce IFN-γ that, along with antigen presentation and production of IL-12 by the APC, activates the T cell and drives it toward a T_H1 phenotype. Meanwhile, naive $CD8^+$ T cells encounter endogenously processed viral antigen on the surface of the APC in the context of MHC I molecules and become activated. Newly activated $CD4^+$ helper T cells (including T_H1 cells) produce IL-2, and differentiated T_H1 cells produce IFN-γ. The IL-2 drives the clonal proliferation of the activated $CD8^+$ T cells, and the IFN-γ stimulates $CD8^+$ T cells to become activated CTLs that produce additional IFN-γ. These activated CTLs lyse virus-infected target cells through the production of perforin and granzyme, which lead to apoptosis of the infected target cell via the activation of cytoplasmic caspases. In addition, IFN-γ secreted by T_H1 cells enhances phagocytosis and destruction of microbial invaders by macrophages. Meanwhile, virus-specific B cells have also encountered antigen and, within the paracortical areas of the regional lymph node, interact with the T_H1 cells by presenting antigen via MHC II molecules. The B cell and T_H1 cell also interact via costimulatory signals through CD28-CD80/86, as well as CD40-CD40L. This further stimulates the T_H1 cell to secrete IFN-γ, inducing the B cell to undergo isotype switching to produce IgG. Within germinal centers of lymphoid follicles in the lymph node cortex, activated B cells in the presence of antigen undergo somatic hypermutation of their BCR variable region genes as part of the affinity maturation process. This results in selection and expansion of B-cell clones that produce antibodies with the highest affinity for the viral antigen. Finally, these B cells differentiate into high-affinity IgG-secreting plasma cells. This combination of high-affinity IgG antibodies and $CD8^+$ CTLs serves to eliminate the virus.

In the second scenario, the introduction of salivary antigens into the skin by the bites of blood-feeding *Culicoides* midges results in the exogenous processing of antigen by dendritic cells. However, in the absence of IL-12 and interferon-γ, and likely in the presence of IL-4, there is the induction of T_H2 cells that produce additional IL-4, IL-5, and IL-13. These cytokines inhibit T_H1 responses and cause antigen-specific B cells to isotype switch to IgE antibodies that bind to mast cells. Subsequent exposure to antigen causes degranulation of these mast cells as the result of antigen cross-linking surface-bound IgE. Mast cell release of vasoactive mediators such as histamine, lipid mediators such as PGE_2, and additional production of IL-4, which exacerbates the response and leads to the accumulation of eosinophils, further contributes to the inflammatory process. The end result in some horses is a seasonally recurrent allergic dermatitis known as insect bite hypersensitivity (IBH; see Hypersensitivity and Autoimmunity later in this chapter). Strong evidence for this paradigm as it relates to susceptibility to IBH is provided by a recent study in IBH-affected and unaffected ponies.[288] Following intradermal injection of *Culicoides* antigen, IL-4 expression was increased in skin biopsies from IBH-affected ponies, whereas IFN-γ expression increased in those from unaffected ponies. Moreover, antigen-specific

stimulation of peripheral blood CD4+ T cells demonstrated a higher percentage of IFN-γ producing CD4+ T cells in the unaffected ponies. Finally, the serum of all ponies contained similar levels of antigen-specific antibodies, but the affected ponies had higher titers of antigen-specific IgE. These results indicate that IBH affected ponies are T_H2 biased with respect to *Culicoides* antigen and that a T_H1-biased response in unaffected ponies is protective against IBH.

In general, T_H1 and T_H2 responses along with their respective roles in immune protection and susceptibility to disease have been well described in horses.[206,208,249,289,290]

T_H17 CD4+ Effector T Cells

The function of T_H17 cells is to recruit neutrophils and induce inflammation, primarily to destroy extracellular bacteria and fungi. Therefore T_H17 cells represent an interaction between the adaptive and innate immune systems. Although T_H17 responses are important in resolving extracellular infections, they also significantly contribute to the pathogenesis of inflammatory diseases. As discussed earlier in the section on innate immunity, PAMPs associated with invading microbes bind pattern recognition receptors on macrophages and dendritic cells, leading to the production of proinflammatory cytokines. During such an infection, the combination of cytokines produced by dendritic cells, including IL-1, IL-6, and IL-23, along with IL-21, promotes the differentiation of activated CD4+ helper T cells to the T_H17 phenotype. Strong T_H1 and T_H2 responses tend to inhibit T_H17 differentiation. Once differentiated, T_H17 cells produce IL-17, an important contributor to the strong acute inflammatory reaction that sometimes occurs during T-cell responses (immune inflammation). IL-17 induces neutrophilic inflammation by stimulating the production of other cytokines and chemokines (such as TNF-α and CXCL8) that attract neutrophils to the site and also stimulates the production of antimicrobial substances (defensins) by numerous other tissue cell types. T_H17 cells also produce IL-22 and IL-21, which further promote inflammation, stimulate production of defensins, and improve barrier function in epithelial tissues. In humans, T_H17 cells have been implicated in a variety of autoimmune and inflammatory diseases, including rheumatoid arthritis, multiple sclerosis, and inflammatory bowel disease.[291,292] In horses, T_H17 cells may be involved in the pathogenesis of inflammatory bowel disease,[293] recurrent uveitis,[294] and recurrent airway obstruction.[295,296] Finally, peripheral blood mononuclear cells (PBMCs) and bronchoaveolar lavage cells from foals within the first 3 weeks of life increase expression of IL-17 mRNA in response to *Rhodococcus equi* stimulation in vitro.[297] Whether T_H17 cells play a role in the pathogenesis of *R. equi* pneumonia is currently speculative.

Regulatory T Cells

Regulatory T cells (T_{reg}) are a specialized subset of CD4+ T cells that play important roles in suppressing immune responses and maintaining self tolerance. T_{regs} express high levels of the IL-2 receptor α (CD25) and the transcription factor FoxP3, which is critical for their development and function. Thymic T_{regs} (also known as natural T_{regs}) are generated by self recognition in the thymus. Although these cells are directed against self antigens, they do not induce autoimmune responses. Rather, they inhibit other T cells recognizing self antigens in the same tissue. Peripheral T_{regs} (inducible T_{regs}) are generated from naive CD4+ T cells in peripheral secondary lymphoid tissues in response to particular antigens. These could be self or foreign antigens, and the antigen-specific peripheral T_{regs} inhibit other T cells recognizing the same antigen. Development of some T_{regs} requires TGF-β, and T_{regs} are dependent on IL-2 for survival and maintenance of function. T_{regs} suppress immune responses by producing inhibitory cytokines (TGF-β and IL-10), by reducing the ability of APCs to stimulate T cells (through CD80/86 interactions), by triggering apoptosis of effector T cells, and by disrupting metabolic pathways.[298] Although TGF-β has multiple effects on the immune system, its suppressive effects are due to its ability to inhibit the proliferation and function of T cells and inhibit the activation of macrophages. IL-10 has several suppressive properties, including inhibiting IL-12 production by dendritic cells and macrophages and reducing expression of MHC and costimulatory molecules on APCs.

A variety of human autoimmune diseases are associated with loss of T_{reg} function, including systemic lupus erythematosus, multiple sclerosis, type 1 diabetes, rheumatoid arthritis, psoriasis, and inflammatory bowel disease.[298] In the horse, reagents and methods are available for the identification of T_{regs}.[299-301] Equine T_{regs} produce IL-10 and TGF-β and demonstrate suppressive function[302] and may be involved in trophoblast T-cell tolerance during pregnancy in the mare.[300] In foals T_{regs} appear to have higher suppressive activity than those derived from adult horses.[303] Finally, failure of T_{reg} suppression could be involved in several inflammatory/allergic diseases in horses, including IBH,[304-306] inflammatory bowel disease,[293] and possibly recurrent airway obstruction.[307] During persistent infections, such as HIV-1 infection in humans, T_{regs} may promote persistence by suppressing virus-specific T cells.[308] Whether this occurs during persistent infections in horses is under investigation.

Lymphocyte Trafficking Pathways

Leukocyte trafficking has been reviewed previously, with a particular emphasis on the innate immune response and the migration of neutrophils into inflamed tissues. Lymphocytes involved in adaptive immune responses differ in their migration from most other cells, in that they recirculate instead of making one-way trips. Memory and naive T lymphocytes, with their different capacities for response to antigens, differ also in their migration pathways through the body. Two general pathways of lymphocyte recirculation have been demonstrated. Naive T lymphocytes take the most common route, which involves entry into the lymph node by extravasation from the high endothelial venule (HEV) and return to the peripheral circulation via the efferent lymphatic. The endothelial cells of the HEV have a distinctive appearance, have specialized receptors, and can support a lot of lymphocyte migration. This allows rapid repeated circulation of naive lymphocytes through lymph nodes where there is the greatest chance of exposure to their specific antigens. Memory lymphocytes, on the other hand, leave the bloodstream in peripheral vascular beds, particularly in inflamed tissues, and return to lymph nodes via afferent lymphatics. This leads to the exposure of primed memory lymphocytes to the most likely early sites of antigenic encounter and allows for an early response to recall antigens. Thus memory lymphocytes are most common in inflammatory lesions and in the epithelial surfaces of the lung and gut wall. Differing expression of the adhesion and homing molecules may play an important role in mediating these different migration pathways.

For lymphocytes to follow the maturation and migration pathway outlined previously, the first step is for the naive lymphocyte to get into a lymph node so that it can meet its antigen on a professional APC. To achieve this the T lymphocyte needs to exit in the HEV. The naive lymphocyte expresses L-selectin, and this can bind to the vascular addressins GlyCAM-1, CD34, and MAdCAM-1, which are expressed on HEVs and promote rolling similar to that mediated by P- and E-selectin when they bind to phagocytes. These molecules are expressed on a variety of tissues, but in HEVs they have specific patterns of glycosylation that make them bind L-selectin. These differences represent the key to the specificity of the migration of lymphocytes to HEVs. This weak interaction initiates the process of extravasation, promoted by locally bound chemokines (i.e., CXCL8), which increase the affinity of the lymphocyte integrins for their ligands.

Approximately 25% of lymphocytes passing through an HEV leave, and this could mean 1.4×10^4 cells in a single lymph node every second, and in the body 5×10^6 lymphocytes may extravasate through HEVs every second (human). The "sticking" process (rolling, activation, arrest) takes a few seconds, with transendothelial migration and passage through the HEV basement membrane occurring in about 10 minutes. Most T cells after leaving the blood travel through the lymph node uneventfully and leave via efferent lymphatics; however, in rare events a naive T cell recognizes its specific peptide/MHC complex and becomes activated, eventually leading to formation of effector and memory T cells. That process takes 4 to 5 days, and once activated the migration pathway of memory T cells differs considerably from naive cells. All activated T cells lose the L-selectin molecules that mediated homing to lymph nodes and increase the expression of other adhesion molecules. The homing of individual lymphocytes to specific sites is regulated by expression of specific adhesion molecules. Memory cells are specifically attracted to areas of inflammation because of the increased levels of adhesion receptor ligands expressed on vascular endothelium in these regions. This is typically a result of TNF-α production by regional macrophages encountering infections. Sometimes infections do not result in TNF-α production, but memory cells also migrate randomly throughout the body. When they encounter their antigen, they can produce cytokines such as TNF-α themselves, which in turn causes local endothelial cells to increase expression of E-selectins. This will subsequently recruit more effector and memory cells to the region.

Mucosal Immunity

The mucosal immune system comprises a series of distinct compartments within the immune system, which are adapted to immunologic responses in unique environments such as the gut, respiratory tract, or urogenital tract. The mucosal immune system is perhaps the most important component of the adaptive immune system, and the reader is referred elsewhere for an appropriately detailed description of its general features[209] and of its role in equine immunity in the context of respiratory disease.[309] The mucosal immune system may represent the original vertebrate immune system, and it certainly protects the largest vulnerable area of the mammalian body and comprises a very large proportion of the total lymphocyte populations and immunoglobulin pool.[310,311]

The mucosal immune system consists of organized and dispersed lymphoid tissues that are closely associated with mucosal epithelial surfaces, and mucosal immune responses generated in one location are transferred throughout the mucosal immune system by lymphocytes programmed to home to regional effector sites. The principal immunoglobulin produced by the mucosal immune system is secretory IgA, which, in humans, is the most abundant immunoglobulin class in the body. Secretory IgA has unique adaptations that promote transport out onto mucosal surfaces, where it protects the body from bacteria and viruses principally by immune exclusion, that is, by physically preventing attachment to mucosal surfaces. The importance of mucosal IgA has already been demonstrated in immunity to numerous equine diseases.[309] Secretory IgA (sIgA) is formed by dimerization of two IgA monomers, which are attached by means of disulfide bonds to a J chain also produced by the same plasma cell that secretes the IgA. This confers the advantage of increased valency to sIgA, which can bind up to four of its targets, increasing its agglutinating ability. Immunoglobulin A is relatively "noninflammatory" (i.e., does not fix complement as effectively as IgG1 or IgG4/7), consistent with a role in defense by immune exclusion. Similarly, although myeloid cells possess Fc receptors for IgA it is not clear that it functions as an efficient opsonin or promotes phagocytosis.

Coordination of the mucosal immune response depends on organized mucosal-associated lymphoid tissue (MALT), principal examples of which are the pharyngeal tonsils and the intestinal Peyer's patches. In the gastrointestinal tract MALT is distributed throughout the gut, but in the respiratory tract these tissues are only found in the nasopharynx and oropharynx. MALT consists of lymphoid follicles containing IgA-committed B cells, surrounded by interfollicular T-cell areas with APCs and HEVs, with an overlying follicle-associated epithelium (FAE). Naive lymphocytes enter the MALT by extravasation from the HEVs (there are no afferent lymphatics in MALT), and after antigen encounter in the MALT they leave through efferent lymphatics. The FAE is specialized for antigen sampling, by having reduced secretion of mucus, and through the presence of specialized antigen uptake cells termed *microfold* or *M cells*. These M cells are typically closely associated with underlying aggregates of lymphocytes, often within large basolateral membrane pockets, and play a critical role in mucosal immune surveillance. Adherent macromolecules or particles bound to the apical M-cell membrane undergo endocytosis or phagocytosis and are released at the pocket membrane, where antigen presentation is initiated by dendritic cells, resulting in activation of antigen-specific B cells (Fig. 1.17). Subsequent trafficking and recirculation of memory IgA–positive B cells to the other components of the mucosal immune system (respiratory tract, intestinal tract, etc.) are responsible for the dissemination of local mucosal IgA responses throughout what is termed the *common mucosal immune system*. After homing of these B cells to effector sites such as the lamina propria of the gut and respiratory tract, and extravasation into the lamina propria from HEVs, further antigen encounter and second signals from APCs and from helper T cells result in further differentiation into IgA-producing plasma cells. The short half-life of IgA-secreting plasma cells requires a constant generation of precursors in induction sites and flow to effector sites. Antigen sampling and presentation are not restricted to organized MALT, as throughout the mucosal surfaces dendritic cells play a key role in antigen uptake and presentation, subsequently migrating to local lymph nodes or MALT to initiate immune responses.

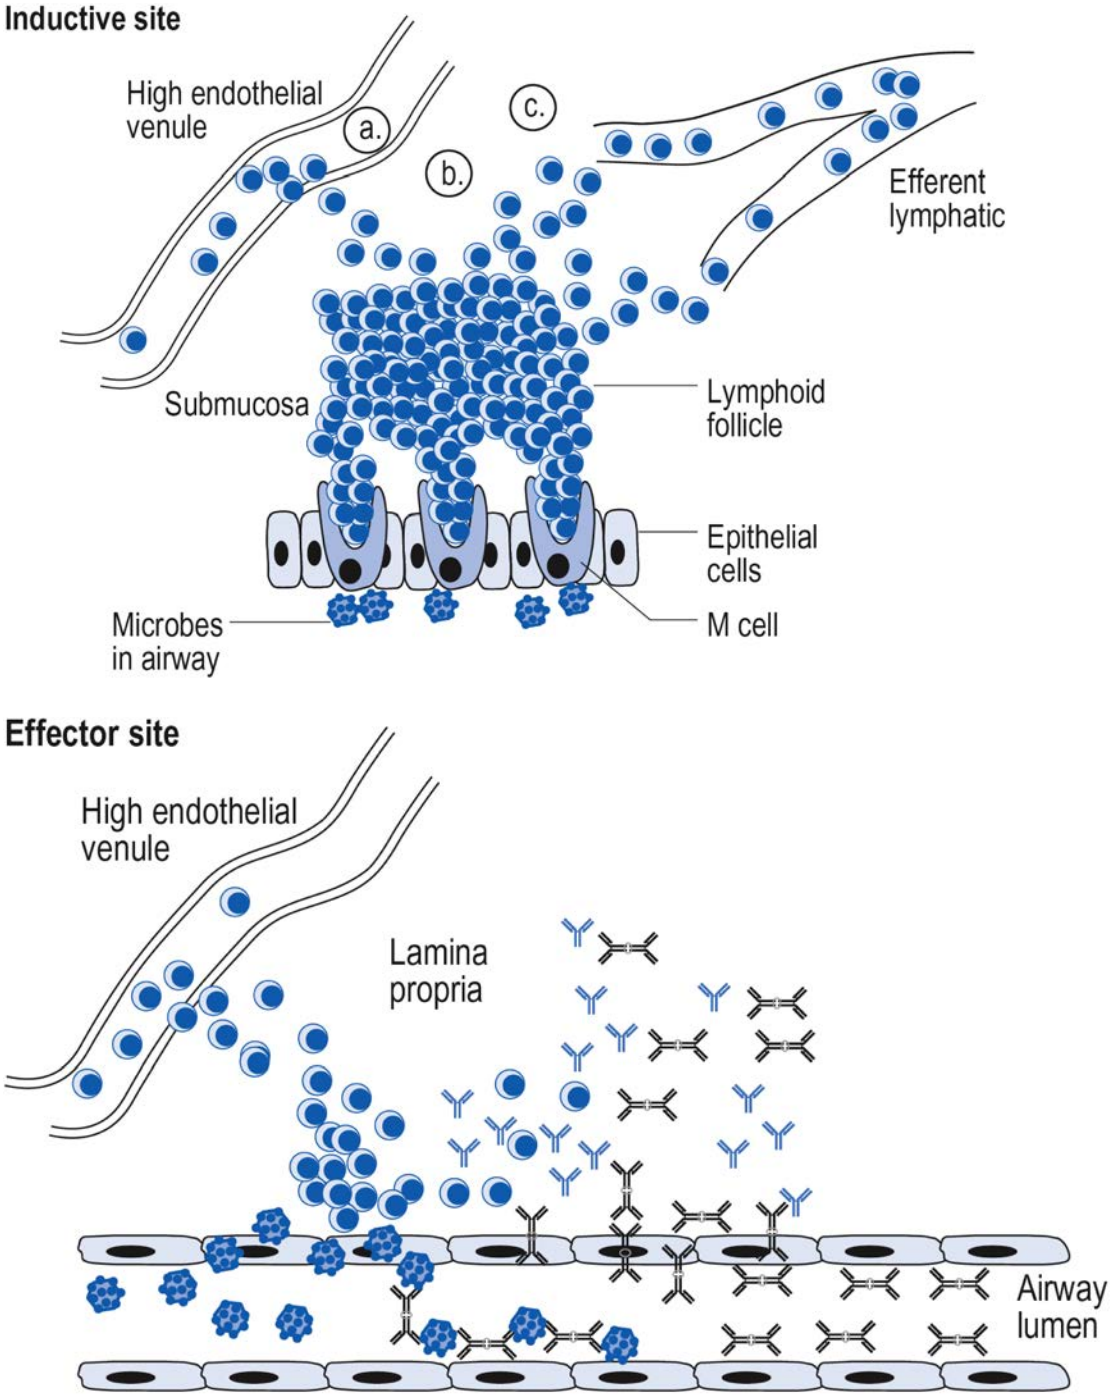

FIG. **1.17** Initiation of mucosal immune responses. Respiratory mucosal immune responses typically originate after antigenic encounter at inductive sites, which are the tonsils of the nasopharynx and oropharynx in the horse. Naive lymphocytes enter the inductive sites from high endothelial venules via the specialized cuboidal endothelium of those vessels in response to specific molecular signals. Antigens, such as microbes, are taken up by microfold or M cells, which are part of the highly specialized follicle-associated epithelium present at these sites. Antigenic material is transported across the M cell, and antigen presentation to B and T lymphocytes is accomplished by dendritic cells in the underlying tissues. The underlying lymphoid follicle is composed primarily of B lymphocytes, surrounded by areas of T lymphocytes. Antigen-specific B lymphocytes become committed primarily to IgA production at these sites, although some IgG-producing B lymphocytes are also generated. Subsequently, the primed lymphocyte populations exit the inductive site via efferent lymphatics, eventually reaching the blood circulation through the thoracic duct. These cells traffic to HEVs of effector sites throughout the respiratory epithelium and extravasate to make up the intraepithelial lymphocyte and lamina propria lymphocyte population and to give rise to lymphoid aggregates. Subsequent antigen encounter results in terminal differentiation to plasma cells, primarily IgA producing, although some IgG plasma cells are also formed. IgG is largely restricted to tissues, but secretory IgA is transported to the respiratory epithelial surface where it can agglutinate and neutralize infectious organisms. (From Lunn et al.,[309] with permission.)

After release of secretory IgA by plasma cells into the interstitium, it is bound by the polymeric Ig receptor on the abluminal surface of epithelial cells. Subsequently the sIgA is transported across the epithelial cell and released at the luminal surface together with the secretory component formed by cleavage of part of the polymeric Ig receptor. The secretory component can also be found in a free form in mucosal secretions. The secretory component confers resistance to proteolytic enzymes found in the respiratory and gastroenteric environment, some of which are secreted by pathogens, and prolongs the longevity of sIgA. During its transit through the epithelial cell sIgA can neutralize intracellular infections encountered in the endosomal compartments of cells. In addition, sIgA can bind antigens in the submucosa and transport or excrete them to the mucosa by this mechanism. The majority of the IgA in the mucosa is dimeric sIgA, whereas the bone-marrow–derived IgA in circulation is predominantly monomeric.

In the horse our understanding of the architecture and functions of the mucosal lymphoid system is best developed for respiratory lymphoid tissues.[309] Although lymphoid tissues are distributed throughout the respiratory tract, the greatest masses comprise the nodular lymphoid tissue of the nasopharynx and oropharynx, which can have an overlying lymphoepithelium specialized for antigen uptake and processing as in the case of tonsillar tissues. Additional nodular lymphoid tissues are typically present at sites where antigen-laden mucus and air currents converge throughout the trachea and bronchi and is called bronchus-associated lymphoid tissue. Tonsils represent the most complex mucosal nodular lymphoid tissues. Horses possess all of the various tonsillar tissues that are recognized in other species, and they are anatomically complex.[309] The nasopharyngeal tonsil is the largest mass of lymphoid tissue in the respiratory tract of horses of all ages, and its epithelium has been extensively characterized.[312] This epithelium has a classical FAE and is heavily folded, forming crypts, and also contains M cells. The nasopharyngeal tonsil exists in the dorsal recess of the nasopharynx and extends ventrally toward the opercula on either side of the nasopharynx. Therefore it is ideally placed for the sampling of antigens before entry to the airways or alimentary tract and may serve as an important target for intranasal vaccines. This tissue appears to be most abundant in young foals and atrophies with age, although many lymphoid follicles remain throughout the nasopharynx.

The nasopharyngeal epithelium also contains numerous lymphocytes. Immunohistochemical studies indicate that the majority of these lymphocytes are $CD8^+$ T lymphocytes, although B lymphocytes are also present.[312] The contribution of these lymphocytes to mucosal cellular immune defenses of the upper respiratory tract is poorly studied. However, following intranasal challenge of yearling and 2-year-old horses with EHV-1, virus-specific cytotoxic activity is detectable in several mucosal lymphoid tissues of the upper respiratory tract, as well as the local draining lymph nodes, and is particularly evident in the nasopharyngeal lining.[313] This cellular immune response is presumably mediated by $CD8^+$ T lymphocytes found in the nasopharyngeal epithelium and underlying lamina propria and may provide an important contribution to the clearance of infectious virus from the upper respiratory tract.

Ontogeny of the Equine Immune System

There have been few studies of the prenatal development of the equine immune system. As in other species, the thymus is the first lymphoid organ to develop, and mitogen-responsive cells can be identified there from day 80 of the 340-day gestational period of the horse.[314] Subsequently these cells appear in peripheral blood at 120 days, lymph nodes at 160 days, and the spleen at 200 days. Cells responsive in mixed lymphocyte reactions are detectable in the thymus from 100 days and the spleen at 200 days. Immunoglobulin production is detectable before 200 days of gestation, and newborn foals have IgM and IgG in their serum.[314-317] Presuckle serum concentrations of these immunoglobulins in the newborn foal are low. The mean concentration of IgM is 31.7 mg/dL, and that of IgG (comprised of IgG1 and IgG4/7) is 7.5 mg/dL.[316] Overall it appears that functional T lymphocytes are present by day 100 and B lymphocytes by day 200 of gestation. Immunologic competence of the equine fetus has been assessed in terms of specific antibody responses. In utero immunization of foals in late gestation with keyhole limpet hemocyanin in an alum adjuvant results in detectable specific antibody production and T-cell responsiveness at the time of birth.[318] In addition, the equine fetus can respond to coliphage T2 at 200 days and Venezuelan equine encephalitis virus at 230 days.[319,320]

Although detailed studies are few, some data regarding the maturation of thymocytes in young horses are available. As discussed, stem cells migrate into the thymus and mature into T cells under the influence of the epithelial microenvironment. In this process different patterns of cell surface molecule expression distinguish successive stages of thymocyte maturation. In humans, the earliest thymic precursor cells express low levels of CD4. This CD4 expression is lost as early thymocytes become double-negative $CD4^-CD8^-$ cells and then demonstrate their T-cell commitment by TCR-β gene rearrangement, which is an essential trigger for subsequent events and leads to low levels of expression of a cell surface TCR-β–CD3 complex. Intermediate thymocytes are $CD4^{lo}CD8^{lo}$, but after TCR-α gene rearrangement and expression of cell surface αβ TCR they rapidly become $CD4^{hi}CD8^{hi}TCR–CD3^{hi}$. Subsequently, thymocytes selected on the basis of productive TCR gene rearrangement and lack of self reactivity become mature T cells expressing either CD4 or CD8 (single positive) in combination with high levels of TCR-CD3. Maturation of T cells and similar patterns of T cell CD3, CD4, and CD8 expression can be demonstrated in the equine thymus.[321-324]

Mature B and T cells are present in the equine fetal spleen and lymph nodes by 90 to 120 days of gestation.[316] B cells are IgM^+, consistent with their naive status, and do not occur in germinal centers. Both $CD8^+$ and $CD4^+$ T cells are present in these tissues. By the time foals are born, $CD8^+$ and $CD4^+$ T cells are abundant in these secondary lymphoid tissues, as are IgM^+ B cells within well-developed germinal centers.[316]

Immunocompetence in Foals

Although normal foals are immunocompetent at birth they are immunologically naive, and infectious disease in neonatal foals is associated with high morbidity and mortality. Although failure of passive transfer is a major cause of this problem, as discussed later, immaturity of the immune system has also been considered a potential contributing factor. As a result numerous studies of neonatal immunocompetence have been completed and reviewed.[249,325,326]

Innate Immune Responses in Foals

Multiple studies indicate that expression of TLRs, proinflammatory cytokines, and acute phase proteins in foals is

comparable to that of adults.[326] A number of studies have reported neutrophils to be fully functional from birth,[327-329] but their function is significantly impaired before absorption of colostral antibodies, which are required for opsonization.[329,330] Killing by foal neutrophils is reduced in the first 2 weeks of life, as is phagocytic ability when assays are performed using autologous serum.[331] However, when serum from adult horses is used, neutrophil phagocytosis and oxidative burst capacity are normal and similar to those of adults from birth through 4 months of age.[331,332] These studies indicate that neutrophil function in foals depends on immunoglobulins and/or complement with adequate opsonizing activity. Another study of foals less than 7 days of age indicates that phagocytosis and oxidative burst activity of neutrophils is reduced compared with adult levels, even when adult serum is used.[333] Although the assays were similar, these apparently disparate results may have been due to the procedures used. Regardless, the importance of complement in foals is illustrated by the finding that the opsonic capacity of foal serum for bacteria is halved when complement is inactivated by heat.[220] Interestingly, complement activity in the first week of life is considerably elevated in colostrum-deprived foals, possibly as an alternative defense mechanism.[334] In bovine colostrum-fed foals, serum complement levels reach adult levels by 1 to 3 weeks of age.[335] Finally, alveolar macrophages recovered from bronchoalveolar lavages may be low in number up to 2 weeks of age and have impaired chemotactic function.[336]

Taken together, available studies indicate that innate immunity is intact in foals and leads to functional neutrophil responses similar to those in adults but that adequate levels of immunoglobulins and complement with opsonizing activity are critical.

Adaptive Cell-Mediated Immunity in Foals

Several studies have measured lymphocyte numbers and subpopulations in foals.[332,337,338] Foals are born with B and T lymphocytes, and with $CD4^+$ and $CD8^+$ T-lymphocyte subsets. Lymphocyte counts rise in the first 4 months of life, and the proportion of B lymphocytes increases. Although proliferation of peripheral blood T and B lymphocytes is lower during the first few weeks of life, it rises to adult levels by 4 weeks of age.[332] During the first 3 months of life, follicular development and the density of B- and T-cell zones increases in secondary lymphoid tissues.[336] In contrast, organized lymphoid tissue is not present in the lungs at birth, and very few lymphocytes are present in bronchoalveolar lavage (BAL) samples during the first week of life.[326,332] The appearance of organized lymphoid tissue in the lungs, along with T and B cells in BAL samples, gradually increases during the first 3 months. These factors likely increase the susceptibility of foals to respiratory infections during the neonatal period.

Compared with adult horses, foals exhibit reduced levels of IFN-γ production in stimulated BAL cells and PBMCs throughout the first 6 months of life, and this reduced T_H1 response might contribute to their susceptibility to *Rhodococcus equi* and other intracellular pathogens.[339] Adult horses immunized with an experimental EIAV plasmid DNA vaccine developed antigen-specific antibodies, lymphoproliferative, and CTL responses, whereas foals immunized within the first week of life with the same construct (and boosted at the same intervals as the adults) developed antigen-specific antibody and lymphoproliferative responses but failed to develop CTL responses.[273] These foals were born to EIAV-negative dams and thus had no passive transfer of EIAV-specific antibodies. Seroconversion occurred later than in the adults, and antibody levels waned sooner than in the adults. Adult horse dendritic cells stimulated with CpG-ODN (a PAMP that binds TLR-9) increase IL-12 expression, but foal dendritic cells do not.[340] This study further demonstrates that although foal dendritic cells express the costimulatory molecule CD86 similar to adult levels, MHC II expression is reduced at birth and does not reach adult levels until 3 months of age. A follow-up study found that foal dendritic cells infected with *R. equi* produce IL-12 and express costimulatory molecules (CD40 and CD86) similar to adult levels, but as previously observed, MHC II molecule expression is limited.[341] Thus foal APCs can produce the costimulatory and IL-12 signals (albeit variably depending on stimulus) required for T_H1 differentiation, but MHC II presentation may be compromised.

Foals less than 1 week of age have significantly lower whole blood basal expression of IFN-γ and IL-4 than adult horses and, unlike adults, fail to develop antigen-specific lymphoproliferative responses following immunization with a killed adjuvanted bovine vaccine.[342,343] Similarly, foals less than 1 week of age and foals between 3 and 6 months of age have a lower frequency of IFN-γ and IL-4 secreting PBMCs than adult horses.[344] Bronchial lymph node lymphocytes from *R. equi*–infected foals have significantly reduced *R. equi*–specific proliferative responses than those from adult horses but, interestingly, have lower IL-4 expression, higher IFN-γ expression, and higher IFN-γ/IL-4 ratios on *R. equi* stimulation than those of adults.[345] Although quantitatively lower than adults, IFN-γ production by foal T_H1 cells (and by $CD8^+$ T cells) following nonspecific stimulation is detectable a few days after birth and increases with age, whereas IL-4 production by T_H2 cells is virtually absent during the first 3 months.[346] In addition, *R. equi* infection of BAL cells from 10-day-old foals results in increased expression of IFN-γ and IL-4 and in PBMCs results in consistent IFN-γ expression during the first 3 weeks of age but decreased IL-4 expression at birth.[297] Finally, foals orally inoculated with *R. equi* within the first 2 weeks of life develop *R. equi*–specific CTL responses and IFN-γ expression by *R. equi*–stimulated PBMCs at similar levels as adult horses, with lower levels of IL-4 expression.[347]

Taken together these observations indicate that foals are capable of mounting T-cell responses, including T_H1 and CTL responses, and under some circumstances these responses can be similar to those of adult horses. Based on the latter studies documenting lower IL-4 expression/production relative to that of IFN-γ, foals appear to have a T_H1 bias. These observations challenge the view that foals are inherently T_H2 biased similar to mouse and human neonates.[348] It should be noted that the equine studies evaluated different cell populations, different stimulation conditions, different methods to measure cytokine expression/production, and, in the immunization studies, different immunogens and routes of immunization, likely contributing to some of the disparate results. Nonetheless, these studies agree for the most part that overall, helper T-cytokine expression/production and T-cell responses are quantitatively lower than those of adult horses. Although the precise mechanisms underlying these differences between foals and adults are unclear, contributing factors likely involve the overall naivete of T cells in young

foals and the relative immaturity of APCs in terms of PAMP responses and MHC II presentation, all leading to inefficient priming of naive T cells.

Antibody-Mediated Immunity in Foals

Passive Transfer of Maternal Antibodies. As a result of epitheliochorial placentation in horses, transfer of maternal antibodies does not occur in utero, and foals are born essentially agammaglobulinemic. Foals therefore depend on the ingestion of colostrum and intestinal absorption of maternal antibodies within the first 24 hours of life for protection against infectious pathogens. See discussion of failure of transfer of passive immunity under Secondary Immunodeficiencies later in this chapter.

De Novo Antibody Production in Foals. Few studies of de novo antibody production have been conducted in foals without the effect of transferred maternal antibodies. In a study of 10 pony foals fed only bovine colostrum, endogenous equine antibody production measured by radial immunodiffusion resulted in serum concentrations of IgG of 200 mg/dL by 2 weeks of age, 400 mg/dL by 1 month, and 1000 mg/dL by 3 months.[349] In a smaller study of two colostrum-deprived pony foals, comparing them to 18 colostrum-fed foals, and measuring serum γ-globulin levels by immunoelectrophoresis, very similar results were obtained, although it was apparent that the colostrum-deprived foals achieved higher serum γ-globulin levels between 6 weeks and 3 months of age than colostrum-fed foals.[350] In a third study, antibody concentrations in six colostrum-deprived foals were substantively higher than in five control foals between 3 and 5 months of age.[334] These three studies provide evidence for substantial endogenous production of IgG in the first month of life in foals deprived of equine colostrum and suggest that the onset of production is earlier and the rate is higher in foals deprived of colostrum. This observation is consistent either with nonspecific immunosuppression in colostrum-fed foals or stimulation of immunoglobulin production in colostrum-deprived foals. In another study of foals from mixed-breed horses fed only bovine colostrum, endogenous IgG production started later and was first detected at 1 month of age in the majority of foals, reaching similar levels to foals fed equine colostrum by 2 months of age.[351] Foals immunized with an experimental EIAV plasmid DNA vaccine within the first week of life and boosted on days 15, 36, and 50 seroconverted between days 47 and 53.[273] By comparison, three adult horses similarly immunized seroconverted on day 29. The foals were born to EIAV-negative dams and thus had no passive transfer of EIAV-specific antibodies. Vaccination of 3-day-old foals with a killed adjuvanted bovine vaccine, for which there was no maternal antibody interference, resulted in considerably decreased antibody responses compared with adults.[343] Although 3-month-old foals had improved antibody responses, the magnitude was less than in adults. In contrast, a similarly designed study demonstrated that vaccination with bacillus Calmette-Guérin (BCG; a modified live *Mycobacterium bovis* vaccine) elicited robust antibody responses similar to those of 4-month-old foals and slightly less than adults, although neither group of foals produced vaccine-specific IgG4/7.[342] The latter result was consistent with the findings of other studies (see later discussion). Taken together, neonatal foals are clearly capable of endogenous antibody production in the absence of maternal antibody, although responses tend to be less robust than in older foals and adults. However, the magnitude of the antibody response in neonates depends on the nature of the antigenic stimulation. Overall, when foals are vaccinated with antigens against which they have no passively transferred antibody, normal antibody responses have been documented from at least 3 months of age.[352]

In colostrum-fed foals, serum IgG concentration falls to its lowest level at 1 to 2 months of age as a result of catabolism of maternally transferred immunoglobulin, subsequently rising toward adult levels as a result of endogenous immunoglobulin production.[331,332,338,353] A study of five Quarter Horse foals in the first 9 weeks of life showed that IgG (the equivalent of IgG1 plus IgG4/7) concentrations were lowest at 1 month of age. However, the subsequent increase in IgG concentration was due to de novo IgG1 production, not IgG4/7. At the end of this study (at 9 weeks of age) there was still no clear evidence of IgG4/7 production, although IgG1 and IgG3/5 concentrations had reached or exceeded adult levels. In adult horse serum, IgG4/7 comprises greater than 60% of total serum IgG and is by far the dominant subclass in foal serum after passive transfer of immunity.[249,317,326] IgG4/7 has also been shown to have a critical role in immunity to a variety of pathogens,[354,355] and it is possible that the naturally late onset of endogenous production may be a factor in the increased susceptibility of foals to bacterial respiratory infections at this age.[249,356,357] A study investigating this possibility during the first 42 days of life measured the opsonic capacity of foal serum against *Escherichia coli* and *Actinobacillus equuli*.[220] No differences were detected over time, and foal serum was as effective as adult horse serum. Because IgG1, IgG4/7, and IgG3 all activate complement, bind Fc receptors, and bind bacterial cell walls,[247] IgG1 and IgG3 may functionally compensate for the slower onset of IgG4/7 production in young foals. Finally, in a study of immunoglobulin concentrations in foals throughout the first year of life, serum levels of all measured isotypes decreased at 4 weeks of age, after which point all but IgG4/7 began to rise. This pattern was the result of catabolism of maternal antibody and the different times of onset and rates of endogenous antibody production as follows: (1) IgA and IgG3/5 levels stabilized at 8 to 12 weeks of age; (2) IgG1 levels peaked at 8 weeks of age and then slowly declined throughout the duration of the study; and (3) IgG4/7 levels reached their nadir at 2 to 5 months of age and did not begin to rise until after 16 weeks of age. These observations could provide a basis for reduced endogenous antibody-mediated immunity during the first year of life. This study also showed that at 1 year of age serum immunoglobulin concentrations had still not reached adult levels.

A factor that significantly affects de novo immune responses in foals is the suppressive effect of passively transferred antigen-specific maternal antibodies. The rate of decline of these antibodies varies for both individuals and different infectious agents. The half-life for maternal IgG in foals is estimated at 20 to 30 days.[350] Studies of antigen-specific antibodies demonstrate similar half-lives for anti-influenzavirus and anti–tetanus antibodies of 27 to 29 days for IgG1, 35 to 39 days for IgG4/7, and 35 days for IgG3/5.[358] For many important pathogens, the concentration of maternal antibodies in foals falls to nonprotective levels by 2 to 3 months of age.[359,360] However, the remaining antibody can still render the foal unresponsive to vaccination for weeks or even months to come. In the case of equine influenzavirus[361,362] and tetanus toxoid, maternal antibodies can persist until 6 months of age and inhibit antibody responses in foals vaccinated before that

age.[358] In contrast, a recent study indicates that 3-month-old foals immunized with a three-dose-series multivalent vaccine had similar antigen-specific antibody and T-cell responses as foals initially vaccinated at 6 months of age.[363] Based on this study it is reasonable to begin vaccinating foals earlier than 6 months of age in circumstances where the risk of infectious disease is high.

Implications for Immunocompetence in Foals

The evidence presented previously indicates that the immune system of the foal is competent in many ways, with the innate immune system completely functional at least by the second week of life, and with the full complement of lymphocytes present from birth. Antibody is entirely provided by passive transfer at first, although endogenously produced immunoglobulin is detectable within a few weeks of birth and predominates from 1 to 2 months of age. Nevertheless, there are some key features of the foal immune system that can limit its ability to defend against infection. A critical factor is maternal antibody interference, which inhibits the binding of antigens to BCRs of naive B cells in the foal, reducing endogenous antibody responses. As foals age, a continuing immunomodulatory effect of maternal antibody may limit foal immunoresponsiveness, while no longer providing comprehensive protection itself. Of similar importance is that although the adaptive immune system is complete from the time of birth, it is naive. In addition, APCs are immature.[364] Neonates can mount normal immune responses but require appropriate presentation of antigen and costimulatory signals. Reduced antigen presentation by APCs, or antigen presentation in the absence of costimulatory signals, can result in a failure to mount the appropriate immune response. This is particularly an issue in neonates. The absence of memory responses and a well-developed repertoire of immune effectors is a serious handicap that only appropriate antigenic encounters can overcome. Despite the fact that humoral and cell-mediated immune responses are less robust during the first year of life, the majority of foals survive to adulthood. However, a better understanding of immune regulation in foals and the precise mechanisms underlying the differences between foal and adult immune responses is needed to develop improved immune-based strategies to prevent critical infectious diseases in foals such as *R. equi* pneumonia.

HYPERSENSITIVITY AND AUTOIMMUNITY

Hypersensitivity refers to an altered state of immunoreactivity resulting in self-injury. Four different types of hypersensitivities can be defined by the type of immunologic process underlying the tissue injury (Table 1.6). The most common and important type of hypersensitivity disease in most species is type I hypersensitivity, mediated by IgE. In these diseases some individuals produce IgE antibodies against a normally innocuous antigen, which is called an *allergen*. Exposure to the allergen triggers mast cell degranulation as described later, and a series of responses result that are characteristic of allergy. Allergic diseases are so important that more is known about the function of IgE in hypersensitivity than about its normal role in host defense. In this definition, and throughout this chapter, the term *allergy* refers only to type I hypersensitivity diseases mediated by IgE, whereas in other definitions allergy can refer to the entire spectrum of hypersensitivity diseases.[365] Other forms of hypersensitivity disease depend primarily on IgG antibodies (type II and III hypersensitivities) or T cells (type IV hypersensitivity). Each of these disease processes can play a role in the immunopathogenesis of autoimmune disease, in which the body mounts an adaptive immune response to self tissue antigens.

Clinical hypersensitivity diseases, such as recurrent airway obstruction (RAO) or equine recurrent uveitis (ERU), can involve more than one type of hypersensitivity reaction simultaneously, which limits the utility of this classification for clinical diagnosis. Alternative strategies for classifying these diseases may have greater clinical utility. For example, antibody-mediated hypersensitivity diseases (types I, II, and III) are immediate in onset if preformed antibody exists in circulation or tissues, with some variation in time course dependent on the antibody isotype involved. Cell-mediated hypersensitivity diseases (type IV) are delayed, even in sensitized individuals, for 1 to 3 days, while effector cells are recruited to

TABLE **1.6 Hypersensitivity**

	Type I	Type II	Type III	Type IV		
Immune Mediator	**IgE**	**IgG**	**IgG, IgA**	**T_H1**	**T_H2**	**CTL**
Antigen	Soluble antigen	Cell or matrix associated antigen	Immune complex formation	Soluble antigen	Soluble antigen	Cell-associated antigen
Effector mechanism	Mast-cell degranuation	Fc-receptor–positive cells (phagocytes of reticuloendothelial system)	Fc-receptor–positive cells, complement	Macrophage activation	Eosinophil activation	Cytotoxicity
Examples of hypersensitivity reaction	Systemic anaphylaxis, *Culicoides* hypersensitivity	Immune-mediated hemolytic anemia, neonatal isoerythrolysis	Purpura hemorrhagica, serum sickness	Equine recurrent uveitis	Chronic *Culicoides* hypersensitivity	Contact dermatitis

Note: The four types of hypersensitivities can be differentiated by the immune mediator involved, the form of antigen recognized, and the effector mechanism elicited in producing pathology. Equine examples of each condition are given when available.

the site of antigen exposure.[365] The goals of this section are as follows:

- Review the classical hypersensitivity types to explain the immunopathogenesis of hypersensitivity diseases
- Describe antibody and cell-mediated hypersensitivities of horses and their immunologic basis
- Identify autoimmune conditions of horses with a known immunologic basis

Detailed descriptions of clinical aspects of hypersensitivity and autoimmune diseases, their diagnosis, and their management are presented elsewhere in this book. Detailed explanations of many immunologic mechanisms involved in these disease processes are provided previously in this chapter.

Classical Types of Hypersensitivity Reactions

Type I Hypersensitivity

As described, type I hypersensitivity, also known as immediate hypersensitivity or allergy, is mediated by IgE antibody specific for allergens, which are extrinsic antigens normally not recognized by the healthy immune system. IgE is predominantly found in tissues, where it is bound to mast cells through the high-affinity IgE receptor, which is called FcεRI and has been identified in the horse.[366] When antigen binds to IgE on the surface of mast cells, cross-linking two or more IgE molecules and their FcεRI receptors, this triggers the release of chemical mediators from the mast cells, which cause type I hypersensitivity reactions. Basophils and eosinophils (when activated) also possess FcεRI receptors and therefore can participate in the same process. In addition to FcεRI receptors, there is an unrelated low-affinity IgE receptor called CD23 that is present on many lymphocytes, monocytes, eosinophils, platelets, and follicular dendritic cells. The role of CD23 appears to be to enhance IgE responses to specific antigens when those antigens are complexed with IgE. Thus CD23 on APCs can capture IgE-bound antigens. In the horse CD23 has been identified and its expression is upregulated by equine IL-4.[367] Monoclonal antibodies against equine CD23 are now available and have been used to identify CD23 primarily on a subpopulation of B cells.[368] These reagents should be useful for further evaluating the role of this low-affinity receptor in IgE-mediated responses in the horse.

The selective stimulation of IgE responses depends on characteristics of the antigen (allergen), the individual affected (genetic factors such as MHC haplotype), and the mechanism of antigen presentation. The antigen must be capable of eliciting a T_H2 immune response to stimulate IgE production. Small, soluble proteins, frequently enzymes, containing peptides suitable for MHC II antigen presentation, and presented to mucosal surfaces at low doses, are particularly efficient at generating IgE responses. Low doses of antigen specifically favor T_H2 over T_H1 responses, and exploiting this relationship is the basis of some therapeutic hyposensitization strategies (see under Immunomodulators). These processes are regulated by T_{regs} (discussed previously), which suppress T_H2 cytokine production in healthy individuals. When T_{regs} are deficient, atopy can result. The process of T_H2 differentiation is critical to promoting IgE responses and may be favored at enteric and respiratory mucosal surfaces, or skin, where parasite invasion typically occurs. This makes teleologic sense, as IgE responses are important for antiparasitic immunity.[369] Dendritic cells at such locations are frequently programmed to stimulate T_H2 responses. Cross-linking of FcεRI receptors on granulocytes also results in CD40L expression and IL-4 secretion, which further promotes IgE production by B lymphocytes and sustains allergic reactions.

Some individuals are predisposed to IgE-mediated hyperactivity to a wide variety of environmental allergens, and this condition is termed *atopy.*[370] Affected individuals have high levels of IgE in the blood and increased eosinophil populations. In humans this condition depends partly on genetic factors, including genetic variations in the IL-4 promoter sequence or association with particular MHC II genes. Nevertheless, environmental factors are also important, as atopy is increasingly common in humans in economically developed parts of the world. Four potential explanations for this observation are decreased exposure to infectious disease during childhood, environmental pollution, allergen levels, and dietary change. The first explanation, known as the "hygiene hypothesis," is supported by epidemiologic and experimental evidence. The premise is that living in areas with poor sanitation, microbial exposure, and infectious diseases early in life biases the immune system toward T_H1 responses and away from T_H2 responses, thus reducing the later development of allergic diseases. This is thought to be due in large part to the composition of the intestinal microbiota, including the presence of helminths, and the resulting induction of T_{regs} that modulate T_H1/T_H2 balance.[371] In developed societies, decreased microbial exposure during early childhood and decreased prevalence of infectious diseases leads to a depleted microbiota and an increased tendency to mount T_H2 responses, which may be the natural bias of the neonatal immune system.[348] It is unclear if atopy occurs in horses and whether or not the hygiene hypothesis applies. Interestingly, a recent study in 593 Warmbloods in Switzerland found that some horses had multiple hypersensitivities.[372] For example, horses with RAO had a 13.1 times higher odds ratio of being affected with IBH, and horses with IBH had a 7.1 times higher odds ratio of being affected with urticaria. In addition, the multiple hypersensitivity phenotype was associated with the absence of nematode eggs in the feces. Icelandic horses living in Iceland have high intestinal helminth burdens and low numbers of IL-4–producing T cells along with significantly higher IL-10 and TGF-β production by PBMCs than Icelandic horses living in Switzerland.[373] These horses do not develop IBH in Iceland because *Culicoides* midges do not occur in Iceland, but they are prone to IBH when imported into countries where *Culicoides* spp. are endemic. This susceptibility is associated with deworming before import, along with increased IL-4 production and decreased regulatory cytokine production.[373] Taken together, the results of these studies suggest that some horses are atopic and that this might be associated with reduced intestinal nematode exposure, consistent with the hygiene hypothesis.

Effector Mechanisms in Type I Hypersensitivity Allergic Reactions. When triggered by antigen cross-linking of IgE bound to FcεRI cell surface receptors, activated mast cells release chemical mediators stored in preformed granules and synthesize leukotrienes and cytokines. In type I hypersensitivity reactions the outcome of this reaction can vary from anaphylactic shock to minor localized inflammation. Mast cell degranulation causes an immediate allergic reaction within seconds, but there is also a sustained late-phase response that develops over up to 8 to 12 hours due to recruitment of T_H2 lymphocytes, eosinophils, and basophils.

Mast cells are highly specialized cells of the myeloid lineage that are common in mucosal and epithelial tissues near small

blood vessels. The range of inflammatory mediators released by degranulating mast cells is wide and includes enzymes that can remodel connective tissues; toxic mediators such as histamine and heparin; cytokines, including IL-4, IL-5, IL-13, and TNF-α; and lipid mediators, including leukotrienes and PAF. Histamine causes an increase in local blood flow and capillary permeability. Enzymes activate matrix metalloproteinases, which cause tissue destruction, and TNF-α increases expression of adhesion molecules and attracts inflammatory leukocytes. These reactions are all appropriate when the mast cell is reacting to an invasive pathogen, but in allergy this is the basis of the immediate inflammatory response and also the initiating step in the late-phase response.

The role of eosinophils in inflammation is tightly controlled at several levels. Synthesis in the bone marrow depends on IL-5 produced by T_H2 cells in the face of infection or other immune stimulation. Transit of the eosinophils to tissues depends on two chemokines, eotaxin 1 and eotaxin 2. Activation of eosinophils by cytokines and chemokines induces them to express FcεRI and complement receptors and primes the eosinophil to degranulate if it encounters antigen that can cross-link IgE on its surface. Mast cell degranulation and T_H2 activation recruit and activate large numbers of eosinophils at the site of antigen encounter. Basophils are similarly recruited, and together their presence is characteristic of chronic allergic inflammation. Eosinophils can trigger mast cells and basophil degranulation by release of major basic protein. This late-phase response is an important cause of long-term illnesses such as chronic asthma in humans.

Clinical Manifestations of Type I Hypersensitivity Reactions Depend on Their Site. The clinical outcome of type I hypersensitivity reactions depends on the amount of IgE present, the dose of allergen, and the site of allergen introduction. Direct introduction of allergen into the bloodstream or rapid enteric absorption can lead to widespread activation of connective tissue mast cells associated with blood vessels. This potentially disastrous event, termed *systemic anaphylaxis,* can cause catastrophic loss of blood pressure and airway obstruction resulting from bronchoconstriction and laryngeal swelling. This leads to anaphylactic shock and can follow administration of drugs against which an individual has an established IgE response. Treatment with epinephrine can control these potentially fatal events.

Penicillin is one example of a drug that can cause type I hypersensitivity reactions in humans, and it may induce this type of hypersensitivity reaction in the horse.[374] Penicillin can act as a hapten (see under Equine Immunology). Penicillin alone can elicit antibody formation by B cells but cannot elicit T-helper cell responses as it is not a protein. However, the β-lactam ring of penicillin can react with amino groups on host proteins to form covalent conjugates, and the modified self peptides can generate T_H2 responses in some individuals. The T_H2 cells can in turn release cytokines, which activate penicillin-binding B cells to produce IgE. In this scenario penicillin is a B-cell antigen and becomes a T-cell antigen by modifying self peptides. Intravenous penicillin results in protein modification and recognition and cross-linking of mast cell IgE leading to anaphylaxis.

Allergen inhalation, in contrast, induces local inflammation of the respiratory tract—for example, in the upper airways as in allergic rhinitis or in the lower airways in human asthma. Similarly allergen introduction into the skin causes local histamine release initially and a wheal-and-flare reaction, followed by a late-phase response several hours later. When allergens are ingested and reach the skin from the bloodstream, a disseminated form of the wheal-and-flare reaction occurs that is termed *urticaria* or *hives.* Prolonged inflammation of the skin results in eczema or atopic dermatitis in some individuals. Ingestion of allergens causes activation of gastrointestinal mast cells resulting in fluid loss across the bowel and smooth muscle contraction. The clinical presentation is diarrhea and vomiting. Sometimes ingestion of allergens can lead to systemic anaphylaxis if they are absorbed rapidly, or urticaria, as is sometimes seen in humans after oral penicillin administration.

Type II Hypersensitivity

This form of hypersensitivity disease occurs when the causal antigen is associated with cells or tissue components of the body, and there is an IgG antibody response to this antigen. Phagocytes, or other cells expressing Fcγ receptors, mediate destruction of the affected tissue, or removal from the circulation by the reticuloendothelial system in the case of antibody-positive erythrocytes or platelets. Additionally, antibody bound to erythrocytes may activate complement resulting in hemolysis. Blood transfusion reactions and neonatal isoerythrolysis are examples of type II hypersensitivities. Immune-mediated hemolytic anemia and thrombocytopenia are examples of drug-associated type II hypersensitivities. In the case of the horse, penicillin is an established cause of hemolytic anemia.[375] Diagnosis can be accomplished using a Coombs test (Fig. 1.18). Penicillin binds to the erythrocyte surface and is targeted by antipenicillin antibodies of the IgG isotype. Interestingly, quite large numbers of horses have antipenicillin antibodies of the IgM isotype, but this does not lead to disease.

Type III Hypersensitivity

In type III hypersensitivity the antigen is soluble and present in the circulation. Disease results from formation of antibody-antigen aggregates or immune complexes under certain specific conditions. Although immune complexes are generated in all antibody responses, they are generally harmless. Large complexes fix complement and are removed from circulation by the reticuloendothelial system. However, small complexes can form at antigen excess (Fig. 1.19), and these can deposit in blood vessel walls and tissues where they ligate Fc receptors on leukocytes, causing an inflammatory response, increased vascular permeability, and tissue injury. Complement activation also contributes to this process. Local injection of antigen can sometimes lead to a necrotizing skin lesion due to type III hypersensitivity, and this is termed an *Arthus reaction.*

The classical example of a type III hypersensitivity reaction is serum sickness, which can be seen after administration of horse antiserum in humans, such as in treating snakebites. After an IgG response to the horse serum is generated (7–10 days), signs of fever, urticaria, arthritis, and sometimes glomerulonephritis result. The foreign antigen is cleared as part of this process, which makes this condition ultimately self-limiting. Alternative scenarios for induction of type III hypersensitivity reactions include persistent infectious diseases where pathogens (or their antigens) are not completely cleared from tissues or autoimmune diseases in which antigen persists. Glomerulonephritis in horses with chronic equine infectious anemia is one example of the former.[376] Purpura hemorrhagica following *Streptococcus equi* infection is another. Inhaled antigens associated with moldy hay that induce IgG responses

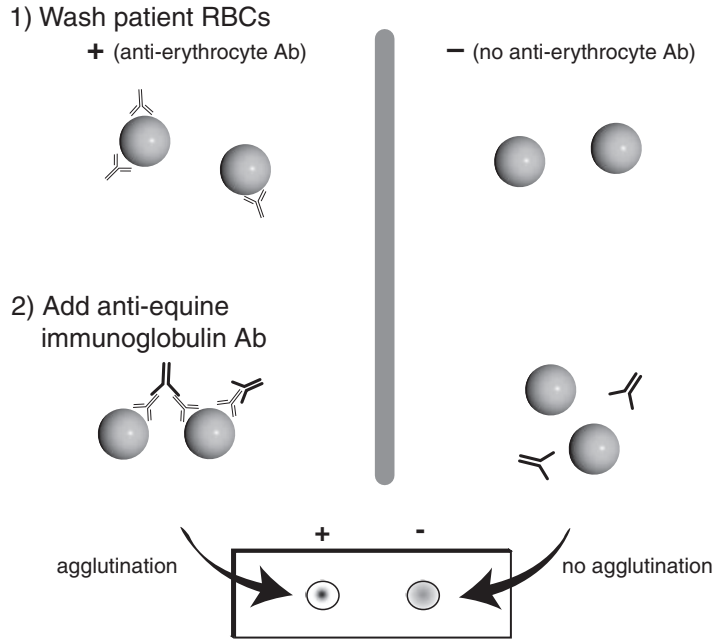

FIG. **1.18** Direct Coombs test. *Ab,* Antibody; *RBCs,* red blood cells.

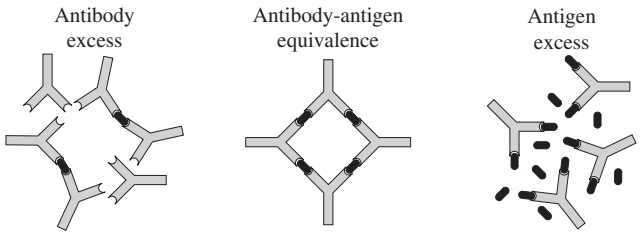

FIG. **1.19** Antibody-antigen precipitation. Antibody can precipitate soluble antigen in the form of immune complexes. This is most efficient when concentrations of antibody and antigen reach equivalence, and large immune complexes are formed. However, when antigen is in excess some immune complexes are too small to precipitate and can produce pathologic changes such as are seen in type III hypersensitivities.

can lead to immune complex formation in the alveolar wall, as occurs in cattle with hypersensitivity pneumonitis. This can also occur in humans and is known as farmer's lung. Any such circumstance in which immune complexes are deposited in tissues can lead to this type of pathology.

Type IV Hypersensitivity

Cell-mediated type IV hypersensitivities cause delayed hypersensitivity reactions. A variety of cutaneous hypersensitivity reactions are seen, such as the contact hypersensitivity seen after absorption of haptens such as pentadecacatechol in poison ivy or the local T_H1 response seen in the diagnostic tuberculin reaction. When type IV hypersensitivity results in a T_H2 response the principal outcomes are eosinophil activation and recruitment such as in chronic asthma in humans.

Antibody-Mediated Hypersensitivity Diseases in the Horse

The study of hypersensitivity disease in the horse was hampered in the past by the lack of reagents capable of detecting equine IgE. Although equine IgE has long been known to exist,[377,378] and the genetic sequence has been known since 1995,[379-381] the only reagents for studying it have historically been conventional polyclonal antisera produced by vaccination with physicochemically purified IgE[382,383] or made in chickens after vaccination with recombinant fragments of the IgE heavy chain.[384] Although many valuable studies have been performed using these reagents,[385-388] the availability of well-characterized monoclonal antibodies recognizing equine IgE has moved the field forward.[389,390] Passive transfer of maternal IgE via colostrum occurs in equine neonates, and cross-linking of this maternal IgE on the surface of neonatal basophils results in intracellular IL-4 production.[391,392] This might help promote adaptive T-cell responses in newborn foals. However, the onset of endogenous IgE production in horses does not occur before 9 to 11 months of age and does not reach adult levels before 18 months.[391] This may help explain why hypersensitivity disease is uncommon in horses before puberty.

The following section describes a series of equine diseases with characteristics of immediate hypersensitivity disease. This is not an exhaustive list of equine hypersensitivity diseases and additional examples can be found throughout this book.

Systemic Anaphylaxis

Systemic anaphylaxis is a severe immediate type I hypersensitivity reaction mediated by IgE. The incidence of true systemic anaphylaxis in horses is unknown, although the condition has been reported in association with administration of a wide range of compounds, including serum, vaccines, vitamin E–selenium preparations, thiamine, iron dextrans, and antibiotics, including penicillin.[393,394] Target organs in experimental equine anaphylaxis are the lung and the intestine.[393] Sudden dyspnea; hypotension, as evidenced by poor peripheral pulse character; rapid onset of urticaria; and collapse are cardinal signs of the onset of systemic anaphylaxis.

The therapeutic goals in treating systemic anaphylaxis are to (1) prevent or reverse the complications caused by mediator release, (2) maintain respiratory integrity, and (3)

maintain cardiovascular stability. Not all anaphylactic reactions require therapy. However, rapid recognition of those that do is critical to patient survival. Intravenous access via an indwelling intravenous catheter and airway patency should be established immediately because cardiovascular collapse and upper airway obstruction caused by angioedema can occur rapidly. The conscious horse does not tolerate tracheal intubation so emergency tracheotomy may be required. Oxygen should be administered if available because bronchoconstriction and cardiovascular collapse result in hypoxemia. The fluid requirement of horses in anaphylactic shock is not known, but large volumes of balanced polyionic fluid should be administered rapidly.

The principal therapeutic agent is epinephrine, which is a potent sympathetic stimulant. Epinephrine administration may cause excitement in the horse. Epinephrine should be administered intramuscularly (0.01–0.02 mg/kg, equivalent to 4.5–9 mL of 1:1000 dilution of epinephrine for a 450-kg horse) if dyspnea and hypotension are not severe.[395] Epinephrine should not be administered subcutaneously because its potent vasoconstriction can lead to poor absorption and tissue necrosis. If dyspnea or hypotension is severe, epinephrine should be administered slowly intravenously at the same dose as above. If there is no venous access, 2 times the above dose intramuscularly or 5 times the above dose intratracheally can be administered.[395] Epinephrine doses can be repeated every 15 to 20 minutes until hypotension improves. The side effects of epinephrine therapy are tachyarrhythmias and myocardial ischemia, which can be life-threatening. Alternatively, an epinephrine or norepinephrine drip can be instituted for cases of refractory hypotension. Other therapeutic agents such as antihistamines, β-agonists, or other pressors may be indicated, although their value is less certain. Though its effects may be delayed, glucocorticoid therapy is indicated to help reverse persistent bronchospasm, reverse angioedema, and break the cycle of mediator-induced inflammation triggered during hypersensitivity reactions. Ideally a rapid-acting glucocorticoid should be used such as prednisolone sodium succinate (0.25–10.0 mg/kg intravenously), but dexamethasone may also be used (0.2–0.5 mg/kg intravenously). Glucocorticoid therapy during the acute phase will aid in preventing the late-phase reaction.

Insect Bite Hypersensitivity

Insect bite hypersensitivity (IBH) occurs in response to salivary allergens of *Culicoides* midges. It is the most common allergic skin disease of horses and is characterized by intense seasonal pruritus, alopecia, and excoriation.[306,396] The clinical signs combined with increased numbers of IgE-positive cells in the skin along with high levels of *Culicoides*-specific IgE in serum provided evidence for immediate (type I) hypersensitivity in the immunopathogenesis of IBH.[385,386] This pathogenesis was further supported by studies using monoclonal antibodies against equine IgE[390] and confirmed by transferring the intradermal allergic reaction to normal horses using IgE from IBH-affected horses.[397] In some breeds a genetic predisposition based on an MHC II linkage has been demonstrated.[286,398,399] Interestingly, Icelandic horses, which are particularly affected, do not develop IBH in Iceland because *Culicoides* spp. do not exist in Iceland. However, when these horses born in Iceland are exported later in life to *Culicoides*-endemic countries, a high percentage develop IBH.[306,400] In terms of lack of exposure to *Culicoides* antigens early in life along with high intestinal nematode burdens in Iceland,[373] these observations are consistent with the hygiene hypothesis. Moreover, it has been shown that horses with IBH have reduced T_{reg} responses compared with unaffected horses.[304-306,400]

Recurrent Airway Obstruction

Recurrent airway obstruction (RAO) is a severe inflammatory disease of middle-aged and older horses induced by exposure of susceptible horses to inhaled organic dust, generally from hay, although a summer pasture–associated form is also observed in the southern United States and in Europe.[296,401,402] Hay dust contains a mixture of mold spores, forage mites, particulates, and endotoxins, which can induce and exacerbate airway inflammation. Removal of the hay dust by returning the horse to pasture leads to decreased inflammation within a few days. In RAO-susceptible horses, exposure to hay dust leads to invasion of the lungs and airways by neutrophils within 4 to 6 hours and concurrent airway obstruction resulting from bronchospasm, inflammation, and increased mucus viscosity, which principally affect the bronchioles. RAO-affected horses develop nonspecific airway hyperresponsiveness, which is a bronchospasm in response to a wide variety of stimuli including inflammatory mediators and neurotransmitters. Horses affected by RAO demonstrate increased histologic lesions and worsening airway function with increasing age. In addition, significant histopathologic changes are present before abnormal airway function can be detected.

The immunologic basis of RAO remains incompletely understood. Two pieces of evidence suggest a role for type I hypersensitivity in this disease. First, IgE levels are increased in bronchoalveolar (BAL) fluid of RAO-affected horses,[382] and second, allergen-specific IgE is increased in affected horses.[387,403,404] However, the immediate onset of airway obstruction typical of type I hypersensitivity to exposure to allergens is rarely observed, as clinical signs of RAO only develop several hours after antigenic exposure.[405] In addition, influx of eosinophils is not a feature of RAO. A study of immunoregulatory cytokines in RAO demonstrated evidence for a T_H2 bias with increased levels of IL-4 and IL-5 and decreased IFN-γ mRNA in BAL cells.[406] However, other investigators have documented increased IFN-γ levels in RAO and a lack of T_H2 polarized responses.[407,408] It seems likely that a number of complex immunologic processes are involved in the pathogenesis of RAO,[296,401] including a predominant T_H2 response or at least a dysregulation of cytokine responses associated with a disruption in T_H2/T_H1 balance,[206,409] IgE-mediated pathology, and T_H17 responses[295] accompanied by increased expression of TLR-4 and CXCL8,[410] leading to neutrophilic inflammation. Neutrophil-mediated inflammation predominates in RAO, and several studies suggest that IL-17 responses, and by extension T_H17 responses, are involved in its pathogenesis.[206,295,296] Finally, the percentage of T_{regs} in the airways of horses with RAO increases, and this may be a mechanism to limit immunopathology.[307]

Neonatal Isoerythrolysis and Alloimmune Thrombocytopenia

Neonatal isoerythrolysis (NI) is a common condition of foals and is extensively reviewed elsewhere in this text. The condition results from the passive transfer of maternal antibodies in colostrum, which recognize allogeneic foal erythrocyte antigens principally of the Aa and Qa blood group inherited from the sire. A similar condition occurs in mules due

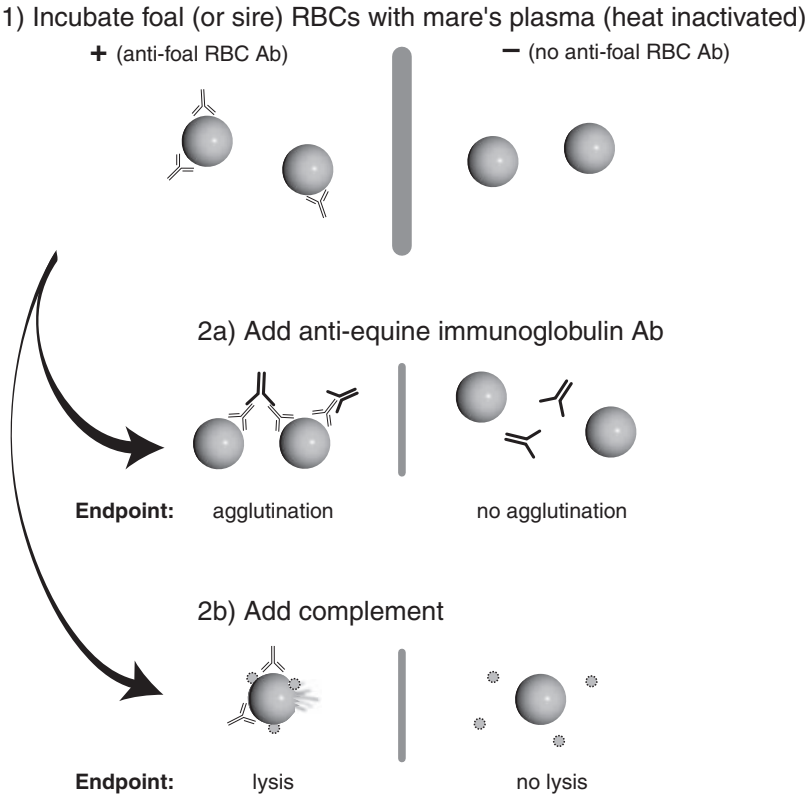

FIG. **1.20** Neonatal isoerythrolysis test. *Ab,* Antibody; *RBCs,* red blood cells.

to inheritance of a donkey-specific erythrocyte antigen.[411,412] A severe, potentially life-threatening, anemia results as the antibody-positive erythrocytes are removed by the reticuloendothelial system or lysed by complement. A similar condition causing severe neonatal thrombocytopenia in horses and mules less commonly affects platelets.[413-415] These conditions are typical of type II hypersensitivities and are mediated by circulating IgG recognizing cell surface antigens on erythrocytes. For newborn foals at risk of NI, a jaundice foal agglutination test can be performed before allowing the foal to nurse by making 1-mL serial dilutions of the mare's colostrum in saline (1:2–1:128), adding 1 drop of the foal's anticoagulated (EDTA) whole blood to each tube and mixing, centrifuging at medium speed (300–500 × g) for 2 to 3 minutes, then observing for agglutination of the red blood cell pellet by inverting the tubes. If strong agglutination occurs at or above the 1:16 dilution (≥1:64 for mule foals), the foal should not be allowed to nurse the mare. To prevent NI, the foal is muzzled and not allowed to nurse during the first 36 hours. An alternative source of colostrum (or commercial equine immunoglobulin product) is administered to the foal, and the mare is milked out during this period and her colostrum discarded. Diagnosis of NI can be confirmed using a variation of the Coombs test (Fig. 1.20).

Purpura Hemorrhagica

Purpura hemorrhagica is an uncommon acute type III hypersensitivity (immune complex) disease in horses characterized by edema of the head and limbs; leukocytoclastic vasculitis; petechial hemorrhages in mucosae, musculature, and viscera; and sometimes glomerulonephritis.[416,417] It is most commonly associated with *Streptococcus equi* exposure or infection but can also occur after *Corynebacterium pseudotuberculosis* infection or after vaccination with *S. equi* M protein (SeM).[418] Serum of affected horses contains immune complexes of *S. equi*–specific antigens (SeM) with IgA.[416] These immune complexes become deposited on the walls of small blood vessels, resulting in vasculitis, as discussed previously. The glomerulonephritis sometimes seen in association with purpura has been attributed to deposition of similar immune complexes containing streptococcal antigens and IgG.[419]

Cell-Mediated Hypersensitivity Diseases in the Horse

There are relatively few documented type IV (cell-mediated or delayed) hypersensitivity conditions in the horse in which the immunologic mechanism has been confirmed, although contact hypersensitivities have been reported.[365] One exception is recurrent uveitis, which is a very well-characterized example of type IV hypersensitivity in the horse.

Equine Recurrent Uveitis

Equine recurrent uveitis (ERU), also known as moon blindness or periodic ophthalmia, is the most important cause of blindness in horses.[420] The disease results in both acute and chronic ocular inflammatory disease, and chronic sequelae include development of posterior and anterior synechiae, cataracts, lens opacities, secondary glaucoma, and blindness. Eyes of affected horses contain IgG antibodies and autoreactive T cells specific for retinal antigens.[421] Although a specific cause has not been identified, sensitization to a variety of pathogens, and in particular to *Leptospira* spp.,[422,423] is

thought to induce the immune-mediated pathology that is central to the disease.[424] Early and aggressive treatment with corticosteroids and other antiinflammatory agents is essential to avoid visual debility or blindness.[425] Unfortunately, treatment failures are common, and the disease frequently recurs with further ocular damage months after the initial event, commonly leading to euthanasia.[420] Of horses with ERU, 56% become blind in one or both eyes, and 20% become completely blind.[426]

The understanding of the immunologic basis of ERU has been extended by studies of the immunoregulatory events in the eyes of affected horses. It has been shown that the T lymphocytes that invade the iris-ciliary body during this disease produce a pattern of IFN-γ cytokine production typical of a T_H1 response.[427] More recently, mononuclear cells in eyes from horses with ERU were found to be positive for IL-17 and IL-23, strongly suggesting that T_H17 cells are involved in the pathogenesis of ERU.[294] Taken together, these studies indicate that type IV hypersensitivity mediated by T_H1 and likely T_H17 cells contributes to the immunopathogenesis of ERU.

Autoimmunity

Autoimmune diseases occur when T and/or B cells respond to self antigens resulting in tissue damage. The hypersensitivity reactions discussed earlier comprise the mechanisms of this damage mediated by self reactive antibodies and/or T cells. Autoimmune diseases are rare and only arise when there is a break in self tolerance. A break in central tolerance occurs when self reactive B or T cells are not negatively selected during the maturation process in the bone marrow and thymus, as discussed previously under Equine Immunology. When self reactive lymphocytes escape deletion in the primary lymphoid organs and are released into the circulation, peripheral tolerance mechanisms exist to control autoreactivity. One of these peripheral tolerance mechanisms is the downregulation of self reactive T cells by T_{regs}. Because B cells have additional mechanisms to generate receptor diversity (i.e., somatic hypermutation), B cells have a higher probability of developing self reactivity than T cells. Thus many autoimmune diseases with known mechanisms involve autoantibodies. Autoreactive lymphocytes may respond to self antigens due to molecular mimicry, in which foreign antigens are similar enough to self antigens that the activated lymphocytes cross react with self antigen. Molecular mimicry is involved in the thrombocytopenia associated with HIV-1 infection in people where antibodies against HIV-1 envelope proteins also react with surface glycoproteins on platelets.[428] It is possible that a similar mechanism contributes to thrombocytopenia in horses infected with EIAV. Autoreactive lymphocytes can also cause damage when they gain access to immunologically privileged sites where they are normally excluded and in which self antigens are normally sequestered. Examples of these sites include the central nervous system and the eye. The autoimmune basis for ERU likely involves molecular mimicry between the *Leptospira* LruA and LruB antigens and equine intraocular proteins,[429] as well as self reactive T cells gaining access to the immunologically privileged intraocular location where they then cause damage.

A number of equine diseases are considered to be autoimmune in etiology, but few have been extensively studied.[430] Much of the explanation given earlier for the immunopathologies involved in hypersensitivity disease can be applied to autoimmune disease. Well-described equine diseases with autoimmune components include those with characteristics of type II hypersensitivities such as immune-mediated hemolytic anemia in adults.[431,432] Autoimmune diseases with skin manifestations, including pemphigus foliaceus, pemphigus vulgaris, and systemic lupus erythematosus (SLE), have been well characterized in humans and dogs. The pemphigus complex involves autoantibodies against skin adhesive proteins (desmoglein 1 and desmoglein 3 for pemphigus foliaceus and pemphigus vulgaris, respectively) and thus is characteristic of type II hypersensitivity disease. SLE is multifactorial, involving autoantibodies and immune complexes, and thus has characteristics of type II and type III hypersensitivity diseases. Although rare, pemphigus foliaceus and vulgaris[433-436] and SLE[435,437] have been described in horses. As discussed, equine recurrent uveitis has features of type II and type IV hypersensitivity, and there is some morphologic and immunologic evidence for classifying polyneuritis equi (cauda equine syndrome) as an autoimmune disease with immunopathology consistent with type IV hypersensitivity.[438-442]

With the exception of a few conditions, including some of those discussed previously, there are few autoimmune diseases where the cause is well understood. One of the exceptions is the anemia that can develop subsequent to administration of human recombinant erythropoietin to horses.[443,444] There is substantial evidence that horses mount an antibody response to the exogenous human erythropoietin that cross reacts with the endogenous equine hormone (molecular mimicry) and results in erythroid hypoplasia. The lesson of this example may be that in the modern world, with increasing availability of recombinant drugs that mimic natural biologic compounds, we would do well to remember that the immune system has an exquisite ability to distinguish what is foreign and to reject it vigorously.

IMMUNODEFICIENCY

Immunodeficiencies occur in both primary and secondary forms and have been extensively reviewed.[325,445-448] Primary immunodeficiencies are congenital and have a genetic basis, whereas secondary immunodeficiencies result from failure of transfer of passive immunity (FTPI) in foals, immunosuppressive infections or drug treatments, neoplasia, stress, or malnutrition. Immunodeficiencies can affect specific components of the immune system, such as the lymphoid or phagocytic system. Typically immunodeficiency is suspected in any of the following circumstances:

- Onset of infections in the first 6 weeks of life
- Repeated infections that are poorly responsive to therapy
- Infections caused by commensal organisms or organisms of low pathogenicity
- Failure to thrive
- Familial history of immunodeficiency
- Disease resulting from the use of attenuated live vaccines
- Failure to respond to vaccination
- Marked neutropenia or lymphopenia that persists for several days

Equine immunodeficiency is most commonly suspected on the basis of the first three reasons: increased susceptibility to infections. The most common immunodeficiency recognized in clinical practice is FTPI in foals.[325,449-451] Other causes of immunodeficiency vary from well-defined clinical entities, such as severe combined immunodeficiency of Arabian

TABLE **1.7 Components of the Immune System That Can Be Evaluated in Horses and Appropriate Tests for Quantitative or Functional Analyses of Each Component**

Component	Quantitative Tests	Functional Tests
Immunoglobulin	**Radial immunodiffusion, membrane-ELISA, electrophoresis, precipitation/coagulation tests**[a]	**Response to vaccination**
Lymphocytes	**Complete blood cell count, DNA-PK$_{cs}$ and SLA5A3 genetic evaluation**,[b] flow cytometric evaluation of lymphocyte subsets	**Response to vaccination, intradermal PHA test**, in vitro lymphoproliferation assays
Neutrophils and macrophages	**Complete blood cell count**	Chemiluminesence and bactericidal assays, flow cytometric evaluation of phagocytosis and oxidative burst
Eosinophils and basophils	**Complete blood cell count**	No commonly available tests
Complement	No commonly available tests	No commonly available tests
Acute phase proteins	SAA,[c] electrophoresis	No commonly available tests

Note: The list of tests is not exhaustive but is restricted to tests of likely practical value for which normal data are available. Tests listed in **bold** are routinely available to clinicians.

foals,[452,453] to cases where immunodeficiency is suspected on clinical grounds but the specific cause or nature of the problem is difficult or impossible to define. Regardless of their cause, immunodeficiencies result in increased susceptibility to infections, which are in turn poorly responsive to appropriate therapy. Defects in antibody production tend to predispose to pyogenic bacterial infection, whereas deficiencies in cell-mediated responses lead to infections with organisms normally nonpathogenic in horses such as *Candida albicans, Cryptosporidium* spp., or adenovirus. When any immunodeficiency is suspected, specific diagnostic tests are indicated to define the deficiency. The aim of the next section is to identify tests clinicians can apply practically in such cases and to explain their merits and limitations.

Tests of Equine Immune Function

Tests of components of the immune system (e.g., lymphocytes, immunoglobulins) generally can either quantitate that component or measure its functional capacity. In Table 1.7 the components of the immune system that currently can be analyzed in this manner are identified, and corresponding quantitative and functional tests are listed. The table also identifies those tests that are likely to be commercially available, and it should be noted that few of the functional tests are available unless the clinician is able to identify a capable equine immunologic research laboratory. Despite these limitations, the available tests do permit the identification of many of the well-defined causes of immunodeficiency in horses.

Tests of Antibody-Mediated Immunity

Although some assays of B lymphocyte function and number are described later, the principal tests of humoral immunity are quantitative assays of immunoglobulin concentration and measurements of specific antibody responses to vaccination. The variety of classes of immunoglobulins in the horse is complex, as reviewed earlier in this chapter. For practical purposes attention is generally focused on IgG, IgA, and IgM.

The current "gold standard" for measurement of concentrations of immunoglobulin classes is the radial immunodiffusion (RID) assay. The disadvantages of this test are its cost and the time required to perform the assay (24 hours or longer), which make it generally unsuitable for screening for FTPI in foals. Nevertheless, this form of test remains the single most valuable assay available to the clinician trying to measure total antibody concentrations in the horse. Currently, test kits are available for equine IgG and IgM (Triple J Farms, Bellingham, WA). The RID test is based on the ability of antigen and antibody to precipitate at equivalence when combined in proportion in agar gel plates. The serum being tested is added to punched-out wells in agar, impregnated with antibody to the specific immunoglobulin class being measured, and allowed to diffuse outward and bind with the anti–class-specific antisera. A precipitate forms when equivalence is reached and the area within the precipitate ring is directly proportional to the concentration of the patient's immunoglobulin class. Enzyme-linked immunosorbent assay (ELISA) test kits are also available for quantitation of equine IgA, IgG3/5 (IgG[T]), and IgM (Bethyl Laboratories, Montgomery, TX). Although not commercially available, serum concentrations of the IgG subclasses (IgG1, IgG4/7, and IgG3/5) can be determined by ELISA in equine immunologic research laboratories. Normal ranges of serum immunoglobulin concentrations are typically provided with commercial kits, and normal serum, milk, and colostrum concentrations of equine immunoglobulins have been described in numerous published studies. These results have been recently summarized and are available in tabular form.[249,326] One of these representative studies reported IgM, IgG, and IgA concentrations in normal adult horse serum to be 103 ± 5 mg/dL, 1913 ± 754 mg/mL, and 225 ± 140 mg/dL, respectively.[316]

By far the most common clinical question regarding immune status is whether a foal has achieved adequate transfer of passive immunity, which is defined as a serum IgG concentration greater than 800 mg/dL. Serum IgG concentrations less than 400 mg/dL and between 400 and 800 mg/dL have defined complete and partial FTPI, respectively. Despite these traditional cutoff values, a recent study in a large number of hospitalized foals demonstrated that foals with serum IgG

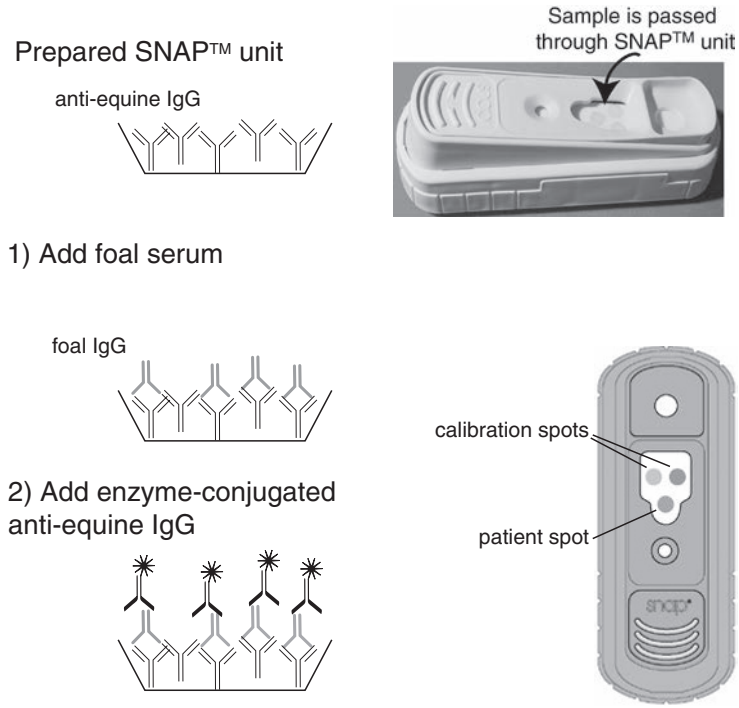

FIG. **1.21** Membrane-based ELISA system (SNAP, Idexx) for measuring serum IgG concentration. The diluted test equine serum sample is applied to a "patient spot" on a membrane impregnated with a capture antibody recognizing equine IgG. Calibration spots corresponding to specific concentrations of equine IgG (400 and 800 mg/dL) are adjacent to the patient spot. An enzyme-conjugated second antibody against equine IgG is applied to the entire membrane, and finally the device is triggered to release an enzyme substrate that produces a colored reaction corresponding to the amount of enzyme-conjugated antibody on the membrane. By comparison with the calibration spots the test sample IgG concentration can be estimated.

concentrations below 800 mg/dL are more likely to die than foals with serum IgG concentrations above 800 mg/dL.[454] The distinction between complete and partial FTPI is therefore not particularly relevant in making therapeutic decisions, at least in the hospitalized foal population. Tests used to determine transfer of passive immunity status should be rapid to allow early initiation of therapy, which decreases the utility of the RID test. A wide variety of other tests have been used for this purpose, including zinc sulfate turbidity, latex bead agglutination, ELISA, turbidometric analysis, glutaraldehyde coagulation, and infrared spectroscopy.[455-460] In the glutaraldehyde coagulation test (Gamma-Check E, Plasvacc USA, Templeton, CA), glutaraldehyde forms insoluble complexes with basic proteins in the serum. Clot formation in 5 minutes or less is equated with a serum IgG concentration of 800 mg/dL or greater. This test is good for initial screening because it is simple, rapid, inexpensive, and accurate for confirming an IgG concentration ≥800 mg/dL (high sensitivity for ruling out FTPI). However, the lack of clot formation within 5 minutes does not always indicate FTPI (can have low specificity), so confirmatory testing is warranted.[461] Although more expensive, the higher specificity and the ease of use and rapid results make the membrane filter–based ELISA tests (e.g., SNAP, Idexx Laboratories, Westbrook, ME) the preferred choice for many (see Fig. 1.21). Like the glutaraldehyde coagulation test, this test can be performed foal-side with whole blood. Although the membrane-filter ELISA is more specific in confirming FTPI, it is slightly less sensitive in detecting FTPI than the glutaraldehyde coagulation test.[461]

An additional test that provides information about serum immunoglobulin content is serum protein electrophoresis. This test gives quantitative information about albumin, α- and β-globulins (acute inflammatory proteins), and γ-globulin (immunoglobulin) concentrations (see Fig. 1.22). The utility of protein electrophoresis is demonstrated when detecting the monoclonal gammopathies that accompany plasma cell myelomas.[462] Hyperglobulinemia can occur during inflammation with increased production of α- and β-globulins and during infections in normal horses with polyclonal production of γ-globulins (immunoglobulins). Nevertheless in the diagnosis of immunodeficiencies, electrophoresis should be seen as an adjunct to RID assays, which are superior in terms of specificity and sensitivity.

Tests of Cellular Immunity

The simplest test of the cellular arm of the immune response is a complete blood count (CBC) to determine total and differential leukocyte numbers, and this should be the starting point for any evaluation. Identification of an absolute lymphopenia, for example, is a critical finding in a suspected case of severe combined immunodeficiency (SCID) in an Arabian foal, although the result must be repeatable in a series of tests given the variability of blood lymphocyte counts. Such a finding would logically lead to genetic testing to confirm the diagnosis.[463] The evaluation of a lymph node biopsy for normal architecture, including the presence or absence of cells in either the B- or T-lymphocyte–dependent areas, is another powerful test of the immune system.

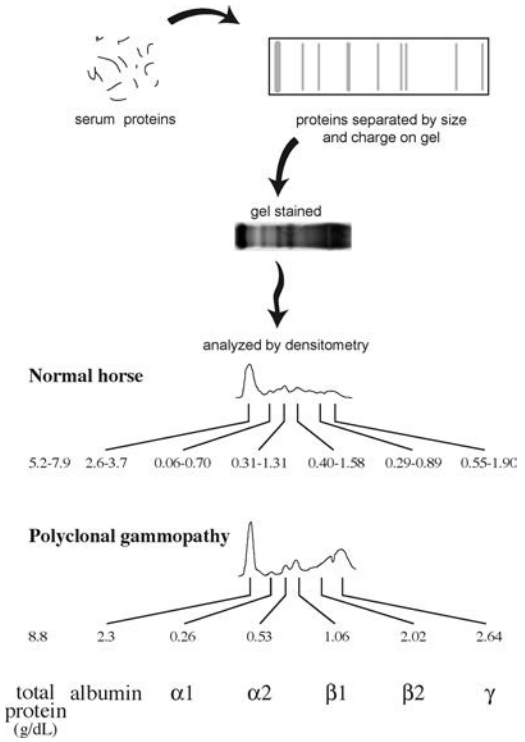

FIG. **1.22** Serum protein electrophoresis. The complex mixture of serum proteins are separated by migration through an agarose gel slab in response to an electric field. Proteins are stained and the intensity of staining of different bands is measured by densitometric scanning. These measurements are used to identify different types of globulins and albumin corresponding to stained bands.

However, in profound immunodeficiencies such as SCID, lymphoid organs may be impossible to locate antemortem. Beyond these readily available conventional techniques, three other more complex types of analyses can be of value: flow cytometric analysis (primarily of lymphocytes, although other cell types can be analyzed), lymphocyte function testing, and functional analysis of phagocytic cells.

Flow Cytometry. Flow cytometry provides additional cellular information by using monoclonal antibodies conjugated to fluorochromes to differentiate morphologically identical lymphocytes into distinct subsets. Flow cytometers use lasers to measure multiple parameters including light scatter and fluorescence characteristics of cells. The fluidics system of the flow cytometer delivers cells one by one to a point in space intersected by a laser beam. The laser beam emits light of a defined wavelength to illuminate the cell, which results in both scattered light of the same wavelength and fluorescent light of a different wavelength that is collected by photodetectors and converted into electronic signals. Optical filtration separates scattered light and fluorescent light to permit their independent measurement. Side-scatter light is dependent on the granularity of cells, whereas forward-scatter light is dependent on the size of the cell. Fluorescent light can be detected independently for a number of fluorochromes of different wavelengths, and typical examples are fluorescein and phycoerythrin. High-end flow cytometers have multiple lasers with different wavelengths and can detect a large number of colors (e.g., 5 lasers with detection of 18 colors), as well as side and forward scatter.

Signals are typically displayed as either histograms or dual-parameter correlated plots (dot plots), and statistical analysis is completed by computer. Histograms are analyzed by setting markers in particular channels and dot plots by drawing rectangular or polygonal boxes around data points. The software also allows the setting of "gates" for determining which events are collected in the first instance or which events are to be included in later analyses. Typically these gating techniques are employed using forward and side scatter to differentiate cell types, such as lymphocytes, monocytes, and granulocytes. The final key characteristic of flow cytometers is their capacity to analyze large numbers of cells in a short time, making it possible to analyze many thousands of cells in a matter of seconds.

An example of such an analysis is shown in Fig. 1.23. The upper panels (A) show side- versus forward-scatter plots of PBMCs isolated from a normal foal (left panel) and SCID foal (right panel). A typical distribution of lymphocytes (red gate), monocytes/blasting cells (blue gate), and granulocytes/neutrophils (green gate) is observed in the normal foal. It should be noted that the Ficoll centrifugation procedure for PBMC isolation removes the vast majority of neutrophils. In the SCID foal, there are very few cells in the normal lymphocyte gate, with the majority of cells being monocytes and larger granular cells, which are most likely NK cells. Standard two-color dot plots analyzing all cells within the lymphocyte and monocyte/blasting cell gates are shown in the next panels (B). In the normal foal, 43% of the PBMCs are labeled by the fluorochrome-conjugated anti–equine CD3 monoclonal antibody and are therefore T cells (upper and lower right quadrants combined). Of these T cells, 26% (or 11.2% of all PBMCs analyzed) are $CD8^+$ T cells (upper right quadrant). These cells are double labeled with the anti–equine CD3 monoclonal antibody and an anti–equine CD8 monoclonal antibody conjugated to a fluorochrome with a different color. The cells in the upper left quadrant are $CD8^+$ but are not T cells and likely represent $CD8^+$ NK cells. Compared with the normal foal, the SCID foal has virtually no T cells but does have a similar percentage of $CD8^+$ non–T cells (NK cells). Additional analysis using fluorochrome-conjugated monoclonal antibodies against equine B-cell and $CD4^+$ T-cell markers would reveal a similar absence of these lymphocyte populations in the SCID foal. Finally, the lower panels (C) show a standard single-color dot plot and corresponding histogram analysis of $CD8^+$ cells in the normal foal.

Lymphocyte Function Testing. Unfortunately tests of lymphocyte function are generally limited in their availability in the field. In vitro tests of lymphocyte function include lymphocyte proliferation responses to mitogens such as pokeweed mitogen, phorbol 12-myristate 13-acetate (PMA) with ionomycin, phytohemagglutinin (PHA), or concanavalin A (ConA). These assays are generally not commercially available, although they are commonly performed by immunologic researchers. It is essential to perform parallel studies on suitable age-matched control horses. The endpoint of these tests is usually read by determining the incorporation of radioactive ^3H-thymidine into the total population of proliferating cells.[464] Nonradioactive alternatives exist, and one strategy utilizes the thymidine analog 5-ethynyl-2′-deoxyuridine (EdU), which readily incorporates into the DNA of replicating cells.[465] The alkyne group of EdU reacts with fluorescent azides in a Cu(I) catalyzed "Click" reaction, which can then be detected using flow cytometry. An EdU incorporation–Click assay kit is available to researchers (Click-iT EdU Imaging Kit, ThermoFisher Scientific),

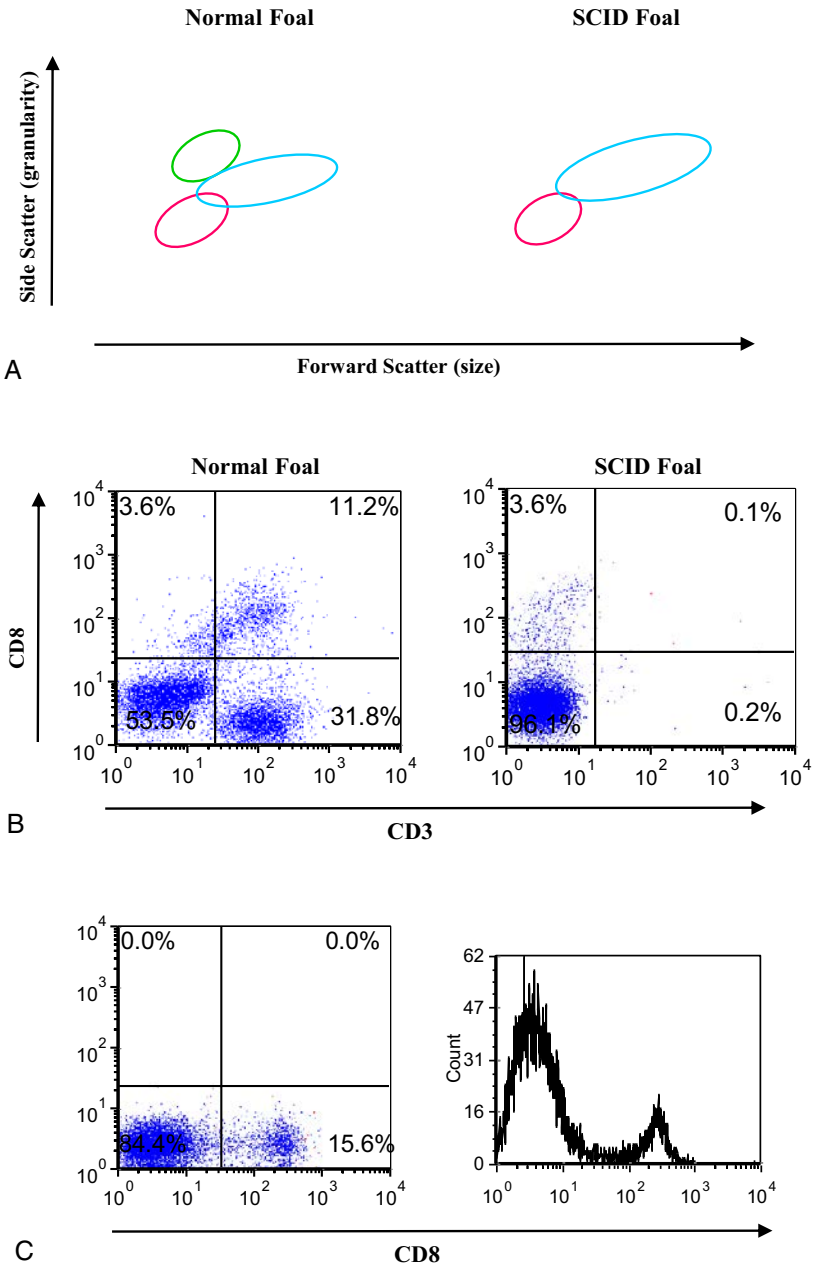

FIG. **1.23** Flow cytometric analysis of PBMCs from a normal foal and an SCID foal. See text for description.

and has shown utility for detecting equine lymphoproliferative responses (see Fig. 1.24). Finally, flow cytometry can be used to determine functional characteristics of various equine lymphocyte subsets by detecting intracellular production of cytokines following nonspecific stimulation with mitogens or antigen-specific stimulation (Fig. 1.24).

Two tests that can be of value and are readily available in practice are response to vaccination, as measured by rising serum titers, and response to intradermal PHA, which is dependent on a delayed-type hypersensitivity T lymphocyte response and develops in normal animals without prior sensitization.[466] A 50-µg dose of PHA in 0.5 mL of phosphate-buffered saline is injected intradermally, and 0.5 mL of phosphate-buffered saline is administered intradermally at a distant site. At the PHA site, an increase in wheal size of 0.6 mm or less indicates a defect in cell-mediated immunity. Response to vaccination has proven to be a potent means of identifying immunodeficiency in such conditions as juvenile llama immunodeficiency syndrome.[467] Similarly the equine immune response to a polyvalent inactivated bovine vaccine has been used to document the immunosuppressive effects of corticosteroid administration.[468] For practical purposes, response to rabies or tetanus vaccination may be the most suitable available tests provided that no routine vaccination had been administered in the immediate past. Equine rabies or tetanus antibody titer determination is typically commercially available, and the majority of available vaccines are sufficiently potent to provoke a fourfold increase in titer in normal horses.

Phagocyte Function Testing. Testing of equine neutrophil migration, phagocytic function, and bactericidal activity has been reported by several investigators,[328,330,469,470] and more quantitative information has been obtained using flow

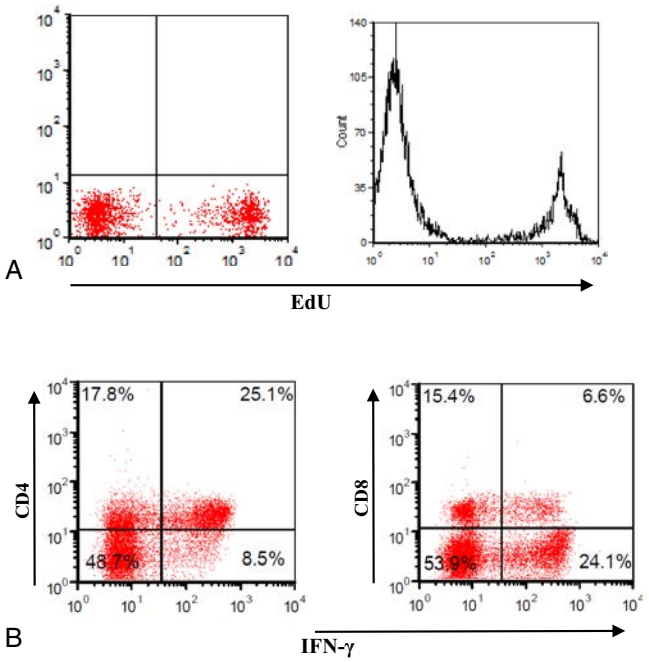

FIG. **1.24** Flow cytometric evaluation of lymphoproliferation and intracellular cytokine production. ***(A)*** Dot plot *(left panel)* and histogram *(right panel)* showing 5-ethynyl-2′-deoxyuridine (EdU) incorporation by proliferating equine PBMCs following in vitro stimulation with antigen. In this case the PBMCs were isolated from a horse infected with *Theileria equi* and stimulated with a *T. equi* sporozoite lysate for 4 days. ***(B)*** Two-color analysis of $CD4^+$ T cells *(left panel)* and $CD8^+$ T cells *(right panel)* for IFN-γ production. Isolated PBMCs were stimulated 24 hours with PMA + ionomycin, then surface labeled with fluorochrome-conjugated monoclonal antibodies against equine CD4 or CD8, followed by intracellular staining using a different fluorochrome-labeled monoclonal antibody against equine IFN-γ. $CD4^+$ cells (or $CD8^+$ cells) producing IFN-γ appear in the upper right quadrants.

cytometric approaches.[220,331,471] The techniques employed are typically only available in research laboratories.

Tests of Innate Immunity

Components of the innate immune response that have been measured in the horse include the numbers of granulocytes and monocytes in peripheral blood (CBC) and their phagocytic function (see earlier discussion), natural cytotoxicity in terms of lymphokine-activated killer (LAK) cell activity,[469,472-474] and measurement of soluble factors including several acute phase proteins.[475-480] Serum amyloid A (SAA) is one acute phase protein that can serve as an early indicator of inflammation, and a rapid stall-side test is now available (StableLab, Sligo, Ireland). Equine complement activity can be measured using hemolytic or flow cytometric assays.[481,482] With the exception of the CBC and SAA tests, tests of innate immune function have very limited availability.

Primary Immunodeficiencies

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a lethal primary immunodeficiency affecting Arabian foals, characterized by failure to produce functional B and T lymphocytes and resulting in the complete lack of adaptive immune responses.[445,453,483,484] The vast majority of affected foals are Arabians, in which the condition is inherited as an autosomal recessive trait[485] and results from a lack of DNA protein kinase (DNA-PK) activity that prevents V(D)J recombination.[452,486] In studies conducted in the United States and reported in 1977, the incidence of SCID among Arabian foals was at least 2% to 3%,[487] suggesting a carrier prevalence rate between 25% and 26%. However, in more recent studies conducted in the United States using a precise molecular diagnosis of the carrier state, carrier prevalence was consistently 8%.[488,489]

Clinical Signs and Laboratory Findings. Affected foals are clinically normal at birth but develop signs of infection during the first 1 to 3 months of life. The age of onset of infection depends on the adequacy of transfer of passive immunity and degree of environmental challenge. As maternal antibodies are catabolically eliminated SCID foals are increasingly susceptible to infections with bacterial, viral, fungal, and protozoal agents. Bronchopneumonia is a prominent disease, often caused by adenovirus (the most significant pathogen of SCID foals, affecting two thirds of them),[490] *Pneumocystis carinii,* or *Rhodococcus equi.* Enteritis, frequently caused by *Cryptosporidium parvum,*[491] arthritis, and omphalophlebitis are common. Adenoviral infection frequently extends to the gastrointestinal and urogenital systems and causes pancreatic disease leading to loss of endocrine and exocrine tissue and possibly contributing to the impaired growth and weight loss observed in SCID foals.[445]

Clinical signs include nasal discharge, coughing, dyspnea, diarrhea, fever, and weight loss. Although antibiotics, plasma, and supportive care prolong the course of disease, death invariably occurs before 5 months of age. The only exception was a single foal experimentally treated with a bone marrow transplant from a histocompatible donor that lived until 5 years of age before dying of an unrelated cause.[492,493]

A consistent hematologic finding is absolute lymphopenia (less than 1000/µl; usually less than 500/µl), with neutrophilia a variable finding resulting from bacterial infection. Total serum globulins and serum IgG can be normal in the first weeks of life if transfer of passive immunity is adequate but decline as maternal immunoglobulins are catabolized. Normal foals synthesize IgM from 180 days of gestation and have detectable IgM at birth in presuckle samples, whereas SCID foals have no IgM.[314] After colostral ingestion SCID foals also have IgM, although with its relatively short half-life it is undetectable by 2 to 4 weeks of age.[445]

Etiology and Pathogenesis. Normal maturation of T and B lymphocytes requires rearrangement of germ line V, D, and J genes to encode the required wide diversity of TCRs and BCRs, through the process of V(D)J recombination (see under Equine Immunology). This process depends on two groups of enzymes, the recombinase activating gene (RAG) products, which cut DNA, and DNA-PK, which is critical for DNA double-stranded break repair. In equine SCID, the genetic defect is a 5-base pair deletion in the gene encoding the catalytic subunit of DNA-PK (DNA-PKcs).[452] This frameshift mutation truncates the protein, resulting in a complete lack of DNA-PK activity.[452,486] Because DNA-PK is required for DNA strand break repair, V(D)J recombination does not occur.[486] As a consequence, developing T cells and B cells do not produce functional TCRs and BCRs and thus fail the positive selection process in the primary lymphoid organs.

Diagnosis. Previously antemortem diagnosis of SCID was suggested by appropriate clinical signs in a foal of Arabian breeding with persistent marked lymphopenia (usually less than 500/µL) and the absence of serum IgM by RID. If presuckle serum is unavailable for testing, serum IgM cannot be used as a diagnostic aid until the foal is older than 3 weeks. All suspected cases required confirmation by the necropsy finding of hypoplasia of the spleen, thymus, and lymph nodes with the absence of any normal lymphoid architecture. With the identification of the genetic defect causing SCID, the current standard for definitive diagnosis is demonstrating that the foal is homozygous for the defective SCID gene. This test depends on PCR amplification of a specific region of the DNA-PKcs gene, and evaluation of the amplicon using probes specific for normal and mutant sequences.[463] This test is commercially available (VetGen, Ann Arbor, MI); can be performed on whole blood, pulled hair, or cheek swabs; and identifies homozygous-affected, heterozygous carrier, and normal animals.

Treatment. Supportive care may prolong the course of disease, but affected foals die by 5 months. Immunologic reconstitution is currently impractical and an ethically questionable procedure.

Client Education. Arabian mares and stallions intended for breeding should be tested for SCID carrier status. When two heterozygous carriers are bred the progeny will include 25% SCID foals, 50% carriers, and 25% homozygous normal foals. Therefore prevention of SCID requires identification of carriers and either their removal from the breeding population or breeding exclusively with homozygous normal animals and subsequent testing of progeny before their own breeding future is planned.

Foal Immunodeficiency Syndrome

In the late 1990s a syndrome of anemia, immunodeficiency, and peripheral ganglionopathy was described in Fell pony foals and termed *Fell pony syndrome*.[494,495] This syndrome has also been identified in Dales pony foals and is now known as foal immunodeficiency syndrome (FIS).[496-498] Affected foals become ill within 2 to 3 weeks of birth and die by 3 months of age. Affected animals have been described outside the United Kingdom[499] and in the United States.[500]

Clinical Signs and Laboratory Findings. Clinical signs include ill thrift, anemia, respiratory infection, glossal hyperkeratosis, and diarrhea. Anemia can be severe and is normochromic and normocytic to macrocytic, with small numbers of late erythroid precursors in bone marrow.[495,501] Although bone marrow erythroid precursors are present at birth, erythroid hypoplasia develops rapidly and progresses to aplasia, resulting in severe progressive nonregenerative anemia.[502] Some foals are affected by cryptosporidial enteritis and adenoviral bronchopneumonia and pancreatitis. Plasma proteins and blood lymphocyte counts can be normal or low. Immunodeficiency is due to profound B-cell lymphopenia,[503,504] with a lack of B cells in the bone marrow and lymph nodes and very few within germinal centers in the spleen.[500,502] Concentrations of IgG subclasses are significantly lower in FIS foals compared with age-matched controls, coinciding with reduction of maternally derived antibodies and correlating with B-cell lymphopenia.[503] Some studies have described normal IgG concentrations in FIS foals, although decreases would likely have been observed had the foals survived longer.[500,502] IgM concentrations consistently decline in FIS foals compared with controls.[502,503] Taken together these observations indicate an absence of endogenous immunoglobulin production in FIS foals caused by the lack of functional B cells. In contrast, T-cell subsets measured by flow cytometry are normal, and lymphoproliferative responses are normal.[500,505] However, MHC II expression is low,[500,505] thymic hypoplasia is observed,[495,500] and T cells can be absent in the bone marrow.[502] Thus it is possible that an unidentified defect in T-cell function exists. This is further suggested by the occurrence of opportunistic infections in the face of adequate levels of maternally derived antibodies. On necropsy, lymphoid organs can be small, and secondary lymphoid follicles and plasma cells are absent.[495,500,502] Neuronal changes are characterized by neuronal chromatolysis in the cranial mesenteric, dorsal root, and trigeminal ganglia.[495]

Etiology and Pathogenesis. FIS is inherited as an autosomal recessive trait,[496] and a mutation in the sodium/myo-inositol cotransporter gene (SLA5A3) on chromosome 26 is strongly associated with the syndrome.[498] This is an osmotic stress response gene that encodes a cell membrane transporter protein that cotransports sodium ions and myo-inositol. Despite the strong association, the specific role of this gene in erythrocyte and B-cell development is unknown, and formal proof that the SLA5A3 mutation is the direct cause of FIS requires additional functional studies.

Diagnosis. The presence of anemia, diarrhea, ill thrift, and/or respiratory and other infections in young Fell and Dales pony foals along with low IgM levels and B-cell lymphopenia (as measured by flow cytometry) allows a presumptive diagnosis. Confirmation of FIS can now be made by demonstrating that the foal is homozygous for the SLA5A3 mutation, using the available DNA test (Animal DNA Diagnostics, Cambridge, UK). This PCR-based test is performed on pulled hair and identifies homozygous-affected, heterozygous carrier, and normal animals.

Treatment. Treatment of specific secondary infections is of limited efficacy in affected foals, particularly those affected by severe anemia and diarrhea, and all die by 3 months of age.

Client Education. The Fell and Dales pony breeds lost significant genetic diversity during World War II, and the overuse of a few popular sires likely resulted in the emergence of FIS, which until very recently affected up to 10% and 1% of Fell and Dales foals, respectively.[498] Genetic testing results reported in 2011 indicated that 38% of adult Fell ponies and 18% of adult Dales ponies were carriers of the FIS defect.[497] Similar to preventing SCID in Arabian horses, all Fell and Dales ponies used for breeding should be tested for FIS carrier status so that carrier-carrier matings are avoided. This will eliminate the production of FIS-affected foals and will eventually reduce the prevalence of the gene defect in the population. Implementation of this testing strategy has significantly decreased the number of FIS-affected foals, but it will take time to reduce the mutant gene frequency in the population given the large number of carriers.[506]

Common Variable Immunodeficiency

In humans, common variable immunodeficiencies are a heterogeneous group of disorders that do not become evident until late childhood or adulthood and comprise the most common forms of primary immunodeficiency.[209] In horses, common variable immunodeficiency (CVID) is a rare adult-onset fatal disorder characterized by B-cell depletion and inadequate antibody production caused by failure of B lymphocyte maturation in the bone marrow.[448]

Clinical Signs and Laboratory Findings. Over 30 cases of CVID have been reported in recent years.[507-511] Age of onset ranges from 2 to 23 years, there is no sex or breed predisposition, and cases are sporadic. Hypogammaglobulinemia leads to recurrent infections, typically caused by *Streptococcus, Staphylococcus, Actinobacillus,* and *Klebsiella* spp. Affected horses can present with pneumonia, sinusitis, meningitis, ataxia, diarrhea, peritonitis, gastrointestinal parasites, uveitis, conjunctivitis, skin infections, weight loss, and muscle atrophy.[448] Neutrophilia and hyperfibrinogenemia occur during infections, and transient lymphopenia (less than 1200 cells/μL) is common. Serum IgG is uniformly low in affected horses (less than 800 g/dL) as is IgM (less than 25 mg/dL), and IgA concentrations tend to decrease as the disease progresses (less than 60 mg/dL). Flow cytometry reveals B-cell lymphopenia (less than 2% of PBMCs) in all cases. Tetanus toxoid vaccination does not result in a rise in antibody titer in affected horses. Necropsy reveals lesions associated with infection in the affected organ systems. Lymph nodes are small and lack germinal centers, plasma cells are absent in lymphoid and mucosal tissues, and B cells are typically absent in the bone marrow and spleen.[448,511]

Etiology and Pathogenesis. To maintain populations of B cells in secondary lymphoid tissues, hematopoietic stem cells in the bone marrow must continuously generate B cells throughout an individual's lifetime. Although the pathogenesis of CVID is still unclear, the progressive B-cell depletion indicates a failure of B-cell development in the bone marrow. Early B-cell commitment genes, including E2A and PAX5, are decreased in the bone marrow of CVID-affected horses.[511] The E2A gene encodes a transcription factor that initiates B-cell differentiation and PAX5 expression, which encodes the B-cell-lineage–specific activator protein (BSAP) that is absent in the bone marrow of affected horses.[511] Thus disruption of pro–B-cell development during the transition from pre–pro–B cells could be the cause of CVID, and epigenetic gene silencing mechanisms may be involved.[448,510,511]

Diagnosis, Treatment, and Client Education. CVID is rare but should be suspected in adult horses with recurrent infections as described previously, hypogammaglobulinemia, B-cell lymphopenia, and failure to respond appropriately to vaccination. Affected horses with mild infections can be managed for variable lengths of time with continuous or intermittent oral antimicrobial therapy, but severe infections require aggressive intravenous antimicrobials and appropriate supportive therapy. Although regular immunoglobulin replacement is used in human patients, this is not practical in affected horses. Affected horses are usually euthanized within 6 months of diagnosis because of financial considerations and poor quality of life.[448]

Selective IgM Deficiency

Selective IgM deficiency is characterized by substantially reduced or absent serum IgM with normal or increased concentrations of other immunoglobulins and no other evidence of immunodeficiency.[445,512] Serum IgM concentrations are more than 2 standard deviations below the mean of age-matched control animals. All other immunologic parameters are normal, although a lack of response to the B-cell mitogen lipopolysaccharide was reported in an affected Standardbred foal.[513] The syndrome has been most frequently described in Arabians and Quarter Horses, although the diagnosis has been made in other breeds.

Clinical Signs and Laboratory Findings. Two clinical syndromes have been described. The first condition affects foals 2 to 8 months of age, which develop severe pneumonia, arthritis, and enteritis with or without septicemia, and many die before 10 months of age. Gram-negative bacterial infections are common (especially with *Klebsiella* species), and age at onset of signs is generally older than in foals with combined immunodeficiency. Some affected foals survive but have a history of repeated bacterial infections that respond temporarily to therapy but recur once antimicrobials are discontinued. These foals grow poorly and generally die within 2 years. Rarely foals can recover from IgM deficiency, suggesting that such cases may actually be secondary rather than primary immunodeficiencies.[514]

The second presentation involves horses between 2 and 5 years of age, many of which have or ultimately develop lymphoma. These individuals may have external or internal lymphadenopathy or both. Chronic weight loss, depression, and other nonspecific signs usually accompany lymphoma. In cases associated with lymphoma, the IgM deficiency is presumed to be a secondary rather than a primary immunodeficiency.

Routine laboratory findings are not diagnostically specific. Hematologic abnormalities consistent with chronic inflammatory disease, such as anemia, neutrophilia, and hyperfibrinogenemia, are commonly present. The total plasma protein and serum globulins are usually normal.

Etiology and Pathogenesis. Although a genetic basis is suspected, the pathogenesis of selective IgM deficiency is unknown.[445] It seems likely that there are primary and secondary forms of this syndrome. The pathogenesis of IgM deficiency is also unclear in humans but might involve decreased T-helper activity, increased isotype-specific suppressor T-cell activity, and intrinsic B-cell defects.[515]

Diagnosis. Definitive diagnosis of selective IgM deficiency is made by measuring the major serum immunoglobulins by RID and determining the absolute lymphocyte count. Horses

with selective IgM deficiency have serum IgM concentrations persistently less than 2 standard deviations below that of age-matched controls (less than 15 mg/dL at 4–8 months; less than 25 mg/dL at greater than 8 months) coupled with normal concentrations of IgG (≥1000 mg/dL) and a normal lymphocyte count. The normal IgM concentration in healthy fit horses is 103 ± 40 mg/dL, and a cut-point for IgM deficiency has been defined as ≤23 mg/dL.[516] Because seriously ill foals may have transiently depressed serum IgM concentration, suspected cases should be tested at least twice to document that IgM concentrations remain low. All other immunoglobulin concentrations are normal.

Treatment and Client Education. Other than supportive care and antimicrobial therapy, there is no effective treatment for selective IgM deficiency. Transfused plasma concentrations of IgM are low and the half-life is quite short; thus any benefit would be only temporary. The prognosis must be guarded; however, recovery has been reported.[514] Because primary immunodeficiency is likely in foals affected during the first year of life, it may be inadvisable to remate the sire and dam.

Other Primary Immunodeficiencies

Transient hypogammaglobulinemia and agammaglobulinemia are reported as established primary immunodeficiency syndromes in horses. However, these conditions have been infrequently reported and consequently remain poorly defined. Available information is presented here. A further form of immunodeficiency affecting humoral immunity was described by Boy and colleagues[517] in a 10-month-old Arabian colt. The animal exhibited an absence of serum of IgM, IgA, and IgG(T) and a normal concentration of IgG. In vitro testing of PBMCs with T-cell mitogens elicited normal responses, whereas responses to B-cell mitogens were weak. On postmortem examination there was generalized lymphocyte depletion of lymphoid organs.

To increase our understanding of these and other currently unidentified immunodeficiency syndromes of horses, it is critical that every effort be made to identify such cases and thoroughly investigate them. New immunologic resources now available may make it possible to further define these diseases and increase our diagnostic and prognostic resources, provided the case material can be identified.

Transient hypogammaglobulinemia has been reported in only two foals, an Arabian and a Thoroughbred, and is characterized by delayed onset of immunoglobulin synthesis.[514,518] Affected foals manifested signs consistent with bacterial and viral infections when passively acquired immunoglobulins are catabolized to nonprotective concentrations. For unknown reasons, the onset of autologous immunoglobulin production, which generally occurs at birth, is delayed until these foals are approximately 3 months of age. Hematologic studies may be suggestive of chronic infection, although total plasma protein is normal or reduced slightly. Diagnosis is based on the presence of low serum IgG (less than 200 mg/dL) and IgG3/5 (less than 20 mg/dL) at 2 to 4 months of age, with low-normal serum IgM (greater than 15 mg/dL) and IgA (greater than 20 mg/dL). Lymphocyte counts are normal. Antimicrobial therapy and plasma transfusions are necessary to minimize infections. Affected foals usually survive if they have not concomitantly suffered FTPI and they receive appropriate support between 2 and 4 months of age. Because foals spontaneously recover from this condition, it may be a secondary immunodeficiency.

Agammaglobulinemia is characterized by absence of B lymphocytes and failure to produce immunoglobulins in the presence of normal cell-mediated immunity.[445] The disease has been described in five colts of Thoroughbred, Standardbred, or Quarter Horse breeds.[514,519,520] Clinical signs commence between 2 and 6 months of age and result from bacterial infections such as pneumonia, enteritis, and arthritis. Multisystemic infections that respond poorly to therapy are common, and laboratory changes reflect chronic inflammatory disease. The fact that this syndrome has only been described in colts suggests an X-linked mode of inheritance, as occurs in X-linked agammaglobulinemia in humans, which is caused by a mutation in a protein tyrosine kinase gene called Bruton's tyrosine kinase *(btk)*.[521] The lack of this kinase activity results in a failure of pre–B cells in the bone marrow to develop into mature B cells. A maturation defect from stem cells to B cells has been suggested in affected horses.[445] Affected foals have persistently subnormal serum concentrations of all immunoglobulin classes and normal lymphocyte counts. Serum IgM and IgA are generally absent at the time of evaluation, and maternally derived IgG and IgG3/5 decline with time. At 2 months of age, IgG is less than 300 mg/dL, which declines to less than 100 mg/dL by 6 months. There is no serologic response to immunization, and B lymphocytes, as determined by immunofluorescence, are absent. Tests of cell-mediated immune function such as intradermal PHA and in vitro blastogenesis are normal. Plasma and antimicrobial therapy only result in transient improvement. Affected horses die of disseminated infection between 1 and 2 years of age.

Secondary Immunodeficiencies

Failure of Transfer of Passive Immunity

FTPI is the most common immunodeficiency disorder of horses and has been extensively reviewed.[325,446] It occurs in all breeds secondary to inadequate absorption of colostral antibodies. FTPI is significantly correlated with increased susceptibility to infectious disease and death in neonatal foals.[522,523] The newborn foal is capable of mounting a normal immune response, as described earlier in this chapter. However, neonatal foals are immunologically naive and thus have not developed memory responses or produced antigen-specific antibody or T-cell responses.

During the first 1 to 2 months of life, foals are dependent on transfer of passive immunity for protection from infectious disease. The diffuse epitheliochorial nature of the equine placenta does not allow for in utero immunoglobulin transfer to foals. Although minor concentrations of IgM and IgG can be detected at birth, the foal is born essentially agammaglobulinemic and acquires passive immunity by the ingestion and absorption of colostrum from the dam.[350,353,522] Colostrum is a specialized form of milk containing concentrated immunoglobulins that is produced during the last 2 weeks of gestation under hormonal influences. Colostrum contains primarily IgG4/7, along with IgG1 and IgG3/5, and lesser amounts of IgA and IgM, all of which have been concentrated into mammary secretions from the mare's blood.[249,315,317,326,524] Although yet to be identified in foals, the neonatal Fc receptor (FcRn) transports maternal IgG from the intestinal lumen through enterocytes and into the systemic circulation in mice.[525] This receptor has also been identified in the mammary gland of cows and other species, but its functional role in transporting maternal IgG into colostrum has not been

confirmed.[526-528] Whether FcRn is involved in this process in the mare is unknown. Colostrum is only produced one time each pregnancy and is replaced by milk that contains negligible immunoglobulins within 24 hours of the initiation of lactation.[350,524] This extremely rapid decline in immunoglobulin concentrations in mammary secretions is consistent with equine colostrum production ending at or even before parturition.[317] Intestinal absorption of immunoglobulins occurs in the small intestine, is greatest during the first 6 hours after birth, and then steadily declines until immunoglobulins can no longer be absorbed when the foal is 24 hours old.[529,530] Absorption is not selective for immunoglobulin as other macromolecules are absorbed,[529,530] potentially along with maternal T cells present in colostrum.[531] Thus the nonspecific intestinal absorption of large molecules within the first 24 hours in foals and other livestock species is the result of pinocytosis by specialized enterocytes and is FcRn independent.[526] This gut "closure" most likely results from the replacement of these specialized enterocytes by more mature cells within the first day of life.

The incidence of FTPI is highly variable among groups of horses and seems to depend primarily on management factors that ensure early colostral ingestion.[532] The reported prevalences of at least partial FTPI have ranged from 3% to 37%.[514,522,532,533]

Clinical Signs and Laboratory Findings. FTPI does not directly cause any clinical signs of disease. FTPI is suspected when signs of generalized or localized bacterial infections such as septicemia, pneumonia, enteritis, and arthritis develop during the first 3 weeks of life. Routine laboratory findings may be suggestive of sepsis, but the presence of infection in the neonatal period is not pathognomonic for FTPI. Common abnormalities include neutropenia or neutrophilia, hypoglycemia, and hyperfibrinogenemia. The total plasma protein may be low, normal, or elevated in foals with FTPI because of the wide variation in normal presuckle total plasma protein and the confounding effects of dehydration secondary to sepsis.

Etiology and Pathogenesis. Causes for FTPI in foals include (1) failure of the foal to ingest an adequate volume of colostrum in the early postpartum period; (2) loss of colostrum via premature lactation; (3) inadequate immunoglobulin content of the colostrum; and (4) insufficient immunoglobulin absorption via the intestine.[325,446,534] There is a highly negative correlation between foal serum IgG concentration and the incidence of severe infections[522]; however, the minimum amount of IgG necessary for protection of a foal from infection varies with the amount and virulence of environmental pathogens, concomitant stress factors, and colostral antibody titer against specific pathogens. Although a serum IgG concentration of at least 400 mg/dL has been considered evidence of adequate transfer of passive immunity, most normal foals attain values more than twice this high,[522,532] and serum IgG greater than 800 mg/dL is likely required for adequate immunity.[523] A recent study in hospitalized foals supports this latter conclusion.[454] Numerous other colostral factors may be important for the immune protection of foals. Colostrum has been variously shown to regulate cell-mediated immunity, activate granulocytes, promote intestinal absorption of macromolecules, decrease intestinal colonization by pathogens, and contain constituents of innate immunity (e.g., lactoferrin, complement) and leukocytes that have a local protective role in the neonatal digestive tract and may be systemically absorbed.[249,531,535,536] At this time the significance of these various phenomena for the health of neonates and their immunologic development is largely unknown. The one exception is the finding that colostral ingestion suppresses de novo antibody responses in foals in both a nonspecific and an antigen-specific manner.[350,358]

Neonatal weakness, musculoskeletal problems, or lack of maternal cooperation (maiden mares) are common reasons for failure to ingest an inadequate volume of colostrum. If colostral ingestion is delayed beyond 6 hours, the absorption of immunoglobulins is significantly reduced. Lactation before parturition is another common reason for FTPI, because colostrum is only produced one time each gestation. The causative factors for premature lactation are unknown at this time, but foals from mares that "leak" milk hours to days before parturition are likely to suffer FTPI.[534]

Subnormal colostral immunoglobulin content (less than 3000 mg/dL) is rare in mares that do not prelactate,[532] but wide individual variation in colostral concentration of immunoglobulins does occur.[532,537-539] Poor-quality colostrum will undoubtedly cause FTPI. Colostral immunoglobulin content can be estimated by specific gravity or quantitated by RID.[534] A Brix refractometer provides a quick and easy stall-side method to accurately estimate colostral immunoglobulin content, with a reading of 20% to 30% equating to an IgG concentration between 5000 and 8000 mg/dL.[540] A glutaraldehyde coagulation test is also available for measuring colostral IgG (Gamma-Check C, Plasvacc USA, Templeton, CA), with clot formation within 10 minutes indicating an IgG concentration of greater than 3800 mg/dL. Malabsorption is implicated as a cause of FTPI when foals are known to have ingested an adequate volume of good-quality colostrum within 12 hours of birth. Because glucocorticoids hasten the maturation of specialized enterocytes, stress-causing endogenous corticosteroid release may be a cause of reduced immunoglobulin absorption. However, obvious stress factors are often not found in foals with apparent impaired ability to absorb IgG.[205]

Diagnosis. Subnormal serum IgG concentration 24 hours after birth is the basis for diagnosis of FTPI. Serum IgG of less than 400 mg/dL is indicative of complete FTPI, and 400 to 800 mg/dL is considered partial FTPI. With the exception of hospitalized foals,[454] many foals under good management conditions may remain healthy if the serum IgG concentration is at least 400 mg/dL, and consequently this cut-point is measured by several rapid diagnostic tests. The most quantitatively accurate method to determine serum IgG is by RID as discussed earlier. However, this assay is time-consuming and expensive and thus inappropriate for the diagnosis of FTPI when timely therapeutic intervention is paramount. Numerous field screening procedures for IgG have been evaluated.[446,455-457,459-461,541] Criteria for selecting a screening test for equine FTPI must include accuracy, the time necessary to perform the test, ease of performance, and cost. The ease and reported accuracy of membrane-based ELISA tests often make them the test of choice in many practice situations. Because failure to diagnose and treat the condition could result in the death of many foals, a sensitive test is required. However, specificity is also important, particularly given the cost of treatment and the fact that treatment is not without its own inherent complications. Generally, all the available immunoglobulin screening tests are relatively accurate in identifying foals with complete FTPI; however,

there is variation in their ability to detect marginally deficient foals.[325,446,461] Individual clinician judgment is therefore important in test selection. As discussed, the glutaraldehyde coagulation test (Gamma-Check E) is good for initial screening because it is simple, rapid, inexpensive, and sensitive for ruling out FTPI (IgG concentration ≥800 mg/dL). However, this test lacks specificity, so a diagnosis of FTPI based on this test should be confirmed with a more specific test, such as the membrane filter ELISA (SNAP).[325,461] Overall, the relatively good performance and the convenience of the semiquantitative SNAP test will continue to make it a popular first choice.

Treatment. If FTPI is anticipated because of premature lactation, neonatal weakness, dam death, or low-specific-gravity colostrum, an alternative source of colostrum or a commercial concentrated equine IgG product (Seramune, Sera, Inc., Shawnee Mission, KS) should be given orally. A minimum of 2 L of equine colostrum given in 500-mL increments during the first 8 hours after birth is optimal. Bovine colostrum may be safely substituted if equine colostrum or commercial equine IgG product is not available[349,351]; however, foals given bovine colostrum may also require plasma transfusion because bovine immunoglobulins have a very short half-life in foals and are not specifically directed against equine pathogens.

If the foal is more than 12 to 18 hours old when FTPI is suspected or diagnosed, an intravenous plasma transfusion is indicated. The U.S. Department of Agriculture (USDA) has approved numerous commercial sources of equine plasma, and use of these products is convenient, saves time, and is safe because donors are free of alloantibodies and negative for infectious diseases. The only potential drawback to the use of commercial plasma is that antibodies specific for pathogens in the foal's environment may be lacking. Optimal plasma would be obtained from a local blood-typed donor known to lack serum alloantibodies and alloantigens Aa and Qa. The volume of plasma necessary to bring serum IgG into an acceptable range cannot be accurately predicted because it is dependent on the severity of FTPI, the immunoglobulin content of the plasma, and concomitant diseases, which may hasten immunoglobulin catabolism. Generally, 1 L of plasma will increase the serum IgG concentration of a 50-kg foal by 200 to 300 mg/dL[237]; thus 2 to 4 L may be necessary to achieve serum IgG greater than 800 mg/dL. A therapeutic dose of plasma should be administered and then serum IgG concentration reassessed. If the desired concentration has not been attained, more plasma is necessary. Some foals with partial FTPI (IgG greater than 400 and less than 800 mg/dL) may do well without plasma therapy if there are no preexisting infections and exposure to pathogens is minimized. These foals should be monitored closely for the development of infections. However, hospitalized foals with IgG concentrations in this range should receive plasma.[454]

Client Education. The prognosis for foals with FTPI depends on the degree of failure, the environment to which the foal is exposed, the foal's age at the time of diagnosis, and the presence and severity of secondary infections. Management factors that ensure the ingestion of at least 2 L of high-quality colostrum within 6 hours of birth are paramount in FTPI prevention. Foaling should be witnessed so that any malpresentations can be corrected, and foals that do not readily nurse within 3 hours can be given colostrum or suitable substitute via nasogastric tube. Colostral IgG concentration can be used as a predictor of FTPI. As measured by specific gravity, a colostral IgG concentration of 3000 mg/dL is the minimum acceptable value, and when colostrum contains less than this amount, some degree of FTPI should be suspected in the foal and corrected.[534] Brix refractometry[542] or the Gamma-Check C test could also be used for this purpose. Routine screening of foal serum IgG at 24 to 48 hours after birth allows necessary plasma therapy before the onset of infections.

Foals that are born prematurely, are weak, or are from prelactating mares should be provided with an alternative colostral source or commercial equine IgG product within 6 hours of birth. A colostrum bank can be established by collecting and freezing (−20°C) 250 mL of colostrum from mares that have not prelactated within 6 hours of foaling, once their own foals have suckled. Ideally, banked colostrum should be screened for alloantibodies, although they are unlikely if the mare's own foal remains healthy. The immunoglobulins in banked frozen colostrum are stable for at least 1 year.

Exercise

Exercise, when conducted at a stressful level, can significantly affect equine immune function.[543] Strenuous exercise significantly suppresses lymphoproliferative responses, whereas lymphokine activated killer (LAK) cell activity increases.[544,545] In racehorses, decreased lymphoproliferative responses can be demonstrated 12 to 16 hours after racing.[546] Protracted high-intensity training results in decreased phagocytosis and oxidative burst activity in neutrophils and lymphocytes, although pulmonary alveolar macrophage function is unaffected.[547] Other studies have demonstrated decreased neutrophil and pulmonary alveolar macrophage function in response to single bouts of intense exercise[548,549] and prolonged suppression of innate immunity after exercise of long duration.[550] Incremental exercise in unfit Standardbred mares results in an increase in inflammatory cytokine expression in blood (IFN-γ, TNF-α, and IL-1) and in muscle tissue (IFN-γ, TNF-α, and IL-6).[551] Strenuous exercise results in neutrophilia, increased apoptotic activity in leukocytes, and decreased leukocyte reactive oxygen species production in response to PMA stimulation, with some of these effects persisting for 72 hours after exercise.[552] In unconditioned ponies strenuous exercise increases susceptibility to experimental infection with equine influenza, associated with alterations in the virus-specific cell-mediated immune response.[553] In an influenza infection study in trained horses, moderate exercise led to increased signs of clinical disease, although duration of disease was unaffected.[554]

These various studies have demonstrated an immunomodulatory effect of exercise, with some specific evidence for increased susceptibility to infectious disease. Some of these effects are likely due to increases in plasma cortisol, which is correlated with the intensity and duration of exercise and with alteration in immune function in horses.[555] In general, moderate exercise appears to be beneficial to the immune system, whereas prolonged and intense exertion likely impairs immune function. The potentially immunosuppressive effect of high-intensity exercise, particularly of protracted duration or in unconditioned animals, should be recognized.

Age

There is a high incidence of respiratory infections in foals and weanlings, which frequently relapse on cessation of antibiotic

treatment.[556] It is also possible that the normal level of immunocompetence in this age group leads to increased susceptibility to respiratory infections, particularly under group housing conditions. Features of the foal's immune system that predispose to such infections have been discussed earlier in this chapter.

Geriatric horses experience a general reduction of immune function similar to humans, a phenomenon called immunosenescence. Also like humans, old horses tend to produce exaggerated inflammatory responses, known as "inflamm-aging."[557,558] Immunosenescence in humans is associated with age-related defects in the thymic and bone marrow microenvironment and a predominance of memory T and B cells with limited repertoire diversity.[559] In addition, increased cell death in the elderly, along with hormonal dysregulation, increased oxidative stress, and the presence of chronic diseases, contribute to a low-grade activation state in innate cells such as macrophages, which characterizes inflamm-aging.[559] Many of these effects are likely due to immune dysregulation, and the underlying cause could involve age-related alterations in the membrane composition and in critical signaling and regulatory molecules in immune cells such as neutrophils and T cells.[560]

Horses greater than 20 years old have decreased total lymphocyte counts and reduced numbers of B cells and $CD4^+$ and $CD8^+$ T cells, as well as decreased lymphoproliferative responses to mitogens.[561,562] In addition, old horses demonstrate reduced immunologic responses during exercise.[544] Although lymphoproliferative responses are decreased in old horses, T cells still produce IFN-γ and other inflammatory cytokines, and elevated expression of inflammatory cytokines occurs in peripheral blood along with elevated levels of TNF-α in serum, consistent with inflamm-aging.[563] Obesity likely contributes to the age-related proinflammatory state as obese old horses have higher frequencies of lymphocytes and monocytes producing IFN-γ and TNF-α than old thin horses.[564] Interestingly, a proinflammatory bias may not occur in the lungs of old horses. As evidence, the frequency of IFN-γ producing lymphocytes in both PBMCs and BAL cells is elevated in old horses, whereas age-related production in TNF-α is only present in PBMCs.[565] Moreover, an age-related decrease in BAL cell proinflammatory cytokine expression has recently been documented in horses.[566] Thus the process of inflamm-aging may be organ specific in the horse.

Telomeres protect the ends of chromosomes and contribute to the stability of the genome; maintenance of telomere length and telomerase activity inversely correlate with age, and shorter telomeres are associated with age-related chronic diseases.[567] Telomere length in PBMCs declines with age in horses and is inversely correlated with inflammatory cytokine expression and positively correlated with lymphoproliferative responses and total immunoglobulin levels.[568] Although these observations suggest a role for telomere length in equine immunosenescence and inflamm-aging, the associations between telomere length and immune function do not apply in the oldest horses, indicating that other factors are also involved.

Finally, old horses can mount a primary humoral immune response against a killed rabies vaccine similar to young horses, but their memory response against a killed influenza virus vaccine results in lower antibody titers than in young horses.[569] Lower antibody titers following influenzavirus vaccination in old horses has been observed by others.[544] A recent study measured antibody and cell-mediated responses in old horses following vaccination with a canarypox recombinant vector influenza vaccine.[570] In young naive horses the vaccine induced antibody and cell-mediated responses as measured by IFN-γ production and reduced viral shedding and protected against clinical disease following influenzavirus challenge. The old horses in this study were not naive, and vaccination slightly enhanced antibody titers whereas vaccine-elicited cell-mediated memory responses were not detectable. Nonetheless, virus shedding was reduced, and clinical protection occurred in the old horses.

The geriatric horse population is on the rise,[557,558] requiring an increased appreciation for age-related diseases and other problems unique to the older horse. Immune responses are diminished in old horses, and old horses are prone to produce inflammatory responses. Some vaccine strategies that are effective in younger horses may result in less robust immune responses in old horses, leading to lower levels of protection and an increased need for boosting. Further studies in this area will hopefully improve the understanding of immune regulation and function in old horses to better inform immunoprophylactic and therapeutic approaches.

Leukoproliferative Disease–Associated Immunodeficiency

Lymphoma is often associated with IgM deficiency[446,516,571] and can also be associated with decreased lymphocyte blastogenesis.[572,573] Affected horses have been diagnosed with bacterial pneumonia in some instances, as well as pulmonary aspergillosis in a horse with myelomonocytic leukemia.[574] These cases demonstrate the importance of considering leukoproliferative disease, and particularly lymphoma, in cases of persistent infections that are refractory to treatment.

Drug-Induced Immunodeficiency

The most common iatrogenic cause of immunosuppression is corticosteroid treatment, often administered with the aim of treating a hypersensitivity disorder. The mode of action and the immunosuppressive effects of corticosteroids are reviewed in the next section, but there is evidence for the capacity of corticosteroids to induce recrudescence of viral diseases such as equine infectious anemia[575-577] or EHV-1 infection[578] and to lead to development of life-threatening bacterial infection.[579] Based on the EIAV studies, dexamethasone administration results in profound reduction of peripheral blood B- and T-cell numbers,[575] and the recrudescence of viremia is most likely due to the suppression of T-cell responses because the virus-specific neutralizing antibody titers do not change.[576] There is also evidence that corticosteroid treatment can bias adaptive immune responses to vaccination in horses, specifically suppressing IgG1 and IgG4/7 responses without affecting IgG3/5 responses.[468] This phenomenon may be consistent with the capacity of corticosteroids to specifically suppress T_H1 immune responses with minimal effect on T_H2 responses.[580,581]

Infectious Disease

Several infectious diseases have been associated with immunodeficiency in horses. The best-characterized example may be perinatal EHV-1 infection.[582] Foals that are infected late in gestation with EHV-1 are often born weak with interstitial

pneumonia and develop a variety of bacterial diseases.[583] Affected foals have profound lymphopenia and generally die, despite therapy. The immunodeficiency is thought to be due to viral-induced lymphoid damage, because necropsy reveals marked necrosis of lymphoid tissue in the thymus, spleen, and lymph nodes. Another example is EIAV infection. During acute viremic episodes, reduction of peripheral blood $CD4^+$ and $CD8^+$ T-cell numbers occurs as does suppression of lymphoproliferative responses.[584,585]

Undifferentiated Immunodeficiencies

A group of foals with oral candidiasis and bacterial septicemia between 2 weeks and 4 months of age were found to have laboratory or histologic evidence of immunodeficiency that did not fulfill diagnostic criteria for any of the recognized primary immunodeficiencies.[586] Oral lesions ranged from focal white plaques on tongue margins to a generalized thick, white pseudomembrane covering the tongue and gingiva. Affected foals showed bruxism, ptyalism, fever, and depression in addition to pneumonia, arthritis, or diarrhea, singly or severally. The lymphocyte counts of the foals were usually normal. Several foals had IgM deficiency coupled with depressed blastogenesis, suggesting cellular immune dysfunction. Many of the foals had low or marginally reduced serum IgG in addition to IgM deficiency or reduced blastogenesis. It was not determined whether the immunologic defects were primary or secondary. All foals died despite extensive therapy with parenteral antimicrobials, topical antimycotics, and intravenous plasma.

Acquired immunodeficiency was identified in a 7-year-old Appaloosa gelding that had no history of previous illness.[587] Clinical signs included lethargy, anorexia, and dyspnea. Pneumonia and septicemia due to *Rhodococcus equi* were confirmed by tracheal wash and blood culture, respectively. Immunologic evaluation revealed marked lymphopenia, subnormal serum IgG and IgA with marginally low IgG concentrations, failure to respond serologically to immunization, and reduced in vitro lymphocyte blastogenesis. Histologic examination of lymph nodes and spleen revealed lymphoid atrophy.

IMMUNOMODULATORS

Clinicians frequently seek to increase normal, restore deficient, and temper overexuberant host immune responses. For these reasons, modulation of the immune system remains an area of intense interest in clinical medicine. Both immunostimulants and immunosuppressants are considered immunomodulators. There are a variety of ways to classify immunomodulators beyond this distinction, but for practical purposes they may be best classified based on their origin: that is, physiologic products (actual normal components of the immune response), microbial products, and chemically defined agents. Immunomodulation can also result from modes of therapy not considered here, including bone marrow transplantation and irradiation.

Although a scientific rationale for the use of immunomodulators exists, a major limitation is the complexity of the immune response to be modulated. There are several major problems in the rational clinical application of immunomodulators. Commonly used diagnostic methods do not allow precise identification of the in vivo defects, deficiencies, or excesses of substances or regulators present within the immunoregulatory network. Consequently, attempts to intervene with immunomodulators are often nonspecific. Some of the information on which the use of immunomodulators is based has come from controlled experimental studies, some performed in vitro and others in vivo. In clinical patients, expectations based on these types of studies are frequently not realized. Reasons for this include the timing of the administration of the immunomodulator during the course of disease and the fact that observation of a single immunologic phenomenon resulting from use of an immunomodulator—for example, an increase in lymphocyte count or lymphoproliferative responses—does not necessarily translate into improved clinical performance in the face of an infectious disease. Because of the complexity of the immune network, the rational use of immunomodulators can be considerably more difficult than the use of antimicrobial agents. An example of the importance of timing in immunomodulatory intervention is the relative success of immunosuppressive therapy in the context of organ allografts, compared with the frequent treatment failures experienced in treating autoimmune disease. In the former case therapy is planned in advance of the introduction of the allograft, whereas in the case of autoimmunity the immune response and resulting disease are well established before they are detected and therapy is initiated.

Immunomodulators have been embraced by clinicians, and the concept of their use remains appealing. The clinical value of immunosuppressive drugs such as corticosteroids and the immunostimulant adjuvants used in vaccines is clearly established. Although the body of work evaluating immunostimulants has grown in recent years, the evidence for the clinical value of many immunostimulants is still sparse and sometimes conflicting. It is important to look critically at the immunomodulatory drugs on the market and make attempts to objectively evaluate the effects of therapy.

This discussion will be limited to drugs currently marketed for use as immunomodulators or for which there is published evidence of activity. Advances in molecular biology have made available recombinant forms of many cytokines with immunomodulatory potential, but only those with some established value will be discussed.

Immunosuppressors

Corticosteroids

Corticosteroids are classic examples of immunosuppressive agents. Corticosteroids exhibit an extensive range of effects on elements of both the innate (inflammatory) and adaptive immune response. Corticosteroids are derivatives of the glucocorticoid family of steroid hormones, and after crossing the cell membrane they bind to cytoplasmic glucocorticoid receptors. Once activated, glucocorticoid receptors are transported to the nucleus where they bind to DNA and interact with other transcription factors, resulting in the regulation of as many as 20% of the genes expressed in leukocytes.[209] The useful antiinflammatory effects of corticosteroids are summarized in Table 1.8. The effect on the adaptive immune response is complex.[588] For example, in cases of autoimmune disease such as autoimmune hemolytic anemia, corticosteroids may act by reducing phagocytosis of antibody-coated cells by the reticuloendothelial system rather than decreasing antibody production. Nevertheless corticosteroids have been shown to have effects on antibody production, and in the horse

TABLE **1.8 Antiinflammatory Effects of Corticosteroid Therapy, Mediated by Regulation of Gene Transcription**

Action of Corticosteroids	
Direct Effects	**Physiologic Effects**
↓ IL-1, TNF-α, GM-CSF, IL-3, IL-4, IL-5, CXCL8	↓ Inflammation caused by cytokines
↓ Nitric oxide synthetase	↓ Nitric oxide
↓ Phospholipase A2, cyclooxygenase type 2 ↑ Annexin-1	↓ Protaglandins, leukotrienes
↓ Adhesion molecules	↓ Emigration of leukocytes from vessels
↑ Endonucleases	↑ Apoptosis in lymphocytes and eosinophils

From Murphy KP, *Janeway's immunobiology,* 8th edition, 2012.

they can suppress de novo antigen-specific IgG1 and IgG4/7 responses while sparing IgG3/5 responses.[468] This may be consistent with the action of corticosteroids to suppress T_H1 responses while sparing T_H2 responses.[580,581,589,590] Cell migration is significantly affected by corticosteroids, and in the horse corticosteroids have been shown to suppress neutrophil migration, together with phagocytic and bactericidal activity.[591] The mechanism whereby migration is decreased involves decreased expression of adhesion molecules including selectins and integrins.[592] Experientially, high-dose dexamethasone (1.0 mg/kg intravenously daily for 9 days) profoundly reduces the numbers of B and T lymphocytes in the peripheral blood of horses.[575] Intravenous administration of single lower doses of dexamethasone (0.05, 0.1, or 0.2 mg/kg) to a healthy horse results in neutrophilia and reduction of peripheral blood $CD4^+$ T-cell numbers, with a corresponding increase in the numbers of $CD8^+$ T cells and B cells.[593]

Although corticosteroids are powerful immunosuppressive agents, they may also predispose patients to life-threatening opportunistic infections[579] or recrudesence of viral infection.[575,576,594] Additional extensive undesirable side effects include fluid retention, decreased wound healing, and the concern that their use can be associated with the development of laminitis in some circumstances.[595-598] For this reason prolonged or high-dose corticosteroid therapy must be used judiciously.

Cytotoxic Drugs

The two commonly used immunosuppressive cytotoxic drugs, azathioprine and cyclophosphamide, both interfere with DNA synthesis and act primarily on dividing cells.[209] This activity is useful for treatment of cancer and for suppression of dividing lymphocytes. Cyclophosphamide has been used along with prednisolone in a chemotherapeutic protocol to achieve remission of thoracic lymphoma in a horse.[599] Toxicity limits the use of these drugs, although at lower doses they can be used in combination with corticosteroids. These drugs have been used in horses to treat immune-mediated hemolytic anemia or thrombocytopenia with success in some cases[600-602] and unsuccessfully for treatment of pemphigus vulgaris.[436]

Bacterial and Fungal Derivatives

This class of drugs includes relatively nontoxic alternatives to immunosuppressive cytotoxic drugs. Cyclosporine is a fungal derivative and has emerged as a major immunosuppressive agent for allograft survival. It selectively inhibits proliferation, cytotoxicity, and lymphokine production of T cells by binding to intracellular proteins known as immunophilins and interfering with signaling pathways that are important for clonal expansion of lymphocytes.[209] Cyclosporine is efficacious in suppressing specific immune responses with minimal nonspecific toxic effects on polymorphonuclear leukocytes, monocytes, and macrophages. Thus immunosuppressed patients suffer fewer severe secondary infections. The drug is not hazard free, as in addition to suppressing lymphocyte responses in general, it is also toxic to the kidneys and other organs.

In horses the use of cyclosporine has been limited to topical and intravitreal therapy for ocular inflammatory disease, including keratitis[603] and uveitis.[604,605] In the treatment of uveitis, numbers of infiltrating T lymphocytes and IL-2 and IFN-γ levels were suppressed by cyclosporine treatment.[606] Use of a suprachoroidal cyclosporine implant results in long-term maintenance of vision in horses with recurrent uveitis.[607]

IMMUNOSTIMULANTS

Physiologic Products

Cytokines

Given the central role of cytokines in immunoregulation (see under Equine Immunology), their potential as immunomodulators is obvious, and a discussion of the possible use of cytokines as therapeutic agents in this regard would be extensive although largely hypothetical. Therefore consideration will be limited to the two cytokines that have found clinical application in horses to date.

Interferon-α. The clinical application of human interferon-α in the horse has been extensively reviewed.[608-610] Interferon-α has antiviral and immunostimulant properties, and oral administration of interferon-α has been shown to reduce inflammatory airway disease[611] in racehorses.[612] The treatment employed was low-dose (50–150 IU) natural human interferon-α, and it resulted in decreased BAL cell counts and a noninflammatory cytologic profile.[613] Higher doses (450 IU) were less effective, consistent with results in other species.[410] The efficacy of oral therapy probably depends on effects mediated through oropharyngeal lymphoid tissue, as the agent is destroyed in the stomach. Recombinant human interferon-α (Intron-A, Merck, Kenilworth, NJ) has similar therapeutic effects as natural human interferon-α.[614]

Granulocyte Colony-Stimulating Factor. The clinical application of granulocyte colony-stimulating factor (G-CSF) in the horse has been extensively reviewed.[609,610] G-CSF treatment in neonatal foals results in a sustained, dose-dependent increase in neutrophil count and a left shift,[615,616] by increasing neutrophil production in the bone marrow and shortening the time to release into the circulation while the half-life remains unchanged at 8 hours. Recombinant human G-CSF (Neupogen, Amgen, Thousand Oaks, CA) has been effective for treating persistent neutropenia in foals with alloimmune neonatal neutropenia.[617,618] Canine recombinant G-CSF has been used to treat sepsis and endotoxemia in foals with some success.[609,610]

Bacterial, Viral, and Plant Products

A variety of bacterial and fungal microorganisms or microbial products have been identified that have immunomodulating effects. A common feature of many of these products is a nonspecific immunostimulant effect, purportedly due to macrophage activation and release of cytokines including interferons, IL-1, TNF-α, or IL-6.[609,619] Consequently mild fever and malaise may be associated with this form of treatment. In the horse these treatments are most commonly used in cases of respiratory infection or sarcoids. Extensive reviews of the use of these and other immunostimulants in the horse have been published.[609,610,620]

Mycobacterial Products

A wide range of mycobacterial fractions have been identified with immunomodulating ability.[609,619] The minimal structure with immunologic (adjuvant) activity is muramyl dipeptide, which is a potent adjuvant.[621] Preparations commercially available for use in horses include bacillus Calmette-Guérin (BCG), a modified live human tuberculosis vaccine, and protein-free mycobacterial cell wall extract (MCWE; Equimune, Immunocidin, and Settle, NovaVive, Athens, GA). Efficacy is reported for treatment of equine respiratory disease (Equimune; intravenous), sarcoids (Immunocidin; intralesional), and endometritis (Settle; intravenous or intrauterine). Intravenous administration of MCWE at the time of artificial insemination downregulates IL-1 expression in mares susceptible to postbreeding endometritis and thus might have therapeutic value in this population.[622] Adverse hypersensitivity reactions have been reported after multiple intravenous treatments in horses, resulting in interstitial lung infiltration and progressive pulmonary fibrosis. In horses, a successful application of these products has been in the intralesional treatment of sarcoids, particularly periocular sarcoids,[623] and this is discussed elsewhere in this book.

Propionibacterium acnes

Propionibacterium acnes is a commensal gram-positive anaerobe, marketed for use in horses as a killed preparation under the trade name EqStim (Neogen, Lexington, KY) for treatment of equine respiratory disease. It is recommended for use prophylactically before weaning, transport stress, or comingling, or for the therapy of chronic infectious respiratory disease. After intravenous administration, *P. acnes* is taken up by macrophages in the liver and spleen and degraded slowly, resulting in macrophage activation. In addition, *P. acnes* CpG motifs (see later discussion) result in immune activation by binding TLR9 on macrophages, dendritic cells, and NK cells.[610,620] In healthy horses, *P. acnes* resulted in increased $CD4^+$ T-lymphocyte numbers and LAK cell activity in peripheral blood and BAL fluid, increased nonopsonized phagocytosis in peripheral blood leukocytes, and decreased pulmonary cellularity.[469] Treatment of horses with *P. acnes* has also been shown to increase IFN-γ and antimicrobial peptide expression in PBMCs.[624] In adult horses, two randomized controlled trials have demonstrated that the addition of *P. acnes* treatment to conventional therapy enhances clinical recovery or improvement of spontaneously occurring infectious respiratory disease.[620] Several other studies have shown that *P. acnes* treatment is beneficial in reducing the prevalence of respiratory disease associated with longdistance transport and in resolving endometritis.[620] Although *P. acnes* treatment had no effect on IFN-γ production by stimulated PBMCs or IFN-γ expression in peripheral blood of neonatal foals less than 1 week of age, both were increased following a second series of doses when the foals were 1 month old.[625] Macrophages isolated from foals treated with *P. acnes* beginning at 1 week of age demonstrate less intracellular proliferation of *R. equi* when infected in vitro compared with macrophages from untreated control foals.[626] Overall this agent is one of the most popular immunostimulants marketed for horses. Based on the published literature it appears to be of therapeutic benefit in adult horses but likely less so in neonatal foals.

Parapoxvirus ovis

Parapoxvirus ovis is a DNA virus of small ruminants that produces a variety of modulatory factors that are maintained after virus inactivation. As such, inactivated *Parapoxvirus ovis* (iPPVO) has been shown to activate APC, leading to upregulation of proinflammatory cytokines IL-6, TNF-α, and CXCL8; T_H1-inducing IL-12; and T-cell production of IL-2, IFN-α, and IFN-γ.[610,620] Marketed under the trade name Baypamun (Bayer Animal Health, DE), iPPVO was used extensively in Europe for prophylaxis and treatment of infectious disease in companion animals, horses, and pigs.[609] In the United States iPPVO was marketed as Zylexis (Zoetis, Florham Park, NJ) for enhancing immunity before stressful events or during disease, particularly to improve resolution of viral respiratory disease, including EHV-1 and EHV-4.[620] At the time of this writing, however, Zylexis has been discontinued and is not currently available. Efficacy has been demonstrated against viral and bacterial disease in several species,[609] and there is evidence in horses that prophylactic administration before weaning reduces signs of respiratory disease after weaning.[627] More recently, however, treatment with iPPVO did not affect the decreased IFN-γ, TNF-α, and IL-10 production by PBMCs associated with the stress of abrupt weaning.[628] In a model of transport stress, treatment with Zylexis led to restoration of suppressed antibody responses to influenzavirus infection in horses.[629] More recently, treatment with Zylexis was associated with a moderate reduction in clinical signs and reduced shedding of EHV-1 and *S. equi*.[630] In healthy yearlings, iPPVO treatment resulted in increased IFN-γ expression in peripheral blood.[631] Neutrophils from foals treated with iPPVO at 1 week of age had enhanced phagocytic and oxidative burst activity against *R. equi* in vitro compared with baseline controls and with foals treated with *P. acnes*.[626] In iPPVO-treated foals, TNF-α induction was higher in monocyte-derived macrophages, and IL-12 induction was higher in BAL macrophages infected with *R. equi* in vitro compared with control foals. In a separate study using foals on an *R. equi* endemic farm, iPPVO treatment initiated within the first 2 days of life resulted in a higher number of PBMC producing IFN-γ by 1 to 2 weeks of age compared with control foals, but there was no difference in the proportion of foals that developed *R. equi* pneumonia.[632] Finally, iPPVO has not shown efficacy for treatment of sarcoids.[633]

Imiquimod

Imiquimod (Aldara) is a synthetic imidazoquinoline immunomodulating cream used for topical treatment of actinic keratosis and genital warts in humans and to successfully treat

sarcoids and aural plaques in horses.[610,623] It acts as a TLR7 agonist, resulting in increased proinflammatory cytokine production, and has potent antiviral and antitumor activity. Studies report that 56% to 82% of treated sarcoids achieve complete remission, with 80% having at least a 75% reduction in size. Mean treatment time is 3.7 months.[623]

Cytosine-Phosphate-Guanosine-Oligodeoxynucleotides

In recent years an extensive body of literature has developed describing the immunomodulatory effects of certain unmethylated bacterial DNA motifs.[634] The specific immunostimulatory DNA motifs are called CpG sequences, and appropriate oligodeoxynucleotides (ODN) containing CpG motifs for immunostimulation of domestic species have been identified.[635] Much work has been done on examining the efficacy of CpG-ODN as vaccine adjuvants,[636] as immunomodulators for hyposensitization (see later discussion), or cancer therapy.[637] The value of CpG-ODN in horses as both vaccine adjuvants[638] and as potential nonspecific immunomodulators[340,639,640] has been demonstrated. Recently intramuscular administration of a CpG-ODN formulation to newborn foals resulted in increased IFN-γ production by neutrophils and modulated neutrophil degranulation.[641] Although CpG-ODN hold promise as immunomodulators, commercial products for clinical use are not yet available.

Chemically Defined Agents

Levamisole

Levamisole is synthetic anthelmintic used for treatment of nematode infections, which has also been reported to restore impaired host immune defenses.[609] Levamisole appears to have little effect on the normal immune system, but it appears to stimulate a subnormal response and suppress hyperactive responses. The effects are dose related, and low doses are reported to enhance whereas higher doses suppress responses. In cattle levamisole has been shown to enhance lymphoproliferative responses in vitro, although in vivo coadministration with a vaccine had no immunostimulant effect.[642] Similarly, levamisole did not prevent corticosteroid-mediated immunosuppression in cattle[643] or enhance postpartum lymphoproliferative responses in pigs.[642] Other than anecdotal reports there are no published controlled studies of its value in horses.

Antigen-Specific Immunomodulation

Vaccination and Adjuvants

Vaccination is a critically important tool in preventing infectious disease in humans and animals, and both passive and active vaccination are extensively employed in the horse. Specific equine vaccination strategies are presented elsewhere in this book, and the scientific principles and the practice of equine vaccination have been extensively reviewed.[644-647] Vaccination implies active immunization where an antigen-specific immune response is induced in the vaccinated animal by administration of subunit, whole killed or attenuated live antigen, or DNA in a plasmid or a recombinant viral vector capable of expressing protein antigens in vivo. Each of these strategies has advantages and disadvantages. For example, killed vaccines do not result in efficient MHC I processing and presentation and thus do not elicit robust CTL responses, limiting effectiveness against predominantly intracellular pathogens. Attenuated live vaccines have the potential to cause disease in some individuals or to revert to virulence. Recombinant viral vector vaccines result in intracellular expression of antigens without the risk of causing disease or reversion to virulence. The success of all of these types of vaccines, subunit and killed vaccines in particular, is frequently dependent on use of an effective adjuvant.[648] Adjuvants are compounds capable of potentiating immune responses and include substances that result in depot formation, induce inflammatory cytokines, recruit leukocytes, enhance antigen uptake and presentation, or increase the expression of costimulatory molecules. As such, adjuvants are some of the most important types of immunomodulating agents in use in equine medicine.

Passive immunization is accomplished by administering preformed antibodies either as a plasma transfusion or in a concentrated form, as in commercially available tetanus antitoxin. This strategy can be highly effective in diseases for which there is no available vaccine (e.g., *R. equi*) or in high-risk situations when there is inadequate time for protection to be generated by active immunization. Although USDA-approved commercial equine plasma and serum products are derived from donors screened for routine blood-borne pathogens, passive immunization carries a risk of transmitting previously unidentified infectious agents. Examples include the association with acute hepatic necrosis with a previous administration of tetanus antitoxin[649] and more recently an outbreak of liver disease associated with transmission of Theiler's disease–associated virus (TDAV) via administration of botulinum antitoxin.[202] Equine blood products could contain other newly reported viruses associated with hepatitis in horses, including equine hepacivirus and equine pegivirus.[650] As was the case in the discovery of TDAV,[202] deep sequencing techniques may reveal other infectious pathogens that could contaminate equine blood products.

Hyposensitization

Because horses suffer from a number of hypersensitivity diseases, attempts have been made to perform antigen-specific immunosuppression. Examples include IBH and RAO.[651] The principle of this type of therapy is that the immune response against an allergen can be redirected to reduce hypersensitivity disease.[652] For example, because type 1 hypersensitivity is associated with a T_H2-biased immune response, treatments that cause a shift to a T_H1 response could eliminate or control the hypersensitivity by changing the antibody response from one dominated by IgE to IgG.[209] Typically hyposensitization treatments, also known as allergen-specific immunotherapy (ASIT), use injections of the allergen itself, starting with very small doses, and gradually increasing the dose over time. This form of treatment depends on correct identification of the allergen against which the hypersensitivity is directed, and the difficulty in identifying these allergens using intradermal or IgE ELISA-based serologic testing methodologies[396,653] may provide an explanation for the mixed success of ASIT in horses.[654,655] Prospects for ASIT have been improved recently with the use of pure recombinant protein allergens, which are far superior in terms of sensitivity (up to 89%) and specificity (up to 97%) for detection of allergen-specific IgE.[656,657] A protein microarray containing a large panel of complex extracts along with pure and recombinant proteins and analyzed using mathematical modeling techniques has been recently described

that is capable of high-throughput detection of allergen-specific IgE.[658] This microarray has yielded a sensitivity and specificity of 100% and 97%, respectively, for the diagnosis of IBH. Even when previous allergen identification methods are used, ASIT can be effective for managing atopic skin disease in horses as described in a recent retrospective study involving 54 horses (1991–2008) treated for urticaria, pruritus, or both.[659] Intradermal and/or serologic testing was used to identify allergens, and 84% of owners reported that ASIT reduced clinical signs, with 59% able to manage clinical signs without the use of immunosuppressive drugs. The majority of owners (75%) discontinued ASIT after a mean of 2.2 years, most because of resolution of clinical signs. The availability of increasingly sensitive and specific allergen testing strategies will undoubtedly further improve the success of ASIT. Of considerable promise, a vaccine approach for potentially preventing IBH has recently been described in which small doses of recombinant *Culicoides* allergens are inoculated along with a T_H1-focusing adjuvant.[660] Immunization results in induction of allergen-specific IgG without inducing IgE, does not produce IgE-mediated hypersensitivity, and produces IgG that is capable of partially blocking the binding of IgE to the vaccine allergens.

Administration of CpG DNA has been evaluated for hyposensitization because it promotes the T_H1 immune responses.[661-663] In horses with RAO, inhalation of CpG-ODN nanoparticles resulted in reduced respiratory effort, nasal discharge, tracheal secretion, and viscosity; decreased tracheobronchial neutrophil percentage; and increased arterial oxygen pressure.[664] Administration of CpG-ODN has been evaluated for the potential to reduce vaccine-associated hypersensitivity reactions in horses. Administration of CpG-ODN along with a killed West Nile virus vaccine increased the differentiation of T_{regs} in response to bovine serum albumin (BSA), and an inverse correlation between numbers of T_{regs} and BSA-specific IgE concentration was observed.[665] Taken together, the progress in this field indicates that new and effective prophylactic strategies and therapies will likely be developed in the future.

CHAPTER 2

Pharmacologic Principles

Jennifer L. Davis*

Introduction to Clinical Pharmacology

Drug administration in equine practice relies on selection of a safe and efficacious dosage regimen based on the individual horse's physiology and the nature and formulation of the drug. It is the veterinarian's responsibility to ensure that the selected drug is efficacious with minimal toxicity or adverse reactions in the patient. Individual animals of various ages and species vary widely in their handling of an administered drug. A basic understanding of pharmacokinetics and the effects of pathophysiology on drug disposition in the horse enables the clinician to optimize therapy while minimizing the risk of adverse drug effects.

PHARMACOKINETICS

Pharmacokinetics describes the effect the body has on a drug, including drug absorption and distribution throughout the body, along with metabolism and excretion from the body. Basic pharmacokinetic studies are usually performed in healthy animals. Unfortunately, however, veterinarians do not often administer drugs to normal, healthy animals. Dosage regimens derived from studies in healthy animals may not be accurate for diseased animals. Clinical pharmacokinetics is the study of the effects of disease states or other variables (age, sex, pregnancy) on the pharmacokinetics of drugs. Clinical pharmacokinetics guides veterinarians in adjusting dosage regimens determined in healthy animals to optimize treatment of diseased animals.

PLASMA DRUG CONCENTRATIONS AS THERAPEUTIC GUIDELINES

Most pharmacokinetic information is derived from plasma drug concentrations, even though pharmacologic action depends on drug concentration at a particular effector site, which is often a specific drug receptor. In reality, measuring drug concentrations at the drug receptor site is not practical. Instead, plasma (or serum) drug concentrations are measured and assumed to represent drug concentrations in the target tissues. Most cells in the body are perfused with tissue fluids or plasma, and drug concentrations usually reach equilibrium between tissue fluids and the blood. Therefore for most drugs pharmacologic action correlates well with the plasma drug concentration.

VARIATION BETWEEN DRUG DOSE AND PLASMA DRUG CONCENTRATION

Drug dosages needed for a therapeutic effect differ widely among individuals. The "usual" dose has no effect in some individuals, causes serious toxicity in others, and produces an optimal effect in a few. The relationship between the dosage of a drug and its concentration in plasma is affected by its bioavailability, the animal's body size and fluid composition, variability in drug distribution within the body, and variability in rates of metabolism and excretion. These factors are all influenced by genetic differences in metabolism and excretion, environmental factors, disease alterations in system function, and concurrent administration of other drugs. Therefore the plasma concentration of a drug is not a perfect index of pharmacologic response. However, pharmacologic response is more closely related to plasma drug concentration than to drug dose, and knowledge of plasma drug concentration should always be used in combination with careful medical observation and judgment to determine optimal therapy.

DEFINITIONS IN PHARMACOKINETICS

Pharmacokinetic information is used to determine drug dosage regimens in clinical patients. An understanding of the way in which drug dosage regimens are derived and how they can be adjusted for different disease states requires knowledge of some basic pharmacokinetic terms. Mathematical *models* provide equations to describe drug concentration as a function of time. With an *open model* the drug is eliminated from the body. An open model describes the fate of most drugs. With a *closed model* the drug is recirculated within the body (e.g., a drug that undergoes enterohepatic recirculation). In pharmacokinetic models the body is represented by a series of *compartments* that

* The editors and authors acknowledge and appreciate the contributions of Patricia M. Dowling as a previous contributor to this chapter. Some of her original work has been incorporated into this edition.

communicate reversibly with one another. A *compartment* is a tissue or group of tissues with similar blood flow and drug affinity. A drug is assumed to be uniformly distributed within a compartment and can move dynamically in and out of compartments. Rate constants represent the entry and exit of drugs from each compartment. The *central compartment* is made up of the highly perfused tissues that equilibrate rapidly with the drug. Overall drug elimination occurs mainly from the central compartment, because the kidneys and liver are well-perfused tissues. The *peripheral compartment* is made up of less perfused tissues such as muscle and connective tissues. The *deep compartment* consists of slowly perfused tissues or depot tissues such as fat and bone. The presence of a deep compartment for drug distribution is important for toxins and drug residues. Most drugs in clinical use are described by one- or two-compartment models. Models with more than three compartments are usually not physiologically relevant. Describing drug disposition with compartment models creates differential equations that describe drug concentration changes in each compartment and provides a visual representation of the rate processes among compartments.

RATES AND ORDERS OF REACTIONS

The drug absorption or elimination rate is the speed with which it occurs. If the amount of drug in the body is decreasing over time, the elimination rate is expressed as follows:

$$\Delta C/\Delta t$$

The absorption and elimination rate of a drug is determined experimentally by measuring the plasma drug concentration at given time intervals. *Rate constants* relate the observed rate of a kinetic process to the drug concentration that controls the process. The elimination rate constant *(K)* is equal to the rate of drug elimination divided by the amount of drug in the body. The absorption rate constant (*K*a) describes the rate of drug absorption into the central compartment. *Reaction order* refers to the way that drug concentration influences reaction rate.

With a *zero order reaction* the amount of drug changes at a constant time interval, regardless of the drug concentration. The rate of drug elimination is as follows:

$$\Delta C/\Delta t = -K_0$$

where K_0 is the zero order rate constant in mg/mL/min. A graph of drug concentration versus time on regular graph paper for a zero order reaction produces a straight line (Fig. 2.1), described by the following equation:

$$C = -K_0 t + C_0$$

where C is the drug concentration at any time t, and C_0 is the drug concentration at time zero. For most drugs zero order elimination occurs only when elimination mechanisms become saturated. Renal tubular secretion and bile secretion of drugs are examples of potentially saturable processes. In veterinary medicine, drugs with well-known zero order elimination include phenylbutazone in horses and deracoxib in dogs. Once elimination processes are saturated, increased dosages of such drugs result in wildly unpredictable plasma concentrations and easily result in toxicity.

With a first order reaction, the amount of drug changes at a rate proportional to the amount of drug remaining. The first order elimination rate is expressed as follows:

$$\Delta C/\Delta t = -KC$$

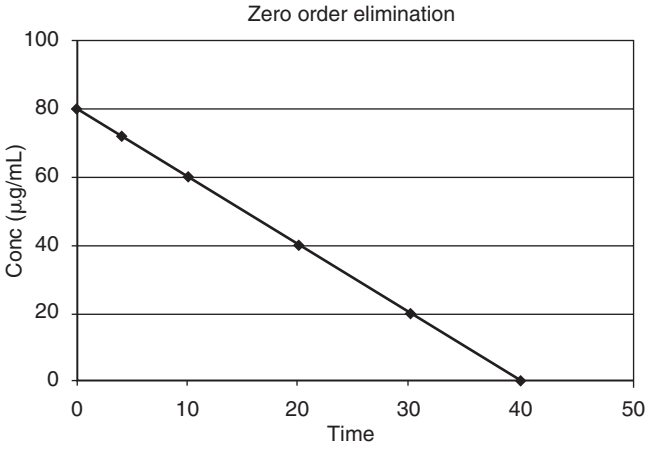

FIG. **2.1** Drug concentration versus time for a zero order reaction produces a straight line on regular graph paper.

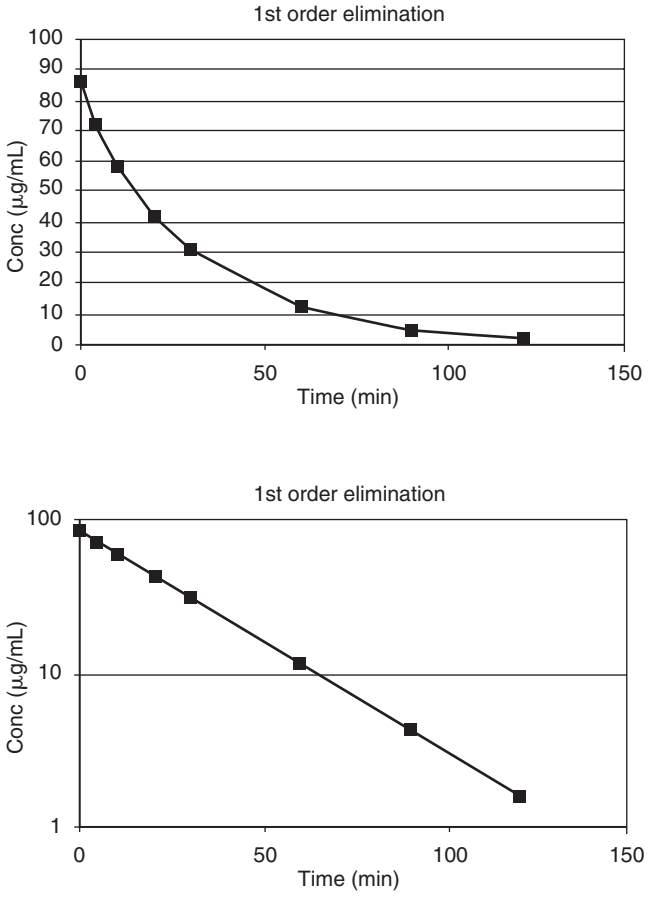

FIG. **2.2** Drug concentration versus time for a first order reaction produces an exponential curve on regular graph paper but produces a straight line on semilogarithmic graph paper.

where K is the first order rate constant, is expressed in units of time^{-1} (min^{-1} or hr^{-1}), and defines the fraction of drug eliminated from the body per unit time; C is the plasma drug concentration at any time t. Although K remains constant, the rate ($>C/>t$) is always changing because C is always decreasing. A graph of drug concentration versus time for a first order reaction produces an exponential curve on regular graph paper

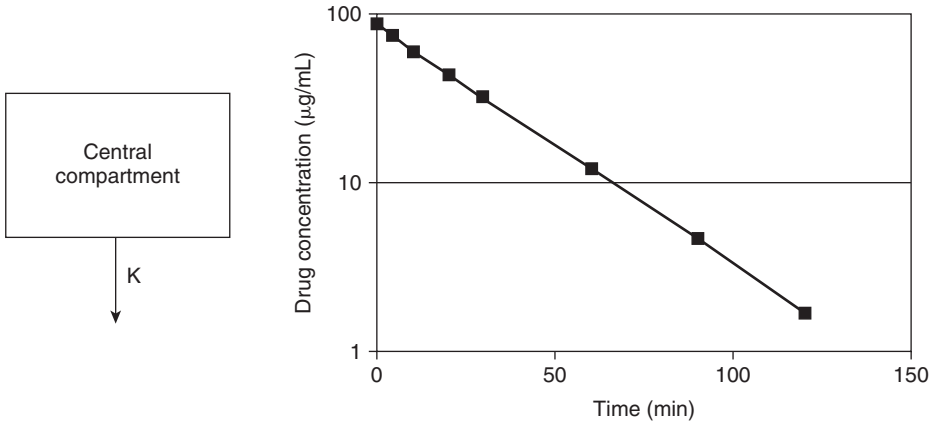

FIG. **2.3** Graphic representation of a one-compartment open model with IV administration and first order elimination.

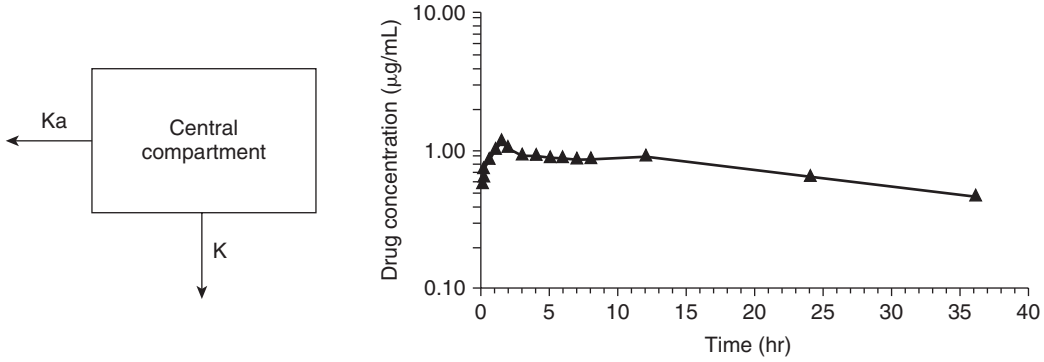

FIG. **2.4** Plasma concentration versus time graph after intramuscular administration of long-acting OTC to a horse, demonstrating a one-compartment open model with first order absorption and elimination.

but produces a straight line on semilogarithmic graph paper (Fig. 2.2) and is described by the following equation:

$$C = C_0 e^{-Kt}$$

where C is drug concentration at any time t, K is the first order rate constant in minutes or hours, and C_0 is the drug concentration at time zero (the moment of injection). Most drugs are absorbed and eliminated by first order processes. Glomerular filtration by the kidney is a first order process.

CLINICAL APPLICATION OF COMPARTMENTAL MODELING, RATES, AND ORDERS OF REACTIONS

The aforementioned concepts can be combined to mathematically describe the changes in the drug concentration in the body over time. Drug disposition described by a one-compartment open model with intravenous (IV) injection and first order elimination (Fig. 2.3) means that the body acts as one homogeneous compartment. A drug's concentration in one part of the body is assumed to be proportional to its concentration in any other part. The movement of drug into and out of the central compartment is described by the rate constants K_{01} and K_{10}.
Many drugs administered by routes other than IV, such as oral (PO), subcutaneous (SC), intramuscular (IM), or intradermal, are described by a one-compartment open model with first order absorption *(Ka)* and elimination *(K)* (Fig. 2.4). With a two-compartment open model with IV injection and first order elimination, the model assumes the body acts as two compartments: the central compartment (blood and highly vascularized tissues) and a peripheral compartment (less vascularized tissues). Many drugs administered in veterinary medicine are described by this model (Fig. 2.5). Elimination is considered to occur only from the central compartment, because the liver and kidneys are highly vascularized tissues. The plasma concentration versus time graph does not produce a straight line on semilogarithmic paper but can be broken into two sections and described by the following biexponential equation:

$$C = Ae^{-\alpha t} + Be^{-\beta t}$$

where C is the concentration at any time t, A is the y-intercept of the first portion of the curve extrapolated to zero, and α is the slope of the line; B is the y-intercept of the latter portion of the curve extrapolated to zero, and β is its slope. The movement of drug between the central and peripheral compartments is described by the rate constants K_{12} and K_{21}.

For some concentration versus time data, the line can be broken into three or more straight lines and described mathematically with three or more exponential terms. Theoretically, drug distribution in the body can be described by as many compartments as there are different tissues, but for practical purposes more than three-compartment models are not necessary. Drugs that are described by three-compartment models usually have some tissue site where the drug is sequestered

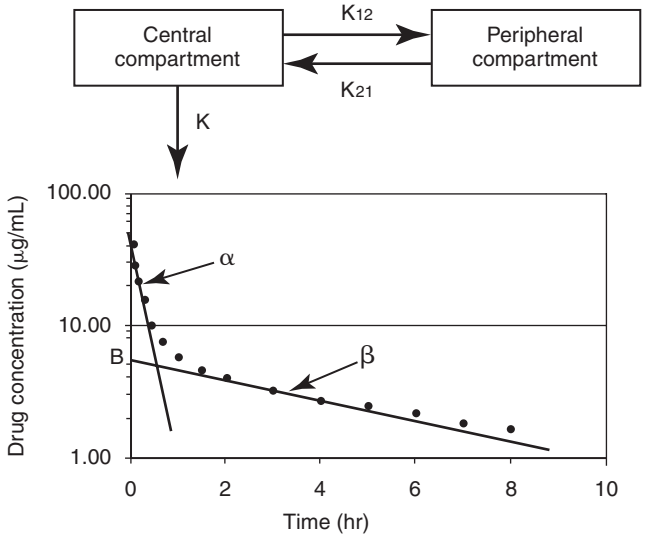

FIG. **2.5** Plasma concentration versus time graph after IV administration of gentamicin to a horse, demonstrating a two-compartment open model with first order elimination from the central compartment. The equation of the line is biexponential, where $C = A\,e^{-\alpha t} + Be^{-\beta t}$.

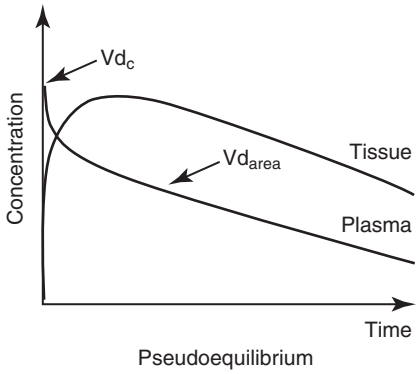

FIG. **2.6** Graphical representation of the difference between the volume of the central compartment and the volume of distribution by area.

and slowly eliminated from the body, such as the aminoglycosides, which sequester in the renal tubular epithelial cells, and oxytetracycline, which sequesters in teeth and bone.

DISTRIBUTION OF DRUGS IN THE BODY

The volume of distribution (Vd) of a drug is the mathematical term used to describe the apparent volume of the body in which a drug is dissolved.[1] The Vd is the parameter used to assess the amount of drug in the body from the measurement of a "snapshot" plasma concentration. The numeric value of Vd can give some indication of the distribution of the drug in the body. A drug's distribution is determined by its ability to cross biologic membranes and reach tissues outside the vascular system. The physical characteristics of the drug molecule, such as ionization, lipid solubility, molecular size, and degree of protein binding, determine its ability to cross biologic membranes.

Three volumes of distribution (Vd) are reported in the veterinary literature: the volume of the central compartment, the steady-state volume of distribution, and the volume of

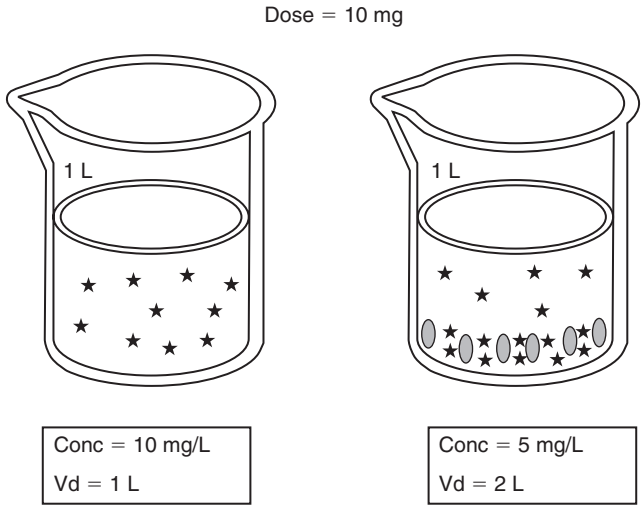

FIG. **2.7** The beaker on the left represents a low Vd drug that is mainly distributed to the extracellular fluid. A sample from the fluid will contain a high concentration of drug and therefore will have a low value for Vd. The beaker on the right represents a high Vd drug that readily crosses membranes and moves out of the extracellular fluid into tissues. A sample from the fluid will contain a low concentration of drug and therefore will have a high value for Vd.

distribution calculated by the area method. Conceptually, the easiest demonstration of the volume of distribution is with the volume of the central compartment (Vd_c). Just after an IV dose, plasma drug concentration is maximal (Fig. 2.6). Assuming that the instant drug concentration (C_0) results from the drug mixing in the blood, the Vd_c is the apparent volume from which drug elimination occurs since the kidneys and liver belong to the central compartment, and is calculated from the following equation:

$$Vd_c = \text{Dose}/C_0$$

where C_0 is the concentration at time zero, extrapolated from the plasma concentration versus time graph. To understand what the Vd_c for a drug represents, consider the body as a beaker filled with fluid (Fig. 2.7). The fluid represents the plasma and other components of extracellular water. If a drug is administered intravenously, it rapidly distributes in the extracellular fluid (ECF). If the drug does not readily cross lipid membranes, it will be confined mainly to the ECF, and a plasma sample therefore will have a high drug concentration. The higher the measured concentration in relation to the original dose, the lower the numeric value for Vd_c. Drugs such as the β-lactam and aminoglycoside antibiotics are poorly lipid soluble and therefore remain predominantly in the ECF and have low values for Vd. In contrast, some drugs readily cross lipid membranes and distribute into tissues. This is represented by the beaker on the right, where the stars at the bottom of the beaker represent drug molecules that have been taken up by tissues. A plasma sample will have a low drug concentration in proportion to the original dose and therefore will have a high numeric value for Vd_c. Given the limitations on measuring drug concentrations at "time zero" and using the aforementioned formula, the measured concentration of highly lipid-soluble drugs can be low enough to result in a value of Vd_c that is greater than 1 L/kg, so it is often referred to as an *apparent volume of distribution*. In the example on

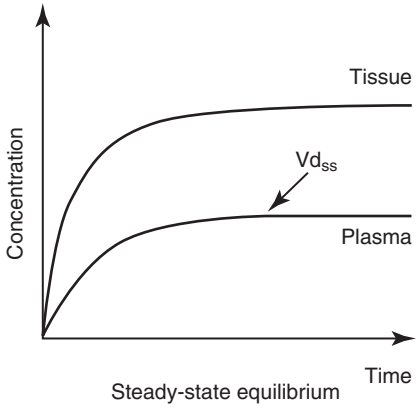

FIG. **2.8** Graphical representation of the volume of distribution when plasma concentrations are measured at steady-state conditions.

the right, the "apparent" Vd is 2 L/kg even though the beaker contains only 1 L of fluid.

For most drugs after a single IV dose, the drug is distributed and begins to be eliminated simultaneously. When concentrations are measured and the data graphed, there is a distribution phase, wherein the plasma drug concentration that is due to elimination and not distribution increases until it reaches an asymptotic value at which pseudoequilibrium is achieved (see Fig. 2.6). When pseudoequilibrium is reached, the movement of drug between the peripheral and central compartments reaches equilibrium, and decreasing plasma concentrations are now due only to irreversible elimination (described by the elimination rate constant, β). The applicable Vd value in this situation is the volume of distribution by area (Vd_{area}):

$$Vd_{area} = Dose \div AUC_{0-\infty}/\beta$$

where $AUC_{0-\infty}$ is the area under the plasma concentration time curve extrapolated to infinity. To be calculated accurately, the amount of drug that enters the systemic circulation must be accurately known, and the terminal phase must be a pure elimination phase. An inaccurate Vd_{area} is frequently published for "long-acting" IM- or SC-administered drugs, where prolonged elimination is due to delayed absorption (flip-flop kinetics).

With an IV infusion or with a multiple-dose regimen, the rate of drug entry into the body is equal to its elimination rate, and the body becomes a closed system with no clearance. In this situation the correct Vd to describe distribution is the Vd at steady-state (Vd_{ss}; Fig. 2.8):

Vd_{ss} = Drug in body at steady state/Concentration in plasma

Clinical Use of the Different Volume of Distribution Values

The Vd_c is used to predict the initial plasma drug concentration after an IV bolus of a drug when a loading dose is needed to rapidly achieve a therapeutic drug concentration. The Vd_{ss} is used to calculate a loading dose when it is clinically necessary to rapidly reach steady-state concentrations. The Vd_{area} is used to predict the amount of drug remaining in the body. For all drugs the value of Vd_{area} is greater than Vd_{ss}, but generally the difference is small and the values are used interchangeably. However, with the IV administration of drugs that are rapidly eliminated into urine (e.g., aminoglycosides), Vd_{area} can be much larger than Vd_{ss} because a large fraction of the drug is eliminated before pseudoequilibrium is reached.

It is useful to compare a drug's Vd to the distribution of water in the body to get an idea of its distribution. Drugs with a Vd value of less than 0.3 L/kg are predominantly confined to the ECF, whereas drugs with a Vd value of greater than 1 L/kg are highly lipid soluble and tend to distribute out of the ECF and into tissue compartments (Box 2.1). Although the value of Vd does not confirm penetration of a drug into specific tissues, in general the higher the value of the Vd, the more likely it is that the drug will reach sequestered sites such as the brain and cerebrospinal fluid (CSF), the prostate and other sex organs, the eye, and the mammary gland. Studies must be performed to confirm that therapeutic concentrations are achieved in such sites.

BOX 2.1 Volume of Distribution (Vd) of Various Drugs

LOW-VD DRUGS (<0.3 L/KG)
Penicillins
Cephalosporins
Aminoglycosides
Nonsteroidal antiinflammatory drugs

MEDIUM-VD DRUGS (>0.3–<1 L/KG)
Phenobarbital
Sulfonamides
Prednisolone
Rifampin

HIGH-VD DRUGS (>1 L/KG)
Macrolides
Tetracyclines
Fluoroquinolones
Chloramphenicol
Metronidazole
Trimethoprim
Dexamethasone
Furosemide
Ketamine
Diazepam
Firocoxib

Conditions That Affect Volume of Distribution

The Vd is constant for any drug and will change only with physiologic or pathologic conditions that change the distribution of the drug. Drugs with high Vd are usually very lipid soluble and typically are not significantly affected by changes in body water status and do not require dosage adjustment. However, there are many medical conditions that affect the disposition of low Vd drugs in a patient (e.g., nonsteroidal antiinflammatory drugs and aminoglycosides), and these drugs do require dosage adjustment because of their narrow therapeutic index. Many conditions in horses, such as colic, are characterized by volume contraction and dehydration and changes in acid-base balance, which affect the ECF volume. Neonatal foals have a higher percentage of body water than adult horses (80% vs. 60% total body water), and the extra 20% is primarily confined to the ECF, so the Vd values of drugs such as gentamicin are higher in neonatal foals than older foals or adult horses.[2] Therefore to achieve equivalent therapeutic

plasma concentrations of gentamicin in a neonatal foal, the dose must be higher than that administered to the older foal or adult horse.

Bioavailability

Bioavailability (F) is a measure of the systemic availability of a drug administered by a route other than IV.[3] Bioavailability is determined by comparing the area under the plasma drug concentration curve versus time *(AUC)* for the extravascular formulation to the *AUC* for the IV formulation. The *AUC* is calculated by computer or by the trapezoidal method, wherein the entire curve is divided into trapezoids, then the area of each trapezoid is calculated and summed to give the *AUC*. For an orally administered drug, use the following equation:

$$F = (AUC_{oral} \div AUC_{IV}) \times 100 = \% \text{ bioavailable}$$

If *F* is significantly less than 100%, the drug dose must be increased to achieve systemic drug concentrations similar to the IV formulation:

$$\text{Adjusted dose} = \text{Dose}_{IV}/F$$

If the oral formulation of a drug has a mean bioavailability of 50%, the drug dose must be doubled to achieve the same concentrations in plasma as achieved using the IV formulation. However, the variability of the bioavailability in the population is more clinically significant than the mean. To make sure that the horse with the poorest absorption is dosed appropriately, the dose must be increased according to the lowest bioavailability, not the mean. For example, if a drug has a mean *F* of 50% with a range of 20% to 70%, then to achieve an exposure of 100% for all the treated horses, the dose must be multiplied by 5, not just 2. However, if this is done, the horses with an *F* of 70% will be overdosed by a factor of 3.5. For a drug with a narrow therapeutic window and a poor bioavailability, there may be no dose that is ideal for all horses in the population. Low bioavailability of antimicrobials and anthelmintics is a major cause of subtherapeutic dosages that promote drug resistance. Poor oral bioavailability is a major limitation of many drugs administered to horses.[4]

Lipid Solubility and Drug Ionization (the pH-Partition Hypothesis)

The degree of lipid solubility determines how readily a drug will cross biologic membranes. Drugs are classified as lipid soluble (or nonpolar) versus water soluble (or polar). Highly lipophilic drugs diffuse easily across almost all tissue membranes. Most of the drugs used in equine practice exist as weak acids or weak bases. Their lipid solubility depends a great deal on their degree of ionization (charged state). An *ionized* drug is hydrophilic and poorly lipid soluble. A *nonionized* drug is lipophilic and can cross biologic membranes. The degree of ionization for a weak acid or weak base depends on the p*K*a of the drug and the pH of the surrounding fluid. At a given pH, there is an equilibrium between the ionized and nonionized proportions of drug. When the pH is equal to the p*K*a of the drug, the drug will be 50% ionized and 50% nonionized (log 1 = 0). As the pH changes, the proportion of ionized to nonionized drug will change according to the *Henderson-Hasselbach* equations:

For a weak acid:

$$\text{pH} = \text{p}Ka + \log(\text{Ionized drug}/\text{Nonionized drug})$$

For a weak base:

$$\text{pH} = \text{p}Ka + \log(\text{Nonionized drug}/\text{Ionized drug})$$

BOX 2.2 Drugs Classified by pH

ACIDIC DRUGS
Penicillins
Cephalosporins
Sulfonamides
Nonsteroidal antiinflammatory drugs

BASIC DRUGS
Macrolides
Trimethoprim
Chloramphenicol
Metronidazole
Aminoglycosides

AMPHOTERIC DRUGS
Fluoroquinonolones
Tetracyclines

Whereas the precise ratios of ionized versus nonionized drug can be calculated from the Henderson-Hasselbalch equations, the relevance of the equations can be understood by simply remembering the sentence "like is nonionized in like." For example, a weak acid will be most nonionized in an acidic environment, so aspirin is most nonionized in the stomach and is readily absorbed. The fluid of most sequestered sites in the body (CSF, accessory sex gland fluid, milk, abscesses) has a pH more acidic than plasma. In cattle with mastitis weak acid antibiotics are typically administered by intramammary infusion, whereas weak bases are administered parenterally. This makes sense according to the pH-partition concept. Weak bases in the plasma are highly nonionized and readily cross into the mammary gland. Then, as the equilibrium shifts, they become "ion trapped" in the more acidic milk, but the fraction of nonionized drug in the mammary gland is available to cross the bacterial cell membrane for antimicrobial action. Weak acids such as penicillins and cephalosporins are highly ionized in plasma and therefore do not penetrate into the mammary gland very well, so these are most effective when administered by local infusion into the udder, where the extremely high local concentrations negate local pH effects.

Typically, drugs that are weak acids will have low Vd values and weak bases will have high values for Vd (Box 2.2). Amphoteric drugs such as the fluoroquinolones and tetracyclines have acidic and basic groups on their chemical structures. These drugs have a pH range where they are maximally nonionized. For example, enrofloxacin is most lipid soluble (nonionized) in the pH range of 6 to 8, so it is lipid soluble at most physiologic pH levels. In acidic urine significant ionization occurs, which reduces enrofloxacin's antibacterial activity. But this reduction in activity is offset by the extremely high concentrations of enrofloxacin achieved in urine, so it is of no clinical importance. Despite being weak bases, the aminoglycosides are very large, hydrophilic molecules and have high p*K*a values, so they are highly ionized at physiologic pH levels. Therefore parenterally administered aminoglycosides do not cross lipid membranes well and do not achieve therapeutic concentrations in milk, accessory sex gland fluids, abscesses, or CSF.

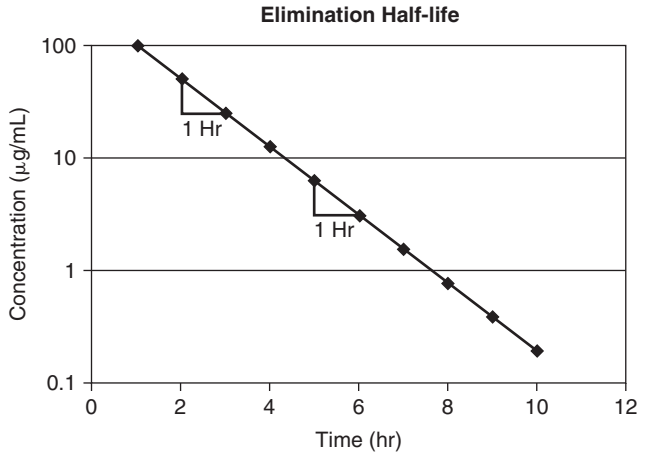

FIG. **2.9** For a drug with first order elimination, the plasma concentration decreases by 50% every hour, so the elimination half-life is 1 hour.

Drug Protein Binding

Protein binding can involve plasma proteins, extracellular tissue proteins, or intracellular tissue proteins. Many drugs in circulation are bound to plasma proteins, and because bound drug is too large to pass through biologic membranes, only free drug is available for delivery to the tissues and to produce the desired pharmacologic action. Therefore the degree of protein binding can greatly affect the pharmacokinetics of drugs. Acidic drugs such as nonsteroidal antiinflammatory drugs (NSAIDs) tend to bind predominantly to albumin.[5] Albumin is the most abundant plasma protein, and it is critical to maintaining the colloidal oncotic pressure in the vascular system. As a negative acute phase protein, albumin concentration decreases during inflammation. Hypoalbuminemia results from decreased production, seen with severe hepatic insufficiency, or by loss through increased rates of urinary excretion, such as in glomerulonephritis or with mucosal damage, as with protein-losing enteropathies. Basic drugs typically bind to α-1 acid glycoprotein, which is an acute phase protein, whose hepatic production increases significantly with inflammatory conditions.[6] Other proteins, including corticosteroid binding globulin, are important for binding of some specific drugs but are less important in overall drug-protein binding.[7] There is equilibrium between free and bound drug, however, just like the relationship of ionized and nonionized drug molecules. Protein binding is most clinically significant for antimicrobial therapy, where a high degree of protein binding serves as a drug "depot," allowing for increased duration of the time the drug concentration remains above the bacterial minimum inhibitory concentration, adding to antimicrobial efficacy.[8] For other drugs changes in plasma protein binding can influence individual pharmacokinetic parameters, but changes in plasma protein binding usually do not influence the clinical exposure of the patient to a drug. Changes in protein binding caused by drug interactions are assumed to instantaneously change free drug concentrations and have been frequently cited as a cause of adverse drug reactions. But the increase in free drug concentration is only transient, because drug distribution and drug elimination change to compensate. The often-cited example of the concurrent administration of phenylbutazone and warfarin leading to bleeding caused by increased free concentrations of warfarin is erroneous. The true interaction is from phenylbutazone-induced inhibition of the hepatic metabolism of warfarin, which results in increased plasma concentrations and increased anticoagulant effect.[7] Therefore adjustments in dosing regimens because of hypoproteinemia or concurrent administration of highly bound drugs are not necessary except in the rare case of a drug with a high hepatic extraction ratio and narrow therapeutic index that is given parenterally (e.g., IV dosing of lidocaine).[9]

DRUG ELIMINATION FROM THE BODY

Drug elimination refers to the irreversible removal of drug from the body by all routes of elimination. Elimination may be divided into two major components: excretion and biotransformation. Drug excretion is the removal of the intact drug. Most drugs are excreted by the kidney into the urine. Other pathways include the excretion of drug into bile, sweat, saliva, or milk. Biotransformation (drug metabolism) converts the drug in the body to a metabolite that is more readily excreted, usually by adding a chemical group to the molecule to make it more water soluble. Enzymes involved in biotransformation are mainly located in the liver. Other tissues, such as the kidney, lung, small intestine, and skin, also contain biotransformation enzymes.

ELIMINATION RATE CONSTANT AND ELIMINATION HALF-LIFE

The rate of elimination for most drugs is a first order process. The elimination rate constant *(K)* represents the sum of drug elimination by excretion and metabolism. Drug elimination is considered always to occur from the central compartment, because the liver and kidney are well-perfused tissues. The elimination rate constant is used to calculate the drug's half-life ($T_{½}$), or the time required for drug concentration to decrease by one half (Fig. 2.9). For first order reactions, $T_{½}$ is constant across the plasma concentration versus time curve and is calculated from

$$T_{1/2} = 0.693/K$$

where 0.693 = ln2 (the natural logarithm of 2). Mean residence time (MRT) is roughly the equivalent of $T_{½}$ when pharmacokinetics is calculated using statistical moment theory. The MRT is an estimate of the average time a drug molecule spends in the body, which typically correlates to the time it takes for drug concentration to decrease by 63.2%. Therefore the MRT value should be slightly greater than $T_{½}$. If the calculated value for MRT is not longer than the $T_{½}$, there was likely an inadequate number of samples in the distribution or elimination phase of the study. Although these parameters are similar, it is the $T_{½}$ that is used to determine the drug dosage interval, how long a toxic or pharmacologic effect will persist, and drug withdrawal times for food animals or performance horses. Notice that it takes 10 $T_{½}$ to decrease the plasma concentration by 99.9% (Table 2.1). Knowing a drug's plasma $T_{½}$ can give the clinician some idea of the drug's withdrawal time for food or performance animals. However, for drugs that undergo hepatic metabolism (e.g., phenylbutazone) or drugs that sequester in specific tissues (e.g., aminoglycosides, isoxsuprine), simply multiplying the $T_{½}$ by a factor of 10 for a withdrawal time may not be sufficient to prevent violative residues. Also note that doubling

TABLE **2.1** Half-Life of Elimination of a Drug

Number of Half-Lives	Fraction of Drug Remaining (%)	Fraction of Drug Eliminated (%)
0	100	0
1	50	50
2	25	75
3	12.5	87.5
4	6.25	93.75
5	3.125	96.875
6	1.56	98.44
7	0.78	99.22
8	0.39	99.61
9	0.195	99.805
10	0.0975	99.9025

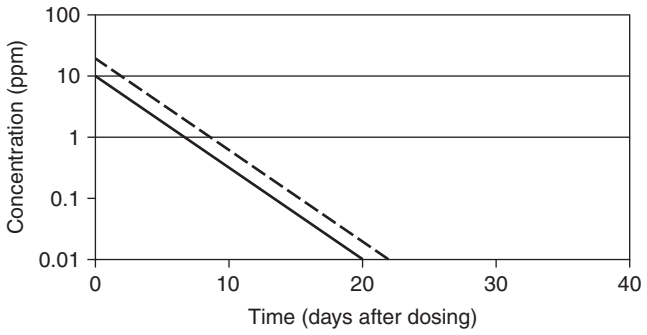

FIG. **2.10** Doubling a drug dose adds only one half-life to its withdrawal time. For this drug with an elimination half-life of 24 hours, if the dose is doubled to reach a plasma concentration of 20 μg/mL, it will take 21 days instead of 20 days to reach an acceptable threshold of 0.01 μg/mL.

a drug dose does not double the withdrawal time; it merely adds 1 half-life to the time it takes to reach the acceptable threshold concentration (Fig. 2.10).

Flip-Flop Kinetics

Long-acting drug formulations are often products whose carriers cause them to be slowly absorbed from the site of administration into the systemic circulation. In these instances, the drug elimination rate is limited by the drug absorption rate. The value for *K* (the elimination rate constant) calculated from the plasma concentration versus time curve is actually the value for *K*a (the absorption rate constant). The easiest way to identify flip-flop kinetics is to compare the plasma concentration versus time curve for the extravascular route of administration to the curve after the drug is given intravenously (Fig. 2.11). If the elimination phases of the curves are not parallel, delayed absorption is prolonging elimination and the flip-flop phenomenon has occurred. Flip-flop kinetics is also one potential reason for a reported bioavailability greater than 100%.

For a two-compartment model, β (from the equation $C = Ae^{-\alpha t} + Be^{-\beta t}$) is the drug elimination rate constant from the entire body once the drug has reached equilibrium between the two compartments. Therefore β is used to calculate the elimination half-life:

$$T_{1/2} = 0.693/\beta$$

Clearance

Clearance is a measure of drug elimination from the body without reference to the mechanism of elimination. It is always reported in pharmacokinetic papers, but its significance is rarely explained in pharmacokinetic studies in horses. Clearance is the most important pharmacokinetic parameter because it is the only parameter that controls overall drug exposure, and it is used to calculate the dosage required to maintain a specific average steady-state concentration.[10]

Clearance (Cl) is the total drug clearance and is the sum of renal clearance (Cl_R), hepatic clearance (Cl_H), and all other elimination mechanisms. By definition, Cl is the volume of fluid containing drug that is cleared of drug per unit of time (mL/kg/min). The most frequent technique for determining plasma Cl is to administer a single IV dose of a drug and then measure plasma concentrations over time. Then,

$$Cl = Dose/AUC$$

where *AUC* is the area under the plasma concentration time curve.

If the body is considered as the whole system clearing the drug, Cl can also be determined by the animal's cardiac output and the extraction ratio *(E),* where *E* is a numeric value between 0 and 1 that is the percentage of the drug that is cleared by a single pass through the clearing organ:

$$Cl = \text{Cardiac output} \times E$$

For a drug with an extraction ratio of 1 (100% removal by the liver and kidney on the first pass), the expected value of Cl is about 50% of the cardiac output, because blood flow to the liver and the kidneys represents approximately half of the cardiac output.

In contrast to Vd values, Cl values have to be interpreted according to the value of cardiac output for the species involved. Given that most drugs are extracted primarily by renal and hepatic mechanisms, the extraction ratio is considered high if *E* is greater than 0.7, medium if *E* equals 0.3, and low if *E* is less than 0.1. Because the liver and kidneys receive about 50% of cardiac output, the overall *E* is high if it is greater than 0.35, medium if it is about 0.15, and low if it is less than 0.05. From this and the cardiac output of the species, breakpoint values can be determined to classify drugs as having high, medium, and low clearance. For the horse with a cardiac output of 55 mL/kg/min, a high Cl value is 19 mL/min/kg, medium Cl is 8.25 mL/min/kg, and low Cl is 3.6 mL/min/kg.

It is sometimes difficult to understand the difference between the elimination half-life and clearance. The relationship is as follows:

$$Cl = (Vd)(K) \text{ or}$$

$$Cl = (Vd)\left(0.693/T_{1/2}\right)$$

Consider the values for clearance and $T_{1/2}$ for four antimicrobial drugs (Table 2.2). Note that the plasma clearance values are similar, but the elimination half-lives are very different. Because the $T_{1/2}$ is influenced by the extent of drug distribution, the drugs have similar clearance, but oxytetracycline has the largest Vd and the longest $T_{1/2}$. Because $T_{1/2}$ is derived from rate constants and does not have a physiologic basis, it is influenced by the sensitivity of the analytic method and by many pharmacokinetic parameters, and it is a poor parameter alone to evaluate physiologic (e.g., age, sex) or pathologic (e.g., renal failure) changes that effect drug disposition.

TABLE **2.2** Comparison of Clearance to Elimination Half-Life

	Penicillin	Gentamicin	Oxytetracycline	Tylosin
Cl (mL/min/kg)	3.5	3.1	4.0	2.2
$T_{½}$ (min)	30	75	360	54

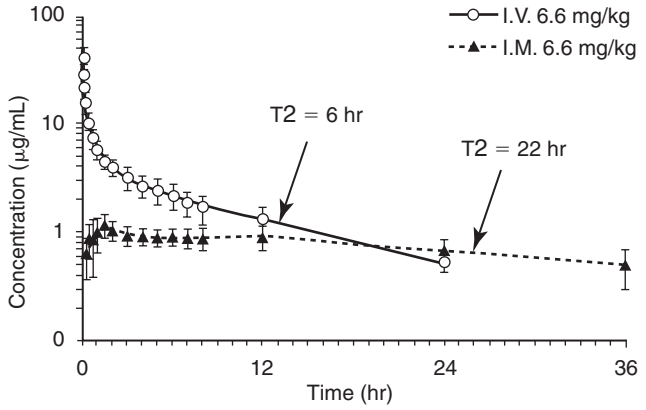

FIG. **2.11** Plasma concentration versus time graph for long-acting oxytetracycline in horses, demonstrating "flip-flop" kinetics. The delayed absorption from the intramuscular injection results in the slow elimination and triples the elimination half-life value.

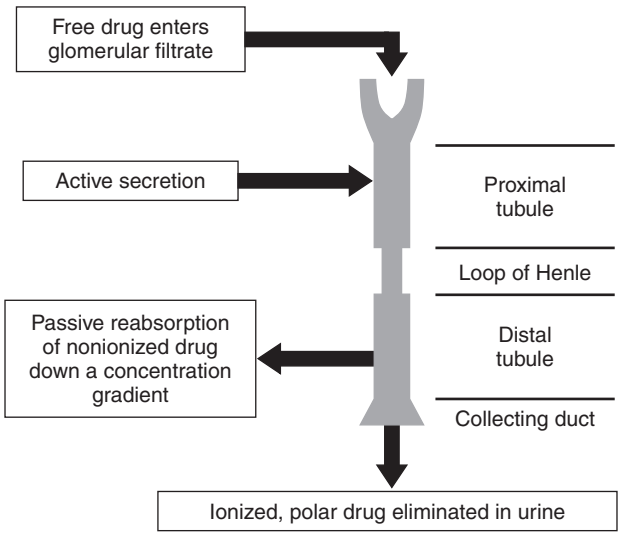

FIG. **2.12** Movement of drugs in the renal tubule.

Renal Clearance of Drugs

Renal excretion is the major route of elimination from the body for most drugs. Drug disposition by the kidneys includes glomerular filtration, active tubular secretion, and tubular reabsorption (Fig. 2.12), such that renal drug clearance is defined by the following equation:

$$Cl_R = Cl_F + Cl_S - FR$$

where Cl_R is total renal clearance, Cl_F is clearance attributed to glomerular filtration, Cl_S is clearance attributed to active tubular secretion, and FR is the fraction of drug reabsorbed from the tubule back to circulation.

TABLE **2.3** Renal Clearance (mL/min/kg) at Different Urinary pHs

			Urine pH		
		p*K*a	4.4	6.4	7.9
Penicillin	Acid	2.4	0.001	0.1	3.0
Oxytetracycline	Base	10.4	1000	10	0.3

Glomerular filtration occurs with small molecules (less than 300 molecular weight) of free (unbound) drug. Large molecules or protein-bound drugs do not get filtered at the glomerulus because of size and electrical hindrance. The kidneys receive approximately 25% of cardiac output, so the major driving force for glomerular filtration is the hydrostatic pressure within the glomerular capillaries. Glomerular filtration rate (GFR) is estimated by measuring a substance or drug that is eliminated only by glomerular filtration, such as creatinine or inulin.

If Cl_R is greater than Cl_F, some degree of tubular secretion is occurring. Active tubular secretion is a carrier-mediated transport system, located in the proximal renal tubule. It requires energy input because the drug is moved against a concentration gradient. Two active tubular secretion systems have been identified: anion secretion for acids and cation secretion for bases. Drugs with similar structures may compete with each other for the same transport system. For example, probenecid competes with penicillin or the fluoroquinolones for the same transport system, effectively decreasing Cl_R of these antimicrobials. In patients with reduced functional renal tissue, remaining transport systems become easily saturated and drug accumulation occurs.

If Cl_R is less than the GFR, tubular reabsorption of drug is occurring. Tubular reabsorption is an active process for endogenous compounds (e.g., vitamins, electrolytes, glucose). It is a passive process for the majority of drugs. It occurs along the entire nephron but primarily in the distal renal tubule. Factors that affect reabsorption include the p*K*a of the drug and urine pH, which in turn influence drug ionization. According to the Henderson-Hasselbach equation, a drug that is a weak base will be mainly nonionized in alkaline urine, and a weak acid will be mainly ionized in alkaline urine. The nonionized form of the drug is more lipid soluble and has greater reabsorption (Table 2.3). The p*K*a of a drug is constant, but urinary pH is highly variable in animals and varies with the diet, drug intake, time of day, and systemic acidosis/alkalosis. Species differences have a major influence on the renal excretion of ionized drugs. Carnivores, with a urine pH of 5.5 to 7.0, will have a greater renal excretion of basic drugs than herbivores, with a urine pH of 7.0 to 8.0, and vice versa. Additional factors affecting drug reabsorption include lipid solubility, drug size, and urine flow.

Hepatic Clearance of Drugs

Nonrenal drug elimination is assumed to be due primarily to biotransformation (hepatic metabolism) and biliary excretion. Clearance of a drug by the liver is determined by hepatic blood flow (Q_H) and the intrinsic ability of the liver to extract the drug (extraction ratio, or ER_H):

$$Cl_H = (Q_H)\,(ER_H)$$

Drugs with a high extraction ratio (approaching 1) have Cl_H equal to the hepatic blood flow. These drugs are called *high*

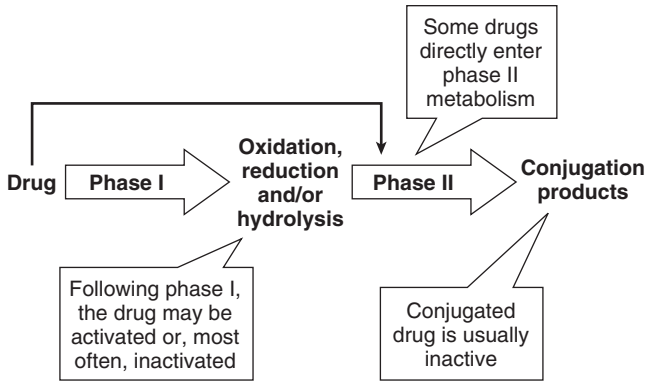

FIG. **2.13** Hepatic metabolism increases the water solubility of drugs, facilitating excretion from the body.

clearance drugs. Examples of drugs with high ER_H are lidocaine, propranolol, and isoproterenol. Clearance of drugs with high ER_H is highly influenced by changes in hepatic blood flow. Drugs that are administered orally and are absorbed across the intestinal mucosa must first pass through the liver via the portal circulation before being distributed to the rest of the body. Most of a drug with a high ER_H will be cleared in one pass through the liver; this is called the *first pass effect,* and it limits the oral administration of such drugs (e.g., morphine). Drugs that have a low hepatic extraction rate ($ER_H \leq 0.2$) are not greatly affected by changes in hepatic blood flow. However, their clearance will be affected by changes in the hepatic microsomal enzyme systems and protein binding. A first pass effect does not interfere with the systemic availability of these drugs. Drugs with a low ER_H include chloramphenicol, phenylbutazone, phenobarbital, and digoxin.

Biotransformation (Hepatic Metabolism) of Drugs

Metabolism is necessary for removal of lipophilic drugs from the body (Fig. 2.13). Biotransformation depends on the chemical composition of the liver, activity of major drug metabolism enzymes, hepatic volume (perfusion rate), drug accessibility to and extraction by hepatic metabolic sites, and physicochemical properties of the drug. Biotransformation of a parent drug results in metabolites that may be active or inactive themselves. A *prodrug* is a drug administered in an inactive form that must be biotransformed to its active form, such as prednisone to prednisolone. Drug metabolic pathways are divided into *phase I* and *phase II* reactions. Phase I reactions (oxidation, reduction, hydrolysis, hydration, dethioacetylation, isomerization) typically add functional groups to the drug molecule necessary for phase II reactions. Phase II reactions (glucuronidation, glucosidation, sulfation, methylation, acetylation, amino acid conjugation, glutathione conjugation, and fatty acid conjugation) typically include conjugation reactions that increase the water solubility of the drug, facilitating excretion from the body.

Among the reactions catalyzed by drug metabolism enzymes, the cytochrome P450 mixed function oxidase system is the most intensively studied. This reaction catalyzes the hydroxylation of hundreds of structurally diverse drugs, whose only common characteristic is high lipid solubility. Species differences in drug metabolic rate are the primary source of variation in drug activity and toxicity. Cats have a poor ability to glucuronidate drugs, pigs are deficient in sulfate conjugation, and dogs are relatively poor acetylators. Compared with other species, the metabolizing pathways of the horse are relatively unknown.

BOX 2.3 Drugs That Affect Enzyme Function

ENZYME INDUCERS
Chlorinated hydrocarbons
Griseofulvin
Omeprazole
Phenobarbital
Phenytoin
Rifampin

ENZYME INHIBITORS
Chloramphenicol
Cimetidine
Dexamethasone
Erythromycin
Fluoroquinolones
Ketoconazole
Phenobarbital
Phenylbutazone
Prednisolone
Quinidine

Induction and Inhibition of Metabolism

Metabolism of drugs can be substantially affected by enzyme induction or inhibition by other drugs or chemicals (Box 2.3). In some cases the drug itself may alter its own metabolic fate by induction or inhibition. Many drugs are capable of inducing enzyme activity, thereby increasing the rate of metabolism and hepatic clearance of concurrently administered drugs, which typically results in a decreased pharmacologic effect. Enzyme induction usually occurs slowly, requiring several weeks to reach maximum effect. Induction is accompanied by increased hepatic ribonucleic acid (RNA) and protein synthesis and increased hepatic weight. Enzyme induction is important in the pathogenesis of hepatotoxicity and therapeutic failure of many drugs. Phenobarbital is a potent enzyme inducer known for hepatotoxicity and for inducing its own metabolism. Rifampin induces the metabolism of azole antifungals; concurrent administration with itraconazole results in subtherapeutic itraconazole concentrations.

Drug-induced enzyme inhibition also occurs and typically results in prolonged clearance of a concurrently administered drug. The potential for toxicity or an exaggerated pharmacologic response is increased. In contrast to induction, inhibition occurs rapidly. Erythromycin and enrofloxacin are known inhibitors of the metabolism of theophylline; concurrent administration can cause central nervous system toxicity and seizures.[11,12]

Kinetics of Drug Metabolism

The enzymes that catalyze drug metabolism typically obey Michaelis-Menten kinetics as a *first order reaction:*

$$V = (V_{max}[C])/(K_m + [C])$$

where V is the rate of drug metabolism, K_m is the Michaelis constant, and C is the drug concentration. In most

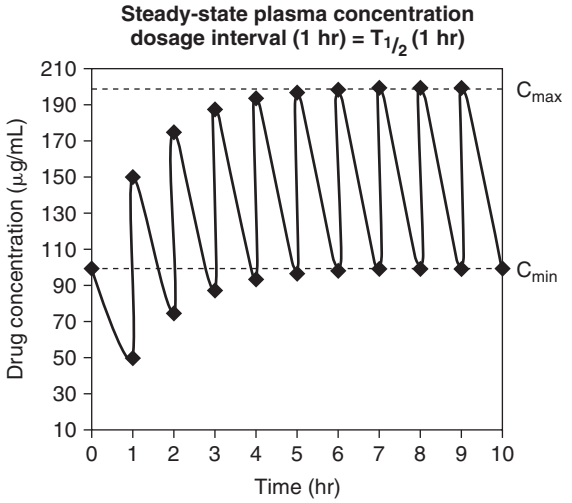

FIG. **2.14** Plasma concentration versus time graph for an IV drug that produces a peak plasma concentration of 100 μg/mL after a single dose. After 6 hours (which equals 6 half-lives), the maximum and minimum drug concentrations become constant, further drug accumulation does not occur, and the drug is steady-state.

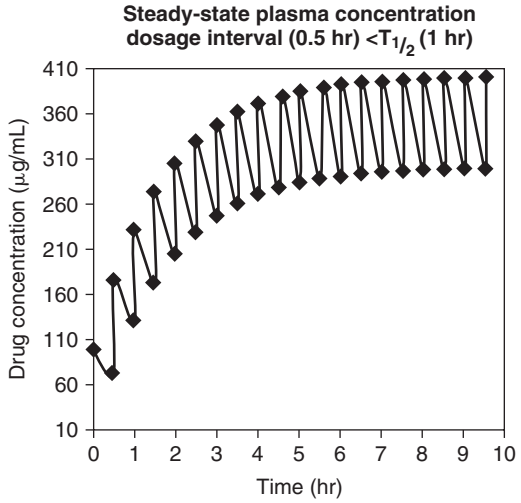

FIG. **2.15** Plasma concentration versus time graph for a drug with a dosage interval (0.5 hour) less than the half-life (1 hour), demonstrating significant drug accumulation at steady-state.

clinical situations the drug concentration is much less than the Michaelis constant, so the equation reduces to the following:

$$V = (V_{max}\,[C]\,)/K_m$$

That is, the rate of drug metabolism is directly proportional to the concentration of free drug, and first order kinetics are observed in that a constant fraction of drug is metabolized per unit of time. With a few drugs, such as phenylbutazone, ethanol, deracoxib, and phenytoin, or if very large doses of a drug are given, the drug concentrations achieved are much greater than K_m and the rate equation is as follows:

$$V = (V_{max}\,[C]\,)/\,[C]\, = V_{max}$$

The enzymes are saturated by the high free drug concentrations, and the rate of metabolism remains constant over time. This is termed *zero order kinetics* or *nonlinear kinetics.*

DRUG ACCUMULATION

Drugs are often given in multiple-dose regimens. To predict plasma drug concentrations, it is necessary to decide whether successive doses of a drug have any effect on the previous dose. The *principle of superposition* assumes that early doses of drug do not affect the pharmacokinetics of subsequent doses. For most drugs, as equal doses are given at a constant dosage interval, the plasma concentration-time curve plateaus and a *steady-state* is reached. At steady-state the plasma drug concentration fluctuates between a maximum concentration (C_{max}, or peak) and minimum concentration (C_{min}, or trough). Once steady-state is reached, C_{max} and C_{min} are constant and remain unchanged from dose to dose (Fig. 2.14). The time to steady-state depends solely on the elimination half-life. It takes approximately 5 to 6 $T_{½}$ to reach 99% steady-state levels. The drug dose and dosage frequency influence the values of C_{max} and C_{min} at steady-state, and the dosage frequency and $T_{½}$ influence the fluctuation between C_{max} and C_{min}.

Clinical Consequences of Dosage Intervals Less Than the Half-Life

Drugs such as phenobarbital, potassium bromide, phenylbutazone, and digoxin are commonly given at dosage intervals much shorter than their $T_{½}$ (Fig. 2.15). This results in drug accumulation and a C_{max} at steady-state that is greater than the peak concentration after a single dose. The predicted accumulation ratio (RA) with multiple-dose administration can be estimated using the following equation:

$$RA = 1/1 - e^{-\lambda z \tau}$$

where λz is the slope of the elimination phase and τ is the dosage interval. There is minimal fluctuation between C_{max} and C_{min}, and missing a single dose will not affect plasma concentrations greatly. There is a lag time to reach the desired plasma concentrations at steady-state, and there will be a lag time for plasma concentrations to change in response to a dose change.

Clinical Consequences of Dosage Intervals Greater Than the Half-Life

Drugs such as IV formulations of penicillin and cephalosporins are administered at dosage intervals that are greater than the $T_{½}$ (Fig. 2.16). As the dosage interval increases, C_{max} at steady-state is closer in value to the peak concentration after a single dose. If the dosage interval is greater than 10 $T_{½}$ (the time required to eliminate 99.9% of the previous dose), drug accumulation essentially does not occur. There is marked fluctuation between C_{max} and C_{min} (peak and trough), and missing a dose will greatly affect plasma concentrations. However, there is minimal lag time to achieve the desired plasma concentration.

DESIGNING DRUG DOSAGE REGIMENS

The success of drug therapy is highly dependent on the dosage regimen design. Not all drugs require rigid individualization

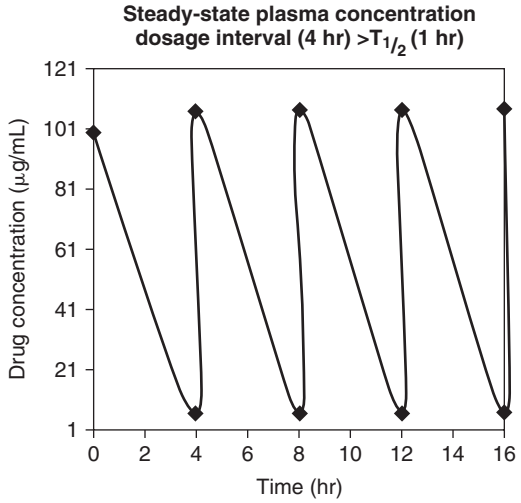

FIG. **2.16** Plasma concentration versus time graph for a drug with a dosage interval (4 hours) greater than the half-life (1 hour), resulting in no significant drug accumulation at steady-state.

of the dosage regimen. In the case of antimicrobials with a broad safety range, such as the penicillins and cephalosporins, the dosage is not titrated precisely but rather determined on the basis of the dose required to maintain an effective plasma concentration above the minimum inhibitory concentration of the bacterial pathogen. For drugs with a narrow therapeutic margin, such as digoxin, the aminoglycosides, and theophylline, the individualization of the dosage regimen is very important. The objective of the dosage regimen for these drugs is to produce a safe, therapeutic plasma drug concentration that does not exceed the minimum toxic concentration. Factors that influence the concentration of drug attained at the drug's site of action include the dose administered, the route of administration, release and absorption of drug from dosage form, the extent of drug distribution, and the rate of drug elimination.

The horse's age may have a profound effect on drug disposition (Table 2.4).[13] The definition of *geriatric* varies among species and may even vary among breeds. Aging may also be influenced by genetics, environment, nutrition, basic health care, and use. In general, horses greater than 18 to 20 years may be considered geriatric. Ponies often age better than horses and can be considered geriatric between 25 and 30 years and older. Body composition and regional blood flow change in geriatric horses. Cardiac output decreases, so regional and organ blood flow also decrease. These changes have an impact on drug absorption, distribution, and elimination. Blood flow is preferentially redistributed to the brain and heart, so there is an increase in risk of drug toxicity in these organs. Gastrointestinal (GI) motility and absorptive capacity are reduced. Hepatocyte number and function decrease along with hepatic and splanchnic blood flow. As renal blood flow decreases, GFR and active secretory capacity of the nephron decrease, resulting in decreased renal clearance of drugs. Lean body mass decreases while fatty tissues increase. The plasma concentrations of water-soluble (low volume of distribution) drugs tend to increase, whereas the plasma concentrations of lipid-soluble (high volume of distribution) drugs tend to decrease. Serum albumin decreases while gamma globulins increase, so total plasma protein concentrations essentially remain the same.

TABLE **2.4** **Age-Related Changes in Geriatric and Pediatric Patients**

Body Part/Function Affected	Geriatric	Pediatric
Organ blood flow	Decreased	Increased
Total body water	Decreased	Greatly increased
Body fat	Increased	Decreased
Serum proteins	Decreased albumin	Decreased albumin
	Increased globulins	Decreased globulins
Hepatic metabolism	Decreased	Greatly decreased

The definition of *neonate* also varies with species and age, but the determinants of drug disposition may be altered as the foal matures.[14] Blood flow to the heart and brain is greater and faster, making the foal more susceptible to drug-induced cardiotoxicity and neurotoxicity. GI absorption may be decreased as a result of decreased gastric emptying and decreased intestinal peristalsis. Absorption from the GI tract may also be affected by the differences in gastric pH between neonates and adults. Gastric pH in foals is highly variable (pH 1.5–7.0) and dependent on feeding status. Absorption from IM and SC sites changes as muscle mass and blood flow change. Neonates have less fat and greater total body water (primarily ECF) than adults. Therefore low-Vd drugs (e.g., gentamicin, ketoprofen) distribute into a larger volume, making it necessary to increase the dose to avoid therapeutic failure. Because of low body fat stores, lipid-soluble drugs will have higher plasma concentrations in foals. For example, moxidectin is much more lipid soluble than ivermectin, so it is more easily overdosed in foals.[15] Drug elimination by both hepatic metabolism and renal excretion is limited in neonates, so drug dosing intervals may need to be increased for some drugs, such as aminoglycosides and nonsteroidal antiinflammatory drugs. Not all drugs behave this way, however, and differences in pharmacokinetics result in a shortened dosing interval for some drugs, such as firocoxib and meloxicam.

Finally, disease states may alter drug pharmacokinetics. The sick horse usually has impaired drug detoxifying and elimination capability. Hepatic damage reduces drug metabolism and may increase drug action, whereas renal damage and impaired excretion decrease drug clearance. Alterations in GI motility affect drug absorption and are a concern in horses with postoperative ileus. Peripheral circulation is decreased in shock, resulting in decreased absorption of intramuscularly and subcutaneously administered drugs.

Pharmacokinetic-Based Dosage Regimens

A drug dose regimen is composed of a dose and a dosing frequency. Some drugs are given as single doses, so a specific plasma concentration will be targeted. When multiple doses of a drug are given, the dosage frequency and drug accumulation must be considered. There are simple calculations that can be used to design a patient-specific dose regimen.

Single-Dose Regimen

A single drug dose has its duration of action determined by the size of the dose, its elimination rate, and the volume of distribution. To calculate a single dose of a drug, or when

assuming a once-a-day dosing, only the Vd and the desired plasma concentration are needed:

$$\text{Dose} = (\text{Vd})(C_0)$$

For drugs administered other than intravenously, the dose must be corrected for bioavailability:

$$\text{Dose} = (\text{Vd})(C_0)/F$$

Continuous Rate Infusion

When the desired response needs to be constant, the drug may be infused intravenously at a constant rate (R_0) following the initial IV dose:

$$R = (C)(\text{Vd})(K)$$

This equation can also be written as

$$R_0 = C_{ss} \times \text{Cl}$$

The infusion rate is essentially the rate of drug loss from the body (mg/min or mg/hr). Therefore to maintain the established concentration of drug in the body, it is necessary to infuse drug at the rate equal to its loss (K = elimination rate). For example, the vasopressive drugs dopamine and dobutamine have extremely short elimination half-lives, so they must be administered by constant infusion.

Multiple-Dose Regimen

Continuous IV infusion offers the most precise control of drug levels in the body and is essential for precise control of drugs with a narrow safety margin or very rapid elimination, as well as for those drugs with a time-dependent effect (e.g., β-lactam antibiotics). This method is not feasible for most drugs in veterinary medicine. It is possible to maintain an average desired plasma concentration by repeat dosing at constant dosing intervals. Obviously, the highest plasma concentrations will occur soon after drug administration, and the lowest concentrations will be just before the next dose is administered. As long as the lowest concentration is acceptable for therapy and the highest concentration does not cause toxicity, these variations in plasma concentration are acceptable:

$$\text{Dose} = \frac{(C_{ave})(\text{Vd})(\tau)}{(1.44)\,T_{1/2}}$$

where τ = dosage interval and 1.44 is a constant to correct for log scale.

Loading Dose Followed by Maintenance Dose Regimen

Drugs that have long elimination half-lives, such as phenobarbital and fluconazole, have a long lag time to acceptable drug concentrations and therefore are usually given by a large loading dose (Dose_L) followed by maintenance doses (Dose_M).

$$\text{Dose}_L = \frac{\text{Dose}_M}{1 - e^{-K\tau}}$$

THERAPEUTIC DRUG MONITORING

Monitoring plasma drug concentrations is valuable if there is a relationship between the plasma drug concentration and the desired clinical effect or an adverse effect. It is particularly helpful in horses with systemic diseases that may affect pharmacokinetics. It is also useful when many drugs are being administered at the same time when interactions may occur. Therapeutic drug monitoring (TDM) is often valuable for regulating the dosage of drugs used chronically or prophylactically. For those drugs in which plasma concentration and clinical effect are not related, other pharmacodynamic parameters may be monitored. For example, clotting times may be measured in patients on anticoagulant therapy.

The drugs for which TDM is most commonly used are characterized by serious toxicity (e.g., digoxin, phenobarbital, aminoglycosides); a steep dose-response curve, wherein a small increase in dose can cause a marked increase or decrease in response (e.g., theophylline); marked pharmacokinetic variability among individual patients, so dose is poorly predictive of plasma drug concentration (e.g., cyclosporine); easily saturable elimination mechanisms that lead to nonlinear kinetics; or when the cost of therapy justifies confirming a desired plasma drug concentration (Table 2.5).

Performing Therapeutic Drug Monitoring

Samples for TDM should not be submitted until plasma drug concentrations have reached steady-state in the patient (after approximately 5–6 elimination half-lives have passed). For conditions in which steady-state concentrations must be reached immediately, administer a loading dose. The risk of adverse drug reactions is obviously increased, so TDM can be used to proactively determine the proper maintenance dose. When a loading dose is being administered, TDM should be done after the loading dose to establish a baseline. The second TDM should be 1 drug half-life later to ensure that the maintenance dose is able to maintain the concentrations achieved by the loading dose. If the drug concentrations at the second sample do not match those of the first sample, the maintenance dose can be adjusted at this time rather than waiting for steady-state, with the risk of therapeutic failure or toxicity. The third time to do TDM is at steady-state to ensure an appropriate dosage regimen.

The number of samples collected for TDM depends on the drug, its $T_{½}$, and the reason for monitoring. To determine optimal aminoglycoside therapy, peak and trough samples are needed. To allow for the distribution phase, blood sampling for the peak concentration is done 0.5 to 1 hour after administration, and the trough sample is usually taken before the next dose. With very long elimination half-lives and twice-daily dosing, there are no statistically significant differences between C_{max} and C_{min} values for phenobarbital or potassium bromide. Therefore a single sample can be collected for TDM at any time during the dosing interval. However, C_{max} and C_{min} samples should be collected in any horse that is not responding as expected to therapy in order to determine whether the horse has a shorter- or longer-than-normal elimination time for the drug (Box 2.4).

Adjustment of Dosage Regimens

Adjustment of the dosage regimen is frequently required when drugs are administered to diseased horses, due to the fact that most dosage regimens have been established in a small number of normal horses. Adjustment is indicated when the drug's elimination or distribution is significantly altered in the animal. In general, the following rules are true:

- If the volume of distribution changes, change the drug dose.

TABLE **2.5 Recommendations for Therapeutic Drug Monitoring**

Drug	Therapeutic Range	Vd (L/kg)	$T_{½}$	Time to Steady State	Sample Collection
Amikacin	40 μg/mL peek <3 μg/mL trough	0.25	1–2 hr	1 day	Peak: 0.5–1 hr after administration Trough: just before next dose or 8 hr after dosing if using once-daily administration; collect in plastic only
Bromide	Monotherapy: 2–3 μg/mL (20–30 mmol/L) W/ phenobarb: 1–2 –g/mL (10–20 mmol/L)		24 days	4 mo	Any time
Digoxin	0.9–2.0 ng/mL	6.7	23 hr	7 days	2–5 hr after dose, collect in glass only
Gentamicin	20 μg/mL peek <2 μg/mL trough	0.3	1 hr	1 day	Peak: 0.5–1 hour after administration Trough: just before next dose or 8 hr after dosing if using once-daily administration; collect in plastic only
Phenobarbital	15–40 μg/mL (70–170 mmol/L)	0.96	24 hr	6 days	Any time
Quinidine	2–6 μg/mL	3.10	6.65 hr	40 hr	Trough
Theophylline	10–20 μg/mL	0.8	13 hr	3 days	1–2 hr after dose

BOX 2.4 Interpreting the Results of Therapeutic Drug Monitoring

PLASMA CONCENTRATIONS LOWER THAN ANTICIPATED

Poor compliance with regimen
Error in dosage regimen
Wrong product (e.g., controlled release instead of immediate release)
Poor bioavailability
Rapid elimination
Increased apparent volume of distribution
Poor timing of blood sample

PLASMA CONCENTRATIONS HIGHER THAN ANTICIPATED

Poor compliance with regimen
Dose incorrect
Very rapid drug absorption
Decreased apparent volume of distribution
Slow elimination

PLASMA CONCENTRATION CORRECT BUT POOR PATIENT RESPONSE TO THERAPY

Diagnosis incorrect
Altered tissue receptor sensitivity (tolerance)
Drug interaction at receptor site

- If the elimination of the drug changes, change the dosing interval.

For drug dosage regimens determined by TDM, modifications are made on a percentage basis:

$$\text{New dose} = \text{Old dose} \times (\text{Target} + \text{Concentration} \div \text{Measured concentration})$$

DOSAGE ADJUSTMENTS IN RENAL FAILURE

Renal disease can have a profound impact on the disposition of drugs administered to animals in renal failure. With reduced renal clearance, the parent drug, its metabolites, or both may accumulate in the patient and cause toxicity. Loss of proteins and electrolytes in urine and the alterations in acid-base balance associated with renal failure affect the pharmacokinetics and pharmacodynamics of drugs. Enhanced drug activity or toxicity can occur as a result of synergy with uremic complications. Altogether, these effects make it difficult to determine safe and effective drug dosages for veterinary patients in renal failure.

The goal of dosage adjustment is to provide a drug concentration–time profile in the horse with renal failure that is as similar as possible to that of a normal horse. The best approach to modifying drug therapy in horses with renal failure would be to carry out therapeutic drug monitoring and adjust the dosage for each patient. This is possible with some drugs, such as phenobarbital and digoxin, but it is impractical and cost prohibitive for most drugs used in veterinary practice. The best approach for most drugs is to estimate a corrected dose from available renal function tests and then to monitor the patient closely for evidence of efficacy or toxicity. For drugs that are eliminated primarily by renal mechanisms, creatinine (Cr) clearance correlates well with drug clearance. Cr is an endogenous product of creatinine phosphate metabolism in muscle. It is removed by glomerular filtration, and serum concentrations are relatively constant in healthy people and animals. The elimination half-life of a drug that is eliminated in urine remains stable until Cr clearance is reduced to 30% to 40% of normal, which is why drug dosage regimens are typically not adjusted until two thirds of

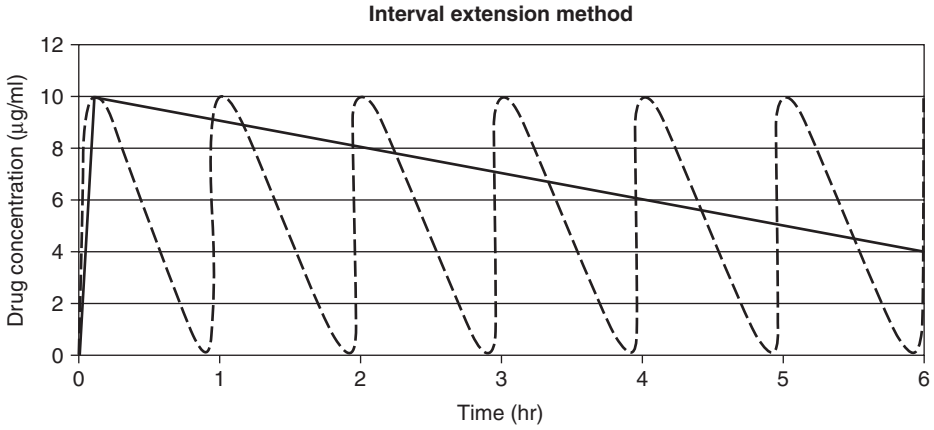

FIG. **2.17** Comparison of an interval-extension dosage regimen *(solid line)* in a renal failure patient with a normal dosage regimen in a healthy patient *(dotted line)*. Normal elimination half-life was 15 minutes; in the patient with renal failure, it increased to 8 hours.

renal function has been lost.[16] In human patients Cr clearance is quantified by determining urinary Cr excretion over a 24-hour period. The measured Cr clearance is then used in formulas to make drug dosage adjustments. Unlike in human medicine, values for Cr clearance are not usually available for veterinary patients. When Cr clearance is not available, a single value of the patient's serum creatinine can be substituted in the formulas. However, the relationship between serum creatinine is not linear once serum creatinine is above 4 mg/dL, so the adjustment formulas are even less accurate for predicting an ideal dose adjustment.[16] These formulas do not account for changes in the volume of distribution, degree of protein binding, and nonrenal clearance mechanisms of the drug that may be caused by the renal dysfunction. Therefore these dosage adjustments must be regarded as preliminary estimations to be followed by adjustments based on observed clinical response.

Dose-Reduction Method

With the dose-reduction method the normal dosage regimen is adjusted by reducing the drug dose and maintaining the drug dosing interval.

$$\text{Adjusted dose} = \text{Normal dose} \times (\text{Patient's Cr clearance} \div \text{Normal Cr clearance})$$

or

$$\text{Adjusted dose} = \text{Normal dose} \times (\text{Normal Cr} \div \text{Patient's Cr})$$

Interval-Extension Method

With the interval-extension method the drug dose is maintained and the drug dosing interval is extended.

$$\text{Adjusted interval} = \text{Normal interval} \left[1/(\text{Patient's Cr clearance}/\text{Normal Cr clearance})\right]$$

or

$$\text{Adjusted interval} = \text{Normal interval} \left[1/(\text{Normal serum Cr}/\text{Patient's serum Cr})\right]$$

Both methods attempt to keep the average plasma drug concentrations constant. The interval-extension method produces C_{max} and C_{min} values similar to those seen in healthy patients (Fig. 2.17), but it does produce substantial periods of time during which drug concentrations may be subtherapeutic. This is the preferred method with aminoglycosides, which have a long postantibiotic effect and in which a low trough concentration is desirable to reduce the risk of nephrotoxicity. Depending on the relationship of the elimination half-life to the dosage interval, significant drug accumulation may occur with the dose-reduction method (Fig. 2.18), but at steady-state there are no periods of time during which concentrations are subtherapeutic. This is the preferred method for the penicillin and cephalosporin antibiotics, wherein maintaining the plasma concentration above the pathogen's minimum inhibitory concentration (MIC) correlates with efficacy and the drugs are relatively nontoxic even if accumulation occurs. To decide which method to use, the practitioner should determine whether drug efficacy and toxicity are related to peak, trough, or average plasma concentrations and then select the method that best balances efficacy against potential toxicity. The interval-extension method is more convenient for the client because the normal recommended dose is simply administered less frequently. In addition, if the drugs are available only in fixed dosage forms (e.g., capsules, unbreakable tablets), it is easier to adjust the dosage interval.

Because the elimination half-life is prolonged in patients with renal disease and it always takes 6 elimination half-lives to reach 99% of steady-state concentrations, there is a delay in reaching steady-state in horses with renal failure compared with horses with normal renal function. Therefore it may be necessary to administer a loading dose to rapidly achieve therapeutic drug concentrations. If the dose-reduction method is used, this is achieved by giving the usual dose initially, followed by the reduced dose at the next time. If the interval-extension method is used, this is accomplished by giving a double dose initially.

For renal failure patients in general, the practitioner must consider the following:

1. Avoid using any drugs at all, unless there are definite therapeutic indications. If a drug is absolutely necessary, try to select one that is hepatically metabolized and excreted in bile rather than eliminated by the kidneys (e.g., doxycycline).
2. If therapeutic drug monitoring is available, tailor the drug dosage regimen to that specific patient.

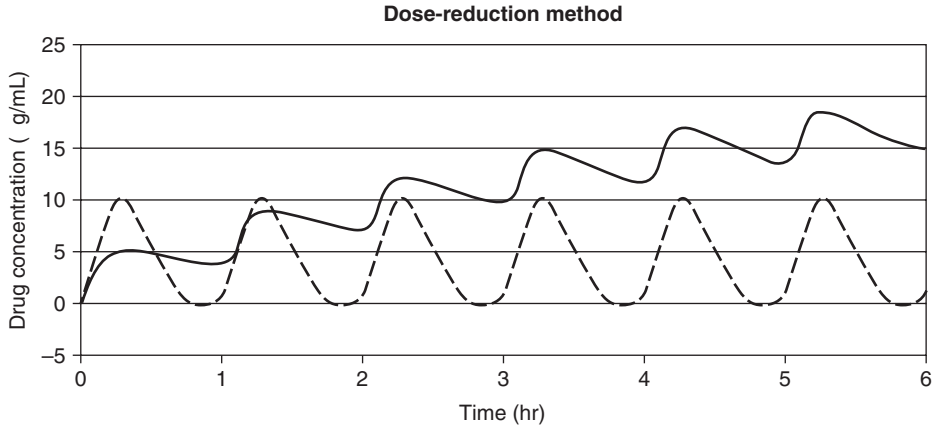

FIG. **2.18** Comparison of a dose-reduction dosage regimen in a renal failure patient *(solid line)* compared with a normal dosage regimen in a healthy patient *(dotted line).* Normal elimination half-life was 15 minutes; in the renal failure patient, it increased to 8 hours.

3. If therapeutic drug monitoring is unavailable, determine whether there are clinically proven, adjusted dosage regimens for specific drugs. The package insert that accompanies pharmaceuticals intended for human use often gives guidelines for adjusting dosages.
4. If the drug has not been sufficiently studied to have dosage adjustment recommendations, determine whether there is sufficient information about its kinetics to estimate the proper drug dose in renal failure.
5. Carefully monitor treated patients for signs of efficacy and toxicity.

Antimicrobial Therapy

Successful antimicrobial therapy relies on administering sufficient doses so that pathogens at the site of infection are killed or suppressed to the extent that they can be eliminated by the host's immune system. There are complex pharmacokinetic (PK) and pharmacodynamic (PD) relationships among the host, the bacteria, and the antimicrobial. Pharmacokinetics is what the body does to a drug; the processes of absorption, distribution to the various organs and tissues, metabolism, and elimination. Pharmacodynamics is what the antimicrobial does to the bacteria. It describes the drug action and responses of the bacteria. Pharmacokinetics and pharmacodynamics are interrelated in that PK effects determine the amount of drug that reaches the site of action, and the intensity of a PD effect is associated with the drug concentration at the site of action. New information on the PK/PD relationships of veterinary pathogens and antimicrobials is rapidly emerging and changing the way in which the dosage of antimicrobials is determined in equine practice.

RATIONAL USE OF ANTIMICROBIAL AGENTS

The following questions must be considered when developing an antimicrobial regimen:

1. *Does the diagnosis warrant antimicrobial therapy?* Using antimicrobials to treat minor infections or purely viral or inflammatory diseases is irrational, expensive, and potentially hazardous to the patient; it also encourages antimicrobial resistance. Clients have come to expect antimicrobials for trivial infections or in the event that an infection may develop. Equine practitioners must resist client pressure to use or prescribe unnecessary drugs.
2. *What organism(s) are likely to be involved?* For many infections the likely organism can be successfully predicted on the basis of the history and clinical signs (e.g., *Streptococcus zooepidemicus* and respiratory infections).
3. *What is the in vitro antimicrobial susceptibility of the organism?* For many pathogens the in vitro susceptibility can be reliably predicted. For example, *Streptococcus* species are typically susceptible to penicillin. However, many gram-negative bacteria have unpredictable susceptibilities, and susceptibility testing is essential for determining appropriate drug therapy.
4. *In what part of the body or tissue is the infection located? Will the antimicrobial penetrate to the infection?* Consideration of the pathophysiology of the infection will help the practitioner select an effective therapy. Treatment of sequestered infections such as mastitis or meningitis requires antimicrobials that readily cross membrane barriers. Antimicrobials characterized by low values for volume of distribution (Vd) are unlikely to reach therapeutic concentrations in such sites.
5. *Will the antimicrobial be effective in the local environment of the organism?* The local infection environment reduces the efficacy of some antimicrobials. Sulfonamides are ineffective in purulent debris because para-aminobenzoic acid (PABA) released from decaying neutrophils serves as a PABA source for bacteria and reduces the competitive effect of the sulfonamide. Aminoglycosides are ineffective in an abscess because of the acidic, anaerobic environment along with the presence of nucleic acid material from decaying cells, which inactivates this class of drug.
6. *What drug formulation and dose regimen will maintain the appropriate antimicrobial concentration for the proper duration of time?* Label doses apply only to label pathogens. For off-label uses the dosage regimen must be adjusted depending on the antimicrobial susceptibility of the specific pathogen.

7. *What adverse drug reactions or toxicities might be expected? Do the benefits outweigh the risks?* The risks of adverse reactions from antimicrobials are often underappreciated. A serious adverse reaction may complicate treatment of the original problem and even be fatal. Failure to communicate the risks of adverse drug reactions to clients is a common cause of litigation.
8. *Can you choose an approved product? If using an antimicrobial in an off-label manner, can you determine appropriate withdrawal times for food animals? Can you determine appropriate withdrawal times for performance horses?* The antimicrobials used in horses are not approved for horses intended for food, and information on appropriate withdrawal times is lacking. Also, competitive horses are subject to the rules of the sport's governing association regarding drugs, which vary according to the organization, state or province, and country. Understanding the principles of drug elimination allows the practitioner to determine appropriate withdrawal times for competitive or slaughter horses.

Documenting the Infection

A diagnosis must be established before any therapy can be administered. It is not always necessary to culture samples from all patients with infectious diseases to identify the organism involved. Often the practitioner can base a diagnosis on clinical experience from similar cases. The signs of some infectious diseases are so obvious that the need for microbiologic identification is minimal; however, for those infectious diseases of unknown cause or for those attributable to organisms with irregular antimicrobial susceptibility, there is no substitute for isolation and identification of the causative agent. For these organisms initial therapy while waiting for culture results must include an antimicrobial with a broad spectrum of activity.

Whenever possible, the veterinarian should obtain a representative sample of material from a clinical patient. Beware of sampling grossly contaminated sites such as purulent nasal discharges. Treatment failure may also be related to sampling of an inappropriate area. For instance, in cases of pleuropneumonia, failure to culture both transtracheal wash fluid and pleural fluid may result in an inability to culture all associated organisms. An immediate Gram stain can be performed from a direct smear and will direct initial therapy. Samples are submitted for appropriate culture and identification. If the identified organism has unpredictable susceptibility patterns, the practitioner should request a susceptibility test, such as Kirby-Bauer, E test, or MIC method.

In some clinical cases identification of the pathogen may be made by serologic demonstration of antibodies (e.g., anaplasmosis, leptospirosis, brucellosis).

Antimicrobial Dosage Regimen Design

The relationship among the host, the bacteria, and the drug may be very complex. High plasma antimicrobial concentrations are *assumed* to be advantageous in that a large concentration of drug will diffuse into the ECF of various tissues. Drug concentration at the site of infection is assumed to be of major importance in determining drug efficacy. In many infections the site of infection is the ECF; however, infections may also occur within cells or other protected sites. Drug movement from the plasma to extravascular tissues depends on molecular size, lipid solubility, drug p*K*a, local pH, specific cellular transport mechanisms, and degree of protein binding. The relationship between bacteria and drug in the laboratory is described by the following:

MIC: The lowest drug concentration that inhibits bacterial growth. Often expressed as the concentration that inhibits 50% (MIC_{50}) or 90% (MIC_{90}) of the bacterial growth.
Minimum bactericidal concentration (MBC): The lowest drug concentration that kills 99.9% of bacteria.
Mutant prevention concentration (MPC): Threshold concentration above which the selective proliferation of resistant mutants is expected to occur only rarely.

The MICs are used to determine the drug dose, in an attempt to achieve blood and tissue concentrations that exceed the in vitro MIC for the pathogen.

Interpreting Minimum Inhibitory Concentrations

According to the Clinical Laboratory Standards Institute (CLSI; formerly called the National Committee for Clinical Laboratory Standards [NCCLS]) definition, the MIC values are derived as serially doubled concentrations (in μg/mL). Susceptible (S), intermediate (I), and resistant (R) designations are derived from *breakpoints* assigned by laboratory-based PK and PD data, pathogen population MIC distribution, and clinical trial results.[17] A CLSI-approved breakpoint is specific for the animal species, disease, pathogen, antimicrobial, and dosage regimen. When a pathogen is reported as *susceptible,* it means that the recommended dosage of the antimicrobial will reach plasma or tissue concentrations that will inhibit bacterial growth in vivo. When a pathogen is reported as *resistant,* inhibitory antimicrobial concentrations are not safely attainable in the patient. If the pathogen is reported as *intermediate,* administering the antimicrobial at higher-than-recommended doses may result in effective therapy.[18] Pathogens with intermediate susceptibility may also be successfully treated if the infection is located in an area of high drug concentration (e.g., urine for renally excreted drugs) or by treatment with local routes of administration (e.g., topical administration to the eye for corneal infections).

Susceptibility testing results predict which bacteria have intrinsic or acquired resistance mechanisms to a particular antimicrobial. In vitro tests do this because bacterial susceptibility usually clusters around a small range of MICs. In Fig. 2.19 the bacterial inhibition of *E. coli* by amoxicillin has a bimodal distribution. The large cluster of *Escherichia coli* inhibited by amoxicillin concentrations of 0.5 to 16 μg/mL are considered the *normal range* and 16 μg/mL is considered the breakpoint of susceptibility. *E. coli* requiring an amoxicillin concentration of 16 μg/mL to be inhibited are likely to have intrinsic or acquired resistance mechanisms, and amoxicillin is unlikely to be a successful treatment for patients infected with these isolates. In vitro susceptibility tests predict treatment outcome fairly well, considering that many variables in the host-pathogen relationship are not taken into account.[17] Antimicrobial susceptibility data may not account for the following:

1. *Host defenses:* The interaction between the host and the pathogen is complex and not predicted by in vitro tests. Antimicrobial drug action takes place in concert with host defenses such as humoral and cell-mediated immunity; complement components; and nonspecific antibacterial factors such as lactoferrin, lactoperoxidase, and lysozyme.[19]

2. *Drug distribution in the body:* The S, I, and R designations assigned by the microbiology laboratory are typically based on safely achievable plasma concentrations. This does not necessarily take into account extremely high concentrations of antimicrobials achieved in organs and fluids of excretion (kidney, urine, bile) or with local administration of high drug concentrations (e.g., ophthalmic ointments). Macrolide antimicrobials are characterized by negligible plasma concentrations despite very high lung and intracellular concentrations.[20] Pathophysiology may alter drug distribution, and some antimicrobials, such as the tetracyclines, accumulate in pneumonic lung tissues.[21]
3. *Growth rates and size of inoculum:* The incubator of the microbiology laboratory is an ideal setting for bacterial growth. Conditions are managed to promote rapid growth, and rapidly dividing bacteria are more susceptible to antimicrobial drugs. Replication rates may be much slower at the infection site, and MICs are generally unreliable for slow-growing bacteria. Standardized inoculums used in the laboratory may overrepresent or underrepresent pathogen numbers in infected tissues.[19]
4. *Mixed infections:* Separate susceptibility testing of pathogens in a mixed infection does not account for the pathologic synergism between bacteria. The byproducts of one bacterium may facilitate the establishment and growth of another.[22]
5. *Infection environment:* Many antimicrobials are inactive in purulent exudate, which is typically anaerobic, acidic, and hyperosmolar. Some antimicrobials have different activity in body fluids (e.g., plasma, milk, bile) than in nutrient-rich laboratory media. Deposition of fibrin may alter tissue penetration of antimicrobials. Many bacteria are capable of producing a polysaccharide slime capsule to protect them from host factors. Mastitis pathogens typically increase their replication rate when incubated in mastitic milk.[19]
7. *Topically administered antimicrobials are not tested:* Veterinary microbiology laboratories may not routinely do susceptibility testing for antimicrobials that are used only topically. Polymixin B is one of the most effective antimicrobials for superficial *Pseudomonas* infections,[23] but because it causes neurotoxicity and nephrotoxicity if administered systemically, it is rarely included in susceptibility testing. Bacitracin and mupirocin are other examples of topical antimicrobials rarely tested by diagnostic laboratories.
8. *In vivo synergism may occur with antimicrobial combinations:* Despite predictions of resistance from susceptibility testing, therapy may be successful because of synergistic combinations of antimicrobials. Synergism between penicillins and aminoglycosides has been recognized for streptococcal, enterococcal, and staphylococcal infections.[24] The synergism is attributed to increased cellular uptake of the aminoglycoside after cell wall damage from the penicillin.
9. *The CLSI breakpoints may be inappropriate:* The CLSI breakpoints were originally established with bacterial isolates from humans, using human PK data and clinical trials. A veterinary subcommittee was established in 1993 and has proposed veterinary-specific guidelines for susceptibility tests for a limited number of antimicrobials.[25] Currently, only ceftiofur, ampicillin, amikacin, and gentamicin have CLSI-approved breakpoints for equine pathogens. Diagnostic laboratories use human-derived breakpoints for other bacteria-drug combinations. It is important to know if your laboratory uses the equine-specific breakpoints, as these can differ widely among species. For example, the amikacin breakpoint in humans is 16 μg/mL, in adult horses 4 μg/mL, and in foals 2 μg/mL.

Therefore the true relevance of any in vitro MIC in predicting the in vivo results of drug therapy is questionable. The MIC results are not a positive order to use a particular antimicrobial. Selection of the optimal antimicrobial must take into consideration other factors, such as the site of infection, pharmacokinetics of the drugs, and effect of underlying diseases. Considering all of these factors, most veterinarians determine a drug dosage regimen that uses a target plasma drug concentration based on a multiple of the in vitro MIC (usually 2–10).

Bactericidal Versus Bacteriostatic Antimicrobials

It is common to classify antimicrobials as *bactericidal* or *bacteriostatic* (Box 2.5). If the ratio of the MBC to MIC is small (less than 4–6), a drug is considered bactericidal, and it is possible to obtain drug concentrations that will kill 99.9% of the organisms exposed. If the ratio of MBC to MIC is large, it may not be

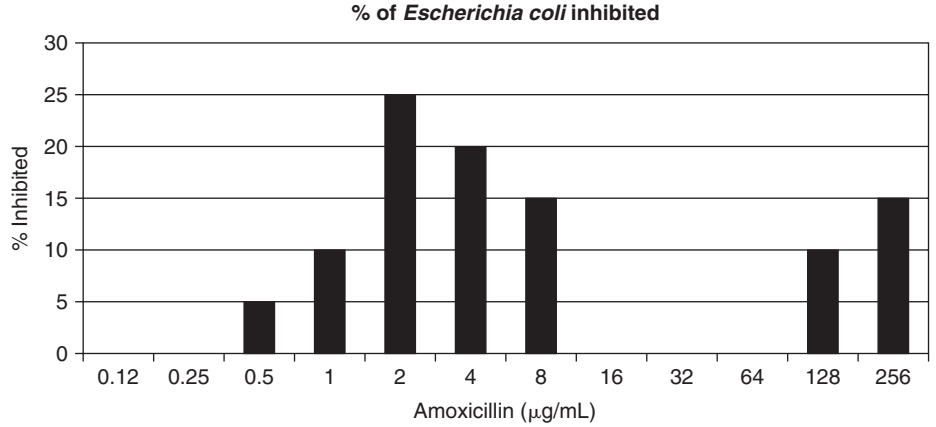

FIG. **2.19** The percentage of *Escherichia coli* inhibited by increasing concentrations of amoxicillin has a bimodal distribution. *E. coli* requiring more than 16 μg/mL of amoxicillin to be inhibited are likely to have intrinsic or acquired resistance mechanisms. Amoxicillin therapy in patients with this pathogen is unlikely to be effective.

possible to safely administer dosages of the drug to kill 99.9% of the bacteria, and the drug is considered bacteriostatic.

For many drugs the distinction between bactericidal and bacteriostatic is not exact and depends on the drug concentration attained in the target tissue and the pathogen involved. Specific situations in which a bactericidal drug is preferred over a bacteriostatic drug include immunocompromised patients such as neonates, life-threatening infections such as bacterial endocarditis and meningitis, and surgical prophylaxis.

Postantibiotic Effect

For some bacteria-antimicrobial interactions, bacterial growth remains suppressed for a period after drug concentration has decreased below the MIC.[26] This postantibiotic effect (PAE) may be the reason that dosage regimens that fail to maintain drug concentration above the MIC are still efficacious. The PAE depends on the antimicrobial and the bacterial pathogen (Table 2.6).

Pharmacokinetic-Pharmacodynamic Relationships

The PK-PD relationship between an antimicrobial and a pathogen determines the way that the dosage regimen is calculated.[27] The PK parameters used in drug dosage design are the area under the plasma concentration versus time curve from 0 to 24 hours (AUC_{0-24}), the maximum plasma concentration (C_{max}), and the time the antimicrobial concentration exceeds a defined PD threshold ($T >$ MIC). In relating the PK and PD parameters to clinical efficacy, antimicrobial drug action is classified as either concentration dependent or time dependent (Box 2.6; Figs. 2.20 and 2.21). For antimicrobials whose efficacy is concentration dependent, high plasma concentrations relative to the MIC of the pathogen (C_{max}:MIC) and the area under the plasma concentration-time curve that is above the bacterial MIC during the dosage interval (AUC_{0-24}:MIC) are the major determinants of clinical efficacy. These drugs also have prolonged PAEs, thereby allowing once-a-day dosing while maintaining maximum clinical efficacy. For fluoroquinolones (e.g., enrofloxacin, orbifloxacin, marbofloxacin), clinical efficacy is associated with achieving either an AUC_{0-24}:MIC greater than 100 to 125 for gram-negative organisms and AUC_{0-24}:MIC greater than 55 for gram-positive organisms or a C_{max}:MIC greater than 10. For aminoglycosides (e.g., gentamicin, amikacin), achieving a C_{max}:MIC greater than 10 is considered optimal for efficacy. Other antimicrobials that appear to have concentration-dependent activity include metronidazole (C_{max}:MIC > 10–25) and azithromycin (AUC_{0-24}:MIC > 25). For some pathogens with very high MIC values, such as *Pseudomonas aeruginosa,* achieving the optimum PK/PD ratios may be impossible with label or even higher-than-label dosages. In such cases underdosing is ineffective and merely contributes to antimicrobial resistance.

For antimicrobials with time-dependent efficacy, the drug concentration at the site of infection must be maintained above the MIC for some portion of the dosing interval. How much above the MIC and for what percentage of the dosing interval concentrations should be above the MIC are still being debated and are likely specific for individual bacteria-drug combinations. Typically, exceeding the MIC by 1 to 5 multiples for between 40% and 100% of the dosage interval is appropriate for time-dependent antibiotics. The $T >$ MIC should be closer to 100% for bacteriostatic antimicrobials and in patients that are immunosuppressed. These drugs typically require frequent dosing or constant rate infusions for appropriate therapy. In sequestered infections penetration of the antimicrobial to the site of infection may require high plasma concentrations to achieve a sufficient concentration gradient. In such cases the AUC_{0-24}:MIC and/or C_{max}:MIC may also be important in determining efficacy of otherwise time-dependent antimicrobials.

BOX 2.5 Classification of Antimicrobials

Anaerobes	Metronidazole	—	—

PAE, Postantibiotic effect.

light of the previous information, antimicrobial dosage regimens are designed in one of two ways: either to maximize plasma concentration or to provide a plasma concentration above the bacterial MIC for some percentage of the dosage interval.

For *concentration-dependent antibiotics* with a prolonged PAE whose PK-PD relationship is to have an ideal C_{max}:MIC, and if the volume of distribution (Vd) of the antimicrobial is known, a precise drug dosage regimen for the pathogen can be calculated from the following equation:

$$\text{Dose} = (\text{Vd})(\text{Desired plasma concentration})$$

where the desired plasma concentration is some multiple of the MIC (usually 8–10) and once-daily dosing is assumed.

For *concentration-dependent antibiotics* whose PK-PD relationship is to have an ideal AUC_{0-24}:MIC, the following equation can be used to calculate a daily dose:

$$\text{Dose} = (AUC_{0-24}\text{:MIC})(\text{MIC})(\text{Cl})(F)(24\text{ hr})$$

where AUC_{0-24}:MIC is ≥ 100, Cl is clearance (volume of blood cleared of drug per day in mL/kg/day), and F is bioavailability.

For *time-dependent antibiotics* the objective is to keep the average plasma drug concentration above the pathogen's MIC for the duration of the dosage interval. Again, by using Vd and elimination half-life information, the practitioner can precisely calculate a dosing regimen:

$$\text{Dose} = \frac{(\text{Desired avg plasma concentration})(\text{Vd})(\text{Dosage interval})1.44}{\left(T_{1/2}\right)}$$

FIG. **2.20** For time-dependent antimicrobials the time during which the antimicrobial concentration exceeds the minimum inhibitory concentration of the pathogen determines clinical efficacy.

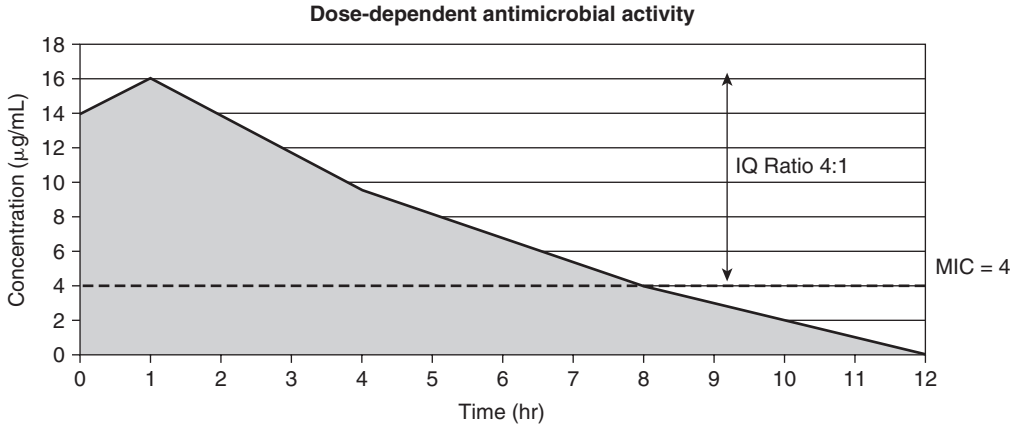

FIG. **2.21** For concentration-dependent antimicrobials, the inhibitory quotient *(IQ)* and the area under the inhibitory curve are the major determinants of clinical efficacy.

CONCURRENT USE OF ADDITIONAL ANTIMICROBIALS

Combination antimicrobial therapy is commonplace in veterinary medicine, but combination therapy has rarely been demonstrated as superior to single-drug therapy through clinical trials. Use of multiple antimicrobial drugs should be limited to the following cases:

1. Known synergism against specific organisms[24]
2. Prevention of rapid development of bacterial resistance[28]
3. To extend antimicrobial spectrum of initial therapy of life-threatening conditions[29]
4. To treat known mixed bacterial infections[30]

Multiple antimicrobial therapy is implicated as a cause of diarrhea in horses, likely from the additive antibacterial effects against normal GI flora.[31] Antagonistic combinations such as chloramphenicol and a macrolide should be avoided; both these classes of drugs competitively bind to the same binding site on bacterial ribosomes, thus effectively battling each other for the site of action.

PROPHYLACTIC USE OF ANTIMICROBIALS

There are few reports examining the efficacy of prophylactic antimicrobials in veterinary medicine in general and in horses specifically.[32] Because of the lack of controlled veterinary studies, information on prophylaxis is largely extrapolated from human studies. The relative risk of infection must warrant the use of prophylactic antimicrobials. The risks of adverse effects from the prophylactic drug must be less than the risk of development of disease and its consequences. In veterinary medicine most of the risk of infection depends on the skill of the surgeon and handling practices in the hospital.[33] The organism or organisms that are likely to cause the infection and their antimicrobial susceptibility should be known or accurately predicted. The antimicrobial should be bactericidal and must be administered and distributed to the site of potential infection before the onset of infection. The veterinarian should consider drugs that can be given intravenously and have a high volume of distribution. Drugs used prophylactically should not be those that would be used therapeutically. The duration of antimicrobial prophylaxis should be as abbreviated as possible. Most of the time a single preoperative dose is sufficient and cost effective.[34]

A comprehensive review of the subject has resulted in several recommendations being made regarding the use of antimicrobials in the absence of culture and sensitivity data or a definitive diagnosis.[35] These include the following:

1. Commonly used antimicrobial combinations remain the mainstay for treating purulent infections. Appropriate choice of an antibiotic that is not inactivated in a purulent environment is recommended.
2. Antimicrobial treatment for compromised foals should be instituted until sepsis is proven or disproven; however, treatment should not extend beyond recovery. Prophylactic administration of antimicrobials to healthy foals is not recommended.
3. Continuation of prophylactic antimicrobials for more than 3 days is likely unnecessary after colic surgery; shorter durations might be equally effective. Exceptions may include large colon volvulus, where an increased risk of septic peritonitis is present.
4. Antimicrobial prophylaxis in adult horses with diarrhea is unlikely to be beneficial, unless suspicion of a specific etiologic agent is extremely high based on prior use of antimicrobials *(Clostridium difficile/perfringens),* season of the year *(Neorickettsia risiticii),* and age *(Lawsonia extracellularis).*

β-LACTAMS: PENICILLINS AND CEPHALOSPORINS

The β-lactam antibiotics include the penicillins, cephalosporins, and carbapenems. They have excellent activity against most gram-positive bacteria and very few associated side effects. They are considered bactericidal and time dependent. Postantibiotic effects have been associated with some drugs in this class. In general, the β-lactam antibiotics have low plasma protein binding, distribute well to the ECF in most tissues, and are excreted renally. With a few exceptions, they have a very short half-life and require frequent dosing. β-Lactams do not distribute well to protected sites, such as the central nervous system, the eye, or the prostate.

Mechanism of Action

β-Lactam antibiotics act on enzymes called *penicillin-binding proteins (PBPs)* responsible for building the bacterial cell wall.[18] Therefore they are active only against rapidly multiplying organisms in which the binding of penicillin within the cell wall interferes with production of cell wall peptidoglycans and results in cell lysis in a hypo-osmotic or iso-osmotic environment. There may be anywhere from two to eight PBPs in a bacterium. When β-lactam antibiotics bind covalently and irreversibly to the PBPs, the bacterial cell wall is disrupted and lysis occurs. Differences in the spectrum and activity of β-lactam antibiotics are due to their relative affinity for different PBPs. To bind to the PBPs, the β-lactam antibiotic must first diffuse through the bacterial cell wall. Gram-negative organisms have an additional lipopolysaccharide layer that decreases antibiotic penetration. Therefore gram-positive bacteria are usually more susceptible to the action of β-lactams than gram-negative bacteria. Because the penicillins poorly penetrate mammalian cells, they are ineffective in the treatment of intracellular pathogens.

Resistance Mechanisms

Resistance mechanisms to the β-lactams include failure of the antibiotic to penetrate the outer bacterial cell layers and alteration of PBPs that decrease the affinity of the PBP for the antibiotic.[36-38] Alterations of the PBPs to a low-affinity PBP2a occur with methicillin-resistant staphylococci and are mediated by the presence of the chromosomal gene mecA.[39] The presence of this gene precludes therapy with any of the currently available β-lactam antibiotics and predicts resistance to several classes of antibiotics. A third mechanism of resistance is from production of β-lactamase enzymes.[40,41]

There may be as many as 50 β-lactamase enzymes (penicillinases, cephalosporinases, and carbapenemases) produced by bacteria. These enzymes hydrolyze the cyclic amide bond of the β-lactam ring and inactivate the antibiotic. Staphylococcal β-lactamases are produced by coagulase-positive *Staphylococcus* spp. The synthesis of these enzymes is plasmid encoded, and the enzymes are exocellular. These enzymes typically do not inactivate cephalosporins and antistaphylococcal penicillins.

Most of these β-lactamases can be inactivated by inhibitors such as clavulanic acid and sulbactam. The β-lactamase inhibitors are a specific class of drugs that inhibit bacterial β-lactamase, so they are administered in combination with β-lactam antibiotics.[42] These drugs combine with β-lactamase enzymes produced by gram-negative and some gram-positive bacteria. An inactive enzyme complex is formed, and the coadministered antibiotic is then able to exert its effect. New evidence suggests that β-lactamase inhibitors, once thought to have little antimicrobial activity of their own, bind to different PBPs, affecting autolysis and contributing to the activity of the concomitantly administered β-lactam antibiotic.[43] The majority of clinically isolated *B. fragilis* spp. are β-lactamase producers. Most of the enzymes are chromosomally mediated cephalosporinases, with activities against many narrow- and broad-spectrum penicillins and cephalosporins.

The gram-negative β-lactamases are a diverse group of enzymes that can be chromosomal coded, plasmid coded, or both. Chromosomal-mediated lactamases hydrolyze penicillin, cephalosporins, or both. In the past few decades, bacteria (mainly *E. coli* and *Klebsiella* spp.) have been discovered that produce what are known as extended-spectrum β-lactamases (ESBLs). These enzymes hydrolyze the extended-spectrum cephalosporins that have an oxyimino side chain, which include third- and fourth-generation drugs such as cefotaxime, ceftriaxone, and ceftazidime. The expression of ESBLs is plasmid mediated, and these plasmids often encode for other genes that infer resistance to antimicrobials of other classes (i.e., aminoglycosides, trimethoprim-sulfamethoxazole, and quinolones). ESBL-producing strains are particularly feared as they are resistant to all penicillins, cephalosporins, and aztreonam.

PENICILLIN G (BENZYLPENICILLIN)

Penicillin G was the first antibiotic developed and remains one of the most effective antibiotics available. It is still the initial drug of choice for many bacterial infections.

Spectrum of Activity

Aerobic bacteria susceptible to penicillin G include most β-hemolytic streptococci, β-lactamase–negative staphylococci, *Actinomyces* spp., some *Bacillus anthracis, Corynebacterium* spp., and *Erysipelothrix rhusiopathiae.*[44] Most species of anaerobes are susceptible, excluding β-lactamase–producing *Bacteroides* spp.[45] Penicillin G is easily inactivated by β-lactamases and has little efficacy against organisms that can produce these enzymes. In addition, penicillin G is ineffective against those bacteria that are resistant by other mechanisms, such as having a relatively impermeable cell wall. Therefore penicillin G has little activity against many staphylococci and most gram-negative bacteria.[40]

Pharmacokinetics

Absorption

Because penicillin is a weak acid with a p*K*a of 2.7, it is highly ionized in plasma. Gastric absorption of penicillin G is poor because it is rapidly hydrolyzed in the acid environment of the stomach. Phenoxymethyl penicillin (penicillin V) can be given orally to horses and has a half-life of absorption of 0.2 hours.[46] The sodium and potassium salts of penicillin G are the only dosage forms that are suitable for IV administration and are quickly absorbed from IM or SC sites of administration.[47] Procaine penicillin G is more slowly absorbed from IM administration than are the sodium or potassium salts and so produces lower but more sustained plasma concentrations. The rate of absorption from IM injections of procaine penicillin G varies depending on the injection site, with injections into the neck muscle producing more rapid absorption and higher plasma concentrations than with injections into the hindquarters.[48] Benzathine penicillin G is the least soluble of the dosage forms; it is very slowly absorbed, producing sustained but subtherapeutic plasma concentrations of penicillin G.[47] Because the benzathine fraction is poorly absorbed and plasma concentrations are below the MICs of most pathogens, use of these products is not recommended in horses.[49]

Distribution

The Vd of sodium penicillin G is 0.7 L/kg,[50] and there is a moderate degree of protein binding (52%–54%).[35] After absorption penicillin is distributed mainly in ECF and may not reach therapeutic concentrations in sequestered infections.[49]

Elimination

Elimination of penicillin is primarily renal, with unchanged drug being excreted by glomerular filtration and active renal tubular secretion. The elimination half-life of penicillin G is 1 hour,[49,51] and total clearance is 8.5 ± 1.33 mL/min/kg.[50] Oral penicillin V has an elimination half-life of 3.7 hours.[46]

Adverse Effects and Drug Interactions

Immune-Mediated Reactions

Penicillin is associated with immune-mediated hemolytic anemia (type II hypersensitivity)[52,53] and anaphylaxis (type I hypersensitivity) in horses.[54] The immune-mediated anemia usually resolves with discontinuation of penicillin therapy. Anaphylaxis usually occurs after previous exposure to penicillin and can be fatal. IV epinephrine and oxygen administration and respiratory support are indicated. Although it is widely assumed that penicillin and cephalosporins are cross-reactive in sensitive individuals, the actual incidence in humans is extremely low.[55]

Procaine Reactions and Use in Performance Horses

When procaine penicillin G products are accidentally administered intravascularly, they cause extreme central nervous system stimulation.[56,57] Most horses will survive unless they fatally traumatize themselves during the reaction. Diazepam will attenuate the reaction if given before procaine administration but has no effect if given afterward.[56] Veterinary formulations contain higher concentrations of procaine than human formulations, and high temperatures increase the solubility of procaine. Therefore penicillin procaine G should be kept refrigerated and administered by careful IM injection. Even with careful IM injection, adverse reactions are still reported in horses. Repeated injections increase the chance of intravascular administration and may increase the sensitivity to procaine as a result of neuronal sensitization. Once absorbed into the circulation, procaine is hydrolyzed by plasma esterases to the nontoxic metabolites PABA and diethylaminoethanol.[58] The presence of PABA may inactivate sulfonamide antibiotics.[59] Horses that have had documented adverse reactions to

IM procaine penicillin G injections had significantly lower procaine hydrolyzing capacity compared with horses that did not have a history of adverse reactions.[60] Procaine is slowly eliminated in urine, is easily detectable by regulatory laboratories, and commonly causes violative residues in racehorses and performance horses given penicillin procaine G.[61]

Electrolyte Imbalances

The sodium or potassium content of IV formulations can contribute to electrolyte imbalances associated with congestive heart failure and renal function impairment. A million units of potassium penicillin contain 1.7 mEq of potassium, so it should be administered by slow IV injection. Potassium penicillin is not recommended for use in horses with hyperkalemic periodic paralysis (HYPP).

Phenylbutazone

Concurrent administration with phenylbutazone in horses increases plasma concentrations of penicillin G but lowers tissue concentrations. The effect is likely due to a lower peripheral distribution.[50]

Formulations

Only procaine penicillin G and combination procaine/benzathine penicillin products are currently labeled for use in horses. These formulations are labeled for a dose of 3000 IU/lb (6600 IU/kg), which is a much lower dose than that considered to be therapeutic. Procaine penicillin products are labeled for IM dosing once daily. Combination products are labeled for IM or SC dosing once every other day. Na^+ and K^+ penicillin (also called *crystalline penicillin*) are human formulation drugs used off-label intravenously, intramuscularly, or subcutaneously. They achieve rapid plasma concentrations but have very short elimination half-lives and therefore must be administered frequently or by continuous rate infusion. Potassium penicillin is usually less expensive than sodium penicillin but must be administered more carefully because rapid IV administration can cause cardiac arrhythmias. Procaine penicillin G is a poorly soluble salt that is slowly absorbed after IM injection. It is the most commonly used formulation of penicillin in horses. Benzathine penicillin G is a very insoluble salt that is used in long-acting penicillin preparations, which contain a 50:50 mixture of procaine penicillin G and benzathine penicillin G.

Clinical Use

Penicillin is still the antimicrobial of choice for many diseases in horses, such as streptococcal and anaerobic infections. Traumatic wounds are frequently infected with *Streptococcus zooepidemicus,* which is routinely susceptible to penicillin.[29] However, iatrogenic wounds are frequently infected with penicillinase-producing *Staphylococcus aureus* or other staphylococci, so culture and susceptibility testing is necessary before initiating penicillin therapy.[29,62]

The dosage of penicillin G is typically 22,000 to 44,000 IU/kg. Dosage frequency varies greatly depending on the formulation and on the disease being treated. Procaine penicillin G should be administered every 12 to 24 hours. Every-24-hour dosing is only recommended for treatment of streptococci. Potassium or sodium formulations are administered every 6 hours, although every-3-hour or constant rate infusion can be used in immunosuppressed patients or those with life-threatening sepsis.

AMINOPENICILLINS

Spectrum of Activity

The aminopenicillins are able to penetrate the outer layer of gram-negative bacteria better than penicillin G; therefore they have activity against many of the gram-negative bacteria (*E. coli, Salmonella, Pasteurella* spp.) as well as gram-positive bacteria.[18] However, resistance to the aminopenicillins is easily acquired by gram-negative bacteria, so they are not usually effective against *Klebsiella, Proteus, Pseudomonas,* and *S. aureus.* Most anaerobes are sensitive, except β-lactamase–producing strains of *Bacteroides.*[45] Amoxicillin penetrates the gram-negative cell more easily than does ampicillin; therefore it has greater activity against gram-negative bacteria.[44]

Pharmacokinetics

Absorption

In horses ampicillin sodium is well absorbed after IM or SC administration; however, oral dosage forms are poorly absorbed by adult horses.[63] The IM administration of ampicillin trihydrate produces lower ampicillin blood concentrations that extend over a longer period of time than does IM ampicillin sodium.[63] Oral absorption of amoxicillin is between 5.3% and 10.4% in adult horses[64,65] but between 36% and 42% in foals.[66] The ampicillin prodrugs are converted to ampicillin as they are absorbed from the GI tract. Compared with the bioavailability of oral ampicillin (2%), the ampicillin esters have improved oral bioavailabilities in adult horses: pivampicillin (31%), bacampicillin (39%), and talampicillin (23%).[51,67] The low oral bioavailability of ampicillin esters is due to chemical hydrolysis in the high pH of equine ileal contents.

Distribution

The aminopenicillins are rapidly and widely distributed into most body fluids; distribution into CSF is low unless the meninges are inflamed. The Vd of amoxicillin in adult horses is 0.19[68] and 0.27 L/kg in neonatal foals.[66] The Vd of ampicillin in horses ranges from 0.18 to 0.7 L/kg.[69,70] Peak serum concentrations of ampicillin are 6.2 to 9.7 μg/mL 16 minutes after an IM dose of 10 mg/kg of ampicillin sodium.[63] Penetration into synovial fluid is high,[63,71] and concentrations are increased and persist in infected joints.[72] In a subcutaneous tissue chamber model in ponies, concentrations of IV ampicillin sodium, oral pivampicillin, and IM procaine penicillin G remained above the MIC of *S. zooepidemicus* for 8, 12, and 24 hours, respectively.[73] The protein binding of amoxicillin is moderate (37%–38%),[74] whereas it is low for ampicillin (6%–8%).[51]

Elimination

Amoxicillin and ampicillin are primarily excreted unchanged in the urine. The elimination half-life of amoxicillin is approximately 1 hour in horses and foals.[65,66,72,74] The elimination half-life of ampicillin ranges from 0.5 hour to 2.3 hours.[63,69,70,75,76]

Adverse Effects and Drug Interactions

Amoxicillin and ampicillin have the same adverse effects as penicillin G. Their spectrum of action is greatly enhanced when combined with β-lactamase inhibitors such as clavulanic acid and sulbactam.

Formulations

Sodium ampicillin is available as a human aqueous formulation for IV, IM, and SC injection. The reconstituted aqueous formulations are unstable after more than a few hours. Ampicillin trihydrate is a poorly soluble, slow-release aqueous suspension approved for use in large animals. Absorption is erratic, and it produces prolonged but low plasma concentrations.

Clinical Use

Indications for ampicillin or amoxicillin are few insofar as they offer little advantage over benzylpenicillins because of acquired resistance in gram-negative bacteria. Based on a tissue cage inflammation model, an IM dosage of 15 mg/kg of ampicillin sodium given every 6 hours would be required to treat ampicillin-susceptible bacteria.[70] Sodium ampicillin may be substituted for potassium penicillin as a choice for surgical prophylaxis in horses with current hyperkalemia or HYPP.

ANTIPSEUDOMONAL PENICILLINS

Spectrum of Activity

Carbenicillin, ticarcillin, and piperacillin are the antipseudomonal penicillins.[18] This group of penicillins can penetrate the outer cell wall of *Pseudomonas* spp. and other gram-negative bacteria. They are susceptible to β-lactamase inactivation by *Klebsiella* spp. For this reason, these drugs are often combined with β-lactamase inhibitors. The drug combination most frequently used in equine medicine is ticarcillin and clavulanic acid (CA). This group has activity against gram-negative bacteria at the expense of activity against gram-positive bacteria. They retain activity against anaerobic bacteria and are synergistic when administered with aminoglycosides.

Pharmacokinetics

Absorption

Bioavailability of IM ticarcillin is 65%, and the elimination half-life is less than 1 hour in horses.[77,78] Absorption of ticarcillin CA in foals is age dependent; neonatal foals have a higher systemic bioavailability after IM administration than older foals (100% and 88% vs. 100% and 27%, respectively).[79] When administered intramuscularly in combination with clavulanic acid, ticarcillin demonstrates flip-flop kinetics, wherein the elimination half-life is longer after IM than IV injection as a result of slow absorption from the injection site.[80] Systemic absorption of both ticarcillin and CA is poor after intrauterine administration.[81]

Distribution

Peak endometrial concentrations of ticarcillin after IV administration were 12.9 μg/g but were greater than 150 μg/g when 6 g were diluted in 250 mL of saline and infused into the uterus.[77] The Vd of ticarcillin in older foals was 0.24 L/kg, and the Vd of clavulanic acid was 0.48 L/kg. In neonatal foals the Vd was higher at 0.69 L/kg, as would be expected for a low-Vd drug in a neonate, with its increased ECF volume.[79] In mares the Vd of ticarcillin was 0.13 L/kg, and the Vd of clavulanic acid was 0.18 L/kg.[81]

Elimination

Ticarcillin CA demonstrates age-dependent elimination in foals. In neonatal foals the Vd and clearance of ticarcillin were approximately double those reported for older foals and mares.[79] The renal elimination mechanism of ticarcillin appears immature in a 3-day-old foal but near normal adult function by 28 days of age. In mares the elimination half-life of clavulanic acid is 0.4 hour.[81]

Adverse Effects and Drug Interactions

When ticarcillin is administered intramuscularly into the hindquarters at a concentration of 400 mg/mL with 13.2 mg/mL CA, foals showed signs of significant local discomfort.[79] A lower concentration of drug did not cause signs of discomfort in neonatal foals.

Formulations

Ticarcillin sodium is approved in horses as a 240-mg/mL solution for intrauterine infusion for the treatment of endometritis caused by β-hemolytic streptococci. Ticarcillin disodium–clavulanic acid formulations are available for human use.

Clinical Use

Because of its strong antipseudomonal activity, intrauterine administration of ticarcillin is used to treat endometritis in mares. The ticarcillin β-lactamase inhibitor drugs can be used in combination with aminoglycosides for a synergistic effect against the pathogens commonly encountered in septicemic foals.[82]

CEPHALOSPORINS

Spectrum of Activity

The cephalosporins are a very large group of β-lactam antibiotics. They are most commonly grouped according to "generations," primarily on the basis of their antibacterial activity, as well as their susceptibility to β-lactamases (Table 2.7).[18] By convention, cephalosporins discovered before 1975 are spelled with a *ph* and after 1975 with an *f*.

Cephalosporins are broad-spectrum antibiotics with a wide range of antimicrobial activity.[18,83] They are usually active against β-hemolytic streptococci and against β-lactamase–producing staphylococci but not against methicillin-resistant (oxacillin-resistant) *Staphylococcus aureus* (MRSA) or mycobacteria. Most enterococci are resistant. In the absence of acquired resistance, *E. coli* and *Salmonella* are usually susceptible, as are some *Proteus* and *Klebsiella* spp. Fourth-generation cephalosporins are effective against Enterobacteriaceae and other gram-negative bacteria that are resistant to earlier generations of cephalosporins because of acquired β-lactamase resistance. Common gram-negative aerobic respiratory pathogens such as *Haemophilus* and *Pasteurella,* including β-lactamase producers, are usually susceptible to cephalosporins. Although most corynebacteria are susceptible, *Rhodococcus equi* is usually resistant. Only antipseudomonal cephalosporins (some third and fourth generation) are effective against *P. aeruginosa.* Activity against non–spore-forming anaerobic bacteria is variable and similar to that of the aminopenicillins. Cefoxitin is notably resistant to β-lactamase–producing anaerobes, including *Bacteroides fragilis.* Ceftiofur is active against respiratory pathogens such as streptococci, *Pasteurella* spp., and *Histophilus* spp. and most

TABLE **2.7 Pharmacokinetics of Cephalosporins in Horses**

Classification of Cephalosporins

	Characteristics	Examples
First generation	Effective against almost all gram-positive bacteria, including β-lactamase–positive staphylococci; enterococci are resistant; effective against some gram-negative bacteria,[a] although sensitive to enterobacterial β-lactamase	Cephacetrile, cephaloridine, cephalothin, cephapirin, cefazolin,[a] cefadroxil, cephadrine, cephalexin
Second generation	Greater activity against gram-negative bacteria due to increased resistance to β-lactamases[b]; similar gram-positive spectrum to first-generation drugs	Cefaclor, cefotetan,[b] cefoxitin,[b] cefuroxime, cefuroxime axetil, cefamandole, cefmetazole, cefonocid, cefprozil
Third generation	Greater activity against gram-negative organisms; some drugs active against *Pseudomonas aeruginosa*[c]; resistant to many β-lactamases; less active against gram-positive cocci, with a few exceptions[d]	Cefoperazone,[c] cefsulodin, ceftazidime,[c] cefotaxime,[d] ceftizoxime proxetil, ceftriaxone, ceftiofur,[d] cevofecin, cefdinir, latamoxef (moxalaxtam), cefetamet, cefixime, cefpodoxime, cefovicin
Fourth generation	Broad spectrum of activity against gram-positive and gram-negative bacteria; resistant to staphylococcal, enterobacterial, and pseudomonal β-lactamases	Cefepime, cefquinome, cefpirome

Relative Activity of Cephalosporins against Common Bacteria[e]

IM, Intramuscular; *IV,* intravenous.

anaerobes but has less activity against *S. aureus* and Enterobacteriaceae than other third-generation drugs. *Bacteroides* spp. and *Pseudomonas* spp. are resistant to ceftiofur. When administered, ceftiofur is rapidly metabolized to the active metabolite desfuroylceftiofur. Desfuroylceftiofur is less active than ceftiofur against *S. aureus* and *Proteus* spp.[84] Diagnostic laboratories use a ceftiofur disk for susceptibility testing because of the instability of desfuroylceftiofur, so susceptibility testing results for staphylococci and *Proteus* spp. may not reliably predict the efficacy of ceftiofur therapy.

The broad-spectrum antibacterial activity of the cephalosporins may cause overgrowth ("superinfection") by inherently resistant bacteria, including *C. difficile,* which no longer have to compete with the normal microbial flora. Nosocomial infection with vancomycin-resistant enterococci (VRE) has become a serious problem in human hospitals. One of the highest risk factors for contracting a VRE infection in a human hospital is treatment with a cephalosporin.[85]

Pharmacokinetics

Absorption, Distribution, and Elimination

Numerous pharmacokinetic studies have been done on horses using multiple different cephalosporin antibiotics (see Table 2.7). In general, IM and SC administration of cephalosporins results in rapid drug absorption, but the extent varies with the drug and the species. Oral bioavailability is acceptable in neonates but rapidly becomes too low to be practical for older foals or adults.[86,87] An ester formulation of cefpodoxime, cefpodoxime proxetil, has been examined for use in horses. In a study in foals, oral absorption was good enough that a dose of 10 mg/kg every 6 to 12 hours produced plasma concentrations that would potentially treat infections.[88] The values for Vd in horses for the cephalosporins are typically low (less than 0.3 L/kg), indicating distribution primarily to ECF. However, they have good distribution into the ECF of most tissues, including pleural, pericardial, and synovial fluid. Penetration into cortical and cancellous bone is usually adequate.[89] Cephalosporins penetrate poorly into the ocular humor and, except for some third-generation drugs, do not achieve therapeutic concentrations in the central nervous system.[18] In general the third-generation cephalosporins have an increased ability to penetrate the central nervous system.[90] Higher Vd values for foals reflect the increased ECF compartment of the neonate.[86,91] Most cephalosporins are rapidly eliminated as the unchanged drug in the urine. Renal excretion of cephalosporins occurs through a combination of glomerular filtration and active tubular secretion. Therefore it may be necessary to modify the dosage regimen of most cephalosporins for patients in renal failure, although there is a low risk of adverse effects at high concentrations. For the cephalosporins that undergo hepatic metabolism, hepatic insufficiency may decrease metabolism and increase drug accumulation.

The two most recent cephalosporins to be approved for veterinary use are exceptions to the general pharmacokinetic attributes of this drug class. Ceftiofur crystalline free acid (CCFA) and cefovicin are sustained release formulations. Of these, CCFA is labeled for use in horses. This drug provides therapeutic concentrations (based on an MIC of ≤0.2 μg/mL for streptococci) for up to 4 days following a single dose and for 10 days using a two-dose regimen. Compared with ceftiofur sodium, it has a lower C_{max} and a longer T_{max}, with an absolute bioavailability of 100%.[92] The half-life of CCFA is approximately 4 times longer than that of ceftiofur sodium (81 hours vs. 21.5 hours), which is consistent with flip-flop kinetics. Pharmacokinetics are not significantly different when the dose is divided and administered in two different sites.[93] CCFA penetrates well into the endometrium and can be used for treatment of endometritis caused by *Streptococcus equi* subsp. *zooepidemicus.* However, it does not appear to cross the blood-placental barrier as administration to mares with streptococcal placentitis did not improve foal survival or prevent septicemia in foals.[94] Investigations in healthy neonatal foals showed that subcutaneous administration of CCFA had a lower *AUC,* shorter observed time to maximum concentration, and higher observed C_{max} compared with adult horses.[95] Weanling age foals (4–6 months old) also exhibit different pharmacokinetics, including higher peak plasma concentrations and *AUC* compared with adults; however, these differences were not significant enough to necessitate a difference in dosing regimen.[96]

Adverse Effects and Drug Interactions

In general cephalosporins have a high therapeutic index. The adverse effects of the cephalosporins are similar to those reported for the penicillins, including hypersensitivity allergic reactions. Bleeding disorders have been reported in humans but not in animals.[97] The reaction appears to be related to vitamin K antagonism and/or platelet dysfunction and is usually only an issue with drugs that contain an *N*-methylthiotetrazole side chain (cefoperazone, cefotetan, cefamandole). High doses of ceftiofur and cefotaxime

may cause anemia and thrombocytopenia. Ceftriaxone and cefepime cause GI disturbances after administration to foals and horses.[98-100] The currently available cephalosporins are considered to be potentially nephrotoxic by way of deposition of immune complexes in the glomerular basement membrane or from a direct toxic effect leading to acute tubular necrosis, although this does not seem to be an issue at clinically relevant doses.[101] Like the penicillins, cephalosporins can be synergistic with aminoglycosides against many pathogens.[102] In human medicine it is recommended that cephalosporins not be used in conjunction with aminoglycosides; however, animal studies demonstrate a protective effect of the cephalosporins against nephrotoxicity.[103]

Ceftiofur is associated with diarrhea caused by altered GI flora in horses.[104,105] Toxicity studies have shown that horses tolerate ceftiofur doses up to 11 mg/kg/day IM, with pain at the injection site and decreased feed consumption as the most common adverse effect at the highest dose. The main adverse effect associated with CCFA has been injection site reactions, which can be minimized by splitting the dose into two different injection sites, injecting no more than 10 mL per site, drawing up the drug with a separate needle and using a new needle for each injection site, and using a 16-g, 1.5-in needle. Subcutaneous administration of CCFA in adult horses appeared to increase the risk for injection site reactions, although this route is considered safe in neonatal foals.[95,106] Reported consequences of injection site reactions include fever (up to 103.5°F), abscessation, and clostridial myositis.

Formulations

Cefadroxil is available as veterinary-formulated tablets or suspension for small animals. Cephalexin is available as human tablets and suspensions for oral administration. Cefpodoxime proxetil is available as veterinary-formulated tablets (100 or 200 mg) for dogs. Cefepime (human) and ceftiofur (food animal "ready to use") are available as hydrochloride formulations. Ceftiofur sodium is labeled for horses and is available as a 1-g or 4-g sterile powder to be reconstituted in sterile water to a final concentration of 50 mg/mL. Once reconstituted, the product is stable for up to 12 hours at room temperature, 7 days when refrigerated, and 6 months when frozen. CCFA is available as sterile suspension equivalent to 200 mg/mL of ceftiofur in a caprylic/capric triglyceride and cottonseed oil base.

Clinical Use

Ceftiofur sodium is approved for treatment of respiratory disease caused by *S. equi* subsp. *zooepidemicus* at a dose of 2.2 to 4.4 mg/kg q24hr IM. Higher doses or more frequent intervals have been recommended for treating gram-negative organisms (e.g., *Klebsiella, Enterobacter, Salmonella*). Because these organisms are inherently more resistant, higher plasma concentrations are needed for efficacy. The susceptibility breakpoint for ceftiofur use in horses is very low (less than 0.25 μg/mL), and organisms other than streptococci may be classified in vitro as resistant. In septic neonatal foals, doses as high as 10 mg/kg IV q6hr have been used. However, more recent studies in foals have shown lower doses (5 mg/kg IV, SC q12hr) are sufficient for the treatment of most bacteria cultured from septic neonates (MIC_{90} < 0.5 μg/mL).[107] Constant rate infusion of ceftiofur has also been shown to be safe in foals at doses up to 20 mg/kg/day.[108] This dose rate is adequate for the treatment of bacteria with MICs up to 4 μg/mL.

CCFA will provide 10 days' worth of therapeutic concentrations against streptococci (MIC < 0.2 μg/mL) following a two-dose regimen (6.6 mg/kg IM, repeated 96 hours later). Extralabel dosing of the drug has been used in clinical practice, mainly through the use of prolonged dosing regimens. For treatment of streptococci, the recommended dosing regimen for CCFA is 6.6 mg/kg IM on day 1 and 4, then every 7 days after.[109] For more resistant bacteria (MIC ≤ 1 μg/mL), the recommended dosing regimen is 6.6 mg/kg IM every 4 days. Similar dosing regimens are recommended in weanling foals. For neonatal foals, administration at a dose of 6.6 mg/kg body weight SC every 72 hours would be expected to provide protection against bacteria isolated from neonatal foals, based on an MIC of 0.5 μg/mL.[95]

CARBAPENEMS

The carbapenems are the newest class of β-lactam antimicrobials. They have an extended spectrum of activity, including many gram-negative bacteria. The only notable exceptions include MRSA and resistant *Enterococcus faecium*. The high activity of these drugs is due to the ability to withstand the β-lactamases (including ESBL) and the ability to penetrate porin channels that usually exclude other drugs. Pharmacokinetic properties are similar to other β-lactam drugs in horses, including poor oral bioavailability, a short half-life, and low to moderate Vd, although carbapenems have a long postantibiotic effect. Clinical use in horses is typically limited to septic neonates because of cost and the need for appropriate antibiotic stewardship, as these are considered critically important drugs in human medicine. Drugs in this class include imipenem and meropenem.

Imipenem has been used in neonatal foals at a dose of 5 mg/kg IV infused over 20 minutes q6–8hr. A pharmacokinetic study in adult horses suggests a dose of 10 to 20 mg/kg imipenem by slow IV infusion q6hr would be necessary to maintain adequate plasma concentrations.[110] Imipenem is available in human injectable formulations in combination with cilastatin. Cilastatin inhibits renal brush border enzymes that would otherwise convert imipenem into a nephrotoxic metabolite. Prevention of this metabolism not only decreases toxicity of the drug, but it also increases the concentration of active parent drug into the urine.

Meropenem is a slightly less expensive than imipenem and is less irritating when injected IM or SC. Pharmacokinetic data on meropenem are lacking; however, based on therapeutic drug monitoring in clinical cases, the clearance was high (5.2 mL/min/kg) and the half-life was short (34.5 min). Due to its short half-life, a constant rate infusion of 10 μg/kg/min (15 mg/kg/day) is recommended. This dose will be adequate for bacteria with MICs ≤ 2 μg/mL. Pharmacokinetics appear to be linear over a range of 10 to 30 μg/kg/min with no noted adverse effects in the small number of clinical cases for which it has been used.

AMINOGLYCOSIDES

The aminoglycoside antibiotics include streptomycin, neomycin, gentamicin, amikacin, tobramycin, and kanamycin. They have a chemical structure of amino sugars joined by a glycoside linkage. The importance of this group in veterinary medicine is to treat serious infections caused by aerobic gram-negative bacteria and staphylococci. Amikacin and tobramycin

have excellent activity against *P. aeruginosa.* Nevertheless, the aminoglycosides remain important drugs in the treatment of severe gram-negative sepsis, although their highly cationic, polar nature means that distribution across membranes is limited. Single daily dosing is now recommended for most dosage regimens because it maximizes efficacy and reduces toxicity.

Mechanism of Action

The aminoglycosides are large molecules with numerous amino acid groups, making them basic polycations that are highly ionized at physiologic pHs. Aminoglycosides must penetrate the bacteria to assert their effect. Susceptible, aerobic gram-negative bacteria actively pump the aminoglycoside into the cell. This is initiated by an oxygen-dependent interaction between the antibiotic cations and the negatively charged ions of the bacterial membrane lipopolysaccharides. This interaction displaces divalent cations (Ca^{++}, Mg^{++}), which affects membrane permeability.[119] Once inside the bacterial cell, aminoglycosides bind to the 30S ribosomal subunit and cause a misreading of the genetic code, interrupting normal bacterial protein synthesis. This changes the cell membrane permeability, resulting in additional antibiotic uptake, further cell disruption, and ultimately cell death.

Aminoglycoside action is bactericidal and concentration dependent. For example, concentrations of gentamicin in the range of 0.5 to 5.0 μg/mL are bactericidal for gram-positive and some gram-negative bacteria. At 10 to 15 μg/mL, gentamicin is effective against the more resistant bacteria such as *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Proteus mirabilis.*[120] The clinical implication is that high initial doses of aminoglycosides increase ionic bonding, enhancing the initial concentration-dependent phase of rapid antibiotic internalization, which leads to greater immediate bactericidal activity. Human clinical studies demonstrate that proper initial therapeutic doses of aminoglycosides are critical in reducing mortality from gram-negative septicemia. For antimicrobials whose efficacy is concentration dependent, high plasma concentration levels relative to the MIC of the pathogen (C_{max}:MIC ratio, also known as the *inhibitory quotient,* or *IQ*) and the area under the plasma concentration–time curve that is above the bacterial MIC during the dosage interval (area under the inhibitory curve, AUIC = AUC/MIC) are the major determinants of clinical efficacy. For the aminoglycosides a C_{max}:MIC ratio of 10 is suggested to achieve optimal efficacy.[27]

The aminoglycosides have a significant PAE, meaning the period of time during which antimicrobial concentrations are below the bacterial MIC but the antimicrobial-damaged bacteria are more susceptible to host defenses. The duration of the PAE tends to increase as the initial aminoglycoside concentration increases.[121]

Antimicrobial activity of aminoglycosides is enhanced in an alkaline environment (pH of 6–8). They bind to and are inactivated by the nucleic acid material released by decaying white blood cells. Therefore they are usually ineffective in the acidic, hyperosmolar, anaerobic environment of abscesses.

Spectrum of Activity

The aminoglycosides are effective against most aerobic gram-negative bacteria, including *Pseudomonas.*[18] They are somewhat effective against staphylococci, although resistance can occur. They are often effective against enterococci, but therapy against streptococci is more effective when combined with a β-lactam antibiotic. *Salmonella* and *Brucella* spp. are intracellular pathogens and are often resistant. Some mycobacteria, spirochetes, and mycoplasma are susceptible. Aminoglycosides are ineffective against anaerobic bacteria because aminoglycoside penetration into the bacteria requires an oxygen-dependent transport mechanism. Amikacin was developed from kanamycin and has the broadest spectrum of activity of the aminoglycosides. It is effective against strains not susceptible to other aminoglycosides because it is more resistant to bacterial enzymatic inactivation and is considered the least nephrotoxic.

Resistance Mechanisms

Aminoglycoside resistance is primarily due to enzymes encoded by genes located on bacterial plasmids. These phosphotransferases, acetyltransferases, and adenyltransferases act internally to alter the aminoglycoside and prevent it from binding to ribosomes.[18] Amikacin is least susceptible to enzyme inactivation. Plasmid-mediated resistance to the aminoglycosides is transferable between bacteria. A single type of plasmid may confer cross-resistance to multiple aminoglycosides and to other unrelated antimicrobials. Bacteria may also utilize other methods that reduce the efficacy of aminoglycosides. Some strains of bacteria are less permeable to aminoglycosides, requiring much higher concentrations of aminoglycosides to kill them and therefore can be selected for during treatment. Chromosomal-mediated resistance is minimal and develops slowly for most of the aminoglycosides, with the exception of streptomycin or dihydrostreptomycin; resistance to streptomycin can occur from a single-step mutation.

First Exposure Adaptive Resistance

Both subinhibitory and inhibitory aminoglycoside concentrations produce resistance in bacterial cells surviving the initial ionic binding.[122] This adaptive resistance is due to decreased aminoglycoside transport into the bacteria. Exposure to one dose of an aminoglycoside is sufficient to produce resistant variants of an organism with altered metabolism and impaired aminoglycoside uptake. In vitro animal and clinical studies show that the resistance occurs within 1 or 2 hours of the first dose. The duration of adaptive resistance relates directly to the elimination half-life of the aminoglycoside. With normal aminoglycoside pharmacokinetics, the resistance may be maximal for up to 16 hours after a single dose of aminoglycoside, followed by partial return of bacterial susceptibility at 24 hours and complete recovery at approximately 40 hours.[123] If the aminoglycoside is dosed multiple times a day or the drug concentration remains constant, as with a continuous infusion, adaptive resistance persists and increases. Adaptive resistance is likely to persist in peripheral compartments, which are often the site of infection because of the persistence of aminoglycosides at these sites. Dose administration at 24-hour intervals, or longer, may increase efficacy by allowing time for adaptive resistance to reverse.[122-124]

Pharmacokinetics

Absorption. See Table 2.8 for the pharmacokinetics of gentamicin, amikacin, and tobramycin in horses. Amikacin and gentamicin are rapidly and well absorbed from IM and SC routes of administration but are not absorbed orally.[119]

Distribution. The aminoglycosides are polar antibiotics; therefore distribution is limited to the ECF space. The Vd in most species ranges between 0.15 and 0.3 L/kg.[125,126] After parenteral administration, effective concentrations are

obtained in synovial, perilymph, pleural, peritoneal, and pericardial fluid.[127] Therapeutic concentrations are not achieved in bile, CSF, respiratory secretions, and prostatic and ocular fluids.[119] Gentamicin does not cross the placenta of late-term mares; however, endometrial tissue concentrations of gentamicin were higher than plasma concentrations after 7 days of IM therapy with a dose of 5 mg/kg every 8 hours.[128,129] The predominant site of drug accumulation is the renal cortex in most species. In endotoxemia, gentamicin concentrations increase in serum as a result of a fever-induced decrease in the volume of the ECF compartment.[130] The administration of therapeutic fluids, colic surgery, or peritoneal lavage does not significantly change the pharmacokinetics of concurrently administered gentamicin.[131-133]

Gentamicin distributed into synovial fluid in normal horses and reached a peak of 6.4 µg/mL at 2 hours with a single 4.4-mg/kg IV dose.[134] Intraarticular administration or regional perfusion techniques are excellent methods to deliver aminoglycosides locally and prevent the adverse effects of systemic therapy.[135-141] When intraosseous perfusion was compared with IV perfusion, each technique produced mean peak concentrations of amikacin ranging from 5 to 50 times that of recommended peak serum concentrations for therapeutic efficacy.[142] Gentamicin-impregnated polymethylmethacrylate beads or collagen sponges may also be used to achieve extremely high local concentrations of drug, while avoiding systemic toxicity.[143,144]

Elimination

The aminoglycosides are almost exclusively eliminated in urine by glomerular filtration.[119] The plasma elimination half-lives range from 1 to 3 hours in adult animals but are increased in animals with renal dysfunction.[126] Renal accumulation results in extended withdrawal times for food animals.

Foals

The pharmacokinetics of aminoglycosides in foals is different from that in adults. The most consistent difference is in the Vd, which is higher in neonatal foals due to a larger volume of ECF. Clearance is usually unaffected, except for slight increases in septic or compromised neonates. This results in an increased elimination half-life in animals less than 2 weeks of age.[126] It also results in a C_{max} lower than that in adult horses, necessitating higher doses and possibly longer dosing intervals.

Adverse Effects and Drug Interactions

Nephrotoxicity

The aminoglycosides enter the renal tubule after filtration through the glomerulus (Fig. 2.22). From the luminal fluid the cationic aminoglycoside molecules bind to anionic phospholipids on the proximal tubular cells.[145] The aminoglycoside is taken into the cell by way of carrier-mediated pinocytosis and translocated into cytoplasmic vacuoles, which fuse with lysosomes.[146] The drug is sequestered unchanged in the lysosomes. With additional pinocytosis drug continues to accumulate within the lysosomes. The accumulated aminoglycoside interferes with normal lysosomal function, and eventually the overloaded lysosomes swell and rupture. Lysosomal enzymes, phospholipids, and the aminoglycoside are released into the cytosol of the proximal tubular cell, disrupting other organelles and causing cell death.[147]

The risk factors for aminoglycoside toxicity include prolonged therapy (longer than 7–10 days), acidosis and electrolyte

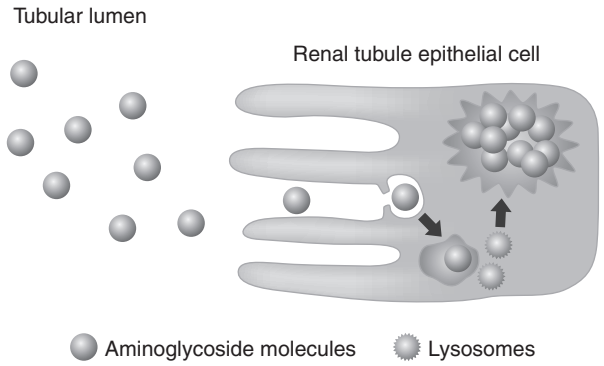

FIG. **2.22** Nephrotoxicity occurs from ionic binding of aminoglycoside molecules to polysaccharide cations on the proximal tubular epithelium, followed by pinocytosis and accumulation within lysosomes.

disturbances (hypokalemia, hyponatremia), volume depletion (shock, endotoxemia), concurrent nephrotoxic drug therapy, preexisting renal disease, and elevated plasma trough concentrations.[147-153] Calcium supplementation can reduce the risk of nephrotoxicity.[154] Administration of antioxidants such as silymarin and vitamin E may decrease aminoglycoside nephrotoxicity.[155] The risk of nephrotoxicity can also be decreased by feeding the patient a diet high in protein and calcium, such as alfalfa hay, because protein and calcium cations compete with aminoglycoside cations for binding to renal tubular epithelial cells.[156] High dietary protein also increases GFR and renal blood flow, reducing aminoglycoside accumulation.[157]

Uptake and accumulation of aminoglycosides into renal tubular epithelium demonstrate saturable kinetics. Because nephrotoxicity is related to aminoglycoside accumulation in the renal proximal tubular cells, it is logical that peak concentrations are not related to toxicity and that longer dose intervals result in less total drug exposure to the renal brush border membrane. High-dose, once-daily dosing of aminoglycosides has now become common in human and veterinary medicine; it takes advantage of the concentration-dependent killing and long PAE of these drugs and prevents first exposure adaptive resistance and toxicity.[132,158-160]

Individual horses can differ widely in the serum concentrations produced by the same aminoglycoside dosage regimen. There is a tendency to underdose neonatal patients, especially those that are receiving aggressive fluid therapy.[161] To maximize efficacy and minimize toxicity, therapeutic drug monitoring is recommended to ensure a C_{max}:MIC ratio of 10 is acheived.[27,119,162] Because the trough concentration is associated with nephrotoxicity, it is recommended that trough concentrations be less than 2 μg/mL for gentamicin and less than 5 μg/mL for amikacin before the next dose is administered.[119,162] To allow for the distribution phase, blood sampling for the peak concentration is performed 0.5 to 1 hour after IV administration, and the trough sample is usually taken before the next dose. The peak and trough concentrations can then be used to estimate the elimination half-life for the individual patient. An increase in the elimination half-life during therapy is a very sensitive indicator of early tubular insult.[163] If a once-daily regimen is used, a blood sample just before the next dose will be well below the recommended trough concentrations and may even be below the limit of detection of the assay. For these patients an 8-hour postdose sample will provide a more accurate estimate of the elimination half-life.

If therapeutic drug monitoring is unavailable, then once-daily high-dose therapy is recommended; the development of nephrotoxicity is detected by an increase in urine gamma glutamyl transferase (UGGT) enzyme and an increase in the UGGT:urine creatinine (UCr) ratio. The UGGT:UCr may increase to 2 to 3 times baseline within 3 days of a nephrotoxic dose.[148,163,164] If these tests are not available, the development of proteinuria is the next best indicator of nephrotoxicity and is easily determined in a practice setting.[163,164] Elevations in serum urea nitrogen and Cr confirm nephrotoxicity but are not seen for 7 days after significant renal damage has occurred.[126] Elimination half-lives of 24 to 45 hours have been reported in horses with renal toxicity, further prolonging the toxic exposure to the drug.[151] Although peritoneal dialysis is useful in lowering creatinine and serum urea nitrates, it may not be effective in significantly increasing the elimination of the accumulating aminoglycoside.[151] The horse's ability to recover most likely depends on the type of medication exposure and the amount of healthy renal tissue remaining to compensate.

Ototoxicity

Aminoglycoside ototoxicity occurs from the same accumulation mechanisms as nephrotoxicity. In the inner ear aminoglycosides appear to generate free radicals that subsequently do permanent damage to sensory cells and neurons.[165] Gentamicin damages the cochlear division of the eighth cranial nerve, resulting in vertigo, and amikacin damages the auditory division of the eighth cranial nerve, resulting in permanent deafness. This drug-specific toxicity may be due to the distribution characteristics of each drug and concentration achieved in each sensory organ.[166]

Neuromuscular Blockade

Neuromuscular blockade is a rare effect, related to blockade of acetylcholine at the nicotinic cholinergic receptor.[167] It is most often seen when anesthetic agents are administered concurrently with aminoglycosides.[168,169] Diseases that affect the neuromuscular junction, such as botulism, can also precipitate blockade. Affected patients should be treated promptly with parenteral calcium chloride at 10 to 20 mg/kg intravenously or calcium gluconate at 30 to 60 mg/kg intravenously to reverse dyspnea from muscle response depression. IV edrophonium at 0.5 mg/kg will also reverse neuromuscular blocking effects.[168]

Drug Interactions

Aminoglycosides are inactivated if combined in vitro with other drugs because of pH incompatibilities. In vitro, penicillins interact chemically with the aminoglycoside antibacterials to form biologically inactive amides by a reaction between the amino groups on the aminoglycosides and the β-lactam ring on the penicillins, inactivating both antibacterials. In vivo however, the aminoglycosides are synergistic against streptococci, *Pseudomonas,* and other gram-negative bacteria if combined with β-lactam antibiotics as a result of the bacterial cell wall being disrupted by the β-lactam antibiotic. Halothane anesthesia causes significant changes in the pharmacokinetics of gentamicin; total body clearance and volume of distribution decrease, and half-life of elimination increases.[169] A longer gentamicin dosing interval after anesthesia may help correct for the changes, but the practitioner should seriously consider selecting another antimicrobial. Neuromuscular blocking agents or drugs with neuromuscular blocking activity should not be used concurrently with aminoglycosides because they

can increase the risk of neuromuscular blockade, particularly during anesthesia.[168] Other nephrotoxic drugs should be avoided when possible during aminoglycoside therapy. Concurrent administration of phenylbutazone with gentamicin decreases the elimination half-life of gentamicin by 23% and decreases the Vd by 26%; the pharmacokinetics of phenylbutazone are not affected.[170] Flunixin has no effect on the pharmacokinetics of gentamicin when administered concurrently to adult horses.[132]

Formulations

Gentamicin and amikacin are available as brand name and generic solutions for intrauterine infusion in mares. Human and small animal labeled products for gentamicin, amikacin, and tobramycin are administered by IV, IM, SC, intraarticular, and intraosseous routes to horses. Gentamicin is also available in ophthalmic formulations for the treatment of gram-negative keratitis.

Clinical Use

Gentamicin and amikacin are commonly used to treat serious gram-negative infection in horses and septicemia in foals, often combined with β-lactam antimicrobials. Amikacin or tobramycin is used when antimicrobial resistance to gentamicin has developed in gram-negative pathogens, but gentamicin has greater activity against streptococci than amikacin.[29] The use of aminoglycosides in horses had previously been limited because of toxicity concerns, but high-dose once-daily dosing greatly reduces the risks. Use of the aminoglycosides is also limited by their poor penetration of cellular membranes and inactivation in purulent environments.

AMPHENICOLS

Chloramphenicol (CHPC) was isolated in 1947 from a soil actinomycete from Venezuela. Florfenicol (FLF) is a fluorinated derivative of CHPC. Although CHPC is well tolerated by horses, FLF alters fecal consistency, enteric flora, and susceptibility of *Salmonella* spp., *E. coli,* and *Clostridium perfringens*, and its use is not recommended.

Mechanism of Action

Chloramphenicol is a bacteriostatic antibiotic that inhibits protein synthesis by binding to ribosomal subunits of susceptible bacteria, leading to the inhibition of peptidyl transferase and thereby preventing the transfer of amino acids to growing peptide chains and subsequent protein formation.[175] There is a very wide spectrum of activity, including streptococci, staphylococci (including many MRSA), anaerobes, *Haemophilus, Salmonella, Pasteurella, Mycoplasma,* and *Brucella* spp., as well as rickettsia, chlamydia, and hemobartonella.[2]

Mechanisms of Resistance

Bacterial resistance to CHPC results from plasmid-mediated bacterial production of acetylase enzymes. Acetylation of hydroxyl groups prevents drug binding to the 50S ribosomal subunit.

Pharmacokinetics

Absorption

CHPC is rapidly absorbed after oral administration. The oral bioavailability of CHPC in foals is 83%[176] but only 40% after a single administration in mares, and bioavailability declines to 20% after five doses.[177] Due to the high lipid solubility of CHPC, even topical administration in the eye can result in significant systemic absorption.

Distribution

Because of high lipid solubility and low protein binding, CHPC is widely distributed throughout the body. Highest drug levels are attained in the liver and kidney, but therapeutic drug concentrations are attained in most tissues and fluids, including abscesses, ocular humor, and synovial fluid.[18] CHPC may achieve CSF concentrations of up to 50% of plasma concentrations when the meninges are normal, and more if inflammation is present.[178] The Vd of CHPC is 2.83 L/kg in horses[179] and 1.6 L/kg in neonatal foals.[160] The degree of protein binding of CHPC in horses is 30%.[180]

Elimination

In most species CHPC is eliminated by renal excretion of parent drug and by hepatic glucuronide conjugation and elimination in feces. The elimination half-life of CHPC in foals older than 7 days and adult horses is less than 1 hour.[176,179-182] In 1- and 3-day-old foals the elimination half-life is 5.3 and 1.4 hours, respectively, indicating the immaturity of the foal's hepatic metabolism capacity.[181] The elimination half-life is greatly prolonged in premature foals, and this drug should be used with caution.

Adverse Effects and Drug Interactions

Insofar as these drugs are protein synthesis inhibitors, dose-related anemia and pancytopenia are associated with chronic therapy (longer than 14 days), causing a decrease in protein synthesis in the bone marrow. FLF is more likely than CHPC to cause reversible bone marrow suppression with chronic dosing or overdose.[183] In humans an idiosyncratic aplastic anemia occurs with exposure to CHPC.[184] The reaction is rare (1 in 30,000) and not dose related. Toxic effects are related to the presence of the para-nitro group on the CHPC molecule. If CHPC is dispensed for client use at home, appropriate client education should always accompany the prescription, including dissolving the drug rather than crushing tablets and wearing gloves during and washing hands after administration.

CHPC is a hepatic microsomal enzyme inhibitor. It decreases the clearance of other drugs metabolized by the same cytochrome P450 enzymes, including phenytoin, phenobarbital, pentobarbital, phenylbutazone, xylazine, and cyclophosphamide.[185,186]

In general, CHPC should not be administered concurrently with penicillins, macrolides, aminoglycosides, or fluoroquinolones. CHPC may antagonize the activity of penicillins or aminoglycosides, and they act on the same ribosomal site as the macrolides.[187,188] Inhibition of protein synthesis by CHPC interferes with the production of autolysins necessary for cell lysis after fluoroquinolones interfere with DNA supercoiling.[189]

Formulations

CHPC sodium succinate is a water-soluble formulation for IV use and is hydrolyzed to CHPC in the liver. CHPC free base and CHPC-palmitate are available for oral administration. The CHPC-palmitate is hydrolyzed in the GI tract to CHPC. Ophthalmic formulations of CHPC are also available.

Clinical Use

CHPC is banned for use in any type of food animal because it can lead to idiosyncratic aplastic anemia in humans. In countries where its use is permitted in horses, it is used for a variety of bacterial infections, especially when penetration into abscesses (e.g., umbilical abscesses) and the central nervous system is desired, but appropriate precautions should be taken in handling the product to prevent human exposure. Because of the short half-life, high doses administered frequently are recommended (50 mg/kg PO q6–8hr).

POTENTIATED SULFONAMIDES

The sulfonamides are a group of organic compounds with chemotherapeutic activity (hence they are antimicrobials, not antibiotics). They have a common chemical nucleus that is closely related to *p*-aminobenzoic acid, an essential component in the folic acid pathway of nucleic acid synthesis. Sulfonamides are combined with diaminopyrimidines such as trimethoprim (TMP) and pyrimethamine (PYM), which inhibit an essential step farther along the folate pathway. Because the potentiated sulfonamides are remarkably synergistic and nontoxic, they are commonly used in equine medicine. Their use is complicated by differences in pharmacokinetics among TMP and PYM and the various sulfonamides used in the combinations.

Mechanism of Action

The sulfonamides inhibit the bacterial enzyme dihydropteroate synthetase (DPS) in the folic acid pathway, thereby blocking bacterial nucleic acid synthesis. Sulfonamides substitute for PABA, preventing its conversion to dihydrofolic acid. Alone, this action is considered bacteriostatic. Because the activity is by competitive substitution, the sulfonamide tissue concentration must be kept high enough to prevent bacterial access to PABA. Therefore the sulfonamides are ineffective in pus and necrotic tissue, which provide additional sources of PABA to the bacteria. The sulfonamides are nontoxic to mammalian cells because they use dietary folate for synthesis of dihydrofolic acid and do not require PABA. The addition of TMP or PYM to a sulfonamide creates a bactericidal combination. TMP inhibits bacterial folic acid synthesis at the next step in the folic acid sequence, inhibiting the conversion of dihydrofolic acid to tetrahydrofolic acid by inhibiting dihydrofolate reductase. This enzyme is present in both bacteria and mammalian cells, but the bacterial enzyme is inhibited at much lower concentrations than necessary to inhibit the mammalian enzyme.[190] The MICs against specific susceptible bacteria for each drug are generally lowered when the antimicrobials are administered in the potentiated sulfonamide combination. The resistance developed to the potentiated sulfonamides is lower than that to each individual drug; this is an important benefit because resistance to sulfonamides is very common and resistance develops rapidly to diaminopyrimidines when used alone.[191]

The potentiated sulfonamides have a broad spectrum of activity. The following bacteria are usually susceptible: *Streptococcus, Proteus, E. coli, Pasteurella, Haemophilus,* and *Salmonella* spp. Staphylococci, anaerobes, *Nocardia, Corynebacterium, Klebsiella,* and *Enterobacter* are susceptible but may become resistant. *Pseudomonas* spp., *Bacteroides* spp., and enterococci are usually resistant.[29,62,192] Other significant organisms that are susceptible to potentiated sulfonamides include protozoa *(Toxoplasma gondii, Sarcocystis neurona)* and coccidia. PYM is more effective than TMP against protozoa.[191] The potentiated sulfonamides are formulated at a fixed ratio of 1:5 of TMP to sulfonamide. The optimum concentration for bactericidal action is 1:20.[190] When and where this optimum concentration is achieved are difficult to predict in vivo, but a 1:20 ratio is used in susceptibility testing.[193]

Mechanisms of Resistance

Bacterial resistance to the sulfonamides is common and may be from chromosomal mutations or mediated by plasmids. Chromosomal mutations can lead to bacterial hyperproduction of PABA, which overcomes the competitive substitution of the sulfonamides. Plasmid-encoded resistance results in a bypass of the drug-sensitive step by production of altered forms of the DPS enzyme with a lower affinity for sulfonamides. Resistance to TMP usually occurs by plasmid-encoded production of TMP-resistant dihydrofolate reductase. Other resistance mechanisms include excessive bacterial production of dihydrofolate reductase (DHFR) and reduction in the ability of the drug to penetrate the bacterial cell wall. Cross-resistance among sulfonamides is considered complete and often occurs with pyrimidines.[190] Resistance to the TMP-sulfonamide combinations develops slowly but is now common among equine bacterial isolates.[29,194]

Pharmacokinetics

Pharmacokinetics of the potentiated sulfonamides are complicated by the distinct differences between disposition of TMP and PYM and the various sulfonamides. When sulfonamides and diaminopyrimidines are administered concurrently to horses, the pharmacokinetics of each drug appears to be unaffected by the presence of the other. Table 2.9 outlines the pharmacokinetics of specific potentiated sulfonamide combinations in horses. Although the potentiated sulfonamides are frequently used interchangeably, pharmacokinetic studies show that they are not bioequivalent in horses.

Absorption

In general, potentiated sulfonamides are readily absorbed from the GI tract of horses, but absorption may be affected by feeding.[195-197] For TMP and sulfachlorpyridazine, peak plasma concentrations and bioavailabilities are significantly reduced when the drug is mixed with concentrate compared with nasogastric administration.[198] Both drugs also demonstrate a biphasic absorption pattern, and it appears that this is due to a portion of the TMP and sulfachlorpyridazine dose binding to feed, with a second absorption phase occurring in the large intestine.[199] Bioavailability following intrauterine administration was 23% to 43% for TMP and 29% to 34% for sulfadoxine, and both were detected in the milk of lactating mares.[200] The oral bioavailability of PYM is 56% in horses.[201]

Distribution

Because the sulfonamides are weak acids and relatively hydrophilic, they distribute well in ECF and typically have values for Vd of 0.3 to 0.7 L/kg. Concentrations of sulfonamides in tissues are generally lower than those in plasma. The diaminopyrimidines are lipophilic weak bases and penetrate intracellularly better than sulfonamides, resulting in values for Vd of 1.5 to 2.7 L/kg and higher tissue concentrations than plasma

TABLE **2.9 Pharmacokinetics of Trimethoprim, Pyrimethamine, and Sulfonamides in Horses**

Drug	Volume of Distribution (L/kg)	Half-Life or MRT (hr)	Protein Binding (%)	Clearance (mL/min/kg)	Dose (mg/kg)
Trimethoprim	—	2.4	—	—	PO: 5
Sulfadiazine[196]		7.4			PO: 25
Trimethoprim	2.0	2.8	35	8.8	IV: 2.5
Sulfadiazine[218]	0.5	4.6	20	1.5	IV: 12.5
Trimethoprim	1.5	3	50	—	IV: 8
Sulfadoxine[206]	0.39	14	14–72		IV: 40
Trimethoprim	2.8	3.4	—	11	IV: 7.5
Sulfamethoxazole[222]	0.5	4.8	—	1.4	IV: 36.5
Trimethoprim	1.6	1.9	—	13	IV: 2.5
Sulfamethoxazole[202]	0.33	3.5	—	1.3	IV: 12.5
Trimethoprim	1.5	2.6	—	7.7	IV: 5
Sulfachlorpyridazine[198]	0.26	3.8	—	2.6	IV: 25
Pyrimethamine[201]	1.5	12	—	1.6	IV, PO: 1
Sulfadiazine[207]	0.4	3.8	43	2.3	IV: 20
Sulfamerazine[207]	0.49	3.2	44	1.8	IV: 20
Sulfamethazine[197]	0.63	11.4	—	0.8	IV: 160
Sulfamethazine[207]	0.33	5.4	69	0.9	IV: 20

IV, Intravenous; *MRT,* mean residence time; *PO,* oral.

concentrations.[190] Distribution of potentiated sulfonamides has been broadly investigated in the horse. Sulfadiazine and TMP and sulfamethoxazole and TMP are all well distributed into peritoneal fluid, CSF, synovial fluid, and urine.[202-204] Inflammation in the meninges or synovium does not significantly affect distribution into the respective fluids. After repeated doses sulfamethoxazole, unlike TMP, accumulates in the CSF.[202] CSF concentrations of PYR reach 25% to 50% of serum concentrations but do not appear to accumulate in horses with daily dosing.[205]

Sulfonamides can be highly bound to plasma proteins, but the extent of binding depends on species, drug, and concentration. In the horse the degree of protein binding varies from 33% for sulfaphenazole to 93% for sulfamethoxine.[190] Approximately 50% of TMP is protein bound, and binding is independent of plasma concentration.[206]

Metabolism

Diaminopyrimidines and sulfonamides are metabolized by the liver, usually by acetylation, aromatic hydroxylation, and glucuronidation.[190] The acetylated, hydroxylated, and conjugated forms of the sulfonamides are significantly less microbiologically active than their parent compounds. The precise metabolic pathways for TMP or PYR have not been elucidated. Metabolites may compete with the parent drug for involvement in folic acid synthesis. They have little detrimental effect on bacteria, so their presence can decrease the activity of the remaining parent drug.[207,208]

Elimination

Sulfonamides are primarily excreted in urine, but excretion in feces, bile, milk, sweat, and tears also occurs. Renal excretion of unchanged drug and metabolites occurs by glomerular filtration and active tubular secretion.[190] Reabsorption occurs in the distal tubule by passive diffusion. Because most sulfonamides are weak acids, alkaline urine increases their ionization and elimination. Renal excretion of TMP occurs by glomerular filtration, active tubular secretion, and reabsorption. In horses it appears that a large percentage of TMP is metabolized before elimination in urine (46%) and feces (52%). The clearance of the diaminopyrimidines is affected by urine pH, plasma concentration, and extent of diuresis. In contrast to the sulfonamides, alkaline urine increases the reabsorption of the basic TMP.[206]

Adverse Effects and Drug Interactions

The potentiated sulfonamides are noted for their widely varying adverse effects. Crystalluria, hematuria, and renal tubular obstruction can result from poorly soluble sulfonamides, especially in dehydrated patients with acidic urine.[190] However, the lower doses of sulfonamide used in the potentiated sulfonamide combinations make crystallization less likely than with sulfonamides administered alone. Local infusion of potentiated sulfonamides into the uterus of mares caused irritation of the endometrium and a decreased pregnancy rate.[200] Intramuscular administration is not recommended because of tissue irritation from the organic solvents, high concentration, and high pH of the formulations. IV administration must be done by slow and careful injection. Rapid administration is associated with thrombophlebitis and anaphylaxis.[190,209] The concurrent use of IV potentiated sulfonamides with detomidine is contraindicated because it appears that the potentiated sulfonamide sensitizes the myocardium and results in cardiac dysrhythmias and hypotension that may be fatal.[210,211] The procaine in procaine penicillin G is a PABA analog and may reduce efficacy if used concurrently with potentiated sulfonamides.[18]

Folate Antagonism Effects

Anemia, thrombocytopenia, and even pancytopenia may be seen in response to long-term, high-dose administration, such as in the treatment of equine protozoal myeloencephalitis (EPM). Anemia may be related to folate deficiency due to inhibition of folate production by intestinal bacteria or inhibition of its conversion to tetrahydrofolate and dihydrofolate. Coadministration of TMP and PYR does not increase the efficacy against protozoa and is suspected to increase the incidence of adverse effects caused by folate reduction. Supplementation with oral folic acid is often recommended for horses on long-term potentiated sulfonamide therapy.[212] The administration of oral folic acid to pregnant mares being treated for EPM may not protect the fetus from the effects of folate deficiency. Mares have delivered foals with congenital defects after oral administration of potentiated sulfonamides, despite supplementation with oral folic acid during treatment.[213] Treatment with TMP-sulfamethoxazole and PYM does not affect semen quality, testicular volume, sperm production efficiency, erection, or libido of healthy stallions. However, treatment may induce changes in copulatory form and agility and alter the pattern and strength of ejaculation.[214] Stallions that develop neurologic signs during treatment should be bred with caution. TMP-sulfamethoxazole has been associated with immune-mediated hemolytic anemia in a horse.[215]

Effects on GI Flora

The effects of potentiated sulfonamides on normal GI flora are controversial. In some studies potentiated sulfonamides alone or with concurrent penicillin or aminoglycoside therapy are associated with diarrhea in horses.[216,217] Other studies show little effect on fecal flora.[218,219] The likelihood of any antimicrobial therapy causing diarrhea in a horse depends on several factors, including the antibacterial spectrum of the drug and the drug concentrations achieved in the GI tract. The presence or absence of potential pathogens in the composition of the individual horse's microflora and the presence of antimicrobial-resistant pathogens in the hospital or clinic environment are also important factors in the incidence of GI disturbances. Despite the low incidence of colitis in horses treated with potentiated sulfonamides, the client and clinician should be aware of the potential, as cases can be rapidly fatal.

Formulations

TMP-sulfadiazine is available as a 48% injectable solution for IV administration in horses. It is also available as oral suspension, paste and powder formulations for horses. Generic tablets of TMP-sulfamethoxazole available for human use are commonly administered to horses. A commercially available PYR-sulfadiazine formulation is marketed for the treatment of equine protozoal myelitis in horses.

Clinical Use

It is very difficult to apply pharmacokinetic principles to determine drug dosage regimens for the potentiated sulfonamides. Different pathogens have varying MIC values, and the optimal ratio of TMP or PYM to sulfonamide also varies among bacteria and protozoa. The most important component of the formulation for efficacy appears to be the diaminopyrimidine, and the choice of sulfonamide may not be nearly as important. Therefore there is considerable controversy regarding the dosage regimen of these combinations. Most veterinary products are labeled for once-daily administration, but studies indicate that twice-daily dosing is better for attaining therapeutic plasma concentrations.[218,220] However, the newest formulation approved in the United States is a suspension labeled for dosing at 24 mg/kg PO q12hr. Pharmacokinetic data available from this product showed that this dosing strategy produced free drug concentrations that exceeded the MIC_{90} for *Streptococcus equi* subsp. *zooepidemicus* (SDZ-TMP: 4.75/0.25) for the entire 24-hour dosing interval. Despite frequent clinical use for equine streptococcal infections, even prophylactic administration failed to prevent abscessation caused by *Streptococcus equi* subsp. *zooepidemicus.*[221]

TETRACYCLINES

Tetracycline was discovered after a team of workers examined 100,000 soil samples from around the world. Tetracycline derivatives include *oxytetracycline, chlortetracycline, doxycycline,* and *minocycline.* Oxytetracycline (OTC), doxycycline (DXC), and minocycline (MNC) are used in horses.

Mechanism of Action

The tetracyclines bind to the 30S ribosomal subunit and interfere with bacterial protein synthesis. They are bacteriostatic at usual therapeutic concentrations but bactericidal at high concentrations. Drug entry into the bacteria is by an energy-dependent mechanism. Mammalian cells do not possess the tetracycline transport mechanism. Tetracyclines are most active at an acidic pH. The tetracyclines are broad-spectrum in activity; they are effective against gram-positive and gram-negative bacteria, as well as *Chlamydia, Mycoplasma,* and *Rickettsia* spp. and some protozoa (*Haemobartonella, Anaplasma* spp.). Their activity against staphylococci is limited, and they are not active against enterococci. *Pseudomonas, E. coli, Klebsiella,* and *Proteus* are usually resistant. Most anaerobes are susceptible to DXC.[18] In vitro concentrations of OTC above 0.01 μg/mL effectively suppress growth of *Neorickettsia risticii.*[223] Tetracyclines are also effective against intracellular pathogens of foals, such as *Lawsonia intracellularis* and *Rhodococcus equi.*[224] Multiple other actions have been attributed to DXC and MNC, including anticollagenolytic activity through inhibition of matrix metalloproteinases (MMPs), antiinflammatory activity, and ability to enhance corneal repair.[225,226]

Mechanisms of Resistance

Widespread acquired resistance in many pathogens limits the clinical usefulness of the tetracyclines. Resistance occurs from plasmid-mediated failure in the active transport of the drug into the bacterial cell and increased efflux from the cell. Another major mechanism of resistance involves cytoplasmic production of a protein that protects the ribosome from tetracycline action.[18]

Pharmacokinetics

Absorption

Oral absorption of OTC is erratic, and oral administration is not recommended in horses because of its adverse effects on GI flora.[219] The long-acting formulation of OTC in polyethylene glycol has a bioavailability of 83% after IM injection in horses.[227]

At an oral dose of 10 mg/kg in fed horses, DXC produced serum, synovial fluid, peritoneal fluid, and endometrial tissue concentrations above 0.25 μg/mL, suggesting effective therapy

for gram-positive infections.[228] At an oral dose of 20 mg/kg in fasted horses DXC produced mean maximum plasma concentration of 0.91 μg/mL following a single dose and 1.74 μg/mL after multiple doses using a 12-hour dosing interval.[229] A precise bioavailability cannot be determined because IV administration of DXC causes cardiac toxicity.[230] However, using allometric scaling, the estimated systemic absorption for DXC after oral administration in horses is only 2.7%.[229] Oral absorption of DXC in foals is higher, with a single oral dose of 10 mg/kg producing mean maximum plasma concentrations of 2.54 μg/mL and 4.05 μg/mL after multiple doses using a 12-hour dosing interval.[231] Steady-state mean plasma concentrations of minocycline following administration of 4 mg/kg PO q12hr were 0.67 μg/mL, and concentrations were above the MIC_{50} and MIC_{90} for many gram-positive equine pathogens (0.25 μg/mL).[232] Although it has not been studied directly, based on data from different studies, MNC oral bioavailability is approximately 23%.

Distribution

The tetracyclines are well distributed to most tissues, except the central nervous system. Therapeutic levels may be achieved, however, when the meninges are inflamed. Tetracyclines readily diffuse into milk.[18] OTC reaches 50% of plasma concentrations in synovial fluid and peritoneal fluid. Urine OTC concentrations are relatively high, with peak concentrations above 1500 μg/mL.[233] The Vd of OTC in neonatal foals is 2 L/kg[234] and 0.34 to 0.95 L/kg in adult horses.[227,235] The apparent Vd of DXC in horses after oral absorption is 25 L/kg, indicating the high lipid solubility and tissue penetration of DXC. Synovial and peritoneal fluids achieve the same DXC concentrations as plasma, and endometrial tissue concentrations are more than twice plasma concentrations. DXC is not detectable in CSF after oral administration.[228] DXC concentrates intracellularly, with mean C_{max} in polymorphonuclear cells approximately 17 times higher than concentrations found in plasma.[229] In foals peritoneal fluid, synovial fluid, and bronchoalveolar lavage cell activity of DXC were similar to plasma concentrations; however, activity in the CSF was significantly lower, and activity in pulmonary epithelial lining fluid and urine was significantly higher.[231] Minocycline has a Vd of 1.53 L/kg in adults. Synovial fluid concentrations of minocycline were approximately 74% of the corresponding trough plasma concentrations. Minocycline penetrates the CSF to a greater extent than OTC and DXC with a mean CSF concentration of 0.39 μg/mL at steady state, which was 69.5% of the corresponding plasma concentration.

Ocular penetration of systemic DXC and MNC has been studied. Vitreal drug concentrations of DXC were 0.17 μg/mL after multiple doses of 10 mg/kg.[236] Aqueous humor concentrations were approximately 0.11 μg/mL after multiple doses of 20 mg/kg, which represented 7.5% of corresponding plasma concentrations.[229] DXC was also detectable in the preocular tear film of horses without ocular disease after once-daily administration of 20 mg/kg.[225] As with the CSF, MNC penetrated into the aqueous humor of horses to a greater extent, with concentrations being 17% to 20% that of plasma concentration at steady-state.[232]

OTC is 50% protein bound in horses.[237] Plasma protein binding of DXC is high (82%), which is similar to that of other species.[229] This impairs distribution of DXC into the ECF. Plasma protein binding of MNC is 68% in horses.[238] The increased free fraction of drug may explain the better penetration into the eye and CSF of MNC compared with DXC.

Elimination

The tetracyclines are not known to be biotransformed to any significant extent before elimination. OTC is eliminated in urine unchanged primarily by glomerular filtration. Unmetabolized drug is also eliminated with bile into the GI tract and may undergo enterohepatic recirculation, prolonging its effects.[18] DXC is primarily excreted into the feces by way of nonbiliary routes in an inactive form. Therefore DXC does not accumulate in patients with renal insufficiency.[239] The clearance of OTC in foals is 3.3 mL/min/kg[234] and 2.2 mL/min/kg in adult horses.[227] When administered intravenously, the elimination half-life is 7 hours in foals[234] and 6 hours in horses.[227] Because of flip-flop kinetics, the elimination half-life is 22 hours after IM administration of OTC in polyethylene glycol.[227] DXC clearance cannot be accurately determined from oral dosing.[229] The half-life of MNC in adult horses is 8 to 11 hours, and the plasma clearance is 2.7 mL/kg/min.[232,238]

Adverse Effects and Drug Interactions

GI Effects and Interactions

Calcium-containing products (e.g., milk, antacids) or other divalent cations will chelate with tetracyclines and interfere with GI absorption.[18] Because DXC is less likely than the older tetracyclines to form chelation complexes with divalent and trivalent metals, there is less interference with oral absorption by calcium or other substances.[239]

The clinical use of OTC in horses is controversial because of reports of adverse GI effects. However, adverse effects were also associated with excessive dosage,[240] concomitant use of other antimicrobials, and stressors such as surgery and transport.[241-244] Anecdotally, OTC therapy has been used successfully in equine practice, and recognition of the equine rickettsial diseases has increased OTC use in horses.[245-247] In a chronic dosing study using a long-acting formulation of OTC, no deleterious effects on fecal flora were detected, and treated horses remained clinically normal.[248] DXC is less likely to cause adverse GI effects because it is bound in an inactive form in the intestines; however, at higher doses the risk of adverse effects may be increased. One study reported that doses of 20 mg/kg orally twice daily produced signs of abdominal discomfort in one horse and a severe enterocolitis in another. The other four horses in that study were unaffected.[229] DXC administered to foals at 10 mg/kg orally twice daily for 8 to 17 days for treatment of *Lawsonia intracellularis* infection did not produce any adverse effects.[224] No adverse GI effects of minocycline have been reported, although clinical use has been limited compared with other drugs in this class.

Renal Effects

Renal tubular necrosis caused by OTC is associated with high doses, outdated parenteral products, endotoxemia, dehydration and hypovolemia, and concurrent pigment nephropathy.[18,249] In normal foals single high-dose IV OTC administration for the correction of flexural deformities does not cause renal toxicity.[250] Multiple doses administered at dosing intervals less than every 48 hours may increase the risk of nephrotoxicity in foals. Oliguric renal failure developed in a foal that had concurrent neonatal isoerythrolysis given 70 mg/kg of IV OTC for a flexural deformity.[249]

Cardiovascular Effects

Rapid IV administration of OTC results in hypotension and collapse. This is attributed to intravascular chelation of calcium, decreased blood pressure from the drug vehicle (propylene glycol), or both. Pretreatment with IV calcium borogluconate prevents collapse.[251,252] Both rapid IV bolus and slow constant rate infusion of DXC to horses causes tachycardia, arrhythmias, systemic arterial hypertension, collapse, and death.[230,253] It is suggested that this reaction is due to chelation of intracellular calcium, resulting in neuromuscular blockade of the myocardium. Plasma total and ionized calcium concentrations are not affected by IV DXC administration.

Musculoskeletal Effects

Intramuscular injection of long-acting OTC formulations causes localized pain and swelling at the injection site.[18,248] OTC causes flexor tendon relaxation; this effect has been used to treat foals with flexural deformities.[254,255] OTC induces a dose-dependent inhibition of collagen gel contraction by equine myofibroblasts. Inhibition of normal collagen organization may provide the mechanistic explanation for the results seen after the pharmacologic treatment of flexural deformities by OTC administration.[256] Because of the neuromuscular blocking effects, tetracyclines are not recommended for the treatment of diseases affecting the neuromuscular junction, such as botulism.

Doxycycline and Rifampin Combination Therapy

Doxycycline is a possible treatment for foals that develop macrolide-resistant *R. equi* infections. However, a study examining the use of DXC combined with rifampin in foals with naturally occurring clinical disease noted that some foals developed hemolytic anemia and icterus or increased liver enzymes 17 to 20 days after initiating the treatment. The cause of these reactions is unknown, and similar clinical findings have not been seen in foals treated with doxycycline alone or with rifampin combined with macrolides.[257] At this time, this combination should only be used with caution and not as a first-line treatment for *R. equi*.

Formulations

Injectable OTC products are formulated as short- or long-acting products. The short-acting solutions are in propylene glycol and have concentrations of 50 or 100 mg/mL. The long-acting solutions are in 2-pyrrolidone or polyethylene glycol and have a concentration of 200 mg/mL. The polyethylene glycol formulation is less irritating than the 2-pyrrolidone formulation. The long-acting formulations may be administered by slow IV injection, but the long-acting effect is lost.[210] DXC and MNC tablets are available in multiple generic and proprietary formulations.

Clinical Use

OTC is the drug of choice for treatment of Potomac horse fever *(Neorickettsia risticii)* and equine anaplasmosis *(Anaplasma phagocytophilum)*. It is also used to treat contracted flexor tendons in foals. Its use for other microbial infections in horses is controversial because of concerns related to adverse GI effects and widespread antimicrobial resistance. DXC and MNC are also indicated for rickettsial diseases in horses and may be a suitable oral alternative to OTC. Tetracyclines are commonly used for treatment of proliferative enteropathy caused by *Lawsonia intracellularis*. DXC is also used for the treatment of keratomalacic diseases in horses because it may decrease corneal proteinases such as MMP-2 and MMP-9.[225]

MACROLIDES AND AZALIDES

The macrolide antibiotics include erythromycin, clarithromycin, tylosin, tilmicosin, and tiamulin. Azalides, such as azithromycin and gamithromycin, have a similar mechanism of action but have a methylated nitrogen in the macrocyclic ring. Triamilides, such as tulathromycin, are semisynthetic macrolides prepared by fermentation followed by organic synthesis. Because of their adverse GI effects, these drugs are typically contraindicated in adult horses; however, erythromycin, clarithromycin, and azithromycin are commonly used in foals.

Mechanism of Action

The macrolides and their derivatives bind to the 50S ribosomal subunit in a manner similar to that of CHPC, and they interfere with protein synthesis. They are usually considered bacteriostatic but may be bactericidal at high concentrations. Macrolides are not effective against gram-negative bacteria, except some strains of *Pasteurella* and *Haemophilus.*[18] Azithromycin is more active than the macrolides against gram-negative bacteria and anaerobes.[223,258] Susceptible bacteria include staphylococci, streptococci, *Campylobacter jejuni, Clostridium* spp., *Rhodococcus equi, Lawsonia intracellularis, Mycoplasma* spp., and *Chlamydia* spp.[259]Antimicrobial activity of these weak bases is optimum at an alkaline pH; therefore they have reduced activity in acidic environments (e.g., pus, abscesses) but may be clinically effective because of high concentrations due to ion trapping. Erythromycin has nonantimicrobial effects on host cell metabolism, inflammatory mediators, and GI motility.[260,261]

Mechanisms of Resistance

The routine use of the macrolides is limited because bacterial resistance develops quickly after repeated exposure.[262] Mechanisms of resistance include decreased drug entry into bacteria, inability to bind to the bacterial 50S ribosomal subunit, and plasmid-mediated production of esterases.[18] Resistance to erythromycin has been reported in 3.9% of *R. equi* isolates.[263] Extensive cross-resistance occurs among the macrolides.[18]

Pharmacokinetics

Absorption

Erythromycin is available for oral administration as enteric-coated erythromycin base, erythromycin esters (ethylsuccinate or estolate), and erythromycin salts (phosphate or stearate). Because of expense, many practitioners administer the drug as crushed enteric-coated tablets of erythromycin base. However, erythromycin base is degraded in the stomach by gastric acid. The esterified formulations are absorbed intact and must be hydrolyzed to the active erythromycin A. The erythromycin salts are absorbed unchanged.[260] The oral bioavailability of erythromycin base is 17% in fasted foals, with most of the drug being degraded and absorbed as the microbiologically inactive anhydroerythromycin A.[264] Microencapsulation of the base improves the oral bioavailability of erythromycin base to 26% in fasted foals, but it remains only 7.7% in fed foals.[265] The oral bioavailability of erythromycin estolate in fasted foals is

36% but only 16% for erythromycin phosphate.[266] The estolate formulation appears to have the best pharmacokinetic profile in foals. Because of injection site irritation, IM administration of erythromycin is not recommended in horses. The reported oral bioavailability of azithromycin in foals ranges between 39% and 56%.[267,268] The oral bioavailability of clarithromycin in foals is similar (57%).[269] Telithromycin, an oral ketolide antibiotic used for treatment of macrolide-resistant *R. equi* in humans, has also been studied in foals. Bioavailability has not been determined; however, although absorption was adequate for treatment of susceptible *R. equi* isolates, it was not high enough for treatment of most macrolide-resistant *R. equi* isolates in foals.[270] The bioavailability of tulathromycin has not been determined; however, after IM administration the drug is rapidly detected in the plasma of foals, with maximum concentrations of 0.41 μg/mL 4 hours after administration.[271] Gamithromycin has maximum concentrations of 0.33 μg/mL 1 hour after IM administration in foals.[272]

Distribution

The macrolides concentrate in leukocytes, making them very effective against intracellular pathogens such as *R. equi*.[273] Concentrations of azithromycin and clarithromycin in bronchoalveolar lavage cells were significantly higher than erythromycin, and azithromycin had a significantly longer elimination half-life from the cells.[274] Bronchoalveolar cell and pulmonary epithelial lining fluid concentrations of azithromycin are 15- to 170-fold and 1- to 16-fold higher than concurrent serum concentrations, respectively, and did not decrease for up to 48 hours after administration.[267] Clarithromycin concentrations in bronchoalveolar cell and pulmonary epithelial lining fluid are 91- to 105-fold and 324- to 585-fold higher than concurrent serum concentrations, respectively; however, in contrast to azithromycin, clarithromycin concentrations significantly decreased within 12 hours of administration.[269] Tulathromycin concentrates in bronchoalveolar cells, and concentrations are detectable for at least 8 days after a single administration, although they are still lower than the MIC for *R. equi* (greater than 64 μg/mL).[271] The relative distribution of macrolide antibiotics into bronchoalveolar cell and pulmonary epithelial lining fluid has been reviewed in depth.[275]

Because they are weak bases, macrolides are ion trapped in milk, CSF, and gastric fluids. The Vd for erythromycin is 2.7 L/kg in foals.[264] Azithromycin is known for its high degree of lipid solubility, and the Vd of azithromycin in foals is 11.6 to 18.6 L/kg.[267,268] Clarithromycin also exhibits a large volume of distribution, with reported values of 10.4 L/kg.[269] Peritoneal and synovial fluid concentrations of azithromycin and clarithromycin parallel serum concentrations.[269] The apparent Vd for tulathromycin after IM administration is 15.2 L/kg.[271]

Elimination

Erythromycin is extensively metabolized, with much of the parent drug and active metabolite excreted into the bile, resulting in an elimination half-life of 1 to 2 hours.[264-266,276] Erythromycin inhibits the metabolism of a number of other drugs by interfering with cytochrome P450 enzymes.[18] In addition, the degradation product anhydroerythromycin A is a potent inhibitor of cytochrome P450–mediated metabolism.[277] Erythromycin undergoes enterohepatic cycling.[18] Azithromycin is not highly metabolized and is primarily eliminated in bile. The elimination half-life is 16 to 20.3 hours in foals.[267,268] Clarithromycin is extensively metabolized in humans, and the active metabolite, 14-hydroxy-clarithromycin, is produced in foals, although the pharmacokinetics have not been quantitated.[269] The elimination half-life of clarithromycin in foals is intermediate between erythromycin and azithromycin at 5.4 hours.[269] Tulathromycin has the longest elimination half-life, reported at 117 hours in foals.[271] Gamithromycin also has an extended elimination phase, with a half-life of 39.1 hours.[272]

Adverse Effects and Drug Interactions

The use of erythromycin in horses is associated with a number of adverse effects. Since erythromycin came into clinical use in the 1950s, it was apparent that therapy was frequently accompanied by adverse GI effects. Macrolide antibiotics, including erythromycin and clarithromycin, are motilin receptor agonists. They also appear to stimulate motility via cholinergic and noncholinergic neuronal pathways. At microbially ineffective doses they stimulate migrating motility complexes and antegrade peristalsis in the GI tract.[261,276,278,279] When used at antimicrobial doses, erythromycin is associated with potentially fatal colitis from *Clostridium* spp.[280-282]

Erythromycin is associated with acute respiratory distress syndrome, gastroenteritis, and hepatotoxicity in foals.[277,283,284] Erythromycin also interferes with host cell metabolism and decreases inflammatory responses in airways, but the clinical significance of this has not been determined.[277]

Hyperthermia following administration of macrolides is most associated with erythromycin, although it also associated with azithromycin and clarithromycin to a lesser degree. The mechanism of macrolide-induced hyperthermia has been shown to be drug-induced anhidrosis, as evidenced by significantly reduced sweating in response to an intradermal sweat tested in treated versus placebo control foals.[285] Anhidrosis begins shortly after initiation of treatment, partially recovers during treatment, and can take at least 10 days after stopping treatment to fully recover. To minimize the risks of macrolide-induced hyperthermia, it is recommended to decrease access to direct sunlight, provide ample shade, avoid turnout during the hottest parts of the day, and provide access to clean, fresh water at all times. Erythromycin is commonly administered in conjunction with rifampin to take advantage of antimicrobial synergism and reduce the chance of resistance development.[28] Erythromycin may interact with other drugs metabolized by the same cytochrome P450 enzyme system. Concurrent administration of erythromycin with theophylline results in a doubling of plasma theophylline concentrations and can result in seizures in foals.[18]

Clarithromycin is also frequently administered in combination with rifampin due to synergistic effects against *R. equi*.[286] However, coadministration of rifampin reduces clarithromycin bioavailability by as much as 90%, resulting in plasma concentrations of clarithromycin that are below the MIC_{90} of *R. equi*.[287] Bronchoalveolar lavage cell and pulmonary epithelial lining fluid concentrations were also decreased, but they remained above therapeutic concentrations. The exact cause of the decrease is unknown. It does not appear to be due to induction of hepatic metabolism by rifampin, as the pharmacokinetics of clarithromycin and its metabolite remain unchanged. It is speculated that the decreased bioavailability is secondary to changes in oral absorption, likely through inhibition of an unknown intestinal uptake transporter.[288] Concentrations of tulathromycin in the lung of foals was also significantly lowered by comedication with rifampin. Because tulathromycin

is only administered via the IM route, the mechanism of this interaction also remains unknown.[289]

Azithromycin is associated with fewer adverse effects than erythromycin in human beings. No adverse reactions were detected during or after repeated intragastric administration of azithromycin or clarithromycin in foals.[273,275] A multiple-dose study of oral azithromycin in adults (10 mg/kg PO q24hr for 5 days) showed mild decreases in appetite and alterations in fecal consistency in some horses.[290] There are anecdotal reports of antimicrobial-associated colitis in older weanlings, particularly those treated with compounded formulations of azithromycin.

In a study that evaluated the use of tulathromycin in foals with evidence of pulmonary abscessation, self-limiting diarrhea, fever, and injection site reactions were the only adverse effects noted. In one foal in that study, the injection site reaction was severe and resulted in temporary lameness and severe swelling.[288] Injection site reactions and colic have been reported following IM gamithromycin administration and may limit the use of this antibiotic in foals.[291]

Formulations

Because the base of erythromycin is unstable in gastric acid, it is formulated as enteric-coated erythromycin tablets. Erythromycin stearate and erythromycin phosphate are insoluble salt formulations that disassociate in the intestine, allowing absorption of the free erythromycin base. Erythromycin ethylsuccinate and erythromycin estolate are ester formulations that are absorbed intact from the intestine, and then plasma esterases release active drug. Erythromycin is available in an IM formulation approved for cattle. Because of its highly irritating nature, this formulation is not recommended for IM use in horses, and it can be fatal if injected intravenously. A human-labeled formulation of erythromycin lactobionate is available for IV use. Tablet formulations are available for azithromycin in 250-, 500-, and 600-mg strengths. Clarithromycin is available as an immediate and extended release tablet. The extended release formulations have not been studied in horses. Tulathromycin is available as a 100-mg/mL injectable solution for cattle and swine. Gamithromycin is available as a 150-mg/mL injectable solution for cattle.

Clinical Use

On account of its association with potentially fatal adverse effects, erythromycin is usually limited to treatment of *R. equi* infections in foals. It also has been shown to be an effective therapy for Potomac horse fever[292] and equine proliferative enteropathy caused by *Lawsonia intracellularis.*[293] Its motilin-like activity is exploited for use as a treatment for adynamic ileus in horses.[261] Azithromycin has become an attractive alternative to erythromycin for the treatment of *R. equi* infections in foals because of its pharmacokinetic profile, which allows once-daily or every-other-day dosing and an apparent reduced incidence of adverse effects.[294] However, in a retrospective study of 81 foals treated for naturally occurring *R. equi* infection, the combination of clarithromycin (10 mg/kg q24hr) and rifampin was shown to be superior to combinations of azithromycin (7.5 mg/kg q12hr) and rifampin and erythromycin (25 mg/kg q6hr, 25 mg/kg q8hr, or 37.5 mg/kg q12hr) and rifampin.[273] Given the drug interactions noted between clarithromycin and rifampin, further work is needed to determine whether monotherapy with clarithromycin alone would be as effective as or more effective than combination therapy. Azithromycin alone has been shown to be as effective as azithromycin and rifampin combined.[295] Tulathromycin is not recommended for treatment of *R. equi* in foals, due to the high MICs (greater than 64 μg/mL). Gamithromycin offers more promise for treatment of *R. equi.* A once-weekly IM dosing regimen (6 mg/kg) may provide a more affordable treatment alternative, although adverse reactions may limit the use of this drug in horses.

Although most frequently used for *R. equi* pneumonia, the macrolide anitbiotics are also effective against *Lawsonia intracellularis,* although the risk of adverse GI effects in weanling age foals limits their use and tetracyclines have replaced them in most cases. Some drugs in this class, including azithromycin and gamithromycin, have good activity against streptococci and may be useful for treatment of abscesses caused by *Streptococcus* spp. in foals.

FLUOROQUINOLONES

The quinolones are a group of synthetic antimicrobials. The first was *nalidixic acid,* which was introduced in 1964. It had good activity against gram-negative bacteria but had a low Vd and numerous adverse effects and was limited to treatment of urinary tract infections. Further chemical manipulation resulted in development of the fluorinated quinolones, which had extended antimicrobial activity with improved safety. Included in this group are ciprofloxacin, enrofloxacin, danofloxacin, difloxacin, orbifloxacin, marbofloxacin, fleroxacin, moxifloxacin, and levofloxacin. No fluoroquinolones are approved for use in horses, but because of their pharmacokinetics and antimicrobial activity, they are commonly used for serious gram-negative infections.

Mechanism of Action

The fluoroquinolones have a unique mechanism of action for bacterial killing. The fluoroquinolones inhibit bacterial deoxyribonucleic acid (DNA) gyrase (also known as *topisomerase II*). Bacteria have a single chromosome consisting of double-stranded DNA. Within the bacterial cell the chromosome is folded around an RNA core, and each fold is supercoiled. DNA gyrase, which has been found in every organism examined, is responsible for supercoiling the strand of bacterial DNA. The DNA gyrase structure has four subunits: two A monomers and two B monomers. The enzyme forms a heart-shaped molecule, with the A monomers forming the atria and the B monomers forming the ventricles. The bacterial DNA binds to the gyrase in the cleft between the A and B subunits. The DNA gyrase nicks double-stranded DNA, introduces negative supercoils, and seals the nicked DNA. The fluoroquinolones bind to the DNA-DNA gyrase complex and inhibit the DNA resealing, resulting in abnormal spatial DNA configuration, which leads to DNA degradation by exonucleases.[296]

Fluoroquinolone activity is concentration dependent, and clinical efficacy is most associated with achieving either an AUC_{0-24}:MIC greater than 125 or a C_{max}:MIC greater than 10. These PK/PD relationships are related, insofar as increasing the dose to increase the peak plasma concentration will also increase the *AUC* value.[18]

All of the fluoroquinolones are bactericidal, although these drugs have an optimum concentration for bacterial killing. Higher or lower drug concentrations result in reduced bactericidal activity. It is thought that the DNA-DNA gyrase complex has two binding sites for fluoroquinolones. At low

drug concentrations only one binding site is occupied, resulting in single-stranded nicks in the DNA. Reduced killing at high concentrations is thought to be due to dose-dependent inhibition of RNA or protein synthesis. RNA and protein synthesis are required for production of bacterial autolysins, which are responsible for the fluoroquinolone-induced cell lysis.[18,296]

The fluoroquinolones are broad spectrum in activity, with activity against most gram-negative bacteria; some gram-positive bacteria; and *Mycoplasma, Chlamydia,* and *Rickettsia* spp. They are particularly effective against the enteric gram-negative pathogens, including some strains resistant to aminoglycosides and cephalosporins. Reported MICs are very low, and MBCs are 1 to 2 times the MIC for most pathogens. They are usually active against staphylococci but have variable activity against streptococci and are not effective against enterococci. Most diagnostic laboratories use ciprofloxacin or enrofloxacin to determine pathogen susceptibility; however, MIC values vary among the fluoroquinolones. Ciprofloxacin has the greatest activity against *Pseudomonas* spp. Orbifloxacin has lower MIC values than enrofloxacin for the gram-negative bacteria *Actinobacillus equuli, E. coli, Pasteurella* spp., and *Salmonella* spp. Enrofloxacin has lower MIC values for the gram-positive bacteria and *Pseudomonas* spp.[18] Even with in vitro evidence of susceptibility, however, enrofloxacin is not a good choice for *Pseudomonas* spp. as resistance develops rapidly.

Most fluoroquinolones are not active against anaerobic bacteria.[297] This susceptibility pattern may be a therapeutic advantage in the treatment of enteric infections in horses, because GI anaerobes rarely cause disease and usually are protective by competitively inhibiting colonization by pathogenic aerobic organisms.

The fluoroquinolones concentrate within phagocytic cells. Uptake occurs by simple diffusion, and intracellular concentrations may be several times greater than plasma concentrations. Intracellular drug is microbiologically active against intracellular pathogens such as *Brucella* spp., *Mycoplasma* spp., and *Mycobacterium* spp.[18] Exposure of gram-negative bacteria to fluoroquinolones at concentrations several times the MIC for 1 to 2 hours results in a PAE with a recovery period of 1 to 6 hours. This effect suggests that fluoroquinolone dosage regimens can tolerate plasma concentrations below the pathogen's MIC for extended periods of time without a reduction in efficacy.[298]

Mechanisms of Resistance

Microbial resistance to the fluoroquinolones is primarily due to chromosomal mutations that alter bacterial DNA gyrase, decrease cell wall permeability, or increase fluoroquinolone efflux from the cell. Plasmid-mediated resistance has only recently been documented for the fluoroquinolones. Fluoroquinolone-resistance plasmids can be transmitted horizontally and provide low-level resistance that facilitates the emergence of higher level resistance at therapeutic levels.[299] The fluoroquinolones must penetrate bacteria to reach the target DNA gyrase. They do so by diffusing through porin channels in the outer membrane of gram-negative bacteria. *Pseudomonas* spp. resistance is associated with alterations in a wide range of outer-membrane proteins. From these mutations the increase in the MICs of the fluoroquinolones is relatively low (2- to 32-fold). However, there is cross-resistance with unrelated antibiotics, most frequently TMP, tetracycline, CHPC, and cefoxitin.[300]

Since the fluoroquinolones have been used intensively in human medicine in the past 3 decades, high-level resistance has emerged in some pathogens. Chronic fluoroquinolone use encourages the development of chromosomally mediated resistance. In high-level resistant bacterial strains, one resistance mechanism alone is usually not responsible; rather, two or three mechanisms of resistance operate in conjunction. In resistant *S. pneumoniae* increased efflux is often coupled with a gyrase mutation.[301] In resistant *E. coli* gyrase mutations are usually associated with changes in the outer membrane proteins.[302]

Pharmacokinetics

Absorption

The fluoroquinolones are rapidly and well absorbed from the GI tract of monogastrics and preruminant calves. Enrofloxacin is more lipid soluble than ciprofloxacin and has a higher oral bioavailability than ciprofloxacin in horses and small animals. The oral bioavailability of ciprofloxacin is only 6.8% to 10.5% in adult horses and ponies.[303,304] The oral bioavailability of enrofloxacin is approximately 60% in adult horses and 42% in foals.[305-307] The moderate oral absorption of enrofloxacin has been determined to be due to hepatic first pass effect.[308] Oral absorption of enrofloxacin is not affected by feeding.[309] Antacids containing divalent cations (calcium, magnesium) chelate fluoroquinolones and reduce oral bioavailability.[18] Oral bioavailability of marbofloxacin and orbifloxacin is 62% and 68%, respectively.[308,310] Administration of the injectable formulation of danofloxacin intragastrically to horses had a bioavailability of only 35.8%.[311] Bioavailability from IM injection is nearly 100% for all fluoroquinolones, but IM injections of enrofloxacin are irritating to tissues.[312] For economic reasons and client convenience, practitioners have attempted to administer the bovine injectable solution of enrofloxacin orally to horses. This results in a bioavailability of approximately 65% in horses when administered intragastrically.[313] Unfortunately, the injectable formulation is highly irritating to the oral mucosa and may cause ulceration with repeated use. A methylcellulose gel formulation compounded from the injectible liquid has better oral absorption but may also cause oral ulceration.[314]

Distribution

The fluoroquinolones are generally lipid soluble and well distributed to most tissues. The Vd of the fluoroquinolones studied in horses ranges from 1.2 L/kg for marbofloxacin[315] to 4.9 L/kg for ciprofloxacin.[304] Tissue concentrations typically exceed plasma concentrations during therapy. Extremely high concentrations are achieved in the kidney, urine, liver, and bile. Therapeutic concentrations for gram-negative bacteria may be achieved in cerebrospinal and ocular fluids.[303,306,316,317] Aqueous humor concentrations of enrofloxacin after IV administration of 3 daily doses of 7.5 mg/kg were 0.32 μg/mL.[318] Plasma protein binding of fluoroquinolones is low to moderate in most species. Protein binding data are available for ciprofloxacin, enrofloxacin, orbifloxacin, and levofloxacon in the horse. Binding is similar across drugs and ranges between 21% and 28%.[310,319]

Elimination

The fluoroquinolones are predominantly excreted in the urine by glomerular filtration and active tubular secretion.[18] For marbofloxacin approximately 40% is excreted unchanged in

the urine, whereas with enrofloxacin only 3.4% is excreted unchanged in the urine.[308] Ciprofloxacin undergoes some sulfoxidation, and its metabolites also have antimicrobial activity. Enrofloxacin is metabolized (de-ethylated) to ciprofloxacin in horses and donkeys,[320] with serum ciprofloxacin concentrations reaching 20% to 35% of enrofloxacin concentrations.[312] Metabolism of enrofloxacin to ciprofloxacin is negligible in foals, and ciprofloxacin was not detected in the plasma of foals in which IV or oral enrofloxacin was administered.[305] The elimination half-life of ciprofloxacin in ponies is 2.5 hours and 5 hours in horses.[303] Enrofloxacin has an elimination half-life of 4.4 hours after IV administration and 10 hours after IM administration, indicating flip-flop kinetics.[312] With oral administration the elimination half-life of enrofloxacin is 8 hours.[317] The elimination half-lives of danofloxacin, orbifloxacin, and marbofloxacin are 8, 5.1, and 4.14 hours, respectively.

Adverse Effects and Drug Interactions

Toxicity of fluoroquinolones is mild in most species, and GI irritation is the most common side effect.[18] Both ciprofloxacin and moxifloxacin have been associated with GI effects in horses.[304,321] These effects with ciprofloxacin ranged from mild transient diarrhea to severe colitis, endotoxemia, and laminitis necessitating euthanasia of three horses on humane grounds. Adverse effects were seen regardless of the route of administration and the high incidence of adverse events precludes oral and rapid IV bolus administration of ciprofloxacin.

The effect of most clinical concern with most fluoroquinolones is cartilage damage with subsequent arthropathy. Arthropathies have been reported in humans, dogs, and foals, but not calves, swine, or poultry.[322-325] The risk of arthropathy is age dependent, with younger animals being at higher risk. Weight bearing and exercise are also associated with increased severity of disease. Arthropathies have been documented in 2-week-old foals after receiving 10 mg/kg of enrofloxacin orally.[325] Damage was characterized by synovial joint effusion and lameness and erosion and cleft formation in articular cartilage. Arthropathies were not seen in adult horses that were given up to 25 mg/kg of IV enrofloxacin daily for 3 weeks or 15 mg/kg orally every 12 hours for 3 weeks.[316,326] Although they are not recommended for use in pregnant humans or animals, the fluoroquinolones appear to have little effect on the developing fetus.[327] Enrofloxacin was successfully used to treat chronic pleuritis in a pregnant mare with no apparent detrimental effects on the foal.[328]

Ciprofloxacin and enrofloxacin interfere with the cytochrome P450 system metabolism of methylxanthines such as theophylline. Serum theophylline concentrations may double and result in central nervous system and cardiac toxicity, so concentrations must be monitored during therapy.[329] Coadministration of nonsteroidal antiinflammatory drugs and enrofloxacin may influence the pharmacokinetics of either drug depending on the species studied and the specific drugs administered. Coadministration of firocoxib and enrofloxacin did not influence firocoxib concentrations in the horse.[330]

The fluoroquinolones may cause adverse central nervous system effects in humans and animals as a result of a γ-aminobutyric acid (GABA) receptor antagonism. This has been associated with an increase in the incidence of seizures in human beings and dogs. Administration of enrofloxacin to human beings results in hallucinations.[18] Rapid IV administration of high doses of enrofloxacin to horses causes transient neurologic signs, including excitability and seizure-like activity.[326] This can be prevented by slow injection or dilution of the dose. Dilution of the dose should be performed in sterile saline solution, because the cations found in other fluids, such as lactated Ringer's solution, may chelate and inactivate the drug. Photosensitivity reactions and Achilles tendon rupture have been associated with fluoroquinolone use in humans but have not been reported in animals.[296]

The fluoroquinolones have been used in combination with other antimicrobial agents to expand the therapeutic spectrum, suppress emergence of drug-resistant bacterial populations, or exploit inhibitory or bactericidal synergism against drug-resistant populations. Minimal synergy occurs between fluoroquinolones and β-lactams or aminoglycosides against gram-negative enteric bacteria because of the already high susceptibility of these organisms. Combinations with aminoglycosides, β-lactams, or vancomycin are additive or indifferent against staphylococci. Antagonism between fluoroquinolones and CHPC or rifampin appears to be due to the inhibition of bacterial autolysin synthesis from concurrent administration of bacterial protein synthesis inhibitors.[18]

Formulations

Ciprofloxacin is available as human-labeled tablets, a diluted solution for IV administration, and a solution for ophthalmic use. Enrofloxacin is available as oral tablets and a 50-mg/mL injectable solution for IM injection in dogs and as a 100-mg/mL injectable solution for the SC treatment of cattle. Both injectable solutions can be administered intravenously to horses. Orbifloxacin and marbofloxacin are available as oral tablets for small animals. Danofloxacin is available as a 180-mg/mL injectable formulation for cattle.

Clinical Use

The use of fluoroquinolones in horses has been limited because of the risk of arthropathies; however, enrofloxacin has been successfully used in clinical cases, and fluoroquinolones may be the only viable option for treating some infections.[328,331-333] Informed consent from the client should always be obtained before using fluoroquinolones in young horses. Because the fluoroquinolones are concentration-dependent killers with a long PAE, the ideal dosage regimen is once-daily high-dose therapy. Enrofloxacin is commonly administered at doses of 7.5 to 10 mg/kg orally or intravenously, once daily.

RIFAMPIN

Mechanism of Action

The rifamycins are antibiotics produced from *Streptomyces mediterranei.* Rifampin inhibits DNA-dependent RNA polymerase in susceptible organisms, suppressing RNA synthesis. It has no effect on the mammalian enzyme. Its action is bacteriostatic or bactericidal, depending on the susceptibility of the bacteria and the concentration of the drug. Rifampin is effective against a variety of mycobacterium species and *S. aureus, Haemophilus,* and *R. equi.* Rifampin is considered especially active in the treatment of staphylococcal and rhodococcal infections and in the eradication of pathogens located in difficult-to-reach target areas, such as inside phagocytic cells. It is active at an acid pH, making it a rational choice for the treatment of septic foci and granulomatous infections. It has moderate activity against *Actinobacillus suis, Actinobacillus equuli, Bordetella bronchiseptica,*

and *Pasteurella* spp. Equine isolates of *P. aeruginosa, E. coli, Enterobacter cloacae, Klebsiella pneumoniae, Proteus* spp., and *Salmonella* spp. are resistant. The ability of rifampin to reach intracellular bacteria can make it difficult to predict in vivo therapy results on the basis of in vitro sensitivity tests.[334] Because bacterial resistance to rifampin develops rapidly, it is usually administered with another antimicrobial.[335] Although it is commonly combined with erythromycin for the treatment of *R. equi,*[28] resistance to the combination has been reported.[262,336] Rifampin is also commonly administered with newer macrolide and macrolide derivative drugs, such as clarithromycin and azithromycin.[273]

Pharmacokinetics

Absorption

The oral bioavailability of rifampin varies from 70% in fasted horses to 26% when administered with feed.[48,334,337] Because rifampin is usually administered with feed, recommended dosages compensate for the decreased bioavailability. Bioavailability after IM injection is 60%.[338] In foals, maximum plasma concentrations reach approximately 18 µg/mL at approximately 3.5 hours.

Distribution

Rifampin is highly lipophilic and penetrates most tissues, as well as milk, bone, abscesses, and the central nervous system. The Vd of rifampin in horses is 0.6 to 0.9 L/kg.[337,338] Rifampin is 78% bound to plasma proteins.[337]

Elimination

In other species rifampin is deacetylated in the liver to a metabolite that also has antibacterial activity. Desacetylrifampin was not detected in equine serum samples after an IV dose of 10 mg/kg or oral doses of 10 mg/kg every 12 hours for seven doses.[337] Desacetylrifampin was measured in urine, but rifampin was much more predominant. However, only 6.82% of the total dose was recovered in the urine as either rifampin or desacetylrifampin. In foals, metabolite concentrations were no higher than 0.1 µg/mL in plasma following a single oral dose. The elimination half-life of rifampin is 6 to 8 hours after IV administration and 12 to 14 hours after oral administration.[334,337] Because of immature hepatic metabolism, elimination of rifampin is delayed in very young foals.[339,340] Plasma clearance ranges between 1.14 and 1.34 mL/min/kg.[337,338] As a hepatic enzyme inducer, rifampin induces its own metabolism so that multiple oral dosing significantly decreases the elimination half-life. Enzyme induction is typically not seen with fewer than 5 days of therapy, but once it occurs, the increase in enzyme activity may last for more than 2 weeks after discontinuation of treatment.[341]

Adverse Effects and Drug Interactions

Rifampin stains everything it touches red, and treated animals may produce red urine, tears, sweat, and saliva. There are no harmful consequences from this effect. Most horses object to the taste of rifampin, so care must be taken to deposit a dose quite far back on the tongue and rinse the horse's mouth afterward. Combination therapy of rifampin and doxycycline in foals with *R. equi* pneumonia resulted in adverse effects severe enough to warrant stopping treatment, including icterus and elevated liver enzymes.

Microsomal enzyme induction from rifampin may shorten the elimination half-life and decrease plasma drug concentrations of CHPC, corticosteroids, theophylline, itraconazole, ketoconazole, warfarin, and barbiturates.[342] Rifampin has a significant effect on clarithromycin bioavailability, decreasing clarithromycin plasma concentrations by 70% to 90%.[288]

Formulations

Rifampin is available as human-labeled capsules or suspension for oral administration or as a diluted solution for IV use.

Clinical Use

Rifampin is primarily used in the treatment of pulmonary abscess caused by *R. equi* and *L. intracellularis* proliferative enteropathy in foals in combination with a macrolide or a macrolide derivative.

METRONIDAZOLE

Mechanism of Action

Metronidazole is rapidly taken up by bacteria, where it is metabolized by a reduction process to cytotoxic derivatives (short-lived free radical compounds). These cytotoxic compounds damage DNA and other critical intracellular macromolecules. Aerobic bacteria lack the reductive pathway necessary to produce the radical compounds.[343] Metronidazole is highly effective against anaerobic bacteria, including *Bacteroides fragilis* (penicillin resistant), *Fusobacterium,* and *Clostridium* spp. Metronidazole-resistant *C. difficile* may cause diarrhea in foals.[344] Metronidazole has good activity against protozoa, including *Giardia* and *Trichomonas* spp.[345] Metronidazole has antiinflammatory effects in human beings, particularly in the GI tract, and has been used for the treatment of chronic inflammatory bowel diseases.[346]

Pharmacokinetics

Absorption

Metronidazole is rapidly and well absorbed after oral administration in horses, with an oral bioavailability of 75% to 85%.[345,347] In horses with GI ileus, metronidazole may be administered rectally and is rapidly absorbed; however, the bioavailability is only 30%.[348] Bioavailability in foals 1 to 2.5 days of age is 100%.[349]

Distribution

Metronidazole is lipophilic and widely distributed in tissues. It penetrates bone, abscesses, and the central nervous system. The Vd in mares is 0.7 to 1.7 L/kg.[345,347] In foals less than 2 weeks of age, the Vd is 0.87 L/kg.

Elimination

Metronidazole is primarily metabolized in the liver. Both metabolites and unchanged drug are eliminated in urine and feces. Plasma clearance is 2.8 mL/min/kg, and elimination half-life is 3 to 4 hours in horses.[345,347,348,350] Age-related differences in clearance have been noted in foals within the neonatal period.[349] At 1 to 2.5 days of age, clearance is 0.84 mL/min/kg and increases to 1.14 mL/min/kg in foals 10 to 12 days of age. This results in a significantly longer half-life in very young foals, with values of 11.8 and 9.1 hours for foals 1 to 2.5 and 10 to 12 days old, respectively.

Adverse Effects and Drug Interactions

With clinical use in horses, anorexia and salivation are the only adverse effects associated with the oral use of metronidazole.[351] Histopathologic evidence of peripheral neuropathy and hepatopathy have been seen in horses administered high doses for prolonged periods of time (30 mg/kg PO q12hr for 30 days). Metronidazole produces mutations in bacteria, and carcinogenicity occurs in laboratory mice with prolonged exposure. Therefore metronidazole is banned from use in food animals. Because it has been implicated as a teratogen in laboratory animals, use in pregnant animals is not recommended.[18] In neonatal foals, central nervous system excitement can be seen with high or frequent dosing. If seen, dosing should be stopped immediately. This appears to occur more commonly with IV dosing, therefore slow administration over 30 minutes is recommended.

Formulations

Metronidazole is available only as human-labeled formulations. It is most commonly administered orally as tablets and capsules. Because it is poorly soluble, the IV formulation must be diluted in a large volume for administration, and it is cost prohibitive in adult horses.

Clinical Use

Metronidazole is used to treat anaerobic infections, especially pleuropneumonia and lung abscesses caused by penicillin-resistant *Bacteroides fragilis* and clostridial enterocolitis.[30,351-353] Although rectal absorption is inferior to oral absorption, it is a viable option for treatment when oral administration is not feasible. Metronidazole has also been used for the treatment of infiltrative bowel diseases in the horse.[354]

Nonsteroidal Antiinflammatory Drugs

The most commonly used drugs for treatment of pain and inflammation in horses are the nonsteroidal antiinflammatory drugs (NSAIDs). NSAIDs inhibit the enzyme cyclooxygenase (COX), which converts arachidonic acid to prostaglandins, thromboxane, and prostacyclin (Fig. 2.23). Blocking these ecosanoids results in antiinflammatory, analgesic, antipyretic, and antithrombotic effects.[355]

MECHANISM OF ACTION

Cyclooxygenase Inhibition

Two different, distinct forms of COX have been identified. A third form (COX-3) has been identified in other species, but its significance in the horse is currently unknown. Of the two forms known to exist in the horse, COX-1 is considered to be the constitutively expressed form and is necessary for normal homeostatic mechanisms in the body, whereas COX-2 is the inducible form produced in response to injury.[356] COX-1 is found in platelets, the kidneys, and the GI tract; COX-2 is identified in fibroblasts, chondrocytes, endothelial cells, macrophages, and mesangial cells. COX-2 is induced by exposure to various cytokines, mitogens, and endotoxin and is upregulated at sites of inflammation.[357]

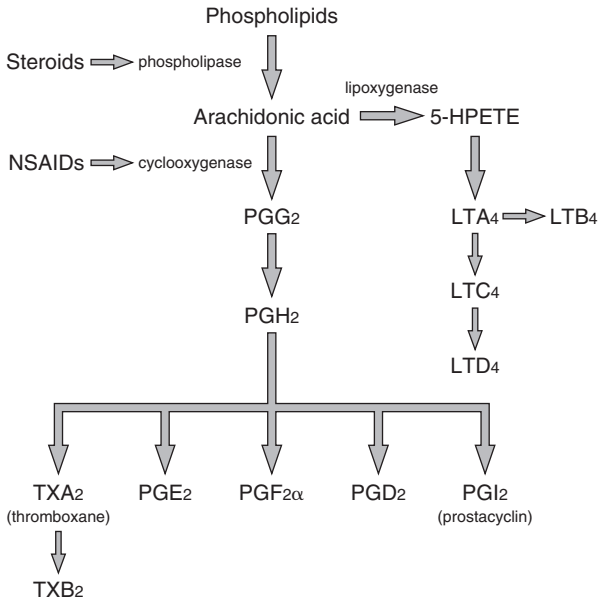

FIG. **2.23** In the arachidonic acid cascade, cyclooxygenase works on arachidonic acid to produce prostaglandins *(PG),* thromboxanes *(TX),* and prostacyclin, whereas lipoxygenase works on arachidonic acid to produce leukotrienes *(LT). NSAIDs,* Nonsteroidal antiinflammatory drugs; *HPETE,* hydroperoxyeicosatetraenoic acid.

Unfortunately, this classification of "good" versus "bad" COX proved too simplistic to explain the roles of the different forms of COX.[358] COX-2 is produced constitutively in the brain, spinal cord, kidney, ovary, uterus, placenta, thymus, bone, cartilage, synovia, endothelia, prostate, and lung. Additionally, COX-2 is involved in cellular processes such as gene expression, differentiation, mitogenesis, apoptosis, bone remodeling, wound healing, and neoplasia[359] but can also be induced by hormones, nitric oxide, cytokines, and lipoxygenase products. The prostaglandins produced in the GI tract and kidney that maintain mucosal integrity in the upper GI tract and renal perfusion, respectively, originally appeared to be derived only from COX-1. It is now widely accepted that both COX-1 and COX-2 are involved in mucosal defense in the GI tract.[360] Likewise, both COX-1 and COX-2 are involved in normal renal function, insofar as prostaglandins affect renal circulation through vasodilation, renin secretion, and sodium and water excretion. As in the GI tract, it was thought that COX-1–derived prostaglandins were involved in regulating homeostatic functions and COX-2–derived prostaglandins were involved only in inflammation or tissue damage. However, constitutive expression has been demonstrated for both isoforms in the kidney. NSAIDs also reduce sodium excretion and may cause acute renal failure when maintenance of adequate renal perfusion is prostaglandin dependent.[361]

Nonselective Versus COX-2–Selective Inhibitors

Newer NSAID products have targeted selective inhibition of COX-2 to supposedly increase the safety profile of these drugs. However, as previously stated, the theory behind this may be oversimplified. Either of the COX enzymes is capable of producing any of the prostanoids. The profile of the mediators produced depends mainly on the cell types present. Additionally, both enzymes are responsible in

some part for the inflammatory response. COX-1, because it is constitutively expressed, is present in the early stages of inflammation. Production of COX-2 will increase as the inflammatory process progresses, because it is an inducible enzyme. COX-2 is also involved in mucosal healing, particularly in the case of gastric and colonic ulceration, and is constitutively expressed in some tissues, such as the kidney. Renal responses to furosemide, dobutamine, and exercise were similar between meloxicam, a COX-2 preferential agent, and phenylbutazone treatment, which suggested that COX-2 was the mediator of prostanoid-induced changes to renal function in horses.[362] Therefore the safety of COX-2 selective inhibitors versus nonselective inhibitors has been called into doubt.[363,364] Nevertheless, there does appear to be a benefit to the use of these selective inhibitors in veterinary practice.

COX-2 inhibitors exert their specificity by taking advantage of the differences in protein structure between COX-1 and COX-2. There is a valine-leucine substitution in COX-2 that is not present in COX-1. This creates a side pocket in the tertiary structure of the molecule, and it is this side pocket that COX-2 inhibitors preferentially bind to. The selectivity of the drug for COX-2 versus COX-1 therefore depends on the affinity a drug has for this site. Regardless of affinity, all COX inhibitors bind both COX-1 and COX-2 to some extent; therefore there are no truly COX-2–specific drugs available at this time. Some drugs that have been described as COX-2 selective include etodolac, meloxicam, deracoxib, carprofen, and firocoxib. Of these, firocoxib is the only drug labeled for use in the horse that has COX-2–selective activity at therapeutic concentrations.

Affinity, or specificity, for COX-1 and COX-2 is generally assessed by in vitro techniques using whole blood assays. The activity against COX-1 is most commonly determined by measurement of thromboxane B_2 (TXB_2), the stable metabolite of TXA_2, which is thought to be specific for COX-1 production in platelets. For COX-2 activity, macrophages are stimulated with lipopolysaccharide (LPS), and production of prostaglandin E_2 (PGE_2) is measured. Enzyme-linked immunosorbent assays (ELISAs) are used for measurement of mediators. These tests are most valuable as comparative assays performed within the same laboratory, by the same investigators, within one class of drugs, as a measure of the potency of the drugs against the specific COX enzymes.

Antiinflammatory and Analgesic Effects

The NSAIDs are primarily antiinflammatory as a result of their inhibition of prostaglandin production. Therefore NSAIDs do not resolve inflammation but prevent its ongoing occurrence. Whereas prostaglandin production will rapidly diminish, any previously present prostaglandin must be removed before inflammation will subside. From tissue cage work, it has been shown that phenylbutazone, ketoprofen, and carprofen have delayed peak concentrations at the site of inflammation and persist in inflammatory exudates for long periods of time after plasma concentrations are negligible.[365-367] This explains the delayed onset and prolonged duration of antiinflammatory action that does not correlate with plasma pharmacokinetics of the NSAIDs.

The NSAIDs are commonly used in horses to attenuate the prostaglandin-mediated effects of endotoxin.[368-370] Flunixin meglumine administered at doses as low as one fourth the label dose will block prostaglandin production when administered before endotoxin exposure without obscuring the signs of colic pain, and with a lesser risk of adverse effects. However, at low doses it does not alter endotoxin-induced leukopenia, and with ongoing inflammation there is little benefit in using the low dose over the recommended dose.[371-377] Flunixin and phenylbutazone significantly inhibit movement of polymorphonuclear and mononuclear cells and antagonize the effects of endotoxin on bowel motility.[368,378]

COX inhibition does not explain all of the antiinflammatory activity of NSAIDs. NSAIDs are more lipophilic at a low pH, such as is found in inflamed tissues. Some antiinflammatory action appears to be related to their ability to insert into the lipid bilayer of cells and disrupt normal signals and protein-protein interactions in cell membranes. In the cell membrane of neutrophils, NSAIDs inhibit neutrophil aggregation, decrease enzyme release and superoxide generation, and inhibit lipoxygenase.[379,380]

The NSAIDs act as analgesics by inhibiting COX and preventing the production of prostaglandins that sensitize the afferent nociceptors at peripheral sites of inflammation. However, increasing evidence suggests that some NSAIDs have a central mechanism of action at the level of the spinal cord for analgesia unrelated to COX inhibition.[381] This action is synergistic with opioids and β_2-receptor–adrenergic drugs.[381,382]

For managing pain and inflammation in horses, NSAIDs are more effective as analgesics when inflammation is a part of the pain process and when they are given before the onset of the inflammatory process or insult. The time to onset and duration of analgesia of NSAIDs does not correlate well with their antiinflammatory properties. Because the analgesic effect has a more rapid onset and shorter duration of action than the antiinflammatory action, dosage regimens for effective analgesia may need to be different than those for antiinflammatory effects, or adjunct analgesics may need to be used.

CHIRALITY

Many of the NSAIDs are *stereoisomers.* Stereoisomers consist of enantiomers with the same molecular formula; however, due to asymmetrically oriented chemical groups on a central carbon, they form three-dimensional, nonsuperimposable mirror images and are known as *chiral* compounds.[383] For the NSAIDs it is common to use the *S (sinister)* and *R (rectus)* designations for each of a pair of enantiomers.[384] Although each member of a pair of enantiomers differs in three-dimensional orientation, their physical properties (e.g., melting and boiling points, refractive index, solubility) are identical. Biologic systems are highly chiral environments, and the pharmacokinetics and pharmacodynamic effects of each of a pair of enantiomers may be very different. Stereospecificity may occur in the pharmacokinetic processes of absorption, distribution, metabolism, and excretion, especially if the process involves a carrier protein.[385] If the fit of a drug molecule into the binding site on a protein, enzyme, or receptor involves the chiral center, the affinity for attachment will be different for each of a pair of enantiomers. Therapeutic efficacy, toxicity, or both may be related specifically to one enantiomer. Work with the specific enantiomers of some NSAIDs has shown the S enantiomers to have good COX-inhibitory effects, whereas R forms can have weak activity against COX yet still produce analgesia.[383,386,387]

Most chiral drugs are formulated as racemic mixtures, containing equal amounts of each enantiomer, because pure

enantiomeric compounds are difficult and expensive to manufacture. All of the propionic acid NSAIDs (i.e., ketoprofen, carprofen, vedoprofen, naproxen) are chiral compounds, and, except for naproxen, they are formulated as racemic mixtures. After administration, some enantiomers undergo *chiral inversion,* as hepatic enzymes convert one form of the enantiomer to the other form. When chiral inversion of the propionic acid derivatives occurs, it is almost invariably unidirectional, from R to S.[383] The degree of chiral inversion varies among species and cannot be predicted from one species to another, making extrapolating dosages for NSAIDs extremely hazardous.

PHYSICAL PROPERTIES

Almost all NSAIDs are weak acids and highly bound to plasma proteins such as albumin.[355] Therefore they are well absorbed from the stomach, and most of the drug in the plasma is protein bound. Because of protein binding, they are predominantly distributed in the ECF, and only low concentrations of NSAIDs are found in normal tissues and joint fluid. In damaged tissues and joints, however, total (bound and unbound) NSAID concentrations increase to therapeutic levels because of increased blood flow, vascular permeability, and acute phase protein penetration into sites of inflammation. Most NSAIDs undergo hepatic metabolism either through oxidation or glucuronide conjugation before being eliminated in the urine.[355]

DRUG INTERACTIONS

The occurrence and potential hazards of drug interactions must be considered before initiating therapeutic use of the NSAIDs. In general, any two NSAIDs administered together will be additive in their effect.[388-391] The downside to this practice is the increased risk of toxicity that occurs when NSAIDs are administered concurrently. Horses administered a combination of phenylbutazone and flunixin at the recommended doses for 5 days had a higher incidence of gastric ulceration, as well as a significant decrease in blood protein concentrations, compared with placebo-treated horses and horses receiving phenylbutazone alone.[391] It is likely that the benefits of giving two NSAIDs at once are far outweighed by the risks. Because most NSAIDs act by similar mechanisms of COX inhibition, a higher dose of a single NSAID should produce the same response.

Antacids, mucoprotective agents, and adsorbent antidiarrheal drugs can interfere with the absorption of NSAIDs.[346] Concurrent use of corticosteroids is generally contraindicated because corticosteroids increase the secretion of gastric acid, pepsin, and trypsin; alter the structure of gastric mucin; and decrease mucosal cell proliferation. This action is synergistic with NSAID-induced GI mucosal damage, but the specific risks of concurrent NSAID and steroid administration are unknown.[392] Several antibiotics have been shown to alter phenylbutazone disposition. Chloramphenicol decreases the elimination rate, and rifampin significantly increases the elimination rate of phenylbutazone.[393] Alternatively, phenylbutazone may affect the disposition of other antibiotics. Coadministration of phenylbutazone and procaine penicillin G results in higher serum concentrations of penicillin because of decreased tissue distribution.[394] Concurrent administration of gentamicin and phenylbutazone results in increased distribution and delayed elimination of gentamicin.[395] Phenylbutazone also decreases urinary excretion of furosemide and attenuates furosemide-induced increases in urinary excretion of sodium and chloride.[396,397]

ADVERSE EFFECTS OF NONSTEROIDAL ANTIINFLAMMATORY DRUGS

The adverse effects of the NSAIDs are primarily related to COX inhibition in tissues where prostaglandins are beneficial and protective. The NSAIDs have a higher incidence of toxicity in neonates because kidney and liver function is not fully developed.[398-400] When indicated in neonates, NSAIDs should be administered at the lowest possible doses and at extended dosing intervals. NSAIDs should be administered very cautiously to dehydrated animals.[401,402] Because they mostly distribute in extracellular water, plasma concentrations will be greater than normal in the dehydrated animal and more likely to cause toxicity. Decreased feed intake may also contribute to an increase in toxicity by increasing mucosal contact of drugs that may be directly cytotoxic. Common adverse drug reactions associated with NSAID use in the horse include renal papillary necrosis (medullary crest necrosis) and oral and GI ulceration.[397,401-408]

The renal toxicity of NSAIDs is a major concern, particularly in the perioperative period. NSAIDs typically have little effect on renal function in normal adult animals.[409] However, they decrease renal blood flow and GFR in patients with congestive heart failure, those that are hypotensive or hypovolemic (especially during anesthesia and surgery), or those that have chronic renal disease.[361] A more severe dose-dependent toxicity associated most commonly with phenylbutazone is renal papillary necrosis.[397,401,408] Although attributed to impaired renal blood flow, other mechanisms, such as direct nephrotoxicity of the drug or its metabolites, also may be involved. Risk for nephrotoxicity is increased when NSAIDs are coadministered with other nephrotoxic drugs, such as polymyxin B or aminoglycoside antibiotics.

Ulceration of the GI tract occurs most commonly in the oral cavity, gastric glandular mucosa, and duodenum. With duodenal involvement, stricture formation is possible, and surgical bypass of the proximal duodenum may be required for successful treatment. Ulceration in the right dorsal colon may also occur and can result in severe disease. The treatment of right dorsal colitis is intensive and mainly symptomatic.[403] The hypoproteinemia that results from loss of plasma proteins into the ulcerated GI tract can be corrected with IV infusions of plasma. The fluid and electrolyte losses that accompany the diarrhea are managed with commercially available IV fluids. Broad-spectrum antimicrobials are indicated when bacterial septicemia appears to exist. Pain must be managed with opioid analgesics. Antiulcer medications may be beneficial and speed recovery. Surgical removal of damaged sections of the colon may be necessary in some cases.[403] Recovery is usually slow, and in severe cases the prognosis is always guarded.

Less common adverse drug reactions include hemostatic effects and altered proteoglycan synthesis. NSAIDs classically inhibit platelet aggregation by preventing thromboxane production via the COX-1 pathway.[355] Recovery of platelet function is dependent on the pharmacokinetics of the NSAID and the mechanism of COX inhibition.[410-414] Aspirin permanently modifies COX, so platelet function is restored only by

the production of new platelets.[410,414] The effects of NSAIDs on proteoglycan synthesis should be considered in their clinical use for equine joint disease. Many NSAIDs affect cartilage anabolism in addition to their antiinflammatory actions.[415,416] A few NSAIDs, such as carprofen, increase proteoglycan synthesis.[415,417] Phenylbutazone does not affect proteoglycan synthesis or chondrocyte viability, but it is protective against chondrocyte-mediated catabolism.[416] The effects of NSAIDs on bone healing are currently controversial, with some laboratory animal studies showing detrimental effects and others showing little or no effect on bone healing.[418] Currently the only NSAID that has shown negative bone healing effects in horses is phenylbutazone.[419] Clinicians should consider the clear benefits of analgesia in equine patients against the potential adverse effects.

ASPIRIN

Aspirin (sodium salicylate) is available only in oral forms. Because it is a weak acid, it is best absorbed in the acidic environment of the upper GI tract, although overall bioavailability is low via the oral route (6%). Absorption is higher when given via the rectal route (17%).[420] During absorption aspirin is partially hydrolyzed to salicylic acid and distributed throughout the body. The highest concentrations are attained in the liver, heart, lungs, renal cortex, and plasma. Protein binding is moderate (about 60%) and depends on species and drug and albumin concentrations.[355] Aspirin is hepatically metabolized by glycine and glucuronide conjugation. Salicylates and their metabolites are rapidly excreted in urine by way of glomerular filtration and active tubular excretion, with an elimination half-life in the horse of approximately 1 hour.[420] In the horse salicylic acid is the primary salicyl compound found in urine.[421] Significant tubular reabsorption occurs, which depends greatly on pH.[355]

Aspirin is the most effective NSAID for antiplatelet therapy.[410,422,423] Aspirin irreversibly acetylates the COX present in platelets, which inhibits the formation of thromboxane A_2, which is responsible for vasoconstriction and platelet aggregation. [410,422,423] Because platelets do not contain a nucleus, they are incapable of synthesizing additional COX; therefore platelet thromboxane production will be inhibited for the life of any circulating platelets. Antiplatelet therapy may be beneficial in the management of equine laminitis, disseminated intravascular coagulation, and equine verminous arteritis. A precise antiplatelet dose has not been established, but a dose of 12 mg/kg prolongs bleeding time for 48 hours.[410]

CARPROFEN

Carprofen is a propionic acid derivative formulated as a racemic mixture that is currently available for use in horses in Europe. The Vd is 0.1 L/kg for the R enantiomer and 0.29 L/kg for the S enantiomer.[365] At the recommended dose of 0.7 mg/kg, carprofen has a longer elimination half-life in horses than most other NSAIDs, at 21 hours for the R enantiomer and 17 hours for the S enantiomer following IV administration. The R enantiomer predominates in plasma and exudates because of the hepatic stereospecificity for glucuronidation of the S enantiomer, leading to its more rapid clearance.[424] Chiral inversion of carprofen does not occur in the horse.[424] Like other NSAIDs, carprofen accumulates in inflammatory exudate but produces only modest reductions in the concentrations of ecosanoids compared with flunixin or phenylbutazone.[386,425] Despite this, carprofen produces significant analgesia, probably owing to the central actions of the R enantiomer.[425] Carprofen may also have other beneficial antiinflammatory effects, including inhibition of matrix metalloproteinases in cartilage explants and inhibition of the activation of NfκB-dependent genes such as inducible nitric oxide synthase.[426,427]

DICLOFENAC

Diclofenac is available as a 1% liposomal suspension cream for topical application in horses. It is used to control pain and inflammation associated with osteoarthritis in the tarsal, carpal, metacarpophalangeal, metatarsophalangeal, and proximal interphalangeal joints in horses. A 5-inch ribbon of diclofenac topical cream can be applied twice daily over the affected joint for up to 10 days. Owners should wear rubber gloves to prevent absorption into the hands. A single topical application of diclofenac cream produced measurable concentrations of diclofenac in transudate within 6 hours and significantly attenuated carrageenan-induced local production of PGE_2.[428] However, in an amphotericin B acute synovitis model, there was no overall difference between the diclofenac-treated group and the control group.[429] In a controlled field study in horses with osteoarthritis, average lameness scores showed statistically significant improvement after treatment with diclofenac topical cream.[430] Topical application over the sites of injection for regional limb perfusion has also been found to decrease inflammation at the site, as well as provide analgesia, potentially allowing extended use of this procedure.[431] The limited systemic absorption of diclofenac makes it useful in the treatment of acute lameness in competitive horses.[432] However, as a result of central sensitization and windup, locally administered diclofenac will be less effective than systemically administered NSAIDs for therapy of chronic pain. Topical diclofenac can be used simultaneously with systemically administered NSAIDs for maximal effect.

FIROCOXIB

Firocoxib is an NSAID in the coxib class introduced in the United States in 2005. It is labeled for use in the horse as a paste preparation for oral administration at a dose of 0.1 mg/kg for 14 days for the treatment of osteoarthritis. In 2011 it was also approved as an injectable formulation for IV administration at 0.09 mg/kg for 5 days. In clinical trials of horses with naturally occurring osteoarthritis, overall clinical efficacy of firocoxib was comparable to that of a paste formulation of phenylbutazone after 14 days of administration.[433] A canine tablet formulation is also available, and data suggest that the canine formulation is absorbed in the horse and may also be used as an effective antiinflammatory agent.[434,435] The use of the canine formulation is controversial, as it is often administered because of the decreased cost compared with the paste. The American Veterinary Medical Association has stated that it will not support the practice and this extralabel use is not justified.[436]

Firocoxib is highly COX-2 selective, with COX-1:COX-2 IC_{50} ratios of 263 to 643 demonstrated in vitro.[437] Several studies have confirmed this in ex vivo models of the horse, with minimal to no COX-1 inhibition noted following oral or IV administration.[434,438] On the basis of in vitro whole blood experiments, the concentration of firocoxib that inhibits 50%

(IC_{50}) or 80% (IC_{80}) of COX-2 activity in LPS-stimulated equine whole blood is approximately 30 ng/mL and 67 ng/mL, respectively.[439] Adjusting for plasma concentrations by assuming a plasma concentration that is 65% of whole blood, the IC_{80} equates to 103 ng/mL.[435] Concentrations of 100 ng/mL firocoxib have been shown to reduce COX-2 and mPGES1 gene expression in isolated equine peripheral blood mononuclear cells.[440] When modeled using plasma concentration profiles in ex vivo models, similar results were found, with an IC_{80} reported between 96 and 110 ng/mL.[434,435] This IC_{80} is similar to what was achieved following IV administration of a single dose[434] and oral administration of multiple doses[435] of either the paste or tablet formulation in the other study.

In safety studies, oral ulcers were detected at 3× and 5× the label dose, but no other adverse effects were noted. However, adverse effects may still occur, particularly in patients with preexisting disease, or those that receive NSAID stacking. A study examining the effects of coadministration of firocoxib with phenylbutazone showed significantly increased serum creatinine, significantly decreased total protein, and a significantly lower urine specific gravity after 10 days of treatment at commonly used doses.[441]

In horses firocoxib is well absorbed, with an oral bioavailability of 79%, although the time to maximum concentration following the first dose is often prolonged. Firocoxib is slowly eliminated, and Vd values are approximately 2 L/kg. Reported elimination half-lives are as long as 2 days.[437,439] Based on the long half-life, it may take multiple days for steady concentrations and maximum efficacy to be reached. To overcome this, a loading dose of 0.3 mg/kg once has been recommended,[442] which allows achievement of average steady-state drug concentrations within 24 hours. After the loading dose, maintenance doses following label directions maintain a relatively constant average drug concentration that produces less variability in onset of action and efficacy.

Foals 4 to 6 weeks of age have similar pharmacokinetics to adult horses[443]; however, the pharmacokinetics differs significantly in neonatal foals. In neonates, firocoxib is more rapidly absorbed, with a higher maximum concentration but a shorter half-life, resulting in less drug accumulation.[444] Steady-state is achieved after approximately 3 doses. In healthy neonates, no clinically apparent adverse effects were noted after 9 days of oral firocoxib at 0.1 mg/kg. Intravenous data in neonates suggest that the difference in pharmacokinetics is due to an increased clearance. Even following multiple doses, IC_{80} levels were not reached in neonates at horse label doses. Further work is needed to determine the IC_{80} necessary for foals and whether or not the use of higher doses or shorter dose intervals is safe and effective; however, current clinical practice is to use 0.2 mg/kg PO or IV q12–24hr.

FLUNIXIN MEGLUMINE

Flunixin meglumine is a very potent inhibitor of COX that is approved for use in horses and is available in injectable and oral formulations. Flunixin is rapidly absorbed after oral administration, with a bioavailability of 86% and peak serum levels within 30 minutes.[445] Absorption is delayed by feeding.[446] The Vd is 0.1 to 0.3 L/kg in horses, and the plasma elimination half-life is 1 to 2 hours.[445-447] In newborn foals the elimination half-life is prolonged at 13.4 hours. The Vd is also increased in the newborn foal, as is expected with a low-Vd drug in the neonate.[448] It is highly protein bound (86%) but appears to readily partition into tissues, hence the relatively high volume of distribution.[449,450] The elimination half-life in inflammatory exudate is 16 hours.[451] The onset of antiinflammatory action is within 2 hours, peak response occurs between 12 and 16 hours, and duration of action is 36 hours. Analgesic effects have a more rapid onset and shorter duration. Only 14% of a dose is excreted in urine, but otherwise little is known about the metabolism of flunixin.[355]

Flunixin is used in horses for a variety of inflammatory and painful conditions, including colic, colitis, exertional rhabdomyolysis, endotoxic shock, respiratory disease, ocular disease, general surgery, and laminitis.[355] Flunixin is more effective than phenylbutazone in preventing the clinical signs of endotoxemia but appears equivalent to ketoprofen.[452] Flunixin may prevent abortion in endotoxic mares.[453] Flunixin is dosed at 1.1 mg/kg every 12 to 24 hours for musculoskeletal pain but may be administered more frequently at lower doses (0.5 mg/kg q6–12hr) for colic pain. Therapy at 0.25 mg/kg every 6 to 8 hours is used as the lowest dose that will provide antiprostaglandin effects, but this dose will not provide much analgesia. Extremely high doses of flunixin may mask signs of surgical colic pain and interfere with treatment decisions.

Flunixin has a good safety profile, but high doses or chronic dosing can cause anorexia, depression, and GI ulcers.[406,454] In normal foals the label dose of flunixin administered for 5 days did not produce adverse effects, but 6 times the label dose resulted in GI ulcers.[400] In another study foals were administered flunixin at the label dose for 30 days, and all treated foals developed gastric ulcers.[398] Area under the curve, clearance, and half-life of flunixin are significantly greater in newborn foals compared with adult horses.[448] The half-life increases from 1 to 2 hours in adults to 6 to 8 hours in neonates. Based on this, higher doses with prolonged dosing intervals should be used in neonatal foals.

IM injections of flunixin are highly irritating to muscle and have been incriminated in cases of clostridial myonecrosis in horses; they should therefore be avoided when possible, despite the label directions.[455,456] If not treated promptly and aggressively, clostridial myonecrosis causes severe tissue damage and may be rapidly fatal. Flunixin treatment of horses with ischemic GI disease may cause prolonged permeability defects in recovering mucosa.[495]

KETOPROFEN

Ketoprofen is a chiral propionic acid derivative approved for horses as a racemic solution for IV or IM injection. The label dose is 2.2 mg/kg administered once daily. Oral and rectal bioavailability is too poor for these routes to be used clinically.[367,457,458] Ketoprofen is 92.8% protein bound in horses.[459] Ketoprofen has a moderate Vd for both enantiomers of approximately 0.5 L/kg and short plasma elimination half-lives of 1 to 1.5 hours.[367,387,451,459,460] Ketoprofen is hepatically metabolized by conjugation reactions, with only 25% of a dose eliminated as unchanged drug in urine.[459] The S enantiomer is associated with antiprostaglandin activity and toxicity, whereas the R enantiomer is associated with analgesia and does not produce GI ulceration.[367,461] Because of chiral inversion, the S enantiomer predominates in horses.[367] Ketoprofen accumulates in inflammatory exudates in the horse, where the elimination half-life of the S enantiomer is 23 hours and the R enantiomer is 20 hours. The maximum antiinflammatory effects of ketoprofen occur at 4 hours after a dose and last for

24 hours, illustrating that the antiinflammatory effects are not related to plasma concentrations.[451] Similar to flunixin, ketoprofen pharmacokinetics are different in neonatal foals, and higher doses with longer dosing intervals are recommended.[462] In studies of noninfectious arthritis, endotoxemia, and colic, ketoprofen is clinically similar to flunixin meglumine in efficacy.[451,452,461] In an experimentally induced synovitis model, phenylbutazone was more effective in reducing lameness and synovial fluid prostaglandin concentrations.[463] In horses with chronic laminitis, ketoprofen was more effective than phenylbutazone at relieving pain but only at a higher-than-label dose (3.63 mg/kg).[464] In comparative toxicity studies in both horses and donkeys, ketoprofen at the label dose had less potential for toxicity than flunixin meglumine or phenylbutazone.[406,465] In drug tolerance studies using 25 times the label dose for 5 days, horses developed depression, icterus, nephritis, hepatitis, and hemorrhagic necrosis of the adrenal glands.[466]

MELOXICAM

Meloxicam is an enolic acid belonging to the oxicam class of NSAIDs. It is slightly COX-2 selective in the horse with an IC_{50} COX-1:IC_{50} COX-2 of 3.8.[467] Meloxicam is labeled for use in Europe as an antiinflammatory drug in the horse for both oral and injectable formulations. Oral bioavailability is nearly complete, and absorption is not affected by feeding.[468] The Vd is 0.12 L/kg, with most drug eliminated unchanged in the urine. The elimination half-life is 5.2 to 8.5 hours.[468,469] Clearance differs significantly between horses and donkeys, with values of 34.7 mL/kg/hr and 187.9 mL/kg/hr, respectively.[470] Pharmacokinetic-pharmacodynamic analysis has shown that a maximum effect is achieved at plasma concentrations of approximately 0.2 μg/mL, which translates into a daily dose of 0.6 mg/kg intravenously or orally.

This dose has proven effective in lameness models, as well as experimental models of colic and abdominal pain. Direct comparison of flunixin and meloxicam in postoperative cases of small intestinal strangulating obstructions showed that meloxicam was as effective as flunixin when comparing most major clinical variables, although more horses in the meloxicam group showed gross signs of pain.[471] Additionally, meloxicam treatment did not impair mucosal recovery after ischemic injury in a small intestinal strangulation model.[472] Meloxicam also had no detectable difference in sucrose permeability following intragastric administration, indicating less compromise to gastric mucosal permeability compared with phenylbutazone.[473] However, chronic dosing with higher doses (1.8–3.0 mg/kg) was associated with dose-dependent adverse effects typical of this class of drugs, including hypoproteinemia and hypoalbuminemia, GI disorders, renal damage, and bone marrow dyscrasias.[474] Administration of meloxicam IV before surgery followed by once-daily oral administration for 4 consecutive days is efficacious in controlling postoperative pain and inflammation in horses undergoing orthopedic surgery.[475]

Meloxicam pharmacokinetics in neonatal foals differs from adults.[476] Similar to firocoxib, meloxicam exhibits a higher clearance in neonates, with an elimination half-life of approximately 2.5 hours. Based on a multiple-dose study, 0.6 mg/kg orally q12hr to foals less than 7 weeks of age produced concentrations thought to be effective for treatment of pain and inflammation. Adverse effects, including gastric ulceration, changes in white blood cell counts, and changes in serum albumin and protein concentrations, were not noted in foals receiving meloxicam at these doses for 21 consecutive days.

Another NSAID in this group, piroxicam, has received some attention in equine medicine, not for treatment of lameness or colic, but for the treatment of squamous cell carcinoma (SCC). Some tumors, particularly SCC, have been shown to produce COX-2.[477] Treatment with piroxicam has produced long-term remissions of SCC in the bladder, urethra, and periocular structures.[478] Adverse effects, even at the low doses used (0.2 mg/kg PO q24hr), have been noted, and include diarrhea and abdominal pain. It is not known at this time whether or not meloxicam would have a similar effect, with a higher safety profile.

PHENYLBUTAZONE

Phenylbutazone is the most widely used NSAID in the horse and is available in many generic IV and oral formulations. After oral administration, phenylbutazone is well absorbed, but time to peak concentration may be delayed by feeding.[479-481] The Vd is 0.15 L/kg, with highest concentrations in the liver, heart, kidney, lungs, and plasma.[482] The elimination half-life is 3.5 to 7 hours.[483] In neonatal foals the Vd is higher (0.27 L/kg) and the elimination half-life is longer (6.4–22.1 hours) than in adult horses.[484] Plasma protein binding in horses is greater than 99%.[483] Phenylbutazone is metabolized in the liver to oxyphenbutazone, an active metabolite that is eliminated more slowly from the body than phenylbutazone. Oxyphenbutazone inhibits the metabolism of phenylbutazone. Phenylbutazone and its metabolite cross the placenta and are excreted in milk. Less than 2% is excreted in the urine as unchanged drug. The capacity of the liver to metabolize phenylbutazone becomes overwhelmed at relatively low drug doses, resulting in dose-dependent kinetics.[485] The elimination half-life increases with increasing dose rates and increasing age.[485-487] The elimination half-life from exudate is 24 hours.[366] Therapeutic efficacy lasts for more than 24 hours as a result of the irreversible binding of phenylbutazone to COX, slow elimination from inflamed tissues, and long elimination half-life of oxyphenbutazone.[483] Therefore high or frequent doses of phenylbutazone result in disproportionately increasing plasma concentrations, which easily result in toxicity.

Phenylbutazone is used extensively in horses for a variety of musculoskeletal disorders. Although phenylbutazone also antagonizes the disruptive effects of endotoxin on bowel motility, flunixin meglumine is generally preferred for treatment of colic in horses.[368] Phenylbutazone appears to inhibit prostaglandin synthesis at low plasma concentrations in the horse (5–15 μg/mL), whereas much higher drug concentrations are needed in human beings (50–150 μg/mL).[483] This discrepancy is probably due to a species difference in the structure of COX. An initial dose of 4.4 mg/kg every 12 hours on the first day of therapy is followed by a decreased dose and increased dosing interval for subsequent therapy. Because of the accumulation from the long elimination half-life of phenylbutazone and oxyphenbutazone, chronic therapy should be at the lowest possible dose and the longest possible dosing interval that still controls pain.

Phenylbutazone has a narrow safety margin, especially in foals and ponies and dehydrated horses.[400,401] Phenylbutazone toxicity most commonly results in adverse GI effects, including oral, esophageal, gastric, cecal, and right dorsal colonic ulcerations, and accompanying protein-losing enteropathy,

hypoproteinemia, leukopenia, and anemia.[401-405,488] Renal papillary necrosis (renal medullary crest necrosis) results from inhibition of prostaglandins that maintain renal blood flow and direct toxicity of phenylbutazone and metabolites.[408] Ulcerative cystitis associated with prolonged phenylbutazone administration has also been reported[489] and may also relate to direct cytotoxic effects of drug secreted in the urine. Because phenylbutazone can mask symptoms of lameness in horses for several days after therapy, it may be used to disguise lameness during soundness examinations or for competitive purposes.[483] Extravascular administration results in severe tissue necrosis. Phenylbutazone may have a negative effect on bone healing in horses.[419] Phenylbutazone significantly suppresses total T_4 and free T_4 concentrations in horses for 10 days.[490]

VEDAPROFEN

Vedaprofen is structurally related to ketoprofen and carprofen and also is formulated as a racemic mixture of S and R enantiomers. It is available in some countries as an IV injectable solution and as a palatable gel for oral administration with a loading dose of 2 mg/kg followed by 1 mg/kg every 12 hours. Oral bioavailability is approximately 100%, and it is highly protein bound (99%). Within 2 hours after IV administration, the mean R:S plasma concentration ratio is 95:5. This is due to marked distribution and elimination differences between the enantiomers, and not chiral inversion. The R enantiomer has an elimination half-life of 2.2 hours and a Vd of 0.23 L/kg, and the S enantiomer has an elimination half-life of 0.76 hours and a volume of distribution of 0.5 L/kg.[491] Both enantiomers accumulate in inflammatory exudate and are more slowly cleared from exudate than from plasma. In an equine acute nonimmune inflammation model, vedaprofen produced significant inhibition of inflammatory swelling and partially inhibited leukocyte migration into the exudate. Inhibition of leukocyte migration was not seen in this model with other NSAIDs.[491] Based on in vitro models, vedaprofen is moderately COX-1 selective.

OTHER DRUGS

Numerous other NSAIDs have been studied in the horse, although their clinical use is sporadic and no formulations are labeled for use in the horse. Etodolac is a relatively selective COX-2 inhibitor in the horse. It has been used clinically in horses with a previous history of gastric or colonic ulceration, as well as in a few horses with active GI disease, with apparent benefits. Doses of 20 mg/kg PO q12–24hr have been reported, although the COX-2 selectivity may be lost at these high doses.[492-495] Deracoxib is a moderately selective COX-2 inhibitor in the horse with a long elimination half-life and average maximum plasma concentration of 0.54 µg/mL following oral administration. Doses of 2 mg/kg PO q12hr would maintain concentrations above the IC_{80} for COX-2.[496] Acetaminophen, although not considered a classic NSAID due to its weak inhibitory effects on COX-1 and COX-2, is another drug occasionally used as an antiinflammatory, analgesic, and antipyretic in horses. It is well absorbed with a bioavailability of approximately 91%[497] and has been used successfully in laminitis cases with no specific adverse effects.[498] Doses range from 20 to 25 mg/kg PO q12–24hr.

CHAPTER 3

Recognizing and Treating Pain in Horses

Rachel C. Hector and Khursheed R. Mama

INTRODUCTION

Following a brief review of general concepts related to pain and its assessment in horses, this chapter will focus on available pharmacologic and to a lesser extent complementary therapeutic options. The intent is to provide information that veterinarians can directly apply to management of acute and chronic pain in horses.

Pathophysiology of Pain

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Box 3.1).[1] Nociception refers to the activation of high threshold receptors (nociceptors) located at the distal ends of unmyelinated (C) or poorly myelinated (Aδ) nerve fibers. Electrical impulses conducted by these afferent fibers reach the dorsal horn of the spinal cord and via ascending pathways (spinothalamic and spinoreticular thalamic) are transmitted to the brain in which they may be perceived or recognized as painful (Fig. 3.1). Nociception may occur in the absence of perception (as in the anesthetized horse) and can trigger neuroendocrine (cortisol and catecholamines), metabolic (hyperglycemia), and physiologic (heart rate and respiratory rate) responses. Perception, which is influenced by external and animal-related factors, will trigger similar responses and behaviors (e.g., avoidance, lameness) intended to protect the horse from further insult. Comprehensive assessment of these responses is useful when evaluating the severity, stress, and impact of pain on the horse's quality of life.

Acutely painful states may resolve with discontinuation of the stimulus and appropriate intervention. Neuronal input may also be modulated by descending inhibitory pathways originating from the brain and by use of alternate nonpainful afferent neural input (e.g., ice at the site of injury). In the absence of these, continued nociceptive input can lead to chronic nervous system pathology resulting from peripheral and central sensitization. Clinically these conditions are associated with hypersensitivity (or a reduction in the intensity of the stimulus required to cause pain) and allodynia (in which a typically nonpainful stimulus is now perceived as pain). Exaggerated responses to a noxious stimulus (hyperalgesia) and persistence of pain after removal of a noxious stimulus (hyperpathia) may also occur.

Peripheral sensitization is caused by the local production, release, and accumulation of chemicals (prostaglandins, leukotrienes, neuropeptides, and nerve growth factors) that sensitize peripheral nerve fibers and activate additional (silent) nociceptors at the terminal ends of Aδ and C fibers.[2,3] Central sensitization results from the cumulative effects of repetitive and sustained nociceptive input on the dorsal horn of the spinal cord and a subsequent release of glutamate and neuropeptides (substance P and neurokinin A) that activate *N*-methyl-D-aspartate (NMDA) and tachykinin receptors, resulting in a gradual "windup" of central neural pathways.[2-4]

Visceral pain (e.g., pain from intestine, liver, spleen, kidney, or bladder), unlike somatic pain, is transmitted by parasympathetic (principally vagal) and sympathetic splanchnic afferent nerve fibers.[5,6] The autonomic fibers involved in transmitting noxious

BOX 3.1 Definitions of Terms Used to Describe Pain

1. **Pain:** Unpleasant sensory or emotional experience associated with actual or potential tissue damage or described in terms of such damage.
2. **Noxious stimulus:** Stimulus (mechanical, chemical, and thermal) of sufficient intensity to threaten or overtly cause tissue damage.
3. **Nociception:** Process of pain perception via pain receptors (nociceptors) and transmission of noxious (painful) stimuli, including transduction, transmission, modulation, and perception.
4. **Hyperalgesia:** Increased response (hypersensitivity) to a noxious stimulus, either at the site of injury (primary) or in surrounding undamaged tissue (secondary).
5. **Hyperesthesia:** Increased sensitivity to *non*noxious stimuli.
6. **Hyperpathia:** Greatly exaggerated pain sensation to nociceptive stimuli.
7. **Allodynia:** Pain produced by *non*noxious stimuli.
8. **Preemptive analgesia:** Prevention or minimization of pain by the administration of analgesics before the production of pain or before the introduction of a noxious stimulus (surgery) if pain already exists. The goal of preemptive analgesia is to provide a therapeutic intervention in advance of pain to prevent or minimize the central nervous system response to a noxious stimulus.
9. **Multimodal therapy:** Administration of multiple drugs that act by different mechanisms of action to produce the desired (analgesic) effect.

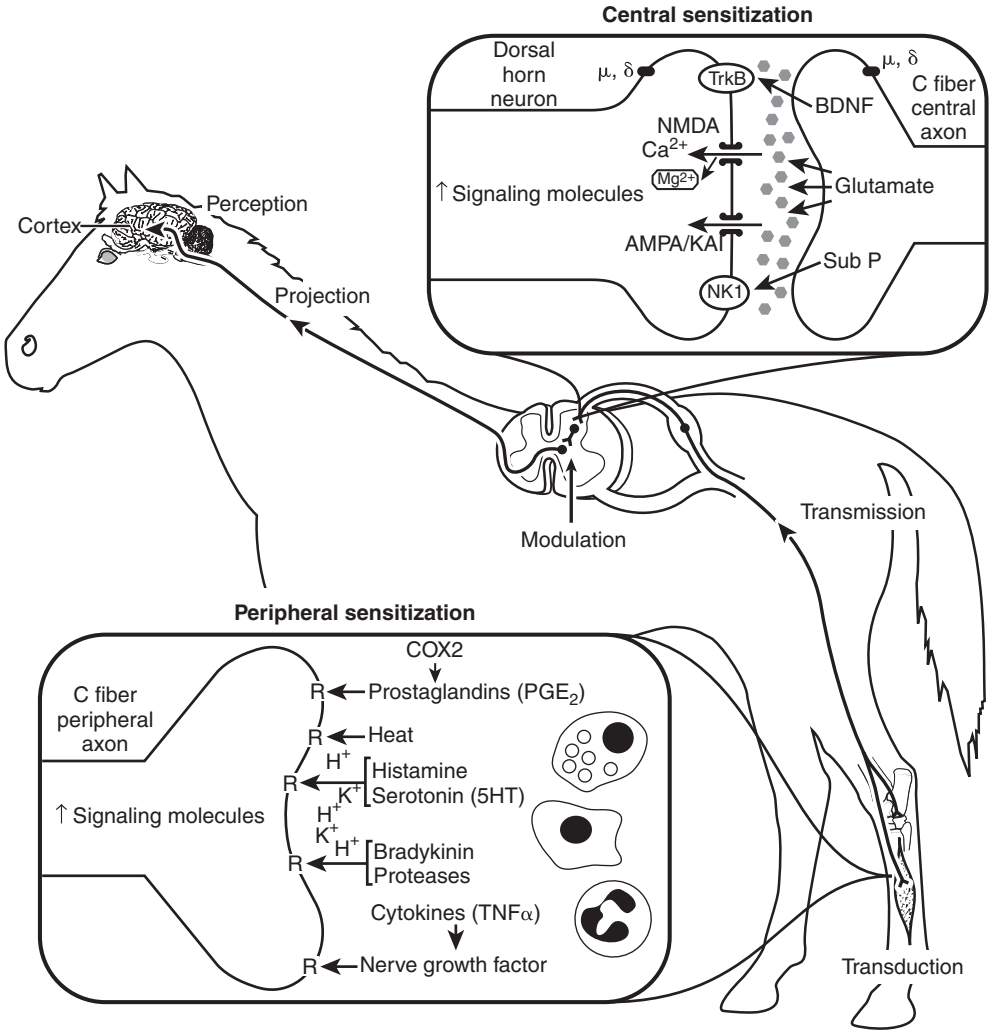

FIG. **3.1** Pain nociception and perception. Painful thermal, mechanical, and chemical stimuli are transduced to electric potentials (action potentials) that are transmitted to the spinal cord, in which they are modulated and then projected to the brain (perception). The major excitatory neurotransmitter in the spine is glutamate, which normally activates α-amino-3-hydroxy-5-isoxazole proprionic acid (AMPA) and kainate (KAI) receptors. NMDA, *N*-methyl-D-aspartate; NK1, neurokinin.

inputs from visceral organs are diffuse and overlap extensively, resulting in difficulty in localization of the site of pain. Neuropathic pain, which is yet another form of pain, may result from injury to the peripheral or central nervous system. For additional details regarding the pathophysiology of pain the reader is referred to McMahon et al. (2013) and Almeida et al. (2004).[7,8]

Pain Assessment

Although horses will demonstrate a variety of behavioral indicators of pain (Box 3.2), assessment of pain in horses has historically been considered challenging.[9] This could be because horses, as prey animals, do not wish to appear vulnerable and so do not fully exhibit signs of pain in unfamiliar or threatening environments until pain becomes severe or unrelenting. Consequently, horses may not be appropriately treated for painful conditions by the inexperienced observer. Although early reports suggest an emphasis on physiologic or limited behavioral parameters to assess pain, today there is the recognition that evaluation of pain requires a multifaceted approach and should be assessed in light of the cause (e.g., gastrointestinal, orthopedic, dental). Additionally, it is recognized that the pain experience is likely to be influenced by animal and environmental factors.[10-12] Among physiologic assessments, stress hormones (e.g., cortisol, β-endorphins), and catecholamines (e.g., epinephrine, norepinephrine) have been measured in both clinical and laboratory settings in an attempt to correlate these "objective data" with pain states.[10,13] Their usefulness has, however, been mixed because shock, stress, and medications influence them like they do other physiologic measurements, such as heart rate. Further, they are not contemporaneous to the pain assessment; thus, they only have retrospective value. Measurement of inflammatory mediators such as prostaglandin E2 and substance P from joints are similarly not consistently reliable as indicators of pain, and results are not immediately available.[14,15]

In an attempt to overcome these challenges, there has been significant recent work on the development of multifaceted pain assessment tools that consider physiologic (e.g., heart rate, blood pressure) and behavioral (both spontaneous and in response to interaction) indices developed specifically for

BOX 3.2 Potential Behavioral Indicators of Pain in Horses

- Considerable restlessness, agitation, and anxiety
- Rigid stance and reluctance to move
- Lowered head carriage
- Fixed stare and dilated nostrils, clenched jaw
- Aggression toward its own foal
- Aggression toward handlers, horses, objects, and self
- Decreased interactions with handlers
- Vocalization (deep groaning and grunting)
- Rolling
- Kicking at abdomen
- Flank watching
- Stretching
- Dullness and depression
- Weight-shifting among limbs
- Limb guarding
- Abnormal weight distribution
- Pointing, hanging, and rotating limbs
- Abnormal movement
- Reluctance to move
- Arched back
- Head shaking
- Abnormal bit behavior
- Altered eating; anorexia, quidding

horses in different clinical scenarios (e.g., postarthroscopy, colic). Each parameter on many of these scales is further categorized in an attempt to indicate severity of pain; for example, the parameter "kicking at the abdomen" is characterized by frequency of the same over a fixed interval, with greater frequency assigned a worse score (greater degree of pain). Hence, these scales serve not only to assess the presence or absence of pain but also the severity (two such scales are included in Figs. 3.2 and 3.3).[16-21] One of these—namely, the horse grimace scale—presents a somewhat unique approach and is worth highlighting. This scale, which was modeled after similar work in rodents, correlates six specific facial expressions with the degree of pain; for example, ears stiffly backward can indicate a greater degree of pain versus none if ears face forward. Although this was developed in horses undergoing castration, it may have applicability or provide a good adjunctive assessment tool in horses with other conditions.[19] Photographic examples of horses demonstrating facial expressions of pain are included in Fig. 3.4.

Note that the majority of these pain scales are targeted toward acute or nociceptive pain in adult horses. Assessment of chronic pain may require additional and different tools (e.g., force plate, gait analysis), owner or trainer input, and greater reliance on response to therapy. Similarly, the authors are not aware of ethograms or pain scales for foals, but based on the author's impressions and in talking with veterinarians who routinely manage foals, additional behavioral signs should be considered. For example, grinding of the teeth is commonly associated with pain from stomach ulcers in foals. Additionally, unwillingness to lie down despite buckling the front limbs, stamping hind feet toward the belly, and lying down in lateral recumbency with one or both legs cranially toward or over the head has been associated with pain in foals.

Although methodology may need to vary based on the circumstance, the goal of pain assessment is to provide objective, repeatable, and consistent categorization of pain, such that therapies can be both targeted and monitored. If multiple individuals are to be involved in assessing the animal, training in use of the preferred pain scale or behaviors is helpful to minimize interobserver variation on parameters that are open to interpretation. Accurate assessment of pain will allow veterinarians to continue to improve analgesic efforts in horses.

Development of a Treatment Plan

Given the multifaceted nature of pain, the many individual breeds of horses, and additional equid species (e.g., donkeys, mules), as well as consideration of a wide age range of individual equids in which veterinarians may be faced with managing pain, a systematic approach to developing and modifying a pain treatment plan should be considered. Because of the significance of well-being, pain is considered the "5th vital sign" in human patients. In addition to the potential emotional association and subsequent avoidance behavior horses exhibit to locations in which they may have experienced pain, physiologic consequences such as negative energy balance, poor wound healing, and altered gastrointestinal motility may be significant.[22]

Management of nociceptive pain such as surgical pain or that associated with acute injury is a common scenario. Nociceptive pain is considered an adaptive or protective strategy, and the associated inflammatory response is considered essential to the healing process. The goal of therapy is to normalize pain sensitivity and not allow it to progress to a maladaptive state or one that is no longer proportional to the noxious stimulus and healing tissue.[23] Nonsteroidal antiinflammatory drugs (NSAIDs) help normalize the inflammatory response generated by tissue injury and are commonly used in horses. Although there have been mixed reports of the overall advantage of preemptive versus postprocedural use of NSAIDs, it is most common to administer these preemptively to limit inflammation. Additionally, medications used in the horse for sedation (e.g., α_2-adrenergic agonists) and general anesthesia (e.g., ketamine) are also analgesic and affect different sites in the nociceptive pathway (e.g., α_2-adrenergic agonist drugs mediate their analgesia through descending inhibition), providing a multimodal approach. Regional techniques (e.g., intraarticular, epidural, perineural) further facilitate this multimodal approach to analgesia and minimize the adverse effects (e.g., gastrointestinal stasis) associated with systemic medications.

Although foals are similarly deserving of a multimodal approach in treating pain, the safety of NSAIDs (e.g., gastrointestinal ulcers) and the cardiovascular side effects of α_2-adrenergic agents when used at doses similar to the adult horse deserve consideration. Conversely, some regional techniques (e.g., lumbosacral epidural) are more feasible, and certain drugs (e.g., opioids) may not be limited by behavioral side effects to the same degree as in adult horses.

The goal in treating pain early and using a multimodal approach is to minimize development of a chronic condition that can be more challenging to evaluate and treat. The subsequent text includes information on pain treatment modalities and medications that the veterinarian may select to best manage individual equine patients.

DRUGS USED TO TREAT PAIN

Almost all types of drugs used to treat pain in small animals have also been used in horses, although there are fewer controlled trials evaluating their efficacy. This may

Physiological Data	Criteria	Score /12
Heart Rate (Compared to Baseline)	<10% increase	0
	>11-30% increase	1
	>31-50% increase	2
	>50% increase	3
Respiratory Rate (Compared to Baseline)	<10% increase	0
	>11-30% increase	1
	>31-50% increase	2
	>50% increase	3
Digestive Sounds	Normal motility	0
	Decreased motility	1
	No motility	2
	Hypermotility	3
Rectal Temperature (Compared to Baseline)	<0.5°C variation	0
	<1°C variation	1
	<2°C variation	2
	>2°C variation	3
Response To Interaction	**Criteria**	**Score /6**
Interactive Behavior	Pays attention to people	0
	Exaggerated response to auditory stimuli	1
	Excessive to aggressive response to auditory stimuli	2
	Stupor, prostration, no response to auditory stimuli	3
Response To Palpation Of Painful Area	No reaction to palpation	0
	Mild reaction to palpation	1
	Resistance to palpation	2
	Violent reaction to palpation	3
Behavior	**Criteria**	**Score /21**
Appearance (reluctance to move, restlessness, agitation, anxiety)	Bright, lowered head and ears, no reluctance to move	0
	Bright, alert, occasional head movement, no reluctance to move	1
	Restless, pricked up ears, abnormal facial expressions, dilated pupils	2
	Excited, continuous body movements, abnormal facial expression	3
Sweating	No obvious signs of sweat	0
	Damp to the touch	1
	Wet to the touch, beads of sweat apparent over body	2
	Excessive sweating, beads of sweat running off the animal	3
Kicking At Abdomen	Quietly standing, no kicking	0
	Kicking at abdomen 1 - 2 times/5 mins	1
	Kicking at abdomen 3 - 4 times/5 mins	2
	Kicking at abdomen >5 times/5 mins, intermittent attempts to roll	3
Pawing On Floor (includes pointing or hanging limb)	Quietly standing, no pawing	0
	Occasionally pawing (1 - 2 times/5 mins)	1
	Frequent pawing (3 - 4 times/5 mins)	2
	Excessive pawing (>5 times/5 mins)	3
Posture (weight distribution and comfort)	Stands quietly, normal walk	0
	Occasional weight shift, slight muscle tremors	1
	Non-weight bearing, abnormal weight distribution	2
	Analgesic posture, attempts to urinate, prostration, muscle tremors	3
Head Movement (lateral or vertical head movements)	No evidence of discomfort, head straight ahead mostly	0
	Intermittent head movement, looking at flanks or lip curl 1 - 2 times /5 mins	1
	Intermittent, rapid head movement, looking at flanks or lip curl >5 times/5 mins	2
	Continuous head movements, looking at flanks or lip curl >5 times/5 mins	3
Appetite	Eats hay readily	0
	Hesitates to eat hay	1
	Little interest in eating hay, takes hay but doesn't chew or swallow	2
	Neither shows interest in nor eats hay	3
Total CPS		39

Equine Comfort Assessment Scale

*This scale is designed to be used in the context of the clinical presentation of each animal. If you do not believe the pain scoring criteria to be accurate for this patient, please explain in the comments section below.

Pain Score		Behavior	Clinical Assessment	Postural Features
0		❑ Responds with interest to gate opening, approach by observer ❑ Takes care in movements around people ❑ Head above withers ❑ Attentive ❑ Moving freely, calmly ❑ Resting comfortably	❑ HR:_____ (usually ≤ 40 bpm) ❑ Eyes: relaxed, normally responsive ❑ Normal muscle tension ❑ No focal areas of heat ❑ Palpation not aversive	❑ No lameness perceptible, bears weight equally ❑ Moves with ease of stride
1		❑ Head at or above withers ❑ Facing forward and watching ❑ Performs normal behaviors less frequently than expected ❑ Responds with quiet interest to gate opening, approach by observer ❑ Takes care in movements around people	❑ HR: _____ (may be ≤ 40 bpm) ❑ Mild muscle tension ❑ Mild focal areas of heat ❑ Slightly steps, leans or pulls away from palpation, +/- muscle twitching	❑ Lameness difficult to observe, inconsistently apparent ❑ Mild injury or stiffness in movement
2		❑ Head level with withers ❑ Moving slowly about with bedding undisturbed ❑ Mild but more frequent restlessness ❑ Responds to approach ❑ Less enthusiastic, less interested, less interactive ❑ Less careful about movements around people	❑ HR:_____(may be ≥ 48 bpm) ❑ Tachypnea +/- RR:_____ ❑ Moderate muscle tension ❑ Increasing areas of heat ❑ Palpation more aversive	❑ Lameness apparent only under certain circumstances, favors leg(s) occasionally ❑ Obvious stiffness in movement
3		❑ Head level or below withers ❑ May face back or corner of stall ❑ More vigorous signs of restlessness ❑ Eyes distracted, far away, weary ❑ Minimally reacts to interaction ❑ Stands in one position ❑ Beginning to become internalized ❑ Less careful about movements around people	❑ HR:_____(may be ≥ 60 bpm) ❑ Tachypnea +/- RR:_____ ❑ Sweating ❑ Severe muscle tension ❑ Widespread areas of heat ❑ Vigorously aversive response to palpation	❑ Moderate lameness, able to bear weight but clearly favors one or more limbs ❑ Obvious discomfort, weight shifting ❑ Arched back ❑ Very stiff movements ❑ Abnormal standing posture
4		❑ Head often below withers ❑ Stands in corner or faces wall ❑ Ears back, eyes weary ❑ Frequent signs of severe agitation ❑ Extremely uncomfortable, panicky OR ❑ Extremely internalized/withdrawn ❑ Unwilling to rise ❑ Careless about movements around people	❑ HR:_____(may be ≥ 70 bpm) ❑ Tachypnea +/- RR:_____ ❑ Profuse sweating ❑ Extreme muscle tension / rigidity +/- fasciculation ❑ Widespread areas of heat ❑ Extremely aversive response to palpation, possibly aggressive	❑ Unable or unwilling to bear weight ❑ May not be able to move ❑ Constant shifting of weight ❑ Very abnormal standing posture OR ❑ In sternal or lateral recumbency

FIG. **3.3** A multidimensional, nonvalidated pain scale that is used at the authors' institution.

FIG. **3.4** Examples of equids demonstrating facial expressions of pain. (A) Note the horse has partially closed eyes and drawn back upper lip. (B) The donkey shows ears pointed back and strained nostrils.

be one reason why there are limited validated pharmacologic options for analgesia in horses compared with those for dogs and cats. Practically, there may also be limitations to the use of certain drugs in horses with respect to drug volume or cost. As in any species, analgesic drugs also have potential adverse effects that may limit their use. Pharmacologic approaches tend to provide the greatest benefit with fewer or less severe adverse effects when drugs are selected for a specific purpose, used preemptively, or as a part of a multimodal approach, and the dose is scaled to the severity of pain.

Classes of drugs most commonly used in the horse include antiinflammatories, opioids, α_2-adrenergic agonists, and local anesthetics. There are, however, several additional drugs that have a place in equine pain management, and these have been included here. Greater detail about some of these drugs may be found in Chapter 2 and numerous additional resources.[24-26] Dosing information is provided in Table 3.1.

Antiinflammatory Drugs

Antiinflammatory drugs used in horses include corticosteroids and NSAIDs. They are often the first-line choice in the management of pain related to inflammatory conditions (e.g., synovitis and osteoarthritis)[27-29] and are administered by various routes, including systemically, intraarticularly, and topically.[30-32] Generally, NSAIDs are the most commonly used drugs in horses.[33] They are readily available and relatively inexpensive and do not require precise record keeping.

Corticosteroids act on the enzyme phospholipase A2 to prevent the breakdown of membrane phospholipids to arachidonic acid, which is the precursor to inflammatory prostaglandins and leukotrienes.[26] NSAIDs act to block cyclooxygenase (COX), the enzyme that produces prostaglandins from arachidonic acid.[34] Prostaglandins and leukotrienes have important housekeeping functions in the body and play a significant role in the development of pain, inflammation, and fever.

There are at least two isoforms of cyclooxygenase, and the most important ones are COX-1 and COX-2. COX-1 is considered constitutively expressed in most body tissues and plays an important role in maintaining renal blood flow, protecting gastric mucosa, and facilitating platelet aggregation (among other processes). The COX-2 isoform has a greater role in the development of inflammation and pain, and traditionally therapeutic effects of NSAIDs are attributed to inhibition of COX-2 effects.[35,36] However, COX-2 can also have housekeeping functions in the gastrointestinal tract and kidney, with greater effects in diseased states,[37] and the traditional absolute separation into constitutive with respect to COX-1 and inducible with respect to COX-2 is an oversimplification of the roles of the COX isoforms.[38,39] The existence of a COX-3 isoform, originally discovered as a variant of COX-1 in dogs, is reported in canine, rodent, and human literature.[40] COX-3 is the purported target of acetaminophen (paracetamol), although considerable debate exists regarding this topic.[41,42] Whether a COX-3 isoform exists in horses is unknown. Regardless, important species differences exist in the expression of different COX isoforms in various tissues, and extrapolation of what works in a dog or a human is not uniformly applicable to the horse.[43,44]

The most common adverse effects associated with blocking the COX pathways are seen in the gastrointestinal and renal systems. In horses gastric ulceration, right dorsal ulcerative colitis, and renal papillary/crest necrosis are reported with NSAID use.[45-47] Renal effects may be worsened by concurrent dehydration.[48] The reader should be aware that although the practice of combining multiple NSAIDs or corticosteroids and NSAIDs may result in increased analgesia, this practice is also associated with increased frequency and severity of adverse effects.[49-52] In circumstances in which pain is best managed by

TABLE **3.1** **Drugs Used for Analgesia in Horses**

Drug	Route	Dose	Comments
NONSTEROIDAL ANTIINFLAMMATORY DRUGS			
Phenylbutazone[28]	IV, PO	2.2–4.4 mg/kg q12–24 h	Lower doses suggested for chronic use
Flunixin meglumine[230]	IV, PO	1.1 mg/kg q 12–24 h	IM route on label but not recommended because of potential for local tissue irritation
Ketoprofen[28,231]	IV	1.1–2.2 mg/kg q 12–24 h	—
Firocoxib[57]	IV	0.09 mg/kg q 24 h	Nonaqueous solution should not be mixed with aqueous flush solutions in IV lines
	PO	Loading dose: 0.3 mg/kg Then: 0.1 mg/kg q 24 h	—
Meloxicam[55,56]	PO	0.6 mg/kg q 24 h	Increased dose frequency may be required for foals (q 12 h)
Diclofenac[32]	Topical	1% liposomal cream applied to bare skin over area of interest	—
OPIOIDS			
Can be combined with acepromazine, α_2-adrenergic agonists. Dilute epidural dose to desired volume.			
Butorphanol[62,63,179,232-235]	IV, IM, SC	0.01–0.22 mg/kg	Common clinically used doses are lower than reported analgesic doses
	IV CRI	CRI: 0.013–0.025 mg/kg/h	Loading dose recommended
Nalbuphine[236]	IV, IM	0.02–0.15 mg/kg	—
Buprenorphine[83,237-239]	IV, sublingual	0.005–0.01 mg/kg	—
	Epidural	0.005 mg/kg	—
Morphine[87-89,91,93,240,241]	IV, IM	0.05–0.2 mg/kg	—
	IV CRI	0.1 mg/kg/h	Loading dose recommended
	Epidural	0.1–0.2 mg/kg	—
	Intraarticular	0.1–0.2 mg/kg	—
Fentanyl[81,201,242]	IV CRI	Loading dose: 0.005 mg/kg CRI: 0.006 mg/kg/h	Less effective analgesic in horses compared with other species
	Transdermal	20- to 30-mg adhesive patch applied to bare skin per approximately 500-kg adult horse	As an adjunct to other analgesics
Remifentanil[240,243,244]	IV CRI	Loading dose: 0.0005 mg/kg CRI: 0.002–0.006 mg/kg/h	As an adjunct to general anesthesia
Methadone[133,245,246]	IV, IM, PO	0.05–0.15 mg/kg	—
	Epidural	0.1 mg/kg	—
Meperidine (pethidine)[62,247-249]	IV, IM	1 mg/kg	—
	Epidural	0.3–0.8 mg/kg	—
Hydromorphone[250]	Epidural	0.04 mg/kg	—
α_2-ADRENERGIC AGONISTS			
Doses provided will cause sedation. Lower doses may be effective for analgesia, especially in combination with opioids. CRI doses are used for standing procedures or as an adjunct to general anesthesia.			
Xylazine[251,252-255]	IV, IM	0.2–1.1 mg/kg	—
	IV CRI	0.016–0.69 mg/kg/h	—
	Epidural	0.17–0.22 mg/kg	Hind limb weakness/recumbency is a possible side effect
Detomidine[93,244,252,256-258]	IV, IM	0.01–0.03 mg/kg	—
	IV CRI	0.005–0.02 mg/kg/h	—
	Epidural	0.015–0.03 mg/kg	Systemic absorption is likely
Romifidine[235,252,259,260]	IV, IM	0.02–0.08 mg/kg	—
	IV CRI	0.03–0.04 mg/kg/h	—
	Epidural	0.03–0.06 mg/kg	—

TABLE **3.1 Drugs Used for Analgesia in Horses—cont'd**

Drug	Route	Dose	Comments
Dexmedetomidine[240,241,261,262]	IV, IM	0.003–0.005 mg/kg	—
	IV CRI	0.001–0.008 mg/kg/h	—
Medetomidine[251,263,264]	IV, IM	0.007–0.01 mg/kg	—
	IV CRI	0.003–0.005 mg/kg/h	—
LOCAL ANESTHETICS			
Epidural doses may be combined with opioids or α_2-adrenergic agonists; recommended volume when local anesthetics are used is not to exceed 5–7 mL in an adult horse.			
Lidocaine[133,247,265,266]	IV CRI	Loading dose: 1.3–1.5 mg/kg CRI: 0.05 mg/kg/min	Loading dose given over 10–20 min
	Sacrococcygeal epidural	0.2–0.35 mg/kg	—
Mepivacaine[267,268]	Sacrococcygeal epidural	0.16–0.2 mg/kg	—
Ropivacaine[269,270]	Sacrococcygeal epidural	0.08–0.15 mg/kg	—
Bupivacaine[271,272]	Sacrococcygeal epidural	0.02–0.06 mg/kg	—
OTHER DRUGS			
Ketamine[150-152]	IV CRI	0.4–0.8 mg/kg/h	In conscious horses higher doses can be used as an adjunct to general anesthesia
Gabapentin[160,161]	IV, PO	5–20 mg/kg q 8–12 h	Low oral bioavailability; higher dosing may be needed; titrate dose to effect
Methocarbamol[236]	PO	40–60 mg/kg q 12–24 h	—
N-butylscopolamine[179]	IV	0.3 mg/kg	Lower doses may achieve desired clinical effect

IV, Intravenously; *PO,* orally; *IM,* intramuscularly; *SC,* subcutaneously; *CRI,* constant rate infusion.

a combination of drugs within these two classes, concurrent use of gastrointestinal protectants is suggested.

Most NSAIDs approved for use in horses (e.g., aspirin, phenylbutazone, ketoprofen, flunixin meglumine, diclofenac) work by inhibiting both COX-1 and COX-2. However, COX-2–selective NSAIDs (firocoxib and meloxicam) have been developed for horses, with the primary goal of reducing gastrointestinal side effects,[53-55] especially because NSAIDs may be used chronically in some horses. Meloxicam specifically may offer further benefit in foals, in which traditional NSAIDs have a higher risk of adverse effects because of prolonged clearance in foals compared with adult horses. Meloxicam is cleared more rapidly in foals than adults, which may result in improved tolerance to longer treatment durations.[56]

The use of a canine chewable tablet formulation of firocoxib has become popular with horse owners because of low cost and ease of use; however, the canine tablet has reduced bioavailability and reduced COX-2 inhibition in horses compared with the oral equine formulation.[57] Additionally, practitioners should be aware that use of the canine formulation may represent extralabel drug use depending on their country of practice. The same is true of the COX-2–selective NSAID carprofen, which is licensed for dogs but has been administered to foals in place of phenylbutazone because of perceived efficacy and lower toxicity.

Opioids

Opioids produce their effects by activating mu (μ), kappa (κ), or delta (δ) opioid receptors.[58] Available opioids include pure μ-agonists (e.g., morphine, methadone, fentanyl), partial μ-agonists (e.g., buprenorphine), and κ-agonist/μ-antagonists (e.g., butorphanol). Morphine is the prototypic μ-agonist with which all other opioids are compared.[59,60] Although traditionally pure μ-agonist opioids are considered to provide the most potent analgesic effects, butorphanol is reported to be equally as or more effective (with potentially fewer adverse effects) than μ-agonists in the treatment of gastrointestinal pain in horses.[60-63] Opioids, especially morphine, produce profound sedative effects when combined with α_2-agonists. This is commonly termed *neuroleptanalgesia* and can be useful in animals that are refractory to analgesia or when standing interventions are necessary.[64,65]

Opioid use in horses is often limited by the potential for adverse effects. μ-Agonists in particular are known to cause excitement, agitation, and increased locomotor activity in horses.[58,66,67] This may be explained in part by the location, density, and binding affinity of μ-opioid receptors in the equine brain.[68] Although this effect is well documented, the clinical importance is confounded by multiple variables, including potential bias in the studies because they were conducted using healthy, nonpainful horses. Dosages used in investigational studies may also be higher than dosages used clinically, contributing to excitatory effects.[69] As mentioned previously, coadministration with sedative drugs ameliorates the potential excitatory effects of opioids and augments sedation.[58,68] In painful horses, low to moderate doses of opioids have a calming effect and in some studies are associated with

improved anesthesia recovery quality,[70,71] but variability exists with respect to behavioral responses to opioids in horses. In other species for which extensive research exists, differences have been attributed to opioid receptor polymorphisms. A μ-opioid receptor polymorphism has recently been shown to significantly affect locomotor responses to fentanyl in adult horses.[72] Continued research in this area may help to clarify varying clinical observations regarding opioid use in this species.

A further untoward effect of opioids is that they can delay gastric emptying and prolong intestinal transit time. Because of this, opioids can predispose horses to constipation and colonic impaction, because water is absorbed from the slow-moving contents of the intestinal lumen.[73,74] Although it has been the authors' experience that horses receiving large doses of opioids such as morphine can show gastrointestinal stasis necessitating passage of a nasogastric tube to relieve gas, studies on the risk of colic associated with morphine use in horses undergoing general anesthesia are conflicting.[69,75-77] Most show no relationship between the perioperative use of morphine and gastrointestinal complications. In addition, pain itself may predispose horses to ileus.[78,79] Although the potential for adverse effects should not to be ignored, it should be noted that complications are most likely when opioids are used systemically at large doses.

Experimental studies on the use of opioids in horses continue to emerge as potential clinical benefits of this class of drugs are increasing recognized. Several new studies describe the pharmacology of specific opioids in horses, but the need for additional evidence to support specific clinical treatment protocols is great. For example, intravenous fentanyl appears to be a relatively ineffective analgesic with undesirable behavioral effects at the doses studied in adult horses,[80,81] but it has a sedative effect in foals at relatively low doses.[82] Buprenorphine shows promise as an analgesic because of its long plasma half-life in horses and its efficacy via sublingual administration.[83] Reports of significant buprenorphine-induced excitement or increases in locomotor activity exist in adult horses and foals, however, even when the drug is given in combination with a sedative.[84-86] The use of systemic opioids in horses will, therefore, continue to be challenged by the need for appropriate case selection and dose titration such that clinical benefits are achieved without undesired effects.

Systemic adverse effects can be mitigated via the use of alternative routes of administration. Routes that have been studied in horses with promising results include intraarticular, transdermal, perineural, and epidural administration. Intraarticular morphine, for example, has a profound and lasting analgesic and antiinflammatory effect and produces a more significant reduction in lameness than intravenous morphine in horses with synovitis.[87-90] Epidural morphine provides useful and prolonged analgesia for a variety of surgical procedures,[91-93] although dose-dependent decreases in gastrointestinal transit time are reported.[79,91]

α_2-Adrenoreceptor Agonists

α_2-Adrenoreceptor agonists (e.g., xylazine, detomidine, romifidine, medetomidine, dexmedetomidine) produce sedation, muscle relaxation, and analgesia via activation of central and peripheral α_2-receptors. Although drug effects are broadly the same, individual differences exist with respect to α_1:α_2-receptor selectivity, chemical structure, drug metabolism, and elimination. Sedation is attributed to activation of central nervous system α_2-receptors in areas of the brain that are responsible for awareness, arousal, and vigilance. Activation of α_2-receptors in the brain and spinal cord decreases the release of excitatory neurotransmitters and interferes with sensory processing and transmission, producing analgesia.[94]

α_2-Adrenoceptor agonists are profound visceral analgesics. This property is crucial in the management of moderate to severe colic. The use of α_2-adrenoceptor agonists can prevent injury to both practitioner and horse and allow critical diagnostic and treatment procedures to be performed. These drugs, however, may also mask signs of clinical deterioration,[95,96] especially if higher doses or drugs with longer half-lives are administered (e.g., detomidine).[97] Behavioral and possibly analgesic effects may be improved when α_2-adrenoceptor agonists are administered with opioids (e.g., butorphanol or morphine).[63]

The use of α_2-adrenoceptor agonists is not without significant adverse effects. Clinically, the administration of α_2-agonists for the purpose of analgesia is accompanied by varying levels of sedation, which may be undesirable. α_2-Adrenoceptor agonists also cause peripheral vasoconstriction and subsequent baroreceptor-mediated reflex bradycardia and bradyarrhythmias (e.g., second degree atrioventricular block).[98,99] The increase in afterload associated with α_2-adrenoceptor agonist administration causes a profound reduction in cardiac output,[99-101] which may be detrimental in a horse with cardiovascular compromise. As the vasoconstrictive effect wanes, a decrease in arterial blood pressure follows, which is caused by a decrease in central nervous system sympathetic output and continued bradycardia.[94,102] Decreases in cardiac output are relatively independent of dose.[103] In horses with severe hemodynamic compromise (e.g., strangulating colic), the benefits of the use of α_2-adrenoceptor agonists must be weighed carefully with the risk of cardiovascular collapse.

Other adverse effects of α_2-adrenoceptor agonists include occasional paradoxic excitement or aggression, changes in respiratory rate and tidal volume, upper airway obstruction caused by relaxation of pharyngeal muscles, hyperglycemia, increased urine production, and immediate and pronounced decreases in gastrointestinal tone and motility that can last well beyond the duration of the drug.[104-110] These effects are dose dependent but can be related to postoperative ileus and colic.[111] Increased urine production could exacerbate dehydration in a debilitated horse if supplemental fluids are not provided. Tachypnea is sometimes observed when febrile horses receive any of this class of drugs.

α_2-Adrenoceptor agonists can be administered as bolus doses or via constant rate infusion.[110] Like opioids, they can also be administered intraarticularly, perineurally, and epidurally. Intraarticular use of α_2-adrenoceptor agonists provides analgesia by an undetermined mechanism; regional and systemic effects (from drug absorption), however, are possible.[112] The potential for chondrotoxic effects of α_2-adrenoceptor agonists are currently under investigation, with early reports indicating the potential for chondrotoxicity with some but not all drugs in this class.[113,114] α_2-Adrenoceptor agonists have been shown to improve duration of analgesia provided by perineural local anesthetics.[115] Epidural administration of α_2-adrenoceptor agonists provides beneficial analgesia for surgical procedures.[93,116] Some α_2-adrenoceptor agonists (e.g., detomidine) demonstrate systemic effects, however, because they are rapidly absorbed from the epidural space.[116,117]

The effects of α_2-adrenoceptor agonists can be reversed with α_2-adrenoceptor antagonists (e.g., atipamezole, tolazoline, yohimbine, idazoxan).[111,118] When using these reversal agents, all α_2 effects, including analgesia, are abolished. If α_2-adrenoceptor antagonists are used in a situation in which pain is anticipated, the practitioner should plan to provide analgesia by an alternate method. The use of α_2-adrenoceptor antagonists has been associated with significant adverse effects in horses, including behavioral changes, tachycardia, hypotension, and death. Adverse effects are more often associated with high doses and rapid (e.g., intravenous) administration.[119] Assessment of peripheral α_2-adrenoceptor antagonists that retain beneficial central effects and reduce the negative cardiovascular effects of α_2-adrenoceptor agonists is ongoing.[120,121]

Local Anesthetics

Local anesthetics (e.g., lidocaine, mepivacaine, bupivacaine, ropivacaine) are frequently used alone or in combination with other analgesic drugs to produce loss of sensation. They may be administered topically, regionally (perineurally and epidurally), or systemically. Analgesia results from a blockade of sodium ion channels, which prevents the initiation and conduction of electrical activity (action potentials) in small-diameter (C, Aδ) sensory nerve fibers. Larger (clinical) doses of local anesthetics also block conduction in large fibers (Aβ), and when administered at certain sites (e.g., epidural, perineural to a mixed nerve) produce a loss of motor function and result in temporary motor paralysis.

The local anesthetic lidocaine when administered intravenously produces mild central nervous depression and has antiarrhythmic, antiinflammatory, free radical scavenging, and gastrointestinal promotility effects.[122-127] It also provides analgesia, decreases the requirement for inhalant anesthetics, and potentiates the analgesic actions of opioids or α_2-adrenoceptor agonists.[122,123,128,129] Because of variable cardiac toxicity, administration of other local anesthetic agents by this route is currently not recommended. Lidocaine produces minimal cardiovascular and respiratory effects in otherwise normal, healthy horses but can decrease cardiac output, arterial blood pressure, and heart rate when administered intravenously because of decreases in central nervous system sympathetic output, myocardial contractile force, and venous return.[123,128] Lidocaine infusion does not improve cardiovascular function in anesthetized horses despite decreases in inhalant anesthetic dose, and in certain circumstances it may predispose horses to a poorer quality of recovery from general anesthesia.[129-131]

Significant differences in metabolism, elimination, and the potential to produce central nervous system toxicity (disorientation, ataxia, and seizures) are seen among different local anesthetics.[125] Horses appear to be more sensitive to the neurotoxic effects than some other species, with large doses producing central nervous stimulation typified by nervousness, agitation, sedation, ataxia, and collapse.[132] Seizures have also been observed by the authors in clinical patients. Although less likely to occur in full-size adult horses, toxic doses may also be reached when these drugs are administered locally or regionally.

Local anesthetics can be administered epidurally to decrease the need for additional analgesics.[133] However, as mentioned previously, they have the potential to produce a loss of motor function (paralysis), which can become problematic in an animal as large as a horse. The horse may injures itself while unable to control its limbs or may becomes recumbent until the local anesthetic effect has worn off. Local anesthetic drugs can also cause respiratory paralysis when administered by epidural or spinal (subarachnoid) routes. Although unlikely unless excessive drug volume is administered inadvertently, the migration of local anesthetic cranially to the cervical region can paralyze the diaphragm, resulting in hypoventilation and apnea. To avoid these adverse effects of epidural local anesthetics, the authors recommend these drugs generally not be placed in epidural catheters and that the volume of local anesthetic drug when using the caudal epidural space be limited to 5 to 7 mL for an adult horse.

Intraarticular use of local anesthetics is common in equine practice for the diagnosis and management of lameness and surgery of the joints. Of concern is the potential for local anesthetic-induced chondrotoxicity, which has been clinically recognized in humans with the use of bupivacaine.[134] An *in vitro* investigation in the horse showed chondrotoxicity associated with bupivacaine, lidocaine, and mepivacaine, with mepivacaine considered the least toxic to cartilage and safest for clinical use.[135] A subsequent *in vitro* human study showed that chondrotoxic effects were worse in arthritic joints.[136] In contrast, a single injection of bupivacaine and lidocaine produced no increases in collagen degradation biomarkers in an *in vivo* study in healthy horses.[137] More data are necessary before the issue is clarified in horses, and practitioners should weigh potential risks with benefits in individual clinical scenarios.

Ketamine

Ketamine is commonly used as an anesthetic induction and maintenance agent in horses and also possesses important analgesic properties. NMDA receptor activation is critical to the development of hyperalgesia and central sensitization mediated through interaction with a number of other receptors.[138,139] Ketamine's antagonism at this receptor helps mitigate these effects. Analgesia may also be partly mediated via the monoaminergic pathway through ketamine-induced release of norepinephrine, dopamine, and serotonin.[138]

At anesthetic doses, ketamine increases heart rate, cardiac output, and arterial blood pressure in horses.[140] When used with a goal of preventing central sensitization as an adjunct to inhalant anesthesia, ketamine infusion both reduces inhalant dose requirement and improves cardiac output.[141] Beneficial cardiovascular effects are attributed to increased circulating catecholamines, even though ketamine in isolation is a direct myocardial depressant.[142,143] Nonsystemic routes of ketamine administration have also been used with some success. For example, short-term local anesthesia is observed when used perineurally in horses.[144] Similarly when administered epidurally, ketamine produces analgesia, but evidence of localized neuronal toxicity, especially with chronic use, limits its use in clinical patients.[145,146]

Behavioral side effects associated with ketamine use in horses must be considered. In humans, ketamine produces hallucinations[138]; in horses, the potential for excitement or delirium during ketamine use in anesthesia is a reality minimized by the provision of other drugs (e.g., α_2-adrenoceptor agonists).[140,147] Subanesthetic doses of ketamine used to prevent central sensitization do not seem to be associated with adverse behavioral effects in people, dogs, and cats.[148,149] In horses, low-dose infusions can be used with minimal to no behavioral effects.[150] Evidence of antinociceptive effect with this dosing of ketamine in horses is conflicting and clinical data are sparse, but subanesthetic infusions appear to be an

effective adjunct for the management of laminitic pain.[150-153] Prolonged infusions of ketamine lead to an increase in gastrointestinal transit time and decreased fecal output in healthy horses,[154] but similar data from clinical patients are lacking.

Magnesium

Like ketamine, magnesium owes its analgesic effects largely to its NMDA receptor blockade. Magnesium is also a calcium channel blocker, and although this attribute has historically been used in the treatment of hypertension and arrhythmias, it is also an important mechanism by which systemic administration of magnesium is used to help treat pain.[155] Although magnesium has not been studied as an analgesic in horses, it has been extensively studied in human medicine. Some data are conflicting, but overall it appears that magnesium reduces postoperative pain and opioid requirements after a variety of surgical procedures.[156,157] In an experimental setting, magnesium also potentiates analgesia provided by morphine and delays the development of morphine tolerance.[158] Adverse effects appear to be minimal with appropriate dosing but include hypotension, bradycardia, and sedation.[157]

Anticonvulsants

Gabapentin is an anticonvulsant drug that also has analgesic effects, which is likely caused by its interaction with the $\alpha_2\delta$-subunit on voltage-gated calcium channels, which is upregulated in chronic and neuropathic pain. In humans, gabapentin is considered a first-line drug for the treatment of neuropathic pain.[159] It has low oral bioavailability in horses.[160] Oral gabapentin given for 2 weeks at common clinical dosages (5–10 mg/kg every 8 hours) failed to reduce the lameness level of chronically lame horses compared with placebo treatment.[161] However, a relatively low oral dose appeared effective for treating neuropathic pain in a horse in one case report.[162]

When given intravenously, 20 mg/kg of gabapentin was associated only with very mild sedation,[160] suggesting this higher dosage could be used without significant adverse effects. In humans, appropriate dose titration may take several weeks to achieve.[163] More clinical data are necessary to determine whether this is a factor in the efficacy of gabapentin in horses. The primary dose-limiting adverse effect of gabapentin in humans is somnolence.[163]

Pregabalin is a similar drug with the same mechanism of action used as both an anticonvulsant and analgesic in humans. When given via nasogastric tube to healthy horses, bioavailability was high and sedation was the most common adverse effect.[164] Use of pregabalin in equine clinical patients has not been reported.

Tramadol

Tramadol is a synthetic weak μ-opioid receptor agonist and serotonin and norepinephrine reuptake inhibitor. Tramadol is not a controlled drug in many countries. There are several metabolites of tramadol, but *O*-desmethyl-tramadol (M1) is considered the primary analgesic metabolite because it has increased affinity for the μ-receptor compared with the parent compound.[165,166]

In pharmacokinetic studies, horses show wide individual variability in production of M1, and this metabolite has either not been detectable or measured in very low concentrations.[167-170] It is possible that horses efficiently glucuronidate the M1 metabolite, affecting M1 concentrations.[167] Regardless, tramadol did not have an antinociceptive effect in horses in multiple research models and caused excitement with increases in dose.[171-173] In clinical patients, tramadol was mildly effective at reducing pain in laminitic horses in multimodal approaches to pain control,[151, 174] and no adverse effects were seen when it was used as an adjunct to acepromazine, detomidine, ketamine, diazepam, and flunixin meglumine for castration.[175] Further study is necessary to determine the clinical utility of tramadol in horses, but it is currently not promising as a sole analgesic in this species.

Soluble Epoxide Hydrolase Inhibitors

Oxidative metabolism of polyunsaturated fatty acids is a critical step in the production of mediators important to the development of inflammation and pain associated with tissue damage. The most well-known group of drugs blocking this process is the NSAIDs, which prevent arachidonic acid metabolism via COX inhibition, as discussed earlier. However, the COX pathway is only part of a much more complex set of processes responsible for inflammatory and neuropathic pain.

Recently inhibition of the cytochrome P450–mediated transformation of polyunsaturated fatty acids into epoxides has been explored as a potential analgesic treatment for horses with laminitis.[176] Soluble epoxide hydrolase activity measured in the digital laminae is increased in laminitic horses, and experimental treatment with the soluble epoxide hydrolase inhibitor *t*-TUCB provided moderate improvement in clinical signs (e.g., limb lifting) and pain scores in a small group of laminitic horses in a recent clinical trial.[177] The novel nature of this treatment means that further research is needed before widespread use is adopted, but it represents a promising addition to a multimodal approach to pain control in horses with laminitis.

Acepromazine

Acepromazine is a phenothiazine tranquilizer that does not have inherent analgesic properties.[178,179] As such, it should not be used as a sole agent with the intent to provide analgesia, nor should its calming effects be interpreted as analgesic efficacy. Although not licensed for such use, acepromazine is used by veterinarians in combination with α_2-adrenoceptor agonists or opioids to augment sedation. The literature also suggests that acepromazine administration improves undesired locomotor activity associated with the use of opioids in horses.[58]

N-Butylscopolamine

Butylscopolamine is an anticholinergic and antispasmodic drug that has a short duration of effect on gastrointestinal pain and is used to treat spasmodic colic,[179-181] and it can be given in combination with other analgesic drugs. Because its duration of action is very short (20–30 minutes), a perceived benefit is that it will not mask pain from a deteriorating, nonspasmodic colic while still providing relief to horses with uncomplicated colic pain. It should be noted that the anticholinergic effect of this drug will increase the heart rate, which may complicate physiologic assessment of pain.

Methocarbamol

Methocarbamol is a skeletal muscle relaxant that has been used in horses for several years to treat discomfort associated with muscle spasms, and it is moderately orally bioavailable in horses.[182] Although there is considerable anecdotal evidence of its use to treat equine back pain, scientific data are lacking.

Bisphosphonates

Tiludronate and clodronate are bisphosphonate drugs used to treat bone-related pain in horses. Bisphosphonates distribute primarily to bone and inhibit bone resorption primarily via negative effects on osteoclasts and macrophages.[183,184] These drugs are given intravenously and intramuscularly, respectively, with a duration of effect of several months.

Small clinical studies with tiludronate have shown some improvement in lameness caused by navicular disease and distal hock arthritis,[185] and a larger double-blind, placebo-controlled trial for hock arthritis also demonstrated this drug's efficacy.[186] Tiludronate has also proven efficacious in the treatment of thoracolumbar vertebral pain in horses.[187] Although it has been administered during regional limb perfusion, its safety and the efficacy of this technique are not known.[188] Colic has been associated with the use of tiludronate in horses,[185] and varying degrees of renal damage have been demonstrated in humans with the use of different bisphosphonates.[189] Extensive clinical data regarding renal toxicity in horses do not exist. However, the potential for adverse effects should be strongly considered in horses before treatment, because anecdotal reports of renal damage are increasing. The practice of pretreating with flunixin meglumine to prevent tiludronate-associated colic signs is discouraged because of the concern for compounding nephrotoxicity.

Autologous Conditioned Serum (Interleukin-1 Receptor Antagonist Protein)

Interleukin-1 receptor antagonist protein (IRAP) is an antiinflammatory cytokine used in the treatment of equine osteoarthritis. Whole blood is collected and incubated with beads that enhance the production of IRAP.[190] Serum is then separated and injected intraarticularly. Clinically, IRAP improves lameness scores in horses with osteoarthritis compared with placebo.[191] Because the product is autologous and includes no drugs, it can be used in performance horses before competition.

SPECIFIC ANALGESIC TECHNIQUES

Epidural Catheters

Epidural catheters (Fig. 3.5) can be placed in horses to provide a safe and efficient way to administer repeated doses of analgesic drugs (e.g., opioids, α_2-adrenoceptor agonists) into the epidural space. Epidural catheter kits that can be used in horses are available commercially (Fig. 3.6). These catheters can be maintained successfully for several days to weeks. In clinical cases, patient-related complications (e.g., inflammation at the catheter insertion site) appear to be very infrequent when proper aseptic technique is used in the placement and maintenance of epidural catheters. The most common catheter-related complications in horses include dislodgement of the catheter or filter, loss of patency of the catheter, or catheter leakage.[192] Indwelling catheters do cause epidural inflammation and fibrosis, which may be responsible for loss of patency over time.[192,193] These issues do not preclude replacement with a new catheter but may make it more challenging.

Perineural Catheters

Continuous peripheral nerve block via the use of perineural catheters has been successfully used in human medicine for a variety of applications, including postoperative analgesia.

FIG. **3.5** An epidural catheter secured with a bandage, which prevents debris (such as straw or shavings) from contaminating the catheter.

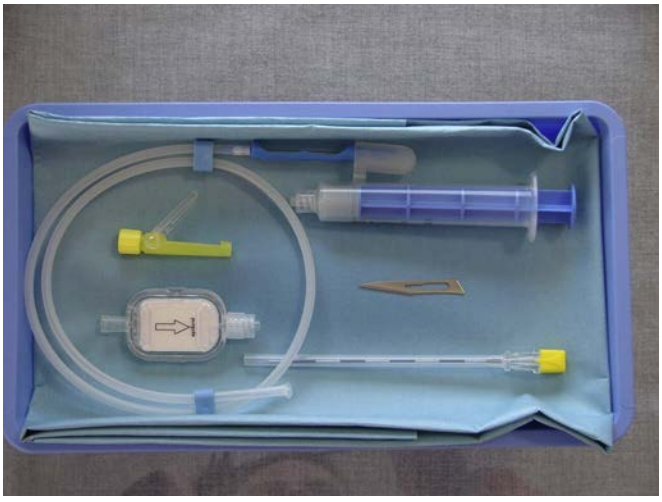

FIG. **3.6** Components of a commercially available epidural catheter kit, including scalpel blade, catheter, connector, filter, plastic loss of resistance syringe, and Tuohy needle for placement. (Photo courtesy Gregg Griffenhagen, DVM, DACVAA.)

This technique involves continuous infusion (or intermittent, low-volume boluses) of local anesthetics in catheters placed adjacent to peripheral nerves. A significant advantage of this technique is the ability to reduce or discontinue systemically administered analgesics, thus avoiding the systemic side effects of those drugs.[194-197]

In horses, this technique has been developed for use in the distal limb, in which a perineural catheter can be placed in a standing, sedated patient and maintained under a bandage thereafter (Fig. 3.7). Possible complications include inadvertent vascular or synovial structure puncture, local infection, nerve injury, and swelling or hematoma. Complications can be avoided by adhering to proper landmarks and using strict aseptic technique.[194,198]

Topical and Transdermal Drug Administration

Topical administration of analgesic drugs offers advantages to systemic drug administration. Application is directed over

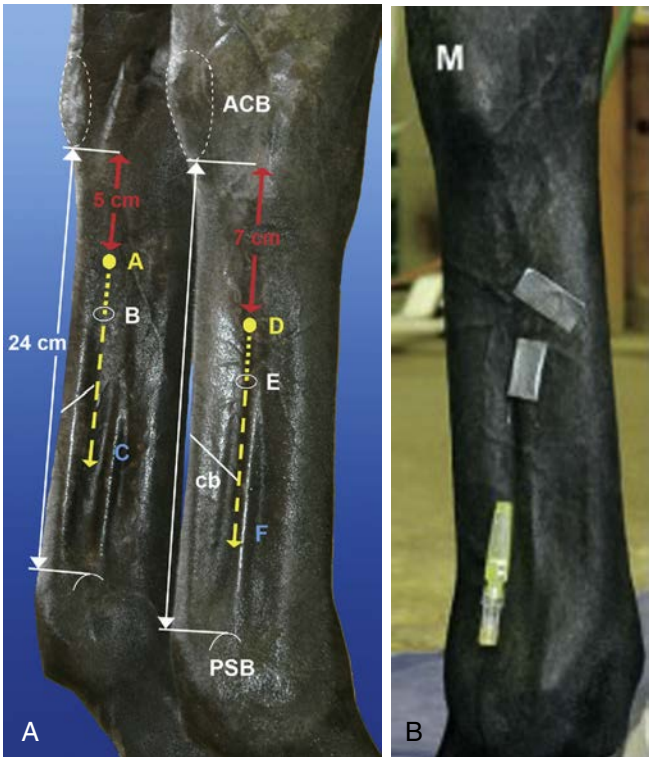

FIG. **3.7** (A) Anatomic diagram showing proper placement of a distal limb perineural catheter in the horse, 5 cm distal to the accessory carpal bone (ACB) on the medial aspect of the limb, and 7 cm distal to ACB on the lateral aspect. Dotted lines between points A and B and D and E represent the intended path for subcutaneous tunneling of the catheter. Dashed lines between points B and C and E and F represent the intended path for the subfascial placement of the catheter, ending distal to the communicating branch (cb) between the medial and lateral palmar nerves and proximal to the proximal sesamoid bones (PSB). (B) Perineural catheter secured in place on the lateral aspect of the left front limb of a horse. (Reprinted with permission from Elsevier. Driessen B, Scandella M, Zarucco L. Development of a technique for continuous perineural blockade of the palmar nerves in the distal equine thoracic limb. Vet Anaesth Analg. 2008; 35:432.)

the desired site of action such that the dose (and therefore side effects) may be reduced. The NSAID diclofenac is available in the United States in a liposomal formulation that has been shown to reduce clinical signs of lameness in horses with osteoarthritis, providing beneficial disease-modifying effects compared with systemically administered phenylbutazone.[199] This equine formulation is not available worldwide, and the use of topical diclofenac products formulated for humans has thus been adopted in many places. These formulations, however, do not offer similar absorption and efficacy, which is likely caused by differences between human and equine skin for which these products were not designed.[200]

Transdermal drug administration offers a method for continuously delivering systemic drugs over several hours or days. This is especially beneficial for drugs with a short duration of effect, such that multiple bolus doses can be avoided. The opioid fentanyl, for example, is widely available as a transdermal patch designed to provide controlled fentanyl release for 72 hours. Intravenous administration of fentanyl has been associated with adverse behavioral effects and questionable analgesic efficacy in horses. In contrast, transdermal fentanyl has not been associated with untoward side effects, and there are promising reports of clinical efficacy in horses in pain.[201] Pharmacologic data, however, show widely variable absorption in both adult horses and foals, in which effective plasma concentrations were not reached in all individuals.[202,203]

Several factors may affect patch efficacy, including improper patch placement and premature patch removal. Conditions under which the patch is applied (e.g., whether hair is clipped and the area cleaned) or anatomic location of the patch on the horse might also affect absorption. Location-dependent differences in absorption could be related to differences in the thickness of the stratum corneum or differences in cutaneous blood flow. *In vitro* work with horse skin suggests that absorption through the groin or thorax is superior to absorption through skin on the distal limb.[204]

COMPLEMENTARY THERAPIES

Complementary techniques may play an important role in multimodal analgesic management of horses. Acupuncture, chiropractic manipulations, massage, and extracorporeal shock wave therapy have been adopted and successfully used by equine veterinarians.[205] At their introduction, these therapies were used in horses with primarily anecdotal evidence, but scientific data on these modalities are emerging, especially as they become increasingly popular with horse owners.

Acupuncture

Acupuncture is purported to act by restoration of energy flow via stimulation of certain points on channels or "meridians" within the body.[206] Points can be stimulated with needles alone, injected substances, or electrically ("electroacupuncture").[207] Modern scientific research has shown that analgesia is produced by the stimulation of specific (acupuncture) points and not produced by similar stimulation of other points on the body.[208] The analgesic effect results from modulation of nociceptive input at the level of the dorsal horn of the spinal cord through activation of antinociceptive pathways and the release of endogenous opioids.[209] Acupuncture is an appealing modality because of its relative safety and lack of systemic drug levels, which allows its use in performance horses during competition.

In horses, acupuncture and electroacupuncture have positive effects on endorphin release and cutaneous analgesia.[207,210] Electroacupuncture has also been used to increase pain threshold in an experimental rectal distention model.[211] Clinical results, however, have been inconsistent. In one study, electroacupuncture may have provided clinical improvement in horses with chronic lameness, but differences from controls were not significant.[212] In a more recent study of naturally occurring palmar heel pain, acupuncture failed to consistently affect pain in those horses.[213] Further research into the use of acupuncture as a clinical modality is needed to define which conditions might benefit the most from this treatment.

Extracorporeal Shock Wave Therapy

Extracorporeal shock wave therapy is used to treat a variety of musculoskeletal injuries in horses, including osteoarthritis, back pain, stress fractures, tendonitis, and desmitis.[214] Although the exact mechanism of action is not known, the basic principle is that when focused, pulsed, high-energy waves are applied to the injured area, they lead to neovascularization and tissue remodeling.[214,215] In some studies, shock

wave therapy produced acute local analgesia for 48 to 72 hours after treatment,[216,217] which has raised concern about potential catastrophic injury in performance horses subjected to work after minor injury and subsequent treatment. However, in further studies with specific lesions, shock wave therapy did not reduce lameness in the immediate posttreatment period, and its acute analgesic effect in these cases has been questioned.[15,218] Nevertheless, shock wave remains a viable potential adjunct therapy in a multimodal approach to analgesia.

Chiropractic Manipulations

Chiropractic manipulations rely on "high-velocity, low-amplitude" manual thrusts that attempt to restore normal joint motion and improve tissue function of the equine spine.[219] These factors might be negatively altered by an underlying pathologic condition, such as limb lameness.[220] Addressing this additional potential source of pain could theoretically improve the overall clinical condition, especially if the underlying condition is also managed. Chiropractic manipulations change the kinematics of horses with back pain, increase mechanical nociceptive thresholds in healthy horses compared with controls, and reduce cervical muscle activity.[219,221,222] The significance of these findings with respect to acute or chronic pain control is unknown.

Low-Level Laser Therapy

Low-level lasers ("cold lasers") have become a popular therapeutic adjunct in the equine veterinary world. Cold lasers are typically relatively low power and nonthermal, such that tissue damage is avoided while beneficial effects are achieved. There is anecdotal support from performance horse owners regarding the use of laser therapy in the treatment of acute and chronic musculoskeletal pain. Despite enthusiasm for this modality, strong scientific data supporting the use of lasers in the horse are sparse.[223] Evidence of laser therapy as an analgesic, antiinflammatory, and aid to wound healing is emerging in human medicine and research models.[224-226] Studies suggest that possible mechanisms of action include modulation of local inflammatory mediators (e.g., prostaglandins, tumor necrosis factor-α [TNF-α]) and reduction or alteration in inflammatory cell infiltration or distribution.[227]

A wide variety of cold lasers are marketed that can be sold directly to horse owners.[228] Lasers are classified on a 1 to 4 scale by the U.S. Food and Drug Administration or by the International Electrotechnical Commission based on the level of potential operating hazard, with higher classes being more powerful and also more likely to cause injury if improperly operated.[229] Lasers available for equine therapy come from one of the two highest classes: class 3B or class 4. Class 4 lasers are typically more expensive, more powerful and more efficient and can treat larger or deeper areas. Protocols and laser types used in human medicine vary across studies, and there is no scientific consensus as to the most appropriate laser or protocol for use in equine therapy. Positive results from human studies, however, should encourage further research on laser therapy in horses, which will help to clarify the place of cold laser therapy in management of equine pain.

SUMMARY

Equine practitioners have more tools now than ever before to assess and manage pain. Detailed pain scales improve clinical pain assessment, and promising clinical studies have emerged showing benefits of many different drugs and nontraditional analgesic techniques. In addition, the importance of treating pain and the use of multimodal techniques is more and more widely accepted. Although pain management in the horse continues to be challenging, the increasing availability of pharmacologic and complementary options provides a reason for optimism.

CHAPTER 4

Critical Care

Samuel D. Hurcombe*

INTRODUCTION

The development of critical care in equine medicine has truly evolved over the past 20 years to deliver high-level care to the sickest patients, both adult horses and foals. To this end, critical care has developed into a specialty stream of medicine in its own right in which many of the leading hospitals and foundation criticalists have pushed the envelope in advancing care to our equine patients with improved outcomes. The development of the American College of Veterinary Emergency and Critical Care (ACVECC) large-animal group was formed and has somewhat legitimized equine critical care as a specialty in its own right. Both members of ACVECC, many of whom are also specialists in internal medicine or surgery, and other like-minded clinicians around the world, are skilled to run an intensive care unit (ICU) and deliver urgent and immediate care. However, there are still significant challenges and clinical obstacles to overcome, yet this exciting field of study is changing rapidly and will surely continue to do so.

Critical care is provided to an animal whose condition is typically severe, life-threatening, and acute. Early recognition of a disease state or complex condition is needed to execute a diagnostic or therapeutic plan, which oftentimes has a significant impact on the outcome. For example, in human emergency departments, the administration of antimicrobials within 60 to 180 minutes of sepsis diagnosis is significantly associated with improved survival.[1]

Intensive care is a dynamic process. Patient condition can change minute to minute, and oftentimes these patients require fine-tuning of a therapeutic plan over several days. As such, this is time-consuming, detail oriented, tiring, and often physically demanding. Therefore a team of personnel including clinicians, technicians, and barn staff is best suited to the ICU setting to optimize patient care.

Patients in the ICU setting are better suited segregated from a general hospital population. There is a twofold positive effect. First, ICU patients are often sick, immunocompromised, and may be at risk of developing opportunistic infection. Second, certain ICU populations may be at higher risk of shedding infectious organisms like salmonella. For example, juvenile horses admitted for gastrointestinal disease, administration of antibiotics, and fasting are such examples.[2]

In addition to dedicated stalls and personnel, some key equipment for diagnostic and therapeutic purposes are necessary to deliver optimal care. Fluid pumps, electrocardiographic (ECG) capabilities, ultrasonography, and point-of-care clinicopathologic testing capabilities are a few examples. However, there is no greater asset in an ICU than methodical, detail-oriented personnel that serially evaluate their patients and are in tune with even subtle changes.

There are no randomized, controlled studies that advocate for the provision of critical care medicine and improved survival outcomes. The precedent has been set time and again in human medicine where, in many instances, dedicated personnel, personalized care, early goal-directed therapies, and novel therapies result in greater survival, shorter duration of stay in the hospital, decreased morbidity, and lower hospital costs. More studies are needed in veterinary medicine to support similar outcomes in equine practice.

The provision of critical care to horses is at the purview of equine clinicians; however, certain criteria appear to be universal among specialists, which include horses with parenteral fluid requirement to support the cardiovascular system, systemic inflammatory response syndrome ([SIRS]; both septic and nonseptic causes), (poly)trauma, hemorrhage, cardiovascular collapse, malignant dysrhythmia, respiratory distress (notably lower respiratory dysfunction), acute abdominal disease (surgical and medical), seizure disorder, and acute neurologic decompensation, to name a few.

Therapeutic goals for all patients include providing appropriate care for the primary problems, anticipating complications and initiating appropriate preventive therapy, and providing appropriate supportive care for all vital body systems.

In this chapter, salient features of the critically ill patient profile, diagnostic options, and immediate life-saving therapeutics for specific body systems will be provided. Additional specific information on select medical conditions will be covered in Chapter 20.

EQUINE INTENSIVE CARE UNIT

Equine ICUs are becoming increasingly prevalent in clinical practice. Common features include housing of patients according to type or severity of illness with appropriate biosecurity precautions; readily available equipment for diagnosing,

*The editors and authors acknowledge and appreciate the contributions of J. Hardy, P. Marsh, P. Mooresey, B. Barr, B. Waldridge, and Y. Nout as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

monitoring, and treating the seriously compromised horse; and 24-hour staffing with professionals who have the knowledge and experience to treat these patients. The goals of the ICU are to provide comprehensive care and improve patient outcomes while using tools and resources that promote efficiency.

Several studies describe the general case population and commonly performed procedures and treatments of patients admitted on an emergency basis to large university referral centers.[3,4] Because equine emergencies are relatively common among patients requiring critical care, such information provides an initial database for understanding population dynamics and the required expertise when staffing the ICU. Colic or acute abdominal pain is the most common type of case encountered in emergency/critical care centers, and studies show that expertise is required that can handle both medical and surgical needs. However, the fact remains that a variety of other problems present as emergencies, and the required skills to deal with these include experience with dysfunction of most all body systems. Each ICU population will reflect the local horse population type, and regular review of hospital populations is useful to appropriately allocate resources (staff and equipment) to meet the unique needs of the region.

Human ICU treatment requires a multidisciplinary team that includes intensivists (i.e., physicians who specialize in critical illness care), nurses, respiratory care therapists, dieticians, pharmacists, and other consultants from a broad range of specialties, such as surgery, internal medicine, and anesthesiology. Because of patient numbers, costs of therapy, and limitations of certain aspects in equine practice, the range of specialists is often consolidated to fewer, multiskilled, broadly trained individuals.

Integral to the ICU are licensed veterinary technicians who provide intensive and continuous care. Generally, good nursing care is pivotal to successful outcomes. The technical staff are the "eyes and ears" of the ICU and are trained to identify early subtle changes in patient status and feel comfortable using a range of equipment. The ability to perform common techniques and to recognize changes in condition early is essential.

Box 4.1 lists basic, intermediate, and advanced equipment that may be used in the ICU. Again, based on patient populations, if a practice rarely sees critically ill foals, purchase of a mechanical ventilator would be a poor economic choice. Regular review of equipment to ensure it is in working order as well as training for all personnel on new equipment are essential.

Commonly performed procedures include patient monitoring, fluid administration, and attention to and provision of appropriate analgesia. Monitoring includes close, astute observation and serial physical examinations. Use of diagnostic techniques and laboratory support are adjunctive measures that complement competent observation to monitor the systemic health of the patient. Parenteral fluid administration encompasses routine administration of a wide range of products, including crystalloids, synthetic colloids, blood, and blood components. Choosing analgesia in the ICU will depend on the type and severity of pain experienced by the patient (e.g., inflammatory pain versus neuropathic pain). The clinician needs to consider potential adverse effects that also may influence the primary disorder (e.g., limiting morphine use in the abdominal patient to minimize ileus). Multimodal analgesia techniques are being used that have the purported benefits of analgesia being delivered through several mechanisms of action while using lower total doses to the patient.

Emergency drugs should be readily available and accessible within seconds to minutes in any hospital. Mobile crash carts and drug bags/packs strategically located around the hospital are advisable. Drug expiration dates should be regularly monitored and expired medications replaced. Table 4.1 lists several emergency drugs and dosages used in adult horses. Having emergency drug cheat sheets located in several key areas with volumes, routes, and indications listed helps all ICU personnel deliver safe, appropriate care in an emergency situation.

In addition, assembling packs for specific anticipated emergency situations, such as all the necessary items for delivering supplemental oxygen or supplies to perform an urgent tracheotomy, and placing these packs in key areas is recommended.

Essential monitoring equipment commonly used in the ICU includes an ECG, a blood pressure monitor, a point-of-care glucometer and lactate meter, a point-of-care electrolyte and chemistry analyzer, an ultrasound unit, a centrifuge for hematocrit determination, a refractometer for determining total protein and urine specific gravity (SG), and urine test strips for urinalysis. Other monitoring tools to consider are a hemocytometer, microscope with 100× magnification, equipment for cytologic examination (including Gram stains), and a blood gas and electrolyte monitoring unit. A colloid osmometer is useful for determining colloid osmotic pressure (COP) in hypoproteinemic horses.

Advanced imaging is becoming more common, and the use of ultrasound has become an essential component of diagnosing and monitoring critically ill patients. Ultrasound can be used for identifying and monitoring effusions, intestinal distention, and motility; identifying umbilical structures; monitoring pregnancy; and visualizing ocular structures, among other anatomic areas. To enable imaging of a wide variety of

BOX 4.1 Equipment List for Different Levels of Equine Intensive Care Units

BASIC

- Fluid administration system: coil sets and fluid hooks
- Electrocardiogram
- Centrifuge
- Refractometer
- Glucose meter
- Lactate meter
- Urinalysis strips
- Microscope for cytologic examination/Gram stain
- Ultrasound including Doppler capability
- Oxygen tank and regulator
- Biosecurity equipment and personnal protective equipment

INTERMEDIATE

- Blood gas/electrolyte/glucose analyzer
- Complete blood count capability
- Coagulation profile testing
- Blood pressure monitor (direct and indirect)
- Intravenous fluid pump delivery systems
- Sling and hoist for down horses

ADVANCED

- Pulse oximeter
- Mechanical ventilator
- Colloid osmometer
- Capnograph
- Continuous electrocardiogram telemetry
- Syringe infusion pumps

TABLE **4.1 Emergency Drugs Used for Adult Horses**

Drug	Dose	Dose per 1000 lb	Route	Comment
Atropine	0.01–0.02 mg/kg	0.3–0.45 mL	IV	Bradycardia; rescue therapy for severe bronchoconstriction
Dobutamine (positive inotrope)	2–10 μg/kg/min (1 vial [250 mg] in 1000 mL = 250 μg/mL)	900–4500 μg/min	IV	Use diluted solution within 24 h; it is compatible with most IV fluids; do not mix with alkaline solution calcium chloride/gluconate
Doxapram (respiratory stimulant)	0.2 mg/kg	4.5 mL	IV or topical under tongue	Do not mix with alkaline drugs/ fluid
Epinephrine For anaphylaxis For asystole	 0.01–0.02 mg/kg 0.1–0.5 mg/kg	4.5–9 mL	IV/IM/SC/ Intratracheal	Do not give with bicarbonate, hypertonic saline, or aminophylline It does not need to be diluted when given IV to adults Double volumes when given intratracheally
Furosemide	0.5–1.1 mg/kg	5–10 mL	IV	Pulmonary edema, diuresis, congestive heart failure
Glycopyrrolate (for bronchodilation and bradycardia)	0.001–0.005 mg/kg	2.25–11.25 mL	IV/IM/SC	Do not mix with alkaline drugs/ fluids
Lidocaine (treatment of ileus)	1.3 mg/kg loading slowly over 5 minutes 0.05-mg/kg/min infusion	Loading: 30 mL Infusion: 67 mL/h	IV	Ensure that product does not contain epinephrine
Lidocaine (treatment of arrhythmias)	Bolus: 0.25–0.5 mg/kg (slowly) Infusion: 20–50 μg/kg/min	Bolus: 5–10 mL Infusion: 30–60 mL/h	IV	Ensure that product does not contain epinephrine
Aminophylline	5 mg/kg	2.5 g	Nebulized	

IV, Intravenously; *IM,* intramuscularly; *SC,* subcutaneously.

structures, access to a variety of transducers ranging from 2.5 to 10 MHz, as well as a rectal probe, is recommended.

Oxygen provision for supplementation through nasal insufflation, demand valve access, or for mechanical ventilation should be available. Compressed gas cylinders can be used but must be stored and handled appropriately to prevent injury. Oxygen cylinders can be fitted with a diameter index safety system for connection to a demand valve. At peak flow, a demand valve can provide up to 160 L/min of oxygen. For each cylinder type, knowledge of the capacity of the cylinder and the flow rate enables calculation of the amount of time provided. The small portable E cylinders contain 655 L of oxygen when full and can provide oxygen for 260 minutes when set at a flow rate of 5 L/min. Adult horses may require flow rates of 10 to 15 L/min to have any significant effect on the fraction of oxygen inspired (Fio_2). Larger G or H cylinders containing 5290 or 6910 L, respectively, allow oxygen supplementation for longer periods.

The design of the ICU should accommodate the care of horses with a wide variety of problems. All stalls should have the equipment necessary for hanging large-volume fluid bags. Stalls should be free of objects that could cause injury. In addition, the design should include one or two stalls for easy unloading of down horses, and the structure must be able to withstand hoisting. A track system to hoist horses off a trailer and transport to a surgical table or ICU stall would be a welcome feature. Commercially made glides are also essential to facilitate safe movement of down horses. If care of neonatal patients is expected to be routine, large foaling stalls should be available. These stalls may feature mobile separators to facilitate treatment of foals while allowing them access to their dams.

A central office facilitates oversight of the entire unit. A central viewing station with either cameras or direct visualization of stalls is ideal. The ICU should have adequate storage and be uncluttered. Hand sanitizer, wash sinks, and boxes of gloves should be easily accessible. Hand washing between patients is essential to prevent spread of nosocomial infection.

Food preparation areas should be separate, and operators should be diligent in washing hands to prevent cross-contamination of pathogens in feed.

In the ICU, strict disinfection and isolation protocols should be in place to prevent nosocomial infections and the spread of infectious disease. In addition to hand washing, hand rubbing with an alcohol-based solution is more effective than hand washing with an antiseptic, probably because it does not require rinsing and drying of hands.[5]

Guidelines and standard operating procedures (SOPs) can be applied to a variety of aspects of the ICU; for example, guidelines for the use of antibiotics, guidelines on how to handle multidrug-resistant pathogens, SOPs for personnel injuries, and so forth. It is recommended that each ICU establish "best practice regimens" to optimize care, minimize complications and mistakes, and maximize patient survival and personnel safety.

The overarching goal of critical care is to support and treat the patient such that normal homeostatic mechanisms

become fully functional and independent of exogenous support. Treating and preventing shock, in all its various forms, is a common theme among patients. Provision of care that maintains oxygen and cellular metabolic substrate delivery to meet the unique demands of the patient is key. The clinician often focuses on a specific disease process or even organ system. However, because of the systemic consequences of several pathologic processes (e.g., inflammation, neoplasia), methodical and serial evaluations of the entire patient are important. This allows the practitioner to identify problems early with hopes of instituting early intervention and avoid morbidity. Severely ill patients require special attention. Their condition is dynamic and can change quickly. These patients may require rechecking key indices such as coagulation panels or ionized electrolyte concentrations as frequently as each hour. Cardiac rhythm reassessment or direct blood pressure measurement may be required on a minute-by-minute basis (continuous telemetry is particularly beneficial in these patients).

Expected and unexpected problems can be encountered in the ICU patient. Horses with focal disease (e.g., injection site abscess) that by itself is unlikely to be life-threatening can develop multisystemic consequences that jeopardize the patient (e.g., hemolytic anemia, fever, anemic hypoxia, and pigment nephropathy). Oftentimes, the development of serious problems can be a consequence of a ramped up immune system and SIRS. In health, inflammatory pathways can be regulated by antiinflammatory pathways. When the balance tips in favor of inflammatory pathways, overwhelming activated systemic inflammation ensues and downstream effects can be observed, such as coagulopathy or acute respiratory distress syndrome (ARDS), which may be seemingly unrelated to the primary disease process.

Medication mistakes can be categorized in two main categories: therapeutic-related unexpected adverse effects in the patient and administration mistakes made by the ICU staff. An example of an adverse effect would be the development of antibiotic-associated colitis (AAC). Horses with acute gastrointestinal disease represent the most common admission to the ICU. In many instances, these patients are stressed, inappetent (often forcibly), and often require intestinal surgery, all of which are considered to be selection pressures for intestinal dysbiosis.[2] These horses also are frequently treated with antibiotics in the perioperative period, which, with preexisting pressures, can lead to life-threatening colitis. It is prudent for the clinician to exercise good judgment on antibiotic usage and try to institute early enteral feeding where possible to help avoid AAC.

Medication administration mistakes can also occur. A recent article highlighted that poor compliance to medication recommendations occurs more frequently than anticipated.[6] Mistakes can be minimized by having clear medical records that list the generic name of the medication, the dose (e.g., number of milligrams), the amount of units delivered (e.g., milliliters), route of administration, and frequency of dosing: for example, gentamicin, 3000 mg (30 mL), intravenously (IV), q 24 h.

ICU orders should be reviewed by a supervising clinician and signed off on as a check and balance, especially when multiple users may be following and carrying out these orders. Daily rounds with ICU personnel on the patient condition, current treatment and monitoring plan, and a discussion of potential complications is highly informative for ICU staff and helps maintain an open line of communication to ensure that the orders are clearly understood.

Adult Horse: Basic Procedures in Critical Care

Samuel D. Hurcombe

Expedient acquisition of important physiologic and physical findings in the critically ill horse is essential to formulating an initial diagnostic and/or therapeutic plan. Regardless of the nature of the particular condition presented to the clinician, expertise in a variety of technical procedures is required to facilitate diagnostic and therapeutic efforts.

VASCULAR ACCESS AND ADMINISTRATION OF FLUIDS

Establishing venous access is often crucial in critical care. Generally, using large veins (i.e., jugular veins, lateral thoracic veins, cephalic veins, and rarely saphenous veins) for access makes it easier to catheterize and deliver medications, fluids, parenteral nutrition (PN), and perform blood draws for clinicopathologic monitoring. IV catheters are available in varying materials, constructions, lengths, and diameters (Tables 4.2 and 4.3). In choosing a catheter, the practitioner should consider the desired fluid rate, fluid viscosity, the length of time the catheter will remain in the vein, the severity of the systemic illness, and the size of the animal. Determinants of catheter flow rate follow the Poiseuille-Hagen law: larger lumen diameter (r), shorter length (L), and higher pressure differences (ΔP) between flow into the catheter versus flow out of the catheter result in greater volumes per unit time through the catheter (Poiseuille-Hagen equation of flow through a tube [e.g., catheter]):

$$\text{Flow } \alpha \text{ Pressure gradient } (\Delta P) \times \text{radius } (r)^4/\text{viscosity } (\eta) \times \text{length } (L)$$

In cases in which volume provision is critical, placement of short, large-bore catheters using a pressurized fluid bag would optimize fluid delivery. Viscosity (η) of the fluid administered also modulates a flow rate in which higher viscosity fluids (i.e., natural colloids, blood, blood products) result in slower rates of fluid administration. Cautious use of high flow rates may be more traumatic to the vascular endothelium, increasing thrombotic risk.

Catheters are generally made of Teflon or polyurethane. The thrombogenic properties of each material should be taken into consideration with the patient's clinical condition. Polyurethane catheters (i.e., MILA International) are considered to be less thrombogenic than Teflon; therefore, it is recommended to use this material in patients with clinical coagulopathy or "at risk for" clinical coagulopathy. Typically these patients are horses with hypoproteinemia; SIRS; those requiring blood products, PN provision, endotoxemic/hemorrhagic shock, septicemia/bacteremia; and horses with inherited or acquired coagulopathic disease. Teflon catheters should be changed every 3 days, and polyurethane catheters can remain in the vein for up to 2 weeks. Regardless of the type of catheter, the site of vascular access should be closely monitored several times daily for signs of flow disturbance, thrombosis, and/or infection.

For most applications, over-the-needle catheters are easiest and faster to place and achieve therapeutic goals in adult

TABLE **4.2 List of Available Catheters (by Material Type)**

Material	Example	Comment
Polypropylene	Polyethylene tubing, Medicut	Highly thrombogenic not recommended
Teflon	Angiocath	Less thrombogenic
Polyurethane	MILA	Much less thrombogenic
Silastic	Centrasil	Least thrombogenic

TABLE **4.3 Commercially Available Catheters (by Construction Type)**

Type	Description	Advantage	Disadvantage
Butterfly	Needle attached to tubing	Ease of use	Laceration of vessel; vessel puncture and extravascular administration
Over-the-needle	Stylet inside catheter for venipuncture	Available in large diameter, ease of insertion	Limited length of catheter, not flexible, break at catheter and hub junction
Through-the-needle	Short needle inserted; catheter threaded through needle	All lengths available, flexible, peel-away needle	Technically more difficult to insert
Over-the-wire	Needle serving as guide to insert wire, which serves as guide for catheter	Flexible, long catheters available, ensures proper catheter placement	More technical expertise required to place catheter, expensive

horses. Over-the-wire (OTW) catheters are more technically challenging to place; however, they are often better tolerated long term and are less traumatic to the vascular endothelium. OTW catheters come in single-lumen and multilumen models and are often placed in foals and adult horses at high risk for thrombotic complications or patients in which multiple solutions may be administered, especially hyperosmolar/hypertonic solutions. OTW catheters are recommended for lateral thoracic vein catheterization caused by the acute angulation that the vessel travels into the thorax. Ultrasound guidance can assist in catheter placement at this location, particularly in obese and edematous horses.

Short- and long-extension sets are available as well as small-bore and large-bore diameters. Using an extension set with a Luer lock that screws into the hub of the catheter is best to prevent dislodgment. In horses with low central venous pressures (CVPs), disconnection of the line can result in significant aspiration of air and cardiovascular collapse, notably from jugular venous catheters. Moreover, one-way hemostatic valves are also available to help prevent backflow of blood and aspiration of air.

Horses receiving multiple infusions (i.e., crystalloid fluids and continuous rate infusions [CRI's]), may benefit from double extensions in which each fluid/medication type has an individual port entering a central line catheter rather than "piggybacking" fluids into each other.

Catheter Maintenance and Care

Before using any placed catheter, drawing back on the catheter to ensure intravascular placement is advised. Catheters should be flushed frequently with heparinized saline (10 units/mL) before and after each medication administered and every 4 to 6 hours after catheter placement. For some catheters that are infrequently used, a "heparin lock" comprised of 20 units/mL heparinized saline instilled in the catheter, followed by line clamps, may help preserve the integrity of flow. Provision of an antithrombotic such as clopidogrel (4 mg/kg PO once, then 2 mg/kg PO every 24 hours) has been used to help prevent thrombotic catheter complications despite proven efficacy.

Injection caps should be changed daily or sooner if excessively perforated with multiple injections. Before inserting a needle, injection caps should be wiped with 70% isopropyl alcohol and allowed to dry.

Catheters and extension sets may be secured using adhesive glue for short-term catheters or directly sutured to the skin using 2-0 nonabsorbable suture material. Care should be taken to ensure that no part of the catheter is exposed when being secured.

Each line can be labeled and the utmost care should be exercised to never break the circuit of any solution containing glucose (e.g., supplemented crystalloid solutions or PN) to help prevent catheter and line sepsis. Some practitioners apply triple antibiotic ointment to insertion sites to prevent infection, although evidence is lacking about the efficacy of this practice. If infection is suspected, the catheter should be removed and the catheter tip should be cultured (aerobic and anaerobic).

Coil sets are used for stall-side fluid administration for most adult horses. These are advantageous because they allow the horse to move around, lie down, and eat without restraint. An overhead pulley system with a rotating hook prevents fluid lines from becoming tangled.

Solution administration sets are used for short-term fluid or drug administration and typically deliver 10 drops/mL. Long coiled extension sets can then be used to connect fluids to the horse.

Calibrated pumps allow continuous even delivery of solutions at designated flow rates (CRI). When using a calibrated fluid pump, one should take care to use the appropriate set calibrated for the brand of pump. These pumps have alarms that signal air in the line, an empty fluid bag, or catheter problems.

TABLE **4.4 Parameters Used for Estimation of Dehydration in the Horse**

% Estimated Dehydration	Heart Rate (Beats per Minute)	CRT (Seconds)	PCV/TP (%/g/dL)	Creatinine (mg/dL)
6	40–60	2	40/7	1.5–2
8	61–80	3	45/7.5	2–3
10	81–100	4	50/8	3–4
12	>100	>4	>50/>8	>4

CRT, Capillary refill time; *PCV,* packed cell volume; *TP,* total protein.

The maximal fluid rate that most commercial pumps can deliver is 999 mL/h, which is insufficient for crystalloid delivery in most adult horses. Infusion pumps are useful for PN, multimodal analgesia, prokinetic therapies, and cardiovascular drugs, to name a few. Some clinicians advocate CRI antibiotic administration for time-dependent drugs (i.e., β-lactams) to minimize peak-trough pharmacodynamics and potential periods of subtherapeutic (sub–minimum inhibitory concentration) drug delivery.

For large-volume fluid delivery, peristaltic or oscillation infusion pumps are available that can deliver up to 40 L/h. One must supervise these pumps constantly when in use because they continue to run even if fluids run out. Large-bore catheters should be used to prevent trauma resulting from the jet effect on the endothelium of the vein.

FUNDAMENTALS OF FLUID THERAPY

The provision of fluid therapy to adult horses is a pivotal modality in treating the critically ill equine patient. Dehydration is detectable clinically when the deficit comprises 5% or greater. Fluids can be delivered in several methods but most commonly enterally and IV. Intraperitoneal and intraosseous delivery is less commonly used but possible with specific indications. Parenteral fluids should be administered to horses who cannot tolerate enteral fluids (i.e., gastrointestinal obstruction, esophageal trauma, dysphagia, and/or dehydration estimates exceeding 5%). Enteral fluids are often more cost-effective and indicated in cases with mild volume deficits (≤5%) and may be more effective for certain conditions than parenteral fluid delivery (e.g., colonic impaction) and maintenance therapy.

Rational Fluid Therapy Planning

An understanding of fluid types and properties as well as the needs of the patient are essential to design a fluid therapy plan. The clinician should consider several key questions that facilitate developing a fluid regimen:

1. What volume of fluid is required?
2. What rate of fluid is required?
3. What type of fluid is required?
4. What specific circumstances (physical and physiologic) do you need to consider?

The volume of fluid required is determined based on the clinical and clinicopathologic data gleaned from a thorough clinical examination and minimum database laboratory work. Skin turgor, heart rate, mucous membrane color and texture, eye position, neurologic status, serum creatinine concentration, and packed cell volume with total protein estimates help the clinician determine a deficit, often expressed as a percentage of body weight. Maintenance fluid requirements should be combined along with either quantification (i.e., number of liters of enterogastric reflux) or estimates of ongoing fluid losses to calculate a total volume deficit/requirement for the first 24 hours.

The rate of fluid administration depends on the severity of the critical illness. Horses with profound deficits and cardiovascular compromise require expedient delivery of resuscitative fluids.

The type of fluid also varies, depending on the critical nature. Replacement crystalloids typically have higher sodium and chloride concentrations than maintenance solutions that have lower sodium and higher calcium, potassium, and magnesium concentrations. Hyperosmolar solutions and/or colloid solutions may also be indicated, and, together with isotonic crystalloids, all three types should be considered.

Special circumstances to consider when delivering fluid therapy include patients with renal failure. Both volume and content of fluid choice should be considered depending on the clinical disease process—for example, anuric renal failure versus acute tubular necrosis of the proximal convoluted tubule (PCT) and abnormal fractional electrolyte clearances. Horses with decreased oncotic pressure may not tolerate high-volume crystalloid therapy without adjunctive colloid support.

Cardiopulmonary arrest, while dire in nature, is the ultimate form of congestive heart failure, and judicious limited fluid therapy to allow for enough circulation of cardioactive therapies is indicated without excess loading of the vascular circuit.

Maintenance Requirements

In the adult horse, maintenance fluid requirements have been estimated at 40 to 60 mL/kg per day. This volume likely overestimates the actual needs of a resting, fasted animal but appears to be safe in most situations. Smaller breeds may be more appropriately dosed at 60 mL/kg per day, and heavier breeds (e.g., draft horses) are more appropriately dosed at 40 mL/kg per day. In horses with renal failure, monitoring of body weight, CVP, and ideally urine output is indicated. If weight gain, edema, or increased CVP (>12 mm Hg) is evident, the fluid administration rate should be decreased if not stopped and other renal replacement therapy (RRT) considered.

Fluid Deficit

Practical evaluation of hypovolemia caused by dehydration is a subjective estimate using both clinical and clinicopathologic findings. Table 4.4 lists useful parameters for evaluating acute, extracellular dehydration.

After obtaining an estimate of dehydration, the clinician can calculate the amount of fluids to be given as follows (Table 4.5):

$$\text{Volume (Liters)} = \text{Body Weight (kilograms)} \times \text{Percent Dehydrated (expressed as a decimal)}$$

TABLE **4.5 Commonly Used Equations in Critical Care**

Maintenance fluids requirement (mL)	40–60 mL/kg/day
Fluid deficit calculation (L)	Body weight (kg) × percent dehydrated (expressed as a decimal)
Electrolyte deficit for monovalent electrolytes in abundance in the ECF space (e.g., bicarbonate)	Body weight (kg) × 0.3 (ECF coefficient) × ($[Electrolyte]_{desired}$ – $[Electrolyte]_{measured}$)
Shock rate of isotonic crystalloid (mL)	80–100 mL/kg in the first 60–90 min
Blood transfusion volume (L)	($[PCV_{desired}$ – $PCV_{patient}]$ × body weight [kg] × 0.08 [blood volume coefficient])/PCV_{donor}
Osmolarity (mOsm)	2 × [Na] + glucose/18 + BUN/2.8 (when glucose and BUN are measured in mg/dL)
Mean arterial pressure (mm Hg)	⅓ × (SAP – DAP) + DAP
Pulse pressure (mm Hg)	SAP – DAP
Cerebral perfusion pressure (mm Hg)	MAP – ICP
Abdominal perfusion pressure (mm Hg)	MAP – IAP
Content of oxygen in arterial blood (Ca_{O_2} [mL O_2/dL])	(1.34 × [hemoglobin] × Sa_{O_2}) + (0.0031 × Pa_{O_2})
Delivery of oxygen (mL/minute)	Q (cardiac output) × Ca_{O_2}
Oxygen extraction ratio	(Ca_{O_2} – Cv_{O_2})/Ca_{O_2} or (Sa_{O_2} – Sv_{O_2})/Sa_{O_2}
Alveolar P_{O_2} (Pa_{O_2})	Fi_{O_2} × ($P_{atmosphere}$ – P_{H_2O}) – Pa_{CO_2}/0.8
A-a gradient	PA_{O_2} – Pa_{O_2}

ECF, Extracellular fluid; *PCV,* packed cell volume; *BUN,* blood urea nitrogen; *SAP,* systolic arterial pressure; *DAP,* diastolic arterial pressure; *MAP,* mean arterial pressure; *ICP,* intracranial pressure; *IAP,* intraabdominal pressure.

Continued Ongoing Losses

Objective quantification of ongoing losses is ideal but seldom truly reflective of all volume deficits. Even measuring enterogastric reflux volume still does not account for the third spaced volume of fluid within the bowel that remains. This remaining volume does not contribute to effective circulating volume and, as such, quantification of reflux in the bucket underestimates the true volume deficit. Horses with high-volume diarrhea can also lose significant volumes as well as third space volume within the large reservoir of the large colon and cecum.

Regardless of the nature of ongoing losses, frequent clinical and clinicopathologic reassessment of the patient is imperative to minimize further deterioration. Heart rate, measurement of packed cell volume, total protein, and L-lactate concentration are clinically useful every 2 to 6 hours, depending on the nature of critical illness.

Daily creatinine concentration assessment and urinalysis are indicated in patients with azotemia until laboratory values normalize. Additional means of monitoring adequate fluid delivery may include measurement of CVP, arterial blood pressure, and urine output.

The fundamental basic principle of establishing a fluid therapy regimen centers on choosing an appropriate volume as follows (see Table 4.5):

$$\text{Fluid requirement (initial 24 hours)} = \sum (\text{fluid deficit} + \text{estimated losses} + \text{maintenance needs})$$

This is a starting point and subject to change based on clinical response of the patient.

Fluid Choices

Isotonic crystalloid fluids almost always constitute the foundation of any parenteral fluid therapy regimen. The type of crystalloid fluid to administer depends on the results of a chemistry evaluation and disease of the patient. Generally, an appropriate volume is most critical. However, when several options are available, one should decide between a balanced electrolyte solution (BES) or isotonic saline (0.9% NaCl) as the baseline fluid. Additives can then be added à la carte to treat specific electrolyte and/or metabolic derangements.

Table 4.6 lists the composition of various commercially available fluids. Generally, BESs are chosen when serum electrolytes are close to normal or when chemistry analysis is unavailable, because BESs are generally considered more physiologic.

Physiologic saline might be preferable in conditions in which potassium restriction is indicated (e.g., hyperkalemic states, such as hyperkalemic periodic paralysis, uroperitoneum, renal failure) because BESs all contain some potassium. BESs, by their nature, also have buffering ability. Lactate in lactated Ringer's solution (LRS) requires hepatic metabolism; thus, LRS may not be an ideal choice in horses with liver dysfunction. In cases of long-term fluid maintenance therapy (greater than 4–5 days), if the oral route is not available, the practitioner should consider half-strength basic fluids (e.g., 0.45% NaCl and 2.5% dextrose) to which potassium and calcium are added. Long-term fluid therapy with routine BESs can result in hypernatremia, hypokalemia, hypomagnesemia, and hypocalcemia.

Routine electrolyte supplementation often includes calcium, potassium, and magnesium provision. This is particularly important when the horse receives limited or no enteral intake (e.g., gastrointestinal disease). These electrolytes are important for smooth muscle function, vascular tone, and intestinal smooth muscle activity.[7,8]

Suggested doses of calcium depend on ionized calcium concentrations. Routine supplementation with 10 mL of 23% calcium gluconate per liter of fluids is used by the author as a starting point. Potassium chloride can be supplemented at up to 0.5 mEq/kg per hour maximum parenteral rate. The author starts at 0.05 mEq/kg per hour for routine supplementation and 1 g magnesium sulfate per liter of fluids.

Horses with high anion gap metabolic acidosis (e.g., lactic acidosis) are often hypobicarbonatemic because of increased buffering of organic acid production. In most instances, this represents a type A lactic acidosis, such as perfusion-mediated hyperlactatemia. As such, volume restoration to optimize systemic perfusion should be the first

TABLE **4.6 Crystalloid Solutions Available for Fluid Therapy**

Product	Approximate pH	mOsm/L	Na (mEq/L)	K (mEq/L)	Ca (mEq/L)	Mg (mEq/L)	Cl (mEq/L)	Buffer (mEq/L)
Lactated Ringer's solution	6.5	273	130	4	3	—	109	Lactate 28
Lactated Ringer's solution and 5% dextrose	5	525	130	4	3	—	109	Lactate 28
Plasma-Lyte A	7.4	294	140	5	—	3	98	Acetate 27 Gluconate 23
Plasma-Lyte 148	7.4	294	140	5	—	3	98	Acetate 27 Gluconate 23
Plasma-Lyte 148	5.5	294	140	5	—	3	98	Acetate 27 Gluconate 23
Plasma-Lyte 56 and 5% dextrose	5	362	40	13	—	3	40	Acetate 16
5% dextrose	4	252	—	—	—	—	—	—
0.9% NaCl	5	308	154	—	—	—	154	—
7% NaCl	—	2400	1196	—	—	—	1196	—
5% dextrose and 0.9% NaCl	4	560	154	—	—	—	154	—
5% dextrose and 0.45% NaCl	4	280	77	—	—	—	77	—
5% $NaHCO_3$	8	1190	595	—	—	—	595	—
8.4% $NaHCO_3$	—	2000	1000	—	—	—	1000	—
1.3% $NaHCO_3$ (must be mixed)	—	308	154	—	—	—	1541	—

step in treating the acidosis; however, in extreme cases, supplemental bicarbonate ($NaHCO_3$) treatment may also be required.

Horses receiving bicarbonate therapy should have their respiratory function assessed because carbon dioxide (CO_2) generated from carbonic anhydrase activity requires normal alveolar ventilation for effective CO_2 removal. Respiratory compromise will result in worsening of acidemia caused by mixed metabolic and respiratory acidosis.

For horses with a pH ≤7.2 caused by metabolic derangements (nonrespiratory) following shock crystalloid dosing (80 mL/kg in 1 h), isotonic bicarbonate (1.3%) therapy is indicated. First, administer 50% of the bicarbonate deficit (see later) rapidly over 1 to 2 hours followed by the remaining 50% over 12 to 24 hours.

Note that parenteral bicarbonate solutions are incompatible with calcium-containing solutions. The 1.3% sodium bicarbonate solutions are isotonic, and 8.4% sodium bicarbonate solutions are hypertonic (1 mEq/mL). To make a 1.3% $NaHCO_3$ solution, remove 130 mL of water from a 1-L sterile water bag. Add 130 mL (130 mEq) of 8.4% $NaHCO_3$ to the sterile water bag.

$$\text{Bicarbonate deficit} = (\text{Bicarbonate}_{\text{desired}} - \text{Bicarbonate}_{\text{measured}}) \times \text{body weight (kilograms)} \times 0.3 \text{ (extracellular fluid [ECF] compartment coefficient; see Table 4.5)}$$

For ongoing losses of bicarbonate not associated with excessive plasma buffering (e.g., hypersecretory diarrhea, renal tubular acidosis), enteral supplementation is a suitable option. The deficit is calculated and the number of milliequivalents converted to a weight (in grams):

$$1 \text{ g } NaHCO_3 = 12 \text{ mEq } NaHCO_3$$

The total number of grams is divided into several administrations per day. Orally administered $NaHCO_3$ may cause minor caustic injury to the gingival mucosa. Mixing $NaHCO_3$ with Karo syrup or molasses and washing the mouth after the horse swallows may help prevent injury.

Rate of Administration

For patients in severe shock, the clinician should strive to administer a shock dose of isotonic crystalloid fluids in the first hour (80 mL/kg), which can be done only with pressurized bags, a fluid pump, and/or multiple catheters.

In other situations, the volume calculated accounting for losses, replacement, and maintenance represents a volume for the 24-hour requirements and estimates as a volume per hour. Accurate record keeping of a running tally of fluids provided is important to ensure that the correct amount is administered.

ORALLY ADMINISTERED FLUIDS

Oral fluids are indicated in horses with only mild volume deficits and who can tolerate enteral fluids (e.g., no intestinal obstruction or reflux). Oral fluid therapy should be administered using the fluid composition shown in Table 4.7. One should administer calcium separately because it causes

TABLE **4.7 Fluid Composition for Orally Administered Fluid Therapy**

For Every L of Water, add:	FOR EVERY 21 L OF WATER
Electrolyte	**Amount (g)**
NaCl	10
$NaHCO_3$	15
KCl	75
K_2HPO_4	60

precipitation of the solution. This electrolyte solution meets daily needs for an adult horse and can be given through a small, preplaced nasogastric feeding tube or by intermittent intubation.

Parenteral Fluids

Crystalloids

The IV administration of isotonic crystalloids immediately reconstitutes effective circulating volume. Crystalloids (all types) rapidly redistribute out of the vascular space (VS) to the entire ECF space. The ECF is roughly 30% of body weight, and the VS is roughly 8% of body weight. As such, to maintain a desired expanded intravascular volume, 3 to 3.75 times as much volume is required to account for redistribution among the entire ECF. BESs are typically chosen such as LRS. Doses of BESs for rapid volume expansion (not maintenance fluid requirements) are 70 to 90 mL/kg per hour with frequent (every 20 minutes) reassessment of additional volume needs.

Replacement Solutions

Lactated Ringer's Solution

LRS has a lower sodium concentration and higher chloride concentration than equine plasma. LRS should be avoided in cases of hyperkalemia because of low levels of potassium and when administering products containing citrate or bicarbonate, because the calcium in LRS may precipitate. Lactate in LRS is metabolized by the liver and, in theory, may accumulate and contribute to metabolic acidosis in patients with hepatic dysfunction.

Plasma-Lyte 148 and Normosol-R

Plasma-Lyte 148 and Normosol-R are similar to LRS but have a more physiologic sodium:chloride ratio and contain magnesium rather than calcium. They may be administered concurrently with blood products and bicarbonate but should be avoided in cases where neuromuscular blockade is a concern (e.g., botulism). The alkalinizing agents in these fluids are acetate and gluconate, respectively.

Normal Saline (0.9% NaCl)

Normal saline consists solely of sodium and chloride in concentrations significantly higher than that of plasma. Saline is acidifying and is useful in the treatment of patients with hyperkalemia and metabolic alkalosis. The use of normal saline in cases of hyponatremia is cautioned because overly rapid correction of sodium concentrations may lead to excessive osmotic draw of water from cells.

Hypertonic Saline Solution (7.2% NaCl)

Hypertonic saline solution (HSS) is approximately eight times the tonicity of plasma and ECF, and the immediate effect is to rapidly expand the vascular volume by redistribution of fluid from the interstitial and intracellular spaces. The rapid increase in vascular volume improves cardiac output (CO) and tissue perfusion with rapid administration of only a relatively small volume of fluid. Initially, this is a roughly 1:3 ratio—that is, for every liter of HSS administered, the patient recruits up to 3 L of volume expansion. This effect is short-lived (estimated to be ~20 minutes). Because the electrolytes redistribute across the ECF, fluid redistribution occurs again and the patient becomes hypovolemic again. Because the principal effect is fluid redistribution, a total body deficit still exists and it must be replaced. For this reason, concurrent or immediately following HSS administration, isotonic crystalloids must be provided to correct the total body volume deficit. The duration of effect of hypertonic solutions is directly proportional to the distribution constant, which is the indexed CO. The dose is 2 to 4 mL/kg, administered as rapidly as possible. Iatrogenic metabolic acidosis, hypernatremia, and hypokalemia may occur after hypertonic saline administration; therefore, plasma electrolyte concentrations should ideally be evaluated in the patient before and after the administration of hypertonic saline.

Maintenance Solutions

Crystalloid maintenance fluids are polyionic isotonic or hypotonic fluids formulated for long-term use in patients needing chronic fluid support beyond fluid volume resuscitation. They contain lower sodium and higher potassium, calcium, and magnesium concentrations. Examples include Plasma-Lyte 56, Normosol-M, and 0.45% NaCl/2.5% dextrose, and these fluids should not be used for rapid volume expansion.

Colloids

Colloid fluids contain large molecular weight particles that do not readily diffuse across healthy cellular barriers, maintaining or increasing COP within the intravascular space. These molecules do redistribute to the ECF but at a much slower rate than crystalloids; thus, the duration of effect is prolonged compared with that of crystalloids. Table 4.8 describes the different colloids available. Critically ill patients often develop endothelial dysfunction, and the associated increased vascular permeability may ameliorate some of the beneficial effects of colloids, dependent, in part, on the average molecular size of the colloid administered. For example, hetastarch (6% hydroxyethyl starch) has an average molecular size of 450 kDa, and albumin in plasma has a molecular size of 70 kDa. Further, meta-analyses in humans failed to support the theory of improved resuscitation through the use of colloids over crystalloids[9]; however, colloids may be indicated in patients with hypoproteinemia, severe blood loss, or those in need of clotting factors or immunoglobulins.

A disadvantage of natural colloids (plasma or albumin) is that they are more antigenic and can cause allergic reactions. Synthetic colloids have a much lower antigenicity, but they can cause bleeding disorders because of their tendency to coat platelets or by causing a decrease in coagulation factors. In the horse Dextran 40 can cause anaphylactoid reactions. Hetastarch administration can cause a decrease in coagulation factors and prolong clotting times, particularly at high doses (20 mL/kg).[10]

TABLE **4.8 Characteristics of Colloid Solutions Available for Fluid Therapy**

Characteristics	5% Albumin	25% Albumin	Dextran 40	Dextran 70	Hetastarch (600/0.75) 6%	Tetrastarch (130/0.4) 6%
Molecular weight (d)	—	—	—	—	—	—
Average	69,000	69,000	40,000	70,000	450,000	130,000
Number average	69,000	69,000	25,000	39,000	70,000	
Range	—	—	10,000–80,000	15,000–160,000	10,000–3,400,000	110,000–150,000
Solvent	—	—	0.9% saline or 5% dextrose	0.9% saline or 5% dextrose	0.9% saline or balanced electrolyte solution	0.9% saline
Maximum water binding (mL/g)	18	18	37	29	20	—
Concentration (%)	5	25	10	6	6	6
Half-life	14–16 days	14–16 days	2.5 h	6 h	25 h	12 h (human)
Plasma percentage (after 24 h)	—	—	18	29	38	—
Extravascular percentage (after 24 h)	—	—	22	33	39	—
Overall survival in blood	—	—	44 h	4–6 weeks	17–26 weeks	—
Colloid osmotic pressure (mm Hg)	20	100	40	—	30	36

Synthetic colloids do not register on a refractometer. Accurate evaluation of oncotic pressure requires the use of a colloid osmometer. If one is not available, the clinician must use clinical evaluation (e.g., observing the presence of edema and poor circulatory volume and pressure).

Synthetic Colloids

Hetastarch is a more cost-effective synthetic colloid. Advantages of hetastarch include maintenance of plasma oncotic effect for up to 24 hours following administration and the ability to give as a rapid bolus.[10,11] However, unlike plasma, there are no functional proteins present in hydroxyethyl starch solutions and a negative effect on coagulation has been demonstrated in healthy equids.[10,12] Further, a 2013 review of the use of colloids as volume replacement in critically ill humans found an increased risk of mortality and acute kidney injury in patients receiving hetastarch.[13] As such, the use of hetastarch in horses with underlying renal insufficiency is cautioned, and its use is restricted to those with clinical signs of acute hypoproteinemia. Recently tetrastarch (6%) was evaluated and shown to have a more sustained effect on COP with fewer adverse coagulopathic effects than hetastarch.[14] Both hetastarch and tetrastarch can be dosed at 10 mL/kg.

Natural Colloids: Plasma

Plasma contains not only osmotically active albumin but a variety of essential proteins, including clotting factors, immunoglobulins, and antithrombin III. The advantage of plasma over synthetic colloids is that these proteins provide carrier sites for exogenous (pharmaceuticals) and endogenous (hormones) compounds. Disadvantages of plasma as a resuscitation fluid in horses include the prolonged time required for administration, a relatively short duration of oncotic effect, the potential for adverse reactions (10% incidence),[15] and the relatively high cost if given for large-volume resuscitation.

Whole Blood

Whole blood can be considered the ultimate colloid replacement fluid when indicated in cases of hemorrhage.[16] Blood transfusion may restore circulating volume, improve oncotic activity, increase oxygen-carrying capacity, is a supply vehicle for therapeutic drug transport, and replenishes coagulation factors. Whole blood is the ideal fluid for blood loss or platelet loss, provided that it is fresh blood and has been cross-matched. It is important to remember that stored blood loses its oxygen-carrying capacity and it can take several hours to restore it after administration.

Access to whole-blood donors that are free of erythrocyte antigenic determinants, particularly Aa and Qa, and of isoantibodies are important hores to have available to ones practice. The practitioner can perform a major and minor cross-match to select an appropriate donor, provided that complement is added to the test for hemolysin detection. Interpretation of the minor cross-match may be difficult if autoagglutination is present. If cross-matching is unavailable, use of a non-Thoroughbred gelding is advised. Up to 20 mL/kg can be safely collected every 3 weeks in adult horses, and whole blood can be collected in sodium citrate using sterile technique provided the product will be used immediately.

Commercial blood collection kits are also available. The reported incidence of transfusion reactions is 16%,[17] and a recent study showed a marked decrease in transfused erythrocyte half-life with an incompatible cross-match (4.7 days versus 33.5 days).[18] Complications of blood transfusion include acute anaphylactic reactions, allergic reactions, hemolysis, fever, tachypnea, and hypocalcemia caused by citrate chelation.

Critical Care Techniques

Samuel D. Hurcombe

MONTORING ARTERIAL BLOOD PRESSURE

The goal of blood pressure measurement is to identify hypotension and follow the response to therapy after interventions. Mean arterial blood pressures (MAPs) of greater than 70 mm Hg are targeted in the adult, and pressures greater than 60 mm Hg are targeted in neonates. Table 4.9 shows expected blood pressures in healthy conscious horses. Hypertension is uncommon in horses. Pheochromocytoma, pain, and transient hypertensive states associated with pressor agents have been described.

Arterial blood pressure can be measured by direct catheterization of a peripheral artery or by indirect measurements that depend on a cuff placed over an artery and cuff inflation until blood flow is occluded. Blood pressure can also be calculated as the product of CO and systemic vascular resistance (SVR). The MAP is a surrogate estimate of tissue perfusion but does not necessarily correlate with blood flow through the tissue. For example, a hypovolemic patient with high SVR may have a MAP within an acceptable range; yet, the actual volume of blood per unit time flowing through the tissue (e.g., perfusion volume) might be inadequate. Horses can have low MAP as a result of hypovolemia, SIRS, heart failure, or any of a wide variety of disorders.

Most monitoring equipment provides an estimation of systolic arterial pressure (SAP), diastolic arterial pressure (DAP), and MAP. MAP is a calculated value determined by integrating the area under the pressure waveform and dividing this by the duration of the cardiac cycle. MAP can also be calculated by MAP = ⅓ × (SAP − DAP) + DAP (see Table 4.5).

Pulse pressure is the difference between systolic and diastolic pressure (SAP − DAP; see Table 4.5). A bounding pulse pressure results from an increased systolic pressure, a decreased diastolic pressure, or both. Conversely, a poor or weak pulse quality indicates little difference between SAP and DAP. Ultimately, pulse pressure is not a good surrogate of perfusion, and clinical markers of perfusion or quantitative methods of CO are required for improved accuracy.

TABLE **4.9 Hemodynamic Parameters in Adult Horses**

Type of Pressure	Blood Pressure Reading
Arterial pressure	
Mean arterial pressure (indirect)	>60 mm Hg
Mean arterial pressure (direct)	106 ± 12 mm Hg
Systolic (indirect)	111.8 ± 13.3 mm Hg
Systolic (direct)	142 ± 18 mm Hg
Diastolic (indirect)	67.7 ± 13.8 mm Hg
Diastolic (direct)	82 ± 12 mm Hg
Central venous pressure	8–12 mm Hg (6–18 cm H_2O)

Data from Magdesian KG. Monitoring the critically ill equine patient. *Vet Clin North Am Equine Pract*. 2004; 20:11-39; Hurcombe SD, Scott VHL. Direct intraabdominal pressures and abdominal perfusion pressures in unsedated normal horses. *J Vet Emerg Crit Care*. 2012; 22(4):441-446.

Oxygen delivery to tissues depends on adequate perfusion of functional capillary density (FCD) of the tissues. FCD has recently become a research interest in veterinary species in which dark-field microscopy has been used to evaluate gingival and colonic perfusion.[19] Clinically, FCD quantification techniques are impractical; thus, blood pressure is used to estimate blood flow and tissue perfusion. MAP as a perfusion estimate does not account for local regulation of tissue bed blood flow. Regional shunting, regional vasomotor tone differences, microthrombi, and interstitial edema may all affect local blood flow. Blood flow through a vessel is also dependent on the viscosity of the fluid (blood) and the radius of the vessel. At high viscosity blood flow may be impaired. Severe vasoconstriction, although maintaining blood pressure, may impair flow.

Direct (Invasive) Blood Pressure Measurement

A 20-gauge or 22-gauge over-the-needle catheter is most commonly used to perform direct or invasive blood pressure measurement. Suitable sites for catheterization include the transverse facial, facial, and greater metatarsal arteries (Fig. 4.1). In the standing horse the transverse facial or the facial artery are most practical. Catheters are placed toward the direction of blood flow (i.e., toward the heart), and noncompliant tubing filled with heparinized saline is used to connect the catheter to a calibrated pressure transducer. It is important to flush all air from the circuit to avoid dampening of the waveform.

Blood pressures are measured in millimeters of mercury (mm Hg), which measures the force exerted by the blood against an area of the vessel wall to raise a column of mercury by a certain number of millimeters. Occasionally, centimeters of water (cm H_2O) are used where 1 mm Hg = 1.36 cm H_2O. Continuous readings of blood pressure are most useful clinically and can be graphically displayed using an electronic transducer that converts a pressure signal to an electronic output. The transducer and flush device (Pressure

FIG. **4.1** Adult horse with an arterial catheter in the transverse facial artery for direct blood pressure monitoring.

Monitoring Kit with TruWave disposable pressure transducer; Edwards Lifesciences, Irvine, CA) then can be used for continuous blood pressure measurement. The transducer should be maintained at the level of the heart base, which is estimated to be at the point of the shoulder. Pressure recording systems should be zeroed to atmosphere before reading from the patient.

When the waveform appears flat or dampened, the line and catheter should be flushed to yield a "square wave." When the flush is stopped, the arterial waveform should resume. This test also evaluates the dampening status of the circuit. Immediately after flushing, wave oscillations are observed before beginning the next arterial waveform. Two oscillations are considered normal. An overdamped system (e.g., clot in the catheter, air bubble in connection tubing) results in fewer oscillations and lower magnitude. An underdamped system (e.g., long stiff tubing) results in a greater number of oscillations.

Indirect (Noninvasive) Blood Pressure Measurement

Indirect blood pressure measurements depend on a cuff placed around the tail (coccygeal artery) or the metatarsus (metatarsal artery). The diameter of the cuff influences the accuracy of the measurement, and cuffs that are too wide result in underestimation of the blood pressure. An ideal cuff width-to-circumference ratio of 0.25 to 0.35 has been recommended for use on the tail or limbs of horses. Cuff widths are available for neonate, pediatric, and adult horses.

FIG. **4.2** Indirect oscillometric blood pressure cuff applied to the tail (coccygeal artery) of this 27-year-old Miniature Horse. Lower left inset is a close-up of the tail cuff. Lower right inset is the electronic indirect blood pressure reading. This horse had apparent blindness and was found to have hypertensive cardiomyopathy on echocardiography.

Doppler (Systolic Arterial Blood Pressure)

Doppler uses a small ultrasound probe placed on a peripheral artery, and a piezoelectric crystal within the probe converts the pulse wave into an audible signal. The probe must be placed over a shaved area (usually under the tail of the horse) after application of a coupling gel. Doppler only measures systolic arterial blood pressure.

Oscillometric Sphygmomanometry

Oscillometric sphygmomanometry relies on detecting changes in oscillations generated by changes in blood flow during gradual deflation of a cuff. Oscillations are initially detected once the cuff pressure decreases to be equal to the systolic pressure. Maximal oscillations are detected when cuff pressure is equal to the mean pressure and then disappear when the cuff reaches diastolic pressure. The meter records and displays systolic, diastolic, and mean pressures (Fig. 4.2).

Photoplethysmography

Photoplethysmography relies on the detection of arterial volume by attenuation of infrared radiation. Photoplethysmography originally was designed for use in human fingers and has been validated for use in small dogs and cats but has not been evaluated for use in horses.

CENTRAL VENOUS PRESSURE

Monitoring Central Venous Pressure

CVP is the hydrostatic pressure within a large central vein, typically the cranial vena cava, and is an estimate of right atrial filling pressure. The CVP is affected by vascular volume, venous tone, and cardiac function. Monitoring CVP is most useful for patients in which the veterinarian is attempting to maintain adequate vascular volume without fluid overload. For example, assessment of CVP may be useful in horses with oliguric or anuric renal failure, horses with large-volume gastric reflux, and horses predisposed to edema formation. The venous system has high volume capacitance, which makes CVP quite insensitive to subclinical volume overload. By the time CVP measurements increase, transvenous fluid shifts, and interstitial edema and volume overload have likely occurred.

Conversely, negative CVP values may reflect hypovolemia, indicating a need for fluid therapy.[20] As with measurements of arterial blood pressure, the trend in CVP seen through repeated monitoring is most informative.

CVP is measured by using an IV catheter placed in the jugular vein and terminating in the intrathoracic portion of the cranial vena cava. The catheter is attached via an extension set to a water manometer positioned such that the pressure is at the level of the base of the heart (point of the shoulder), or it can be connected to an electronic transducer. The latter is preferred by the author because the typical CVP waveform can be visualized to confirm accurate location of the catheter tip. Normal CVP in adult horses is 8 to 12 mm Hg (6–18 cm H_2O).

EMERGENCY TRACHEOSTOMY

Acute respiratory distress referable to obstruction of the upper respiratory tract represents a true emergency and need to establish a patent airway. It is important for the clinician to make a rapid assessment of that patient to determine the anatomic location (upper versus lower respiratory tract) of obstruction

BOX 4.2 Materials Needed for an Emergency Tracheostomy Pack

Local anesthetic (2% without epinephrine)
20-gauge needle and 10-mL syringe
Sterile, disposable no. 10 surgical blade
Metzenbaum scissors
Hemostats
J-type tracheostomy tube or self-retaining tube

and to decide if a tracheostomy is indicated. Box 4.2 shows the typical equipment needed for a tracheostomy.

When possible, the clinician should clip and prepare the planned incision site and infiltrate it with 2% local anesthetic. In cases of true acute respiratory obstruction, the patient may be in such distress that surgical preparation is unnecessary. At this time, the operator should not waste time and immediately perform the tracheostomy without preparation. The clinician makes an 8- to 10-cm longitudinal incision at midline at the junction of the proximal and middle third of the neck, just above the V made by the junction of the sternothyrohyoideus muscles. Blunt dissection with Metzenbaum scissors is used to expose the tracheal rings. Next, an incision is made between two tracheal rings, taking care not to damage the tracheal cartilages. This incision should be no more than 50% of the circumference of the trachea. In emergency situations a J-type tracheostomy tube is used because of its ease of insertion. When the horse is calm, or if the situation is not critical, a metal self-retaining tube is preferable for maintenance because J-tubes tend to fall out. Silicone-cuffed tubes are also available for closed-system ventilation.

The tracheostomy tube should be cleaned daily and changed as needed. The surgical site should be cleaned with dilute antiseptic, and saline with petroleum gel applied around the incision prevents skin scalding. Generally, but particularly in foals, tracheostomy tubes should be removed as early as possible to avoid permanent tracheal deformity. To help decide when to remove the tube, the clinician can occlude the tube temporarily to see if the horse can breathe without it. After the tube is removed, the site should be cleaned of exudate twice daily and allowed to heal by second intention. It is the author's opinion that broad-spectrum antibiotics, such as potentiated sulfonamides, should be administered to help prevent local cellulitis and dissecting infection down fascial planes of the neck. The wound generally closes in 10 to 14 days and heals in 3 weeks.

THORACOCENTESIS

Pleural fluid drainage is integral in cases of effusive disease and can be life-saving. Prolonged increased pleural pressures can lead to pulmonary collapse; associated respiratory dysfunction; dyspnea; and in severe cases, cardiac tamponade. Auscultation and percussion of the chest, an increased field of cardiac auscultation, and transthoracic ultrasound can identify pleural effusion. Different tools can be used to facilitate drainage depending on the volume, shock status of the patient, quality and tenacity of the fluid, and likelihood of the need for continued drainage. Small volumes can be drained using a teat cannula or 14-gauge catheter with the stylet removed. Larger volumes, hyperechoic fluid (e.g., pyothorax), proteinaceous fluid, and horses with infectious pleuritis usually require placement of chest tubes. Indwelling tubes used are typically 20 to 32 Fr and sterile. The location for tube placement is ideally identified by ultrasound; however, a rough guide for safe placement is a hand span caudal to the olecranon and a hand span dorsal to the lateral thoracic vein. Where possible, the most ventrally dependent location that minimizes trauma to the heart and lateral thoracic vein is ideal.

The clinician clips and prepares the site with antiseptic, infiltrating it with 2% local anesthetic. An incision is made in the desensitized skin slightly cranial to the proposed point of entry, and the trocar is inserted through the skin. The clinician moves the incision in a caudal direction to the cranial margin of the nearest rib. Using controlled pressure, the trocar is advanced perpendicular to the chest wall and in a slight caudal direction. Fluid is seen to fill the tube, and the tube is fed off the trocar. A unidirectional flow apparatus should be placed on the free end of the tube (e.g., Heimlich valve, latex glove finger, condom) to allow egress of pleural fluid but preventing air entry into the chest. The tube is secured at the entry point using 0 or 2-0 suture with a purse-string and Chinese finger trap pattern.

Normal pleural fluid has a protein concentration <2.5 g/dL and total nucleated cell count <5000/μL.

Pneumothorax is classified as open (e.g., external wound) or closed (e.g., bronchopleural fistula). As pleural pressure equilibrates with atmospheric pressure, lung collapse occurs and can be seen as a cranioventral retraction of the lung field on radiographs. Tension pneumothorax develops when air continuously enters the chest without evacuation and represents a most serious and life-threatening condition in which supraatmospheric pleural pressures causes rapid cardiorespiratory demise.

With open pneumothorax, rapid recognition, sealing of the open wound, and evacuation of air must occur. In open pneumothorax sealing of the chest must occur, followed by evacuation of air. Clear plastic wrap (e.g., Saran wrap) makes an ideal temporary sealant that conforms to the chest and can be wrapped around the thorax. Application of silver sulfadiazine cream around the wound before plastic wrap application provides a secure air-tight seal.

Pleural air is then evacuated via placement of a cannula or 14-gauge catheter in the caudodorsal lung field. The 12th or 13th intercostal space is a suitable location. Air is gradually removed using 60-mL syringes. Reexpansion pulmonary edema is a concern and can be avoided by slow, gradual air evacuation with evacuation pressures <25 mm Hg. As the lung expands, it begins to "tickle" the cannula end, which is seen as a twitching of the cannula during inspiration. The cannula is removed once the air has been evacuated satisfactorily. In closed pneumothorax or tension pneumothorax, the catheter must be kept in place until the source of air entry can be sealed.

NASOGASTRIC INTUBATION

Nasogastric intubation is an essential and possibly life-saving procedure performed in cases of equine colic. Unless contraindicated (e.g., dangerous patient; head, neck, or esophageal trauma), failing to pass a tube may be construed as negligence.

The patient should be adequately restrained, with a twitch and sedation if needed. The clinician should stand on the side of the horse, with the hand closest to the horse placed on the nose, and the thumb in the nostril. With the other hand, the clinician passes the tube in the ventral meatus, using the

thumb to keep it directed ventromedially. If any resistance is met or a hard structure is encountered (possibly ethmoid turbinates), the user should stop, retract, and redirect ventrally. On reaching the pharynx, the practitioner should feel a soft resistance. The tube can be turned 180 degrees to direct its curvature dorsally. The clinician stimulates the horse to swallow by gentle to-and-fro movement or by blowing in the tube. Keeping the head of the horse flexed at the poll is helpful to direct esophageal passage. Once the horse swallows, the clinician pushes the tube into the esophagus. Blowing into the tube to dilate the esophagus facilitates insertion. If the horse coughs, the clinician withdraws the tube and repeats the procedure until the tube is positioned correctly. Determining correct anatomic placement in the esophagus and stomach is imperative. It is signaled by gentle suction, which should elicit a negative pressure; shaking of the trachea, which should not elicit a rattle; and visual confirmation of correct placement (typically just dorsal to the left jugular furrow). Direct observation is the safest method. The tube is advanced until it is in the stomach (14th rib). If the clinician encounters difficulty in passing the cardia, 60 mL of lidocaine may be injected into the tube.

Once placed, spontaneous egress of fluid may occur. If not, creation of a water siphon to empty the stomach can be achieved by filling the tube with water using a pump or funnel under gravity and then immediately directing the end of the tube downward. One sign of an empty stomach is retrieving froth or foam that can sit on the surface of accumulated gastric fluid. It is not uncommon to lose fluid during the refluxing process in horses in which no appreciable fluid accumulation is present.

Medication or intragastric fluids should never be administered by nasogastric tube to a horse with colic with any net positive volume of fluid accumulation.

To remove the tube, creating a fluid lock is achieved by occluding the tube (putting a thumb on the end or folding it) to prevent its contents from spilling out in the pharynx and possibly the trachea as it is withdrawn. Gentle traction is then applied in a direction parallel to the nose. If bleeding occurs, a towel can be placed over the horse's nose. Epistaxis, even if severe, is typically self-limiting. In rare cases of severe hemorrhage, ε-aminocaproic acid administration, nasal packing, and intranasal phenylephrine (10 mg in 10 mL saline) can be used to help resolve bleeding.

Nasogastric reflux is not normal. Occasionally, a small amount of reflux (≤1 L) is obtained if a horse has had a tube in place for a long time.[21] When reflux occurs, the clinician should note the amount, character, and timing in relation to the onset of colic. In addition, the clinician should note the response to gastric decompression. Reflux originating from the small intestine is alkaline, whereas reflux composed of gastric secretions is acidic. Typically, *reflux* refers to small intestinal ileus, functional or mechanical. Lesions of the proximal small intestine produce large amounts of reflux early in the onset of the colic. Inflammatory lesions (e.g., duodenitis proximal jejunitis) are typically associated with copious volumes of reflux caused by the hypersecretory nature of the disease process. With lesions of the distal small intestine (ileum) and often mechanical obstructions, one initially obtains no reflux, and as the condition persists, one obtains reflux but usually several hours after the onset of the colic. Occasionally, large colon disease can be associated with reflux, notably left dorsal displacement/nephrosplenic entrapment of the large colon. Colonic distention can exert extraluminal pressure on the stomach and/or duodenum.

The clinician should note the amount of reflux obtained because this factors into ongoing losses, and the volume of fluids given IV must be adjusted accordingly. Horses with functional ileus need gastric decompression usually every 2 to 4 hours. The nasogastric tube should be left in place only as long as required, because some horses develop pharyngeal and laryngeal irritation associated with its presence.[22] These horses may show pain on swallowing when they resume feeding. Sinusitis can also occur because of nasogastric tube placement.[23] When tubes are left in place, a small-bore tube that still allows effective gastric emptying should be used.

ABDOMINOCENTESIS

Abdominocentesis is important for evaluating abdominal disease, whether it is colic, weight loss, or postoperative problems. Box 4.3 provides the materials needed to perform this procedure.

The clinician clips a 2 × 2-inch area approximately 3 cm caudal to the xiphoid and 1 to 2 cm to the right of midline or using transabdominal ultrasound to guide fluid localization.[24] Various methods are described with different instruments. Regardless, the procedure is performed under sterile technique. Use of a sterile 18-gauge 1.5-inch needle does not require local anesthetic infiltration of the skin and subcutis. If a teat cannula or bitch catheter is used, local anesthesia infiltration is necessary. The operator makes a stab incision with a no. 15 scalpel blade before cannula entry. Two points of resistance will be encountered: as the device goes through the abdominal wall and as it goes through the peritoneum. Horses may become agitated when the peritoneum is "tented" before penetration.

Fluid should be collected into ethylenediaminetetraacetic acid (EDTA) and sterile culture containers. Low-yield samples should be collected in EDTA tubes in which the anticoagulant is shaken out to avoid misinterpretation of fluid analysis.[25] Obtaining fluid from very dehydrated horses is often difficult, especially in cases of simple obstruction.

Normal values and characteristics for abdominal fluid are as follows: clear, yellow in color (able to read newsprint through), low turbidity, total protein concentration should be less than 2.5 g/dL, and total white blood cell count should be less than 5000 cells/μL. On cytologic examination, neutrophils make up approximately 40% to 50% of cells, with the remainder being lymphocytes, macrophages,

BOX 4.3 Materials Needed for Abdominocentesis

- 18-gauge, 1½-inch needle
- Local anesthetic (2% without epinephrine)
- Teat cannula
- Bitch catheter
- Peritoneal dialysis catheter
- Sterile gloves
- Ethylenediaminetetraacetic acid and culture tubes
- Sterile, disposable no. 15 scalpel blade
- Sterile gauze

and peritoneal cells. L-Lactate concentration should be equal to that of systemic circulation and in normal horses, with <2 mmol/L is appropriate.

With intestinal strangulation, total protein increases initially (in the first 1–2 hours) such that the fluid is clear but more yellow. After 3 to 4 hours of strangulation, red blood cells also leak, and the fluid is more orange or pink. After 6 hours or more, white blood cells increase gradually, with the progression of intestinal necrosis. Serosanguineous fluid is indicative of small bowel strangulation and, in concert with the rest of the examination, likely indicates a need for bowel resection if possible. L-Lactate concentration in horses with strangulating small bowel lesions is greater than systemic concentrations. An L-lactate of ≥4 mmol/L or an increase in L-lactate concentration on repeat assessment is highly associated with small bowel strangulation.[26]

Inadvertent enterocentesis can occur, particularly in cases with increased abdominal pressure and/or large bowel impactions. Enterocentesis must be differentiated from intestinal rupture. Cytologic features of enterocentesis include plant material, bacteria, and debris but no polymorphonuclear cells. Moreover, the clinical condition of the horse is not consistent with rupture (septic shock). With early rupture, clinical evidence may not be evident for several hours. Cytologic examination of abdominal fluid with intestinal rupture shows neutrophils, bacteria, and bacteria that have been phagocytized by neutrophils.

Peritonitis can be classified as primary or secondary. Primary peritonitis is often idiopathic or associated with *Actinobacillus equuli* and covered in more detail elsewhere.[27] Secondary peritonitis is often associated with polymicrobial species when fluid is evaluated cytologically and on Gram stain. Degenerate neutrophils (>90%), the presence of multiple bacteria, and certainly gram-negative enteric species should alert the clinician to the possibility of compromised bowel and may warrant surgical exploration.

Blood contamination must be differentiated from internal hemorrhage or severely devitalized bowel. Blood from skin or body wall vessels and inadvertent splenocentesis can cause a bloody "tap." When centrifuged, the sample often spins clear with minor blood contamination from skin. Inadvertent splenocentesis will result in a higher packed cell volume than peripheral blood, which is caused by the erythrocyte reservoir of the spleen. All fresh blood contamination shows platelets, which are not present with blood older than 12 hours. In internal hemorrhage blood is hemolyzed such that the supernatant is reddish after centrifugation; the sample has no platelets and shows erythrophagocytosis. Ultrasonography also reveals fluid swirling in the abdomen, especially with acute internal hemorrhage of various causes.

Excess EDTA in a low-volume sample will falsely increase the total protein on refractometry (often by 0.9–1.0 g/dL higher). When performing an abdominocentesis, the clinician should shake out the EDTA from the tube to avoid this sampling error.

Abdominal surgery increases the total protein level and white blood cell count postoperatively.[28] Typically, if no enterotomy was performed, the white blood cell count increases for 4 to 7 days and returns to normal by 14 days. The total protein level may remain elevated for 3 to 4 weeks after surgery. Neutrophils appear to be nondegenerate. After an enterotomy or an anastomosis, degenerate neutrophils and occasional bacteria may be seen in the first 12 to 24 hours.[29] Subsequently, the white blood cell count remains elevated for approximately 2 weeks, but on cytologic examination the neutrophils appear to be nondegenerate and no bacteria are apparent. The total protein level remains elevated for 1 month after surgery.

TROCARIZATION

Trocarization of the cecum, or occasionally ascending colon, is useful to decompress the bowel and improve abdominal perfusion pressure ([APP]; see Table 4.5). By decreasing intraabdominal pressure, APP can be improved in cases where obstructive disorders of the large intestine are diagnosed. Trocarization provides analgesic relief by reducing visceral distention and may relieve dyspnea where significant abdominal bloating is apparent. Box 4.4 lists the materials needed for this procedure.

Trocarization is only indicated for large bowel distention. Rectal palpation, abdominal auscultation and percussion, and transabdominal ultrasound can help decipher which segment of bowel is distended. Segments of large bowel adjacent to the body wall are suitable cases. The right paralumbar fossa and cecal trocarization are ideally suited because of the fixed location of the cecal cupula in the right dorsal abdomen. Cecal tympany commonly accompanies obstructions of the ascending colon because of cecal outflow obstruction. These are ideal candidates for trocarization.

The clinician clips and prepares the site with antiseptic, infiltrating a 4 × 4-cm area of skin with a local anesthetic. With gloved hand, the clinician inserts a 14-gauge catheter with an extension tube perpendicular to the skin. The clinician places the end of the extension in water so that gas bubbles are visible when the tip of the catheter is positioned correctly. When gas is obtained, the trochar part of the catheter should be withdrawn slightly or removed to keep from lacerating the bowel. It may be necessary to reposition the catheter several times when gas is not obtained. Connecting the catheter to an extension set in water can help visualize gas egress (Fig. 4.3). Occasionally, a second operator can apply gentle pressure per rectum to facilitate gas egress. After decompression, the clinician removes the trocar and infuses an antibiotic (e.g., gentamicin or procaine penicillin) while withdrawing the catheter through the body wall.

Complications with trocarization include peritonitis and local abscessation. The horse should be observed for 24 hours for signs of peritonitis. If the practitioner suspects peritonitis, confirmation is with abdominocentesis, and systemic broad-spectrum antibiotics should be administered to the horse until the condition resolves. Serum amyloid A concentrations may be useful for monitoring the response to treatment and optimal time to cease therapy. If a local abscess develops, percutaneous external drainage with local lavage of sterile fluids is recommended.

BOX 4.4 Materials Needed for Trocarization

14-gauge, 5¼-inch catheter
Local anesthetic (2% without epinephrine)
Sterile gloves
Extension tubing
Small water container (syringe case works)

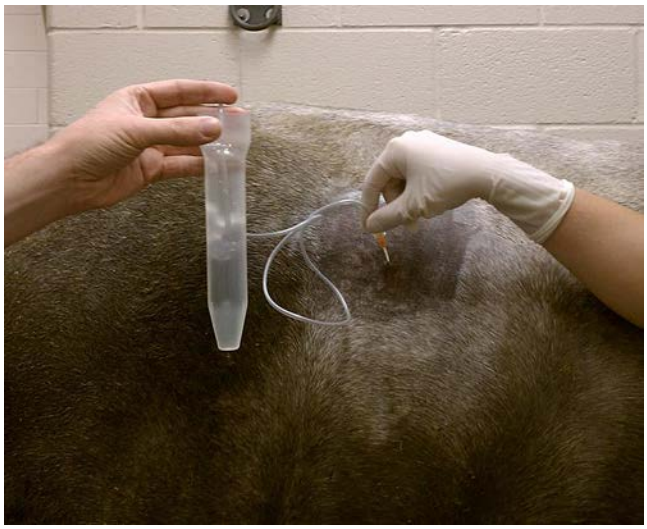

FIG. **4.3** Cecal trocarization using a 14-gauge catheter connected to an extension set in a syringe case of water.

URINARY CATHETERIZATION

Micturition disorders (lower motor neuron bladder, upper motor neuron bladder, and urethral detrusor dyssynergy) may require manual evacuation to relieve the patient and provide comfort. Measurement of urine output in adult horses is indicated in horses with oliguric renal failure or when 24-hour volumetric measurements are needed. Thorough cleansing of the urethral fossa and glans penis in males and the vulva and perineal region in mares is indicated before catheter placement. Gentle soapy water or saline with roll cotton are suitable options. In mares, urine is easily collected by placing a Foley catheter connected to collection tubing. A closed system can be fashioned by using a solution administration set and empty fluid bag. In geldings one can insert a male urinary catheter and suture it in place using a Chinese finger trap pattern. If the horse is recumbent and thrashing, leaving as little as possible of the catheter protruding to keep it from being pulled out is important. Normal horses produce 1 to 2 mL/kg per hour of urine.

Cardiovascular Critical Care

Tiffany L. Hall

REVIEW OF CARDIOVASCULAR PHYSIOLOGY

The cardiovascular system functions to deliver oxygen and nutrients to tissues throughout the body, as well as to deliver carbon dioxide to the lungs for elimination and other wastes from the tissues for detoxification and excretion from the body. It is comprised of the heart, the pulmonary circulation, and the systemic circulation, which act in coordination to deliver blood and its constituents to tissues. Through a complex interplay of neuroendocrine pathways, the cardiovascular system is able to adapt to different physiologic and disease states to meet the body's oxygen and nutrient requirements. When the cardiovascular system fails to meet tissue oxygen demands, a state of shock ensues. Support of cardiovascular function can be achieved through the administration of intravenous fluids, antiarrhythmics, inotropes, and/or vasopressors, depending on the nature of dysfunction.

The volume of blood, and therefore the amount of oxygen, delivered to tissues depends on arterial oxygen content and CO, which is defined as the amount of blood pumped out of the heart per minute and is the product of heart rate and stroke volume. Heart rate may be influenced by a number of neurologic, endocrine, and physical factors. Stroke volume is the amount of blood ejected from the heart with each contraction and is influenced by the venous return of blood to the heart (preload), the force/duration of contraction of the heart (inotropy), and the resistance to forward flow (afterload).

CO is not evenly distributed to all tissues in the body as a result of varying resistance to arterial blood flow dependent on tissue demands. Contraction of arteriole smooth muscle maintains a pressure gradient that allows blood to flow from arterioles through tissue bed capillaries, to venules, and back to the heart. SVR is related to blood pressure and is determined by vasomotor tone, or degree of vessel constriction, in the systemic circulation. The greater the SVR, the less blood flow from the heart through the systemic circulation and the greater the heart must work to achieve the same CO achieved at a lower SVR.

CARDIOVASCULAR INSUFFICIENCY: SHOCK STATES

When the cardiovascular system fails to supply sufficient oxygen to meet tissue demands, shock develops and cells shift to anaerobic metabolism. If left uncorrected, the shock state can result in irreversible cellular dysfunction. There are four major categories of shock that are differentiated by underlying pathophysiology: hypovolemic, cardiogenic, obstructive, and maldistributive.[30]

Hypovolemic shock is the most common type of shock recognized in equine patients and results from decreases in effective circulating blood volume, which may occur through external loss (e.g., diarrhea, reflux), third spacing of plasma volume, or hemorrhage. Decreased blood volume results in decreased venous return to the heart (decreased preload), reduced stroke volume, and decreased CO if heart rate cannot compensate. The mainstay of intervention is through restoration of circulating volume via intravascular fluid administration.

Cardiogenic shock is associated with impaired ventricular function as a result of myocarditis, ventricular dysrhythmias, or valvular pathology resulting in cardiac chamber enlargement.[31] A decrease in contractility (inotropy) results in reduced stroke volume and decreased CO. Therapy is directed at improving cardiac pumping through treatment of the underlying condition and use of inotropes when indicated.

Obstructive shock results from lack of blood flow through the heart or great vessels as a result of thrombosis (atrial or pulmonary), constrictive pericarditis, cardiac tamponade, or pleural space disease (e.g., pneumothorax).[32] This condition is characterized by decreased preload or increased afterload and results in circulatory failure.[33] Therapy is directed at addressing the underlying cause.

Maldistributive (vasodilatory) shock is the result of abnormal shunting of blood through microcirculation in the face of

normal CO, leading to tissue hypoxia and metabolic derangement. This may be caused by septic, anaphylactic, or neurogenic causes.[33] Central to the pathogenesis of maldistributive shock is endothelial dysfunction in response to neutrophil-generated cytokines, proteases, lipid mediators, and oxygen-derived free radicals.[34] Therapy is directed at addressing the underlying cause, reducing systemic inflammation, and use of vasopressors to improve SVR.

Regardless of the inciting cause, if shock is prolonged and severe, the terminal physiologic disturbance will manifest as maldistributive shock.[35] Successful management of shock depends on early recognition and aggressive intervention.[36]

CARDIOVASCULAR SUPPORT THERAPIES

Principles of Management

The goal of therapy in patients with cardiovascular compromise is to restore tissue perfusion and oxygen delivery. Therapies include fluid resuscitation to restore circulating blood volume, administration of vasoactive medications (inotropes/vasopressors) to improve CO and vascular tone, and directed therapies at the underlying disease condition. Fluid therapy has been discussed earlier, and the remainder of this section will focus on cardiovascular-specific therapies.

Vasoactive Drugs

Vasoactive drugs (e.g., inotropes and/or vasopressors) may be administered if tissue perfusion is inadequate following IV fluid resuscitation. Desirable qualities of vasoactive drugs include a short onset of action and rapid metabolism, so they may be quickly titrated to effect in response to changes in patient condition and administered as a CRI. Vasopressors and inotropes exert their effects through interaction with adrenergic and nonadrenergic receptors.

Adrenergic receptors targeted by vasoactive therapy include α_1-, α_2-, β_1-, and β_2-adrenergic receptors and dopaminergic receptors. α_1-Adrenergic receptor stimulation results in peripheral arterial vasoconstriction and altered metabolism as well as increased cardiac contractility.[37-39] Postsynaptic α_2-receptor stimulation results in vasodilation.[40] β_1-Adrenergic receptor stimulation results primarily in cardiac effects with increases in both heart rate (chronotropic effect) and contractility (inotropic effect). β_2-Receptor stimulation results in vasodilation of the arteries of coronary vessels, visceral organs, and skeletal muscle. Slight chronotropic and inotropic improvement after β_2-stimulation is also seen.[41] Dopaminergic stimulation improves myocardial contractility, increases heart rate, and results in peripheral vasoconstriction.[42] Nonadrenergic mechanisms include activation of vasopressin-specific receptors (chiefly V1) and effects on phosphodiesterase activity.[31] Vasopressin receptors (V1) are present throughout the vascular system and stimulation results in vasoconstriction, especially at peripheral arterioles.[43,44] During hypovolemic shock, markedly increased levels of V1 stimulation lead to significant increases in vascular resistance, which is an important mechanism for restoration of arterial blood pressure.[45]

Inotropes

Inotropic drugs increase myocardial contractility, increasing stroke volume and CO. Cardiac workload and oxygen consumption are increased, which is of concern in hypoxemic or dysoxic patients. If response to fluid resuscitation is inadequate, inotropes provide another means to increase tissue perfusion; however, these medications increase cardiac oxygen consumption, so oxygenation should be monitored.[31]

Dobutamine

Dobutamine is a synthetic catecholamine that has primarily β_1-adrenergic agonist activity with weak α- and β_2-affinity. Dobutamine is useful in patients with diminished CO or decreased central venous oxygen tension despite adequate fluid volume restoration. Beneficial effects include increased stroke volume and decreased heart rate with improved splanchnic perfusion and urine output. Dobutamine administered to foals with anesthesia-induced hypotension resulted in increased cardiac index, increased blood pressure, decreased oxygen consumption, decreased oxygen extraction ratio, and apparent maintenance of splanchnic perfusion.[46]

Vasopressors

Vasopressors increase vasomotor tone (SVR), which is reflected as an increase in MAP. Further, decreased venous compliance/capacitance increases venous return (preload), which improves CO.[37,38] Careful monitoring and titration of these medications must be performed to avoid excessive vasoconstriction, which would increase SVR (afterload), thus increasing cardiac workload and potentially decreasing stroke volume and CO.

Norepinephrine

Norepinephrine (NE) has predominantly α_1-adrenergic agonist activity, and it improves organ perfusion pressure during maldistributive and vasodilatory shock in patients nonresponsive to fluid resuscitation and inotrope administration. Resulting vasoconstriction increases cardiac afterload, potentially decreasing CO; however, this effect is countered by its β_1-effects, which facilitate increased stroke volume. Compared with dopamine, NE appears to have increased benefits in sepsis, demonstrating improved outcomes and increased splanchnic perfusion in humans and increased urine output in septic foals when combined with dobutamine.[47,48]

Epinephrine

Epinephrine is a strong α- and β-adrenergic agonist, making it a potent vasopressor. Splanchnic, renal, and coronary blood flow is decreased compared with NE.[49] Increased risk of dysrhythmia is associated with an increase in myocardial irritability, and postresuscitation myocardial depression with increased myocardial oxygen consumption is also reported.[50]

Dopamine

Dopamine is active at adrenergic (α and β) and dopaminergic receptors in a dose-dependent manner. High infusion rates of dopamine tend to result in a predominance of α-adrenergic effects and marked vasopressor response, whereas β-adrenergic effects (inotropy) predominate at lower infusion rates. Considerable controversy exists regarding the utility of dopamine, with mixed experimental evidence regarding its "renal protective" effects and meta-analysis data showing increased mortality in some subsets of patients.[3,51-53]

Phenylephrine

Phenylephrine is primarily an α-agonist resulting in increased SVR, MAP, and decreased CO. When phenylephrine is used as

a vasopressor, concurrent use of a β-agonist (e.g., NE, dobutamine) is often beneficial.

Vasopressin

Vasopressin, or antidiuretic hormone, is a regulatory peptide integral in regulating body water balance through promotion of water conservation in the collecting tubule of nephrons (V2 receptor) in response to centrally mediated detection of dehydration (osmoreceptors). In addition, vasopressin induces vasoconstriction via V1 receptors, particularly during sepsis, and human research demonstrates beneficial effects of vasopressin when used concurrently with catecholamines, such as NE.[37,50,54,55] Vasopressin works through nonadrenergic mechanisms, even in the face of moderate acidosis. This is in stark contrast to catecholamines that do not function as optimally under similar conditions. As with other vasopressors, V1 agonists may be unsuitable for use in horses that have not been volume resuscitated before administration because of a reduction in splanchnic perfusion.[56] Research in clinical equine practice indicates that endogenous vasopressin concentrations are increased in sick or septic animals compared with healthy controls, and that nonsurvivors have higher concentrations at admission compared with survivors.[55,57-62]

CARDIOVASCULAR SUPPORT STRATEGIES

Practical Approach to Fluid Resuscitation

The goal of fluid resuscitation is the restoration of tissue perfusion through increased stroke volume and improved blood pressure by correcting blood volume deficits. The key to fluid resuscitation is, therefore, balancing rapid volume expansion with monitoring to prevent fluid overload and avoiding the negative effects of oversupplementation.

There is little evidence to support one fluid resuscitation protocol over another in horses. Therefore selection of fluid type is highly subjective in most situations, and recommendations are extrapolated from human critical care. Most clinicians select a polyionic isotonic crystalloid fluid (e.g., LRS or Plasma-Lyte A) administered alone, or in combination with hypertonic saline in the presence of clinical shock symptoms. The use of hypertonic saline should be cautiously considered or avoided in cases of uncontrolled hemorrhage or where marked interstitial dehydration is likely; however, it has demonstrated a more rapid return of normal heart rate and urination in endurance horses requiring IV fluid support compared with normal saline.[63,64] Considering the risks/benefits of colloid administration, the concurrent administration of colloids with crystalloids may be indicated where symptoms of decreased plasma oncotic pressure (e.g., edema, effusions) are present or where a critical decrease in oxygen-carrying capacity is detected.

Ideally, volumes to be administered and administration rates are based on estimates of fluid deficits; however, clinical interpretation of percentage dehydration and degree of hypovolemia is insensitive and may result in oversupplementation or undersupplementation. Therefore a fluid challenge method is more commonly used in practice where a bolus of 10 to 20 mL/kg of isotonic crystalloid is administered over 30 to 60 minutes with monitoring of perfusion parameters between sequential boluses. Administration of boluses is stopped when normalization or plateau of perfusion parameters is observed or when limits to fluid resuscitation (e.g., 60–80 mL/kg total volume, CVP >15 mm Hg, declining Pao_2, peripheral edema) are reached. In most situations, an increase in circulating volume to achieve subnormal values for blood pressure are adequate to balance critical tissue perfusion while limiting the risk of fluid overload, secondary compartment syndrome, and tissue edema. Once hypovolemia is corrected, fluids may be administered at 1 to 2 times maintenance to correct the remaining fluid deficits and account for ongoing needs/losses. If limits of fluid resuscitation efforts are reached before perfusion parameters improve, vasoactive medications may be administered to increase cardiac contractility or SVR.

Practical Use of Vasoactive Medications

When normalization of fluid volume fails to correct perfusion abnormalities or limits to volume resuscitation are reached, the clinician should consider the use of vasoactive medications (Table 4.10). Inotropes and vasopressors should not be administered in patients who are hypovolemic because of a risk of tachycardia, increased myocardial oxygen demand in the face of decreased coronary perfusion, and marked vasoconstriction resulting in increased afterload and decreased CO.[53,65] The choice of which medication is most appropriate is case dependent and sometimes patient dependent; however, all medications should be titrated to effect based on cardiovascular monitoring, including serial heart rate/ECG, blood pressure, urine volume, and, when possible, CO determination. Scientific data regarding inotrope/vasopressor use under clinical conditions is limited in horses; therefore, our knowledge is based on human data and limited experimental research in horses.

Administration of an inotrope, such as dobutamine, is currently the first-line choice of vasoactive medication in equine patients, particularly when adequate CO cannot be confirmed. Administration of a vasopressor in the face of inadequate cardiac function would result in a further decrease in CO associated with increased SVR; however, if administration of low-dose dobutamine (2–5 μg/kg/min) fails to improve perfusion indices then a vasopressor may be added. Clinically, this situation is generally limited to neonatal foals with sepsis or adults with vasodilatory shock. NE appears to be the best vasopressor for use in the horse based on the available data and clinical experience, and data would suggest that concurrent administration with dobutamine has a favorable effect on blood pressure and renal perfusion while preserving splanchnic circulation.[47,53,66] If the patient's cardiovascular status remains poor, administration of vasopressin may be considered, especially in the case of septic shock, during which the body's responsiveness to catecholamines may be reduced.[37,67] Research regarding the administration of exogenous vasopressin in the equine patient is limited, but preliminary data support its use.[68]

Therapeutic Goals and Monitoring

The primary goal of the criticalist related to the cardiovascular system is to restore tissue perfusion and oxygen delivery. Early goal-directed therapy (EGDT) outlines management procedures to optimize global tissue perfusion and oxygenation in critical patients and was once considered revolutionary in human sepsis treatment to improved patient outcomes; however, recent clinical trials show no benefit over routine care.[69] Research related to EGDT in veterinary patients is limited.[70,71]

Dysfunction of the cardiovascular system may be identified clinically through abnormal mentation or weakness,

increased heart rate, weak peripheral pulse quality, cool extremities, prolonged jugular refill time, altered mucous membrane color or capillary refill time, and/or decreased urine production. Clinicopathologic abnormalities reflecting poor tissue perfusion include elevated L-lactate concentrations, increases in cardiac troponin I activity, decreased central venous oxygenation, and increased urine SG. The evaluation of each of these and other cardiac monitoring modalities are described in this section.

Physical Examination Parameters

Positive clinical response to therapies are indicated by improved patient mentation and responsiveness to the environment, normalization of the heart rate, and the presence of pink mucous membranes with a capillary refill time of 1 to 2 seconds. Further clinical indicators of adequate tissue perfusion include warming of the extremities, palpation of strong peripheral pulses, and improved jugular refill. In the normal standing horse, the jugular vein should fill quickly in response to occlusion of the vein in the middle of the neck. The presence of jugular pulsation may be a crude indicator of elevated CVP, and thus fluid overload, when occlusion of the vein eliminates jugular pulsation.[72] Other clinical evidence of fluid overload includes elevated respiratory rate, weight gain, and subcutaneous-dependent edema.

Urine Production

Urine production is considered a reflection of renal blood flow and hence CO and serves as an indication of adequate organ and tissue perfusion.[73] Therefore when urine production remains low (< two thirds of fluid volume being administered) in a euvolemic hypotensive horse, the administration of inotropes/vasopressors should be considered. However, the urine output and glomerular filtration rate are unreliable indicators of renal function in humans receiving vasopressors. Please see the section Renal Critical Care later in this chapter for additional information.

L-Lactate

L-Lactate is the terminal product of anaerobic glycolysis, and increases in blood lactate concentration in the horse are most often the result of inadequate delivery of oxygen to peripheral tissues resulting from hypovolemia, hypoxemia, anemia, or decreased perfusion pressure (type A lactic acidosis).[74,75] Other causes of hyperlactatemia include abnormal tissue utilization of oxygen, including mitochondrial dysfunction, or abnormal clearance of lactate (type B lactic acidosis).

Lactate measurement is useful clinically in monitoring the response to fluid therapy and vasoactive drugs in patients with cardiovascular dysfunction. Decreases in plasma lactate concentration temporally follow improvements in cardiovascular performance; therefore, the trend in serial plasma lactate concentration is most clinically useful. In situations of appropriate volume restoration in which lactate concentration remains increased, unresolved inflammatory stimulus or uncontrolled sepsis should be considered.

Arterial Blood Pressure

Arterial blood pressure is the product of CO and SVR. Mean blood pressure, not systolic or diastolic blood pressure, is considered the driving perfusing pressure for tissue and organs.[73] Arterial blood pressure can be measured by direct (invasive) and indirect (noninvasive) means, as described earlier in this chapter. Trends in arterial blood pressure, as opposed to individual readings, combined with other indicators of perfusion (examination and urination) should be used to guide therapy.

Central Venous Pressure

CVP is determined by central venous blood volume, muscular tone of the venous system, and the balance between venous

IV, intravenously.

return and CO. CVP is an estimate of right atrial pressure and cardiac preload. It is used to guide fluid therapy, because normalization of CVP may reflect success of fluid volume resuscitation, whereas elevations in CVP may reflect volume overload and limits of fluid resuscitation. As with measurements of arterial blood pressure, the trend in CVP seen through repeated monitoring is most informative.

Venous Blood Gas

Arterial blood gas values are required to assess pulmonary gas exchange, as described in the later section Respiratory Critical Care; however, in patients with cardiovascular compromise in which severe hypoperfusion may be present, tissue level hypoxemia, hypercapnia, and acidemia are more accurately represented in central venous blood. Central venous oxygen saturation is a reflection of oxygen delivery and consumption by tissues and is used in monitoring the efficacy of the cardiovascular system. Decreases in venous oxygen saturation may reflect decreased respiratory function, decreased CO/tissue perfusion, or increased oxygen demand. In goal-directed therapy, normalization of central venous oxygenation serves as a therapeutic target.

Colloid Osmotic Pressure

COP, also referred to as oncotic pressure, results from the osmotic force created by macromolecules within the intravascular compartment and is essential to retaining appropriate intravascular volume. Proteins and colloid molecules are sufficiently large in mass to limit permeability across the vascular endothelium and retain water within the vasculature by virtue of their osmotic draw. In addition, the Gibbs-Donnan effect, in which sodium cations are attracted to negative residues on protein (albumin), adds further to the intravascular osmotic draw.

COP can be measured or calculated, with reasonable agreement in healthy but not hospitalized horses. Because albumin is the major contributor to COP, alterations in the albumin-to-globulin ratio alter COP at any given total plasma protein concentration. Direct measurement of COP is necessary after synthetic colloid (hetastarch) administration because these starch molecules have considerable osmotic effect but are not measurable by refractometry.

Electrocardiogram

Indications for ECG monitoring of equine patients with cardiovascular compromise include dysrhythmias, marked electrolyte abnormalities (e.g., hyperkalemia), and during vasoactive drug therapy. The base-apex lead system is most commonly used in equine medicine, and telemetry units allow remote monitoring of horses free in stalls. A more complete review of the cardiovascular system and its monitoring is available in Chapter 9.

Cardiac Output Measurements

The use of advanced technologies such as lithium dilution, indicator dilution, bioimpedance, and pulse contour analysis for assessment of CO has been extensively reviewed elsewhere.[76] These techniques are impractical in the clinical setting or have not been validated for the horse; however, echocardiography (see Chapter 9) may be used in calculating CO. Volumetric determination (four-chamber and bullet methods) and right ventricular outflow tract Doppler are reliable, accurate, and noninvasive means of determining CO in horses.[77]

Respiratory Critical Care

Tiffany L. Hall

REVIEW OF RESPIRATORY PHYSIOLOGY

The major function of the respiratory system is gas exchange and, in conjunction with the cardiovascular system, to deliver oxygen to the tissues and facilitate carbon dioxide elimination. Table 4.11 shows expected arterial blood gas indices from normal horses. The respiratory control center maintains Pao_2 and $Paco_2$ within a narrow homeostatic range despite the body's wide variety of demands. Under normal conditions the primary driving force of alveolar ventilation is changes in $Paco_2$, which are sensed by chemoreceptors in the brainstem.[78] Changes in Pao_2 are sensed by peripheral chemoreceptors in the carotid and aortic bodies and also have an impact on alveolar ventilation but typically alter respiratory rate or effort only in states of marked hypoxemia.[78]

The basic components of the respiratory system are the upper airways, the sequentially branching respiratory passageways, and the alveolar-capillary membrane. The upper airways and respiratory passageways are not involved in gas exchange; therefore, they are referred to as *anatomic dead space*.[78] The alveolar-capillary membrane is the primary region that participates in gas exchange, although some areas may not be equally perfused and ventilated, resulting in *physiologic dead space*.[78] The alveolar-capillary membranes form a dense network within the alveoli, allowing for maximum exchange of oxygen and carbon dioxide. Factors that affect the rate of gas diffusion include thickness and surface area of the membranes, diffusion coefficient of the gas, and the gas pressure difference between the two sides of the membrane.[78,79]

In the body, oxygen diffuses down a pressure gradient from the alveolar space to the pulmonary capillaries to release within tissue capillary beds. Oxygen in the blood is either bound to hemoglobin (Sao_2) in the erythrocyte or dissolved (Pao_2) in plasma, with approximately 97% of total blood oxygen content (Cao_2) bound to hemoglobin under normal conditions.[78,79] The oxygen-hemoglobin dissociation curve depicts the association between partial pressure of oxygen in the blood (Pao_2) plotted on the *x*-axis and percentage (%) oxygen saturation of hemoglobin (Sao_2) on the *y*-axis. Factors such as pH, temperature, carbon dioxide levels, and the concentration of 2,3-diphosphoglycerate alter the hemoglobin affinity for oxygen and, therefore, the ability of oxygen to be

TABLE **4.11** **Normal Range of Arterial Blood Gas Values for Adult Horses**

Variable	Normal Range
pH	7.4 ± 0.2
$Paco_2$	40 ± 3 mm Hg
Pao_2	94 ± 3 mm Hg
Base excess	0 ± 1 mm Hg
Spo_2	98–99%

From Aguilera-Tejero E, Estepa JC, Lopez I, et al. Arterial blood gases and acid-base balance in healthy young and old horses. *Equine Vet J*. 1998;30:352.

carried to and unloaded at the tissue level.[78,79] Disorders that affect the binding of oxygen to hemoglobin have a tremendous impact on oxygen delivery to the tissues associated with a marked decrease in total oxygen content (Cao_2). As such, Pao_2 is primarily an indicator of pulmonary gas exchange within the lungs, whereas oxygen extraction ratios and venous oxygen indices are better predictors of tissue oxygenation.

RESPIRATORY INSUFFICIENCY: HYPOXEMIA AND HYPERCAPNIA

Respiratory insufficiency leading to hypoxemia, a decrease in oxygen content in arterial blood (low Pao_2), occurs for one of five reasons: decreased inspired oxygen content (Fio_2), diffusion barrier impairment within the lungs, alveolar hypoventilation, right-to-left shunting of blood, and/or ventilation-perfusion (V/Q) mismatch. Hypercapnia (elevated $Paco_2$) results from insufficient elimination of carbon dioxide from the blood to the alveoli, or alveoli to the atmosphere, and is commonly observed in cases of hypoventilation and V/Q mismatch. For practical purposes decreased inspired oxygen is a very rare primary cause of hypoxemia because horses breathing room air inspire sufficient quantities of oxygen to maintain adequate dissolved oxygen fractions.

Diffusion impairment is an uncommon cause of hypoxemia or hypercapnia in horses at rest because pulmonary disease must be very severe before gas exchange is limited, which is caused by a high functional residual capacity of the lungs. Diffusion is impaired because of decreased surface area or increased thickness of the alveolar-capillary membrane, as might occur in pulmonary fibrosis. Carbon dioxide diffuses more rapidly than oxygen (20-fold). Thus, hypoxemia is observed before hypercapnia.

Hypoventilation results in both hypoxemia and hypercapnia and occurs when there is a reduction in the volume of air entering and exiting the alveoli per minute (decreased alveolar ventilation), resulting in decreased gas exchange. Metabolic production of CO_2 is fairly constant under normal metabolic circumstances, so $Paco_2$ is primarily controlled by its rate of elimination through the lungs and, therefore, is an accurate reflection of alveolar ventilation. Hypoventilation may occur with disorders of the central nervous system ([CNS]; e.g., trauma, HIE, pharmaceutical drugs), thoracic cavity (e.g., pleural space disease, pain), respiratory tract (e.g., obstruction), or neuromuscular disease (e.g., botulism).[78,79]

Hypoxemia caused by a right-to-left shunt occurs when blood bypasses the pulmonary circulation and is, therefore, not oxygenated within the lungs. This deoxygenated blood mixes with oxygenated blood in the left heart resulting in hypoxemia. Shunting may be extrapulmonary, such as a right-to-left cardiac shunt (e.g., tetralogy of Fallot), or intrapulmonary, such as occurs with severe V/Q mismatch (e.g., ARDS).

A V/Q mismatch is the most common cause of hypoxemia in the horse and occurs when alveolar ventilation and blood flow are not closely matched, resulting in inefficient gas exchange. V/Q mismatch may result from all forms of pulmonary disease. A high V/Q mismatch occurs when regions of the lung are ventilated but not perfused, such as occurs with pulmonary thromboembolism.[78,79] Conversely, a low V/Q mismatch occurs when regions of the lung are perfused but not ventilated, as with bronchopneumonia and consolidation.[78,79] If V/Q mismatch is severe, the result is a right-to-left intrapulmonary shunting of blood.[78,79]

Hypoxemia is only one of several possible causes of oxygen deficiency at the tissue level, such as a condition referred to as *hypoxia*. Tissue hypoxia can occur in the face of normal respiratory function as a result of any condition that causes decreased oxygen delivery to the tissues or abnormal oxygen utilization within the tissues, including decreased CO, decreased blood oxygen-carrying capacity, peripheral arteriovenous shunting, mitochondrial dysfunction, increased peripheral oxygen consumption, and/or hypermetabolic conditions (e.g., hyperthermia, seizures, sepsis).[78,79]

APPROACH TO THE PATIENT WITH RESPIRATORY DISTRESS

Respiratory dysfunction may be the primary reason that a veterinarian is consulted, or it may occur while a horse is treated for another problem. *Respiratory distress* is defined as an inappropriate degree of breathing effort based on an assessment of respiratory rate, rhythm, and character. Causes of respiratory distress may be respiratory or nonrespiratory in origin. The physiology of this condition is discussed elsewhere (Chapter 8).

Upper respiratory disorders that result in respiratory distress usually do so because of respiratory tract obstruction (Box 4.5). Complete upper airway obstruction is a true emergency because inspiration against a closed airway results in the inability to inspire and marked negative intrathoracic pressures leading to pulmonary edema, which can be fatal.[84] Diagnosis is usually based on physical examination and endoscopy of the upper airway. Horses with upper airway obstruction may require an emergency tracheotomy and additional therapies, depending on the primary cause of the obstruction.

Lower airway diseases that may be associated with respiratory distress are listed in Box 4.6. Diagnosis is based on a thorough physical examination, thoracic imaging, transtracheal aspirate, and arterial blood gas analysis. Treatment depends on the nature of the primary disorder and may include antimicrobial agents, antiinflammatory agents, oxygen administration, or thoracic drainage as indicated. Diagnosis and treatment of specific disorders are described in Chapter 8.

Nonpulmonary causes of respiratory distress include anemia, compensation for metabolic acidosis, pain, anxiety, and hyperthermia. Evaluation of nonpulmonary causes of respiratory distress include a thorough history, physical examination, and blood work. After the initial evaluation further diagnostic testing might include endoscopy, ultrasound, or radiographs.

Oxygen Therapy

Nasopharyngeal administration of oxygen is the most common form of respiratory support in horses suffering from hypoxemia (Fig. 4.4). Oxygen supplementation is indicated when the Pao_2 falls below 60 mm Hg or $Sao_2 < 90\%$.[80] Research demonstrates a significant and dose-dependent increase in Pao_2 and Sao_2 with increasing flow rates of oxygen to a maximum of 10 to 20 L/min, beyond which airway irritation is observed.[81,82] Although adequate delivery of oxygen to tissues is essential, oxygen is also toxic when in excess through production of reactive oxygen species. Serial arterial blood gas measurements will aide in determining the response to treatment and ability to decrease supplementation, with the goal of providing

BOX 4.5 Upper Airway Disorders That May Be Associated with Respiratory Distress in Adult Horses

NASAL DISORDERS
- Trauma, foreign body
- Hemorrhage or hematoma
- Neoplasia
- Abscess
- Granuloma
- Amyloidosis

PHARYNGEAL DISORDERS
- Neoplasia
- Subepiglottic or pharyngeal cyst
- Persistent dorsal displacement of the soft palate
- Trauma, foreign body
- Abscess

LARYNGEAL DISORDERS
- Laryngeal paralysis
- Laryngeal hemiplegia
- Trauma, foreign body
- Edema
- Arytenoid chondritis
- Epiglottitis and epiglottic granuloma

MISCELLANEOUS
- Guttural pouch enlargement
  - Empyema
  - Tympany
  - Mycosis and hemorrhage
- Head swelling: edema, cellulitis, anaphylactic shock, bilateral jugular occlusion

BOX 4.6 Lower Airway Disorders That May Be Associated with Respiratory Distress in Adult Horses

PULMONARY DISORDERS
- Pulmonary edema (cardiogenic or neurogenic)
- Acute interstitial pneumonia
- Chronic interstitial pneumonia including equine multinodular pulmonary fibrosis (equine herpesvirus 5) infection
- Aspiration pneumonia
- Abscessing or coalescing bronchopneumonia
- Acute respiratory distress syndrome/acute lung injury
- Silicosis
- Smoke inhalation
- Tracheal/bronchial foreign body

EXTRAPULMONARY DISORDERS
- Pleural effusion (hydrothorax, pyothorax, chylothorax, and hemothorax)
- Thoracic trauma
- Pneumothorax (open, closed, and tension)

the lowest flow rates (lowest Fio_2) possible to achieve adequate oxygenation.

Inhalational Therapy

Inhalational therapy is beneficial in respiratory disorders of the lower airways, including bronchopneumonia and inflammatory airway conditions. Mucolytics, bronchodilators, and antimicrobials (including amikacin, gentamicin, and sodium ceftiofur [Naxcel]) may be administered by ultrasonic nebulization.[83,84] Inhalers may be used for the administration of bronchodilators, mast cell stabilizers, and corticosteroids (CSs) in horses with inflammatory airway conditions such as inflammatory airway disease or recurrent airway obstruction (RAO).[85,86] Advantages of inhalation therapy include a localized delivery to the target site allowing for higher concentrations at lower doses administered, as well as reduced incidence of adverse systemic effects.

Pharmacologic Ventilation

Hypoxemia and hypercapnia resulting from hypoventilation may respond to the administration of medications that stimulate respiration centrally. Caffeine, doxapram, and theophylline are three such medications that may benefit equine patients with hypoventilation secondary to head trauma, encephalitis, or hypoxic-ischemic encephalopathy. Caffeine is most frequently used in practice because of ease of administration, cost, and wide therapeutic index. Doxapram has a short duration of action requiring frequent or CRI administration, which limits use despite evidence of improved ventilation compared with caffeine.[87] Disadvantages of doxapram use include an increase in myocardial oxygen consumption and cost. Theophylline is similar to caffeine; however, it has a narrow therapeutic index with adverse effects including colic, seizure, tachycardia, and sudden death.[80]

FIG. **4.4** Horse with a nasal oxygen cannula. Suturing to the nostril and affixing the tubing to the halter helps maintain the cannula in place.

Acute bronchoconstriction and decompensation may be seen with severe RAO, inhalation of noxious gases, or other chemical irritants and can be managed with bronchodilating agents. β_2-Agonists (e.g., inhaled albuterol [720 µg per 450-kg horse]) and anticholinergics (e.g., intravenous glycopyrrolate) are beneficial. Atropine may be used as a rescue therapy only. Bronchial inflammation can both trigger and perpetuate

bronchoconstriction and warrants the justified use of inhaled or systemic glucocorticoids in some cases.

Mechanical Ventilation

Mechanical ventilation, when administered in a hospital setting by experienced clinicians, has resulted in improved outcomes in foals[80] and may be beneficial in adults.[88] Indications for mechanical ventilation include marked hypoxemia or hypoventilation (pHa <7.3 with $Paco_2$ >65 mm Hg or Pao_2 <60 mm Hg) despite maximal medical therapy, and fatigue or excessive work of breathing. Clinical diagnoses in equine patients that may benefit from mechanical ventilation include botulism, hypoxemic-ischemic encephalopathy, or ARDS. Long-term mechanical ventilation techniques in adult horses are poorly described and represent a significant challenge for equine critical care.

Therapeutic Goals and Monitoring

The goals in supporting respiratory function are recognition of improved respiratory rate and effort, improved oxygen indices, and normalization of oxygen and carbon dioxide blood concentrations.

Blood Gas Analysis

Blood gas analysis is the most common method for assessment of pulmonary function and acid-base status in horses that are critically ill. Arterial samples may be obtained from the facial artery, transverse facial artery, or lateral metatarsal artery.[89] In the clinical setting, venous samples are best collected from a catheter placed in the cranial vena cava or jugular vein. Correct interpretation of the information obtained from blood gas analysis allows the clinician to make appropriate decisions regarding diagnosis, therapy, and prognosis related to respiratory function and acid-base status.

Samples for blood gas analysis must be collected and handled appropriately to ensure accurate results. A small amount of heparin is used to coat the hub of the needle before aspiration of the sample, which should be stored anaerobically after collection by removing the needle and placing a syringe cap over the tip of the syringe. Prolonged exposure to air or bubbles in the syringe can result in a decrease in $Paco_2$ and an increase in Pao_2 as the sample equilibrates with room air in the bubble.[79,89] A sample stored at room temperature should be analyzed within 10 to 15 minutes. Delayed analysis may result in an increased $Paco_2$, decreased pH, decreased glucose, and increased lactate as blood cells continue to metabolize nutrients.[90]

Blood Gas Interpretation

Respiratory Function

A systematic evaluation of blood gas values includes consideration of pH, Pao_2, arterial and venous oxygen saturation of hemoglobin (Sao_2, Svo_2), $Paco_2$, and bicarbonate concentration. The partial pressure of oxygen dissolved in arterial blood (Pao_2) is a reflection of pulmonary oxygenating capability and is not affected by hemoglobin-bound oxygen. Causes of low Pao_2 (hypoxemia) are discussed in the preceding sections. The partial pressure of CO_2 dissolved in arterial blood ($Paco_2$) is a reflection of the balance between alveolar minute ventilation and metabolic CO_2 production.[78,79,89]

The first step in interpreting the blood gas information with respect to pulmonary function is to assess ventilatory status. Increased $Paco_2$ indicates hypoventilation, whereas decreased $Paco_2$ indicates hyperventilation, the presence of which cannot be accurately assessed based on physical examination alone. Hypoventilation may be caused by central apnea (CNS disease), obstructive apnea (upper respiratory tract disease), increased dead space ventilation (shunt and decreased CO), reduced lung compliance (low lung volume), respiratory muscle weakness or fatigue, poor control when mechanical ventilation is used, thoracic pain, or abdominal distention. Hyperventilation, with decreased $Paco_2$, may result from pain, hypoxemia of any cause, pulmonary disease, or neurologic disease.

Oxygenation status is then determined by the assessment of Pao_2 and Sao_2 in light of the partial pressure of alveolar oxygen (PAo_2) and hemoglobin levels. PAo_2 is influenced by the fraction of inspired oxygen (Fio_2), atmospheric pressure, and $Paco_2$. Pao_2 is typically five times the Fio_2 in the healthy standing horse; therefore, in a patient breathing room air at sea level (Fio_2 = 21%), expected Pao_2 concentration is approximately 100 mm Hg with an Sao_2 >93%.

Calculation of the alveolar-arterial oxygen gradient (A-a gradient) is helpful in evaluating causes of hypoxemia and hypercapnia.[78,79] In the normal horse breathing room air, the Pao_2 should be only slightly less than PAo_2 with an A-a difference of 5 to 10 mm Hg. In patients with a normal A-a gradient, hypoxemia and/or hypercapnia are the result of alveolar hypoventilation. Hypoxemia and hypercapnia in patients with an increased A-a gradient may be associated with V/Q mismatch, right-to-left shunt, or diffusion impairment; however, nonpulmonary causes may also be present, including an imbalance of oxygen demand and delivery, hypermetabolism, or overfeeding.

The causes of hypoxemia can be further differentiated through the administration of supplemental oxygen and evaluation of oxygen saturation and extraction ratios. When the administration of oxygen fails to increase Pao_2 to 100 mm Hg, right-to-left shunting or massive pulmonary thromboembolism should be suspected and appropriate diagnostic testing used. Improvement of Pao_2 above 100 mm Hg with oxygen therapy suggests hypoxemia associated with V/Q mismatch or a diffusion disturbance. Venous blood gas analysis has limited usefulness for evaluation of respiratory tract disease; however, Svo_2 may be used in calculating the oxygen extraction ratio, which provides some information about tissue oxygenation in the horse. Oxygen extraction ratios greater than 30% may reflect increased oxygen consumption (e.g., exercise, hypermetabolism) or inadequate oxygen delivery to tissues associated with hypoxemia, anemia, or cardiovascular dysfunction.

Acid-Base Status

An interpretation of blood gas analysis is not complete without assessment of the patient's acid-base status. In a simplified approach to acid-base status, the clinician first determines whether the blood pH is normal (approximately 7.40) or whether acidemia (pH <7.36) or alkalemia (pH >7.44) exist. There are four primary acid-base disturbances that may occur in a patient based on interpretation of the blood gas: respiratory acidosis, resulting from hypoventilation and reflected by increased $Paco_2$; respiratory alkalosis, resulting from hyperventilation and reflected by decreased $Paco_2$; metabolic acidosis (decreased HCO_3^-); and metabolic alkalosis (increased HCO_3^-). These may exist as sole disorders or in combination (mixed disorders). A complete discussion of acid-base disorders and the approach to critically evaluating acid-base status is beyond the scope of this text, and the reader is referred to

additional resources regarding the physiochemical approach to evaluation of acid-base status in animals.[91,92]

Pulse Oximetry

A useful adjunct to arterial blood gas analysis is pulse oximetry, which is a technique that relies on the reflection of different wavelengths of light to differentiate oxygenated and deoxygenated hemoglobin reported as a percentage of oxygenated hemoglobin (Spo_2). Generally, an Spo_2 greater than 91% is considered indicative of an arterial oxygen level within physiologically normal limits.[79,93] Pulse oximetry has a limited sensitivity for determining changes in pulmonary gas exchange at ranges above 90% hemoglobin saturation; however, Spo_2 below 91% represents increasingly severe reductions in arterial oxygen levels.[79,93] The accuracy of Spo_2 may be influenced by several factors including pigmented skin, hypoperfusion at the measurement site, anemia, hypothermia, and motion. False readings of Spo_2 may occur in the presence of carboxyhemoglobin and methemoglobin, in which cooximetry is the preferred analytical method. Because of the limitations of pulse oximetry, response to treatment in a patient with critical hypoxemia is best monitored with arterial blood gas analysis.

Gastrointestinal Critical Care

Tiffany L. Hall

The primary role of the gastrointestinal tract is digestion of food so that nutrients including proteins, vitamins, minerals, and fluids may be absorbed into systemic circulation for use throughout the body. Normal function of the gastrointestinal tract includes appropriate motility, balanced microbiota, digestion, and absorption through complex interactions among the nervous system, enteric nervous system, endocrine system, and musculature of the gastrointestinal tract. The gastrointestinal mucosa forms a barrier between the body and a luminal environment, which not only contains nutrients but also is laden with potentially hostile microorganisms and toxins. Thus normal function also requires that nutrients be transported across the epithelium while excluding passage of harmful molecules and organisms.

GASTROINTESTINAL DYSFUNCTION

Complications related to the gastrointestinal tract are common in the critically ill horse and include inappetence, pain, endotoxemia/SIRS, ileus, enteritis or colitis, malassimilation (malabsorption/maldigestion), and protein-losing enteropathy. The details of many of these conditions are discussed in Chapter 12. Inappetence is probably the most common complication in the critical equine patient and will be the focus of the remainder of this section. Decreased feed intake may be caused by a mechanical inability to eat (dysphagia) or a loss of appetite associated with a variety of conditions and diseases including pain, stress, systemic infection, or loss of palatability associated with medications. The regulation of appetite is an immensely complex process involving the gastrointestinal tract, central and autonomic nervous systems, and many hormones.

Severe illness or injury has been associated with hypermetabolism characterized by a pronounced catabolic state that is made worse by a patient's inappetence. Inflammatory mediators increase basal metabolic rate, contributing to the inefficient use of oxygen and calories, and may also modulate the body's response to starvation.[94,95] Negative energy balance, in which nutritional intake does not meet the energy demands of the body, depletes the body of structural and functional proteins, impairing wound healing, decreasing immune function, and altering many other normal physiologic functions. The effects of an ongoing, profound negative energy balance may manifest in musculoskeletal weakness, disruption of the gastrointestinal barrier (villous blunting), sepsis, multiorgan dysfunction, and even death.

EVALUATION OF GASTROINTESTINAL FUNCTION

Methods used to recognize gastrointestinal dysfunction in the critically ill horse include changes in the physical examination, abdominal ultrasonography, and clinicopathologic testing. Serial physical examinations will identify changes in vital parameters, mentation, behavior, fecal production, and abdominal size. Transabdominal ultrasound (2.5- to 3.5-mHz transducer) can be used to evaluate the anatomic location, contents, wall thickness, and motility of various regions of the intestine. Classic patterns identified by ultrasound are useful in narrowing a list of differential diagnoses for gastrointestinal disorders. The identification of peritoneal fluid by ultrasound warrants abdominocentesis and fluid analysis to better evaluate the disease process and can help guide therapy and decisions regarding prognosis. Clinical pathologic abnormalities are often nonspecific regarding gastrointestinal disorders but may reflect the presence of systemic inflammation, major fluid shifts or deficits, decreased tissue perfusion, acute protein loss, negative energy balance (e.g., disorders of glucose and triglycerides), and/or electrolyte disturbances. See Chapter 12 for a more in-depth discussion of the use of complete blood count (CBC), biochemistry, ultrasonography, and radiography for disorders of the gastrointestinal tract.

Assessment of the nutritional status of the critically ill equine patient at presentation and at regular intervals during hospitalization is necessary to identify patients that would benefit from early nutritional support. The most practical methods for evaluation of nutritional status and body fat composition in horses are monitoring of body weight (e.g., scale or weight tape) and body condition score (BCS), which is a subjective, semiquantitative method of evaluating body fat and muscle mass by visual inspection and palpation of certain areas of the body. BCS is positively correlated to body fat but not to weight or height. A nine-point scale was described by Henneke in which 1 is extreme emaciation, 9 is obese, and 4 to 6 are ideal.[96] The appropriate assessment and monitoring of nutritional status would include both the body weight and BCS.

NUTRITIONAL SUPPORT

Early nutritional support is indicated in underweight or obese horses, those with highly catabolic disease states (e.g., pleuropneumonia), or in patients that are unable to eat (e.g., dysphagia, ileus). Healthy horses at rest may have feed withheld for 2 to 3 days without significant consequence; however, all hospitalized horses may benefit from early nutritional intervention. Numerous reports in human critical care document

the benefits of early nutritional support because it hastens recovery, diminishes complications of the critically ill, and decreases length of hospitalization.[94,95,97] The goals of early nutritional support are to maintain host defenses and preserve lean body mass while avoiding oversupplementation.

The nutritional requirements of the critically ill adult horse have not been determined and are influenced by size, age, disease state, and metabolic stress. Maintenance requirements for healthy adult horses at rest are estimated to be 30 to 40 kcal/kg per day.[98-100] More research is available in critically ill foals whose resting energy requirements are approximately 50 kcal/kg per day and increase as the foal's clinical condition improves.[101]

Enteral feeding is preferred to PN if the gastrointestinal tract is even partially functional because local delivery of feed bulk and nutrients improves intestinal motility, maintains mucosal integrity, protects against bacterial translocation, and supports organ and immune function.[94,95,97] Even if a horse cannot tolerate enteral feeding sufficient to meet maintenance energy demands, lesser amounts of enteral nutrition are shown to be beneficial while the remainder of energy requirements are met through parenteral means (sometimes termed *trophic feeding*). It can be difficult to determine caloric intake for a horse on a voluntary feeding plan; however, weighing the feed and hay offered compared with that left behind by the patient allows one to estimate the number of ingested calories. If consumption is below 75% of the maintenance requirements for 48 hours, or if the horse is anorexic or dysphagic, feeding by nasogastric tube is recommended.[99,100] See Chapter 5 for a discussion of different enteral diet regimens and methods of administration. It is recommended that enteral feeding begin gradually, with a goal of reaching maintenance requirements over 3 to 7 days, because rapid changes may result in colic or diarrhea.[99,100]

PN is indicated for aged animals off feed, pregnant or lactating mares off feed, horses with a BCS <4, critically ill breeds at risk for hyperlipidemia/hyperlipemia, and critical patients who cannot tolerate enteral feeding because of gastrointestinal dysfunction.[102-104] PN is a combination of nutrients designed to meet the patient's energy requirements through IV administration and may consist of supplementation with dextrose alone or in combination with amino acids and/or lipids. Other components added to PN solutions include vitamins (A, D, E, and B complex) and minerals. Macrominerals such as potassium, calcium, and magnesium are best added to crystalloid fluids. The reader is referred to Chapter 5 for a complete discussion of PN.

Complications associated with PN administration include hyperglycemia, hyperlipidemia, hypokalemia, hypophosphatemia, hypomagnesemia, and thrombophlebitis.[105,106] Hyperglycemia is the most common complication reported in horses and foals administered PN and may be avoided through slow introduction of the fluid, beginning at 25% of the target rate. This allows an appropriate endogenous insulin response to occur in response to dextrose supplementation. Blood glucose levels should be monitored every 4 to 6 hours to avoid hyperglycemia, glucosuria, and osmotic diuresis. A sudden onset of hyperglycemia in a patient that had been tolerating PN can indicate the presence of complications such as infection or sepsis. If hyperglycemia persists, exogenous insulin therapy should be considered. Parenteral formulations containing lipids should be avoided in horses with hyperlipidemia, hyperlipemia, or severe liver disease and used with caution in horses with severe endotoxemia or SIRS. Hypokalemia can result from decreased intake of food and the delivery of a high concentration of dextrose causing pancreatic insulin release; thus, potassium should be supplemented in horses receiving PN.

GASTROINTESTINAL MOTILITY SUPPORT

The promotion of gastrointestinal motility and function in the postoperative patient is discussed elsewhere in this text (see Chapter 12). However, maintenance of normal blood volume, physiologic electrolyte concentrations, and gastrointestinal blood flow will aide in maintaining gastrointestinal integrity and function. The reader is referred to other sections of this text for further information regarding support of normal gastrointestinal tract function.

Renal Critical Care

Samuel D. Hurcombe

Primary renal disease in horses may be underdiagnosed in adult horses. Standard testing using blood work (blood urea nitrogen [BUN] and creatinine concentrations) may only increase once advanced or severe acute disease is established. Horses with critical illness are superb candidates for secondary renal disease, which in many cases critically ill horses may be underperfused, in various shock states, and frequently administered nephrotoxic therapies.

Horses with fluid deficits, severe myopathies, hemolysis, and septic/endotoxemic shock are at high risk of renal disease. Optimizing renal perfusion, glomerular perfusion, and tubular flow should be of highest importance in supporting renal function. Electrolyte imbalances, acid-base disorders, urine output volumes, and neurohormonal regulation of splanchnic blood flow should be evaluated and considered in the development of all fluid therapy strategies in the renal patient.

Evaluation of renal function through clinicopathologic testing of blood and urine are best performed before fluid therapy. Provision of IV fluids may lead to changes in blood electrolyte composition and SG findings.[107]

GENERAL PRINCIPLES

Horses with renal disease should be assessed for their ability to produce urine before fluid therapy. Low-volume resuscitation (<40 mL/kg/day) should be used until it is known that the patient can tolerate maintenance and the previously mentioned maintenance IV fluid rates. Monitoring body weight and/or urine output volumes is the most practical method for determining volume infusion tolerance.

Caution should be exercised in the anuric patient and those with low-volume oliguric renal failure. Patients with uremic encephalopathy and intolerance to IV fluids have a grave prognosis.

If the patient demonstrates volume tolerance, maintenance rates (40–60 mL/kg/day) of isotonic crystalloids and/or bolus infusions of hyperosmolar solutions (7.2% hypertonic saline [2–4 mL/kg]; mannitol 20% solution [0.25–1 g/kg]) may be useful to promote renal perfusion, tubular flow, and nephron recruitment.

Specific treatment and diagnosis of acute and chronic renal failure are discussed in greater detail elsewhere in this text.

COMMON NEPHROTOXIC SUBSTANCES IN THE INTENSIVE CARE UNIT

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are commonly used in equine practice. Renal perfusion, notably to the inner medulla and medullary pyramids, relies on perfusion of the vasa recta. Intrinsic flow through the vasa recta is affected by both volume status of the patient and vasomotor tone. Vasomotor tone is regulated, in part, by prostaglandins. Prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2) promote vasodilation, perfusion, and health of the inner tissues. These are constitutively produced via metabolism of arachidonic acid shunting through cyclooxygenase-1 (COX-1) activity.[108] With the exception of firocoxib, other NSAIDs used in horses are not selective for COX-2, which is induced by inflammatory stimuli.[108] Therefore most NSAIDs inhibit activity of both enzymes to some degree, which blocks renal production of prostaglandins and prevents the compensatory increase in renal blood flow during dehydration, potentially leading to vasomotor nephropathy and renal papillary necrosis (also termed *renal ischemic necrosis*). The mechanism of action and toxicity for NSAIDs is discussed elsewhere in this text.

Aminoglycoside Antibiotics

Aminoglycoside antibiotics (e.g., gentamicin, amikacin) are freely filtered at the glomerulus and excreted into the urine.[109] In low tubular flow states (e.g., dehydration), aminoglycosides are actively taken up by proximal convoluted tubular cells and stored in lysosomes. Drug accumulation exceeds drug disposition and leads to rupture of PCT cells and acute tubular necrosis.[109] Alternative drugs should be considered over systemic aminoglycoside in the hypovolemic and/or azotemic patient.

Endogenous Toxins: Myoglobin and Hemoglobin

Liberation of myoglobin (myopathies, e.g., rhabdomyolysis, myositis) or hemoglobin (intravascular hemolysis, e.g., immune-mediated hemolytic anemia, red maple leaf toxicity) may lead to acute kidney injury via several mechanisms including physical plugging of nephron tubules via polymerization, reflexive renal vasoconstriction causing ischemia, and free radical injury via reduction-oxidation reactions from iron-containing pigments and genesis of reactive species (e.g., hydroxyl radical). free radicals.

IDENTIFYING RENAL DYSFUNCTION

Recognition of renal dysfunction is easily overlooked in critical care patients. It is advisable to monitor serum BUN and creatinine concentrations at least every 48 hours to assess glomerular filtration and renal function. Regular measurement of BUN and creatinine concentrations and assessment of results in light of physical examination findings (e.g., evidence of dehydration) and results of urinalysis are the most readily available methods for monitoring renal function in equine critical care patients. Increases in serum creatinine concentration as small as 0.3 mg/dL can be significant.[110]

Diagnostic samples to assess renal function would include blood (CBC, serum chemistry, and leptospirosis microagglutination serology), urine (cytology, cast assessment, darkfield microscopy, SG, and quantitative urine culture), and renal tissue (histopathology with or without special stains and culture).

Dilute urine (SG ≤1.012) concurrent with azotemia generally indicates decreased renal function. Azotemia with isosthenuria (SG 1.008–1.012) indicates renal failure. Urinary indicators of tubular damage include granular casts in urine, an increased urinary γ-glutamyl transferase-to-creatinine ratio (>25), abnormal fractional clearance of electrolytes such as sodium and potassium,[110] and increased urinary glucose. The presence of white blood cells, bacteria, and excess protein concentration as determined by dipstick or other methods as well as increased urine to protein ratio are abnormal findings in urine and should prompt more in-depth investigation.

To understand and best prognosticate the severity of renal damage and chances of tissue restitution, ultrasound-guided renal biopsy and histopathology are recommended.

A more complete discussion of laboratory methods of renal function assessment is found in Chapter 14.

THERAPY FOR RENAL DYSFUNCTION

Many cases of acute kidney injury respond favorably to fluid therapy and avoidance of nephrotoxic drugs. In some instances, establishing a polyuric state can be beneficial when horses are treated with the previously mentioned maintenance fluid rates and can tolerate IV fluids. High tubular flow rate is essential in establishing endogenous waste clearance (e.g., creatinine) and other noxious substances (e.g., myoglobin). Diuresis may be induced through increased fluid rates above the maintenance requirements (>60 mL/kg/day) of polyionic isotonic solutions, administration of hypertonic solutions, and use of diuretic therapies. Azotemia that decreases by ≥50% in 24 hours in response to fluid therapy (usually at rates >80–100 mL/kg/day) indicates prerenal azotemia.

If fluid therapy does not produce the expected increase in urine output, then diuretics (furosemide, 1 mg/kg, IV) can be administered. Urination should be expected within 30 minutes of furosemide administration. CRIs of furosemide may yield a more consistent diuretic response.[111] Bags and infusion lines should be covered to prevent exposure to light because furosemide is light sensitive.

Volume replacement should always be attempted before diuretic therapy because the resultant increase in urination at blood volume expense will contribute to severe dehydration and reduce systemic perfusion and exacerbate renal damage.

Active treatment of refractory hypotension (hypotension unresponsive to fluid therapy) is important to treat or prevent perfusion-mediated causes of acute kidney injury. Autoregulation begins to fail at a MAP <60 mm Hg. Maintaining an MAP ≥65 mm Hg is recommended to minimize reduced urine output and kidney injury.[53]

Vasoactive therapies such as dobutamine (1–5 μg/kg/min) have been advocated to improve blood pressure. Low-dose dopamine therapy (2–5 μg/kg/min) and fenoldopam (0.04–0.4 μg/kg/min) have purported benefits in healthy subjects on renal blood flow. The effects of dopamine or fenoldopam on renal blood flow in critically ill equine patients is

unknown.[110,53] Blood pressure should be measured in patients at risk for hypotension and those that fail to produce urine despite appropriate therapy.

In horses with oliguric renal dysfunction and certainly anuric renal dysfunction, the CVP may be monitored to assess the potential for fluid overload and edema formation. Normal CVP in the standing horse is <12 mm Hg. Values >12 mm Hg should prompt the clinician to reassess the patient's' tolerance to fluid therapy.

Aminoglycoside toxicity is best prevented by ensuring appropriate dosing regimens and limiting the use of aminoglycosides to hydrated animals without preexisting renal dysfunction.[111] Administering aminoglycoside antibiotics every 24 hours decreases the amount of time that renal tubular cells are exposed to higher concentrations of aminoglycosides. The peak concentration (C_{max}) dictates the efficacy of the drug; however, the trough concentration dictates the safety of the drug. Therapeutic drug monitoring allows for the detection of elevated trough (usually 24 hours after the previous dose) concentrations, which are more likely to cause toxicity. Drug-dosing adjustments should be based on trough concentrations, either as a lower dose administered or a prolonged dosing interval.[109]

Renal Replacement Therapy

RRT such as peritoneal dialysis (PD) or hemodialysis is technically possible in horses. PD is technically easier but less effective than hemodialysis. Recently venovenous hemodiafiltration was described in healthy adult horses and well tolerated.[112] The need for specialized equipment and familiarity with creatinine clearance kinetics, etc., makes the application of hemodialysis in clinical patients somewhat limited currently.

PD has been described in horses as either intermittent or continuous. The concept involves using the peritoneum as an accessory kidney to dialyze blood. In one clinical report, continuous flow PD (CFPD) was more effective than intermittent PD.[113] LRS with 1.5% dextrose and 1 unit of unfractionated heparin per milliliter is an easy dialysate solution to obtain and use. For intermittent PD, 40 mL/kg of dialysate is infused and left for 30 to 60 minutes and then allowed to drain. This is repeated 2 to 6 times per day. With CFPD, an ingress catheter is placed in the left flank and an egress catheter on ventral midline connected to a closed bag collection system for volumetric assessment. Dialysate fluid ingress is provided at ~3 L/h. Eighty percent of ingress volume should be recovered in the collection system. Marked improvements in azotemia have been observed within the first 24 hours of starting CFPD, and it is continued based on creatinine clearance responses.

RRT should be considered in cases where azotemia is unresponsive to fluid therapy and/or diuretic medications or the horse is severely oliguric to anuric. Acute kidney injury would likely yield potentially favorable outcomes using RRT compared with chronic disease states.

Neurologic Critical Care

Samuel D. Hurcombe

Any neurologic condition can represent a true emergency requiring expedient assessment, stabilization, and targeted therapy. Severe manifestations of common diseases can be challenging cases to treat, and horses that present acutely and/or deteriorate in the face of therapy require immediate veterinary attention. Disorders of the forebrain (seizure activity and changes in behavior), spinal cord (ataxia and recumbency), peripheral nervous system (inability to ambulate or severe generalized weakness), and autonomic nervous system (urinary/fecal incontinence) may all require emergency care. Extracranial causes of neurologic dysfunction can also be challenging and represent a multisystemic disorder (e.g., hepatic and other metabolic encephalopathies).

Certain disorders may present as a neurologic disorder but may be caused by other systemic causes. For example, cardiovascular or respiratory diseases and gait abnormalities caused by musculoskeletal diseases such as bone fractures, rhabdomyolysis, or laminitis.

Peripheral nerve damage in horses is not uncommon and most often involves the suprascapular, radial, ulnar, femoral, and selected cranial nerves. Occasionally, the brachial plexus can be injured after a collision accident. Peripheral nerve injury is commonly traumatic and associated with additional musculoskeletal abnormalities (e.g., fracture).

Traumatic head injury with traumatic brain injury (TBI) represents a dynamic neurologic emergency. Depending on the nature of the injury, primary and secondary TBI can cause the clinical presentation of the patient to change frequently as processes such as edema, inflammation, and changes in intracranial pressure (ICP) occur.

Abnormal neurologic function can cause secondary excitement, agitation, and stress in the patient and worry for the owner or caretaker. Horses with alterations in the content of consciousness and behavioral changes may be unpredictable, vacillating between somnolence and maniacal rage. It is prudent to ensure safety of not only the patient to prevent additional injury but also any handler or personnel. In cases of unexplained neurologic deterioration, notably of inapparent causes, a thorough understanding of vaccination history of the patient and use of barrier protection strategies (e.g., medical examination gloves, coveralls) should be performed. Taking note of any "'in-contact" personnel is important if potential zoonotic disease is suspected (i.e., rabies).

DIAGNOSTICS

Performing a thorough neurologic examination is critical. To come to a diagnosis, the practitioner performs a careful neurologic examination followed by appropriate ancillary diagnostics. Ancillary diagnostics used in emergency situations typically include hematology and serum chemistries, radiographs, and potentially cerebrospinal fluid analysis. When available, these patients may require further diagnostic tests, notably imaging such as computed tomography, magnetic resonance imaging, endoscopy and electrodiagnostics, or a combination of tests.

A neuroanatomic localization of the disease should be made after a thorough examination,[114,115] as described in (Chapter 11). The neuroanatomic localization can be simplified by determining whether there is CNS, peripheral nerve, or multifocal nerve disease. In the case of CNS disease, it is helpful to determine whether the lesion is localized cranial or caudal to the foramen magnum (i.e., whether there is brain involvement). If there is brain involvement, it may be possible to further differentiate among cerebral, cerebellar, vestibular, or brainstem disease. If disease is localized caudal to the foramen magnum, the disease may be located in the cervical spinal cord or in the spinal cord caudal to T2.

Stabilization and symptomatic treatment are the primary goals of emergency management of neurologic disease. A definitive diagnosis may not be known for several days following the initial presentation of the emergent neurologic patient—for example, waiting for diagnostics for infectious agents (e.g., protozoal myelitis, West Nile virus, etc.). As such, the clinician's thorough neurologic examination provides a framework for a list of likely differential diagnoses. Empiric treatments, often for several differential diagnoses at once, are often provided until further testing supports a definitive diagnosis.

TREATMENT

The goal of therapy should be to optimize CNS perfusion and delivery of neurotropic substrates. Perfusion to the CNS is modulated by both the perfusing pressure (MAP) and local ICP. To promote global CNS perfusion, increasing MAP and/or decreasing ICP are desirable.

Judicious use of sedation may be needed to facilitate safe examination of the neurologic patient. Low-dose, short-acting drugs such as xylazine hydrochloride are recommended. However, for more fractious and refractory patients, longer acting continuous infusions and anesthetic agents may be required. Stabilization of hemorrhagic and hypovolemic conditions is necessary in trauma patients. Medical treatment of specific primary conditions is described in detail in Chapter 11. This section discusses select groups of drugs that are commonly used in horses with acute neurologic disease.

Analgesics

Analgesic drugs are indicated if horses experience pain (e.g., in traumatic disease). NSAIDs are the mainstay drugs in equine medicine because of their antiinflammatory and analgesic properties. Flunixin meglumine (0.5–1 mg/kg, IV, every 12–24 hours) is suitable. Opioids should be considered when additional analgesia is required, or when analgesia is required in situations of suspected NSAID toxicity, or when the risk of developing NSAID toxicity is high (e.g., dehydration). Opioids do not have specific antiinflammatory effects and in theory, κ-agonists over μ-agonists are advisable. Naloxone, μ-antagonist, has been shown to improve spinal cord blood flow. Multimodal analgesia, including the use of ketamine, may offer advantages in blocking neuroexcitation through *N*-methyl-D-aspartate blockade.

Corticosteroids

Corticosteroids (CSs) are potent antiinflammatory medications and may be indicated in certain types of neurologic diseases. Known inflammatory disease and acute trauma still appear to be indications for short-term corticosteroid therapy. Dexamethasone sodium phosphate is commonly administered (0.05–0.1 mg/kg, IV, every 12–24 hours) for up to 48 hours. A favorable response is expected within 4 to 8 hours after CS administration. Horses being given corticosteroid therapy should be monitored closely for the development of laminitis or secondary infection. If improvement in clinical signs is observed, transition to oral prednisolone therapy (0.5–1.0 mg/kg, PO, daily tapered over 3–5 days) to decrease the chance of adverse effects is indicated. The neuroprotective effect of CSs is thought primarily to be mediated by free radical scavenging.[116] Recently, it has been shown that, similar to methylprednisolone, dexamethasone decreases apoptosis-related cell death in rats that were subjected to traumatic spinal cord injury.[117] Other potential beneficial effects of CSs include reduction in the spread of morphologic damage, prevention of the loss of axonal conduction and reflex activity, preservation of vascular membrane integrity, and stabilization of white matter neuronal cell membranes in the presence of central hemorrhagic lesions. Furthermore, their antiinflammatory properties may be useful in reducing edema and fibrin deposition, as well as their ability to reverse sodium and potassium imbalance caused by edema and necrosis.

Methylprednisolone sodium succinate (MPSS) is a synthetic glucocorticoid with four times more antiinflammatory activity and 0.8 times less mineralocorticoid action compared with cortisol. Beneficial effects of MPSS on neural tissue include inhibition of lipid peroxidation, eicosanoid formation, and lipid hydrolysis, including arachidonic acid release, maintenance of tissue blood flow and aerobic energy metabolism, improved elimination of intracellular calcium accumulation, reduced neurofilament degradation, and improved neuronal excitability and synaptic transmission. The dose of MPSS used in human trials (30 mg/kg) exceeds that necessary for activation of steroid receptors, which suggests that MPSS acts through mechanisms that are unrelated to steroid receptors. Investigators have concluded that high-dose MPSS treatment within 8 hours of spinal cord injury improved neurologic recovery.[118,119] Controversy regarding the beneficial effects of MPSS and other steroids remains.[120,121] A suggested dose for horses is 25 mg/kg, IV bolus, then 5 to 8 mg/kg per hour for 23 hours.

Intracranial Pressure Reduction

Osmotic diuretics such as 20% mannitol (0.25–2.0 mg/kg, administered IV over 20 minutes) and 7.2% hypertonic saline (2–4 mL/kg, administered IV as a bolus) are effective in combating cerebral edema and increased ICP. These have a rapid onset of action (10–20 minutes) and are ideal therapies because they reduce ICP by drawing volume into the vascular compartment and they increase MAP. Animals receiving osmotic diuretics should be adequately hydrated. Mannitol administration is very effective in reducing ICP, although despite some technical limitations to the administration of this osmotic diuretic, multiple doses of mannitol can lead to intravascular dehydration, hypotension, reduction of cerebral blood flow (CBF), and elevation of spinal fluid osmolarity.[122,123]

Hypertonic saline administered early in the treatment of shock associated with head trauma may enhance the return of CBF and cell membrane function. Hypertonic saline may be the maintenance fluid of choice in head injury.[124] It is associated with significant decreases in ICP and cerebral water content compared with isotonic fluid treatment. Another study comparing the effects of a hypertonic saline + solution and mannitol on increased ICP found that the hypertonic saline hydroxyethyl starch reduced the ICP more effectively than mannitol alone.[125] Induction of prolonged hypernatremia using 3% hypertonic saline administered as a continuous infusion appears to be a promising therapy for the control of cerebral edema.[126]

Head and neck elevation at least 30 degrees above shoulder height is also advised to minimize venous pooling in the head. Increased venous pressures lead to increases in ICP via Queckenstedt's phenomenon. Use of a wire and pulley system connected to a halter is useful for the technique (Fig. 4.5).

Dimethyl sulfoxide (DMSO) 1 g/kg, administered IV as a 10% to 20% solution for 3 consecutive days, followed by three

FIG. **4.5** This horse sustained head (and body) trauma. The head and neck are kept elevated to reduce central nervous system venous pooling and intracranial pressure.

treatments every other day may be of benefit in acute neurologic disease. Reported benefits of DMSO include increased brain and spinal cord blood flow, decreased brain and spinal cord edema, increased vasodilating PGE_1, decreased platelet aggregation, decreased PGE_2 and PGF_2, protection of cell membranes, and trapping of hydroxyl radicals. The exact mechanism of DMSO remains unknown and remains controversial because purported positive effects are unsubstantiated.[127] Antioxidants such as vitamin E and selenium have been shown to be beneficial in certain neurologic diseases. Their purported beneficial effects include reduced lipid peroxidation and free radical scavenging[116]; however, they have not proved beneficial in cases of acute injury because of the length of time required to achieve therapeutic concentrations in the CNS.

Antibiotics

Antimicrobial drugs may be required to treat the primary disease process (e.g., in bacterial meningitis) or to treat/prevent secondary complications such as deep decubital ulceration, pneumonia, and cystitis. Horses with prolonged recumbency or dysphagia are at high risk of aspiration pneumonia and warrant broad-spectrum antibiotic therapy.

Ideally, the choice of antibiotic should be based on culture and sensitivity testing; however, empiric coverage while awaiting results should include drugs that can penetrate the site of action desired (e.g., meninges) and be tolerated by the patient (e.g., parenteral drugs in patients with dysphagia).

For CNS penetration, parenteral fluoroquinolones (enrofloxacin 7.5 mg/kg, IV, every 24 hours) or enteral chloramphenicol (50 mg/kg, PO, every 6 hours) appears to be a good choice. Potentiated sulfonamides and third-generation cephalosporins also achieve therapeutic cerebrospinal fluid concentrations. For empiric therapy of secondary sites of infection, trimethoprim-sulfamethoxazole (20–30 mg/kg, PO, every 12 hours) or procaine penicillin (22 mg/kg, IM, every 12 hours) or crystalline penicillin (22,000 IU/kg, IV, every 6 hours) in combination with gentamicin (6.6 mg/kg, IV, every 24 hours) can be used. For anaerobic coverage, metronidazole (15 mg/kg, PO, every 8 hours) is indicated. Gentamicin and tetracyclines have poor cerebrospinal fluid penetration.

SUPPORTING THE DOWN HORSE

Establishing venous access, controlling pain and anxiety of the patient, and performing a thorough examination and frequent repeat examinations should be done. Caution should be exercised and safe handling practices are imperative when dealing with a fractious patient and/or rabies is a concern. Management of a recumbent horse requires intensive supportive care and specific treatment aimed at the underlying or complicating disease processes.[128,129] Supportive care is mainly directed at protection of the animal and maintenance of adequate hydration and nutritional status. Care of down horses is time-consuming and more difficult if the horse is very large.

Down horses should be safely turned every 4 to 6 hours to help prevent muscle compartmental injury, peripheral nerve injury, and decubital ulcers. Treatment and prevention of decubital ulcers are critical in recumbent animals,[130] because prolonged or repeated unrelieved pressures to skin can result in damage and ischemia to underlying tissues and subsequent tissue ulceration.[131] Pressure ulcers usually occur over bony prominences, and in horses the most common sites of decubital ulcers are the tuber coxae, the points of the shoulder, and the caudal to the eye protuberance. Furthermore, pressure sores can occur along the distal extremities. For horses preventive strategies include appropriate padding and bedding, frequent changes in body positioning (i.e., turning), efforts to improve mobility, frequent examination of skin, maintenance of a well-balanced diet, and skin that is kept dry. Pressure sores generally heal well once the horse is able to stand. Rarely, infection of underlying bone can occur with prolonged severe decubitus and require debridement and local therapy.

Surgical intervention may be required in some cases—for example, traumatic skull injury with unstable fragmentation. Successful treatment of such cases has been reported in horses.[132]

Bedding should be absorbent, nonabrasive, and conformable. It may be necessary to adjust the type of bedding when the horse makes (successful) attempts to stand or is standing in the sling. Once the patient begins to make attempts to stand, bedding with good footing is helpful. Deep bedding in those situations may hinder the horse's attempts to stand or ambulate, and straw may be slippery. Where possible, keeping the down horse in sternal recumbency will help V/Q mismatch and respiratory effort. Straw bales can assist in patient positioning. Padded helmets and head bandages are advised to help protect the head and eyes. Damage to the eyes can occur directly by pressure to the eye or from bedding material. Moreover, specific diseases may result in a horse's inability to blink (e.g., botulism, Horner's syndrome, facial nerve paralysis). The most common ophthalmic disorders seen in recumbent horses are corneal ulcers and keratitis. Eyes should be examined daily and assessed and treated carefully. Triple antibiotic without steroid should be applied to the patients' eyes daily to help prevent keratopathy.

Nutrition and Hydration Maintenance

Parenteral fluids are indicated in cases where swallowing is impossible or the patient is in critical condition. Maintenance

fluids (40–60 mL/kg/day) are typically appropriate. Where enteral therapy can be tolerated, intragastric fluids may be preferable and more physiologic. Intermittent nasogastric tube passage or an indwelling small-bore enteral feeding tube placement is a good choice. Depending on the dietary protocol used, electrolytes and glucose may be added to the fluids. Recumbent animals lose body condition rapidly when no nutrition is provided. Dramatic changes are often noticeable within 1 week because of protein-calorie malnutrition. To prevent weight loss and maintain muscle strength and immunity, nutrition provision is essential. A more thorough discussion of nutrition in the critically ill horse can be found in Chapters 5 and 20.

Down horses are prone to developing impactions of the cecum, large colon, or small colon. Horses with botulism are notable cases. Reduced fecal output is an early sign, and judicious use of laxatives (magnesium sulfate or sodium sulfate; 1 g/kg, intragastrically) and/or lubricants (mineral oil 2–4 L per 500-kg horse, intragastrically) is indicated.

Additional Considerations

Horses with autonomic dysfunction (i.e., urine and/or fecal retention) require frequent emptying of the rectum and bladder. Use of stool softeners and frequent manual rectal evacuation should be performed several times each day. Special caution should be made when performing rectal evacuation, especially in the down horse, to avoid traumatic rectal tearing.

An indwelling urinary catheter with either a one-way valve or closed collection system should be placed to assist bladder emptying. Closed systems are recommended to avoid ascending cystitis. Empiric use of potentiated sulfonamides can assist in preventing catheter-related urinary bladder sepsis.

Physiotherapy is advocated to facilitate the rehabilitative process of injured horses. Physiotherapy can be provided in the recumbent animal by manipulating limbs, depending on the horse's attitude, or assisting the horse to stand with a sling. Controlled exercise allows the unaffected parts of the nervous system to compensate for the affected parts by increasing strength and conscious proprioception. Exercise is especially helpful in improving spinal cord deficits (e.g., weakness, ataxia, and spasticity).

Sling usage in the management of the down horse can be very helpful in reducing recumbency-related concerns. Placing the neurologic patient with normal mentation may be useful to facilitate a more thorough examination of individual limb deficits. The presence of lameness, weakness, and ataxia as well as the number of affected limbs is much more easily assessed when the horse is in an upright position. In this position the horse may be able to stand freely and demonstrate clinical signs that may help in determining a diagnosis.

Deterioration or improvement of disease may be determined relatively easily by daily sling assistance to provide short-term recommendations and prognosis. For long-term management the sling can be useful, depending on the horse's primary disease and compliance. Horses may become used to using the sling and can be comfortably managed until they have regained sufficient control and strength to ambulate freely. Use of the sling may also help with physiotherapy during which periodic sessions of partial or assisted standing can facilitate manipulation of limbs.

CHAPTER 5

Internal Medicine and Clinical Nutrition

Raymond J. Geor*

Veterinarians are a primary source of nutritional information and advice for horse owners. Therefore it is reasonable to expect equine practitioners to have some expertise in the clinical assessment of the nutritional status and feeding programs so that they may assist horse owners in the selection of rations for an individual horse or group of horses. Additionally, because diet composition can contribute to the pathophysiology and clinical manifestations of certain chronic diseases (e.g., some forms of chronic exertional rhabdomyolysis), the veterinarian is often consulted to make recommendations for special diets. Special dietary considerations are also required for sick neonatal foals or adult horses. This chapter provides an overview of the principles of clinical assessment of nutritional status and feeding programs, reviews carbohydrate nutrition for horses (including the types of carbohydrates in horse feeds, terminology and methods for analysis of carbohydrates in feeds, and strategies for mitigation of gastrointestinal disturbances associated with carbohydrate nutrition), and summarizes current recommendations for the nutritional support of neonatal or adult horses with acute illness. Other topics are feeding management of thin and starved horses and dietary recommendations for the management of obesity, which is becoming a significant problem in equine medicine. The reader is referred to the most recent edition of the National Research Council's *Nutrient Requirements of Horses* for a complete discussion of equine nutrition.[1]

EVALUATION OF NUTRITIONAL STATUS AND FEEDING PROGRAMS

Clinical assessment of a feeding program for an individual or group of horses involves three basic elements: assessment of general health and dietary history, clinical examination, and evaluation of current diet and feeding method (i.e., types and amounts of feeds and how they are fed). The physiologic state and intended use of the horse (e.g., pregnant, lactating, in athletic work) affect its nutritional requirements; therefore, they are vital to the evaluation of the feeding program and when making any necessary adjustments. It also is useful to inspect housing and feeding facilities, including feed bins, hay storage, and the watering system. Commercial software programs are available to assist with ration evaluation in relation to nutrient requirements.[2] Fig. 5.1 shows an example of a simple form that can be used to collect clinical data, including signalment, body weight (BW) and condition, and details regarding the horse's current and recommended ration. Box 5.1 provides explanations for a number of nutritional terms used to describe feed nutrients and fractions, the knowledge of which is relevant to the interpretation of feed analysis data.

Clinical Examination

Body condition scoring (BCS) and measurement of BW are the cornerstones of the clinical assessment of nutritional status. In some situations laboratory analysis of blood or other tissue samples may be indicated as part of the nutritional evaluation (e.g., measurement of whole-blood selenium concentration). It must be recognized that no single laboratory value is a reliable indicator of nutritional status in an individual animal. Nonetheless, blood or tissue measurements may be valuable for the evaluation of herd problems, in which samples should be obtained from a representative number of animals.

BW and BCS, which assesses subcutaneous fat deposition, are indicators of long-term energy balance, or energy (calorie) intake relative to the horse's needs. Generally, horses that receive inadequate dietary energy will lose BW and condition, whereas weight gain and the development of overconditioning (high BCS) signify energy intake in excess of requirements. Although a number of systems have been used to determine BCS, the most widely applied method is that developed by Henneke.[3] The Henneke system uses a 1- to 9-point scale and requires the assessment of subcutaneous fat deposition in six areas: over the crest of the neck, withers, behind the shoulder, over the ribs, along the back, and around the tailhead. Considerable variation may exist in the pattern of fat deposition among horses; for example, some horses have little fat deposited over the ribs even when other areas of the body are well covered. In addition, fat deposits are sometimes asymmetrically distributed. Therefore it is important to evaluate all six areas of the body on both sides. A score between 1 and 9 is assigned, in which 1 indicates severe emaciation and 9 indicates extreme fatness (Table 5.1). Body condition scores of 4 to 6 are regarded as ideal depending on use of the horse. Studies of weight gain and loss in moderately conditioned (BCS = 4–7) Thoroughbred, Quarter, and Arabian horses indicate that one BCS unit represents approximately 25 to 35 kg of BW.[4,5] The BW associated with each unit of body condition may be higher in fat or thin horses.

The Henneke BCS system, originally developed for use in Quarter Horse broodmares,[3] is most appropriate for use in light breeds such as Thoroughbreds, Arabians, and Standardbreds. This system may not be suitable for ponies and larger

NUTRITIONAL STATUS AND FEEDING PROGRAM EVALUATION FORM

HORSE INFORMATION Date _____

Owner _____ Horse Name _____

Description _____
(e.g., age, gender, breed)
Use/physiological state _____

Housing/environment _____

Medical history_____
_____

PHYSICAL ASSESSMENT

Dentition _____ Normal _____ Poor
Hooves _____ Normal _____ Founder lines (laminitic)
Hair Coat _____ Normal _____ Long _____Other
Current Body Condition Score _____
(1 = very thin; 5 = moderate; 9 = very obese)

Notes:_____
(e.g., abnormal fat deposits)

Optional: Neck Circumference (cm or inches)_____

ESTIMATED ENERGY INTAKE ON CURRENT DIET

Forage Consumption

Excellent hay (1.1 Mcal/lb) × _____ lb/d = _____ Mcal digestible energy (DE)
Very good hay (0.9 Mcal/lb) × _____ lb/d = _____ Mcal
Average hay (0.8 Mcal/lb) × _____ lb/d = _____ Mcal
Below-average hay (0.7 Mcal/lb) × _____ lb/d = _____ Mcal

Concentrate Consumption

Oat grain (1.3 Mcal/lb) × _____ lb/d = _____ Mcal
Sweet feed (1.4 Mcal/lb) × _____ lb/d = _____ Mcal
High-fat sweet feed (1.5 Mcal/lb) × _____ lb/d = _____ Mcal

Other Feeds (e.g., protein supplements, beet pulp)

_____ (_____ Mcal/lb) × _____ lb/d = _____ Mcal
_____ (_____ Mcal/lb) × _____ lb/d = _____ Mcal
_____ (_____ Mcal/lb) × _____ lb/d = _____ Mcal

Current Total Energy Intake _____ **Mcal/d**

(NOTE: Other nutrient intakes should also be checked for adequacy)

FIG. **5.1** Worksheet for evaluation of nutritional status and feeding program. (Adapted from Dr. Laurie Lawrence, University of Kentucky, Lexington, Kentucky.)

ESTIMATING THE APPROPRIATE DAILY ENERGY INTAKE

Target Body Condition Score (BCS) _____

Recommended Change in BCS _____

(+1, +2, –1, –2, etc.)

Current Horse Weight _____ **Target Horse Weight** _____

Guide: For an 1100- to 1200-lb horse, change in 1 BCS unit = 45 to 70 lb, but greater weight change may be necessary to alter BCS in very thin or very obese horses. Also, note that altering feed intake can have a rapid effect on body weight by increasing or decreasing gut fill. Thus, a change in gut fill can affect body weight by 10 to 20 lb, without a concomitant change in body condition score.

Recommended Energy Intake for Target Weight _____ **Mcal/d**
(see Box 2)

Suggested Adjustments for Weight Change (estimates)

Increase BCS 1 unit in 60 days (add 6 to 7 Mcal/d)
Increase BCS 2 units in 90 days (add 9 to 10 Mcal/d)
Decrease BCS 1 unit in 60 days (subtract 6 to 7 Mcal/d)
Decrease BCS 2 units in 120 days (subtract 6 to 7 Mcal/d)

Adjusted Recommended Daily Energy Intake _____ **Mcal/d**

RECOMMENDED DIET

Current Level of Dietary Energy

Adequate _____ Insufficient _____ Excessive _____

Current Diet Could Include Minor Modifications: _____

Current Diet Should Be Adjusted as Follows:

Suggestions:

For weight loss: concentrate amounts should be reduced first
For weight gain: hay intake and quality should be adjusted first

ENERGY INTAKE WITH SUGGESTED DIET

Forage Consumption

Excellent hay (1.1 Mcal/lb) × _____ lb/d = _____ Mcal DE
Very good hay (0.9 Mcal/lb) × _____ lb/d = _____ Mcal
Average hay (0.8 Mcal/lb) × _____ lb/d = _____ Mcal
Below-average hay (0.7 Mcal/lb) × _____ lb/d = _____ Mcal

Concentrate Consumption

Oat grain (1.3 Mcal/lb) × _____ lb/d = _____ Mcal
Sweet feed (1.4 Mcal/lb) × _____ lb/d = _____ Mcal

FIG. **5.1, cont'd**

Continued

High-fat, sweet feed (1.5 Mcal/lb) × _____ lb/d = _____ Mcal

Other Feeds (e.g., protein supplements, beet pulp)

_____ (_____ Mcal/lb) × _____ lb/d = _____ Mcal

_____ (_____ Mcal/lb) × _____ lb/d = _____ Mcal

_____ (_____ Mcal/lb) × _____ lb/d = _____ Mcal

Total Energy Intake _____ **Mcal/d**

FIG. **5.1, cont'd**

BOX 5.1 Nutritional Terminology Relevant to the Interpretation of Feed Composition Data

Moisture: Percentage of feed that is water

Dry matter (DM): 100% minus the water in feed
Most hays and concentrates are approximately 90% water. Fresh pasture can contain 60% to 80% water.
Feed compositions are usually compared on a *DM basis* (100% DM), but feeds with similar concentrations of DM can be compared on an *as-fed basis.*

Crude protein (CP): Also called *total protein;* this value is calculated by measuring total nitrogen.

Acid detergent fiber (ADF): A chemically determined fraction that contains cellulose and lignin. ADF is inversely related to digestibility and is used to estimate the digestible energy content of horse feeds.

Neutral detergent fiber (NDF): A chemically determined fraction that contains cellulose, lignin, and hemicellulose. NDF contains most of the structural carbohydrates in plants. As plants mature, they contain more stem (more structure); therefore, DF increases with maturity. The NDF fraction includes the ADF fraction. There is a general inverse relationship between NDF in forages and voluntary forage intake by horses; in other words, when two hays of similar variety are compared, the forage with lower NDF will be consumed in higher amounts by horses.

Nonfiber carbohydrates (NFCs): This is not a measured fraction. NFC is determined by calculating the difference between total DM and the sum of NDF, crude fat, ash, and CP. Types of carbohydrates that are included in the NFC fraction are true nonfiber carbohydrates, such as monosaccharides and starch, but it also includes some carbohydrates that are resistant to mammalian enzymatic digestion such as pectin (found in beet pulp and alfalfa hay) and fructan (found in some grasses).

Ethanol-soluble carbohydrates (ESCs): Part of the nonstructural carbohydrate fraction. The ESC fraction contains mostly simple sugars (disaccharides). Some laboratories categorize this fraction as *sugars.*

Starch: Contains amylose and amylopectin. The starch analysis does not separate easily digested starch and starch resistant to small intestinal digestion.

Nonstructural carbohydrate (NSC): Previously, the NSC fraction included all carbohydrates not included in NDF, but today it is commonly defined as starch plus ESC. Therefore the NSC in a feed represents the carbohydrates that are expected to be digested and absorbed from the small intestine as glucose or other simple sugars.

Water-soluble carbohydrates (WSCs): This fraction includes the simple carbohydrates that appear in the ESC fraction as well as *some* longer chain carbohydrates, including fructans. Fructans are storage carbohydrates synthesized by some plants, especially cool season grasses. Some nutritionists calculate fructan as the difference between WSC and ESC, but this estimate has not been validated.

Digestible energy (DE): This is not a measured value. DE is calculated from other analyzed fractions, including ADF and CP. The amount of fat in the feed affects the true DE value of a feed, but if crude fat was not a requested item on the feed analysis, the DE might be calculated using an average value for crude fat. For common forages (e.g., hay and pasture), the DE value calculated by a laboratory is a relatively accurate assessment of the true DE value. For concentrate feeds the calculated DE value may not represent the true DE value.

Adjusted CP, % total digestible nutrients (TDN), net energy of lactation (NEL), net energy of maintenance (NEM), net energy of gain (NEG), relative feed value: Not relevant to horse diet analyses.

breed horses (e.g., drafts) that have a different pattern of fat distribution. A 9-point BCS system for Warmblood horses was developed to account for differences in conformation and patterns of fat deposition in this breed compared with Quarter Horses.[6] For example, fat begins to cover the hip bones of Quarter Horses at a BCS of 4, whereas the hip bones of Warmblood horses remain prominent at a BCS of 6 (using the system developed for Warmbloods).

It also should be noted that the BCS system does not register differences in regional adiposity that may signify increased risk of disease. In humans visceral (abdominal) adiposity is more closely linked than generalized obesity to the risk for diabetes and cardiovascular disease, and measurement of waist circumference is a better indicator of abdominal fat accumulation than is body mass index.[7] In horses and ponies there may be a similar association between regional adiposity and disease risk. In studies of horses and ponies with a predisposition to pasture-associated laminitis, some affected animals are not obese on the basis of BCS (i.e., BCS <7) and have no external evidence of regional adiposity, but others have enlarged fat deposits on the neck ("cresty neck") and thoracic and tailhead regions; these fat deposits

TABLE **5.1 Description of Body Condition Scores in Horses**

Condition Score	General Condition	Neck	Shoulder	Withers	Ribs	Loin	Tailhead
1	Very poor	Individual bone structure visible; feels very bony	Bone structure very visible and sharp to touch	Bones easily visible; no fat; razor-like	Ribs very visible and skin furrows between ribs	Spine bones visible; ends feel pointed	Tailhead and hips very visible
Animal extremely emaciated; no fatty tissue can be felt							
2	Very thin	Bones just visible; animal emaciated	Possible to outline bone structure	Withers obvious, very minimal fat covering	Ribs prominent, slight depression between ribs	Slight fat covering other vertical and flat spin projections; ends feel rounded	Tailhead and hip bones obvious to the eye
3	Thin	Thin, flat muscle covering, no raised muscle or fat	Shoulder accentuated; some fat cover but thinner than desirable	Withers thin and accentuated with some, although little, fat cover	Slight fat cover over ribs; rib outline obvious to the eye	Fat buildup halfway on vertical spines, but easily visible; flat spinal bones not felt	Tailhead prominent; hip bones rounded but easily visible; pin bones covered
4	Moderately thin	Neck with some fat; horse not obviously thin	Shoulder not obviously thin with some fat cover	Withers not obviously thin, smooth edges but prominent	Faint outline visible to the eye	Slight outward ridge along back	Fat palpable
5	Moderate	Neck blends smoothly into body with some fat cover	Shoulder blends smoothly into body	Withers smoothly rounded over top	Ribs cannot be seen but can be easily felt	Back level	Fat around tailhead beginning to feel spongy
6	Moderately fleshy	Fat easily palpable	Fat layer palpable	Fat palpable	Fat over ribs feels spongy	May have slight inward crease	Fat around tailhead soft and palpable
7	Fleshy	Visible fat deposits or lumps along neck	Fat buildup behind shoulder	Fat covering withers is firm	Individual ribs still palpable	May have slight inward crease down back	Fat around tailhead soft and rounded off
8	Fat	Noticeable thickening of neck	Area behind shoulder filled in flush with body	Area along withers filled with fat	Difficult to feel ribs	Crease down back evident	Tailhead fat very soft and flabby
Fat deposited along inner buttocks							
9	Extremely fat	Bulging fat	Bulging fat	Bulging fat	Patchy fat over ribs	Obvious deep crease down back	Building fat around tailhead
Fat along inner buttocks may rub together; flank filled in flush							

are sometimes asymmetrically distributed.[8,9] Neck crest adiposity, assessed by the ratio of mean neck circumference to height at the withers (NCHR), is negatively associated with insulin sensitivity in horses and ponies.[9,10] Although cutoff values for NCHR in relation to obesity and disease risk have not been defined, the repeated measurement of mean neck circumference is useful for monitoring the effectiveness of a weight loss program.

Knowledge of a horse's BW is needed for accurate calculation of nutrient and feed requirements. It is important to note that the BW of an individual horse can vary between 5% and 15%, depending on hydration and feeding status and on gastrointestinal fill. Accordingly, it is important to standardize the time of feeding relative to measurement of BW. BW may be measured directly by use of a platform scale or, in mature horses, estimated from body measurements such as heart girth circumference and body length.[11,12] Heart girth is measured immediately behind the elbows, and body length is measured from the point of the shoulder to the tuber ischii:

$$\text{BW (kg)} = \left[\text{Heart girth (cm)}^2 \times \text{length (cm)}\right]/11,800$$

BW also can be estimated from measurement of heart girth circumference by use of a weight tape calibrated for horses. Measurements should be taken in a consistent manner, with the horse standing on a flat surface, and care must be taken not to pull the tape too tightly. Clinicians are advised to take the average of several (e.g., three or four) measurements. Accuracy of these measurements is affected by a number of factors, including breed, conformation, level of fitness, thickness of hair coat, gastrointestinal fill, and pregnancy status.[12] BW based on heart girth is most accurate when this method is applied to mature horses with an average BCS (i.e., 5–7). Underestimation or overestimation of BW may occur when weight tapes are used to estimate the BW of horses with low or high condition scores.

Diet and Ration Evaluation

It is useful to first examine the physical characteristics of feeds (i.e., visual appearance [color, presence of foreign material such as mold and dust] and odor). Preserved forages (e.g., hay) should be evaluated for type (grass vs. legume), leaf-to-stem ratio, and presence of seed heads. Hays with good nutritional value are characterized by a large proportion of leaf; compared with stems, leaves have higher nonstructural carbohydrates (NSCs; starches, sugars, and fructans), lower structural carbohydrates (SCs; hemicellulose, cellulose, and lignin), and higher protein.[1] Therefore second- and third-cutting hays, which often have a higher stem-to-leaf ratio, tend to provide higher nutritional value than first-cutting hay. The latter is usually harvested at a more mature stage. The presence of seed heads and a stemmy, coarse appearance are also indications of advanced maturity at cutting. Some studies have reported an inverse relationship between the neutral detergent fiber (NDF; the fraction that contains cellulose, hemicellulose, and lignin) and voluntary hay intake (i.e., the voluntary intake of stemmy hays with high NDF content will be lower compared with that of hays with high leaf-to-stem ratio).[1,13]

The next step in the evaluation is to estimate daily feed intake. Owners or stable managers should be questioned to determine the amounts of hay, concentrates, and supplements provided (and whether the horse regularly refuses any of these feedstuffs). All feeds, including several flakes or biscuits of hay, should be weighed to estimate the actual amounts of feed provided to the horse. Significant errors may occur when volume (e.g., "a coffee can–full") rather than weight is used to estimate feed provision because grains, concentrates, and hays vary markedly in weight per unit volume. A handheld fish scale or similar scale works well for this task. It is difficult to measure actual feed intake, particularly when forage is fed on the ground, where wastage can be as high as 25%, or fed to groups of horses. The other challenge is estimation of pasture forage intake, which is generally taken as the difference between the mean intake of digestible energy (DE) for horses, with consideration given to their weight, age, and physiologic condition, minus actual daily intakes of hay and grains. As previously mentioned, regular assessment of BW and BCS over time will provide the best guide to the adequacy of energy intake. Reported values for daily dry matter intake (DMI) by horses, ponies, and donkeys range between 0.8% and 5.2% of BW.[1] Young and mature horses appear to have a maximal daily DMI of 3% to 3.2% of BW, but intakes in the range of 2.0% to 2.5% of BW are more typical (this includes horses maintained on an all-hay diet). Some evidence suggests that ponies may have higher daily DMI than horses.[1]

The clinician also should evaluate feeding management, particularly when a problem under investigation may be due to poor feeding practices (e.g., weight loss, colic). For example, what are the relative proportions of forage and grain/concentrate? Does the ration contain adequate high-quality forage? How many times a day is the horse fed? How frequently is the diet changed, and are these changes made gradually (ideally over 7–10 days) or suddenly? Several epidemiologic studies have reported that changes in diet (grain/concentrate or hay, even when switching to hay of the same type) significantly increase the risk of colic.[14-16] The risk of gastrointestinal problems also increases when horses are fed large quantities of starch-rich grain and concentrate feeds or inadequate long-stem roughage.[14,16] As a general guide, all horses should receive a *minimum* of 1.0% of BW per day as hay or the equivalent; forage at 1.5% of BW per day is preferred. For a 450- to 500-kg horse, grain or concentrate meals should be no more than 2.5 kg (approximately 5 lb) to reduce risk of hindgut disturbances associated with the cecal delivery of undigested starch. If the daily ration includes more than 5.0 kg of grain or concentrate, it should be provided in more than two feedings per day (see the section Carbohydrates in Equine Nutrition).[16]

Information on the nutrient content of the diet is needed to determine the adequacy of the ration. Several approaches can be used to estimate the nutrient contents of feeds. The feed tags on commercial feeds provide some nutritional information, including a list of ingredients and data on some nutrients. However, feed manufacturers are required to guarantee only that minimums were met and maximums were not exceeded; in other words, the actual content of listed nutrients is not provided. An alternative source of data on the nutrient content of feeds is published databases (e.g., National Research Council [NRC] publications, feed company websites). Although the nutrient profiles available from these databases provide a useful guide, these data may not correspond exactly to the feedstuff provided to the horse under evaluation because of differences in geography, growing and harvesting conditions, and other factors. The ideal, although not always practical, approach is to submit samples of feed and forages (core hay samples and pasture clippings) for laboratory analysis of nutrient content. At least two samples (approximately 250 g each) of each grain or concentrate should be taken; these should be mixed thoroughly with the composite sample submitted for analysis. Approximately 10% of the hay store should be sampled by use of a hay probe. Again, these samples should be well mixed, with the composite sample shipped to the laboratory in a sealable plastic bag. Garden shears can be used to obtain pasture clippings, which should be sampled in a Z-pattern and cut to grazing height. It may be necessary to sample clippings taken from several pastures to determine the range of nutrients on the farm. The basic nutrient profile from analysis includes dry matter (DM), DE, crude protein (CP), acid detergent fiber, NDF, fat (ether extract), ash, calcium, magnesium, phosphorus, sodium, and potassium (see Box 5.1). Trace element and vitamin analyses are available depending on need and expense. Some laboratories will perform additional analyses and calculations to provide estimates of some of the carbohydrate fractions. For example, Equi-Analytical Laboratories (Ithaca, NY; www.equianalytical.com) analyzes starch and ethanol-soluble carbohydrates (ESCs; which are mostly simple sugars). More information on dietary carbohydrates is presented later in this chapter.

With data on feed composition (and estimated intake of feeds), it is possible to formally evaluate the ration against published feeding standards (e.g., NRC 2007[1]). The NRC developed a simple Web-based program that calculates nutrient requirements derived from the 2007 *Nutrient Requirements of Horses* (http://nrc88.nas.edu/nrh/); this program can also be downloaded to a personal computer. The user is first required to enter basic information such as age, BW, and physiologic state (e.g., stallion, lactating mare, working horse) and then data on the horse's ration, specifically, the amount and nutrient profile of each feed and supplement fed to the horse. The program uses these data to calculate nutrient requirements, dietary supply, and the difference between the two amounts. Unfortunately, only a limited number of nutrients are evaluated: DE, CP, lysine, Ca, P, Na, Cl, and K. The NRC recommendations are also based on minimum nutrient requirements, whereas many nutritionists favor feeding standards based on optimal ranges. Several nutrition companies have developed more comprehensive computer software programs. For example, MicroSteed, developed by Kentucky Equine Research, Inc. (Versailles, Kentucky), can evaluate the ration against both the NRC minimums and a set of optimums recommended by company nutritionists.[17]

The process outlined in the preceding paragraphs will facilitate decisions regarding the adequacy of the current ration. If gross deficiencies or excesses are identified, adjustments can be recommended and implemented. Another important aspect is the need for follow-up monitoring, particularly if a goal has been set for weight loss or gain. Fig. 5.1 outlines a simple way to estimate energy needs and intake and calculate ration adjustments necessary to facilitate weight loss or gain. A more detailed discussion of dietary management of thin or obese horses is presented later in this chapter.

CARBOHYDRATES IN EQUINE NUTRITION

Carbohydrates are the primary source of energy in the diet of horses. As nonruminant herbivores, horses evolved to utilize forages high in SCs, with bacterial fermentation and production of volatile fatty acids (VFAs) in a highly developed large intestine. However, modern horses, particularly those in athletic training, are often fed cereal grains or other starch-rich feeds to meet energy requirements. For example, some survey studies indicate that racehorses weighing 450 to 550 kg typically receive 3 to 6 kg of feed per day, with some horses receiving more than 8 kg per day.[18,19] Such high grain intakes by horses (or a low forage-to-grain ratio such as 30:70) have been implicated in the development of gastrointestinal problems, particularly colic associated with disturbances to hindgut function[20,21] and gastric ulcer disease.[22,23] Additionally, diets rich in starch and sugar contribute to the clinical expression of chronic muscle diseases (polysaccharide storage myopathy and recurrent exertional rhabdomyolysis) in genetically susceptible horses[24] and likely exacerbate insulin resistance and susceptibility to laminitis in horses and ponies with the metabolic syndrome phenotype.[25] Therefore equine veterinarians should have working knowledge of carbohydrate digestion and metabolism and methods for assessment of the carbohydrate fractions in feeds. This information can be used in the formulation of diets and feeding programs that control intake of certain carbohydrates and potentially mitigate risk of these conditions.

Classification and Nomenclature

Plant carbohydrates in equine feeds can be subdivided into the SCs, which largely make up the fibrous portion of the diet and originate from the plant cell wall, and the NSCs, which originate from the cell content. Diets for horses, whether based on pasture, conserved forage, concentrates, or a combination of all three, contain both SCs and NSCs.[26]

All dietary carbohydrates contain similar amounts of gross energy. However, when used by the horse, they provide variable amounts of DE, metabolizable energy, and net energy.[27] Carbohydrates digested and absorbed as monosaccharides in the small intestine yield more energy than carbohydrates digested by microbial action (predominantly fermentation), and a glycemic response to the ingestion of such carbohydrates tends to occur.[28] The type of linkage between the monosaccharide residues in the carbohydrate also affects the site of digestion of these compounds and thus their nutritional value. Hydrolysis of the α1-6 and the α1-4 linkages of starch and maltose, for example, can occur in the equine small intestine, but horses do not produce the enzymes necessary to digest the β1-4 linkages found in cellulose or the mixed linkages found in hemicellulose.[28] Therefore digestion of cellulose and hemicellulose must occur as a result of microbial fermentation, which does not result in a pronounced glycemic response. Stachyose, raffinose, β-glucans, fructooligosaccharides (or fructans), and pectin are also thought to be resistant to enzymatic hydrolysis. Thus an understanding of the various carbohydrate fractions in plants (including means of digestion) is needed to determine the potential for a feed to result in a glycemic–insulinemic response.

Simple Sugars

This fraction comprises monosaccharides and disaccharides (i.e., glucose, fructose, sucrose). The simple sugar content of these plants is low; the sugars produced by way of photosynthesis can be used immediately by the plant to supply energy for metabolism, protein synthesis, and growth, or they can be elaborated into more complex *oligosaccharides* (e.g., raffinose and stachyose) or the *structural polysaccharides* of the plant cell wall (e.g., cellulose, hemicellulose, pectin). When sugar production exceeds the immediate requirements for metabolism, the excess sugars are polymerized to form "storage," or "reserve," carbohydrates. Storage carbohydrates mostly are in the form of starch or fructan. Starches and fructans, together with the simple sugars and the oligosaccharides, make up the NSC fraction of the diet.[26]

Oligosaccharides

The raffinose family of oligosaccharides are α-galactosyl derivatives of sucrose. The most common are the trisaccharide raffinose (composed of galactose, fructose, and glucose) and the tetrasaccharide stachyose. These oligosaccharides are found in sugar beet molasses and whole grains. Soybean oligosaccharides make up approximately 5% of DM in whole beans and up to 8% of DM in soybean meal. Together raffinose and stachyose rank second only to sucrose in abundance as water-soluble carbohydrates (WSCs). However, raffinose and stachyose cannot be directly digested by the horse because of the absence of the enzyme α-galactosidase.

Structural Polysaccharides

This fraction includes dietary fiber that is composed of cellulose, pectin, and hemicelluloses, along with mannans,

galactans, and xyloglucans.[26] Total nonstarch polysaccharides (NSPs) are the sum of the water-soluble and water-insoluble NSPs and include cellulosic and noncellulosic polysaccharides. Although some of the NSPs are water soluble, these are not digestible by mammalian enzymes; therefore, digestion can occur only through fermentation, which may occur proximal to the cecum.

Starch

Starch is the main storage polysaccharide in a number of higher plants, including the forage legumes (e.g., clover, alfalfa). Starch is stored in both the vegetative tissues (i.e., nonreproductive tissues such as leaves and stems) and the reproductive tissues (i.e., flowers, seeds). The starch content of grass seed ranges from approximately 300 to 400 g starch/kg seed DM, whereas oats, barley, and corn contain approximately 400, 550, and 700 g starch/kg DM, respectively.[26] The amount of starch stored in the leaves of legumes rarely exceeds 75 g starch/kg DM.

Starch consists of polymers of glucose, which occur in two forms: amylose and amylopectin. Amylose is a linear α-(1–4) linked molecule, and amylopectin is a larger, highly branched molecule containing both α-(1–4) and α-(1–6) linkages. The ratio of amylose to amylopectin largely depends on the botanical origin of the starch. For example, in wheat flour amylose is around 30% of the total starch, whereas corn can contain up to 70% amylose. The extent to which starch is digested prececally depends on many factors, including the availability of the starch to mammalian enzymes (e.g., the extent to which any outer husk or hull has been broken down), the ratio of amylose to amylopectin within the starch granule, the effect of processing (thermal treatment, for example, improves the digestibility of corn and barley starch), and intestinal passage rate.[29] Glucose availability in the small intestine tends to be higher for starches with high amylopectin content. As discussed in more detail later, the ingestion of excessive levels of starch may exceed the relatively limited amylolytic capacity of the equine foregut. Any undigested starch (including resistant starch) that has not been fermented in the stomach and small intestine by resident microbes will pass into the large intestine, where it will be fermented and yield less net energy than when it is absorbed as glucose.[29]

Fructan

Fructan is the major storage carbohydrate of the vegetative tissues of temperate grasses. Depending on the number of fructose molecules, fructans can be described as oligosaccharides (<10 monosaccharide units) or polysaccharides (>10 units). High levels of fructan can accumulate in the vegetative tissues of pasture grasses, with implications for the development of pasture-associated laminitis.[26] In a 3-year northern European study of the WSC (sugar plus fructan) components in the vegetative structures of temperate grasses, fructan contents of up to 279 g/kg DM were recorded.[26] Fructan accumulation (unlike that for starch) can occur below the temperature threshold for plant growth (approximately 6°C).[30] Therefore cold, bright days that result in high rates of photosynthesis but minimal plant growth may lead to the production of large quantities of excess sucrose and, in turn, substantial fructan accumulation.

Evaluation of the Carbohydrate Content in Feeds

A number of analytical techniques and terms have been used to describe the carbohydrate fractions in feeds. It is important to understand what the different terms mean and to recognize the variation among laboratories with respect to analytical methods and definitions (see Box 5.1).

Water-Soluble Carbohydrates

The WSC fraction includes the simple (glucose, sucrose, and fructose) and more complex (oligosaccharides and fructans) sugars. Although not all of these components can be digested by mammalian enzymes, most can be rapidly fermented by gram-positive bacteria, resulting in the production of lactic acid. However, it is important to note that starch, which also can be fermented in this way, is not included in this category. Some commercial laboratories measure WSC (i.e., free sugars plus oligosaccharides and fructans) but report it simply as sugar, whereas others use the term *sugar* to describe the free sugar fraction only.

Ethanol-Soluble Carbohydrates

The term *ethanol-soluble carbohydrates* (ESCs) refers to the component of the WSC that is digestible by mammalian enzymes and elicits a glycemic response (i.e., simple sugars). The difference between the WSC and ESC fractions has been used to approximate the amount of fructan in a particular feedstuff, although the accuracy of this calculation has not been verified.

Nonstructural Carbohydrates

The NSC fraction includes the monosaccharides and disaccharides, oligosaccharides (including fructan), fructan polysaccharides, and starch. Several methods have been used to estimate the NSC content of feeds. The system developed by Van Soest[31] estimates NSC *by difference,* in which the feed is partitioned into neutral detergent solubles and NDF. The NDF fraction contains cellulose, most of the hemicellulose, and lignin. Until recently, the NSC content of a feed was determined on the basis of feed analysis and the "by-difference method," according to the following equation:

$$\text{NSC} = 100 - (\text{CP \%} + \text{NDF \%} + \text{moisture \%} + \text{fat \%} + \text{ash \%})$$

This estimate was taken to represent the combined sugar, starch, and fructan content of the feed. However, it also includes pectins, gums, and mucilages that, unlike starch, sugar, and fructan, are not subject to very rapid fermentation; therefore, they do not induce the marked changes in lactic acid concentrations and pH within the hindgut that can occur with excess intake of sugars, starch, or fructan. Therefore the NSC by-difference fraction is now referred to as *nonfiber carbohydrate,* or *NFC.* The quantitative difference between measured NSC and NFC is small for some feeds (e.g., cereal grains) but can be quite large for other feeds (e.g., feeds with substantial pectin, such as sugar beet pulp; Table 5.2).

Most commercial feed analysis laboratories do not completely fractionate the carbohydrates that make up the NSC, but in most feeds the amount of NSC can be approximated by summing the amount of starch and WSC. The extent to which the sum of starch and WSC accounts for all NSC depends on the analytic procedures used to measure these fractions. This determination probably more accurately reflects the potential for a feed to be rapidly fermented to produce lactic acid.

TABLE **5.2 Neutral Detergent Fiber, Nonfiber Carbohydrate, and Nonstructural Carbohydrate Composition of Selected Feedstuffs on a Dry Matter Basis**[a]

Feedstuff	% NDF	% NFC[b]	% NSC[c]
Alfalfa hay	43.1	22.0	12.5
Beet pulp	47.3	36.2	19.5
Corn gluten meal	7.0	17.3	12.0
Mixed, mostly grass hay	60.9	16.6	13.6
Soybean meal (48% CP)	9.6	34.4	17.2
Soyhulls	66.6	14.1	5.3

[a]The values shown here may vary from those shown elsewhere in this chapter. They are provided to illustrate differences among feeds and carbohydrate categories. Actual values for individual feeds may vary by stage of maturity, variety, and source.
[b]%NFC = (100% – %CP – %EE – %ash – %NDF).
[c]%NSC determined by direct measurement.
CP, Crude protein; *EE,* ether extract; *NDF,* neutral detergent fiber; *NFC,* nonfiber carbohydrate; *NSC,* nonstructural carbohydrate.

Carbohydrate Nutrition and Colic

Colic is caused by many conditions, each of which may be related to specific risk factors, such as changes in diet, feeding practices, exercise patterns, and housing or inappropriate parasite control programs. An association between feeding practices and disturbances in gastrointestinal function has long been hypothesized,[32,33] but the mechanisms linking diet with the development of intestinal dysfunction are poorly understood. Indeed, the exact relationship between diet and colic is difficult to determine because of the variety of feeds and feeding practices used throughout the world as well as differences in study populations. Furthermore, it is often difficult to separate the effects of diet and feeding schedule from other management practices, which often depend on the horse's breed and use. Nonetheless, the results of recent epidemiologic studies support the proposition that diet composition and recent changes in diet are important risk factors for the development of colic.[34-39] Tinker et al.[37] prospectively examined the risk for colic at 31 horse farms over a 1-year period. Both a change in concentrate feeding (odds ratio [OR] = 3.6 relative to no colic) and the feeding of high levels of concentrate (>2.5 kg/day DM, OR = 4.8, >5 kg/day DM, OR = 6.3, relative to feeding no concentrate) were identified as risk factors for colic. In addition, colic risk increased when processed feeds such as pellets were fed. Hudson et al.[36] reported that a recent (within 2 weeks) change in type of grain or concentrate fed (OR = 2.6), the feeding of more than 2.7 kg of oats per day (OR = 5.9), and a change in the batch of hay fed (OR = 4.9) were significant risk factors for an episode of colic. In another prospective case-control study, neither the amount nor type of concentrate fed was associated with the colic risk, although the researchers did conclude that horses at pasture may have a decreased risk of colic.[38] On the other hand, a recent (within 2 weeks) change in diet, in particular the type of hay fed (including hay from a different source or cutting of the same type of hay) was a significant risk factor for colic.[38] In this study feeding hay other than coastal/Bermuda or alfalfa significantly increased the colic risk, but this finding may have reflected hay quality and digestibility rather than type of hay per se. Changing to a poorer quality, less digestible hay or feeding wheat straw or cornstalks may predispose horses to large colon impaction.[38] In a practitioner-based colic study in the United Kingdom, a recent change in management was associated with at least 43% of the cases of spasmodic or mild undiagnosed colic. The most common management change was turnout onto lush pasture in the spring.[39] In reviewing the results of available epidemiologic studies, Cohen estimated that approximately one third of colic cases had a history of a recent change in diet.[40] The ingestion of high-concentrate and low-forage diets has also been implicated in the development of gastric ulcers, which in turn may result in signs of colic.[23]

These observations raise several questions regarding the effects of diet composition and dietary change on gastrointestinal function, including the capacity of the equine digestive tract for grain (starch) digestion, possible reasons for increased colic risk with high levels of grain feeding, and the effect of a sudden change in diet (grain or forage) on gastrointestinal function.

Carbohydrate Digestion and Hindgut Function

From a digestive viewpoint carbohydrates in horse feedstuffs can be divided into three main fractions: (1) hydrolyzable carbohydrates (CHO-H), which can be digested in the small intestine by mammalian enzymes (or they can be fermented, both in the foregut and hindgut); (2) rapidly fermented carbohydrates ($CHO\text{-}F_R$), which cannot be broken down by mammalian digestive enzymes but are readily available for microbial fermentation; and (3) slowly fermentable carbohydrates ($CHO\text{-}F_S$). The hydrolyzable fraction includes hexoses, disaccharides, some oligosaccharides, and the nonresistant starches. Although some fermentation of these compounds may occur in the stomach, the primary products of digestion of these compounds are monosaccharides that can be absorbed in the small intestine, with a relatively high energy yield. The rapidly fermentable fraction included pectin, fructan, and some oligosaccharides not digested in the small intestine. Resistant starch and neutral detergent hemicellulose could also be included in the rapidly fermentable fraction. The slowly fermentable carbohydrate fraction includes cellulose, hemicellulose, and lignocellulose that result primarily in the production of acetate in the large intestine.

Foregut Digestion

Carbohydrate digestion begins in the stomach, which in the horse is relatively small and inelastic (capacity 9–15 L for a 500-kg horse). Bacterial fermentation of ingested feed is initiated in the cranial (squamous) portion of the stomach, with conversion of some of the available simple sugars or starches to lactic acid.[41] This microbial activity and starch/sugar degradation slows when the gastric contents pass to the fundic

gland region and are mixed with gastric secretions containing pepsinogen. Horse saliva contains minimal amylase activity, and little enzymatic carbohydrate digestion occurs in the stomach.

The small and large intestines are the primary sites of carbohydrate digestion. Starch digestion in the small intestine first involves degradation by α-amylase into disaccharide (maltose), trisaccharide (maltotriose), and α-dextrin units. Subsequently, there is hydrolysis of maltose, maltotriose, and α-dextrin units by small intestine brush border glycanases, primarily amyloglucosidase, to form free glucose.[42] The disaccharidases sucrase, lactase, and maltase are expressed along the length of the small intestine.[43] D-Glucose and D-galactose are transported across the equine intestinal brush border membrane by a Na^+/glucose cotransporter type 1 isoform (SGLT1),[43] and fructose is absorbed by way of an equine-specific GLUT-5 transporter.[15] The activity of both transport proteins is highest in the duodenum and lowest in the ileum.[15] Sugars taken up by enterocytes are transported down concentration gradients into the circulation by way of the GLUT-2 transporter. Preliminary studies have demonstrated upregulation of small intestinal SGLT1 expression with an increase in dietary starch content.[44]

It has been proposed that starch digestion in the small intestine is limited by amylolytic activity (e.g., the availability and activity of α-amylase). The activity of α-amylase in the pancreatic tissue of horses is low relative to that of other species,[45] although the activities of brush border glycanases appear to be comparable to those observed in humans, pigs, and dogs.[46,47] The activity of α-amylase in the pancreatic tissue of horses fed either hay or hay and concentrate for at least 8 weeks was unaffected by diet.[46] However, in a related study, the amylase activity of jejunal chyme was modestly higher in horses that received a diet with added corn, oats, or barley compared with only hay.[47]

The extent of starch digestion in the small intestine is affected by the type and amount of starch digested (see the section Recommendations for Minimizing Digestive Disturbances).[48] At low levels of starch intake (<100 g/100 kg BW from oats, barley, or corn as a single meal), approximately 80% of the starch was digested in the small intestine. When starch feeding was doubled (250–270 g/100 kg BW), prececal starch digestibility decreased to between 50% and 55%.[49] Therefore most nutritionists recommend that an individual grain or concentrate meal should contain no more than 2 g starch/kg BW. For example, if a grain concentrate is 50% starch, no more than 4 g/kg BW or approximately 2 kg for a 500-kg horse should be fed. At higher intakes in a single meal, particularly when unprocessed corn or barley is fed, there is the risk of substantial starch overflow into the hindgut, where it will undergo rapid fermentation.

Hindgut Digestion

The equine large intestine (cecum and colon) is an enlarged fermentative chamber that contains an extremely abundant and highly complex community of microorganisms. Although some fermentation of feedstuffs occurs in the stomach and small intestine, most fermentation occurs in the hindgut. The microbial hydrolysis of dietary plant fiber within the large intestine leads to the release of soluble sugars that are subsequently fermented to the VFAs acetate, propionate, and butyrate, which are an important source of energy. In addition, the VFAs (particularly butyrate) regulate the expression of genes controlling proliferation, apoptosis, and differentiation of gut epithelial cells.[50]

The rate of fermentation and the microbial and biochemical contents of the large intestine are affected by diet composition and feeding pattern (i.e., continuous grazing, or small, frequent meals, versus large meals administered twice daily). A change from forage only to a forage and concentrate diet will result in an increased rate of fermentation and marked changes in the microbial population, luminal pH, and the contents of VFA and lactate.[51] The extent of these changes is likely dependent on the nature and abruptness of the dietary change. With a sudden increase in grain (i.e., starch) feeding, a portion of the ingested starch passes into the cecum undigested, in which it undergoes rapid fermentation with increased production of lactate and gas and a decrease in cecal–colonic pH. Increasing proportions of grain result in decreased acetate and increased propionate and lactate contents of the cecum and colon.[51] Other biochemical changes with the rapid fermentation of starch (or other CHO-F_R, such as fructan) in the hindgut may include an increase in the production of vasoactive monoamines (e.g., tyramine, tryptamine), endotoxins, and exotoxins, all of which have been implicated in the pathogenesis of laminitis.[52]

After an increase in starch feeding, the numbers of lactobacilli and total anaerobic bacteria increase, whereas the numbers of xylanolytic and pectinolytic bacteria decrease.[53] Overall, there is an increase in amylolytic, lactic acid–producing bacteria and decreases in the proportions of acid-utilizing (particularly lactate) and cellulolytic (i.e., fiber-degrading) bacteria. Reduced efficiency of fiber utilization and decreased energy yield may result from the decline in cellulolytic bacteria with high grain feeding. In horses fed forage only, pH within the cecum and colon is in the range of 6.7 to 7.0. The feeding of increasing amounts of corn or barley starch is associated with proportionate decreases in cecal pH, with values approaching 6.0 when 3 to 4 g/kg BW is fed as a single meal.[51,54,55] A similar dose of oat starch was not associated with a significant decrease in pH, consistent with other data demonstrating higher prececal digestibility of oat starch versus barley and corn starch.[55] Some nutritionists have suggested that a cecal pH of 6.0 represents subclinical acidosis and that the risk of clinically apparent intestinal dysfunction (e.g., increased permeability) is substantially increased when hindgut pH is less than 6.0.[2,55] Similar disruptions to the hindgut environment probably occur with the delivery of other rapidly fermentable substrate, such as fructan, which can compose 5% to 40% of grass DM,[26] particularly temperate species such as perennial ryegrass and Timothy grass. In vitro experiments have demonstrated that fructan induces a more rapid decrease in the pH of cecal contents compared with corn starch,[56] and one type of fructan (Raftilose) has been used to induce carbohydrate overload and laminitis.[57]

These disturbances to the hindgut environment put the horse at greater risk for digestive disturbances such as colic, osmotic diarrhea, and laminitis.[32,33] Scenarios favoring the presentation of large loads of rapidly fermentable substrate to the hindgut include (1) a sudden introduction to grain feeding or an abrupt increase in the amount of grain concentrate; (2) the feeding of large grain meals that, even in horses adapted to such feeds, overwhelm the hydrolytic or absorptive capacity of the small intestine; and (3) the grazing of lush pasture or forage with high contents of rapidly fermentable substrate such as

fructan and simple sugars. It is therefore apparent that feeding strategies designed to minimize hindgut disturbances must focus on reducing the flow of rapidly fermented substrate to the cecum and large colon.

Recommendations for Minimizing Digestive Disturbances

Feeding Frequency

Ideally, feeding strategies for horses kept under intensive conditions would mimic the pattern of a grazing animal; that is, an almost continuous feeding pattern that minimizes fluctuations in the rate of delivery of substrate to the large intestine and, when forage makes up the bulk of the diet, ensures some stability of the hindgut ecosystem. A more continuous feeding pattern also may minimize fluctuations in gastric acidity and therefore be of benefit in horses at risk for squamous mucosal ulcer disease. For stabled horses fed two large meals daily, foraging behavior should be encouraged by increasing the availability of hay (or even a variety of different forages) and pasture or dry lot turnout (with forage available). Provision of more frequent (e.g., thrice daily rather than twice daily), smaller concentrate meals throughout the day is also recommended to minimize delivery of undigested hydrolyzable carbohydrate to the hindgut. Extending eating time by diluting the energy density of the meal (e.g., chopped hay mixed with concentrates) or feeding forage before grain or concentrate may be helpful. For some greedy eaters placement of several large stones in the feeder trough may slow the rate of intake.

Adequate Forage and Fiber

For hard-working horses with high DE requirements, the provision of roughage is often restricted in favor of grain concentrates to ensure adequate DE intake within limits of typical DM consumption. However, there is considerable circumstantial evidence associating low-roughage diets with digestive disturbances (e.g., hindgut acidosis, colic, gastric ulcers) and behavioral problems. There also is evidence that the adverse effects of high starch intake on hindgut function are mitigated when the ration is at least 50% NDF.[58] Accordingly, there is rationale for feeding programs that promote higher roughage intake. An absolute fiber requirement has not been defined, but a minimum of 1.0 kg long-stem forage per 100 kg BW (i.e., 5.0 kg for a 500-kg horse, as-fed basis) has been recommended. Some nutritionists have suggested that a rate of 1.5 kg per 100 kg BW is preferable. Alternatively, fiber intake can be increased by feeding other sources such as sugar beet pulp or soya hulls, both of which are highly digestible (i.e., the DE yield is higher compared with that of hay) and are now commonly added to energy supplements for horses. This approach also facilitates a decrease in reliance on grain or sweet feed for energy, decreasing the risk of digestive disturbances associated with high starch intake.

Forage quality is another important consideration. The feeding of highly lignified fiber sources (e.g., straw), which are poorly degraded in the large intestine, may increase the risk of impaction colic. High intake of straw is possible when it is used for bedding, particularly when an inadequate amount of hay (or roughage with low palatability) is offered. An increase in the provision of palatable forage or a change in bedding can be helpful in these situations. Moldy forage should not be fed to equids.

Limiting Delivery of Rapidly Fermented Substrate to the Hindgut

Size of Grain-Concentrate Meals. The feeding of large meals rich in starch and sugar can overwhelm the digestive capacity of the small intestine and destabilize the hindgut because of rapid fermentation of these substrates. No more than 2 g starch/kg BW should be fed in a single meal. For a grain or sweet feed mix that is 40% to 50% starch, this upper limit equates to approximately 2.0 kg per meal for a 500-kg horse.

Feed Starch Sources with High Prececal Digestibility. Prececal starch digestibility varies with the type of grain and the nature of any mechanical or thermal processing. Although oat starch has a prececal digestibility of around 80% to 90%, approximately 35% of equivalent doses of barley or corn starch (from unprocessed grains) reaches the cecum undigested. The higher prececal digestibility of oat starch may relate to the small size of the starch granules compared with other grains, providing a large surface area for exposure to intestinal amylase. Milling, grinding, and various heat treatments (e.g., steam flaking, micronization, extrusion) improves the prececal starch digestibility of oats, barley, and corn. In one study the preileal digestibility of ground oats was 97% compared with 83% for whole oats. Rolling or breaking did not improve the preileal digestibility of oats. For corn and barley preileal starch digestibility is substantially increased after heat (e.g., steam-flaked corn, micronized barley) but not mechanical treatment. Overall, oats appear to be the safest source of starch for horses, although barley and corn are acceptable *if* they are subjected to some form of heat treatment.

Use Alternative Sources of Energy. The energy demands of growth, lactation, and performance can be readily met by provision of alternative energy sources such as vegetable oil (fat) and nonstarch carbohydrates (e.g., sugar beet pulp, soya hulls). Commercial concentrates made with these ingredients contain varying amounts of starch and sugar, but generally amounts are substantially lower compared with straight cereals or sweet feed mixes. Compared with more traditional fiber sources such as hay, soya hulls and beet pulp contain lower indigestible material (e.g., lignin) and higher amounts of NSPs, pectins, and gums, which can be digested to a large extent within the time period that they remain within the gastrointestinal tract. This translates to a higher energy yield. A variety of vegetable oils (e.g., corn, soy, safflower, or flaxseed) and other sources of fat (e.g., stabilized rice bran; approximately 20% fat) are suitable for inclusion in equine diets. Corn oil tends to be the most palatable oil, but most types have acceptable palatability provided that they are fresh and not rancid. One recommendation is to feed up to 100 g oil/100 kg BW daily. For reference purposes, 450 mL of oil (approximately 420 g) provides about 3.4 megacalories (Mcal) of DE. This daily amount should be divided into two or three meals and introduced gradually (e.g., starting at 50 mL/day). Vitamin E (100–200 IU/100 mL of oil) should be added to the ration if supplemental vegetable oil is provided.

Pasture Grazing. An unresolved problem is management of the intake of rapidly fermentable substrate (e.g., fructan) by horses on pasture, particularly animals with a history of pasture-associated laminitis or those with recognized risk factors for this disease (i.e., obesity, insulin resistance). The most obvious avoidance strategy is to prevent access to pasture and feed-preserved forage with a low NSC content (e.g., <10% NSC). Alternative approaches are to restrict access to pasture at certain times of the day, avoiding peaks in forage

NSC content that may increase risk of laminitis, or to apply a grazing muzzle that limits forage intake (but allows water intake). Several factors affect the accumulation of fructans and other forms of NSC in pasture plants, including plant growth rate, temperature, and light intensity. There also is marked diurnal variation, with peak concentrations in the afternoon and a nadir during the night and early morning, and it has been suggested that horses grazing in the afternoon may ingest twofold to fourfold quantities of NSC compared with that ingested during night or early morning grazing. These observations are the basis for the recommendation to restrict grazing to late night and early morning, with removal of the horse or pony from pasture by midmorning.

Gradual Dietary Changes

The increased risk of colic in the 2-week period after a change in hay or grain feeding suggests that all changes in diet and pattern of feeding should be gradual. Horses should receive a blend of old and new hays during the transition between hay batches (e.g., over a 7- to 10-day period, with a gradual increase in the proportion of the new forage) and a conservative introduction to concentrate feeding or changes in type of grain or concentrate. One suggestion is to start at about 0.5 kg/day (split into two feedings) for a 450- to 500-kg horse, with increasing increments of no more than 0.5 kg/day until attainment of the target feeding rate.

Efficacy of Probiotic Supplements and Feed Additives Purported to Stabilize the Hindgut Environment

There is considerable interest in the use of feed additives such as live yeast culture, probiotics (bacterial species), and buffers (e.g., sodium bicarbonate) as a strategy to minimize the negative effects of cereal-based diets. Yeast cultures might be beneficial for stabilization of the hindgut environment in the face of high cereal feeding. In horses fed high-starch meals (3.4 g/kg BW per meal, as barley), daily supplementation with 10 g of a live yeast *(Saccharomyces cerevisiae)* culture preparation attenuated postfeeding decreases in cecal and colonic pH and alterations in hindgut microbial populations.[59] Thus supplementation with live yeast culture may be beneficial in horses fed a high grain ration. From a practical standpoint it may be more important to ensure adequate fiber in the diet, decrease the quantity of grain, and emphasize use of nonstarch energy sources that do not adversely affect the hindgut environment.

Probiotics have been defined as live microorganisms that, when ingested or administered orally, provide a beneficial effect beyond that of their nutritional value.[60] Many probiotics are marketed for use in horses; the primary rationale is the treatment or prevention of gastrointestinal diseases (e.g., as an adjunct therapy in the management of acute or chronic diarrhea) or prophylactic administration for prevention of colic associated with disturbances to gut microflora (e.g., for horses fed a high-cereal ration). Anecdotal data suggest that the use of probiotics in horses is widespread; however, as with many nutritional supplements, there is a dearth of scientific data regarding safety and efficacy. An effective probiotic organism must be resistant to destruction by gastric acid, pancreatic secretions, and bile salts and be able to colonize the intestinal tract. Weese and Rousseau[60] have screened equine intestinal microflora for organisms meeting these criteria and initially identified *Lactobacillus pentosus* (WE7) as a potential equine probiotic. However, in a randomized controlled clinical trial of 153 neonatal foals (24–48 hours old), the administration of freeze-dried *L. pentosus* WE7 for 7 days was significantly associated with the development of signs of depression, anorexia, and colic and more days with diarrhea compared with the placebo treatment.[60] On the other hand, supplementation with *S. boulardii* reduced significantly the duration of diarrhea in horses with enterocolitis.[61]

The feeding of a protected sodium bicarbonate product has been reported to moderate the decrease in fecal pH associated with grain feeding in horses,[62] perhaps as a result of the buffering of lactic acid produced in the cecum and colon. This approach may be useful for mitigation of hindgut disturbances associated with grain feeding or the grazing of lush pasture.

NUTRITIONAL SUPPORT OF SICK HORSES

There are few data on the effects of different feeding practices on short- and long-term outcomes of sick horses, and many recommendations regarding nutritional management are based on anecdotal evidence or clinician experience rather than the results of controlled studies. In human medicine nutritional status is an independent determinant of morbidity in hospital patients.[63,64] Nutrient deprivation is associated with immunosuppression and alterations in gastrointestinal function, including decreased motility, villous atrophy, and a decrease in gut barrier function resulting from an increase in intestinal permeability, particularly in patients with preexisting malnutrition.[65] Consequently, nutritional support is standard practice in the care of sick people.

Healthy adult horses can tolerate 2 to 3 days of feed withdrawal without ill effect. Starvation invokes neuroendocrine responses that lower metabolic rate, conserve lean tissues (i.e., skeletal muscle), and promote use of fat stores to meet energy demands.[66] This strategy prolongs life in the face of nutrient deprivation. The metabolic response to critical illness (e.g., sepsis) contrasts with that of simple starvation. Increased sympathetic nervous system activity, inflammatory cytokines (e.g., interleukin-1[IL-1], IL-2, IL-6, tumor necrosis factor-α [TNF-α]), and catabolic hormones (catecholamines, cortisol, and glucagon) combine to increase metabolic rate and induce a state of hypercatabolism.[67] Stimulation of proteolytic pathways in skeletal muscle provides amino acids for hepatic gluconeogenesis and synthesis of acute phase proteins. Amino acids (from catabolism of lean tissues) rather than fatty acids are the primary source of energy substrate. There also is disruption of glucose regulation with the development of marked insulin resistance. Unabated, this hypercatabolic state results in large nitrogen losses, severe muscle wasting, and compromise of immune function and tissue healing.[66-68]

Severe hyperlipidemia has been described in horses with colic, colitis, or both that had clinical and laboratory evidence of systemic inflammatory response syndrome (SIRS).[69] The increase in circulating lipids likely reflects both an increase in the mobilization of fat reserves (lipolysis) and a decrease in lipid clearance from blood, with both processes potentially modulated by SIRS, endotoxemia, or both. Studies in other species have demonstrated that the activity of endothelial lipoprotein lipase, the enzyme responsible for tissue uptake of circulating lipids, is decreased by TNF-α, whereas the activity of hormone-sensitive lipase is increased during

endotoxemia.[68,70,71] In horses with severe hypertriglyceridemia, treatment with intravenous dextrose solution or partial parenteral nutrition (PN) resulted in a decrease in serum triglyceride concentrations to reference limits, and appetite improved coincident with the decrease in circulating lipids.[69]

Candidates for Nutritional Support

Several factors affect the decision to provide nutritional support to a sick horse, including the duration of inappetence or anorexia, the nutritional state before illness (e.g., poor versus good body condition), physiologic state (e.g., growing animals, last trimester of pregnancy, lactation), and the presence of clinical indicators of a hypercatabolic state (e.g., hyperlipidemia or lipemia).[72,73] As a general guide, horses that have not eaten for 48 to 72 hours are candidates for nutritional support. However, earlier intervention should be considered when there is evidence of compromised nutritional status, such as horses in thin body condition (BCS <3); those with a history of weight loss, poor feed intake, or both for more than 48 hours before examination; and those with evidence of sepsis, SIRS, or severe hyperlipidemia (e.g., triglycerides >500 mg/dL). Aggressive nutritional support also is indicated for obese (BCS >7) animals, particularly pony breeds, Miniature Horses, donkeys, and lactating mares, all of which are at high risk for development of hyperlipemia and hepatic lipidosis during periods of negative energy balance. Old horses or those with evidence of endocrine (pituitary pars intermedia dysfunction, equine Cushing's disease) and metabolic disease (equine metabolic syndrome) also are candidates for early nutritional intervention.

Estimating Nutrient and Feed Requirements

The nutritional requirements of sick horses have not been determined, so recommendations are largely based on data from healthy horses, with some extrapolation from data in other species. As for healthy animals, however, the first consideration is energy (calories). As discussed, negative energy balance caused by starvation or underfeeding can compromise immune function, delay wound healing, and result in a marked decrease in lean mass (e.g., skeletal muscle), the latter resulting from the breakdown of endogenous protein for use in energy-requiring processes. On the other hand, studies in humans and other species have shown that an oversupply of energy *(hyperalimentation)* is also detrimental, with complications such as hyperglycemia, hyperinsulinemia, hypertriglyceridemia, insulin resistance, and increased risk of septic complications.[74] A proposed mechanism of increased complications induced by hyperalimentation is an increase in the expression of TNF receptors associated with an increase in nuclear factor κB binding to the nucleus.[75] Furthermore, in septic animals high caloric intake results in an increase in mortality.[76,77] For these reasons, the current thinking in human medicine is to underfeed nonprotein calories (15–25 kilocalories [kcal]/kg daily or no more than 66% of calculated energy requirements) to minimize risk of septic complications.[74]

The sixth edition of *Nutrient Requirements of Horses*[1] reported that the DE needs of mature horses at maintenance range between 30.3 and 36.3 kcal/kg BW daily. The lower end of this range is suitable for minimally active animals with a tendency to gain weight ("easy keepers"), and the high value should be applied to animals with a nervous temperament ("hard keepers"). For healthy horses confined to a stall, daily energy requirements are probably 25% to 40% lower than in horses kept at pasture or in similar circumstances that require them to engage in some voluntary activity. Pagan and Hintz[78] reported that the DE requirement of healthy horses kept in stalls was approximately 22 to 23 kcal/kg BW per day, or 30% lower than the DE required by horses kept at pasture. This *stall maintenance* caloric requirement can be estimated by the following equation:

$$\text{RER} = [21\ \text{kcal} \times \text{BW}\ (\text{kg})] + 975\ \text{kcal}$$

where RER is resting energy requirement. Energy requirements are also affected by the level of feed intake. Thermogenesis associated with the digestion, fermentation, and metabolism of feed can account for 15% to 25% of daily energy expenditure. Because horses recovering from illness generally consume less feed, some reduction in the energy losses associated with digestion and nutrient processing is to be expected.

Another consideration in the estimation of energy requirements is the effect of disease or surgical intervention on metabolic rate. There is conflicting evidence from human studies regarding the effects of surgery, injury, or illness (e.g., sepsis) on metabolic rate and energy requirements. Some studies have demonstrated that abdominal surgery increases energy needs by as much as 30%, whereas others have reported minimal change in energy requirements after gastrointestinal surgery, perhaps a reflection of the decrease in physical activity during hospitalization.[79,80] On balance, it appears that energy needs are minimally altered by surgery or injury unless there are major complications, such as generalized burns or sepsis, in which case energy requirements may increase by 40% to 100%.[80] The potential effects of underlying disease (e.g., endotoxemia or SIRS) on the energy requirements of horses are unknown. However, in sick neonatal foals the resting metabolic rate and energy requirements were considerably lower compared with those of healthy foals of the same age,[81,82] and horses that underwent resection of the small intestine gained weight when fed at true maintenance (i.e., 32–33 kcal/kg/day) during the postoperative period.[83] This author recommends that the caloric requirements of sick horses initially be based on the RER or stall maintenance equation (i.e., 22–23 kcal/kg/day). Thereafter there should be a gradual increase in the ration, although true maintenance DE may not be required until the horse returns to normal management (e.g., field turnout). Practitioners should keep in mind that regular measurement of BW or assessment of BCS should be undertaken during convalescence to judge the adequacy of energy provision and provide a basis for adjustments in feeding.

Protein serves an important role in tissue maintenance, immune function, wound healing, and the slowing of endogenous protein catabolism. Protein requirements must be considered in light of caloric intake and underlying disease process. When energy supply from carbohydrate and fat is limited, endogenous protein will be used for energy, contributing to a loss of lean body mass. Therefore the practitioner should, when developing a nutritional plan, first ensure that minimal energy needs are met and then calculate protein requirements. For humans suggested protein requirements range between 1.2 and 2.0 g protein/kg per day, with the higher end of this range recommended for patients undergoing major intestinal surgery.[84] The CP requirement of healthy adult horses at maintenance is approximately 1.25 g CP/kg BW per day, and this value is an appropriate starting point in the development of a nutritional plan for sick horses: As the efficiency of digestion for most dietary proteins in horse feeds is about 70%, this

level of CP will provide approximately 0.9 g available protein per kilogram BW. For parenteral feeding a slight lowering of protein feeding is reasonable given the higher metabolic availability of amino acids administered by the intravenous route. In recent reports of parenteral feeding of horses, 0.6 to 0.8 g protein/kg per day (1 g per 40–50 kcal) was administered (as a balanced amino acid solution).[83,85] There may be justification for higher levels of dietary protein (e.g., 2 g CP/kg/day), particularly for horses in poor body condition (BCS <3) or those with SIRS, hypoproteinemia, or hypoalbuminemia.

Modes of Nutritional Therapy

The mode of nutritional therapy will depend on the underlying disease, the horse's appetite, and complications that arise during convalescence. The popular phrase in human clinical nutrition "if the gut works, use it" is used when discussing the pros and cons of enteral nutrition (EN) versus PN support. Historically, PN has been associated with several complications, including intestinal atrophy, failure of gut barrier function, bacterial translocation, increased incidence of sepsis, and hyperglycemia. In rodent models intestinal villous atrophy develops within a few days of the start of PN, and withdrawal of enteral feeding has been associated with bacterial translocation, systemic inflammation, and sepsis.[86-88] Early human studies also suggested that complication rates (particularly sepsis) and mortality were higher in patients receiving PN compared with those who received EN. However, critical review of human studies has indicated that PN (i.e., complete bowel rest) is not associated with intestinal atrophy, whereas the incidence of bacterial translocation is the same in patients receiving PN and those receiving EN.[74] Although EN is preferable when the gastrointestinal tract is functional, the weight of evidence from human studies indicates that PN is an important alternative to EN when a risk of malnutrition is present and EN is not tolerated or not possible because of poor gastrointestinal function. These same principles can be applied when developing a plan for the nutritional management of sick horses. PN should be considered for horses with ileus and other intestinal conditions that prevent voluntary or enteral feeding, particularly when the withholding of oral feeding is expected to exceed 48 hours.

Assisted Enteral Feeding

Assisted enteral feeding (AEF) is accomplished by the infusion of a liquid diet through a nasogastric tube. Diet options for AEF include human-marketed enteral products, commercial pelleted horse feeds, and homemade recipes.[89,90] Formulations marketed for humans that have been administered to adult horses include Vital HN and Osmolite HN (Ross Laboratories, Columbus, Ohio). Both formulations are devoid of fiber, which is an advantage because it facilitates administration through a small-diameter nasogastric tube, but there is also a disadvantage: it may lead to the development of diarrhea when these products are fed to horses. There also have been anecdotal reports of laminitis in horses fed these diets. Risk of these complications may be mitigated by gradually introducing the liquid diet over a 3- to 4-day period, but diarrhea remains common, perhaps indicating the importance of dietary fiber for maintenance of normal hindgut function. It also should be recognized that the mix of energy substrates in these fiber-free enteral formulas for human use differs from that in typical equine rations. Osmolite contains approximately 29% of calories from lipid and 54% of calories from hydrolyzable carbohydrate (mostly sugars), and Vital HN provides about 10% of calories from lipids and 74% from carbohydrates. The high lipid content of Osmolite may contribute to digestive disturbances in horses not adapted to fat-supplemented rations, and use of a high-carbohydrate diet such as Vital HN may be contraindicated for horses with abnormal glucose metabolism (insulin resistance). Collectively, these considerations argue against using fiber-free enteral products intended for human use in horses. Diets containing a moderate amount of fiber (10%–20% crude fiber [CF], DM basis) appear to be a more suitable choice for AEF in horses.

A simple approach is to use a commercially available pelleted feed that contains a source of fiber, such as Equine Senior (Land O' Lakes-Purina Feed, St. Louis, MO) or similar "complete feeds" that contain added fiber and can be fed without hay. These products contain about 14% to 25% CF and provide 2.6 to 3.1 Mcal DE/kg diet (as fed). Therefore 3.5 to 4.0 kg of diet would be needed to meet the stall energy requirements of a 500-kg horse. Vegetable oils (75–375 mL per day) can be added to increase the caloric density of the diet (Table 5.3). One standard cup (approximately 225 mL [210 g]) of oil provides about 1.7 Mcal of DE. Vitamin E (100–200 IU per 100 mL of oil) should be added to the ration if supplemental vegetable oil is provided. When providing supplemental fat to a sick horse (450–500 kg BW), 75 to 125 mL/day (¼ to ½ cup) should be given initially and then gradually increased if no adverse response is seen (e.g., diarrhea, steatorrhea, lipemia). Feeding vegetable oil may be contraindicated in horses and ponies with hypertriglyceridemia (triglyceride concentration >40–500 mg/dL) or hepatic lipidosis.

Variations on the alfalfa/dextrose/casein enteral formulation first described by Naylor et al.[90] also can be used for AEF (Table 5.4). The recipe designed by Naylor et al.[90] provides about 3 Mcal DE/kg diet and is 33% CP and 12% CF. The higher protein content, compared with that of typical equine diets, may be beneficial for debilitated or hypoproteinemic horses. In healthy horses this diet reportedly maintained BW and

TABLE **5.3 Enteral Formulation Based on a Complete Pelleted Ration and Recommended Feeding Schedule for a 500-kg Horse**[a]

Ingredient	Day 1 (¼ Ration)	Day 2 (½ Ration)	Day 3 (¾ Ration)	Day 4 (Full Ration)
Complete pelleted horse feed (g)[b]	885	1770	2650	3530

Water (L)	8	16	24	24
Digestible energy (Mcal)	3	6	9	12

[a]Energy requirements are at *stall maintenance* for a 500-kg horse (~12 Mcal DE/day). These allowances should be divided and administered into a minimum of four feedings daily.
[b]Equine Senior (Land O'Lakes-Purina Feed, St. Louis, Missouri), 2.6 Mcal DE/kg (as fed).

serum biochemical parameters within reference limits. However, diarrhea and laminitis were occasional complications.

Suggested feeding protocols for a complete pelleted feed with supplemental vegetable oil and for the alfalfa/dextrose/casein formulation are presented in Tables 5.3 and 5.4, respectively. The rate of diet administration should be gradually increased over a 3- to 5-day period. A suggested rate of introduction is to administer ¼ of the final target volume of feed on day 1, ½ total volume on day 2, ¾ total volume on day 3, and the total volume on day 4 or 5. Clinical signs of intolerance to enteral feeding will dictate a slower rate of introduction. In hospital settings the enteral diet should be administered in a minimum of four and preferably six feedings per day, with no more than 6 to 8 L per feeding for a 450- to 500-kg horse (including volume of water used to flush the tube). This volume should be administered over a 10- to 15-minute period. In field settings a more practical approach is to administer two treatments daily, although it will not be possible to meet stall maintenance nutritional requirements with this treatment regimen.

Pelleted feeds should be soaked in warm water to soften before mixing in a blender (ratio of 1 kg pelleted feed to 6 L of water). A fresh batch of diet should be made before each feeding. A tube with a ½-inch (12-mm) inner diameter is suitable for most enteral diets that contain fiber. The end of the tube should be open ended, rather than fenestrated, to prevent the tube from becoming clogged. Intermittent nasogastric intubation or placement of an indwelling nasogastric tube can be used to facilitate feeding. In hospitalized horses feeding tubes can be left in place for up to 8 days, although nasopharyngeal irritation and mucoid nasal discharge are expected outcomes (when longer term AEF is anticipated, placement of the tube through cervical esophagostomy is recommended). Softer silicon tubes are less irritating compared with tubes made of polyvinylchloride, do not tend to harden when left in place, and are generally recommended for horses requiring AEF for a number of days. Before placing the tube, the clinician should establish that the diet solution flows adequately through the tube. It may be necessary to add more water or to mix the feed in a blender a second time. The tube should be positioned in the stomach rather than the distal esophagus to minimize risk of reflux of feed around the tube. The tube should be secured to the halter; between feedings application of a muzzle may be necessary to prevent the horse from dislodging the tube. A marine bilge pump is recommended for infusion of fiber-containing diets. After administration of the diet, the tube should be flushed with approximately 1 L of water followed by a small volume of air to ensure that no feed material remains in the tube. The end of the tube should be capped with a syringe case between feedings.

Close clinical monitoring, particularly of gastrointestinal function, is imperative for horses receiving AEF. Repeated ultrasonographic examinations can be useful for the evaluation of gastric distention and intestinal motility. The presence of residual gastric fluid should be assessed (i.e., by siphoning) before each feeding. Substantial gastric reflux (>1–2 L) is an indication to withhold enteral feeding for at least 1 to 2 hours, with reevaluation before recommencement of diet administration. Persistent gastric reflux indicates intolerance to enteral feeding and the need for parenteral feeding. Similarly, signs of colic, ileus, abdominal distention, and increased digital pulses suggest intolerance to enteral feeding and are an indication to discontinue therapy or decrease the volume and frequency of feedings. The passage of loose feces is not uncommon in horses receiving AEF and of minimal concern if not accompanied by clinical signs of depression, dehydration, ileus, or colic. It is important to measure the total volume of water administered through the nasogastric tube. Daily water requirements (approximately 50 mL/kg/day) can generally be met during AEF if the horse is fed four to five times daily. Frequent measurements of hematocrit and plasma total protein concentration also are useful for monitoring hydration status and the adequacy of water administration. Hypokalemia, ionized hypomagnesemia, and ionized hypocalcemia can occur in horses with gastrointestinal disease. Accordingly, frequent measurements of serum electrolytes and ionized calcium and magnesium are recommended during AEF in these patients. Supplementation with potassium, calcium, magnesium, or both may be necessary. Horses also should be monitored for development of complications associated with repeated or indwelling nasogastric intubation, including rhinitis, pharyngitis, and esophageal ulceration. BW should be measured daily to assess the adequacy of nutritional support, although changes in BW may reflect alterations in fluid balance rather than the effect of feeding.

Parenteral Nutritional Support

PN is indicated for horses with gastrointestinal tract dysfunction (e.g., ileus, gastric reflux) or conditions that mandate complete bowel rest (e.g., small intestinal resection,

duodenitis-proximal jejunitis). Durham et al.[83,85] examined the effects of postoperative PN in 15 horses (vs. 15 control horses) recovering from resection and anastomosis of strangulated small intestine and reported no beneficial effect of PN on time to first oral feeding, duration of hospitalization, costs of treatment, or short-term survival (up until 5 months after discharge). The PN protocol did confer improved nutritional status, as reflected by lower serum concentrations of triglycerides and total bilirubin and higher concentrations of glucose. However, the duration and volume of postoperative gastric reflux were longer in the PN group than in the control horses, perhaps as a result of alterations in gastric or small intestinal motility, and there was an insignificant trend for catheter-site complications in the PN group.[83] The authors concluded that further study of a larger number of horses is necessary to determine the clinical benefits and possible harmful side effects of PN in horses recovering from small intestinal surgery. Studies of the effects of PN in human patients also have yielded equivocal findings. Several studies have demonstrated that perioperative PN is associated with reduced morbidity and mortality in malnourished patients.[91-93] In contrast, perioperative PN in well-nourished human patients has been associated with increased morbidity, particularly septic complications.[94,95] Nonetheless, as previously discussed, the current consensus in human clinical nutrition is that PN is an important component of overall case management, particularly in patients with evidence of malnourishment, gut failure, and increased nutritional requirements (e.g., pregnancy, lactation, growth).

The following paragraphs provide a brief overview of the composition of PN solutions, methods for delivery, and potential complications. As with EN support, the goal of PN is to administer calories and amino acids such that loss of body protein (and lean body mass) is minimized.[73] Carbohydrates, in the form of a 50% dextrose solution (3.4 kcal/g or 1.7 kcal/mL; osmolarity 2525 mOsm/L), and lipid, as a 10% to 20% emulsion (20% emulsion: 9 kcal/g or 2 kcal/mL; osmolarity 260 mOsm/L), are the primary sources of energy used in PN solutions, whereas an amino acid solution (e.g., Travasol 8.5% or 10%; Baxter Health Care Corporation, Deerfield, IL) is used to meet protein requirements (e.g., protein synthesis, immune function). Commercial lipid emulsions (e.g., Intralipid 20%; Baxter Health Care Corporation, Deerfield, IL) consist of soybean oil, egg yolk phospholipid, and glycerin. These emulsions provide mainly unsaturated fatty acids (linoleic, 44%–62%; oleic, 19%–30%; linolenic, 4%–11%; palmitic, 7%–14%). PN solutions with and without lipid can be used (i.e., dextrose/amino acid or dextrose/lipid/amino acid mixtures). The addition of lipids to the PN formula results in a solution with lower osmolarity compared with a dextrose/amino acid mixture of similar caloric density. Hence the lipid-containing solution should be less irritating to peripheral veins. Lipid solutions must be included in the formula if target calorie provision approaches true maintenance (32–33 kcal/kg/day) because this level of calorie delivery from a dextrose/amino acid PN solution often results in marked hyperglycemia and glucosuria. However, when the target daily energy provision is 20 to 22 kcal/kg per day, dextrose/amino acid mixtures can be used. In human medicine this approach is referred to as a *partial PN* and is often used in postoperative patients who require only a few days of intravenous nutritional support;[74] similarly, partial PN is recommended for horses requiring short-term (3–7 days) intravenous feeding. Lipid administration is not recommended for patients at high risk for severe hypertriglyceridemia or hyperlipemia (e.g., ponies, Miniature Horses, donkeys). Serum triglyceride concentrations should be monitored on a regular basis if lipid solutions are administered to these patients. As discussed previously, the provision of amino acids (protein) at a rate of 0.6 to 0.8 g/kg BW daily is one guideline for meeting protein requirements in adult horses, although some authors have recommended 1 to 1.5 g/kg per day, and provision of amino acids at 0.6 to 2 g/kg per day has been used in sick horses without apparent complications.

A suggested PN formula (Table 5.5) comprises 1 L of 50% dextrose (0.5 g/mL dextrose × 3.4 kcal/g × 1000 mL = 1700 kcal), 1 L of a 10% amino acid solution (0.1 g/mL of amino acids × 4 kcal/g × 1000 mL = 400 kcal), and 500 mL of 20% lipid emulsion (0.2 g/mL lipid × 9 kcal/g × 500 mL = 900 kcal). These components are diluted with 4 L of isotonic fluid, yielding a final volume of 6.5 L and a caloric density of approximately 0.45 kcal/mL. A multivitamin supplement may be added to this mixture. This solution can be prepared up to 24 hours before administration, with storage at 4°C until use. Administration of PN solutions should be through a dedicated intravenous catheter (i.e., do not administer

TABLE **5.5 Parenteral Nutrition Formula and Recommended Administration Rate for a 500-kg Horse**[a]

other medications with this catheter), preferably one inserted into a large vein such as the jugular, to minimize the risk of complications associated with the infusion of hyperosmotic solutions. Alternatively, a double-lumen catheter can be used, allowing the PN solution to be given through one port and medications and other fluids through the other port. To minimize the risk of thrombophlebitis, nonthrombogenic catheters such as those made from polyurethane are recommended. Meticulous attention to sterile technique is needed during catheter placement to further minimize the risk of thrombophlebitis and other septic complications. The fluid lines used for delivery of the PN solution should be changed every 24 hours. An infusion pump is required to ensure accurate delivery of the PN solution. The bag containing the PN solution should be covered with a brown bag during administration to protect it from light, which can degrade the amino acids within the solution.

Table 5.5 provides a recommended rate of parenteral feeding for a 500-kg horse. The initial rate of PN solution administration should be approximately 35% of target calorie provision, increasing to 60% to 65% after 12 hours and 100% (23 kcal/kg/day) at 24 hours, provided that there are no complications, such as the development of marked hyperglycemia, glucosuria, or hyperlipemia. Hyperglycemia and hyperlipemia were the most common complications of postoperative PN in horses after intestinal surgery. In one report hyperglycemia was observed in 52 of 79 horses receiving PN,[96] perhaps because of insulin resistance, an excessive rate of administration, or both. Blood glucose concentrations should be measured every 4 to 8 hours in horses receiving PN, and the rate of dextrose administration should be decreased if glucose concentrations exceed renal threshold (approximately 180–200 mg/dL). A constant-rate insulin infusion (e.g., regular insulin at a starting dose of 0.05–0.1 IU/kg/h) can be instituted if the reduction in dextrose administration rate fails to correct the hyperglycemia. Blood glucose concentrations must be closely monitored (e.g., every 2–6 hours). Adjustments in insulin dose may be required to achieve glycemic control. Serum blood urea nitrogen (BUN), triglycerides, and electrolytes should be monitored at least daily. Hypokalemia, hypocalcemia, and hypomagnesemia have been reported in horses receiving PN, and it may be necessary to supplement these nutrients if parenteral feeding is used for more than 48 hours. Finally, BW should be recorded daily or every other day.

Transition to Voluntary Feeding

A decrease in AEF or PN is indicated when appetite returns (or when voluntary oral feeding is no longer contraindicated). Initially, small amounts of palatable (e.g., fresh grass or leafy hay) feed should be offered. If these feedings are tolerated, the level of tube or parenteral feeding can be gradually reduced as the provision of feed for voluntary consumption is increased. Nutritional support can be withdrawn when voluntary feed intake provides at least 75% of stall maintenance DE and protein requirements. As with any feeding program, all changes in diet should be gradual. Hay should be the primary, if not sole, component of the convalescent diet, preferably leafy hay with a fresh aroma. Grain or commercial grain-concentrate feeds should be offered only if hay alone does not meet requirements. An alternative to grain is to feed 1 to 2 lb/day of a high-protein product (approximately 20%–25% CP, usually with added minerals and vitamins) as a supplement to hay.

NUTRITIONAL MANAGEMENT OF THE ORPHANED OR SICK FOAL

Foal Metabolism and Nutrient Requirements

The foal's nutritional requirements and dietary composition change substantially during the gradual transition from neonate to weanling. At birth the foal must transition from a continuous supply of nutrients provided by the dam by way of the placenta to intermittent absorption of ingested nutrients. At the same time, the metabolism of the neonate is no longer able to depend on the maternal glucose concentration to maintain normoglycemia, and the pancreas assumes responsibility for regulating glucose homeostasis.[97] These dramatic alterations in energy metabolism may not always occur smoothly, and the neonatal foal possesses limited energy reserves in the form of glycogen and fat. The result is that hypoglycemia occurs frequently in even the normal neonatal foal, and the sick foal is at risk for profound hypoglycemia if deprived of energy intake for even a few hours.[97]

The neonatal foal has a high metabolic rate and requires frequent ingestion of high volumes of milk to meet its energy requirements for maintenance and growth. In light breeds the average rate of daily gain over the first month of life is 1 to 1.5 kg/day. During the first week of life, calorie needs are as follows: approximately 150 kcal/kg per day, with a gradual decrease to approximately 120 kcal/kg per day at 3 weeks of age, and then to 80 to 100 kcal/kg per day by 1 to 2 months of age.[81,82] Healthy neonatal foals (<7 days of age) have up to seven nursing bouts per hour, most lasting for 1 to 2 minutes. Subsequently, there is a gradual decrease in the frequency of nursing but an increase in the duration of each nursing bout. During the first 24 hours of life, foals consume approximately 15% BW as milk (i.e., 8 L in a 50-kg foal), increasing to between 23% and 25% BW (15 L) by day 3 or day 4.[98] On a DM basis, mare's milk averages about 64, 22, and 13% sugar (as lactose), protein, and fat, respectively, compared with cow's milk, which contains 38, 26, and 30% sugar, protein, and fat, respectively. As a result, glucose (from lactose) is the primary source of energy for the foal.

Starting as early as the second day of life, foals begin ingesting small amounts of hay, grass, and grain while also ingesting maternal feces, which likely provides the initial microbial flora required to support digestion of these feedstuffs. It is unlikely that grain and roughage are well digested until at least several weeks of age, at which point the foal begins the gradual transition from a milk-based diet to a forage-based diet. The amount of milk produced by the mare peaks after approximately 2 months of lactation and then begins a steady decline, which continues until the time of weaning, when the foal must begin relying on solid feed for an increasing proportion of its nutritional requirements. Full maturation of hindgut function may occur by 3 to 4 months of age.

Nutritional Support of Orphan Foals

The primary options for management of orphan foals are to raise by hand or foster to a nurse mare.[98,99] Fostering is the best option for a foal younger than 6 to 8 weeks of age. Draft or Draft-cross mares that are mild in temperament make good nurse mares. Any disparity between the stage of lactation and age of the foal should be noted. A mare that is 4 to 6 weeks into lactation may not have the quality of milk needed to sustain a neonate; it may be necessary to provide the neonatal foal with a mineral supplement when fostered to a mid- to late-lactation mare.

Hand rearing has several disadvantages, including the need for high labor input, the expense of milk substitute, and a high incidence of behavioral problems. The risk of behavioral problems can be mitigated by ensuring that the foal is raised with an equine companion (e.g., a quiet horse or pony or even another orphan foal). Teaching a foal to drink from a bucket is preferable to bottle feeding because it is less labor intensive for the owner and allows the foal to drink milk on demand. Feeding from a bucket also helps prevent some of the behavioral problems that develop in foals that have bonded to people. Bottle feeding may be the only option in newborn foals, but a quick transition to bucket feeding is recommended. It is also important to ensure adequate colostral intake (and acquisition of passive immunity) in foals that are orphaned at birth.

Fortified cow's milk (by the addition of 20 g/L dextrose to 2% part skimmed milk); goat milk; and calf, lamb, and kid milk substitutes have been used to rear foals, but a high-quality mare-milk formula is preferred. On a DM basis foal milk replacers should contain approximately 15% fat and 22% CP, with a fiber content of less than 0.5%.[99] Milk replacers should be fed as a 10% to 15% solution when diluted with water and generally provide about 500 kcal/L when mixed according to the manufacturer's instructions. The volume of milk should be fed over a 7- to 10-day period. One recommendation is to start at 5% to 10% of BW, increasing to 20% to 25% BW by day 10. Intake of 20% to 25% BW/day as milk replacer will meet energy and nutrient requirements for growth. As a general guide, most light-breed foals need 14 to 17.5 L (4–5 gallons) of milk substitute each day during the first 2 to 3 weeks of life, and draft foals require 21 to 28 L (6–8 gallons). Foals may be fed as infrequently as two to four times daily, although more frequent feedings (six to nine daily) are recommended for young foals and during the initial phase of hand rearing to keep from overwhelming the digestive tract. Feeding buckets should be thoroughly cleaned on a daily basis. Similarly, strict hygiene is required during the preparation of the milk substitute. Fresh water should be available at all times.

BW or linear measures that predict weight and height gain[100] should be monitored on a regular (e.g., weekly) basis. Expected rates of growth and weight gain are available for some horse breeds. Studies of hand-reared foals have demonstrated growth rates similar to those observed in foals reared with their dams.[101] Solid feed should be introduced as early as 2 to 3 weeks of age (e.g., small amounts of high-quality hay, milk-based pellets, or both). Up to 1 kg of milk pellets per day can be fed with a concomitant reduction in liquid milk feeding. Orphan foals can be weaned from milk at 10 to 12 weeks of age, with a transition to a diet of forage and a balanced foal feed (16%–18% CP).

Nutrition of the Sick Neonatal Foal

The energy (calorie) requirements of sick, recumbent foals are less than those of healthy foals, in part because of their lower physical activity and a temporary decrease in growth rate compared with healthy neonates. In one study the metabolic rate of healthy foals was 130 to 140 kcal/kg BW per day, whereas metabolic rate in immature foals and foals with perinatal asphyxia syndrome was approximately 62 to 69 kcal/kg BW per day.[81] It is possible that sepsis and endotoxemia increase metabolic rate, although studies in neonatal humans indicate that critical illness is not accompanied by a hypermetabolic state. Currently providing critically ill, recumbent foals approximately 45 to 50 kcal/kg BW per day is recommended.[98,102] This "hypocaloric" approach to nutritional support may prevent complications associated with overfeeding, such as hyperglycemia and glucosuria, particularly in foals with sepsis in which the systemic inflammatory response contributes to insulin resistance and carbohydrate intolerance. Neonatal foals require approximately 1.5 g protein/kg BW per day.

The adage, "if the gut works, use it", also applies to the nutritional support of sick neonatal foals. Milk contains trophic substances that promote growth and development of the gastrointestinal tract. Additionally, enteral feeding is believed to lower the risk of sepsis associated with bacterial translocation. However, parenteral feeding is required in foals with poor gastrointestinal tract function.

Enteral Nutrition

Thorough assessment of gastrointestinal function is needed before institution of EN support, including abdominal auscultation and evaluation of abdominal distention and the presence of gastric reflux. Abdominal radiographs and ultrasonographic examination for evaluation of bowel dimensions and motility also may be indicated. Foals with evidence of gastrointestinal dysfunction such as gastric reflux, bowel distention, increased bowel wall thickness, and ileus are unlikely to tolerate enteral feeding. A conservative approach to enteral feeding is also indicated for premature or immature foals in which the gastrointestinal tract may not be completely developed. Foals with perinatal asphyxia syndrome or severe sepsis may be intolerant of enteral feeding as a result of intestinal ischemic injury.

Mare's milk is the preferred substrate for enteral feeding; it is highly digestible and obviously provides the correct balance of nutrients for normal growth and development. Commercial mare milk replacers can be used, but practitioners should bear in mind that these products are bovine in origin and have lower digestibility compared with mare's milk. This may increase the risk of intestinal dysfunction associated with enteral feeding. Part skimmed (2% fat) cow's milk to which 20 g/L dextrose (corn sugar) is added can be used if mare's milk (or a mare's milk replacer) is unavailable. Foals that are unable to nurse the mare (or when no mare is available) may be fed through a bottle, bowl, or nasogastric feeding tube. Bottle feeding is recommended when the foal is expected to be transitioned to a mare within a short period of time. The practitioner should remember, however, that bottle feeding is very labor intensive and does carry some risk of milk aspiration if the milk flow rate from the bottle exceeds the foal's capacity to nurse properly. The risk of aspiration is lower with bowl feeding because the head is positioned with the nose down during drinking.

Many sick, recumbent foals have a weak or uncoordinated suck reflex and are at risk of milk aspiration and pneumonia. Milk should be administered to these patients through a feeding tube. Use of small-bore, indwelling nasogastric feeding tubes (e.g., NG1243–12Fr × 108 cm [43 inches], MILA International, Erlanger, KY) and feeding of small volumes at frequent intervals (e.g., every 20 minutes) are preferred over repeated passage of a nasogastric tube at 1- to 2-hour intervals. Large-bolus feedings may overwhelm digestive capacity, and repeated passage of a stomach tube is an unnecessary stress on the foal. Another advantage of the small-bore indwelling tubes is that they do not interfere with the suckle response. Therefore the tube may be left in place as the foal is transitioned to feeding from the mare. The feeding tube should be inserted with the foal in sternal recumbency, and correct placement

TABLE **5.6 Feeding Recommendations for Neonatal and Growing Foals**

Foal Age (days)	Energy Requirement	Volume of Mare's Milk or Milk Replacer	Percentage of Body Weight Fed
0–1	150 kcal/kg/day	2–3 mL/kg/h	5%–7%
2–3	150 kcal/kg/day	4–5 mL/kg/h	10%–12%
4–7	150 kcal/kg/day	6–8 mL/kg/h	14%–20%
8–30	120 kcal/kg/day	9–10 mL/kg/h	22%
30–weaning	80–100 kcal/kg/day	Gradually decreasing and replaced with solid feed	—

within the esophagus should be confirmed by radiography or endoscopy. The tube should be fastened to the external nares by sutures or may be retained using a circumferential elastic bandage around the muzzle. It is important to check at each feeding that the tube is still in place and there is no gastric reflux. The foal should be in sternal recumbency or standing when it is fed. Milk should be administered by gravity flow and followed by a small amount of clean water to flush the tube. The tube should be capped between feedings to prevent aspiration of air. Feeding tubes should be replaced every 1 or 2 days to reduce the risk of gastrointestinal tract infection.

A suggested initial rate of milk delivery is 2 to 3 mL/kg BW per hour or 100 to 150 mL/h for a 50-kg foal, which will provide 2.4 to 3.6 L of milk to a 50-kg foal during the first 24 hours of enteral feeding (Table 5.6). Dextrose-containing fluids can be administered intravenously to provide additional calories during the transition to an adequate level of enteral feeding. The feeding rate can be gradually increased over the next 2 to 3 days (e.g., increase to 4–5 mL/kg/h on day 2 and then to 6–8 mL/kg/h on day 3), which represents a total daily intake of 10% to 15% BW. As the rate of enteral feeding increases, intravenous caloric support (dextrose) can be gradually withdrawn. This feeding level will likely meet the maintenance energy requirements of hospitalized foals. Depending on the rate of clinical improvement and the length of hospitalization, it may be possible to increase the volume of feeding to 22% to 23% BW per day, which approximates the milk intake of healthy neonatal foals. Clinical monitoring should include frequent assessments of gastrointestinal function, including gastric reflux, intestinal sounds, abdominal distention, and quantity and quality of feces. Gastric reflux, bloating, colic, diarrhea, or constipation can indicate intolerance to enteral feeding and the need for adjustments to the feeding program. Adjustments may involve a decrease in the volume or frequency of enteral feedings. Foals fed milk replacers appear to be more likely to develop loose feces than foals fed mare's milk. In some cases clinical improvement is observed after supplementation with 6000 units of lactase (Lactaid; McNeil Nutritionals, LLC, Ft. Washington, PA) per 50-kg foal every 3 to 8 hours, mixed into the milk replacer before feeding.[103]

Parenteral Nutrition

PN support is indicated for foals with poor gastrointestinal function and intolerance to enteral feeding. Short-term parenteral supplementation (less than 24 hours) does not require the use of a balanced PN solution that contains sources of carbohydrate, amino acids, and lipids. However, if PN is expected to be administered for a longer period, then a more complete formula should be used.

Short-term caloric supplementation can be accomplished by administrations of an intravenous fluid containing 5% dextrose (e.g., 5% dextrose in water [D_5W], lactated Ringer's solution with 5% dextrose, 0.45% saline with 5% dextrose), and hypotonic maintenance electrolyte solutions containing 5% dextrose.[97] Fluids containing dextrose should not be used for initial large-volume fluid resuscitation because this often results in profound hyperglycemia. After initial fluid resuscitation the solutions containing electrolytes as well as dextrose may be used as the primary fluids for maintenance therapy in foals with minimal ongoing fluid losses. As a maintenance solution, D_5W is not a good choice because it lacks electrolytes; it is primarily useful in providing free water to patients suffering from hyperosmolar conditions. The caloric content of a 5% dextrose solution is 0.17 kcal/mL, so an infusion rate of 10 mL/kg per hour would be required to deliver approximately 40 kcal/kg per day (0.17 kcal/kg/h × 24 h/day = 41 kcal/kg/day). However, this rate of infusion is more than twice the maintenance fluid requirements of neonatal foals (4–5 mL/kg/h). Therefore an infusion rate of 5 mL/kg per hour (providing approximately 20 kcal/kg/day) is a more appropriate target for partial caloric support using 5% dextrose solutions.[97] Caution is required when adjusting the infusion rate in response to changes in hydration state to prevent excessive dextrose administration, especially in premature or very sick foals that may be glucose intolerant.

An alternative approach involves the administration of a 50% dextrose solution by use of an infusion pump, provided that isotonic fluids are administered concurrently to minimize the risk of vascular endothelial injury caused by the hyperosmolar 50% dextrose solution. Use of 50% dextrose solution is not recommended unless an infusion pump is available. The caloric content of 50% dextrose solution is 1.7 kcal/mL; therefore, an infusion rate of 1 mL/kg per hour will provide about 40 kcal/kg per day (1.7 kcal/kg/h × 24 h/day = 41 kcal/kg/day). At this low rate of infusion, the primary fluid needs of the patient can be met with a dextrose-free isotonic electrolyte-containing fluid, the infusion rate of which can be altered in response to changes in patient fluid status without concerns related to the requirements of the nutritional plan.[97]

Two approaches have been used for formulation of PN solutions for foals.[97,98,104] The first involves the exact determination of the anticipated metabolic needs of the patient, followed by the development of a formulation that will meet all of these needs using a mixture of dextrose, amino acids, and lipids. The second approach is simpler and more practical and uses one of two basic PN formulas (Table 5.7):

1. Solution I: A mix of equal volumes of 50% dextrose and 8.5% amino acid solutions, intended for short-term use (caloric density = 1.02 kcal/mL)
2. Solution II: A mix of three parts 50% dextrose, four parts 8.5% amino acid, and one part 20% lipid solutions; this solution is preferred for foals that are poorly tolerant of infused dextrose (caloric density = 1.08 kcal/mL)

TABLE **5.7 Formulation of Parenteral Nutrition Solutions for Neonatal Foals**

Formulation	Composition	Caloric Density (kcal/mL)	Nonprotein Calories/g Nitrogen
Formula I	1500 mL 50% dextrose, 1500 mL 8.5% amino acids	1.02	125
Formula II	1500 mL 50% dextrose, 500 mL 20% lipids, 2000 mL 8.5% amino acids	1.08	131

As previously discussed, protein degradation in muscle tissue occurs during critical illnesses such as sepsis. Thus provision of adequate energy and amino acids to counter this catabolic response is an important goal of PN support. The recommended ratio for nonprotein calories to nitrogen is 100 to 200 nonprotein calories per gram of nitrogen.[105] In one report the amount of protein provided affected weight gain of neonatal foals, with a negative association between the nonprotein nitrogen calories: grams nitrogen ratio (NPC/g N) and the rate of weight gain.[106] Solution I provides 125 NPC/g N, and Solution II contains 131 NPC/g N.

The inclusion of lipids in the PN formulation allows for the provision of a larger number of calories per unit volume compared with solutions containing only dextrose. Another advantage of lipid emulsions is that they are isotonic, moderating the hypertonicity of the PN formulation and potentially decreasing the risk of thrombophlebitis. In a recent report the use of lipid-containing PN solutions allowed for the provision of 40 to 92 kcal/kg per day (mean = 63 kcal/kg/day) to foals, compared with 25 to 66 kcal/kg per day (mean = 41 kcal/kg/day) with a dextrose-based solution.[104]

Methods for delivery of PN solutions have been discussed (see the previous section Nutritional Support of Sick Horses). The catheter and catheter site should be monitored at least twice daily for heat, swelling, or exudation. Increased resistance to fluid flow in the catheter may be an indication of thrombosis deeper within the vasculature and will often necessitate the placement of a catheter in an alternative site, such as the opposite jugular vein, a cephalic vein, or a lateral thoracic vein. The rate of infusion (in mL/h) is calculated on the basis of the desired kcal/kg per day to be administered. A reasonable initial goal is 40 to 50 kcal/kg per day; higher rates of energy administration often result in hyperglycemia and hyperlipidemia. The initial infusion rate of PN solutions should be 50% of the calculated final rate, and the rate should be gradually increased every 1 to 3 hours after monitoring of the blood glucose concentration to ensure that hyperglycemia (blood glucose >180 mg/dL) is not present.

Rectal temperature should be closely monitored during PN support because fever is a common early manifestation of systemic infection. Blood glucose concentrations should be closely monitored, the frequency of which depends on the stability of blood glucose concentrations. Blood glucose should be maintained between 90 and 180 mg/dL. Although the renal threshold for glucose is not well described in foals, glucosuria and diuresis will be observed in many when blood glucose levels exceed 180 mg/dL. Urine output should be monitored continuously, in combination with intermittent monitoring of urine glucose concentration, because of the risk of hyperglycemia-induced diuresis and glucosuria. Additional clinicopathologic monitoring should consist of daily complete blood counts and serum chemistry profiles in the critical case; these can be performed every 48 to 72 hours in more stable patients. BW should be assessed on a daily basis to ensure that the foal is at least maintaining BW while on PN support.

Some critically ill foals are intolerant of even a conservative rate of dextrose administration because of insulin resistance. The administration of insulin is needed to control hyperglycemia and allow attainment of the goal level of PN support.[97] Use of continuous rate infusion (CRI) for the administration of insulin is preferred to intermittent bolus dosing. An initial insulin infusion rate of 0.07 IU/kg per hour is generally well tolerated. If possible, simultaneous alterations in both the insulin and PN infusion rate should be avoided, because this can result in marked fluctuations in blood glucose concentrations. Blood glucose monitoring should be performed at least hourly for the first 2 to 3 hours after initiation of the insulin CRI, and if hyperglycemia (blood glucose >150 mg/dL) is persistent beyond the first 2 hours of insulin therapy, then the insulin infusion rate may be increased by 50%, followed by hourly blood glucose monitoring for an additional 2 or 3 hours. This procedure for increasing the insulin infusion rate may be repeated if hyperglycemia persists. Conversely, if hypoglycemia (blood glucose <60 mg/dL) is noted, then a bolus of 0.25 to 0.5 mL/kg of 50% dextrose solution should be administered intravenously over 3 to 5 minutes. The blood glucose level should then be reassessed every 30 minutes for at least 90 minutes. If hypoglycemia recurs, a second bolus of dextrose should be administered and the insulin infusion rate decreased by 50%. Close monitoring will then be required for an additional 60 to 90 minutes to assess the stability of blood glucose concentration. Further changes to the insulin infusion rate are not usually necessary once a steady state has been achieved, in which the blood glucose level is stable and the desired rate of PN administration has been achieved.

When PN support is to be discontinued, it is recommended that the infusion rate be gradually reduced by 25% to 50% increments every 4 to 6 hours while gradually introducing enteral feeding. The monitoring of blood glucose must continue during this weaning process to prevent severe hypoglycemia.

MANAGEMENT OF OBESITY

Obesity is an emergent problem in companion animal equid populations. It has been associated with insulin resistance in horses and ponies, and both obesity and insulin resistance have been associated with increased risk of laminitis, particularly the pasture-associated form of this disease.[8,9,107] There is no universal definition of obesity in horses and ponies. According to the Henneke system, horses with a BCS of 8 (fat) or 9 (extremely fat) can be defined as obese, and animals with a BCS of 7 might be considered overweight, if not obese. Few studies have examined the prevalence of obesity in horse and pony populations. The 1998 National Animal Health Monitoring System (NAHMS) study estimated that 4.5% of the horse

TABLE **5.8 Recommended Digestible Energy Intake by Mature Horses (Mcal/day)**[a]

	Target Body Weight		
Type of Horse	**400 kg (880 lb)**	**500 kg (1100 lb)**	**600 kg (1320 lb)**
Adult sedentary[b]			
Minimum voluntary activity	12.1	15.2	18.2
Average voluntary activity	13.3	16.7	20.0
Elevated voluntary activity	14.5	18.2	21.8
Adult light exercise	16.0	20.3	24.0
Adult moderate exercise	18.6	23.3	28.0
Adult heavy exercise	21.3	26.6	32.0
Adult very heavy exercise	27.6	35.6	41.4
Pregnant: 0–4 months	13.3	16.7	20.0
5 months	13.7	17.1	20.5
6 months	13.9	17.4	20.9
7 months	14.3	17.9	21.5
8 months	14.8	18.5	22.2
9 months	15.4	19.2	23.1
10 months	16.2	20.2	24.2
11 months	17.1	21.4	25.7

4th month	23.6	29.4	35.3
5th month	22.7	28.3	34.0
6th month	21.8	27.2	32.7

[a]Recommended intakes for stallions and growing horses can be found in the NRC publication.
[b]Sedentary adults: Minimum = very inactive in stall/paddock, easy keeper; elevated = very active in stall/paddock, hard keeper. Light exercise: 1 to 3 h/week; walking, trotting. Moderate exercise: 3 to 5 h/week; walking, trotting, some canter; easy skills. Heavy exercise: 4 to 5 h/week; trotting, cantering; hard skills. Very heavy: racing; elite 3-day; endurance racing.
From Committee on Nutrient Requirements of Horses, National Research Council. *Nutrient Requirements of Horses*. 6th ed. rev. Washington, DC: National Academies Press; 2007.

population in the United States was overweight or obese.[108] However, the accuracy of this estimate may be questioned because it was based on owner reports, not the results of physical examination. Anecdotal observations by equine veterinarians suggest that the prevalence of obesity is far higher than the NAHMS estimate. In support of this contention, a recent cross-sectional, prospective study of 300 mature horses (ponies were excluded) in southwestern Virginia reported obesity (BCS of 8 or 9) in 56 animals (i.e., a prevalence of 19%).[109] In a study of 319 pleasure riding horses in Scotland, 32% were obese and a further 35% were considered fat.[110]

The cause of obesity in horses and ponies is likely multifactorial. However, overfeeding and lack of physical activity are likely contributing factors. Many horses are kept in confinement (e.g., stall, small pen) for much of the day, and even if used for riding activities 2 or 3 days per week, they may not require any more than maintenance energy intakes. Nevertheless, many of these horses are fed much more than the maintenance energy requirement, which is a problem that is compounded by the provision of grains, sweet feeds, and other feeds with high caloric density. Obesity also can be a problem in some horses and ponies given unrestricted access to pasture, particularly during the spring and fall, when pasture forage is actively growing, plentiful, and energy rich. In a study by Thatcher et al., more than 60% of the surveyed horses were maintained at pasture year round and were not used for any type of riding activity.[109]

Maintenance DE requirements for horses range between 30 and 36 kcal/kg BW (Table 5.8), with variation among horses resulting from differences in dietary composition, age, breed, environment, and body composition, among other factors.[1] Thus for a 500-kg (1100-lb) horse, minimum maintenance energy needs are 15.2 Mcal DE/day. This requirement can be met by about 7 kg (15 lb) of high-quality hay (i.e., no supplemental grain is required). To illustrate the impact of even moderate overfeeding on BW, consider the effect of adding 1 kg of grain or sweet feed per day to this horse's ration for a 1-year period (i.e., an additional 3 Mcal/day or >1000 Mcal over the 1-year period); if it is assumed that 20 to 25 Mcal of DE *over maintenance* is required for 1 kg of weight gain, the horse in this example will gain upward of 40 kg BW during this period (with a 1- to 1½-unit increase in BCS).

Genetics may be another factor in the predisposition to obesity. Horse owners and veterinarians often use the term *easy keeper* to describe a horse or pony that has a tendency to be overweight and appears to require fewer calories than most horses to maintain condition. Ponies and certain horse breeds (e.g., Morgans, Arabians, Paso Finos) appear to fit this description. One hypothesis is that certain lines of horses and ponies have inherited genetic traits that have facilitated survival on

poor-quality forages or in the face of limited feed availability: the so-called thrifty genotype.[8,111] When these animals are supplied with abundant feed, particularly grains or pasture forage rich in NSC, weight gain and obesity result.

Obesity in horses and ponies is a risk factor for laminitis. Mechanical trauma caused by increased load on the feet is one possible reason that obesity is linked with laminitis. However, the increased risk of laminitis in obese equids is more likely related to the attendant insulin resistance. In one recent study of ponies, a phenotype characterized by generalized or regional adiposity (especially a cresty neck), hyperinsulinemia, and hypertriglyceridemia was associated with 10-fold higher risk for development of pasture-associated laminitis. The clustering of these risk factors for laminitis is termed *prelaminitic syndrome*.[8] Similar associations between obesity, insulin resistance, and laminitis have been observed in horses, leading to the use of the term *equine metabolic syndrome*.[112] Obese ponies, donkeys, and Miniature Horses are prone to the development of hyperlipemia during times of stress or negative energy balance (e.g., concurrent disease, lactation). Other proposed effects of obesity include impaired thermoregulation in hot weather, reduced athletic performance, and increased risk of joint injuries, but evidence is lacking. In broodmares obesity and insulin resistance have been associated with prolonged luteal phase and lengthened interovulatory intervals,[112] but the impact of these alterations in the estrous cycle on reproductive performance has not been extensively studied.

Weight Management Programs

In horses, as in humans, eating less and exercising more are the key strategies for improving BW and condition. Important steps in the development of a weight management program include the following:

- Owner/trainer recognition that the horse or pony is overweight or obese: As the old adage states, "beauty is in the eye of the beholder," and different equestrian disciplines and breeds have adopted different standards to evaluate body condition. Nonetheless, the effectiveness of any weight loss program is critically dependent on the willingness of the owner or caregiver to comply with the plan.
- Evaluation of the current feeding program and housing: This includes a thorough evaluation of the type of feed that is being provided (including supplementary feed, hay, pasture quality, and time allowed for grazing) and in what quantities.
- Assessment of the weekly workload and soundness for exercise: Is the horse or pony engaged in structured physical activity (e.g., being ridden)? If so, how much? Many obese equids receive little structured exercise. Information on current activity level and soundness for exercise forms the basis for recommendations regarding physical activity.
- Set realistic goals for weight loss and regularly monitor progress: In this author's experience, there is wide variation in the response of obese horses and ponies to weight loss treatment programs. Some undergo a substantial loss of BW and adiposity after 2 to 3 months of diet restriction and increased physical activity. In others, progress can be frustratingly slow, and further adjustments to diet and the level of physical activity may be needed for satisfactory improvement. As a guide, an effective weight loss regimen should result in the loss of approximately 25 to 30 kg over a 4- to 6-week period. This decrease in BW may be accompanied by the loss of approximately 1 unit of BCS. However, initial weight loss may result from a decrease in abdominal fat or abdominal fat mass, and further weight loss may be required before noticeable changes in BCS occur. BW and body condition should be assessed regularly (e.g., every 2–4 weeks) during the *weight reduction* program so that progress can be monitored and the program adjusted accordingly.
- Make all dietary changes gradually and avoid prolonged periods of feed withholding. Abrupt starvation in obese ponies, donkeys, and Miniature Horses carries the risk of hyperlipemia and hepatic and renal lipidosis.
- Develop an appropriate *weight maintenance* program once the target weight and body condition have been achieved. This includes monthly assessment of BW and condition to ensure that the feeding program is appropriate to the current level of physical activity and other environmental influences on energy requirements (e.g., ambient conditions).

In obese people the combination of caloric restriction and regular physical activity can result in more substantial weight loss than either strategy alone. However, studies in humans also have demonstrated that physical activity is beneficial even when weight loss does not occur, as demonstrated by improvements in insulin resistance, blood lipid profile, and markers of inflammation, all of which are risk factors for cardiovascular disease. Similarly, a study in a small number of obese mares demonstrated improvements in insulin sensitivity without a change in BW after 7 days of round pen exercise (15–20 min/day).[113] Accordingly, a program of regular exercise is likely to be beneficial in the management of obese (but sound) horses and ponies. In the author's experience, weight reduction and subsequent control are improved when dietary restriction is combined with a program of riding or longeing. A suggested exercise regimen is to start with two or three exercise sessions per week (20–30 min per session), subsequently building to 4 or 5 times per week, with a gradual increase in the intensity and duration of exercise.

Feeding Obese Horses

Caloric restriction is of paramount importance in the management of obese equids; creation of a state of negative energy balance is needed to achieve loss of BW. Several different dietary strategies can be applied depending on the horse's present and desired body condition and other individual circumstances. A certain amount of trial and reassessment is invariably required to achieve the goal weight and condition in an individual animal. Key considerations are the quantity and composition of the ration. Removal from pasture (e.g., to a large dry lot) is necessary for adequate control of dietary intake. Some nutritionists and veterinarians have recommended restrictive grazing as a means to decrease caloric intake in overweight equids. However, a study in obese pony mares reported no change in BW when ponies were allowed access to pasture for 12 hours daily (either during day or night),[114] perhaps because of increased forage consumption during the restricted grazing period. In another study it was estimated that ponies could consume 40% of their daily DM intake during 3 hours of pasture turnout.[115] Strategies that allow turnout while minimizing forage intake include application of grazing muzzles, strip grazing behind other horses, mowing the pasture and removing clippings before providing access, putting a deep layer of wood chips over a small paddock, and using dry lots or indoor arenas. It is important to ensure that horses wearing grazing muzzles are able to consume water. In some obese horses and ponies, a return to less restricted pasture access is possible after attainment of goal BW

and condition. Even then, however, reduced grazing may be justified during periods of rapid growth (i.e., spring and fall) given the likelihood for weight gain and exacerbation of insulin resistance, with attendant increased risk of laminitis.

Generally, rations for overweight and obese horses should be high in fiber and low in NSC. Horses at maintenance require approximately 2% BW as forage or forage plus supplement to meet daily nutrient requirements. As a first step toward calorie restriction and weight loss, grain and other concentrated sources of calories (e.g., commercial sweet feeds, feeds containing added fats) should be reduced (for overweight animals) or totally removed (for obese animals) from the diet. Excessive feeding of other treats, such as carrots and apples, also should be curtailed. Forage (as hay or hay substitute such as chop, chaff, or haylage) should be the primary, if not sole, energy-providing component of the ration. In some areas forage-based, low-calorie feeds complete with vitamins and minerals are available commercially; this type of feed is convenient and may be used as a substitute for hay or fed as a component of the ration along with hay. In a study of obese ponies provided a free-choice forage (chaff) diet during winter and summer, voluntary intake (DM basis) was about 2% of BW, and BCS was unchanged during the study period.[116] As a general guide, therefore, hay or hay substitute should initially be provided at no more than 1.5% of current BW per day (clients should be instructed to weigh the ration), with subsequent further reductions in feed depending on the extent of weight loss (e.g., 1% of *target* BW). It is preferable not to decrease forage provision below 1% of BW; feeding smaller amounts of forage can increase the risk of hindgut dysfunction, stereotypical behaviors (e.g., wood chewing), ingestion of bedding, and coprophagy. The ration should be divided into three to four feedings per day.

Mature grass hay (i.e., with visible seedheads and a high stem-to-leaf ratio) has higher fiber and lower energy and NSC than immature hay and is suitable forage for the obese horse or pony. Alfalfa hay or other legumes, such as clover, are less preferred because, on average, these forages have higher energy and NSC content than grass hay. Ensiled forages generally have lower NSC contents than hay made from the same crop. However, despite the generally lower NSC content of haylage compared with hay, the high palatability of some haylages may result in higher total NSC intake. Ideally, the results of proximate nutrient analysis, including direct measurement of starch and ESC, should be reviewed before selection of the hay. An NSC content of less than 10% is recommended. Poorly digestible, highly silicated forages should be used with caution; according to anecdotal reports, this practice increases the risk of impaction colic in some animals.

Forage-only diets do not provide adequate protein, minerals, or vitamins. It is possible that the lack of protein over the long term could lead to the loss of muscle mass rather than fat. Therefore the forage diet should be supplemented with a low-calorie commercial ration balancer product that contains sources of high-quality protein and a mixture of vitamins and minerals to balance the low vitamin E, vitamin, copper, zinc, selenium, and other minerals typically found in mature grass hays. These products are often designed to be fed in small quantities (e.g., 0.5–1.0 kg/day); they can be mixed with chaff (hay chop) to increase the size of the meal and extend feeding time, which may alleviate boredom in animals provided a restricted diet.

Ponies, donkeys, and Miniature Horses must not be abruptly starved to reduce their BW or prevented from eating for prolonged periods; these strategies have been associated with the development of hyperlipemia. This risk is increased at times of stress, such as during transportation, lactation, pregnancy, and management changes. As mentioned previously, the target duration for weight loss should be weeks to months rather than days.

Additional factors should be considered when planning a weight reduction program, including strategies to extend feeding time and relieve boredom in the face of limited feed provision, the need for individual rather than group feeding, the potential need for a change in the type of bedding, and the potential use of pharmacologic agents (e.g., levothyroxine) purported to enhance weight loss or mitigate comorbidities such as insulin resistance. Recent studies have demonstrated that levothyroxine sodium (48 mg/day for an adult horse) can enhance weight loss in healthy horses.[117]

Use of hay nets with small openings or double hay nets can extend feeding time in some horses. The size of the meal and duration of feeding can be increased by mixing the feed with chaff or chopped straw. In group housing situations it may be necessary to separate the obese horse or pony to allow strict control of feed intake. For animals housed in stalls, dietary restriction can promote intake of bedding. Because some straws retain some of the cereal heads, ingestion of bedding can substantially increase daily caloric intake (and possibly the risk of colic). In this situation use of shavings, paper, or other nonstraw alternatives for bedding is recommended.

FEEDING THIN AND STARVED HORSES

Failure to meet a horse's energy (DE) requirements will result in weight loss. Prolonged nutritional restriction (energy and protein) will result in emaciation and, in severe cases, death. Chronically starved horses have low body condition (BCS of 2 or lower), with minimal subcutaneous fat and reduced muscle mass. The hair coat is often unthrifty in appearance, and muscle weakness may result in recumbency. Healthy horses starved of feed take approximately 60 to 90 days to become recumbent. After 36 to 48 hours of recumbency, horses are often in lateral recumbency, may not be able to raise their heads, and can display seizure-like activity. The prognosis for survival is very poor in horses recumbent for more than 72 hours, even when appropriate nutritional support and nursing care are instituted.[118]

Laboratory findings in chronically starved horses may include anemia, hypertriglyceridemia, hyperbilirubinemia (especially unconjugated bilirubin), high nonesterified fatty acid concentrations, lymphopenia, hypophosphatemia, and hypomagnesemia. Protein deficiency may result in hypoalbuminemia and low BUN concentration. When presented with a thin or emaciated horse, the clinician first must determine the cause (e.g., feed restriction versus medical problems such as intestinal parasites, malabsorption syndromes, poor dentition, old age). Thorough clinical evaluation is therefore required to identify the cause of weight loss and emaciation. If the horse has been neglected, obtaining an accurate history of its diet and feeding program may be difficult. However, observation of the environment and other horses on the farm may indicate feed restriction as the cause of thin body condition or starvation. Herdmates also may be in poor body condition, pastures overgrazed, and hay quality poor or fed in quantities insufficient to meet the requirements of the individual or herd. Harsh environmental conditions (e.g., dry summer, cold winter) can contribute to feed restriction in horses kept at pasture.

Recommendations for feeding management of thin and emaciated horses vary depending on the severity and chronicity of starvation and appetite. Severely debilitated horses with poor appetite may require AEF with a slurry made from commercial complete feeds or PN support (as described earlier in this chapter). For horses in moderately poor body condition (BCS 3 or 4) with good appetite, a simple increase in energy intake will result in weight gain. The first step is to thoroughly evaluate the current ration, with particular reference to the adequacy of DE and protein intake (see Fig. 5.1 and Table 5.8). Requirements for weight gain can then be estimated. The relationships among energy intake, change in BW, and change in BCS have not been well described. However, in light-breed horses it appears that each unit of body condition increase requires at least 20 kg of weight gain. Some experts suggest that 16 to 24 Mcal of DE are required per kilogram of gain in mature horses of about 500-kg (1100-lb) BW.[1] Using an average value of 20 Mcal DE/kg weight gain, a 1-unit increase in BCS (20-kg gain) will require 400 Mcal of DE over maintenance requirements, or an additional 6 to 7 Mcal per day for the 500-kg horse over a 60-day period. Using similar assumptions, a 2-unit increase in BCS (approximately 40 kg) may be achieved over a 90-day period by feeding an additional 9 to 10 Mcal of DE per day (see Fig. 5.1). Note that these estimates have been derived from limited data, and individual responses are likely to vary. Also bear in mind that the efficiency of conversion of DE to usable energy for tissue deposition (net energy) varies among energy sources; less DE may be needed per unit of gain if a high-fat feed is provided compared with a high-fiber feed such as grass hay. The addition of 3 kg of good-quality hay (e.g., alfalfa, DE 2.4 Mcal/kg on DM basis) or sugar beet pulp (2.8 Mcal DE/kg DM) to the ration will provide the extra DE required for a 1-unit increase in BCS over a 60-day period. Alternatively, a smaller amount of additional hay or beet pulp may be combined with vegetable oil (1.7 Mcal DE per standard cup [225 mL]). The provision of 2 to 2.5 kg/day of a commercial fat-supplemented feed (8%–10% fat; typical DE of 3–3.5 Mcal/kg) is another option.

A more conservative approach is indicated for the initial nutritional support of starved horses. In malnourished human patients aggressive refeeding can result in potentially fatal shifts in fluids and electrolytes as a result of hormonal and metabolic responses to rapid refeeding, whether enteral or parenteral; this problem has been named *refeeding syndrome.* The hallmark biochemical feature of refeeding syndrome is hypophosphatemia, but other electrolyte abnormalities may occur, including hypokalemia and hypomagnesemia.[119] Thiamine deficiency is another possible feature of refeeding syndrome. During prolonged starvation the intracellular concentrations of these substances become severely depleted, although serum concentrations may remain within reference limits. With refeeding, glycemia leads to an increase in circulating insulin, which stimulates glycogen, and fat and protein synthesis. These processes require cofactors such as phosphate, magnesium, and thiamine. Insulin stimulates cellular uptake of potassium, and magnesium and phosphate also move into the cells. Water follows by osmosis. Consequently, there can be marked decreases in serum phosphate, magnesium, and potassium, with potential development of cardiac dysfunction (e.g., arrhythmias, cardiac arrest) and neuromuscular complications.

The incidence of refeeding syndrome in chronically starved horses is unknown. Anecdotally, however, metabolic and electrolyte derangements similar to those observed in humans with refeeding syndrome have been observed in starved horses provided a diet rich in starches and sugars (i.e., high NSC). Therefore some experts recommend restricting dietary NSC in the ration provided to chronically starved horses, specifically less than 20% NSC in the total diet.[73] One study evaluated the metabolic responses of chronically starved horses refed one of three diets: alfalfa hay, oat hay, or a diet of half oat hay and half an extruded (commercial) feed.[120] The diets were initially offered at 50% of estimated daily DE requirements and, over the subsequent 10-day period, gradually increased to 100% of daily needs. There were minimal differences among treatments regarding metabolic responses (e.g., blood glucose, nonesterified fatty acid, mineral concentrations), but serum insulin concentrations were higher in horses fed hay in addition to extruded feed. Weight gain over the 10-day period did not differ among treatments. Another study compared starved horses fed a diet of alfalfa alone and those fed alfalfa and corn oil.[121] Phosphorus intake was lower in horses fed the alfalfa and corn oil diet, which is associated with lower serum phosphorus concentrations.

Generally, a diet consisting mostly of forage (e.g., hay) is recommended during the rehabilitation of chronically starved horses. Grass or legume hay (or a mixture of the two) should be fed. The NSC content of these forages is generally less than 15% DM. Alfalfa hay is a good choice for initial refeeding because it has a higher mineral content than grass hay. Grains (e.g., oats, corn, barley) and sweet feeds are not recommended because of their high NSC content. It is advisable to supplement the hay ration with a vitamin and mineral supplement or balancer pellet. The energy density of the ration may be increased by adding vegetable oil (e.g., ¼ to 1 cup per day, starting at the low end of this range) or providing a commercial fat-supplemented feed (8%–12% fat, as fed with NSC <20%). As previously mentioned, thiamine deficiency is thought to contribute to the pathophysiology of refeeding syndrome in humans. Accordingly, the administration of a B-vitamin preparation may be justified.

The DE (caloric) requirements should be calculated on the basis of *RERs* at the current BW (22–23 kcal/kg/day) and the true maintenance requirements at the ideal BW (30–36 kcal/kg/day; see Table 5.8). Starved, emaciated horses may have lost 25% to 30% of BW; therefore, maintenance DE needs for ideal BW will be based on 125% to 130% of BW measured at the time of first examination. A gradual increase in daily DE intake has been recommended,[73] starting at 25% to 50% of resting requirements at current BW, building to 100% of resting requirements over the next 2 to 3 days, and followed by a gradual (over 7–10 days) transition to maintenance energy requirements for the ideal BW. Energy provision should not exceed 100% of resting requirements if AEF is used for provision of the ration, with transition to true maintenance after the start of voluntary feed consumption. Regardless of feeding method (voluntary vs. AEF), the ration should be divided into four to six feedings daily during the first 10 to 14 days of rehabilitation. Subsequently, the ration can be provided into two to three meals per day.

Regular (every 1–2 days) measurement of blood glucose, serum magnesium, phosphorus, and potassium is advised during the first 7 to 10 days of refeeding. Frequent assessment of hydration status and gastrointestinal function (e.g., borborygmi, quantity and character of feces) is also recommended. Administration of intravenous fluids, oral electrolyte-mineral preparations, or both may be necessary to correct electrolyte imbalances.

CHAPTER 6

Clinical Epidemiology and Evidence-Based Medicine

Kenneth W. Hinchcliff

INTRODUCTION

Contemporary veterinary clinical practice is the art and science of providing optimal care for the animal in a context that is consistent with the informed consent of the person responsible (owner) for the care, well-being, and use of that animal. These are two important considerations: the provision of optimal care, which implies knowledge of what is best practice, and provision of this care in a context in which the wishes and resources of the owner are considered. Best practice increasingly relies on an awareness of the scientific and clinical literature on a specific topic and the ability to evaluate the reliability of this information. This process has been called "evidence-based veterinary medicine" (EBVM), and it underlies much of modern veterinary clinical practice. This topic was previously discussed in earlier editions of this textbook.

EBVM can be defined broadly as the dispassionate assessment of the evidence underlying our approaches to diagnosis, treatment, and control of diseases or conditions. This consideration of the evidence is scientifically based and is intended to provide objective assessment of the evidence leading to a finding of the best intervention, diagnostic method, or means of control of a disease. The term *evidence-based medicine (EBM)* was proposed in human medicine in the early 1990s, and the concept was soon extended to veterinary medicine including equine medicine. There is now a substantial body of literature on human EBM and a smaller, but still important, amount of literature on veterinary evidence-based medicine.[1-7]

The basis of EBM and EBVM is scientific in that both the evidence and the method of assessing it are grounded in science. EBVM is an evaluation of the scientific evidence, as available in the published literature, using prescribed and predetermined methodologies and criteria, as discussed further in this chapter. What is often not clear is the role of clinical experience in evaluating this scientific evidence. Early definitions of EBM in human medicine explicitly included consideration of individual clinical expertise, but a definition of veterinary EBM referred to the "use of current best evidence," implying that individual, or collective, clinical experience is not a basis for the application of the evidence.[7] Although perhaps not the intended approach, exclusion of clinical experience would appear to be a limitation of the purely evidence-based approach to practice, and this is recognized in more current definitions.[1]

The emerging practice in human medicine is more holistic and includes a consideration of the evidence and its quality in the context in which the evidence will be used. This approach, which is captured in the Grading of Recommendations Assessment, Development and Evaluation (GRADE) process explicitly acknowledges that good clinical practice is complex and not solely based on the use of high-quality evidence. Good clinical practice includes a consideration of multiple factors such as the seriousness of the outcome, risk of adverse events, and preferences of the owner or trainer (or, in human medicine, the patient; see later). GRADE provides a conceptual framework that involves a systematic and transparent approach to moving from the evidence to a recommendation or decision while recognizing that the high quality of evidence is a fundamental, but not the sole, basis for making strong recommendations for clinical practice.[8,9]

Evidence-Based Veterinary Medicine: Arriving at a Recommendation

There are three key components and five steps to arriving at a recommendation using EBVM.[1] The fundamental components of EBM are identifying and clearly stating the question, assembling and evaluating the evidence through a systematic review, and considering the evidence in making a recommendation.[10] These aims can be divided into five steps.[1]

Ask the Pertinent Question

All EBVM begins with asking the right question. The start of any search for evidence must begin with a clear and concise response to "What is the question?" A common method of formulating the question is the PICO method: patient (animal including species, age, sex, disease, and other demographically or clinically defining characteristics), intervention (or diagnostic method or prophylaxis), comparator (the situation to which the intervention is being applied, such as a placebo, different surgical or diagnostic technique), and the outcome of interest.[10] A relevant question must include a consideration of the setting (primary practice or referral hospital), the population of interest (e.g., foals <5 months of age on a stud farm with endemic *Rhodococcus (Prescottella) equi* pneumonia), the intervention being applied (e.g., administration of azithromycin), the comparator (e.g., administration of a placebo), and well-defined and measurable outcomes (e.g., survival at 300 days of age).[11]

The question should be framed in a very utilitarian context: the population, intervention, comparator, and outcomes should all be practicable and available to the person seeking to apply the recommendations arising from the evidence in their particular setting. In particular, the outcome should be important to the patient, owner, or trainer. An irrelevant or trivial outcome yields only low-grade evidence and at best enables recommendations that are weak or ineffectual.

Acquire the Evidence

There are essentially two ways of sourcing evidence with which to answer the question being considered: find evidence that someone else has generated or generate the evidence (i.e., do research) yourself. The latter approach is usually, but not always, restricted to academic institutions or large practices and often has a time frame of months to years. The former approach involves going to the literature to find evidence that someone else has created. This approach can be very efficient, compared with actually doing a research study yourself, but involves finding the relevant literature, evaluating its applicability to your situation, and making an assessment of its quality.

Appraise the Quality of Evidence

Generally, the strength of a recommendation for a particular intervention is strongly correlated to the quality of the evidence used to develop the recommendation.[12] High-quality evidence (as defined later in this chapter) provides clear indications of the magnitude of the effect of the intervention on the key outcome in the population of interest.[10] It should also include high-quality evidence of adverse effects or outcomes. This then allows formulation of strong recommendations. Weak or equivocal evidence or evidence from a population that is not relevant to the question does not provide the confidence to make strong recommendations.

Apply the Evidence to Practice

Taking evidence and converting it to a practice situation is not quite as easy as one might first think. For any particular question there might be a body of evidence, some of it conflicting, and often the body of evidence will have important gaps. These complexities mean that rather than relying on the results of one study (a much less than ideal situation), one must consider a diversity of evidence in formulating an answer to the question. The author's answer, the recommendation, must be a synthesis of the evidence and ideally considers factors other than just the quality of the evidence. For instance, the recommendation should also include consideration of the cost of the intervention, its availability for use in the population in question, the preferences of owners and trainers, and the risk and severity of adverse effects or outcomes.

Systematic reviews of evidence do not, or should not, make recommendations. A process that is additional to evaluating the quality of evidence is needed to make recommendations applicable to clinical practice. This process has been formalized as the GRADE process in which the quality of evidence is considered along with a number of other factors (see later) in arriving at a recommendation about an intervention.[13]

Assessing the Efficacy of the Intervention

A key component of any evidence-based approach to clinical practice is evaluating if the intervention, diagnostic technique, or prophylaxis was effective. This should ideally be done prospectively with metrics that provide evidence of the effect of the intervention on the outcome of interest.

This chapter will consider what represents evidence in veterinary practice, how the quality of this evidence is assessed, and how this evidence can be used to inform the practice.

What Is Evidence and What Is Quality of Evidence?

Evidence is an observation, fact, or organized body of information offered to support or justify inferences or beliefs in the demonstration of some proposition or matter at issue.[14] Evidence evaluated in EBVM is usually in written format and is commonly in the form of a scientific article or report. However, it could be contained in a database, such as online collations of,[15] or in hospital records or similar clinical databases.

Not all evidence has the same usefulness (evidentiary value) in informing our decision, and an important aspect of EBM is deciding on the evidentiary value of evidence in the context in which you need it. High-quality evidence exists in publications that describe studies of high quality and in which we have higher degrees of confidence that the results of the study accurately reflect our reality. High-quality evidence gives confidence that the results are repeatable, provides estimates of the effect of the intervention that are usefully narrow, and is consistent with other high-quality studies addressing the same question. Most important, information of high evidentiary value is relevant to the practice situation and the question we are seeking to answer. For this reason, even the highest quality evidence of efficacy of an intervention in, for example, humans, dogs, or cats, has limited evidentiary value in equids.

Veterinary Scientific Literature

Perhaps the greatest single advance in veterinary medicine has been the increase in the amount of information and, presumably, the proportionate increase in knowledge. This increase in the amount of information is most clearly demonstrated by the 2.3-fold increase in the number of articles published each year in the veterinary scientific literature (from 8815 in 1996 to 20,549 in 2014).[16,17] Not only did the number of articles increase, but so did the number of veterinary journals indexed by Scopus (from 109 in 1996 to 211 in 2014), although this does not include all journals that publish veterinary material.[16-18] These increases are representative of the increase in information available for equine veterinary science, with 123,146 equine-related articles published between 1996 and 2014, rising from 2534 in 1996 to 7722 in 2014.[19] There is clearly an abundance of scientific literature in which we can seek answers to important clinical questions.

The large increase in the volume of information creates some important challenges for practitioners and veterinarians seeking to use this information. These challenges include the following:

- Identifying that the information exists: how does one find out that the relevant publications exist?
- Sourcing the information: having identified that the information exists, how does one then access these publications?
- Evaluating the information: is the information reliable, is it valid, and does it apply to this particular circumstance?
- Using the information: how does one make sense of and apply the information that is related to a particular problem?

Identifying That the Information Exists

The first challenge facing a veterinarian is to locate current information about the topic. There are various ways of doing

so, including sourcing information from colleagues, continuing education events or notes, scientific or clinical journals, textbooks, and Internet sources.[20]

When presented with a difficult case, 44% of veterinarians in the United Kingdom first sought advice from a colleague (not a specialist), and 23% consulted a textbook.[20] Accessing information in publications was less important to veterinarians, with fewer than 5% seeking information in scientific articles. Equine veterinarians in the United Kingdom most frequently read the journal *In Practice* (81%), which publishes only commissioned, peer-reviewed articles; the peer-reviewed *Veterinary Record* (75%) and *Equine Veterinary Education* (43%); and nonpeer-reviewed material in the *Veterinary Times* (79%) and *UK Vet* (49%). This usage is likely a reflection of the availability of these publications, with the *Veterinary Times* and *UK Vet* being free resources, the *Veterinary Record* and *In Practice* included as part of membership of the British Veterinary Association (BVA), and *Equine Veterinary Education* included as part of membership of the British Equine Veterinary Association.[20] Uncertainty about how to identify suitable information through Internet-based searches, limited access to publications, and esoteric content (for practitioners) of many scientific articles could be reasons for limited uptake of information from scientific journals.

Veterinary Literature Database

Until late in the last century, sourcing information in the scientific or peer-reviewed clinical literature was only achieved by physically visiting scholarly libraries and pouring through printed indices (Index Veterinarius), consulting specialized textbooks or tomes, and scouring the index of scientific journals. Sourcing of information has changed markedly with the availability of specialized veterinary electronic databases and almost universal access to the Internet and search engines. However, access to specialized databases and many scientific journals is limited to academics and those who choose and have the financial resources to subscribe to these resources. Although there is greater availability of open access journals, which make the articles they publish available without payment by readers, most veterinarians rely on nonspecialized sources identified using search engines.[20] For instance, 71% of veterinarians in the United Kingdom rely on Google searches as their primary source of electronic veterinary information, although not surprisingly veterinarians in academia prefer PubMed (which is also available to the public).[20] The concern with accessing information from the Internet is that the source, while ostensibly authoritative, might not be so. This is balanced with the ease with which the information can be accessed. Finding the answer will involve using information sources that provide reliable, contemporary, and current information or guidance.

There are a number of databases that cover topics in veterinary medicine and related fields.[21,22] Many of these databases restrict access by requiring a subscription, such as through a university library or institution, and are not readily accessible to veterinarians in practice. However, a number of professional organizations, such as the American College of Veterinary Internal Medicine,[23] have agreements that provide access to these databases by their members. Access to relevant databases by practicing veterinarians is an impediment to use for EBVM in clinical practice outside of universities.[24]

Databases that index journals that publish articles relevant to veterinary medicine include the following[21,22]:

- Agricola: Indexes the agricultural literature including topics such as animal science, cytology, feed science, microbiology, and parasitology. Agricola is open access.[25]
- Biological Abstracts: As the major index for life sciences literature, Biological Abstracts covers bioengineering, biotechnology, microbiology, and other areas of biology.[26]
- CAB Abstracts: Indexes the veterinary medical literature more completely than any other database.[18] CAB Abstracts contains records from more than 8000 journals, conference proceedings, and books. It can be accessed through the following platforms: CAB Direct (Center for Biosciences and Agriculture International [CABI]'s own platform), Dialog, Dimdi, EBSCO, OvidSP, STN International, and Thomson Web of Knowledge. In 2012 CAB Abstracts indexed almost all the principal veterinary journals (98%) and 90% of journals that include any veterinary content.[18,27]
- CONSULTANT: This is a database of animal diseases indexed and searchable by diagnosis or clinical signs. Outcomes of a search include citations of selected scientific articles. CONSULTANT is open access.[28]
- Embase: This an Elsevier product that offers additional tools for compiling systematic reviews. As of 2012 it indexed 85% of the principal veterinary journals and 38% of journals that publish any veterinary content.[18,29]
- Google Scholar: This is a search engine provided by Google that searches the scholarly literature. It, and Google, are frequently used sources of information for veterinary students and veterinarians in practice.[20,30] Google Scholar searches provide different results from PubMed searches in the human literature, often missing the "gray" literature of abstracts and conference proceedings.[31-35] Use of Google Scholar is free, but there is no information about the proportion of veterinary journals that it indexes or locates. Google Scholar is open access.[36]
- MEDLINE: Indexes roughly 100 veterinary medical journals, but overall coverage of veterinary science is mediocre with the database covering approximately 82% of the principal veterinary journals and only 37% of journals that publish any veterinary content.[18] Notable journals not covered by MEDLINE include *Advances in Veterinary Dermatology, Equine Veterinary Education, Veterinary Economics,* and *Veterinary Medicine.*[37]
- PubMed: The overlap between PubMed and MEDLINE is roughly 98% with PubMed including life science journals that submit full text to PubMed Central and additional articles in journals that are selectively indexed by MEDLINE.[21] PubMed Central is a free online archive of the biomedical and life sciences literature.[38]
- Scopus: This database, owned by Elsevier, in 2012 covered almost all the principal veterinary journals (98%) but only 58% of journals that publish any veterinary content.[18,39]
- SPORTDiscus: This is the major database for sports medicine. It covers horse biomechanics, medicine, and physiology.
- VetMed Resource: Produced by CABI Abstracts, this database and resource center includes all CAB Abstracts of [?] veterinary-related records for journals and conference proceedings. The VetMed Resource is marketed to practicing veterinarians and includes an attractive and useful landing page, continuous alerts to recent articles, ready access to full text sources, information about continuing education, and the capacity to create user profiles (as do some other sites).[40]

- VetSRev: This is a database of systematic reviews of the veterinary literature. It is useful for identifying reviews on particular topics.[41]
- Web of Science: Indexes the major journals in biomedicine, the sciences, and engineering including, as of 2012, 93% of principal veterinary journals and 53% of journals that publish any veterinary content.[18,42]
- Wikipedia: This also contains articles that address veterinary topics. The articles are not primary source research articles, do not have an identified single author or identified groups of authors, and are sometimes unreliable or assertions are not verified. The articles are publicly curated.[43]

Searching the Literature

Regardless of the database used, key to identifying relevant literature is formulating an effective search strategy. Briefly, an effective search strategy involves clearly defining the purpose of the search, which can usually be framed in terms of PICO.[22] For instance, searching for articles on the effectiveness of the use of ponazuril compared with pyrimethamine in treatment of horses with clinical signs consistent with equine protozoal myeloencephalitis can be framed as P, equine; I, ponazuril; C, pyrimethamine; and O, protozoal myeloencephalitis. This search yields four articles dealing with the use of ponazuril to treat equine protozoal myeloencephalitis. Further details on effective search strategies in veterinary medicine are available in publications dealing with this important topic.[1,2,7,22,44] Search techniques useful for identifying evidence in human medical literature are not sufficiently sensitive (detect a sufficient proportion of the articles) for use in veterinary medicine.[45]

Sourcing the Information

Accessing information in scientific publications can be challenging for veterinarians who are not associated with universities or similar institutions that have subscriptions to large numbers of veterinary and other journals. Most scientific journals require a subscription to access articles that they publish or they provide access to individual articles at a cost per article (often $25 or more). Other journals charge authors to publish and then make their articles freely available to readers (so-called open access publishing). The availability of journals publishing open access articles of interest to practicing veterinarians is increasing, and a catalog of journals that provide free access to readers is available at the Directory of Open Access Journals.[46]

Journals that publish veterinary topics and provide open access to articles include *Acta Vet Scandinavica, BMC Veterinary Research, Equine Disease Quarterly, Frontiers in Veterinary Science, Irish Veterinary Journal, Journal of Veterinary Internal Medicine, PLoS One, Veterinary Record Open, and Veterinary Research,* among others. Articles that are available through open access can be accessed through searches of databases, including using VetSRev or CONSULTANT. PubMed Central is a repository of open access articles that contains many veterinary articles.[38]

The International Veterinary Information Service (IVIS) is an online publisher of veterinary books and proceedings. The IVIS website currently includes 1673 book chapters and proceeding articles and access is free.[47] It does not publish articles describing primary scientific research. Similarly, the Veterinary Information Network (VIN) indexes more than 150 core veterinary journals and publishes the proceedings of at least 21 veterinary conferences including the American College of Veterinary Internal Medicine (ACVIM) Forum. VIN is a commercial product marketed to practicing veterinarians.[48]

A list of libraries holding collections of veterinary literature is available from Veterinary Medical and Related Libraries: An International Directory (http://vmls.mlanet.org/libraries).

Evaluating the Quality of Evidence

Confidence in an evidence-based approach to veterinary practice depends on our assessment of the quality (evidentiary value) of the available evidence.[49] The higher the quality of evidence, the greater confidence we have in recommendations derived from this evidence. Assessing the quality of evidence is not simple and must involve the consideration of a combination of factors including the design of the study, with some study designs being considered more likely to provide high-quality evidence (e.g., a randomized, controlled trial [RCT] compared with a case report); the rigor of the design, conduct and reporting of individual studies, with studies that are considered likely to provide high-quality evidence being "rated down" because of flaws in the design of the individual study; and the journal or format in which the study is published, with some scientific journals being of higher reputational value than others and, by implication, publishing articles that are of higher evidentiary value.

Grading Quality of Evidence. There are a number of methodologies, and reporting scales, that are used to categorize the quality of evidence. All scales are ordinal; thus, they rank the quality of evidence. A relatively simple but effective series of definitions of varying quality of evidence is provided by GRADE[13]:

- High: Further research is very unlikely to change our confidence in the estimate of the effect (i.e., the magnitude, precision, and direction of the effect of an intervention).
- Moderate: Further research is likely to have an impact on our confidence in the estimate of the effect (magnitude, precision, and direction) and might change the estimate.
- Low: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
- Very low: Any estimate of the effect is very uncertain.

This methodology for ranking the quality of evidence is particularly important in conducting systematic reviews and forming guidelines for practice.

Journal Reputation and Article-Level Metrics. Veterinary scientific journals do not all have the same reputational value; some are considered to commonly publish articles of higher scientific merit. This reputational value has been based on the "impact factor" developed and reported annually by Thomson Reuters as Journal Citation Reports.[50-52] Scopus provides a similar ranking of journal impact factor (journal analytics) using slightly different methods of calculating impact.[53] Impact factor is calculated by dividing the number of citations to articles that were published in a 2-year, 3-year, or 5-year period by a journal by the number of articles published by that journal during a defined period. For example, if a journal received 800 citations to articles it published during a 2-year period, and during that time the journal published 400 articles, the impact factor would be 800/400 = 2. This is the average number of citations per article published in that journal and is considered to be a metric of the influence of the journal; it is not a measure of the impact of individual articles or of each article's evidentiary value. Other, more

sophisticated indices take into account the quality of journals that cite articles in a particular journal (assessing quality of a journal by the company it keeps), whereas others attempt to normalize or account for variations in citation rates across disciplines. The usefulness of these metrics as surrogates for the quality of individual or particular articles in a journal is quite limited.

There are a number of shortcomings in using the impact factor to assess the quality of evidence of individual articles. Importantly, articles in clinical areas in human medicine, and especially those describing therapeutic interventions, receive fewer citations than do articles describing basic biomedical research or diagnostic testing.[54] Citation counts are not evidence of research impact on clinical applications, public health outcomes, or meaningful health outcomes in human medicine, nor do high citation counts provide evidence of a higher quality of research or greater influence.[50] It is likely that a similar situation exists in veterinary medicine and that articles with high clinical utility and providing high quality of evidence for clinically important topics are not always more frequently cited. Furthermore, for articles in veterinary journals there is no association between the number of citations to an article and the level of evidence of the study design of that article.[55] The impact factor ranking of the journal and the number of citations to an individual article are generally not important factors to consider when determining the evidentiary value of an article.

Article level metrics, such as the number of times an article is downloaded or viewed online, the amount of social media comment it attracts, and the number of links to online referencing services provide other metrics that could indicate the influence of an article.[50] However, the link between these article-level metrics and the quality of evidence is unknown; more frequently downloaded or commented on articles might not provide higher quality of evidence.

Appraising the Evidentiary Value of an Individual Article. Articles are considered to have a certain evidentiary value by virtue of their overall study design (see the later section "Study Design and Evidentiary Value"). This initial rating of evidentiary value is based on the assumption that the individual article conforms with the highest standards in terms of conduct and reporting of the study and that the study patients, intervention, comparator, and outcomes are those of interest to the person seeking the evidence. Unfortunately, this is frequently, indeed mostly, not the case, and the evidentiary value of individual articles must be considered in the context of the features of that study. This usually involves decreasing the evidentiary value of an article, although GRADE provides for a mechanism for increasing the value of some very well-conducted and reported observational studies.

Critical appraisal of an article is a systematic process that aims to identify the strengths and weaknesses of the publication.[56] Critical appraisal is the basis for deciding on the use of the article by clinicians. Evaluation of the quality of an individual article often requires some expertise or understanding of experimental design and statistics and the recognition that different study designs are prone to particular weaknesses

TABLE **6.1** **Summary of Strengths and Limitations of Various Types of Studies Included in the Veterinary Literature**

Study Type	Strengths	Limitations
Systematic review or meta-analysis of randomized, controlled trials	Involves use of the full body of literature to estimate the direction and magnitude of effect of potential risk factors, protective factors, and interventions Provides analytic methods to estimate magnitude of effect and degree of certainty	Restricted to combining studies with a similar design and duration of follow-up (meta-analysis) Findings subject to publication bias
Randomized, controlled trials	Allows good control for bias and confounding Provides the strongest evidence for cause-and-effect relationships	Involves restrictive study population and environment that can limit generalizability of results to real-word settings. Allows testing of few variables Often involves a brief follow-up period between interventions and outcome assessment Involves experimentally induced (not naturally occurring) disease in some situations
Retrospective or prospective cohort study	Involves use of real-world population and environment Able to test a large number of risk factors provided the study population is sufficiently large Able to test for effect of uncommon risk factors Allows prolonged follow-up period between factors or exposures and outcomes	Can be prone to selection bias, information bias, and confounding Can be expensive to conduct prospectively because of the long follow-up period between factors or exposures and outcomes Subjects can be lost to follow-up when conducted prospectively Dependent on quality of case records
Case-control study	Involves use of subjects from real-world populations and environments Can be used to investigate risk factors for uncommon diseases while involving few animals Less expensive to conduct than randomized, controlled trials and prospective cohort studies Can generate questions that can be investigated by use of study types with better control for bias and confounding	Highly prone to selection bias, information bias, and confounding Relies on accuracy and completeness of historical records Does not provide evidence for causation because timing of exposure to risk factors is different from that of the outcome of interest Occurrence of risk factors and outcomes is unclear

TABLE **6.1 Summary of Strengths and Limitations of Various Types of Studies Included in the Veterinary Literature—cont'd**

Study Type	Strengths	Limitations
Cross-sectional study	Involves use of subjects from real-world populations and environments Often inexpensive to perform Results can be used to generate hypotheses or objectives that can be investigated in other studies	Can be prone to selection bias, information bias, and confounding Does not provide evidence of causation because chronology of exposure to the risk factor(s) differs to that of the outcome
Case reports or series	Useful for reporting rare diseases or novel potential treatments or interventions Inexpensive Results can generate questions that can be studied in other formats involving larger populations or more controlled study conditions.	A descriptive account of clinical findings Inconsistent format results in variable quality of reporting Does not control for bias or confounding Do not provide evidence of proof; the intervention might not have had the effect that was observed
Induced disease in species of interest	Demonstrates clinical signs and diagnostic features of the disease Enables testing of accuracy of diagnostic tests or efficacy of therapeutic interventions in controlled conditions	Does not replicate full range of conditions occurring in the naturally occurring disease that might affect efficacy of treatment, disease progression, or accuracy of diagnostic tests Expensive to conduct Concerns about animal welfare
Physiologic studies or in vitro studies	Provide understanding of mechanisms of disease Usually high quality with internal validity (good experimental design) Readily reproduced	Do not provide evidence of risk factors or outcomes for naturally occurring disease Require cautious and considered extrapolation to naturally occurring disease
Consensus statement and guidelines	Useful for providing narrative summary of a topic compiled by a panel of experts Provides guidance on topics that are contentious Provides best assessment of available evidence	Variable quality of reporting of methodology; hence, they provide evidence or recommendations of variable quality Expert panel is often self-appointed Subject to group think bias Often do not differentiate between systematic reviews, which should not provide recommendations, and guidelines
Expert opinion	Provides considered opinion of an expert, or self-appointed expert, in the field	Unreliable or unknown evidence base and subject to bias Not subject to peer review or critique by peers

Modified from Larson RL, White BJ. *Importance of the role of the scientific literature in clinical decision making. J Am Vet Med Assoc*. 2015;247:58–64.

(Table 6.1). A series of "filters" can be applied when deciding if an individual article is likely to be useful and are based on the following questions: (1) Is the study valid?, (2) What are the results?, and (3) Are the results of use to me?[57-59]:

1. Decide on the question, preferably using the PICO format, and conduct the literature search.
2. Review each article's title and abstract to decide if the topic of the article is relevant to your question. If the topic is relevant, proceed to the next step; if not, discard the article.
3. Review the results of the study. If correct, will they change your current practice or inform your decision in a meaningful way? If not, discard the article. If so, proceed to the next step.
4. Review the materials and methods for appropriate study design (controls, randomization, interventions, blinding, etc.) and control of bias and confounding factors. If these are not adequate, discard the article. If they are of acceptable standards, proceed to the next step.
5. Review statistical handling and reporting of data. If they are adequate, proceed to the next step.
6. Interpret the findings of the study in the light of your particular clinical context.

The previous six points provide a rudimentary guide to evaluating a single article. More detailed guidelines for appraising the quality of studies are available including a comprehensive set of tool kits and guides from the Critical Appraisal Skills Programme (CASP).[59]

Quality of Reporting of Studies. Fundamental to the evaluation of the quality of the study described in an article is that the details of the study are reported in sufficient detail that the reader can evaluate the validity of the study. This realization has led to the development and use of reporting guidelines. These guidelines, which are tailored to particular study designs, provide advice and direction on optimal reporting of the study. There is evidence in the veterinary literature that inadequate, or poor, reporting of the details of studies is significantly associated with reports of positive outcomes in the study.[60] This result implies that imperfectly or inadequately reported studies are more likely to report positive effects or estimates that are not reliable. Guidelines for reporting are useful to editors, reviewers, and readers in assessing the completeness of reporting and, therefore, the quality of the article and evidence it contains.[61,62] For example, the CONSORT checklist provides a means of assessing quality and completeness of reporting of randomized clinical trials (Table 6.4),[63] and the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines provide a structure for conducting and reporting systematic reviews (Fig. 6.1).[64]

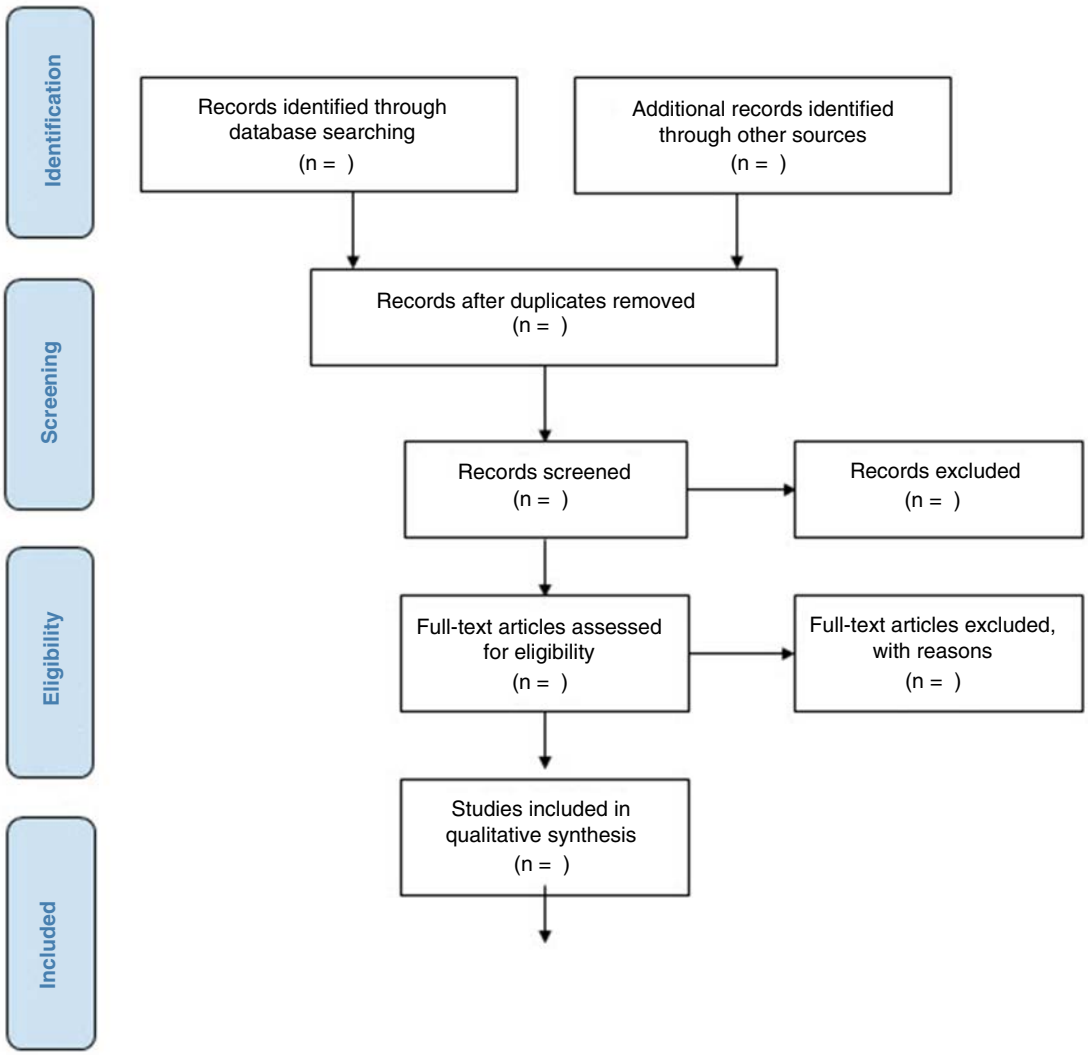

FIG. **6.1** Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) flow diagram for inclusion of articles in systematic reviews.[74]

There are a large number of reporting guidelines (>317) with a small number tailored for the veterinary literature (REFLECT[65] and STROBE-vet). Guidelines are available at the EQUATOR network site.[66]

Study Design and Evidentiary Value. The design of studies reported in the veterinary literature varies, but they can be grouped broadly into one of nine categories (see Table 6.1). The conventional view is that not all study designs are of equal merit or utility and that the type of study design should be considered when evaluating the quality of the evidence derived from that article. This view, which is held steadfastly by some authorities, provides for a hierarchy of quality of evidence based on overall study design (Table 6.2).[7] Others contend that evidence can be understood not as being ordered by methodology but rather in the context of its use and method of its production.[14] An intermediate view is presented by the GRADE process, which while allocating an *a priori* ranking (high, moderate, low, and very low) based on the design of studies, allows for the quality of evidence of a particular study, or group of studies, to be revised up or down (Table 6.3). For instance, RCTs are initially categorized as "high quality," and observational studies are initially categorized as "low quality."[67] The categorization of an RCT can be decreased by at least one level (to "moderate") if there are particular methodological problems with the RCT and that of an observational study increased by up to two levels (to "high") if the evidence from the observational study is particularly strong. Using the GRADE approach, some observational studies might provide higher quality evidence than do some RCTs.

The Oxford hierarchy of evidence has been modified and revised by numerous authors to fit the veterinary context and can be restated as follows[1,7]:

- Systematic review including meta-analysis
- Systematic review of RCTs
- RCTs performed under field conditions
- Nonrandomized trials, cohort studies, or models of induced disease in the species of interest
- Case-control or cross-sectional studies
- Case reports and case series
- Expert opinion/editorials

TABLE **6.2 Levels of Quality of Evidence**

Level of Evidence	Method
1a	Systematic review (with homogeneity of outcomes and narrow confidence intervals around consistent effects of the intervention) of RCTs
1b	Individual RCT (with narrow confidence interval about the effect of the intervention)
1c	All or none: met when all patients died before the intervention became available, but some now survive on it, or when some patients died before the intervention became available, but none now die on it
2a	Systematic review of cohort studies demonstrating homogeneity of outcomes or effect measures
2b	Individual cohort study or low-quality RCT
2c	"'Outcomes"' research such as audit studies
3a	Systematic review of case-control studies demonstrating homogeneity of outcomes or effect measures
3b	Individual case-control study
4	Case-series or poor quality cohort and case-control studies
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research, or "first principles"

RCT, Randomized, controlled trial.
Modified slightly from the evidence hierarchy of the Oxford Centre For Evidence-Based Medicine. *Anon*. Oxford Centre for Evidence-Based Medicine: levels of evidence (March 2009). http://www.cebm.net/oxford-centre-evidence-based-medicine-levels-evidence-march-2009/; 2016. Accessed 9 May 2017.

TABLE **6.3 Methodology for Assigning the Grade of Quality of Evidence for Individual or Groups of Studies**[13]

A priori evidence grade based on study design:
- Randomized trial = high
- Observational study = low
- All others = very low

Decrease grade of evidence if the following are evident in the study:
- Serious (–1 grade) or very serious (–2) limitations to study quality
- Important inconsistency with other studies (–1)
- Some (–1) or important (–2) uncertainty about directness
- Imprecise or sparse data
- High probability of reporting bias (–1)

Increase evidence grade if
- There is evidence of a strong association–significant relative risk of >2 or <0.5 based on two or more observational studies with no plausible confounding (+1)
- Evidence of very strong association–significant relative risk of >5 or <0.2 based on direct evidence with no major threats to validity (+2)
- An evident dose:response gradient (+1)
- All plausible confounders would have reduced the effect (+1)

Notes: Inconsistency refers to lack of similarity of estimates across a number of studies, which then reduces confidence in estimates of effect for that outcome. Directness refers the extent that patients, interventions, and outcomes are similar to those of interest.[13]

- Animal models of the disease of interest (induced disease in species other than the species in which the disease occurs naturally, e.g., mouse model of a disease in horses)
- In vitro studies with an appropriate control group

The characteristics and evidentiary value of publications in veterinary medicine and veterinary science vary and can be categorized as described in Table 6.1. They can be further differentiated as being of either experimental or observation study designs.[7,68]

Observational Studies

Observational studies are those in which there is no intervention by the investigators. Data are obtained by simply observing and recording events without any attempt to impose interventions that could alter the course of events. There is no experimental aspect to observational studies in that there is no testing of a hypothesis. These studies are solely based on observing details about a case or series of cases, or groups of animals, and summarizing associations among variables. Observational studies can be descriptive or analytic.

Descriptive studies are useful in providing information on the presentation of disease including such information as clinical signs, outcomes, or simply that the disease occurs. They do so by observing events and recording facts, often in a retrospective fashion using medical or other case records or, less frequently, in prospective studies. Observational descriptive studies do not include numeric or statistical analysis and cannot report on formal assessments of risk factors or effects of interventions. Examples of descriptive studies include case reports and case series and some types of cross-sectional studies.

Descriptive Observational Studies (Case Reports and Case Series). *Case reports* provide a detailed description of a small number (usually 1–3) of cases with no attempt to formally identify common characteristics of the cases beyond one factor (such as the diagnosis or presenting signs). Reports of a series of cases (usually >3) can attempt to subjectively identify common characteristics, such as breed, sex, predisposition to the disease, or outcome, in a series of nonrandomly selected cases. These reports can be useful in identifying new diseases or rare adverse effects with treatments but without providing definitive evidence of these associations.

The shortcomings of observational descriptive studies are the high risk of selection bias or confounding caused by the nonrandom availability of cases and case records. Selection bias occurs because the investigators cannot take measures to increase the likelihood that cases included in the study reflect the larger population of cases. For instance, reports of outcomes of cases treated at a referral hospital might have little similarity to outcomes of cases of the same disease treated in ambulatory practice. The quality of observational studies can also be impaired by the quality of record keeping, especially in retrospective studies, and the often high frequency of missing data. Results of case reports or case series are usually not generalizable to a larger, or different, population of animals and have limited external validity. Indeed, the characteristics of the case or cases might not be representative of the more common or important manifestations or outcomes of the disease.

TABLE **6.4 CONSORT Checklist for Reporting of Randomized, Controlled Clinical Trials**[63]

Section/Topic	Number	Checklist Item	Reported on Page Number
TITLE			
Title	1	Identify the report as a systematic review, meta-analysis, or both	
ABSTRACT			
Structured summary	2	Provide a structured summary including, as applicable, background; objectives; data sources; study eligibility criteria, participants, and interventions; study appraisal and synthesis methods; results; limitations; conclusions and implications of key findings; and systematic review registration number	
INTRODUCTION			
Rationale	3	Describe the rationale for the review in the context of what is already known	
Objectives	4	Provide an explicit statement of questions being addressed with reference to participants, interventions, comparisons, outcomes, and study design (PICOS)	
METHODS			
Protocol and registration	5	Indicate if a review protocol exists, if and where it can be accessed (e.g., web address), and, if available, provide registration information including registration number	
Eligibility criteria	6	Specify study characteristics (e.g., PICOS, length of follow-up) and report characteristics (e.g., years considered, language, publication status) used as criteria for eligibility, giving rationale	
Information sources	7	Describe all information sources (e.g., databases with dates of coverage, contact with study authors to identify additional studies) in the search and date last searched	
Search	8	Present full electronic search strategy for at least one database, including any limits used, such that it could be repeated	
Study selection	9	State the process for selecting studies (i.e., screening, eligibility, included in systematic review, and, if applicable, included in the meta-analysis)	
Data collection process	10	Describe method of data extraction from reports (e.g., piloted forms, independently, in duplicate) and any processes for obtaining and confirming data from investigators	
Data items	11	List and define all variables for which data were sought (e.g., PICOS, funding sources) and any assumptions and simplifications made	
Risk of bias in individual studies	12	Describe methods used for assessing risk of bias of individual studies (including specification of whether this was done at the study or outcome level) and how this information is to be used in any data synthesis	
Summary measures	13	State the principal summary measures (e.g., risk ratio, difference in means)	
Synthesis of results	14	Describe the methods of handling data and combining results of studies, if done, including measures of consistency (e.g., I^2) for each meta-analysis	
Risk of bias across studies	15	Specify any assessment of risk of bias that may affect the cumulative evidence (e.g., publication bias, selective reporting within studies)	
Additional analyses	16	Describe methods of additional analyses (e.g., sensitivity or subgroup analyses, metaregression), if done, indicating which were prespecified	
RESULTS			
Study selection	17	Give numbers of studies screened, assessed for eligibility, and included in the review, with reasons for exclusions at each stage, ideally with a flow diagram	
Study characteristics	18	For each study, present characteristics for which data were extracted (e.g., study size, PICOS, follow-up period), and provide the citations	
Risk of bias within studies	19	Present data on risk of bias of each study and, if available, any outcome level assessment (see Item 12)	
Results of individual studies	20	For all outcomes considered (benefits or harms), present, for each study (a) simple summary data for each intervention group, (b) effect estimates and confidence intervals, ideally with a forest plot	
Synthesis of results	21	Present the main results of the review If meta-analyses are done, include for each confidence intervals and measures of consistency	
Risk of bias across studies	22	Present results of any assessment of risk of bias across studies (see Item 15)	
Additional analysis	23	Give results of additional analyses, if done (e.g., sensitivity or subgroup analyses, metaregression [see Item 16])	

TABLE **6.4 CONSORT Checklist for Reporting of Randomized, Controlled Clinical Trials[63]—cont'd**

Section/Topic	Number	Checklist Item	Reported on Page Number
DISCUSSION			
Summary of evidence	24	Summarize the main findings including the strength of evidence for each main outcome; consider their relevance to key groups (e.g., health care providers, users, and policy makers).	
Limitations	25	Discuss limitations at study and outcome level (e.g., risk of bias) and at review level (e.g., incomplete retrieval of identified research, reporting bias)	
Conclusions	26	Provide a general interpretation of the results in the context of other evidence and implications for future research	
FUNDING			
Funding	27	Describe sources of funding for the systematic review and other support (e.g., supply of data) and role of funders for the systematic review	

A particular type of observational study is a cross-sectional description of cases in a population at a single point in time. These studies provide a one point in time estimate of prevalence and can attempt to identify risk factors if both cases and controls are included in the study; however, there is considerable risk of selection bias and of confounding (in which a third, perhaps unidentified, variable influences the effect of another variable on the outcome of interest). Cross-sectional studies can be inexpensive to undertake. Surveys are a form of cross-sectional study.[7]

Analytic Observational Studies. This type of study design is often useful when studying naturally occurring diseases. Common designs in veterinary medicine are cohort and case-control studies.[7]

A *cohort study* is a type of longitudinal study that is commonly used to study associations between naturally occurring exposure to a putative risk factor for disease and subsequent development of disease. Another variation is to look at responses to different therapeutic interventions. In either case, an initial population of animals is identified and then animals in that population are categorized as exposed to the particular risk factor of interest or not and their progression to disease determined. Similarly, a population of animals with a particular disease might be divided in two or more groups, each of which receives a different treatment. The outcomes of each group are then compared. Cohort studies can be retrospective or prospective.

Prospective cohort studies can require long time periods to complete if there is a delay between exposure and appearance of disease. Retrospective cohort studies are relatively inexpensive to conduct because they use already collected data, often in the form of medical records. However, a disadvantage of retrospective cohort studies is that the data were collected for purposes other than research; thus, information relevant to the study may not have been recorded. Cohort studies do not permit blinding, and matching of animals in each group of factors other than the risk factor of interest can be difficult. Prospective cohort study results should be reported as relative risk, and retrospective cohort studies should be reported as odds ratios.

The *case-control study* is retrospective in that cases are identified and then matched with animals that did not develop the disease. The records of each group are then examined to identify risk factors that differ between cases and controls. Case-control studies are relatively inexpensive and easy to perform, but they do not usually allow for control of confounding variables because of the difficulty in closely matching cases and controls. As with other retrospective observational studies, data quality can be limiting.

Experimental Studies

Experimental study designs are those in which the investigator chooses the animals being studied and assigns the intervention to a proportion of the study population. By manipulating one variable, the aim is to establish a causal relationship by measuring the outcome or dependent variable. Typically, experimental studies involve a group of animals to which the new intervention is applied, a control group that might receive an alternative intervention, or no active intervention (placebo) with random assignment of animals to each group. This design attempts to minimize the effect of known or unknown factors, other than that of the interventions, on the outcome. The best justification for placing RCTs at the top of evidence hierarchies for individual studies is that RCTs minimize certain forms of bias, especially selection bias, therefore producing the best evidence of a treatment effect or of causation.

RCTs in equids can be conducted under laboratory conditions, usually with induced disease, or as clinical trials using animals with naturally occurring disease.[7] When evaluating an RCT for quality of evidence, it is important to consider the relevance of the intervention, the population being studied (especially if the study uses induced rather than naturally occurring disease), and the setting (field service versus referral clinic). RCTs using experimental animals are efficient and effective to perform and provide for strict control of potentially confounding factors. Such experimental trials might not mimic or replicate the condition or disease in the field, and care should be taken extrapolating results of these studies to animals with naturally occurring disease. Conversely, RCTs conducted in the field are often highly relevant to animals with naturally occurring disease but are more challenging to perform than laboratory studies.[7]

RCTs should include blinding (masking) of those investigators who determine which treatment an animal receives, of those administering the treatments, and those evaluating the outcomes of the intervention to minimize the likelihood of conscious or unconscious bias.

RCTs are also parsimoniously powered to get answers related to the efficacy of the intervention on the outcome, which is usually treatment of a disease. As a result, RCTs and meta-analyses that use them are often underpowered to detect infrequent or rare adverse effects.[69]

Synthesis of Evidence: Reviews

The wealth and volume of veterinary scientific literature have both prompted and enabled individuals or groups to attempt to provide a considered synthesis of information on a particular topic. The purpose of such reviews is to take the primary literature and create a generalizable understanding of the disease or intervention on the assumption that compiling information from a number of studies will provide more reliable information than that from one study alone. Although there are at least 14 forms of review identified in the library literature, most reviews in the veterinary literature are narrative (integrative) or systematic (aggregative) reviews or meta-analyses.[70,71] The most common form of this information synthesis in veterinary medical literature is the narrative (integrative) review. Detailed descriptions of these types of reviews, including strengths and weaknesses, are available elsewhere.[70]

Narrative Review. Narrative, or otherwise known as integrative, reviews seek to bring together the literature on a particular topic, not with the intention of answering a specific question or questions but rather to provide a commentary on the results of the available primary studies on the topic. These types of reviews, which are typical of textbooks or review articles in journals, are often useful summaries of a body of literature. Such reviews do not typically include an explicit methodology, such as how the literature search was conducted, how evidence was appraised, and how articles were included or excluded. As such, narrative reviews might not consider all the available literature on a topic. Lack of a predetermined methodology also increases the possibility of conscious or unconscious bias in the inclusion of primary studies in the review or the interpretation of results. Authors of narrative reviews are often self-selected and might, or might not, be expert in the topic of the review. The author's reasons for writing the review might not be revealed to readers.

Systematic Reviews. The highest quality evidence is provided by systematic reviews, which might include a meta-analysis. Systematic reviews differ from narrative reviews, which have much lower evidentiary value, in that systematic reviews are approached in a manner and with methodology designed to ensure the validity of the conclusions.[70] Systematic reviews should be based on a clearly defined question and prespecified criteria for inclusion and evaluation of the literature, among other factors. Criteria and methodology for performing systematic reviews are available.[44,72,73] The PRISMA statement provides a widely, although not universally, used methodology for reporting systematic reviews, including a recommended flowchart and reporting checklist (see Fig. 6.1).[64,74,75]

Systematic reviews should be methodologically rigorous assessments of the literature and should not make recommendations on clinical practice.[12] The fundamental characteristics of systematic reviews are as follows[76]:

1. A clearly stated set of objectives with predefined eligibility criteria for inclusion of studies
2. An explicit and reproducible methodology
3. Use of a systematic and thorough search that attempts to identify all reports of studies that meet with eligibility criteria
4. A systematic assessment of the validity of the findings of studies that are included in the review
5. A systematic assessment of the characteristics and findings of the included studies and a systematic presentation of those findings

A systematic review therefore provides a dispassionate assessment of the published evidence on an issue. It makes an assessment about the quality of evidence and, in doing so, enables readers to weigh the use of the evidence as they decide on the answer to their clinical question. Systematic reviews consider only the quality of the evidence and do not provide a methodology for taking the next step, which is that of making a recommendation on use of the evidence.

From Evidence to Recommendation: Practice Guidelines

The approach of using evidence to guide clinical decision making has been formalized in the past two decades in human medicine and is gaining traction in veterinary practice. As veterinary clinicians we have ethical and legal obligations to use methods and practices that are most likely to provide the "best" outcomes for the animals we treat and their owners. A traditional approach to deciding on the "best" treatments, diagnostic tests or methods, and preventive measures has been to identify the highest quality evidence of effectiveness and to adopt the approach with the strongest evidence of efficacy. The Cochrane collaboration and the Cochrane reviews exemplify and lead this approach in human medicine.[76]

This "evidence-based" approach has the implicit assumption that one should rely on the highest quality evidence and that high-quality evidence of efficacy necessarily leads to the adoption of that treatment, diagnostic test, or prophylaxis. However, this approach falls short when formulating recommendations for use in clinical practice. What practitioners need are recommendations that are based on the available evidence but that also take into account the other factors that must be considered when advising an owner or trainer on the "best" approach to dealing with their animal's (and their) problem. Clinical practice guidelines are statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options.[77] Importantly, development of practice guidelines (recommendations) includes both a systematic review and consideration of the trade-offs between benefits and harms.[77]

Although an analysis of the quantitative literature, such as RCTs, is important, it is also important to consider the literature describing more qualitative outcomes. This literature can be evaluated according to four criteria, each of which has five grades (Table 6.5). The criteria are feasibility, appropriateness, meaningfulness, and effectiveness.[78]

The recognition that systematic reviews of the literature are an essential but not the sole, or best, means for making recommendations for interventions resulted in the development of the GRADE process.[79] GRADE works by providing a framework to determine a final recommendation on an intervention through use of the following:

1. Quality of evidence (Cochrane and similar evaluations of quality of evidence stop here)
2. Seriousness of the outcome
3. Magnitude of the treatment effect
4. Precision of the treatment effect
5. Risk of the target event (how frequent)
6. Risk of adverse events associated with the intervention
7. Cost of the intervention
8. Values and preferences of the end users

TABLE **6.5 Example of Elements of Qualitative Assessment and Review Instrument Levels of Applicability of Evidence**

Feasibility	Appropriateness	Meaningfulness	Effectiveness
Immediately practicable	Acceptable and justifiable and within ethical guidelines	Provides a rationale for practice development	Effectiveness established to a degree that merits application in clinical practice
Practicable with limited local training or modest additional resources	Acceptable after minor revision	Provides a rationale for local, regional, or national reform	Effectiveness established to a degree that suggests application in some clinical situations
Practicable with extensive additional training or resources	Acceptable after major revision	Provides a rationale for practice-relevant research	Effectiveness established to a degree that warrants consideration of applying the findings
Practicable with significant national or regulatory reforms	Acceptable after development of new ethical guidelines	Provides a rationale for advocating change	Effectiveness established to a limited degree and benefits are unclear
Impracticable to practitioners	Ethically unacceptable	Evidence unlikely to make sense	Effectiveness not established

Modified from Pearson A. Balancing the evidence: incorporating the synthesis of qualitative data into systematic reviews. *JBI Rep*. 2004;2:45–64.

All of these criteria have at least some applicability in veterinary medicine. Briefly, judgments about the quality of recommendations require consideration of the following:

- The quality of evidence on which the recommendation is based: The quality of evidence is assessed on the type of study imprecision of the results over a number of studies, inconsistency of the studies, indirectness, reporting bias, magnitude of the effect, biologic plausibility, and strength of association.[67,80-83] Systematic reviews of the literature are fundamental to the development of appropriate recommendations.
- The balance between benefits and harms: Will the intervention do more good than harm? What is the extent of the benefit and of the potential harm?
- Feasibility of translating the evidence into the circumstance in which the intervention will be made: Can I apply this in my practice? Is it affordable?
- Certainty of the baseline risk (i.e., How important is the problem?)
- Cost (both monetary and in terms of resources)

The balance between benefit and harm (the trade-off) can be categorized as follows:

- Net benefits: The intervention clearly does more good than harm.
- Trade-off: There are important trade-offs between the benefits and harms.
- Uncertain trade-offs: It is unclear whether the intervention does more good than harm.
- No net benefits: The intervention clearly does more harm than benefit.

Finally, these considerations can be distilled down to the following recommendations being "a judgment that most well-informed people would make"[12]:

- "Do it": There is high-quality evidence of net benefits within appropriate resource constraints (costs) for a problem that has significant importance (a judgment that most well-informed people would make).
- "Probably do it": When the strength of evidence is moderate or when the benefit:harm trade-off is unclear or marginal.
- "Probably do not do it": When the strength of evidence is low or very low, when the benefit:harm trade-off is unclear or marginal, or when the baseline risk is low.
- "Do not do it": There is high-quality evidence of harm clearly exceeding benefits, the cost is too great compared with benefits, or the baseline risk is very low (i.e., the problem is not important).

The GRADE guidelines, although not well established for veterinary medicine, have been used and provide the opportunity to make evidence-based recommendations to practitioners.[84]

CONCLUSIONS

The techniques underlying EBVM are useful as we seek answers to problems in equine medicine. The techniques allow us to ask the relevant question, seek out the information, and assess its quality. We can then decide how best to apply this information to the problem. This final step involves more than just an evaluation of the quality of evidence; it requires that we consider a number of other factors in arriving at a recommendation and deciding on the strength of that recommendation. This final step is crucial to the sensible application of the principles of EBVM.

CHAPTER 7

Clinical Approach to Commonly Encountered Problems

Melissa T. Hines*

CHANGES IN BODY TEMPERATURE

Assessment of body temperature is an essential part of every physical examination. As with all mammalian species, horses normally maintain their core body temperatures within a narrow range despite extremes in environmental conditions.[1,2] The core temperatures may vary by approximately 1°C (2°F) between individuals. In adult horses the normal body temperature ranges from 37.2° to 38.3°C (99.0°–101.0°F), whereas in neonatal foals the temperature tends to be slightly higher, ranging from 37.8° to 38.9°C (100.0°–102.0°F). Diurnal variation of up to 1°C (2°F) may occur, with the low point typically occurring in the morning and the peak in the late afternoon.

Mechanisms Controlling Body Temperature

The set-point, which is the crucial temperature that the body attempts to maintain, is regulated primarily via neuronal control operating through temperature centers in the hypothalamus.[3-5] Both peripheral and central thermoreceptors sense changes in ambient and core body temperatures and activate feedback mechanisms that bring the temperature back to the set-point. Specifically, peripheral thermoreceptors, which are generally most sensitive to low temperatures, are located in the skin and around certain great veins, as well as in some deep tissues, such as the spinal cord and abdominal viscera. Central thermoreceptors include large numbers of heat-sensitive neurons and lower numbers of cold-sensitive neurons in the preoptic area of the anterior hypothalamus (POA). In response to changes in temperature, the peripheral and central thermoreceptors transmit signals into the posterior hypothalamic area, subsequently activating autonomic and behavioral effector responses to regulate body temperature. These responses affect the balance between heat loss and heat production.

There are multiple mechanisms for cooling in response to elevations in body temperature, which include both means of increasing heat loss and decreasing heat production.[3-5] One means of increasing heat loss is by transferring heat from the body core to the surface by increasing blood flow to the skin. Changes in core body temperature and environmental temperature cause the sympathetic nervous system to regulate the degree of vasoconstriction and thus the amount of blood flow, with increases in temperature resulting in cutaneous vasodilation and increased skin blood flow. Heat is lost from body surfaces to the surroundings by several physical mechanisms, including radiation, conduction, and convection. Evaporation is also an important mechanism of heat loss in horses.[5] To some extent, the amount of evaporative heat loss is controlled by the rate of sweating. However, even when the animal is not sweating, water evaporates insensibly from the skin and lungs, resulting in continual heat loss. In horses, evaporative heat loss, primarily through increased sweating but also through increased respiration, becomes more important as the ambient temperature rises and during exercise.[5,6] In addition to increased heat loss when the body temperature rises, the horse also decreases temperature further by inhibiting means of heat production, such as shivering, and by behavioral responses, such as seeking shade and wind currents and wading into water.[6-8]

Mechanisms that increase body temperature are triggered when the body temperature is too low.[2] Heat is conserved by stimulation of the posterior hypothalamic sympathetic centers, leading to cutaneous vasoconstriction and piloerection. Heat production also increases and may occur through increased muscle activity ranging from inapparent contractions to generalized shivering. Shivering may increase heat production by 4 to 5 times baseline. The primary motor center for shivering is in the posterior hypothalamus, which normally is stimulated by cold signals from the peripheral receptors and to some extent central receptors in the POA. Digestion of food also contributes to total body heat. Sympathetic stimulation may increase the rate of cellular metabolism, increasing heat production by chemical thermogenesis. Cooling also increases the production of thyrotropin-releasing hormone, ultimately increasing thyroid hormones and cellular metabolism and further contributing to chemical thermogenesis. In addition to these physiologic adaptations, behavioral responses to conserve heat also occur, such as adopting a huddled stance, aggregating in groups, and seeking shelter.[9-11] It has been demonstrated that horses voluntarily select shelter, especially under wet, windy conditions and that shelter selection is affected by breed, body condition score, and hair coat weight.[9]

Increased Body Temperature: Hyperthermia and Fever

Elevation of the body temperature above normal is one of the most common clinical problems encountered, and although

*The editors and authors acknowledge and appreciate the contributions of Bonnie R. Rush, Kenneth W. Hinchcliff, and Siddra A. Hinesas as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

classically associated with infection, a variety of disorders may cause increased body temperature.[3-5] Veterinarians should distinguish between conditions of hyperthermia, in which the temperature set-point is unaltered, and true fever, in which the set-point actually increases.

Hyperthermia

Mechanisms of Hyperthermia. The body temperature may become elevated without an increase in the set-point when there is a loss of equilibrium in the heat balance equation.[4] Increased heat production or absorption of heat beyond the ability of the body to dissipate heat may occur. In some conditions impaired heat loss also may occur.

Conditions Associated with Hyperthermia. Hyperthermic conditions include problems such as exercise-related hyperthermia, heat stroke, anhidrosis, malignant hyperthermia, central nervous system disorders, and reactions to certain toxins or drugs (Box 7.1). In general, these conditions do not respond to treatment with antipyretic drugs.

Exercise-Related Hyperthermia. During sustained or high-intensity exercise, increased heat production is associated with muscular activity.[5,6,12,13] The heat produced may exceed the ability of the body to lose heat, resulting in an increased core body temperature. Typically, the temperature returns to normal with rest as heat loss mechanisms remain activated. There is some evidence that ageing compromises the ability of horses to thermoregulate during exercise.[14] Elevated temperature also may occur with the intense muscle activity associated with generalized seizures.

BOX 7.1 Causes of Changes in Body Temperature

HYPERTHERMIA

Exercise-related hyperthermia
Heat stroke
Anhidrosis
Malignant hyperthermia
Central nervous system disorders
Toxins or drugs
Macrolide-induced hyperthermia

FEVER

Infection
Neoplasia
Immune-mediated disease
Other
- Toxic hepatopathy
- Inflammatory bowel disease
- Other

HYPOTHERMIA

Accidental Hypothermia

Exposure to harsh environmental conditions
Surgical procedures/anesthesia

Pathologic Hypothermia

Sepsis/inflammation (maladaptive response)
Intracranial disease
Hypothyroidism (neonates)

Heat Stroke. Heat stroke occurs when the body temperature rises above a critical temperature, leading to multisystemic problems. In horses signs of heat stroke may develop when the body temperature is above 41.5°C (107°F), which most often occurs in association with exercise in environmentally stressful conditions.[13,15] Although horses can acclimatize to various weather conditions to some extent, the efficiency of evaporative heat loss may be compromised significantly in hot, humid weather.[6,12,13,15] Susceptibility to heat stroke may increase if sweating leads to dehydration and electrolyte imbalances. Once the body temperature reaches the critical point, the homeostatic mechanisms of thermoregulation fail, resulting in peripheral vasoconstriction, decreased cardiac output, and decreased blood pressure. Affected horses are lethargic with weak, flaccid muscles. Prostration, circulatory shock, disseminated intravascular coagulation, multiple organ failure, and death may occur.

Anhidrosis. Anhidrosis is an inappropriate response to prolonged climatic stress characterized by a partial or total loss of the ability to sweat.[16-18] This condition occurs primarily in horses living in hot, humid environments and has been documented in about 2% to 6% of horses living in Florida.[16,19] The impaired sweating results in diminished heat loss, frequently resulting in hyperthermia. Other clinical signs include tachypnea, poor performance, and poor hair coat.

Malignant Hyperthermia. Malignant hyperthermia (MH) encompasses a group of inherited skeletal muscle disorders in which calcium metabolism is altered. Although the condition is most common in human beings and pigs, it has been reported in several species, including dogs and horses.[20-23] MH is characterized by a hypermetabolic state of muscle that generally is induced by halogenated inhalation anesthetics, depolarizing skeletal muscle relaxants, and occasionally local anesthetics or stressors such as heat or vigorous exercise. Clinical signs include a rapid increase in core body temperature, skeletal muscle rigidity, and tachycardia. Affected animals may develop significant acidosis and muscle necrosis, and the condition can be fatal. MH is most often associated with a defect in the ryanodine receptor.[20,23] In Quarter Horses and American Paint Horses, MH is inherited as an autosomal dominant trait that is linked to a single point mutation in the skeletal muscle ryanodine receptor 1 (RyR1) gene at nucleotide C7360G.[23,24] This mutation can be identified by genetic testing. Horses with polysaccharide storage myopathy tend to have a more severe clinical phenotype if they are concurrently affected with the MH mutation.[24]

Central Nervous System. Alterations in body temperature have been documented with a variety of conditions affecting areas of the hypothalamus involved in thermoregulation, with hyperthermia being more common than hypothermia.[1,3,4,25] Central hyperthermia has been associated with conditions such as hemorrhage, traumatic brain injury, neoplasms or abscesses, infectious/inflammatory changes, and degenerative disorders. It is usually characterized by a lack of diurnal variation, absence of sweating, resistance to antipyretic drugs, and excessive response to external cooling. In some cases, damage to the hypothalamus results in a disruption in the hypothalamic set-point temperature, resulting in neurogenic fever rather than true hyperthermia.[25]

Toxins or Drugs. Hyperthermia has occasionally been associated with some toxins or drugs.[26-28] Exposure to compounds that uncouple oxidative phosphorylation, such as the wood preservative pentachlorophenol, could potentially

cause a significant rise in body temperature.[27] Foals treated with macrolide antibiotics are at risk of developing hyperthermia.[28,29] Erythromycin causes a drug-induced anhidrosis that is the likely cause of the hyperthermia.[29] Because the sweat response of treated foals is impaired, these foals are at particular risk of hyperthermia when exposed to hot, humid environments and direct sunlight.

Fever

Mechanisms of Fever. In true fever the set-point for the desired core body temperature increases and then is maintained by the same mechanisms that maintain the normal body temperature. Fever is a part of the acute phase response to infection or inflammation. The pathogenesis of fever is complex, and multiple integrative signaling pathways come into play[3,4,30,31] (Fig. 7.1). Currently it is thought that both neuronal and humoral mechanisms are involved in the induction of fever. Neuronal mechanisms in part involve stimulation of vagal afferents, whereas humoral mechanisms involve several proinflammatory cytokines that act as endogenous pyrogens.[32,33] Prostaglandin E2 (PGE2), which may be produced peripherally or centrally, is regarded as the principal downstream mediator of fever, acting on thermosensitive hypothalamic neurons to influence the febrile response.[34,35] Other mediators, such as orexin, may also play a role in thermoregulation.[36,37]

The substance most often used in experimental studies of the febrile response is bacterial lipopolysaccharide (LPS).[38-40] Like many microbial products acting as exogenous pyrogens, LPS initiates fever by activation of the innate immune system, specifically via the complement cascade and Toll-like receptors (TLRs). The response is generally biphasic, with early and late phases. In the early phase of fever, LPS taken up by the Kupffer cells of the liver activates the complement cascade, with C5a rapidly stimulating the Kupffer cells to produce PGE2. This peripherally produced PGE2 may then act primarily via two pathways to affect thermoregulation. First, this PGE2 may be transported by the bloodstream to the ventromedial POA where it acts on thermoregulatory neurons to increase the set-point. Second, it may interact with receptors on hepatic vagal afferents, leading to activation of pathways projecting to the medulla oblongata and then to the POA via the ventral noradrenergic bundle. Consequently, norepinephrine is secreted, which then stimulates α_1-adrenoreceptors on thermoregulatory neurons, evoking a rise in core temperature. In the late phase of fever, there is further production of PGE2 following

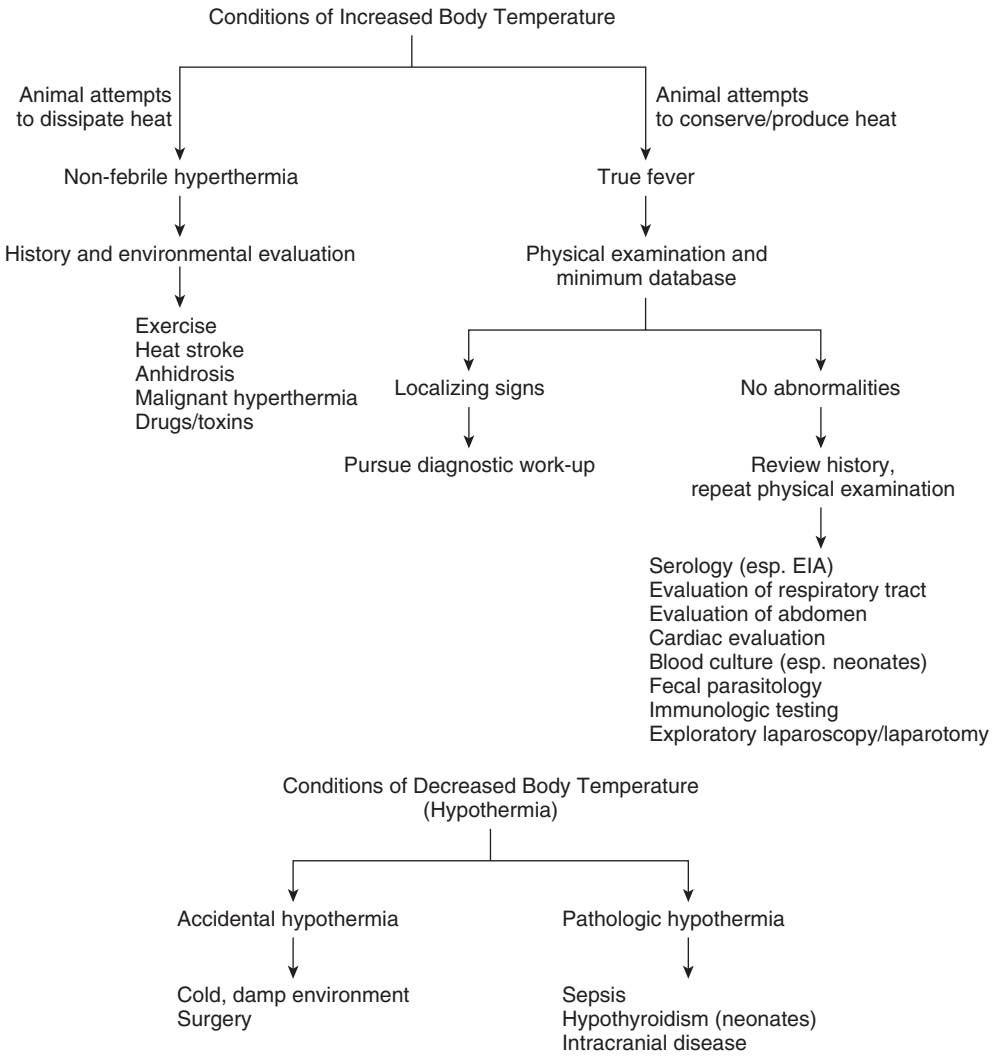

FIG. **7.1** Approach to changes in body temperature.

both direct induction of its synthesizing enzymes via TLR signaling and the production of endogenous pyrogens resulting in the central production of PGE2.

Endogenous pyrogen was initially assumed to be a single molecule produced by leukocytes, thus the name *leukocytic* or *granulocytic pyrogen*. Currently, at least 11 cytokines have been shown to be intrinsically pyrogenic.[30,32,33] These cytokines are produced predominantly by monocytes and macrophages. Among the most potent of the endogenous pyrogens are interleukin-1 (IL-1) α and β and tumor necrosis factor–alpha (TNF-α). Others include TNF-β, IL-6, and interferon-α. The precise means by which these cytokines influence thermoregulation are complex and remain to be fully elucidated. It appears that endogenous pyrogens have both peripheral and central mechanisms of action that include stimulation of afferent neuronal pathways, induction of PGE2 synthesis in endothelial cells in both the periphery and brain, and direct action in the brain via neuronal cytokine receptors.

The organum vasculosum laminae terminalis (OVLT) is a rich vascular network associated with neurons of the POA that plays an important role in the generation of fever.[33,35,41,42] This region is part of the circumventricular organs, which are unique structures of the brain with extensive vasculature and a minimal blood-brain barrier. As such, endothelial cells lining this region may allow direct movement of exogenous or endogenous pyrogens and peripherally produced PGE2 into the brain. Also, exogenous and endogenous pyrogens may interact with specific receptors on endothelial cells of the OVLT to further produce PGE2. Ablation of the OVLT prevents fever after a peripheral injection of endogenous pyrogens but has no effect when endogenous pyrogens are injected directly into the brain tissue.[42]

The production of both peripheral and central PGE2 is key in the pathogenesis of fever. PGE2 is basically synthesized in three steps involving phospholipase A2, cyclooxygenase, and terminal PGE synthetase. These enzymes are upregulated in fever.[34] The cyclooxygenase 2 (COX-2) pathway is clearly important in the pathogenesis of fever because COX inhibitors, and specifically COX-2 inhibitors, effectively reduce the febrile response but have no effect on the normal body temperature.[43,44] At the same time that there is upregulation of proteins involved in prostaglandin production, there is transcriptional downregulation of proteins involved in PGE2 inactivation, such as 15-hydroxy-prostaglandin dehydrogenase. Once produced, PGE2 interacts with E type prostaglandin receptors (EP receptors), of which there are currently four identified subtypes with differential expression in various areas of the hypothalamus and brainstem.[45] It appears that the EP3 receptor in the median preoptic nucleus within the POA of the hypothalamus is particularly important in the febrile response. The interaction of prostaglandins with their receptors initiates neuronal signaling by producing a cascade of changes in cyclic nucleotides, calcium, and monoamines leading to a higher set-point in the hypothalamic thermoregulatory center. For example, interaction with the EP3 receptor mediates decreases in intracellular cyclic adenosine monophosphate (cAMP), which results in decreased firing of warm-sensitive neurons, increased firing of cold-sensitive neurons, and ultimately fever.

Feedback mechanisms exist to prevent an excessive rise in body temperature. A number of antipyretic substances, sometimes referred to as either *endogenous* or *autogenous cryogens*, may be liberated systemically or within the brain during fever.[31,46-50] Some of the antipyretic effects occur via an inhibitory influence on the formation or action or endogenous pyrogens or via effects on neuronal thermoregulatory circuits that are activated during fever. The interactions between pyrogens and cryogens are complex, and some cytokines function as either depending on the circumstance. Some endogenous antipyretic substances include glucocorticoids, neuropeptides/hormones (arginine vasopressin, adrenocorticotropic hormone, α-melanocyte-stimulating hormone MSH, γ-MSH), cytokines (TNF-α, IL-10), lipocortin, nitric oxide, and epoxyeicosanoids.[31,47,49] One of the major antipyretics is IL-10. Following induction by pyrogenic cytokines, IL-10 inhibits further production of IL-1 and TNF. Also, α-MSH has significant antipyretic effects, being more effective in controlling fever than acetaminophen when administered to human beings.[49] Nitric oxide also has an antipyretic role, mediated by cyclic guanosine monophosphate in the POA.[50] Even PGE2, whose role is primarily in the induction of fever, may produce hypothermic responses when interacting with the EP4 receptor.[45]

The cytokines that act as endogenous pyrogens are generally proinflammatory, with a variety of biologic effects in addition to fever.[1,4,30,33,40,51] Thus fever is usually accompanied by additional hematologic, immunologic, and metabolic changes referred to as the *acute phase response*. Among these effects is the synthesis of acute phase proteins by hepatocytes, including fibrinogen, C-reactive protein, haptoglobin, serum amyloid A, and others. Also, hypoferremia, hypozincemia, and hypercupremia are cytokine mediated, as is the activation of lymphocytes, which in turn produce additional cytokines.

Prostaglandins induced by endogenous pyrogens stimulate the muscle catabolism associated with fever and induce collagenase synthesis from synovial cells, contributing to the muscle and joint pain often seen with fever. Local tissue responses to IL-1β and TNF-α may stimulate afferent neural impulses that lead to behavioral responses associated with fever, such as lethargy and anorexia. As expected, treatment with COX inhibitors can diminish many of the signs of fever.

Fever is a host defense mechanism that has been preserved within the animal kingdom. Although much attention is focused on the adverse effects of fever, including patient discomfort, there is evidence that fever can be beneficial.[52-58] Some studies have demonstrated an association between a rise in body temperature and a decrease in mortality and morbidity during infection. Although the elevation in temperature may directly impair organism growth in some cases, the beneficial effects are thought to be primarily associated with enhanced host defenses.[40,52-57] Fever has beneficial effects on multiple aspects of both the innate and adaptive immune response. As part of the acute phase response associated with fever, the concentration of iron, which is required by many bacteria for multiplication, decreases.[59-61] The beneficial effects of fever, however, are not universal, and many of the positive effects of fever are reversed when temperature becomes extremely high.[43,62] In rabbits experimentally infected with *Pasteurella multocida*, the survival rate increased in association with elevations in body temperature up to 2.25°C (4.5°F) above normal but decreased with elevations above this level.[63] The increased catabolism, variable anorexia, and increased metabolic rate can lead to muscle wasting and weakness when fever is prolonged. Although seizures induced by fever are uncommon in horses, they

can be seen in neonates when the temperature is above 42°C (108°F).[2] In debilitated animals, prolonged fever has been associated with cardiovascular failure.

Conditions Associated with Fever. Fever is part of the physiologic response to infection and inflammation (see Box 7.1). It is considered a cardinal sign of infection and has been associated with infections caused by essentially all types of organisms. Although there is considerable variation, viral infections are often associated with high fevers. In addition to infection, fever can be a prominent component of many inflammatory, neoplastic, and immunologic conditions. In intensive care units in human hospitals, the incidence of fever ranges from 23% to 70% and is related to an infectious process in approximately half of the cases.[64,65]

Fever of Unknown Origin. *Fever of unknown origin* in human medicine is defined specifically as a fever that occurs on several occasions over at least 3 weeks in which the diagnosis remains unclear after an initial diagnostic workup. In veterinary medicine, the term *fever of unknown origin* is often used more loosely, referring to any prolonged, unexplained fever. In many cases, the cause of a fever of unknown origin is a common disease with an unusual presentation. In a review of 63 cases of fever of unknown origin in the horse, the specific criteria used to define fever of unknown origin included (1) illness of at least 3 weeks' duration associated with nonspecific signs, (2) body temperature of at least 38.6°C (101.5°F) on several occasions, and (3) no clear diagnosis after an initial complete blood count and serum biochemical profile.[66] The most common cause was found to be infection, which was responsible for 43% of the cases. Other causes included neoplasms in 22% of cases; immune-mediated diseases in 6.5%; and miscellaneous diseases such as toxic hepatopathy, parasitism, and others in 19%. In 9.5% of cases no diagnosis was made. Specifically, the most common conditions identified were abdominal infections (peritonitis/abdominal abscessation) and lymphosarcoma, each accounting for approximately 16% of cases. Pneumonia, pleuropneumonia, or both were found in 11% of cases. Three horses (approximately 5%) were found to have bacterial endocarditis, and in each case a murmur was not identified initially but developed within several weeks of the onset of illness. Thus the diagnosis of fever of unknown origin requires a systematic approach with emphasis on the evaluation of infectious disease.

Diagnostic Approach to Elevations in Body Temperature

Increased body temperature is a common clinical sign with diverse causes. Fortunately, in many cases the cause may be readily apparent on the basis of the signalment, history, and physical examination. In other cases, additional diagnostic testing may be required (see Fig. 7.1).

Hyperthermia. Many causes of hyperthermia, such as exercise-related hyperthermia and malignant hyperthermia, can be distinguished from fever based largely on the signalment and history of the patient. Older horses may be more susceptible to exercise-related hyperthermia.[14] Treatment with macrolide antibiotics is significant due to the potential for macrolides to cause hyperthermia.[28,29] A sweat test, such as the quantitative intradermal terbutaline sweat test, can be useful in confirming anhidrosis.[18,67] Genetic testing is available for detection of the RyR1 mutation in cases of suspect malignant hyperthermia.[23,24]

Fever. Multiple conditions may result in fever. Infectious diseases remain the most common cause, although other inflammatory conditions such as neoplasia and immune-mediated disease may also cause fever. Often localizing clinical signs such as nasal discharge or diarrhea aid in determining the specific etiology. If the underlying condition responsible for the fever is not readily apparent, additional diagnostic tests are warranted.

Documentation of Fever. It may be useful to have the body temperature taken twice daily over a period of time to document fever and identify any pattern. Fevers can be categorized as intermittent, remittent, biphasic, or sustained, although some inconsistencies in the precise definitions of these patterns exist. In general, intermittent fevers are characterized by recurring paroxysms of elevated temperature followed by periods of normal temperature, such as those fevers that demonstrate diurnal variation. In most cases of intermittent fever the temperature tends to peak in the late afternoon or evening. Intermittent fevers most often are associated with infectious causes, particularly viral infections, although they may be seen with a variety of other conditions. Remittent fevers are those in which diurnal variation is exaggerated without a return to normal body temperature or those with a cyclic pattern in which the temperature elevation lasts for several days, such as may be seen with equine infectious anemia virus. Biphasic fevers, in which an initial rise in body temperature precedes a period of normal temperature and then a second rise, are characteristic of certain diseases such as equine neorickettsiosis (Potomac horse fever). Sustained fevers are those in which the elevation of temperature is consistent.

Signalment and History. The signalment and history should be considered when investigating fever. Some causes of fever may be more common in certain age groups. For example, although not a consistent finding, fever is often seen in neonatal foals in association with septicemia, omphalophlebitis, or septic arthritis. *Rhodococcus equi* is predominantly seen in foals 1 to 6 months of age and is often associated with fever. Young horses, especially those that have been recently exposed to new horses, may be particularly at risk for respiratory tract infections. Any exposure to *Streptococcus equi* subspecies *equi* (strangles) may be significant because of the association of this organism with internal abscessation. Geographic location and travel history may be relevant, as some diseases, such as equine neorickettsiosis, piroplasmosis, and coccidioidomycosis, are more common in certain geographic locations.

Physical Examination. A thorough physical examination, including auscultation of the thorax with a rebreathing bag and rectal palpation, is indicated in the evaluation of fever. Repeating the physical examination may yield new information. A neurologic examination can also be useful as disorders of the central nervous system may cause aberrations in temperature through pyrogenic cytokines or in some cases through direct effects on thermoregulatory centers.

Ancillary Diagnostic Aids. Ancillary diagnostic tests are commonly used in the diagnosis of fever, particularly in cases of fever of unknown origin. Localizing signs may help direct selection of the most appropriate tests but are not always present.

CLINICAL PATHOLOGY/LABORATORY TESTING. A database, including complete blood count (CBC), fibrinogen, biochemical profile with bile acids, and urinalysis, should be obtained. Hemoparasites may occasionally be seen on the blood smear,

but the apparent absence of organisms does not rule out a parasitemia that is below detectable limits. Abnormalities consistent with chronic infection or inflammation, including anemia, hyperfibrinogenemia, hyperglobulinemia, and thrombocytosis, are common but nonspecific findings. Although inflammation is the most common cause of hyperglobulinemia, further assessment by serum protein electrophoresis and specific immunoglobulin quantitation may be indicated in some cases. A monoclonal gammopathy is characteristic of plasma cell myeloma but may also be seen with other tumors of the reticuloendothelial system and occasionally other conditions. Immunodeficiencies, which in some cases are associated with low lymphocyte counts or low immunoglobulin concentrations, can predispose affected horses to chronic infections. In cases of hypoalbuminemia, gastrointestinal or renal loss, third space loss, and decreased production associated with significant hepatic disease should be investigated. The presence of hypercalcemia can be helpful in the diagnosis of disease, as it is most often linked with either renal disease or certain neoplasms in horses. Bone marrow aspiration may be useful, particularly in those horses with persistent abnormalities in circulating cell populations.

Infections of the respiratory tract and abdomen frequently are associated with fever in the horse, and therefore these systems should be thoroughly evaluated. In many cases this includes cytologic evaluation and culture and/or polymerase chain reaction (PCR) of samples from the respiratory tract and abdomen. The upper airway is often sampled by nasal swabs, nasal washes, or guttural pouch lavage, and the lower airway can be sampled by bronchoalveolar lavage or transtracheal aspiration. Thoracocentesis may be considered because abnormalities of pleural fluid are occasionally present even without increases in the volume of fluid. Similarly, abnormalities in peritoneal fluid can be found without increases in fluid volume, and abdominocentesis should be considered as part of the diagnostic plan. It should be remembered that neoplastic cells often do not exfoliate into fluid; therefore neoplasia cannot be ruled out based on cytologic evaluation of fluid.

Although only occasionally associated with fever, the presence of gastrointestinal parasites is so common that feces from horses with fever of unknown origin should be examined for parasite ova. In cases of suspected gastrointestinal protein loss, diarrhea, or melena, one should consider diagnostic procedures such as fecal culture and analysis for clostridial toxins, culture and PCR for *Salmonella,* rectal mucosal biopsy, or absorption tests.

Blood cultures are generally most useful in neonates but can yield valuable information in adult horses with fever as well. Ideally, three to five samples should be collected at least 45 minutes apart when the horse is not on a regimen of antibiotic therapy. Sampling just before and during a temperature rise is most likely to yield a positive culture.

Serologic evaluation can be useful in the assessment of fever, and specific tests can be prioritized based on the patient and the geographic area. Due to variability in the clinical presentation and regulatory concerns, equine infectious anemia should be considered as a differential diagnosis for horses with fever of unknown origin, and testing should be performed. A serologic test for detection of antibodies to the M protein of *Streptococcus equi* ssp. *equi* has been developed and may be a useful aid in the diagnosis of metastatic abscessation associated with the strangles organism.[68] Serologic tests for several other infectious diseases are also available, including tests for *Corynebacterium pseudotuberculosis,* equine piroplasmosis, brucellosis, and coccidioidomycosis, among others.

Immune-mediated disorders such as immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, systemic lupus erythematosis, vasculitides, and rheumatoid arthritis have been implicated as causes of fever of unknown origin but more commonly in human beings and small animals than in horses. Appropriate diagnostic tests, such as the Coombs' test, skin biopsy, and antinuclear antibody testing, may be useful in some patients.

ENDOSCOPY. Endoscopy is commonly used for evaluation of the respiratory tract, especially the upper respiratory tract including the guttural pouches. Pleuroscopy allows direct visual examination of the pleural space and may facilitate biopsy of any masses. Also, endoscopy can be useful in evaluation of the esophagus, stomach, and urinary tract.

DIAGNOSTIC IMAGING. Ultrasound is a practical, noninvasive means of assessing the thorax and parts of the abdomen. It can help identify abnormalities that need further evaluation, such as consolidated lung, abdominal masses, or pathologic liver and kidney conditions. It may also help identify fluid for collection. Echocardiography can aid in the diagnosis of bacterial endocarditis.

Radiographs of the thorax are helpful in the evaluation of pulmonary disease. Although the practicality and utility of abdominal radiographs are limited, especially in adult horses, they may be of value in individual cases, especially in neonates. Nuclear imaging using labeled white blood cells may identify a site of infection or inflammation.

OTHER. Exploratory laparoscopy or laparotomy is indicated when abdominal involvement is suspected or the animal is becoming progressively debilitated. In horses for which a specific diagnosis has not been made, therapeutic trials with antimicrobials may help, and in cases of suspected immune-mediated disease, corticosteroids may help.

Decreased Body Temperature: Hypothermia

Mechanisms of Hypothermia

Hypothermia occurs when the core body temperature drops below accepted normal values.[4] Clinically, hypothermia can be characterized as either accidental or pathologic. In accidental hypothermia the body's ability to produce heat is overwhelmed, often in association with harsh environmental conditions. There is a spontaneous decrease in the core body temperature independent of actual disruption to the thermoregulatory system.

Pathologic causes of hypothermia should be considered when no clear reason for accidental hypothermia is evident. Pathologic hypothermia occurs in association with disorders that decrease metabolic activity or directly affect the thermoregulatory center, such as endocrine disorders, sepsis, and intracranial disease. When hypothermia is seen with systemic inflammation, it is often considered a maladaptive thermoregulatory response. The mechanisms involved in producing hypothermia are not fully understood, but several cytokines (including TNF-α, interleukins, and interferon-gamma [IFN-γ]) are involved.[69] Some of these same cytokines may also act as pyrogens under other conditions.

The ability to generate heat through shivering is impaired or lost once the body temperature becomes too low. The animal experiences a decrease in the metabolic rate of most tissues. Heart rate, cardiac output, glomerular filtration, and blood pressure may decrease.

Conditions Associated with Hypothermia

Accidental Hypothermia. Accidental hypothermia is most often associated with cold or cold, damp, windy environments (see Box 7.1). Occasionally extreme situations occur, such as an animal falling through ice. Mild accidental hypothermia sometimes occurs with surgical procedures. Accidental hypothermia is particularly common in neonates and geriatric or debilitated adult horses. Although central thermoregulation through the hypothalamus is normal in neonates, foals have a large ratio of surface area to body weight, enhancing heat loss.[2] Sick or debilitated animals often have decreases in activity and nutritional intake and alterations in circulation that can contribute to hypothermia. Severe hypothermia may result in significant metabolic changes and death.

Pathologic Hypothermia. Pathologic hypothermia can be associated with sepsis, neurologic disorders, and endocrine disorders (see Box 7.1). Hypothermia has been observed with septicemia and shock, especially in neonates, in which 24% of septic foals were found to have a decreased body temperature.[2]

Hypothyroidism is an uncommon clinical problem in horses; however, impaired thermoregulation has been seen in foals with congenital hypothyroidism.[70,71] Hypothermia may be more common in donkeys than horses. In one study, histologic lesions of the thyroid gland were identified in four of five hypothermic donkeys.[72]

Approach to Hypothermia

Accidental Hypothermia. Accidental hypothermia can generally be identified from the signalment and history (see Fig. 7.1). It is important to assess environmental conditions to determine whether environmental stress, especially cold, wet, and windy conditions, is contributing to the hypothermia. Neonatal, geriatric, and debilitated patients are at high risk.

Pathologic Hypothermia

SIGNALMENT AND HISTORY. The signalment and history should be considered when assessing cases of potential pathologic hypothermia (see Fig. 7.1). It is important to consider environmental conditions, as in some cases both accidental and pathologic causes may contribute to the hypothermia, such as in septic neonates born in cold, damp environments.

PHYSICAL EXAMINATION. A thorough physical examination should be performed in horses with hypothermia. Patients should be assessed for potential underlying conditions such as sepsis or inflammation and neurologic or endocrine disorders. A neurologic examination may be useful.

ANCILLARY DIAGNOSTIC TESTS. A CBC, serum biochemical profile, fibrinogen, and urinalysis can be useful in determining the underlying cause of hypothermia. Blood cultures are indicated in cases of potential sepsis. Hypothyroidism is uncommon, but if suspected, diagnostic testing may include a thyroid-stimulating hormone or thyrotropin-releasing hormone (TRH) response test. Ultrasound and aspiration or biopsy of the thyroid may also be useful, especially in foals with suspected congenital or nutritional hypothyroidism.

CHANGES IN BODY WEIGHT

Changes in body weight and condition are common clinical problems in horses. Both weight loss and obesity have the potential to adversely affect the health of the horse. Weight loss can range from mild physiologic weight loss, such as that seen with increased exercise, to dramatic, life-threatening weight loss.[73,74] Severe malnutrition, regardless of the underlying cause, can result in starvation and the accompanying signs of marked weakness and wasting, known as *inanition*. Ultimately starvation can lead to organ failure and death. Obesity appears to be increasing in prevalence in the horse population and has been linked to serious health concerns, particularly laminitis.[75-78] Some horses that are prone to obesity ("easy keepers") have an endocrinologic disorder known as *equine metabolic syndrome* (EMS).[79-81]

The most accurate means of assessing body weight and monitoring changes in weight is to use a scale, but this has practical limitations. Thus a variety of weight tapes and equations based on morphometric measurements have been developed to estimate body weight.[82,83] To account for differences in body type between breeds, some breed-specific equations are available.[82] The ideal body weight depends on the type and use of the horse, and equations have been developed to calculate the ideal body weight for horses of certain breeds. Several online tools are available to aid in the calculation of actual and ideal body weight.

Weight alone does not necessarily reflect the body condition of the horse. Because muscle weighs more than fat, athletic horses may be heavier than nonathletic horses of similar size. To better evaluate body condition, a number of scoring systems have been developed to estimate the extent of adiposity.[83-87] One commonly used system to determine a body condition score (BCS) is the Henneke system, which uses a scale of 1 to 9, with 1 representing an extremely emaciated horse, 9 representing an extremely fat one, and 5 being close to ideal[86,87] (Table 7.1). A BCS system that ranges from 0 to 5 is also occasionally used, with 0 being emaciated, 3 good, and 5 very fat. In addition to body condition scoring, a number of morphometric measurements can be used to help estimate adiposity, some of which may be particularly useful in evaluating localized adiposity.[83,88,89] The girth-to-height ratio correlates well with the BCS and is a suitable morphometric measure for assessment of overall adiposity.[83] The cresty neck score, which ranges from 0 to 5, can be used to evaluate adiposity in the neck, with a score of 3 or greater being considered a cresty neck (Table 7.2). Some additional measurements used to assess neck adiposity include crest height, neck circumference, and neck circumference–to–height ratio. It has been demonstrated in ponies that measures of generalized and localized obesity, including a BCS of 7 or greater, a cresty neck score of 4 or greater, and a neck circumference–to–height ratio greater than 0.71, are useful in the prediction of laminitis.[88] A more quantitative means of measuring adiposity is by ultrasound.[90] One method is to take a measurement 5 cm lateral from the midline at the midpoint of the pelvic bone and the percent body fat is calculated by the following equation: % body fat = 2.47 + 5.47 (rump fat in cm). Most lean horses are approximately 8% to 14% body fat, whereas overconditioned horses are 16% to 30%. Ultrasound can also be used to assess retroperitoneal fat. A topline score can be used to evaluate epaxial musculature. Body condition scoring is also valuable in evaluating thin horses and is often used to assess horses in animal welfare cases.

Mechanisms Controlling Body Weight

The stability of body weight and body composition is related to the balance of energy intake and energy expenditure.[73] Dietary carbohydrates, fats, and proteins provide energy to support the body's metabolic needs. When the energy intake exceeds the expenditure, the excess energy is stored, primarily as fat, resulting in an increase in body weight. When the

TABLE **7.1 Horse Body Condition Scores on the Henneke Scale**[86]

Score	Description
1. Poor	Extremely emaciated; no fatty tissue; vertebrae, ribs, tail head, and bones of withers, shoulder, and neck are visible
2. Very thin	Emaciated; slight tissue cover over bones; vertebrae, ribs, tail head, and bones of withers, shoulder, and neck are visible
3. Thin	Slight fat cover over body; individual vertebrae and ribs no longer visibly discernible; withers, shoulders, and neck do not appear overly thin
4. Moderately thin	Ridge of spine and outline of ribs are visible; tail head may or may not be visible depending on the breed; withers, shoulders, and neck do not appear overly thin
5. Moderate	Spine and ribs cannot be seen, but ribs can be felt; tail head is spongy; withers, shoulders, and neck are rounded and smooth
6. Moderately fleshy	Slight crease down spine; ribs and tail head feel spongy; fat deposits along withers and neck and behind shoulders
7. Fleshy	Crease down spine; ribs have fat filling between them; tail head spongy; fat deposits along withers and neck and behind shoulders
8. Fat	Apparent crease down spine; ribs difficult to feel; soft fat surrounding tail head; fat deposits along withers, behind shoulders, and on inner thighs; neck is large
9. Extremely fat	Obvious crease down spine; patchy fat on ribs; bulging fat on tail head, withers, behind shoulders, and on neck; fat fills in flank and on inner thighs

TABLE **7.2 Cresty Neck Score Used in the Assessment of Regional Adiposity**[83]

Score	Description
0	No palpable crest
1	No visual appearance of a crest but slight filling felt with palpation
2	Noticeable appearance of a crest Fat deposited fairly evenly from poll to withers Crest easily cupped in one hand and bent from side to side
3	Crest enlarged and thickened Fat deposited most heavily in middle of neck giving a mounded appearance Crest fills cupped hand and begins losing side-to-side flexibility
4	Crest grossly enlarged and thickened May have wrinkles perpendicular to the topline Crest can no longer be cupped in one hand or easily bent from side to side
5	Crest is so large it falls to one side

energy intake is insufficient to meet metabolic needs, energy stores are used and there is a loss of body weight. Both weight loss and obesity can be serious clinical problems.

Weight Gain/Obesity

Obesity is being increasingly recognized in the equine population. In the 1990s, a study by the National Animal Health Monitoring System of the U.S. Department of Agriculture (USDA) estimated that approximately 5% of the horse population was obese. Several more recent studies in the United States and Europe have found that 45% to 50% of horses are overconditioned, with 10% to 35% being obese.[75-78,91-93] Breed has been shown to be strongly associated with the risk of obesity. In many cases, owners do not recognize their horse as obese. Horses that are not ridden or used for pleasure riding rather than competition appear to be at increased risk of obesity.[75,76] In a study of outdoor-living horses in the United Kingdom, seasonal variation in BCS was documented, with the prevalence of obesity increasing from 27% at the end of winter to 35% at the end of summer.[76] In this study, providing supplementary feed was not a strong predictor of obesity, supporting the belief that grass consumption is an important factor influencing obesity in outdoor-living horses.

Obesity has been linked to adverse health effects in many species. In horses, the increased risk of laminitis associated with obesity is a major concern.[81,94] Other potential problems seen with obesity include thermoregulatory inefficiency, exercise intolerance, altered reproductive performance, hyperlipemia syndrome, and the development of lipomas in mesenteric adipose.

Mechanisms of Weight Gain

Weight gain occurs when energy intake exceeds energy expenditure. Although this is a fairly straightforward concept, the actual etiology of obesity can be complex, involving interactions between genetics, hormones, and management. In many cases, management factors including diets high in sugar and starch coupled with a lack of sufficient exercise contribute to obesity. Even when horses are ridden regularly as pleasure horses, the relatively low-intensity exercise provided often does not use significant energy.[75,76]

Some horses are particularly susceptible to obesity. At one time, it was proposed that this was due to hypothyroidism, but evidence did not support this. In 2002 EMS was introduced as a metabolic and endocrine disorder contributing to obesity.[79] EMS is a complex problem that shares some characteristics with metabolic syndrome in people.[79-81,94,95] The major phenotypic features of EMS include obesity and/or regional adiposity, insulin resistance, and a predisposition for laminitis.

The pathophysiologic mechanisms involved in both obesity in general and EMS are complex, involving interactions between multiple factors including genetics. It appears that some individuals may inherit traits that facilitate survival in harsh environments, making them especially thrifty. EMS can be recognized in any breed of horse, but an increased susceptibility has been recognized in certain breeds, including several pony breeds, Morgan Horses, Paso Finos, Arabians, Saddlebreds, Spanish Mustangs, and Warmblood breeds.[81] Studies are ongoing to help better define the role of genetics in EMS.

Insulin dysregulation is a key factor in the diverse physiologic processes that contribute to EMS.[79-81,96,97] Insulin dysregulation refers collectively to abnormalities of insulin metabolism including excessive insulin responses to sugars,

fasting hyperinsulinemia, and insulin resistance (IR). The relationship between IR and obesity might be described as a vicious circle, as each may promote the other. In one study that demonstrated differences in the insulin response to glucose between ponies and horses, all animals were in moderate body condition, suggesting that the breed-related differences in insulin dynamics were independent of obesity.[98] In addition to genetics, EMS, and obesity itself, some factors that can potentially cause IR include physiologic responses to stress or pregnancy, systemic inflammation, and pituitary pars intermedia dysfunction (PPID).

There is increasing awareness of the role fat itself plays in the development of metabolic disease and inflammation.[99-101] Previously, adipose tissue was considered simply an energy storage depot with a fixed number of adipocytes. Any increase in adipose mass was thought to occur due to increased fat storage within existing cells resulting in hypertrophy. However, it is now recognized that adipose tissue is a complex endocrine organ that contains a large pool of stem cells and preadipocytes that can be recruited once existing adipocytes reach a critical level of hypertrophy. Thus in obesity there is generally both hypertrophy and proliferation of adipocytes. The adipocytes are biologically active and influence multiple physiologic processes including energy metabolism, cardiovascular function, reproductive function, inflammation, and immunity. The cells secrete a wide variety of cell-signaling proteins, or cytokines, known as *adipokines*, that function in both an autocrine/paracrine and endocrine fashion.[100] Due to local influences, adipocytes from differing anatomic locations may vary in their specific pattern of expression of these adipokines. Currently at least 100 substances are thought to be secreted by adipocytes. Some important adipose-derived hormones include leptin, adiponectin, resistin, visfatin, and angiotensinogen. Adipokines that act as proinflammatory cytokines and inflammatory mediators include TNF-α, IL-1α and IL-1β, IL-6, and IL-8, as well as monocyte chemotactic protein–1 and plasminogen activator inhibitor. The altered expression of adipokines in obesity can influence a number of metabolic processes and contribute to EMS.[101-107] Adipokines may inhibit insulin signal transduction pathways contributing to insulin resistance. Leptin, which is involved in satiety and regulation of obesity, is elevated in horses with IR, suggesting leptin resistance. Adiponectin, an insulin-sensitizing hormone, can be decreased in obese horses. In humans and rodents, obesity is linked with an upregulation of proinflammatory cytokines secreted by adipocytes. This results in a chronic inflammatory state and contributes to insulin dysregulation. Studies in horses, however, have yielded variable results regarding the expression of inflammatory mediators in obese horses, and further investigation is needed to understand their role in EMS.[95,104-106]

Several other factors may influence the development of obesity in addition to insulin dysregulation and the action of adipokines. The mechanisms of central control of body weight remain somewhat obscure, and it has been proposed that there is a set-point for body weight regulated through a region of the hypothalamus.[108] Myostatin, a myokine and negative regulator of skeletal muscle mass, has been implicated in obesity in other species, and limited data in the horse suggest a possible role for myostatin and its receptor in equine obesity.[109] Recently, the central role of the intestinal microbiota in the progression and prevention of metabolic dysfunction has become apparent, and the role of the gut microbiota in obesity and insulin dysregulation is under investigation in multiple species, including horses.[110-112]

BOX 7.2 Causes of Weight Gain/Obesity

PHYSIOLOGIC WEIGHT GAIN
Growth
Pregnancy

MANAGEMENT
Overfeeding/excessive grass consumption
Lack of exercise

ENDOCRINOLOGIC/METABOLIC DISORDERS
Equine metabolic syndrome
Pituitary pars intermedia dysfunction
Often causes weight loss

An increased risk of laminitis is an important feature of EMS.[79-81,113] The mechanisms involved in the relationship of obesity and insulin dysregulation to laminitis are not fully understood, and this remains an active area of research. The pathogenesis is likely multifactorial, and some proposed mechanisms include impaired glucose uptake by epidermal laminar cells, altered function of epidermal cells, endothelial cell dysfunction within the vasculature of the foot, digital vasoconstriction, and activation of metalloproteinase by glucose deprivation or reactive oxygen species.

Conditions Associated with Weight Gain

An increase in body weight occurs when the energy intake is greater than the energy expenditure. Being overweight should be distinguished from the normal physiologic weight gain associated with pregnancy and from pathologic conditions that cause abdominal distention, such as ascites or peritonitis (Box 7.2).

Overconditioning and obesity are often related to management problems associated with supplemental feed or excessive grass consumption, often combined with a lack of significant exercise. Horses with EMS are particularly susceptible to weight gain, and EMS is an important cause of obesity and regional adiposity. PPID can have variable effects on body weight. Whereas many horses with PPID may experience weight loss and muscle wasting, others may exhibit obesity or regional adiposity, especially if they have concurrent IR.

Diagnostic Approach to Weight Gain

Signalment and History. Any breed may develop EMS, but some appear to be at increased risk, including pony breeds, Morgan Horses, Paso Finos, Arabians, Saddlebreds, Spanish Mustangs, and Warmblood breeds.[81] The condition has also been commonly recognized in American Miniature Horses, draft breeds, and Norwegian Fjords, as well as donkeys and mules. It appears to be less common in Thoroughbreds and Standardbreds. The prevalence of PPID increases with age.

A thorough history is important. Particular attention should be given to the feeding practices as well as the amount and type of exercise that the horse receives. Previous episodes of laminitis may point to an increased likelihood of EMS or PPID. A history of abnormal shedding or polyuria/polydipsia increases the suspicion of PPID. The breeding history should be established. In some cases, the breeding history may be unknown, especially if the horse has changed ownership.

Physical Examination. A complete physical examination should be performed in cases of weight gain. This may help to rule out medical conditions that may cause abdominal distention such as ascites, bloat, uroperitoneum, hemoabdomen, or peritonitis. Palpation per rectum may be indicated to rule out pregnancy, especially in horses that have an unknown breeding history.

The body weight and BCS should be assessed, and the horse should be evaluated for regional adiposity.[82-87] Several morphometric measurements can be useful in the evaluation of body weight and condition. It is important to palpate carefully over the shoulder, elbow, ribs, withers, sternum, loin, and tailhead. The girth:height ratio can be useful in the assessment of overall adiposity.[83] A cresty neck score, as well as the neck crest height and neck circumference–to–height ratio, are useful in the assessment of neck adiposity.[83] In many cases, careful evaluation for lameness, increased digital pulses, and sensitivity to hoof testers is warranted due to the association of obesity with laminitis.

Ancillary Diagnostic Tests. Routine blood work is often unremarkable in cases of weight gain. As normal values may vary among laboratories, it is ideal to use reference ranges specific for the laboratory being used, especially when evaluating IR and PPID. Also, any significant ongoing pain or stress should be taken into account as these conditions can affect glucose and insulin dynamics, as well as adrenocorticotropic hormone (ACTH) and cortisol. Horses with both suspected EMS and PPID should be screened for IR. Current tests for evaluating IR focus primarily on measurements of glucose and insulin.[80,81] It is generally recommended to limit feed before sampling to one flake of grass hay low in nonstructural carbohydrates per 500 kg of body weight given no later than 10 PM the night before. As IR is often well compensated, baseline concentrations of glucose and insulin may be normal or in many cases the glucose is normal whereas the insulin is elevated. Occasionally horses will develop diminished glycemic control and become hyperglycemic (greater than 150 mg/dL) consistent with type 2 diabetes mellitus. There are several mathematical calculations such as the glucose:insulin ratio and reciprocal inverse square of insulin (RISQI) that are occasionally used to help assess insulin sensitivity.[114] Because resting concentrations of both glucose and insulin can be normal in IR, dynamic testing is often indicated. Practical dynamic tests include the oral sugar test (OST) and the combined intravenous glucose-insulin test (CGIT). Other diagnostic tests that may be useful in assessing IR include measurement of triglyceride and leptin concentrations, both of which may be elevated in IR.

Evaluation for PPID should be considered in horses with weight gain or regional adiposity, as well as in those with loss of body condition.[115,116] There are several options for diagnostic testing. Currently, frequently recommended tests include measurement of baseline ACTH, a low-dose dexamethasone suppression test, and a TRH stimulation test with measurement of ACTH.

Weight Loss

Mechanisms of Weight Loss

Weight loss occurs when the energy intake is exceeded by the expenditure. Thus there are basically two general mechanisms of weight loss, decreased energy intake and increased energy demand. In many horses with weight loss, both of these mechanisms come into play. Muscle loss often occurs with weight loss but can also occur as a result of neurogenic or disuse muscle atrophy, in which case the muscle loss may be independent of generalized weight loss.

Causes of Decreased Energy Intake

1. *Limited access to feed or poor quality feed:* The most direct cause of protein-calorie malnutrition and weight loss is an inadequate volume or quality of feed to meet the dietary requirements of the animal. This can result from actual underfeeding or from other factors such as excessive competition between horses or lameness preventing the horse from accessing the feed easily.[117] Also, the nutritional value of feed, particularly forage, can vary widely, and poor quality feed can be a significant factor in malnutrition.
2. *Dysphagia:* Dysphagia, difficulty with prehension, mastication, or swallowing, can occur in horses for many reasons with resultant decreased feed intake and weight loss. One common cause of difficulty eating, especially in older horses, is abnormal dentition.
3. *Malabsorption/malassimilation:* Malabsorption is the inadequate assimilation of dietary substances due to defects in digestion, absorption, or transport.[118] Both macronutrients (carbohydrates, fats, and proteins) and micronutrients (vitamins and minerals) can be affected. Normal absorption is a complex process involving multiple organs, enzymes, and hormones, as well as transport and secretory mechanisms. Impairment of any of the steps in this process can result in malabsorption. Rapid gastrointestinal transit time can also contribute to malabsorption. In horses, malabsorption is often associated with conditions that damage the intestinal wall, such as inflammatory bowel diseases, infiltrative neoplasms, parasitism, and certain gastrointestinal infections.[119] In foals, both primary and secondary lactase deficiency have been identified as causes of malabsorption.[120] Depending on the underlying cause of the malabsorption, weight loss may occur in the face of normal dietary intake.
4. *Anorexia:* Anorexia, which is a loss of appetite, frequently contributes to weight loss, especially when prolonged. Anorexia may be either partial or complete, and occasionally the term *hyporexia* is used to describe partial anorexia. A wide variety of diseases are associated with anorexia, and in many cases, the decreased desire for feed is combined with increased energy expenditure, resulting in significant weight loss. The pathophysiologic mechanisms involved in anorexia are not fully understood, but it appears that there are disturbances of hypothalamic pathways controlling energy homeostasis and that multiple mediators including hormones, neuropeptides, and cytokines such as IL-1 and TNF-α are involved.[121,122]

Causes of Increased Energy Demand. In general, causes of increased energy demand can be categorized as physiologic or pathologic.

1. *Physiologic causes of increased energy demand:* Physiologic weight loss may be seen with conditions requiring increased energy, such as late pregnancy, early lactation, and intense exercise. Environmental stress, especially decreased ambient temperature, can also have a significant impact on caloric requirements.[123-125] In adult horses, the lower critical temperature, which is the temperature below which the horse must increase metabolic heat production to maintain normal body temperature, ranges from 5°C (4°F) to −15°C (5°F) depending on the horse's adaptation to the environment. The digestible energy requirements are estimated to increase by 2.5% for every degree Celsius below the lower critical temperature. Energy requirements are further

increased by wet, windy conditions. It is estimated that in cold temperatures when the hair coat is wet the maintenance digestible energy requirement may increase by as much as 50%.

2. *Pathologic causes of increased energy demand:* Many disease processes will result in weight loss, not only because anorexia is common, but because there is frequently a concomitant increase in energy expenditure.[126] Fever itself appears to increase energy needs. In human patients, the resting energy requirement is estimated to increase by approximately 14% for each degree C increase in body temperature. However, the increase in energy requirement associated with disease is not consistent. For example, it was determined that the resting energy requirement of critically ill neonatal foals (40–50 kcal/kg body weight per day) was less than that of control foals (60–80 kcal/kg body weight per day).[127] The regulation of energy requirements in disease is complex and remains poorly understood.
3. Cachexia is a specific multifactorial syndrome associated with underlying illness that is defined by the loss of skeletal muscle with or without the loss of fat mass.[128-130] Cachexia is characterized by a negative protein and energy balance driven by a variable combination of reduced feed intake and abnormal metabolism, and it cannot be fully reversed by nutritional support. The pathophysiology of this syndrome involves multiple mechanisms.[130-133] It is in part mediated by cytokines, including TNF-α, IL-6, IL-1β, IFN-γ, and proteolysis inducing factor. TNF-α was originally designated as cachectin due to its catabolic effects. In human patients, muscle catabolism has been associated with TNF-α in a variety of conditions such as cancer, congestive heart failure, and chronic obstructive pulmonary disease. Based on studies in cultured muscle cells, it appears the increased muscle catabolism associated with TNF-α is mediated by reactive oxygen species and nuclear factor-κβ, which upregulate ubiquitin/proteasome activity.[134] There are several additional mechanisms of cytokine mediated cachexia, including activation of the hypothalamic melanocortin system and upregulation of the cytokine-activated transcription factor STAT3.[128,129,132-134] The endocrine system also has a role in cachexia. There is often a reduction in circulating anabolic hormones associated with disease. In cancer patients, tumor-derived parathyroid hormone–related protein (PTHrP) appears to play a role in cachexia.[131] In chronic disease states such as congestive heart failure and chronic kidney disease, it appears that the renin-angiotensin system has a major role in producing cachexia.[133] Angiotensin II concentrations are often elevated in chronic disease, and treatment with angiotensin converting enzyme inhibitors can improve weight loss.
4. Several additional mechanisms may contribute to increased energy requirements during systemic disease.[126,128-130] The stress associated with disease may alter metabolism due to increases in sympathetic and hormonal activity. Chronic pain may also result in elevated systemic catecholamine and cortisol concentrations, resulting in a catabolic state. In recurrent airway obstruction, the work of breathing can increase energy requirements. An increase in nutrient demand can be seen in association with protein loss in conditions such as peritonitis, pleuritis, colitis, inflammatory bowel disease, and burns. Also, although thyroid disease is uncommon in horses, weight loss has been recognized in association with hyperthyroidism and the accompanying increase in basal metabolic rate.[135,136]
5. Aging in multiple species has been associated with unintentional weight loss and sarcopenia, which is a loss in muscle mass, quality, and strength associated specifically with aging. The mechanisms behind this structural and functional decline in skeletal muscle are complex.[137] In horses, aging alone has been associated with a loss of weight and muscles.[138,139] Horses affected with PPID may be particularly susceptible to muscle loss due to atrophy of type 2A and 2B muscle fibers and loss of type 2B fibers.[115,140] Proposed mechanisms of steroid-related myopathy in horses with PPID include myocyte apoptosis, negative regulation of nuclear factor kappa B (NF-κB) activation and function, and oxidative stress.
6. It is not uncommon for weight loss to involve multiple mechanisms at the same time. Not only may decreased energy intake and increased energy demand be present concurrently, but there may be multiple mechanisms contributing to the decreased intake and increased demand. For example, in recurrent airway obstruction there may be increased demands from both the work of breathing and the presence of inflammatory cytokines. In parasitism, there is competition for nutrients within the gastrointestinal tract, as well as damage to the gastrointestinal wall resulting in inflammation and malabsorption of both macronutrients and micronutrients.

Conditions Associated with Weight Loss

A wide variety of problems can be associated with weight loss (Box 7.3). An inadequate amount or quality of feed for the age and use of the horse is an important cause that should not be overlooked. In some cases, adequate feed is provided, but the horse is unable to eat a sufficient amount due to factors such as competition with other horses or the presence of a gait deficit that limit's the horse's ability to access feed readily. Also, actual dysphagia can contribute to weight loss if prolonged. Some of the more common problems causing dysphagia include dental disorders, oral or pharyngeal foreign bodies, esophageal disorders, masseter myopathy, and several neurologic conditions such as neuropathy associated with guttural pouch disease, nigropallidal encephalomalacia, equine protozoal myelitis, and botulism.

Almost any disease process, including parasitism, infectious diseases, neoplasms, immunologic disorders, toxicities, chronic organ dysfunction, and endocrinopathies, can result in weight loss. In some instances the underlying cause of weight loss is readily apparent, such as in cases of pleuropneumonia or diarrhea. Weight loss is common with many gastrointestinal diseases, particularly protein losing enteropathies. In a retrospective study of 40 horses presented for weight loss despite a good appetite, a definitive diagnosis was established in 24 of 40 cases (60%), and 16 of 40 cases (40%) were idiopathic.[141] The most common diagnoses were inflammatory bowel disease (13 of 40, 32.5%) and intestinal lymphosarcoma (4 of 40, 10%). Hypoalbuminemia was identified in 58% of the total cases, and the severity of hypoalbuminemia was related with nonsurvival. A review of inflammatory bowel diseases of the horse identified cases of granulomatous enteritis, multisystemic eosinophilic epitheliotropic disease, lymphocytic-plasmacytic enterocolitis, and idiopathic eosinophilic enterocolitis.[142] Some other potential gastrointestinal causes of weight loss and hypoproteinemia in horses include

BOX 7.3 Mechanisms and Selected Differential Diagnoses for Decreased Body Weight

Mechanism	Differential Diagnoses
Lack of access to appropriate food	Unappetizing or inappropriate types of feed Poor-quality feed Insufficient quantity of feed Inability to access the available feed: Lameness, other musculoskeletal abnormality Social factors within the herd ("pecking order")
Lack of ingestion of available nutrients	Lack of appetite Inadequate prehension Nigropallidal encephalomalacia Masseter myodegeneration Abnormal mastication Poor dentition Masseter myodegeneration Abnormal swallowing Dysphagia Abnormal esophageal transit Esophageal abnormalities
Abnormal digestion, absorption, or metabolism of nutrients	Gastrointestinal dysfunction Gastrointestinal ulceration Inflammatory bowel disorder Neoplasia Parasitism Hepatic dysfunction Toxicities
Inadequate delivery of nutrients to peripheral tissues	Cardiovascular disease Heart failure Respiratory disease Recurrent airway obstruction (chronic obstructive pulmonary disease) Hepatic disease
Increased rate of protein and energy use or loss	Unusual levels of physical activity Late gestation, early lactation Adaptation to environmental conditions (e.g., cold) Neoplasia Infection, inflammation Pneumonia Pleuritis Peritonitis Equine infectious anemia Pain Heart failure Endocrine disorder Pituitary pars intermedia dysfunction Gastrointestinal disease Renal disease
Primary muscle wasting disorders	Neurogenic muscle atrophy Primary muscle disease Equine motor neuron disease Immune-mediated myopathy Polysaccharide storage myopathy

parasitism, right dorsal colitis, and proliferative enteropathy due to *Lawsonia intracellularis.*

Other important causes of weight loss include internal abscessation, neoplasia, and chronic organ dysfunction.[141,143-149] Internal abscesses can be difficult to diagnose. Although a multitude of organisms may be involved, *Streptococcus equi* subspecies *equi* (strangles) and *Corynebacterium pseudotuberculosis* (pigeon fever) are particularly important. Weight loss is a common clinical finding in horses with either chronic hepatic or renal disease, and weight loss has also been recognized with heart failure. In some cases, recurrent airway obstruction can also be associated with significant weight loss. Several neoplastic conditions can cause weight loss, and in horses, lymphosarcoma is particularly common.

Endocrine disorders have also been associated with changes in body weight. In horses, PPID is a common disorder that can be associated with either abnormal fat deposition or weight loss and muscle wasting.[115,140] Although uncommon, hyperthyroidism has been documented in horses, with weight loss being a major feature.[135,136,150,151] Rarely, diabetes mellitus has been identified in horses.[152]

Weight loss can be a component of a variety of other conditions. Persistent infection with equine infectious anemia virus can result in weight loss, although many cases are subclinical.[153] Several toxins have been associated with weight loss through a variety of mechanisms. For example, yellow star thistle toxicity causes significant dysphagia, and pyrollizidine alkaloids and alsike clover cause hepatic disease. Some other potential toxic causes of weight loss include selenium, lead, wild jasmine *(Cestrum diurnum),* and hairy vetch *(Vicia villosa),* among others. Chronic pain may also result in weight loss.

Muscle atrophy may occur either as a component of generalized weight loss, as in starvation and cachexia, or as a separate entity. Muscle loss is often prominent in association with aging and PPID. Some direct causes of muscle atrophy include disuse and neurogenic muscle atrophy. Progressive muscle wasting and weight loss are prominent features of equine motor neuron disease, which is a neurodegenerative disorder linked to vitamin E deficiency.[154] Other signs include weakness, muscle fasciculations, shifting weight, and increased recumbency. Also, rapid muscle atrophy affecting primarily the epaxial and gluteal muscles has been associated with immune-mediated myositis, particularly in Quarter Horses.[155]

Diagnostic Approach to Weight Loss

Signalment and History. The signalment and history should be considered when evaluating a horse with weight loss. Some conditions, such as certain dental disorders and PPID, are more common in older horses. *Lawsonia intracellularis* primarily affects weanling-age foals.

An accurate diet history is particularly important. The type, amount, and quality of feed should be documented, and it should be determined whether additional micronutrients or supplements are being fed. It is important to ensure that assessment of the amount is accurate by weight, because many owners feed by volume. The age, use, and condition of the horse should be considered when evaluating the feeding program because these may affect nutritional requirements. The feed should be evaluated for the presence of mold or toxic plants. The potential availability of vitamin E in the diet should be considered. Feed analysis can often be beneficial in assessing feed quality. The particulars of the feeding management should be determined, such as the feeding schedule, the types

of feeders, potential access to sand, and the water source. It should be established if there are other horses on the property and if so whether there is competition among horses for feed and if the weight loss affects more than one individual. Also, the appetite of the horse should be determined.

General historical information is also important when evaluating weight loss. This includes the history of deworming, dental care, and any use of medications, such as nonsteroidal antiinflammatory drugs. Any history of abnormal shedding, as well as any history of previous disease, such as strangles, pigeon fever, or laminitis, can be relevant.

Physical Examination. A complete general physical examination should be performed. The BCS and, if possible, the body weight should be determined. Observing the animal while eating can be important to establish whether it can prehend, masticate, and swallow normally. Neonatal foals should be observed suckling and evaluated for milk coming from the nostrils. The mare's udder and the milk should be examined. The clinical examination should include a thorough oral examination, rebreathing examination, and rectal palpation. A neurologic examination may also yield useful information. The presence of concurrent clinical signs, such as fever, diarrhea, cough, nasal discharge, a heart murmur, polyuria/polydipsia, icterus, and abnormal shedding or hypertrichosis, can point more quickly to a specific cause of weight loss and help direct additional testing.

Ancillary Diagnostic Tests. A number of ancillary tests can be useful in the diagnosis of weight loss, and tests should be prioritized based on the signalment, history, and physical examination findings.

CLINICAL PATHOLOGY/LABORATORY TESTING. A CBC, fibrinogen, and serum chemistry can be useful and is generally part of the minimum database. The white blood cell count and fibrinogen may be elevated with active infection. Several parameters may support a diagnosis of chronic inflammation including anemia, hyperfibrinogenemia, hyperglobulinemia, and thrombocytosis. These changes may support internal abscessation. Hypoproteinemia, and particularly hypoalbuminemia, is seen with protein losing conditions, such as gastrointestinal or renal disease and third space loss, or with decreased protein production, which can be seen with significant liver disease. A common cause of hypoalbuminemia in horses with weight loss is protein losing enteropathy. The serum chemistry may support a diagnosis of renal or hepatic disease, and a urinalysis can help in the evaluation of renal disease. The presence of hypercalcemia may indicate possible renal disease, hyperparathyroidism, or neoplasia. However, it should be remembered that hypercalcemia of malignancy is an inconsistent finding in horses with neoplasia.

Parasitism can contribute to weight loss even if it is not the primary problem. Assessment of parasite status should include fecal flotation with a fecal egg count; a Baermann analysis and tapeworm enzyme-linked immunosorbent assay (ELISA) should be considered. Feces should also be assessed for the consistency and fiber length, as well as the presence of sand.

Sampling of the airway via transtracheal aspirate or bronchoalveolar lavage can be useful in evaluating pulmonary disease. Culture and cytology of pleural or peritoneal fluid can also be useful; however, it should be remembered that many neoplastic conditions do not exfoliate significant numbers of cells, making diagnosis of neoplasia often challenging. Aspiration or biopsy of appropriate tissues may be indicated when possible.

Additional diagnostic testing, such as serum or whole blood trace mineral analysis, determination of vitamin E concentrations, thyroid testing, and testing for PPID, may be indicated for some horses with weight loss, determination of vitamin E concentrations, thyroid testing, and testing for PPID. Baseline concentrations of thyroid hormones often do not accurately reflect thyroid status due to the number of confounding variables, and additional testing is generally recommended.[150,151,156-158]

ENDOSCOPY. Endoscopic evaluation may aid in the evaluation of pharyngeal function and guttural pouch disease. It can also be helpful in assessing the esophagus and examining the stomach for equine gastric ulcer syndrome or gastric squamous cell carcinoma.

DIAGNOSTIC IMAGING. Imaging of the thorax by ultrasound and radiographs can be useful in the evaluation of thoracic disease. Ultrasound can be used to assess the abdomen and can help to assess fluid volume and character, intestinal wall thickness, and abdominal masses. Abdominal radiographs may be useful in foals, but in adult horses they are often impractical, and the diagnostic utility is generally limited to the identification of enteroliths or excessive sand accumulation. Echocardiography may be indicated especially in cases where a murmur or arrhythmia is identified on physical examination.

OTHER. Oral absorption tests using either D(+)-xylose or glucose to identify malabsorption can be useful in the evaluation of unexplained weight loss.[142,159,160] Although xylose is less affected by metabolic factors, glucose absorption is a valid, practical means of assessing malabsorption. Intestinal biopsy is often necessary to identify the specific cause of the malabsorption.

COUGH

Cough is a sudden, forceful expulsion of air through the glottis that generates a characteristic sound. Although cough is a normal reflex mechanism that is important in protection of the airways, it is also a common sign of disease in multiple species. Cough promotes ciliary activity and generates the high air flows necessary to shear mucus from the airway walls, thus acting to remove secretions and foreign particles from the respiratory tract and prevent pulmonary aspiration. Specific data related to the importance of an intact cough mechanism in horses are limited, but in human patients an inefficient cough reflex has been associated with atelectasis and recurrent pneumonia.[161-163] Although cough is an important protective mechanism, excessive cough is a common sign of disease and can have deleterious effects. In human medicine, cough has been estimated to account for up to 40% of outpatient practice.[164-166] Cough is also a common clinical problem in horses. Even when not associated with significant systemic disease, cough can be performance limiting in the equine athlete.

Mechanisms of Cough

Cough is a highly coordinated reflex action that can be modulated by voluntary input. All mammalian species that have been studied either cough or display a similar respiratory reflex.[167] Despite the prevalence and clinical importance of cough, the precise mechanisms involved are not fully understood. Much of the information reported regarding the mechanism of cough in horses has been extrapolated from other species. Some species-related differences, however, are known

to exist.[167] Age and gender are also known to influence cough. The cough reflex can be poorly developed in neonates and can be compromised in association with aging.[168,169] These age-related differences may contribute to an increased susceptibility to aspiration and respiratory infections in these age groups. Interestingly, in humans an increased sensitivity of the cough reflex has been recognized in females following puberty, and women are more likely to develop chronic cough.[170-172]

Cough Cycle

There are three phases of the cough cycle: inspiratory, compressive, and expiratory.[173-175] These phases are generally followed by a period of relaxation. In the inspiratory phase, inhalation essentially generates the volume necessary for an effective cough. A variable amount of air is inhaled and serves to lengthen the expiratory muscles, optimizing the length-tension relationship. This expansion of lung volume allows for an increase in the subsequent velocity of expiratory airflow due to greater force of contraction from the lengthened muscles and greater elastic recoil pressure.

The compressive phase of cough consists of a very brief (200 msec) closure of the glottis to maintain lung volume as isometric contraction of the expiratory muscles occurs. Muscles of the chest wall, diaphragm, and abdominal wall contract against the closed glottis, resulting in a rapid rise in intrathoracic pressure.

The expiratory phase starts with opening of the glottis as the expiratory muscles continue to contract, resulting in the release of air. There is a brief period of supramaximal expiratory flow, sometimes referred to as the *cough spike,* which is then followed by lower expiratory flows. Due to relative changes in pleural and airway pressures there is dynamic compression of the larger airways during expiration, which helps to maximize the velocity of airflow by decreasing the airway diameter. The high-velocity turbulent airflow results in airway vibration, which is largely responsible for the sound recognized as cough. Importantly, the high flows generated in the expiratory phase dislodge mucus and facilitate the removal of mucus and debris from the tracheobronchial tree. At the end of cough, expiratory muscles relax, intrapleural pressure decreases and transient bronchodilation may occur.

The specific pattern of cough can vary and is sometimes broadly categorized into two types.[173] Laryngeal cough, which functions primarily to protect the airway from aspiration, is triggered by mechanical stimulation of laryngeal receptors and is a true reflex, sometimes referred to as the *expiratory reflex*. The inspiratory phase is minimal, and expiration occurs rapidly. Tracheobronchial cough is stimulated primarily by receptors distal to the larynx and has a more prominent inspiratory phase in order to generate the greater airflows necessary to remove secretions and debris from the tracheobronchial tree. It may occur either as a reflex or by voluntary control.

Neurophysiology of Cough

Coughing is a complex visceral reflex that can be both voluntarily and involuntarily regulated.[176-179] The neurologic control of cough is still under investigation, and an improved understanding has therapeutic implications for the control of cough. Basically, cough can be compartmentalized into three components: (1) stimulation of sensory afferent nerves, (2) integration of the information in the brainstem and higher brain centers, and (3) activation of efferent pathways to the muscles involved in the generation of cough[176-179] (Fig. 7.2).

Afferent Pathways Regulating Cough. Cough is initiated by the activation of sensory vagal afferent nerves that primarily innervate the respiratory tract, although they may be found in additional sites such as the ear in some species.[178-182] Though all vagal in origin, this population of afferent nerves is not homogeneous, and several subtypes have been identified. Some of the differences between subtypes include their distribution within the respiratory tract as well as the presence of myelination, the receptor type and sensitivity to various stimuli, and the location of the cell bodies, which can be within either the nodose and/or jugular ganglia. In general, these nerves respond to chemical and/or mechanical stimuli, with different thresholds for the various stimuli. There is no single classification scheme, but the subtypes are often functionally classified broadly as being either *primarily* sensitive to mechanical stimuli (mechanosensors) or to chemical stimuli (chemosensors, sometimes referred to as nociceptors). Although both types can be located throughout the airways, mechanosensors tend to predominate in the larynx and large airways. Among the most studied subtypes of sensory afferents are the rapid-adapting receptors (rapidly adapting stretch receptors), slow-adapting receptors (slowly adapting stretch receptors), and C-fibers. Several other receptors, including a possible specific cough receptor, have been described. Overall, the relative contribution of the various subtypes in the generation of cough is still uncertain and may be species dependent. These nerves often contribute to other functions within the respiratory tract, such as enhancing mucus secretion, initiating bronchoconstriction, and influencing the rate and depth of respiration.

RAPID-ADAPTING RECEPTORS AND SLOW-ADAPTING RECEPTORS. Rapid-adapting receptors (RARs) and slow-adapting receptors (SARs) are myelinated nerves that originate primarily in the nodose ganglion.[178-181] RARs are present in both extrapulmonary and intrapulmonary airways, whereas SARs are predominantly within the intrapulmonary airways and lung parenchyma and are sparse in extrapulmonary airways. Although there are some differences in the exact stimuli they respond to, they are both predominantly low threshold mechanosensors that may respond to a variety of stimuli such as changes in lung volume and changes in airway diameter due to smooth muscle constriction, airway wall edema, or the presence of mucus.

C-FIBERS. The majority of vagal airway afferent nerves are unmyelinated C-fibers that originate primarily in the jugular ganglion.[178-181] They innervate the epithelial layer throughout the extrapulmonary and intrapulmonary respiratory tract. A type of nociceptor, C-fibers are predominantly chemosensors that respond to a wide variety of stimuli including both high and low temperatures, nonisotonicity, low pH, irritants, and inflammatory mediators. They can have multiple receptors, including neuronal transient receptor potential (TRP) channels such as ankyrin 1 (TRPA1) and vanilloid 1 (TRPV1).[183,184] Most C-fibers are known to react with capsaicin, and it appears that this occurs primarily through the TRPV1 receptor. Also, the TRP receptors may be important in disease states as they can be activated by reactive oxygen species generated during inflammation, and TRP channel antagonists are being investigated as potential antitussive agents.[185-187] PGE_2, which is released in association with airway inflammation, acts directly on pulmonary C-fibers to increase their sensitivity and lower the cough threshold.[188]

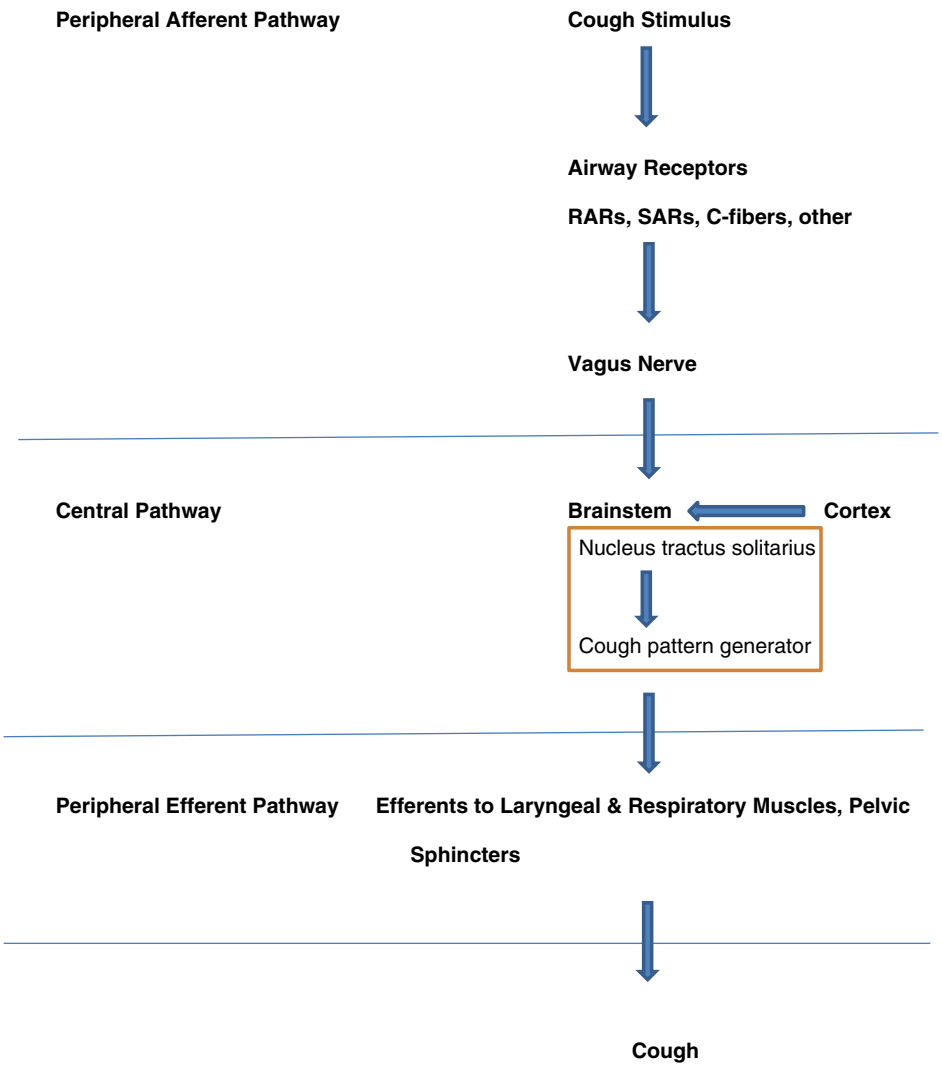

FIG. **7.2** Simplified schematic of the neurophysiology of cough.

The initiation of cough is a complex activity with multiple interactions between the afferent nerve subtypes.[178-181,189] For example, activated C-fibers release neuropeptides including substance P, neurokinin A, and calcitonin gene–related peptide. These neuropeptides can cause bronchospasm, edema formation, and mucus secretion, which in turn can lead to activation of the RARs. Without the activity of the RARs and SARs, C-fibers are limited in their ability to evoke cough.

Bronchoconstriction and cough are closely interrelated but can also have distinct pathways.[190,191] Some, but not all, stimuli for cough will also cause reflex bronchoconstriction, which generally has a slower onset and longer duration than cough. Bronchoconstriction itself can be a stimulus for cough and, up to a point, can improve the efficiency of cough by decreasing airway diameter and thus increasing airflow velocity. Some therapies affect either bronchoconstriction or cough, whereas others affect both. For example, some bronchodilator drugs can also decrease cough by desensitizing airway receptors that initiate cough.

Central Regulation of Cough. The mechanisms controlling the central regulation of cough are complex, involving both the brainstem and higher brain centers.[177,179,192-194] The afferent sensory nerve input arising from the respiratory tract is centrally integrated primarily within the nucleus tractus solitarius (nTS) of the medulla oblongata in the brainstem. Neurons within the nTS communicate with other brainstem neurons as part of a multifunctional, dynamic neural network that functions in both generation of the normal breathing pattern and cough. This neural network has been referred to as the cough pattern generator as well as the respiratory pattern generator or central controller. When cough occurs, there is reshaping of the discharge patterns of respiratory neurons within this neural network resulting in discharges being transmitted to the motor neurons involved in cough. Projections between the brainstem and cortical centers add complexity to the regulation of both breathing and cough. Due to cortical modulation, some cough can be voluntarily initiated and suppressed. Among the receptors involved in the generation of cough in the brainstem are *N*-methyl-D-aspartate (NMDA) receptors, and in several species antagonists of NMDA-type glutamate receptors such as dextromethorphan have been effective antitussives.[195,196]

Activation of Efferent Pathways. Signals from the brainstem and cerebral cortex are transmitted via a number of efferent nerves to the muscles involved in cough.[173,178] Important efferent nerves include the vagus, phrenic, intercostal, and

lumbar nerves. In addition to the vagus, several other cranial nerves play a role, including the trigeminal, facial, hypoglossal, and accessory nerves. The efferent nerves involved in cough supply the muscles of the larynx and tracheobronchial tree, the diaphragm, and the intercostal, abdominal, and pelvic muscles, as well as secretory glands of the respiratory tract. The coordinated activity of these muscles results in cough.

Cough Efficiency/Adverse Effects. The effectiveness of cough is dependent on the ability to generate high flow velocities and the interaction of the flowing air with airway secretions.[173] In general, cough is more effective in clearing large airways as opposed to smaller peripheral airways. Cough efficiency is affected by the integrity of the neurophysiologic pathway of cough as well as physical aspects, such as respiratory muscle strength and mucus quality. Normal mucus acts to improve airway clearance and protect receptors from irritants, and changes in the amount or tenacity of mucus can both mechanically stimulate cough receptors and cause flow limitation.[173,197,198] Cough is often less effective as a clearance mechanism when airway disease is present.

Not only does cough lose its defensive function is some disease conditions, but it may even have deleterious effects.[173,199] Lung expansion during the inspiratory phase may allow for the spread of infectious agents and particulate matter into the smaller airways. Paroxysmal or persistent coughing can cause fatigue and may decrease feed intake, particularly in foals. Chronic cough can result in bronchial muscle hypertrophy. Cough can also have significant cardiovascular effects due to changes in abdominal and intrathoracic pressures.[199,200] During the expiratory phase of cough there is an initial rise in systemic arterial blood pressure and a concurrent rise in cerebral venous and cerebrospinal fluid pressures. This is followed by a period of hypotension, which can reduce the effective perfusion pressure of the brain, especially when there is high cerebral venous pressure. The resulting cerebral hypoperfusion and anoxia have been associated with cough-induced syncope in dogs as well as people.[201,202] Some other potential adverse effects of cough that have been reported in small animals and people include pneumothorax, pneumomediastinum, and lung lobe torsion, as well as rib and vertebral fractures.[199,202]

Conditions Associated with Cough

The potential causes of cough are diverse, as the cough receptors can respond to a wide variety of mechanical and irritant stimuli.[173-181,183,203] Some general stimuli of cough include inhaled particles or irritants, inflammatory mediators, bronchoconstriction, excessive mucus, exposure to cold or hot air, sloughing of airway epithelial cells, and pulmonary edema. Intramural or extramural tension on the airways, such as that seen in association with masses or decreased pulmonary compliance, can result in cough. The sensitivity of cough receptors is influenced by a number of factors, such as genetics, age, and the presence of disease. Most often, the cough reflex becomes hyperresponsive once respiratory disease is established due to both increased exposure of the cough receptors due to a loss of the integrity of the epithelial lining and increased sensitivity of the receptors in response to inflammation. It is important to remember, however, that significant respiratory disease can be present without cough.

The specific causes of cough have been categorized in a number of ways, such as the duration of signs (acute or chronic), the presence or absence of fever, whether the cough is productive or not (wet or dry), and whether it originates from the upper or lower airway. Categorizing cough can be useful in establishing a list of differentials for cough, although there can be considerable overlap between the categories. The presence or absence of fever may be particularly useful when considering the causes of cough (Box 7.4).

BOX 7.4 Causes of Cough with Fever

Common Causes	Major Diagnostic Test(s)
Viral respiratory tract disease Equine influenzavirus Equine herpesviruses Equine rhinitis viruses A and B Equine viral arteritis Adenovirus Other	Nasal or nasopharyngeal swab Polymerase chain reaction (PCR) Viral isolation Viral antigen detection Serology
Bacterial pneumonia/pleuropneumonia (including aspiration pneumonia, pulmonary abscesses)	Radiographs/ultrasound Transtracheal aspirate/thoracocentesis Cytology Culture and sensitivity PCR
Less Common Causes	**Major Diagnostic Test(s)**
Fungal pneumonia	Radiographs/ultrasound Transtracheal aspirate/thoracocentesis Cytology Fungal culture Serology
Interstitial pneumonia Equine multinodular pulmonary fibrosis Syndromes of acute lung injury, acute respiratory distress	Radiographs PCR—EHV 5 Lung biopsy
Neoplasia	Radiographs/ultrasound Endoscopy Transtracheal aspirate/thoracocentesis Cytology (often low yield) Biopsy
Smoke inhalation	History
Other—parasitic pneumonitis, cardiogenic cough	

Causes of Cough Associated with Fever

Cough in conjunction with fever is most often associated with infection of the respiratory tract, although some noninfectious conditions such as neoplasia can also occasionally present with fever. Infection of the respiratory tract may be primary or may be secondary to an underlying condition such as inflammation of the airways. Viral infections of the respiratory tract are a common cause of cough in horses and are particularly important as they can cause outbreaks of respiratory disease.[203,204] Affected horses often present with an acute onset of a dry cough in conjunction with fever, lethargy, and anorexia. Some important equine respiratory

viruses include equine influenzavirus, equine herpesviruses (EHVs), equine rhinitis A and B, and equine viral arteritis. With regard to the equine herpesviruses, EHV-4 and EHV-1 are the major pathogens associated with acute respiratory disease in the domestic horse population.[204,205] Respiratory viruses frequently cause exposure and sensitization of cough receptors, along with injury to epithelial cells and decreased mucociliary clearance, which can predispose the affected horse to secondary bacterial infection. In addition to viruses, both bacterial and fungal agents can cause infection of the respiratory tract, and are often associated with a periodic wet cough due to increased mucus production and neutrophil accumulation. Bacterial infection is particularly common in the lower respiratory tract and can cause bronchitis, pneumonia, or pleuropneumonia.[206,207] A variety of organisms have been isolated and polymicrobial infections may occur. Some common pathogens include *Streptococcus equi* subspecies *zooepidemicus, Pasteurella, Actinobacillus* spp., *Escherichia coli,* and *Klebsiella pneumoniae. Rhodococcus equi* is an important cause of pneumonia in foals. Anaerobic organisms, such as *Bacteroides fragilis* and *Peptostreptococcus anaerobius,* may also infect the lower airways of horses. *Mycobacterium* and *Mycoplasma* spp. are occasionally isolated from horses with respiratory tract disease.[206,208] Fungal respiratory disease in horses is uncommon and is most often recognized in the paranasal sinuses, guttural pouches, and lungs.[209,210] Some primary fungal pathogens that have been identified in association with respiratory disease in the horse include *Coccidioides immitis, Cryptococcus neoformans, Histoplasma capsulatum, Blastomyces dermatitidis,* and *Conidiobolus coronatus.* Opportunistic fungi, such as *Aspergillus* spp., *Candida* spp., and *Pneumocystis carinii,* can also cause respiratory tract disease. Following recovery from infectious respiratory tract disease of any cause, horses will often have a persistent wet or dry cough as the cough receptors remain hypersensitive.

Interstitial pneumonia has been reported in horses of all ages in association with both acute and chronic respiratory disease.[211,212] Horses with interstitial pneumonia frequently have marked tachypnea with increased respiratory effort, and cough and fever can be present as well. Some specific types of interstitial pneumonias include equine multinodular pulmonary fibrosis and syndromes of acute lung injury and acute respiratory distress. Although interstitial pneumonia has been linked to a variety of causes, in many cases an underlying cause is not identified. Equine multinodular pulmonary fibrosis has been linked to EHV-5 infection.[212]

Other conditions may occasionally present with cough in association with fever. Thoracic neoplasia is uncommon in horses and presents with variable clinical signs that may include cough with or without fever.[213] Smoke inhalation may cause a significant inflammatory response and edema resulting in tachypnea, cough, and fever.[214] Fever may occasionally be present with parasitic or cardiogenic cough.

Causes of Cough Without Fever

Among the most common causes of cough without fever in horses is a spectrum of chronic inflammatory airway disease that is now referred to as *equine asthma syndrome*.[215-218] Included in this syndrome are inflammatory airway disease (IAD, mild to moderate equine asthma) and recurrent airway obstruction (RAO, severe equine asthma). Summer pasture-associated RAO (SPARAO, summer pasture-associated obstructive pulmonary disease, SPAOPD) is a subset of RAO in which signs occur after exposure to pasture in warm summer months. RAO primarily affects horses over 7 years of age. The prevalence of RAO is approximately 10% to 20%, and a familial predisposition has been identified.[219-222] Affected horses typically have frequent coughing, increased respiratory effort at rest, and exercise intolerance. With IAD, horses may be affected at any age, and the clinical signs are more subtle. Both RAO and IAD are characterized by increased mucus in the airways. With regard to the specific cytologic abnormalities in the bronchoalveolar lavage fluid (BALF), RAO is typically characterized by pronounced neutrophilia (greater than 25%), whereas in IAD the abnormalities tend to be milder and more variable. Other conditions that can resemble equine asthma clinically include silicosis, lungworm infection, and idiopathic eosinophilic pneumonia.[223-226]

It is not uncommon for horses to cough occasionally, especially at the beginning of exercise. These coughs are sometimes referred to as *arena cough, warm-up cough,* or *nuisance cough* depending on the exact circumstances. This type of cough may reflect cough's function as part of the normal defense mechanisms of the respiratory tract, as it is not uncommon for clinically normal horses to have some mucus accumulated behind the larynx waiting to be expelled. Also, horses breathe more deeply during exercise, and the environment in some riding arenas can be dusty. Although this type of cough is generally relatively innocuous, it may indicate poor air quality and may also be a sign of early disease. Thus all horses with cough should be monitored closely.

Parasitic pneumonitis is another cause of cough that is generally afebrile, although occasionally fever may be seen. In foals, the larvae of *Parascaris equorum* migrate through the lungs and can occasionally cause a significant inflammatory response resulting in cough and nasal discharge.[203] Horses infected with the lungworm *Dictyocaulus arnfeldi* can have chronic cough and mucoid nasal discharge.[224,225] Affected horses often have a history of contact with donkeys or mules. In donkeys and mules, infection is generally asymptomatic but is patent, providing a source of eggs in the feces. In horses and ponies, infection often results in an inflammatory response and cough and is typically not patent, with larval development arrested in the lungs.

Exercise-induced pulmonary hemorrhage (EIPH) is defined by the presence of hemorrhage in the airways of a horse after exercise.[227,228] It is common in Thoroughbred and Standardbred racehorses and in other horses performing strenuous exercise, such as barrel racing horses. The clinical abnormalities seen with EIPH are not consistent but may include epistaxis, increased respiratory rate, poor performance, and coughing.

Congestive heart failure, although not common in horses, can result in cough.[229,230] In particular, in left-sided heart failure, blood is not effectively pumped from the left side of the heart, leading to increased blood in the pulmonary circulation and increased pulmonary vascular pressure. Vascular congestion and pulmonary edema follow, and cough receptors are stimulated. In a study of 14 horses with congestive heart failure, all horses presented with a heart murmur and tachycardia.[229] Other common clinical signs included cough, crackles, tachypnea, ventral edema, and either jugular distention or pulsation. The underlying causes for heart failure included congenital defects, traumatic vascular rupture, pericarditis, pulmonary hypertension secondary to RAO, and valvular

dysplasia. Fever is not generally associated with cardiogenic cough but may be present in some horses, especially those with pericarditis or endocarditis.

A number of disorders of the upper airway can result in cough. Pharyngitis, also referred to as *pharyngeal* or *follicular lymphoid hyperplasia,* is a relatively common disorder that is recognized primarily in young horses.[203,231,232] It is most likely the result of the lymphoid response to a variety of irritant or infectious stimuli. Although many cases are subclinical, coughing, nasal discharge, and mild submandibular lymphadenopathy may be present. Dynamic or static compression of the upper airway such as may be seen with dorsal displacement of the soft palate, fourth branchial arch defect (rostral displacement of the palatopharyngeal arch, laryngeal dysplasia), aryepiglottic fold entrapment, subepiglottic cyst, arytenoid chondritis/chondrosis, and laryngeal hemiplegia, may also be associated with cough, which is often dry in nature.[203] Although clinical signs vary, these disorders are often characterized by abnormal breath sounds such as stridor or stertor at rest or during exercise as well as normal lung sounds and absent or minimal mucopurulent discharge. Soft palate problems, including soft palate paresis, dorsal displacement of the soft palate and cleft palate, and other causes of dysphagia, can result in cough that is often associated with eating. In some cases, disorders such as sinusitis and guttural pouch mycosis or empyema will result in cough due to the presence of exudate in the upper airways.

Tracheal abnormalities may also result in cough. These include tracheal stenosis, collapse, and partial obstruction such as may be seen with a foreign body or neoplasia. Tracheal collapse is typically associated with an inspiratory honking sound. It is most often diagnosed in American Miniature Horses but may be seen in other horses as well and has been reported in association with pneumonia.[233-235]

Diagnostic Approach to Cough

Cough is a common clinical problem that can be associated with a number of diverse disorders. The diagnosis of the specific cause of cough is based on consideration of the signalment, history, and clinical signs, as well as the use of appropriate diagnostic aids.

Signalment and History

The signalment can help to prioritize the differential diagnoses in a horse presented for cough. Pneumonia caused by *Rhodococcus equi* is most common in foals 1 to 6 months of age.[207] Although viral respiratory diseases can be seen in any age horse, they are particularly common in weanling and yearling horses.[204] Pharyngitis is also most common in young horses.[231,232] Horses with RAO are typically over 7 years of age, and a familial predisposition has been identified.[215-218] The risk of developing RAO is threefold when one parent is affected and almost fivefold when both parents are affected.[221,222]

Several components of the history are important in the assessment of a horse with cough. Routine management factors such as vaccination, deworming, stabling, and bedding type, as well as the feed type, feed quality, and feeding practices, are of particular importance. Risk factors for infectious respiratory disease include exposure to new horses, either at an event or through new arrivals to the farm, and stress, such as recent transport, surgery, weaning, or strenuous activity. A history of other clinical signs such as fever, lethargy, and anorexia, as well as the involvement of other horses, may increase the suspicion of infectious respiratory disease. The risk of lungworm infection is increased by exposure to donkeys or mules.[224,225] EIPH is associated with strenuous exercise.[227] The geographic area may raise the suspicion of some conditions such as silicosis, which has been reported primarily in California, and certain mycotic infections, such as *Coccidioides immitis,* which is found primarily in the southwestern United States.[209,210,223] Any history of previous disease, as well as a history of signs such as stridor or exercise intolerance, can also be important.

The historical aspects of the cough itself can be helpful in the evaluation of horses with cough. These include whether the cough is acute or chronic, any seasonal pattern, the frequency of the cough, and any association with feeding or exercise. It can be helpful to establish if the cough is nonproductive or productive, although this can be difficult to discern.

Physical Examination

A complete physical examination, including a detailed examination of the respiratory system, should be performed in horses presented for evaluation of cough. The character of any nasal discharge should be noted. The presence of a fever increases the likelihood of infectious respiratory tract disease, although noninfectious conditions may occasionally be associated with fever. It should be remembered that fever can be intermittent and can be suppressed by the administration of nonsteroidal antiinflammatory drugs. Careful auscultation of the thorax should be performed. The presence of a heart murmur and tachycardia may suggest congestive heart failure, especially if there is jugular distention or pulsation.[229] If the horse can tolerate it, a rebreathing examination should be performed, especially if there are no obvious abnormal sounds during quiet breathing. The rebreathing examination, which is performed by loosely placing a plastic bag over the nostrils, will cause the horse to increase tidal volume, accentuating breath sounds. Cough may be induced, especially if there is exudate in the airways. The presence of crackles and/or wheezes on auscultation suggests pulmonary parenchymal disease. With pulmonary consolidation, atelectasis, or pleural fluid, breath sounds are typically decreased or absent ventrally, although occasionally sounds may be accentuated due to referral of sounds from aerated lung. Percussion can be used to identify areas of dullness. In horses with significant RAO, percussion can be used to identify a shift of the caudal lung border.[236]

Ancillary Diagnostic Tests

Clinical Pathology. A CBC and fibrinogen are frequently indicated in the assessment of horses with cough, and in some cases a serum chemistry may also be useful. Acute viral infection can be associated with leukopenia characterized primarily by lymphopenia.[204] A transient anemia may be seen as well. Neutrophilia and hyperfibrinogenemia are seen with many inflammatory conditions, especially bacterial or fungal pneumonia.[206] Inflammatory conditions may also be associated with anemia, hyperglobulinemia, and thrombocytosis, especially if chronic. Hematologic values are usually unremarkable in horses with uncomplicated equine asthma.[216] Although not consistent, peripheral eosinophilia may be seen with idiopathic eosinophilic pneumonia, parasitic pneumonitis, and occasionally eosinophilic IAD.[216,224-226] Hypercalcemia can be seen in some horses with malignancy.

An arterial blood gas evaluates air exchange and helps to monitor the severity of respiratory disease. In some horses

with chronic or recurrent infectious disease, measurement of immunoglobulin concentrations may help identify an underlying immunodeficiency. There has been a growing interest in the use of biomarkers to evaluate disease states. Although findings are often nonspecific, serum amyloid A and fibrinogen are two biomarkers commonly used to evaluate inflammatory disease.[237] In racehorses with IAD, increased concentrations of surfactant protein D (SP-D) have been described, and in horses with RAO, soluble CD14 concentrations are increased compared with controls.[238,239]

Airway Cytology. Several techniques have been described for sampling the respiratory tract of horses.[240-246] The primary means of sampling the lower respiratory tract include bronchoalveolar lavage and tracheal wash. Tracheal wash is often used for the diagnosis of infectious pneumonia. Analysis of BALF is recommended for the diagnosis of equine asthma.[215,216] RAO is characterized by a moderate to severe neutrophilia (greater than 25%), whereas in IAD the changes are more varied and may include a mild to moderate increase in neutrophils (greater than 10%), eosinophils (greater than 5%), and/or mast cells (greater than 5%). BALF fluid cytology is also useful in the diagnosis of EIPH, which is characterized by the presence of erythrocytes and hemosiderophages.

Assessment of Infection. Currently a nasal or nasopharyngeal swab is the preferred sample for diagnosis of most viral respiratory infections.[204] A Dacron or rayon swab is preferred compared with cotton. Detection of genetic material by PCR is a common means of virus identification, although virus isolation can be performed as well. There are also several means of viral antigen detection. For example, direct immunofluorescence can be used to demonstrate EHV antigens and several enzyme-linked immunosorbent assays are available for the detection of influenza-virus nucleoprotein.

Appropriate samples for the identification of bacterial or fungal agents in respiratory tract disease depend on the suspected site of infection and organism. Common techniques for sampling the upper airways include nasal or nasopharyngeal swab, nasal wash, guttural pouch wash, and sinus trephination. Transtracheal aspiration is commonly used for sampling the lower airway in cases of suspected pneumonia. Other techniques include endoscopic tracheal aspiration or brushing and sterilely performed BAL. Pleural fluid can be sampled by thoracocentesis. Cytology and Gram stain of the samples can support the presence of infection. Culture and PCR are used for identification of specific pathogens. Many laboratories now offer diagnostic panels for respiratory disease that test for multiple common pathogens.

Serologic testing is available to detect the host response to several infectious agents. Depending on the organism, however, it may be difficult to distinguish active infection from exposure or vaccination. Serology can be useful in the diagnosis of several fungal infections, such as cryptococcosis, coccidiomycosis, blastomycosis, and conidiobolomycosis.[209,210]

The Baermann fecal flotation technique can be used in horses with suspected lungworm infection. However, as infections in horses are often not patent, a negative Baermann does not rule out the presence of lungworms.[224,225] Routine fecal flotation can be used to detect *Parascaris equorum* in foals with suspected parasitic pneumonitis, but in some cases the infection may not yet be patent.

Endoscopy. Endoscopic examination is particularly valuable in evaluation of the upper airways and trachea. Because sedation can alter airway function, endoscopy is best performed without sedation if possible. Endoscopy can identify exudate, anatomic or functional abnormalities, mass lesions, and airway obstruction. On occasion, lungworm larvae may be seen in the trachea. Pleuroscopy can be used to evaluate the pleural space.

An endoscopic mucus scoring system has been developed to quantify mucus in the trachea (0—no visible mucus, 1—single to multiple small blobs of mucus, 2—larger but nonconfluent blobs, 3—confluent or stream forming mucus, 4—pool forming mucus, 5—profuse amounts of mucus).[247] Normal horses tend to be either grade 0 or 1, whereas those with equine asthma are 2 to 5.[216,248] Studies have shown associations between the amount of mucus present in the airways with coughing and poor performance.[232,249-251]

Diagnostic Imaging. Radiographs and ultrasound are useful in the evaluation of horses with either suspected upper or lower airway cough.[246] Radiographs of the upper airway can demonstrate fluid accumulation, soft tissue masses, and abnormalities of pharyngeal and laryngeal structures. Ultrasound can be used to evaluate laryngeal problems such as left laryngeal hemiplegia, laryngeal dysplasia, arytenoid chondritis, and congenital malformations. Thoracic ultrasonography is a practical means of assessing the thorax and can provide diagnostic information about the pleural cavity, lung, and mediastinum. The presence and character of pleural fluid can be determined, and abnormalities such as consolidation and abscessation in the periphery of the lung can be identified. In addition, the caudal lung borders can be determined. If congestive heart failure is suspected, the heart can be evaluated by echocardiography. Thoracic radiography can identify abnormalities of the pleural space, pulmonary parenchyma, mediastinum, and diaphragm. In the lungs, pulmonary consolidation, abscesses, peribronchial disease, and interstitial disease may be evident.

Other Diagnostic Aids. Several additional diagnostic tests can be helpful in the evaluation of equine asthma, especially pulmonary function testing.[215-218,249,252] Other tests that may be useful include a hay challenge to induce disease, histamine provocation tests to assess airway reactivity, and bronchodilator response testing, typically with atropine, *N*-butylscopolammonium bromide, or albuterol. Although allergen testing has limitations in horses, it may be useful in some cases to identify specific triggers. Endobronchial biopsy specimens have also been used in the evaluation of horses with asthma.[253] Percutaneous lung biopsy, although not commonly performed, can be used to evaluate respiratory disease.[254] Both histologic and microbiologic evaluation of tissue may be useful. Lung biopsy may be particularly helpful in the diagnosis of pulmonary neoplasia, equine multinodular pulmonary fibrosis, and silicosis.

RESPIRATORY DISTRESS

Respiratory distress is defined as labored breathing and is characterized by an inappropriate degree of effort to breathe based on rate, rhythm, and subjective evaluation of respiratory effort.[255] *Dyspnea* refers to the sensation of arduous, uncomfortable, or difficult breathing that occurs when the demand for ventilation exceeds the patient's ability to respond.[256] Because dyspnea describes a subjective feeling, it is technically a symptom rather than a clinical sign and thus not strictly applicable in veterinary medicine although the term is often used. The clinical signs of respiratory distress vary with the severity and

origin of impaired gas exchange. Clinical signs commonly observed in horses with respiratory distress include flared nostrils, exercise intolerance, inactivity, exaggerated abdominal effort, abnormal respiratory noise (stertor or stridor), anxious expression, extended head and neck, and synchronous pumping of the anus with the respiratory cycle.[255,257,217] In severe cases, cyanosis may be seen. Horses with chronic respiratory distress may develop a heave line resulting from hypertrophy of the cutaneous trunci and abdominal muscles, which assist during forced expiration.[257,217] Weight loss may be seen in association with decreased feed intake and a high energy demand for respiration. In fact, it has been shown that in horses with recurrent airway obstruction (RAO), which is part of the syndrome of equine asthma, the work of breathing has the potential to approximate the energy expenditure of a horse trotting for 12 hours a day.[258,216]

Mechanisms of Respiratory Distress

Problems with both ventilation, which is the process of moving air into and out of the lungs, and respiration, which is the process of gas exchange, can impair the efficient exchange of oxygen and carbon dioxide leading to respiratory distress. Common causes of respiratory distress include primary pulmonary disease, airway obstruction, or impairment of the muscles and supporting structures necessary for ventilation.[255,256,259] In some horses, respiratory distress can occur in the absence of impaired gas exchange in response to pain, metabolic acidosis, or high environmental temperature. Familiarity with the mechanics of breathing and control of ventilation in healthy and diseased lungs facilitates the diagnosis and treatment of respiratory distress.[217,257]

Control of Ventilation

The partial pressure of oxygen (Pa_{O_2}) and the partial pressure of carbon dioxide (Pa_{CO_2}) in arterial blood are maintained within a narrow range through rigid control of gas exchange.[256] The control of ventilation is complex but essentially involves three components: (1) stimulation of sensory afferents via chemoreceptors and mechanoreceptors, (2) integration of the information in the brainstem, and (3) efferent signals to the muscles of respiration[256,260-262] (Fig. 7.3). Within the brainstem, ventilation is controlled by a complex neuronal network known as the central controller or respiratory pattern generator, which is the same neuronal network involved in the cough reflex. In response to afferent signals, the central controller alters the rate and depth of respiration via efferent signals to the muscles of respiration. The central controller therefore adjusts alveolar ventilation to the metabolic rate of the individual. Although this process is involuntary, higher brain centers can influence ventilation, and there can be voluntary, conscious control of ventilation.

Neuromuscular Physiology of Ventilation

SENSORY AFFERENTS. Afferent input into the central respiratory centers in the brainstem arises primarily from three groups of neural receptors: (1) peripheral arterial chemoreceptors, (2) central chemoreceptors in the brainstem, and (3) chemoreceptors and mechanoreceptors in the respiratory tract[260-264] (see Fig. 7.3). In addition, mechanoreceptors in the diaphragm and thoracic wall have some influence on the level and timing of ventilatory activity in response to changes in length, tension, or movement. All of these receptors collectively provide information to the central controller, resulting in the modification of ventilation.

CENTRAL AND PERIPHERAL ARTERIAL CHEMORECEPTORS. The major chemoreceptors include the central chemoreceptors in the ventral medulla of the brainstem and the peripheral chemoreceptors in the arterial vasculature.[256] These chemoreceptors identify changes in metabolism and oxygenation, providing feedback to the central controller and thus influencing ventilation.

The central chemoreceptors monitor alterations in the pH of intracerebral interstitial fluid and cerebrospinal fluid. As the blood-brain barrier is impermeable to bicarbonate and hydrogen ions but is freely permeable to carbon dioxide, acidification of the intracerebral interstitial fluid and thus stimulation of the central chemoreceptors occur predominantly in response to hypercapnia and respiratory acidosis. The severity of acidosis in the intracerebral interstitial fluid caused by hypercapnia is amplified by two features of the central nervous system: (1) hypercapnia produces cerebral vasodilation, increasing the delivery of CO_2 to the central nervous system, and (2) cerebrospinal fluid has poor buffering capacity because of low total protein concentrations.[256]

Peripheral chemoreceptors include the carotid bodies, situated at the bifurcation of the common carotid artery, and the aortic bodies, which are located near the aortic arch.[256] Carotid bodies are generally considered the primary peripheral chemoreceptor, but the aortic bodies can also influence ventilation. These receptors relay information to the central controller regarding arterial gas tensions via the glossopharyngeal and vagus nerves. Their responsiveness to alterations in Pa_{CO_2} is less consequential than the central chemoreceptors. They also can have a slight response to metabolic acidosis. The peripheral chemoreceptors are highly sensitive to changes in the partial pressure of oxygen, however, and are solely responsible for the hypoxic ventilatory drive. The peripheral chemoreceptors demonstrate a nonlinear response to low arterial oxygen tension. They are insensitive to alterations in Pa_{O_2} above 100 mm Hg, exhibit moderate response to arterial O_2 tensions between 50 and 100 mm Hg, and demonstrate a dramatic increase in responsiveness when the partial pressure of oxygen falls below 50 mm Hg in the arterial circulation.[256] The respiratory pattern elicited by hypoxia differs from that stimulated by hypercapnia.[265,266] Hypoxia evokes an increase in respiratory frequency, whereas hypercapnia triggers an elevation in tidal volume. In addition, hypoxia stimulates recruitment of the inspiratory muscles, whereas hypercapnia potentiates the activity of inspiratory and expiratory muscles.

The sensitivity of peripheral chemoreceptors should be considered in the treatment of patients with complex acid-base and blood-gas abnormalities. A patient suffering simultaneously from impaired gas exchange caused by pulmonary disease and metabolic acidosis resulting from shock can manifest respiratory distress in response to hypoxemia, hypercapnia, and acidosis. Oxygen supplementation likely will improve the patient's arterial oxygen tension; however, such treatment may abolish the hypoxic ventilatory drive and consequently slow the ventilatory rate. This decreased ventilation could exacerbate respiratory acidosis and result in decompensation of the patient.[259] Although treatment of metabolic acidosis may be indicated, it can also contribute to respiratory acidosis by ultimately increasing CO_2. Thus to prevent life-threatening acidemia, treatment of respiratory acidosis, often by assisted ventilation, may be indicated depending on the specifics of the case.

Respiratory Tract Receptors. Receptors located in the upper and lower respiratory tract respond to mechanical and

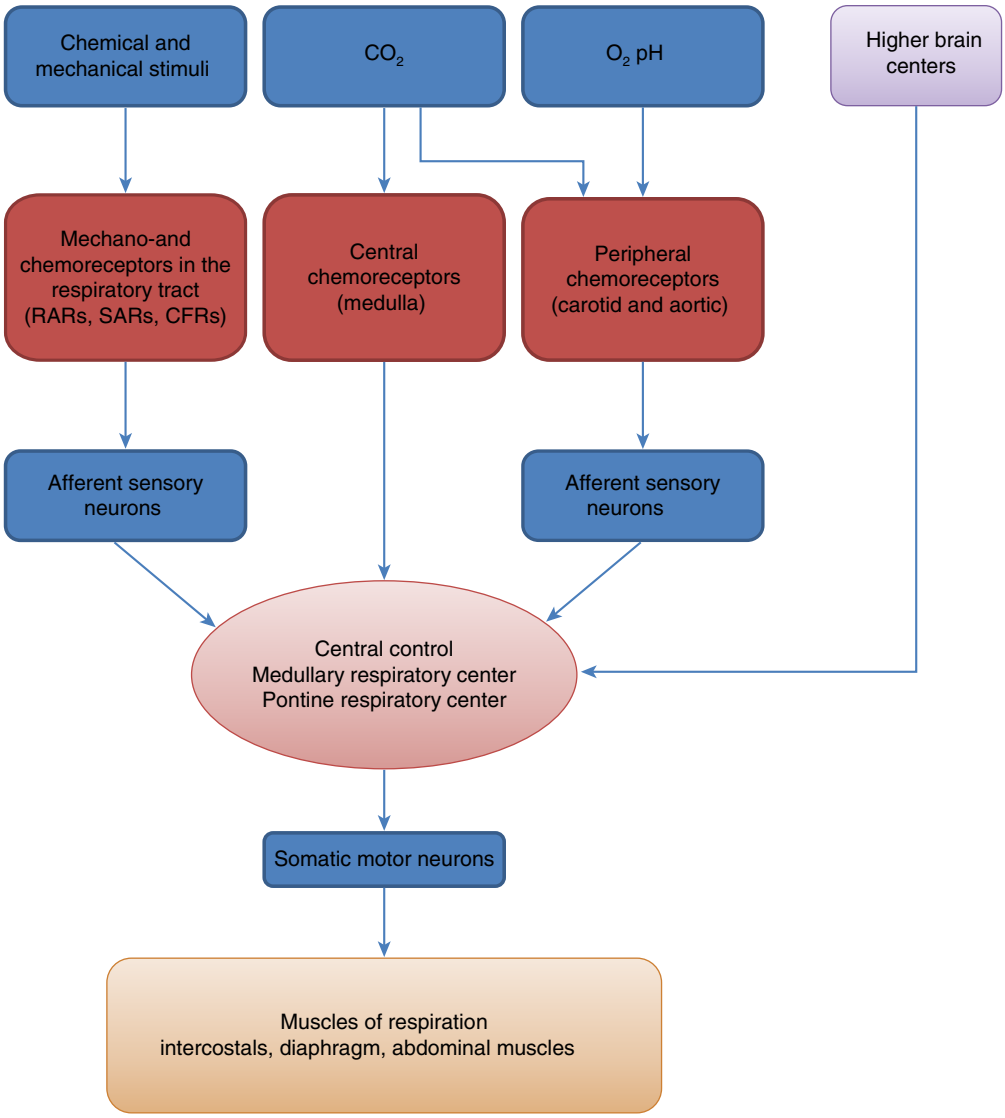

FIG. **7.3** Simplified schematic outlining the control of ventilation. *CFRs,* C-fiber receptors; *RARs,* rapid-adapting receptors; *SARs,* slow-adapting receptors.

chemical stimuli and relay afferent information to the central controller of respiration via the vagus nerve.[255,256,263,264] Vagal blockade abolishes tachypnea in horses with pulmonary disease; therefore these receptors are likely to play an important role in development of respiratory distress associated with primary pulmonary disease.[267-269]

As discussed earlier, some of the major respiratory tract receptors influencing ventilation are the *slow-adapting receptors* (SARs, slowly adapting stretch receptors), *rapid-adapting receptors* (RARs, rapidly adapting stretch receptors), and *C-fiber receptors* (CFRs).[261,263,264] These receptors also function in mucus secretion, bronchoconstriction, and the generation of cough.[180] The SARs, also known as pulmonary stretch receptors, are located primarily within smooth muscle fibers in the walls of the trachea and bronchi and are sparse in extrapulmonary airways.[256,259,263] The SARs are primarily mechanosensors and are stimulated in part by pulmonary inflation, inhibiting further inflation of the lung (Hering-Breuer reflex). Conversely, at end expiration these receptors stimulate inspiratory activity. These receptors are considered to be partially responsible for controlling the depth and rate of respiration.

The RARs are found in and under the epithelium of the respiratory tract from the nasopharynx to the bronchi, and their pattern of response varies with their location.[256,264] Although they are highly sensitive to mechanical stimuli, those in the bronchi are more chemosensitive and are sometimes referred to as *irritant receptors*. The wide variety of stimuli they may respond to include exogenous agents such as smoke, irritant gases, and dust, as well as endogenously produced inflammatory mediators, including histamine and prostaglandins. RARs are not likely to function in regulation of breathing in

a normal resting horse.[259] Stimulation of these receptors by noxious stimuli triggers bronchoconstriction, cough, tachypnea, mucus production, and release of inflammatory mediators.[255,256,180] In horses with RAO (severe equine asthma), the production of histamine, prostaglandins, and other inflammatory mediators increases, and the resulting stimulation of RARs by these inflammatory mediators may be in part responsible for the bronchoconstriction, mucus production, and tachypnea observed in horses with this disorder.[217,270-272] In addition to their role as chemoreceptors, the RARs or irritant receptors also function as mechanoreceptors throughout the airways.[263,264] An abrupt change in end-expiratory lung volume, such as occurs with pneumothorax or pleural effusion, can produce tachypnea in response to stimulation of these receptors. Increased negative pressure (upper airway obstruction) within the airway stimulates the mechanoreceptors of the larynx and produces prolongation of inspiratory time and activation of upper airway dilator muscles.[273,274]

Unmyelinated C-fibers innervate receptors found in the epithelial layer throughout the intrapulmonary and extrapulmonary respiratory tract.[256,263] C-fiber receptors are predominantly chemosensors, although they may also respond to hyperinflation of the lung. These receptors respond to pulmonary edema, congestion, and inflammatory mediators, and stimulation activates tachypnea. In addition, C-fiber receptors may stimulate the release of pulmonary neuropeptides, which produce bronchoconstriction, vasodilation, protein extravasation, and cytokine production. C-fiber receptors located within the alveolar walls in juxtaposition to pulmonary capillaries are sometimes referred to as juxtacapillary receptors. Information from other species suggests that these receptors can respond to increased interstitial fluid volume and may be involved in the sensation of difficult breathing.[256]

CENTRAL CONTROL OF VENTILATION

Brainstem Control. The mechanisms involved in the central control of ventilation are still not completely understood. The central controller of the brainstem integrates signals from the sensory afferent neurons and then initiates phasic activity of the diaphragmatic, intercostal, and abdominal respiratory muscles.[256] Although it is a complex neuronal network, the central controller consists of two basic regions with several subregions: (1) the medullary respiratory center in the reticular formation, which includes the ventral and dorsal respiratory groups, and (2) the pontine respiratory center, which includes the pneumotaxic and apneustic centers. The medullary respiratory center controls the rhythmic pattern of respiration. The dorsal respiratory group helps to coordinate inspiratory activity by assimilating afferent information from the glossopharyngeal and vagus nerves and transmitting efferent signals to the muscles of inspiration and neurons in the ventral respiratory group. The ventral respiratory group consists of inspiratory and expiratory motor neurons. One subregion, the pre-Botzinger complex, appears to have a major role in generating the basic breathing rhythm.[260-262,275] Closely associated neurons in the retrotrapezoid nucleus and parafacial respiratory group are important in regulating expiration.[275,276] The ventral respiratory group also helps to regulate ventilation during exercise. In the pontine respiratory center, the apneustic center provides stimulatory input to inspiratory motor neurons, activating and prolonging inhalation.[260-262] Damage to this region, which can result from problems such as trauma or neonatal encephalopathy, results in prolonged inspiratory gasps interrupted by transient expiratory efforts.[259] The pneumotaxic center, also in the pons, inhibits the inspiratory centers and helps to regulate the volume and rate of respiration. The pneumotaxic center is not required to maintain a normal respiratory rhythm; instead, this center functions to fine-tune the respiratory rhythm, receiving afferent input from the vagus nerve regarding Pao_2, $Paco_2$, and pulmonary inflation.

Input of Higher Brain Centers. Ventilation is primarily under involuntary control via the brainstem, but higher brain centers can also play a role.[260-262] Conditions that influence ventilation via higher brain centers include the emotional state, via input from the limbic system, and temperature, via input from the hypothalamus, as well as conscious control. Conscious or voluntary control of ventilation, which is centered in the cerebral cortex, can be overridden by the chemoreceptor reflex.

EFFECTORS OF VENTILATION. The muscles required for ventilation include the diaphragm, the external and internal intercostal muscles, and the abdominal muscles.[256] Horses have a somewhat unique biphasic inspiratory and expiratory airflow pattern in which there is both a passive and an active phase to inspiration and expiration.[277] The single most important muscle required for the inspiratory phase of the respiratory cycle is the diaphragm.[278] The relaxation volume is the static equilibrium volume of the relaxed respiratory system at which the net elastic recoil pressure is zero. In horses, the first part of inhalation following exhalation is passive until the relaxation volume is reached, at which point the diaphragm and external intercostal muscles complete the inspiratory phase. Contraction of the diaphragm forces the abdominal contents back, increasing the length of the thoracic cavity, and pulls the ribs abaxially, increasing the width of the abdominal cavity. In addition, the external intercostal muscles participate in inspiration by pulling the ribs abaxially to increase the width of the thoracic cavity. The net effect is an increase in the size of the thoracic cavity, producing subatmospheric intrathoracic pressure that drives inspiration and pulmonary inflation. In most species, expiration at rest is a passive process and relies on elastic recoil of the lung to create positive intrathoracic pressure.[256] This is the case during the first portion of expiration in horses, which relies on elastic recoil to the point of relaxation volume, when the tendency for pulmonary collapse equals the tendency for expansion by the thoracic wall. Horses then further decrease lung volume by active compression of the chest wall through contraction of the internal intercostal muscles and muscles of the abdominal wall.[278] The passive phase of inhalation follows. Dysfunction of the diaphragm and intercostal muscles due to either mechanical (abdominal distention, trauma to the thoracic wall) or neuromuscular (botulism, phrenic nerve damage, nutritional myodegeneration) problems prevents expansion of the thoracic wall and can produce hypoventilation, hypoxemia, and respiratory distress.[255,257] Horses with torsion of the large colon can develop significant abdominal distention and respiratory distress, and respiratory failure caused by impaired diaphragmatic function can play an important role in the pathophysiology and mortality associated with this intestinal accident.

Control of Airway Diameter

The diameter of the conducting airways, which is primarily controlled by the autonomic nervous system, is an important determinant of the degree of pulmonary resistance and work of breathing.[256] The control of airway diameter by the autonomic nervous system involves both sympathetic and

parasympathetic innervation with activation of adrenergic and muscarinic receptors, respectively.[256,279-281] The receptors are generally widely expressed in the lung, although the pattern of specific receptor expression can vary among species. The control of normal airway function and airway diameter is complex, requiring interactions or "crosstalk" between receptors. Vagal-mediated parasympathetic stimulation is important in the regulation of airway smooth muscle tone, and stimulation can cause bronchoconstriction as well as mucus secretion and bronchial vasodilation. Specifically, bronchoconstriction can occur due to the action of acetylcholine from parasympathetic fibers on M3 muscarinic receptors located on airway smooth muscle. This mechanism of bronchoconstriction has been associated with allergic airway disease in several species. The administration of anticholinergics such as atropine or *N*-butylscopolammonium bromide can result in rapid relief of bronchoconstriction in some horses with RAO, demonstrating the important role of parasympathetic bronchoconstriction in the pathogenesis of this disorder.[257,259,282,283] With regard to sympathetic effects, both α- and β-adrenergic receptors are found in the lung.[28-30] However, direct sympathetic innervation of airway smooth muscle is minimal to none, and thus stimulation of the adrenergic receptors is primarily via circulating catecholamines.[279-281] β_2-Adrenergic receptors are abundant throughout the lung on multiple cell types, including bronchial smooth muscle, bronchial epithelial cells, and several immune cells, and thus activation can have multiple effects. The stimulation of β_2-receptors on airway smooth muscle can cause smooth muscle relaxation and bronchodilation. Airways must be constricted for β_2-receptor stimulation or the anticholinergic action of atropine to increase airway diameter.[284,285] β_2-Receptors appear to be present in normal or increased numbers on asthmatic airway smooth muscle but appear to be hyporesponsive, thus allowing bronchoconstriction.[281,286] β_1-Adrenergic receptors are less abundant than β_2-receptors in the airways. The effects of both β_1- and α_1-adrenergic receptors in the regulation of airway diameter in horses appear to be minimal.[285-287]

Nonadrenergic-noncholinergic (NANC) innervation, including both excitatory and inhibitory components, also contributes to large airway diameter.[288,289] Stimulation of excitatory NANC nerves initiates a process of neurogenic inflammation that involves bronchoconstriction, mucus secretion, increased vascular permeability, vasodilation, and cough. Inhibitory NANC nerves appear to be important neural pathways for bronchodilation, and activation results in the relaxation of smooth muscles of the trachea and bronchi. Dysfunction of the NANC system may play a role in asthma in both people and horses, although the precise role remains to be elucidated. In RAO-affected horses with clinical signs of airway obstruction, inhibitory NANC function is absent.[290] Failure of the inhibitory NANC system may result from the inflammatory response during acute RAO or may be an inherent autonomic dysfunction of the conducting airways of RAO-affected horses.

Role of Hypoxemia and Hypercapnia in Respiratory Distress

Respiratory distress most often originates from inadequate pulmonary gas exchange to meet the metabolic demands of the individual, resulting in hypoxemia and hypercapnia. Hypoxemia results from one or more of five basic pathophysiologic mechanisms: hypoventilation, ventilation-perfusion mismatch, right-to-left shunting of blood, diffusion impairment, and reduced inspired oxygen concentration.[256] The degree of associated hypercapnia and the response to oxygen supplementation vary depending on the mechanism of impaired gas exchange, and determination of these two parameters is useful in defining the pathophysiologic process predominantly responsible for the development of hypoxemia.[256]

Hypoventilation. *Alveolar hypoventilation* is defined as insufficient ventilation leading to hypercapnia.[256] The elevation in $Paco_2$ is inversely proportional to the reduction in alveolar ventilation; halving alveolar ventilation doubles $Paco_2$.[256] The reduction in arterial oxygen tension is almost directly proportional to the increase in CO_2. For instance, if $Paco_2$ increases from 40 to 80 mm Hg, the Pao_2 decreases from 100 to 60 mm Hg. Therefore hypoxemia resulting from hypoventilation is rarely life threatening. In addition, oxygen supplementation easily abolishes hypoxemia caused by pure hypoventilation. Acidosis caused by hypercapnia is the most clinically significant feature of hypoventilation and may be life threatening.[256] Metabolic alkalosis or central nervous system depression (e.g., from head trauma, encephalitis, narcotic drugs) can produce hypoventilation; however, horses with these disorders may not demonstrate clinical signs of respiratory distress. Disorders that can cause alveolar hypoventilation that are often associated with clinical signs of respiratory distress include dysfunction of the respiratory muscles from mechanical (abdominal distention, trauma to the thoracic wall) or neuromuscular (botulism, phrenic nerve damage, nutritional myodegeneration) conditions, restrictive pulmonary disease (silicosis, pulmonary fibrosis, pneumothorax, pleural effusion), and upper airway obstruction.[255,257,259]

Ventilation-Perfusion Mismatch. Ventilation-perfusion (V-Q) mismatch is the most common cause of hypoxemia and is characterized by unequal distribution of alveolar ventilation and blood flow.[256,259] Either a low or high V-Q ratio can result in hypoxemia. Pulmonary regions that are overperfused in relation to ventilation (low V-Q ratio) contribute disproportionate amounts of blood with low arterial oxygen content to the systemic circulation.[256] Respiratory diseases characterized by low V-Q ratios include RAO, pulmonary atelectasis, and consolidation.[259] If ventilation exceeds perfusion (high V-Q ratio), the ventilated pulmonary units are inefficient for CO_2 elimination and O_2 uptake. Ventilation of poorly or nonperfused units is wasted ventilation, termed *alveolar dead space.*[256] Conditions associated with high V-Q ratios include pulmonary thromboembolism and shock (low pulmonary artery pressure). Patients with V-Q mismatch often have a normal arterial Pco_2. The ventilatory drive to maintain normal $Paco_2$ is powerful, and as the CO_2 dissociation curve is basically a straight line (direct relationship), increased ventilation efficiently decreases $Paco_2$ at high and low V-Q ratios. However, also due to the nearly flat shape of the O_2 dissociation curve, increasing ventilation is inefficient for proportionally increasing the arterial Po_2. Only pulmonary units with moderate to low V-Q ratios benefit from increased ventilation. Therefore the increased ventilatory effort to maintain normal $Paco_2$ is wasted and unnecessarily increases the work of breathing. Oxygen supplementation tends to increase $Paco_2$ in patients with a V-Q mismatch. Also, elevation in arterial O_2 is delayed compared with hypoventilation and in some cases may be incomplete.[256] Compensatory mechanisms are present to minimize unequal distribution of ventilation and perfusion in diseased lungs to prevent the development of hypoxemia

until the pulmonary pathologic condition is severe.[256] Reflex pulmonary arterial constriction (hypoxic vasoconstriction) prevents perfusion of unventilated alveolar units and attempts to redirect blood flow to alveoli that are ventilated adequately. Airway hypocapnia causes bronchoconstriction of airways that conduct to unperfused alveolar units, redirecting air flow to better perfused alveoli.

Shunt. *Shunt* is defined as blood that is not exposed to ventilated areas of the lung and is added to the arteries of the systemic circulation.[256] Shunting can occur as an extreme form of V-Q mismatch or with direct addition of unoxygenated blood to the arterial system. *Physiologic shunting* is defined as perfusion of nonventilated or collapsed regions of the lung and occurs with pulmonary consolidation, atelectasis, and edema. Certain congenital heart diseases, such as tetralogy of Fallot and some cardiac septal defects, are examples of direct right-to-left shunts wherein unoxygenated blood from the right side of the heart is added to oxygenated blood from the left side of the heart. Right-to-left shunting may also contribute to hypoxemia in some cases of persistent pulmonary hypertension. In these conditions hypoxemia cannot be abolished by increasing the oxygen content of inspired air. The shunted blood is never exposed to the higher concentration of inspired oxygen in the alveolus, and the addition of a small amount of shunted blood with its low O_2 content greatly reduces the P_{O_2} of arterial blood. Compared with breathing room air, the decrement in P_{O_2} is much greater at P_{O_2} levels associated with the inhalation of O_2-enriched air because the O_2 dissociation curve is so flat at high P_{O_2} levels. Only hypoxemia caused by right-to-left shunting behaves in this manner when the patient is permitted to inspire high percentages of oxygen (70%–100%). Shunts do not usually cause hypercapnia.[256] Chemoreceptors detect excess arterial CO_2, and ventilation increases to reduce the content of CO_2 in unshunted blood until arterial P_{CO_2} reaches the normal range. In some cases of shunt the arterial P_{CO_2} is below normal because of hyperventilation stimulated by the hypoxemic ventilatory drive.

Diffusion Impairment. Gas exchange between the alveolus and the capillary occurs by passive diffusion, which is driven by the property of molecules to move randomly from an area of high concentration to one of low concentration.[256] Factors that determine the rate of gas exchange include the concentration gradient between the alveolus and capillary blood, solubility of the gas, surface area available for diffusion, and width of the air-blood barrier. Diseases characterized by pure diffusion impairment are rare in veterinary medicine.[259] However, some degree of diffusion impairment can occur with disorders such as pulmonary fibrosis, interstitial pneumonia, silicosis, or pulmonary edema and is most often associated with increased width of the barrier or decreased surface area available for gas exchange. Although the major component of hypoxemia in these conditions is a V-Q mismatch, diffusion impairment can contribute to the severity of hypoxemia. Supplemental oxygen therapy is effective in treating hypoxemia caused by diffusion impairment because it creates a more favorable concentration gradient and increases the driving pressure of oxygen to move from the alveolus into the blood. Transport of CO_2 is less affected by diseases of diffusion impairment because of its greater solubility compared with O_2.[256]

Reduction of Inspired Oxygen. Hypoxemia resulting from decreased inspired oxygen content is uncommon and occurs only under special circumstances. High altitude and iatrogenic ventilation with a low oxygen concentration are the most common circumstances in which hypoxemia is attributed to reduction of inspired oxygen content.[256]

Most pulmonary diseases in horses incorporate more than one of these pathophysiologic mechanisms for the development of hypoxemia. Horses with pleuropneumonia, for example, may develop hypoxemia caused by hypoventilation (extrapulmonary restriction by pleural effusion), V-Q mismatch (accumulation of exudate and edema within alveoli and conducting airways), and diffusion impairment (exudate and edema within the interstitial spaces).

Role of Obstructive Disease in Respiratory Distress

Airway obstruction can limit air flow and contribute to respiratory distress. The location (intrathoracic or extrathoracic) and nature (fixed or dynamic) of airway obstruction determine whether impedance to air flow occurs during inspiration, expiration, or both.[257] The phase of the respiratory cycle that is affected by air flow obstruction is prolonged and may be associated with a respiratory noise (stertor, stridor, or wheeze).[256,257,291]

The horse is an obligate nasal breather and can breathe efficiently only through the nares.[259] Therefore upper airway obstruction within the nasal passages cannot be bypassed by mouth breathing. In addition, approximately 80% of the total airway resistance to air flow is located in the upper airway.[291] A 50% decrease in the radius of an airway increases its resistance by 16 times (Poiseuille's law).[256] Therefore small changes in the upper airway diameter dramatically affect the overall resistance to air flow and work of breathing for the horse. Extrathoracic airway pressures are subatmospheric during inspiration; therefore poorly supported structures in the upper airway narrow or collapse during inspiration (dynamic collapse). There are several causes of upper airway obstruction in horses, the most common being laryngeal hemiplegia.

Of the total airway resistance 20% is attributable to the small airways.[291] Although the radius of individual bronchioles is small, many of them exist and the sum or collective radius is large, with the result that their overall contribution to pulmonary resistance is low.[256] Because the resistance of the bronchioles is low, advanced disease must be present for routine measurements of airway resistance to detect an abnormality, and obstruction of these airways must be extensive before a horse would suffer from respiratory distress. During pulmonary inflation intrathoracic pressures are subatmospheric. Small airways are pulled open by negative intrathoracic pressure and stretched parenchymal attachments at high lung volumes. Thus resistance to air flow in small airways is low during the inspiratory phase of respiration.[256] During exhalation intrathoracic pressure is positive and the diameter of small airways is decreased, and bronchioles may even close at low lung volumes. Therefore resistance to air flow in small airways is greatest during the expiratory phase. In horses with RAO the airway diameter is reduced by inflammatory exudate, edema, and bronchoconstriction.[257,259,290] As lung volume decreases during expiration, the narrowed bronchioles are compressed shut (dynamic airway collapse) and trap air distal to the site of closure.[259] This is an example of severe flow limitation, which may lead ultimately to the development of emphysema. Flow limitation forces horses with RAO to breathe at higher lung volumes and maintain a higher functional residual capacity to reduce or prevent dynamic airway collapse. Affected horses

attempt to reduce the end-expiratory lung volume by recruiting abdominal muscles to increase the intrathoracic pressures during expiration. However, the greater the end-expiratory pressure, the greater is the likelihood of small airway compression and collapse. Hypertrophy of the cutaneous trunci and expiratory abdominal muscles, especially the external abdominal oblique, produces the characteristic "heave line" associated with RAO.[259] Because dynamic airway narrowing and collapse occur during exhalation, wheezes are typically loudest at end expiration in horses with RAO.[257,259]

Role of Restrictive Disease in Respiratory Distress

Restrictive disease is less common than obstructive pulmonary disease in horses.[259] By definition, restrictive disease inhibits pulmonary expansion and leads to inspiratory respiratory distress.[256] The vital capacity and compliance (pulmonary or chest wall) decrease, expiratory flow rates and elastic recoil increase, and airway resistance is normal. The characteristic respiratory pattern in horses with restrictive pulmonary disease is rapid, shallow respiration at low lung volumes.[259] This strategy takes advantage of high pulmonary compliance at low lung volumes and decreases the work of breathing. This respiratory pattern has the disadvantage of increased ventilation of anatomic dead space.[256] Restrictive diseases may be classified as intrapulmonary (pulmonary fibrosis, silicosis, and interstitial pneumonia) and extrapulmonary (pleural effusion, pneumothorax, mediastinal mass, botulism, and nutritional myodegeneration).[255,259] Hypoxemia observed in horses with intrapulmonary restrictive disease is largely attributed to V-Q mismatch and diffusion impairment, although hypoventilation may also have a role. Stimulation of juxtacapillary receptors may contribute to respiratory distress observed in these patients.[256] The pathophysiologic mechanism for hypoxemia in horses with extrapulmonary restriction is hypoventilation.[259] In horses with pleural effusion and pneumothorax, respiratory distress is likely to be exacerbated by thoracic pain.

Nonpulmonary Respiratory Distress

Respiratory distress does not always originate from dysfunction of the pulmonary system and its supporting structures. Nonpulmonary respiratory distress can occur because of inadequate oxygen-carrying capacity of the blood, pain, hyperthermia, or compensation for metabolic acidosis.[255-257]

Impaired oxygen-carrying capacity of the blood may occur because of anemia (blood loss, hemolytic, or aplastic) or dysfunction of red blood cells (methemoglobinemia, carbon monoxide toxicity). In these cases the arterial Po_2 tension (quantity of dissolved oxygen) is normal; however, the total oxygen content of the blood is reduced greatly.[256] Tachypnea and respiratory distress occur in response to impaired oxygen delivery and tissue hypoxia.

The respiratory system can compensate for metabolic acidosis by increasing ventilation to lower $Paco_2$ and attenuate acidemia.[256] The ventilatory drive increases in response to stimulation by peripheral chemoreceptors by circulating hydrogen ions. Hypocarbic compensation for mild to moderate metabolic acidosis is effective in returning blood pH to normal until renal compensatory mechanisms can be established.[256]

Pain and anxiety are physiologic causes of tachypnea and hyperpnea. Horses with musculoskeletal pain are unlikely to demonstrate significant respiratory distress; however, rhabdomyolysis and laminitis are painful musculoskeletal conditions that may produce tachypnea.[257] Marked respiratory distress is observed frequently in horses with abdominal pain; however, the respiratory distress is not caused solely by pain and is exacerbated by abdominal distention, shock, acidosis, and endotoxemia.

Elevations in body temperature caused by fever or hyperthermia associated with exercise, heat stroke, anhidrosis, or macrolide-induced hyperthermia can produce respiratory distress in horses. Hyperpnea is an effective means of heat dissipation in human beings, dogs, and ruminants.[257] Unfortunately, in horses increased ventilation is an inefficient mechanism for heat dissipation.[257,259]

Conditions Associated with Respiratory Distress

A number of conditions, both respiratory and nonrespiratory in origin, can cause some degree of respiratory distress in horses (Box 7.5). Among the more common respiratory causes are infectious conditions. In particular, bacterial infections of the respiratory tract such as bacterial pneumonia, aspiration pneumonia, pleuropneumonia, pleuritis, and pulmonary abscessation can result in respiratory distress.[206,207] Strangles can result in respiratory distress in association with airway obstruction from lymph node abscessation and less frequently due to pneumonia. Viral respiratory tract infections, which are common in horses, may sometimes result in respiratory distress.[204] Fungal pneumonia can result in significant respiratory distress in some patients but is uncommon in horses.[209,210] Respiratory distress is often a prominent feature of syndromes of interstitial pneumonia, including acute lung injury, acute respiratory distress, and equine multinodular pulmonary fibrosis.[211,212,292,293] In neonatal foals, immature lungs and lack of surfactant can contribute to respiratory distress.[294] Idiopathic or transient tachypnea has been reported in neonatal foals, especially in Clydesdales, Thoroughbreds, and Arabians.[294] RAO is a common condition in horses that has the potential to cause significant respiratory distress, both in association with acute exacerbations of the condition and with chronic disease.[215,216,217,218,290] Some other respiratory problems that can be associated with respiratory distress include exercise-induced pulmonary hemorrhage, eosinophilic pulmonary disease, silicosis, smoke inhalation, and neoplasia.[213,214,223,226,227,295-297]

Upper airway obstruction is another important cause of respiratory distress in horses, especially when oxygen demand is increased by exercise.[255,257,259] The most common cause of non–fixed upper airway obstruction in horses is laryngeal hemiplegia, which produces inspiratory stridor during exercise.[257,298-300] Intraluminal masses and arytenoid chondritis cause fixed upper airway obstruction and produce inspiratory and expiratory respiratory distress.[257] Several other upper airway abnormalities have been documented, such as fourth branchial arch defect, subepiglottic cyst, aryepiglottic fold entrapment, and dorsal displacement of the soft palate.[257,301] Laryngeal and pharyngeal dysfunction has been reported in horses that are homozygous for hyperkalemic periodic paralysis.[302,303] Infrequently, laryngeal paralysis has been associated with hepatic dysfunction.[304] A wide variety of other conditions have been associated with respiratory distress such as pneumothorax, diaphragmatic hernia, choanal atresia, nasopharyngeal cicatrix syndrome, tracheal collapse, and others.[233-235,305,306] Although heart disease is relatively uncommon in horses, it may result in respiratory distress via pulmonary

BOX 7.5 Causes of Respiratory Distress

RESPIRATORY CAUSES

- Respiratory tract infection
  - Bacterial pneumonia, pleuropneumonia (including aspiration, pulmonary abscesses)
  - Strangles
  - Viral respiratory tract infection
  - Fungal respiratory tract infection
- Interstitial pneumonia
  - Equine multinodular pulmonary fibrosis
  - Syndromes of acute lung injury, acute respiratory distress
- Recurrent airway obstruction (severe asthma)
- Upper airway obstruction
  - Left laryngeal hemiplegia
  - Arytenoid chondritis
  - Fourth branchial arch defect
  - Subepiglottic cyst
  - Dorsal displacement of the soft palate
  - Aryepiglottic fold entrapment
  - Intraluminal masses, abscessation (strangles, other)
  - Laryngeal and pharyngeal dysfunction associated with HYPP
  - Choanal atresia
  - Nasopharyngeal cicatrix syndrome
- Exercise-induced pulmonary hemorrhage
- Pneumothorax
- Diaphragmatic hernia
- Tracheal abnormalities
  - Tracheal collapse, stenosis
  - Foreign body
  - Intraluminal mass
- Cardiac disease
  - Pulmonary edema
  - Left-to-right shunting
- Other
  - Silicosis
  - Smoke inhalation
  - Neoplasia
  - Eosinophilic pulmonary disease
  - *Crotolaria equorum*—pyrrolizidine alkaloid toxicity
- Additional causes in foals
  - Inadequate surfactant, pulmonary immaturity
  - Idiopathic tachypnea (transient)

NONRESPIRATORY CAUSES

- Systemic inflammatory response syndrome
- Pain
- Elevated body temperature
- Fever
- Hyperthermia
  - Exercise-related hyperthermia
  - Heat stroke
  - Anhidrosis
  - CNS disorders
  - Macrolide-induced hyperthermia
- Anemia
- Monensin
- Snake envenomation
- Neuroborreliosis

edema or right-to-left shunting.[229,230] Respiratory distress is a prominent sign of a rare form of pyrollizidine alkaloid toxicity associated with *Crotolaria equorum*.[307]

Several nonrespiratory conditions can also cause respiratory distress. Respiratory distress is often a feature of the systemic inflammatory response syndrome.[255,257] Pain, fever, or hyperthermia may lead to respiratory distress. Tachypnea and elevation in body temperature are the most prominent clinical signs in horses with anhidrosis.[16] Other nonrespiratory causes of respiratory distress include disorders that cause anemia, such as blood loss, autoimmune hemolytic activity, neonatal isoerythrolysis, and red maple toxicosis. In addition to red maple, other toxins that can affect respiration include monensin and snake envenomization. Episodic respiratory distress was seen in 5 of 16 horses diagnosed with neuroborreliosis.[308]

Approach to Respiratory Distress

Signalment and History

Both breed and age have been linked with specific causes of respiratory distress. For example, American Miniature Horses are at increased risk of tracheal collapse.[233] Idiopathic laryngeal hemiplegia is more common in large, long-necked horses such as draft horses, Thoroughbreds, and Warmbloods.[298,299] In Quarter Horses and related breeds, some foals affected with hyperkalemic periodic paralysis will show signs of respiratory stertor usually within the first week of life as a result of laryngeal dysfunction, especially if homozygous.[302,303] Inadequate lung development, surfactant deficiency, persistent pulmonary hypertension, and meconium aspiration are problems unique to neonatal foals.[294] Congenital problems such as choanal atresia and cardiac defects should also be considered in neonates. Rhodococcal pneumonia is primarily a disease of foals 1 to 6 months of age.[207] Horses affected with RAO are generally over 7 years of age, and a familial predisposition has been identified.[215,216]

Some important historical considerations include environmental conditions such as heat and humidity and relocation to high altitude. A history of recent transport may raise the index of suspicion for pleuropneumonia. Useful information can also be obtained from specifics related to the respiratory distress such as the speed of onset, progression of signs, history of previous episodes, and association with exercise or specific locations/housing. Any history of recent trauma or potential exposure to toxins should be determined. A history of any other problems such as cough, nasal discharge, dysphagia, anorexia, or lethargy can also be important.

In neonatal foals, the circumstances of gestation and parturition can help to establish the likelihood of problems such as immaturity, rib fractures, meconium aspiration, and sepsis.

Physical Examination

A thorough physical examination is essential to determine the origin of respiratory distress, identify concurrent disease, and direct further diagnostic testing. Prolonged inspiration is consistent with restrictive or extrathoracic, nonfixed, obstructive disease, whereas horses with intrathoracic airway obstruction exhibit expiratory difficulty.[256,257] Respiratory distress

associated with inspiration and expiration may indicate an extrathoracic fixed obstruction. Stertor is a low-pitched, "snoring" respiratory noise caused by partial obstruction above the larynx and is inspiratory. In comparison, stridor is a more musical sound that is generated by obstruction of the larynx and less frequently the trachea or bronchi. Stridor can be heard during inspiration and/or expiration but is most often audible during inspiration.[257]

Thoracic auscultation identifies abnormal respiratory sounds (crackles and wheezes) or regions of decreased breath sounds caused by pleural effusion, pneumothorax, or pulmonary consolidation.[259,308] Percussion of the thoracic wall generates a resonant and hollow sound when performed over regions of normal lung. Pleural effusion and pulmonary consolidation sound dull and flat during thoracic percussion, whereas pneumothorax produces a hyperresonant sound.[246,259]

Normal air flow occurs in laminar flow; therefore normal horses at rest do not generate easily audible sounds.[259] If the horse is not in significant distress, auscultation with a rebreathing bag can help enhance sounds by increasing tidal volume. Respiratory sounds are generated from vibration in tissue and sudden changes in pressure of gas moving within the airway lumen. Airway narrowing and exudate generate audible sounds by creating disturbances in laminar flow, turbulence, and sudden changes in pressure of moving gas.[256] Crackles are intermittent or explosive sounds, generated by bubbling of air through secretions or by equilibration of airway pressures after sudden opening of collapsed small airways. The generation of crackles requires an air-fluid interface, and these abnormal lung sounds occur in horses with pneumonia, interstitial fibrosis, RAO, pulmonary edema, and atelectasis.[246,259] Wheezes are continuous, musical sounds that originate from oscillation of small airway walls before complete closing (expiratory wheeze) or opening (inspiratory wheeze).[256] Expiratory wheezes are the hallmark of obstructive pulmonary disease.[256]

Horses with nonpulmonary respiratory distress demonstrate increased rate and/or depth of respiration without producing abnormal respiratory noise. Stertor and stridor are absent, and auscultation of the thorax is normal.

Ancillary Diagnostic Tests

Clinical Pathology

BLOOD WORK. A CBC and fibrinogen can help to evaluate hemoconcentration, anemia, and the presence of inflammation. Serum amyloid A can also be used in the assessment of inflammation.

Arterial blood gas analysis provides a quantitative evaluation of pulmonary function, alveolar ventilation, and acid-base status and may identify the origin of respiratory distress (hypercapnia, hypoxemia, or acidemia).[256] The clinician may determine the pathophysiologic mechanism of hypoxemia by examining the $Paco_2$ level and by investigating the response of Pao_2 to supplemental oxygen therapy. In addition, serial blood gas monitoring can determine response to bronchodilator, parasympathomimetic, or anti-inflammatory therapy.

Airway Cytology/Assessment of Infection. Appropriate samples for cytologic evaluation and culture can be obtained from the respiratory tract depending on the primary differential diagnoses.[240,241,246] The degree of respiratory distress should be considered, as some diagnostic procedures can be stressful in horses with significant respiratory distress, especially foals. Currently, for most viral respiratory tract infections, the most common means of diagnosis is detection of viral genetic material by PCR from a nasal or nasopharyngeal swab. For strangles, PCR and/or culture of a nasal or nasopharyngeal swab, nasal wash, guttural pouch wash, or abscess can be diagnostic. Several techniques have been described for sampling the lower airways of horses including transtracheal aspiration, bronchoalveolar lavage, and various transendoscopic procedures. Thoracocentesis can be useful in cases of suspected pleuropneumonia and in some cases of suspected neoplasia. For the diagnosis of RAO, cytologic analysis of bronchoalveolar lavage fluid is recommended and is typically characterized by a significant increase in neutrophils (greater than 25%). Bronchoalveolar lavage can also be helpful in the evaluation of suspected EIPH.

Endoscopy. An endoscopic examination of the upper airway is indicated in horses with stertor or stridor and suspected upper airway obstruction.[246,259] Endoscopy can be used to evaluate the trachea and can help to identify tracheal collapse, foreign bodies, mucus, or hemorrhage. Horses with extreme respiratory distress may resent endoscopic examination, and forced examination may precipitate a respiratory crisis.

Diagnostic Imaging. The findings during thoracic auscultation and percussion are valuable in determining whether ultrasonography rather than radiography is indicated.[246,259] Pulmonary consolidation, abscessation, fibrosis, interstitial pneumonia, peribronchial infiltration, and mediastinal masses are typically imaged best via thoracic radiography. Thoracic ultrasonography is superior to radiography in detecting and characterizing pleural fluid and peripheral pulmonary abscessation and consolidation in horses.[309] Air reflects the ultrasound beam; therefore ultrasonography does not image deep pulmonary lesions if the overlying lung is aerated.

Other Diagnostic Aids. The administration of atropine or *N*-butylscopolammonium bromide in horses with RAO may provide rapid relief of respiratory distress if the major component of airway obstruction is reversible bronchoconstriction.[282] The bronchodilatory properties of *N*-butylscopolammonium bromide appear to be similar to those of atropine, although of shorter duration and associated with fewer systemic side effects.[283] Horses that respond to an atropine or *N*-butylscopolammonium bromide challenge likely will respond favorably to bronchodilator therapy. Incomplete response to these bronchodilators in horses with RAO indicates that exudate or fibrosis is contributing to airway obstruction, and limited response to bronchodilator therapy is anticipated.[257,259] Other tests that may be of value in the assessment of equine asthma include a hay challenge, histamine provocation test, and pulmonary function testing.

Both endobronchial and percutaneous lung biopsies may be used in the diagnosis of respiratory disease but are not commonly performed.[253,254] In horses with suspected anhidrosis, a terbutaline sweat test can be used to evaluate the patient's ability to sweat.[67]

EDEMA

Edema is defined as the excessive and abnormal accumulation of fluid in the interstitium, which is the intercellular connective tissue that lies between the cellular elements of tissues.[310,311] Interstitial fluid accumulates as a result of imbalances between the rates at which fluid enters and exits the interstitium. Factors that either increase the rate of fluid flux from the capillary or impair reabsorption and lymph drainage to the extent that

normal compensatory mechanisms are overwhelmed result in the accumulation of fluid in the interstitial space and the development of edema.

Edema is often classified according to the anatomic location. The most frequently recognized type of edema in horses is peripheral edema, which is often seen in the limbs or along the ventrum. Most peripheral edema is "pitting," which means that an indentation persists after pressure is applied to an area and released—for example, using the tip of a finger to indent the fluid. Occasionally nonpitting peripheral edema will be recognized, which in horses is most often associated with lymphedema, which is fluid retained in the interstitium as a result of impaired lymphatic drainage. Organ-specific edema, such as cerebral, pulmonary, and corneal edema, also occurs and is often clinically important. Generalized edema occurs when edema is present both peripherally and in multiple organs.

General Physiology of Fluid Movement

The volume of interstitial fluid and lymph fluid in the normal horse is 8% to 10% of body mass,[310] or 36 to 45 L in a 450-kg horse. Interstitial fluid consists largely of water, protein, and electrolytes. Compared with plasma, interstitial fluid has a slightly lower concentration of cationic electrolytes, a slightly higher concentration of chloride, and a much lower concentration of protein (1.2 vs. 0.2 mOsm/L of water).[311] The overall amount and function of the proteins within the interstitial space are not inconsequential. A constant circulation of plasma proteins occurs between the vascular and interstitial spaces, with about half of the protein circulating every 24 hours in human beings. More than half of the plasma protein content of the body is contained within the interstitial space at any one time. Plasma proteins within the interstitial space are important in the transport of water-insoluble substances from the vascular space and in resistance to infection.[312]

The extracellular tissue of the interstitium, except in the case of bone, consists of a three-dimensional collagen fiber network embedded in a proteoglycan gel matrix.[313] Normally most of the interstitial water is contained within the proteoglycan interstitial gel, with a small proportion existing as free water. However, in edematous states, the proportion of fluid as free water within the interstitium increases.[311]

The source of interstitial fluid is the intravascular space. The volume of interstitial fluid is determined by the functional relationships of three major anatomic structures: the capillary, the interstitial space, and the lymphatics.[314] Functionally, the volume of fluid that accumulates in the interstitium is determined by the rate of ingress of fluid from the vascular space, the compliance of the interstitium, and the rate at which fluid is evacuated from the interstitium.

Traditionally the fundamental principle guiding microvascular filtration and transcapillary fluid shifts has been defined by the Starling equation, first introduced in 1896. In this model, fluid movement is passive and dependent on pressure gradients across the endothelium, which are determined by hydrostatic and colloid osmotic pressures.[311,315] However, it is now recognized that the regulation of fluid flux is not simply governed by transcapillary hydrostatic and oncotic pressure differences but is much more complex. The role of non-Starling mechanisms of barrier regulation and fluid movement are an area of active investigation. Important factors that mediate processes central to the development of edema include the endothelial glycocalyx layer, the endothelial basement membrane, and selective water channels known as *aquaporins*.[312,316-319]

The Starling Equation

The net rate of ingress of fluid from capillaries into the interstitium is determined by a number of factors acting across the capillary membrane, the effects of which are related by Starling's equation:

$$J = Kf\left([P_c - P_t] - \sigma\left[\pi_p - \pi_t\right]\right)$$

in which J equals the volume flow across the capillary wall; Kf equals the filtration coefficient of the capillary wall (volume flow per unit time per 100 g of tissue per unit pressure); P_c equals capillary hydrostatic pressure; P_t equals interstitial fluid hydrostatic pressure; σ equals the osmotic reflection coefficient; π_p equals the colloid osmotic (oncotic) pressure of the plasma; and π_t equals the colloid osmotic (oncotic) pressure of the interstitial fluid.[315] Although all these factors act in concert to determine the rate of net fluid efflux from the capillary, considering them individually is conceptually easier.

Filtration *(Kf)* and Reflection (σ) Coefficients. Together the filtration and reflection coefficients describe the properties of the capillary membrane that determine the ease with which water, protein, and other plasma constituents move from the vascular space to the interstitium. The filtration coefficient, which is the product of the hydraulic permeability and surface area of the capillary, is a measure of the ease with which water crosses the capillary membrane. The reflection coefficient is a mathematical expression of the capillary permeability to a particular substance and ranges from 0, indicating the substance crosses the membrane as easily as water, to 1, indicating that the substance does not cross the membrane. The reflection coefficient is dependent on both the substance in question and the tissue bed.[311,320,321] For example, in lung endothelium, the reflection coefficients for urea, glucose and albumin are approximately 0.3, 0.5, and 0.7. Reflection coefficients for albumin vary among tissues, being 0.1 in the hepatic sinusoids, 0.9 in muscle, and 0.99 in brain.

The filtration and reflection coefficients together partially determine the rate of fluid flux across the capillary wall and the composition of the fluid. For a given hydrostatic and oncotic pressure difference, tissues with higher filtration coefficients (whether because of a larger capillary surface area or more porous capillaries) will have a greater fluid flux. Conversely, under the same circumstance, increases in the reflection coefficient will reduce solute movement across the capillary wall, affecting the osmotic pressure gradient and reducing fluid flux. The differential permeability of the capillary membrane to water and protein has important consequences in the maintenance of the oncotic pressure difference between plasma and interstitial fluid. Multiple factors influence the movement of fluid and solutes across the endothelium, including the concentration of the solutes on either side of the membrane, solute charge and interaction with other solutes, and capillary pore configuration.[322]

Hydrostatic and Colloid Osmotic Pressures (Starling's Forces). Transcapillary fluid flow results from an imbalance between the hydraulic forces favoring movement of water from the capillary into the interstitium and the forces favoring movement of water in the reverse direction. The forces contributing to fluid movement out of the capillary are the intracapillary hydrostatic pressure and the interstitial colloid

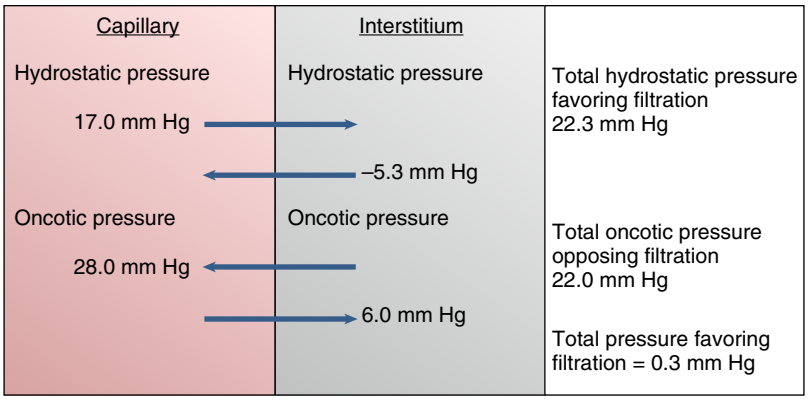

FIG. **7.4** Basic Starling's forces—mean forces influencing fluid movement into or out of the capillary. (From Guyton AC, Hall JE: The microcirculation and the lymphatic system: capillary fluid exchange, interstitial fluid and lymph flow. The body fluid compartments: extracellular and intracellular fluids; interstitial fluid and edema. In Guyton AC, Hall JE, editors: *Textbook of medical physiology,* ed 11, Philadelphia: Elsevier/Saunders; 2006.)

osmotic pressure, whereas those forces favoring movement of fluid from the interstitium to the capillary are the interstitial hydrostatic pressure (if it is positive) and the plasma colloid osmotic pressure[323] (Fig. 7.4).

The principal force favoring fluid efflux from the capillary is the hydrostatic pressure within the capillary. Capillary hydrostatic pressure varies among different tissues and decreases along the length of the capillary. Hydrostatic pressure within a capillary is determined by the arterial and venous pressures and by the precapillary and postcapillary resistances.[324] Specifically, capillary pressure *(Pc)* is determined by the ratio of the postcapillary resistance *(Ra)* to the precapillary resistance *(Rv),* and by the arterial *(Pa)* and venous *(Pv)* pressures:

$$Pc = [(Rv/Ra)\,Pa + Pv] / [1 + (Rv/Ra)]$$

Thus although an increase in either arterial or venous pressure will increase capillary pressure, a small increase in venous pressure has a much greater effect than does an increase in arterial pressure. For this reason the hydrostatic pressure is greater in capillaries below the heart (e.g., legs) than in those above the heart (e.g., head).

The colloid osmotic pressure of the plasma is the principal force minimizing fluid efflux from the capillary. The colloid osmotic pressure is generated both because the plasma and interstitial fluid are separated by a semipermeable membrane, the endothelium, and because they vary slightly, but significantly, in composition. As noted previously, the interstitial fluid has a lower protein concentration than does plasma but has an essentially identical electrolyte concentration. The difference in protein concentration across the semipermeable endothelium generates an osmotic force that tends to draw water from the interstitium into the plasma.

In addition to the capillary hydrostatic pressure, the colloid osmotic pressure and negative hydrostatic pressure of the interstitial fluid favor fluid movement out of the capillary. Fluid flux across the capillary results from the summation of these forces (see Fig. 7.4). These figures should be recognized as representing the forces at the midpoint of an idealized capillary; the forces are dynamic, changing between tissues and even along the length of the capillary. In fact, a large net flux of fluid from the capillary occurs at its arteriolar end, where capillary hydrostatic forces are greatest and the oncotic gradient is least, whereas a net flux of fluid into the capillary occurs toward its venous end, where capillary hydrostatic forces are least and the oncotic pressure gradient favoring reabsorption is greatest following dilution of protein in the interstitium (Fig. 7.5).

The small imbalance in filtration forces results in a net efflux of fluid from the capillary into the interstitial tissue. Normally this fluid does not accumulate in the interstitium, as it is removed by the lymphatics.

Other Factors Influencing Fluid and Solute Movement

Vascular Endothelium. The endothelium forms a dynamic barrier between the blood and the tissue. Although endothelial cells can have distinct morphologies and functions depending on the tissue and even the specific vessel, in general one function is to restrict the extravasation of larger molecules and cells from the vasculature to the interstitium.[325] The endothelial glycocalyx, which is a layer of macromolecules at the luminal surface of the vascular endothelium, plays an important role in fluid homeostasis and solute exchange.[317,325,326] The composition of the endothelial glycocalyx is dynamic, but the major constituents are hyaluronic acid and the negatively charged heparin sulfate proteoglycans. Changes in the endothelial glycocalyx appear to play a key role in endothelial dysfunction and the formation of edema. Also, endothelial permeability is in part regulated by the dynamic opening and closing of cell-cell adherens junctions that are composed primarily of vascular endothelial-cadherin.[318,327,328]

Aquaporins. Aquaporins are a diverse family of membrane proteins that are expressed predominantly in tissues in which edema and fluid imbalances are of major concern.[319,329] Water movement across cell membranes is driven by osmotic and hydrostatic forces, but the speed of this process can be influenced by the presence of specific aquaporin channels. These channels are primarily water channels, although some are also permeable to small solutes. Aquaporin-4 water channels play a central role in brain water regulation in neurologic disorders.[330-332] The pharmacologic modulation of the expression and activity of various aquaporins potentially could provide novel treatments for a variety of disorders, including brain edema.

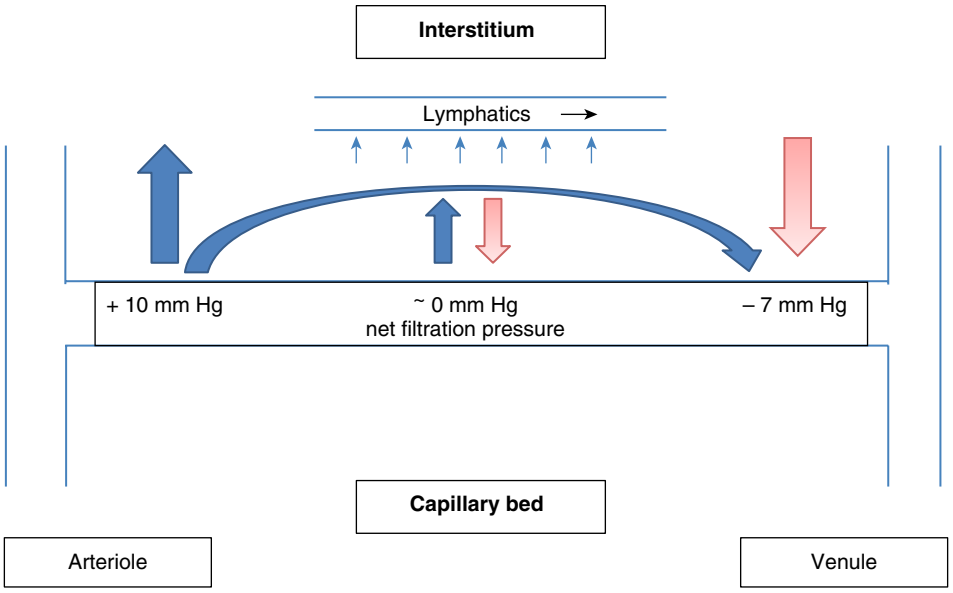

FIG. **7.5** Schematic of normal fluid movement in a capillary bed. Filtration occurs at the arterial end where capillary hydrostatic pressure is highest, and absorption occurs at the venous end where capillary hydrostatic pressure is lower, allowing plasma colloid oncotic pressure to predominate. Excess fluid is removed by the lymphatics.

Lymphatics. The lymphatics drain the interstitium of fluid and substances, notably proteins, that are not absorbed by the capillaries.[311] The lymphatics represent the only means by which interstitial protein is returned to the circulation. Interstitial fluid (and, with it, protein) moves down a pressure gradient into lymphatic capillaries through clefts between the lymphatic endothelial cells. Lymphatic endothelial cells are supported, and the lymphatic capillaries maintained patent, by anchoring filaments that attach the endothelial cells to surrounding connective tissue. Lymphatic fluid progresses centripetally through progressively larger vessels before draining into the great veins of the chest. Lymphatic valves prevent the retrograde flow of fluid from the lymphatics. Lymph is propelled by factors extrinsic to the lymphatics, including muscle activity, active and passive motion, posture, respiration, and blood vessel pulsation. Exercise increases lymph flow, at least in part because of the increase in tissue pressure that is associated with muscle contraction, although passive motion also increases lymph flow. In human beings, standing results in significant diminution or cessation of lymph flow from the lower extremities, which can result in the accumulation of interstitial fluid and edema. In addition to the extrinsic factors affecting lymph flow, coordinated contractions of lymphatic vessels contribute substantially to the centripetal flow of lymph.[313]

Mechanisms of Edema Formation

Simply stated, accumulation of excessive fluid in the interstitial spaces—edema—results from an imbalance of the rates of fluid filtration from the capillaries and drainage by the lymphatics. The exact pathophysiologic mechanisms involved in edema formation are complex and involve some tissue-specific mechanisms. Basic mechanisms of edema include alterations in Starling's forces, changes in vascular permeability, and impaired lymph drainage.

BOX 7.6 Mean Forces (mm Hg) Influencing Fluid Movement into or out of the Capillary

Type of Pressure	Mean Force
HYDROSTATIC PRESSURES	
Mean capillary pressure	17.0
Interstitial pressure	–5.3
Total hydrostatic pressure favoring filtration	22.3
COLLOID ONCOTIC PRESSURES	
Plasma oncotic pressure	28.0
Interstitial oncotic pressure	6.0
Total oncotic pressure opposing filtration	22.0
Total pressure favoring filtration	0.3

Data from Guyton AC: *Textbook of medical physiology,* ed 11, Philadelphia, Saunders, 2005.

Alterations in Starling's Forces

Perturbations of one or more of the forces that affect filtration across the capillary alter the rate at which fluid enters the interstitium.[311,312] Increases in capillary hydrostatic pressure, decreases in plasma oncotic pressure, and increases in interstitial oncotic pressure all favor increased fluid filtration. Conversely, increased interstitial hydrostatic pressure and decreased interstitial oncotic pressure act to inhibit fluid filtration.

There are several fundamental mechanisms by which excessive interstitial fluid can accumulate (Box 7.6). Increases in capillary hydrostatic pressure, which occur with venous obstruction or arteriolar dilation, such as that associated with inflammation, increase net fluid efflux. The edema that occurs with congestive heart failure likely has an increase in capillary hydrostatic pressure as one of its causes, although the mechanism is complex.[313]

Posture also affects capillary hydrostatic pressure; capillaries below the level of the heart have higher hydrostatic pressures than do capillaries above the level of the heart.

A decrease in the oncotic gradient across the capillary endothelium, which occurs with a decreased plasma oncotic pressure or an increased interstitial oncotic pressure, results in an increase in efflux of fluid from the capillary. A decrease in plasma oncotic pressure decreases the oncotic gradient that favors movement of fluid into the capillary. Consequently, the capillary hydrostatic pressure, which favors filtration, predominates and fluid accumulates in the interstitium. Plasma oncotic pressure decreases when plasma protein concentration declines. Albumin is the plasma protein that exerts the preponderance of the oncotic force and edema often is associated with hypoalbuminemia.[311,321]

Changes in Vascular Permeability

An increase in the permeability of the capillary membrane can increase fluid and protein transport into the interstitium and decrease the ability of the membrane to maintain a difference in oncotic pressure between the plasma and the interstitium.[314] Thus changes in vascular permeability can affect fluid flux both directly and via changes in Starling's forces.

The regulation of vascular permeability is complex with multiple pathophysiologic triggers contributing to increased permeability.[325-327] The microvasculature is sensitive to damage via several mechanisms including mechanical forces, ischemia-reperfusion injury, sepsis, and inflammation. Vasodilation and increased blood flow alone can increase vascular permeability. Numerous molecular regulators affect vascular permeability, including hormones, inflammatory cytokines, and other plasma constituents. Vascular endothelial growth factor is a potent angiogenic factor that can affect regulation of the vascular barrier.[325,333,334] Also, a number of inflammatory cytokines contribute to vasculitis. Among these are histamine and bradykinin, both of which can ultimately increase the generation of nitric oxide.[325]

The precise means by which vascular permeability is increased after stress to the endothelium are complicated and still under investigation. Inflammatory mediators and hormones can affect the integrity and function of the endothelial glycocalyx layer, and the changes in this layer frequently result in increased permeability and edema.[317,325,326] The organization and function of vascular endothelial-cadherin and other proteins at the adherens junctions can also be affected.[318,325,327,328] In addition, changes in the transcriptional, translational, and posttranslational regulation of transporters and ion and water channels, including aquaporins, occur.[325,329-332] The complexity of the regulation of vascular permeability and other factors contributing to edema can in part explain some of the limitations of colloid therapy. Improved understanding of the mechanisms controlling vascular permeability might lead to the formulation of pharmacologic strategies to control the barrier function of the endothelium.

Impaired Lymph Drainage

Lymphatic obstruction prevents the removal of interstitial fluid and protein.[311] Filtration of fluid and passage of small amounts of protein into the interstitial space continues in the presence of lymphatic obstruction. The interstitial fluid is reabsorbed by the capillaries, but the protein is not. Consequently, the protein content of the interstitial fluid gradually increases, with a resultant increase in interstitial oncotic pressure that favors filtration of fluid. The increased interstitial oncotic pressure causes fluid to accumulate in the interstitium, thus exacerbating the edema.

Compensatory Mechanisms Limiting Edema Formation

Alterations in the magnitude of one or more of Starling's forces can be offset by compensatory changes in lymph flow and other of Starling's forces.[311] In concert Starling's forces and lymph flow act as "edema safety factors" to prevent the excess accumulation of interstitial fluid and development of frank edema. For example, lymph flow increases with the increased filtration associated with increased capillary hydrostatic pressure. Thus a larger volume of fluid enters and is removed from the interstitial space. The interstitial protein concentration decreases as increased fluid flow washes protein out of the interstitial space. Reduced interstitial space protein concentration minimizes oncotic forces drawing fluid from the capillary to the interstitial space.[315]

Conditions Associated with Edema

Edema is not in itself a disease; rather, it is a sign of a disease process. Therefore the identification of conditions leading to the accumulation of edema is based on an understanding of the pathogenesis of edema. The most common form of edema recognized in horses is peripheral edema, and multiple causes have been identified (Table 7.3). Some specific causes of peripheral edema are discussed later.

A nonpainful edema of the limbs is often seen in horses in association with immobility. This condition, commonly referred to as "stocking up," is apparently associated with venous congestion and decreased lymph flow. It can affect all four limbs but is most common in the hindlimbs.

Hypoproteinemia, particularly hypoalbuminemia, is an important cause of edema.[311] In horses, the most common cause of hypoalbuminemia is protein loss, particularly through the gastrointestinal tract. In addition to acute colitis, some specific gastrointestinal conditions that are frequently associated with protein loss include right dorsal colitis, proliferative enteropathy due to *Lawsonia intracellularis,* and inflammatory bowel disease.[142.335,336] Other potential causes of protein loss include renal disease, especially chronic renal failure, amyloidosis, extensive skin wounds (burns), and third space loss as is seen in some cases of pleuritis or peritonitis. Occasionally hypoalbuminemia can be seen in association with decreased albumin production due to liver disease.[337] Severe burn injuries can induce generalized edema independent of protein loss, likely secondary to endothelial injury.[214,338]

Vasculitis is another important cause of edema in horses.[339-343] Some infectious diseases in which vasculitis is often prominent include equine viral arteritis, equine infectious anemia virus, African horse sickness, and equine granulocytic anaplasmosis *(Anaplasma phagocytophilum).* Purpura hemorrhagica is an immune-mediated vasculitis that is often associated with marked edema.[343] Many, but not all, horses affected with purpura hemorrhagica have been exposed to or infected with *Streptococcus equi* subspecies *equi.*

Several other causes of edema have been recognized in horses. Congestive heart failure is relatively uncommon in horses, but when it does occur ventral edema is among the most common clinical signs along with a heart murmur accompanied by either jugular distention or pulsation, tachycardia, and tachypnea.[229] Lymphangitis is an inflammation of the lymphatic vessels that often results in impaired lymphatic drainage and swelling. The condition can occur in any limb

TABLE **7.3 Common Causes of Peripheral or Ventral Edema in Horses**

CONGESTIVE HEART FAILURE
Valvular disease
Myocarditis
Monensin toxicosis
VASCULITIS
Equine viral arteritis
Equine ehrlichiosis
Purpura hemorrhagica
Equine infectious anemia
VENOUS OBSTRUCTION AND CONGESTION
Catheter-related thrombophlebitis
Disseminated intravascular coagulation
Tight bandages
Tumors
Immobility
CELLULITIS
Staphylococcal
Clostridial
Counterirritant application
LYMPHATIC OBSTRUCTION
Ulcerative lymphangitis
Lymphadenitis *(Streptococcus equi, Corynebacterium pseudotuberculosis)*
Lymphosarcoma
Tumors
HYPOALBUMINEMIA
Parasitism
Pleural and peritoneal effusions
Protein loss (gastrointestinal, renal, or wounds)
Inadequate production (starvation)
Hemodilution (subsequent to hemorrhage)
SHOCK
Hemorrhagic
Endotoxic
PLEURITIS
Late-term pregnancy
Prepubic tendon rupture
Starvation (inadequate intake; malabsorption)

but is more common in the hindlimbs. It is usually caused by a bacterial infection, although culture is frequently unrewarding. Some cases of *Corynebacterium pseudotuberculosis* infection manifest as an ulcerative lymphangitis.[344] Chronic progressive lymphedema is a condition recognized in some draft horse breeds including Clydesdales, Shires, and Belgians.[345] The condition is thought to be caused by altered elastin metabolism leading to impaired lymphatic function. Affected horses have chronic lymphedema with swelling of the distal limbs and development of fibrosis. Massive envenomation by bees (bee stings) causes generalized edema in horses.[346] Snake envenomation can also cause edema.[347]

Diagnostic Approach to the Patient with Edema

The diagnostic approach to the patient with edema is dependent on an understanding of the mechanisms of edema formation and a knowledge of the diseases likely to be involved. The diagnostic approach to an animal with edema should not be any different from that for any other sign of disease. A clinical examination, including history and physical examination, permits the development of a list of potential diagnoses and dictates the appropriate subsequent steps in confirming the diagnosis. The reader is referred to those sections of the text that deal with specific diseases for a more in-depth description of the conditions and their diagnosis.

Signalment and History

The signalment can be important when considering specific conditions associated with edema. For example, *Lawsonia intracellularis* is primarily a disease of weanling-age horses.[335] Chronic progressive lymphedema is particularly common in certain draft breeds, including Shires, Clydesdales, and Belgians.[229]

When taking the history of a horse that has edema, the veterinarian should focus on acquiring facts that have the greatest diagnostic use in differentiating among those diseases that have edema as a sign. The veterinarian should consider the following aspects: housing, season, and geographic region; vaccine and parasiticide administration; exposure to other horses and diseases present within the herd; the duration of the edema and its distribution; and the presence of any other clinical signs. The veterinarian should investigate the remainder of the history depending on the responses to initial questions.

Physical Examination

The physical examination should begin with a visual evaluation of the attitude and physical condition of the horse. The temperature, pulse rate, and respiratory rate should be recorded. Although the physical examination should be complete, particular attention should be paid to those body systems that the preliminary examination indicates might be involved in the disease process. The physical examination reveals the distribution and severity of edema. Edema that is localized to one extremity or is not bilaterally symmetric is more likely to be caused by local factors (e.g., lymphangitis, venous obstruction) than by systemic disease. Conversely, edema that involves several areas of the body and has a symmetric distribution is likely to be associated with systemic disease, such as the ventral edema of congestive heart failure. It is important to note that distribution of edema associated with hypoproteinemia can vary and can be widespread or limited to the ventrum, limbs, or submandibular area.

Ancillary Diagnostic Tests

The clinician will have developed an ordered list of potential diagnoses after the initial clinical examination, and this list will help direct the most appropriate ancillary diagnostic tests. Confirmation or elimination of the potential diagnoses may depend on the subsequent diagnostic procedures, including the response to therapy. A CBC and serum biochemical profile are often useful as part of a minimum database and will establish whether hypoproteinemia is present. Sections of this text deal with the specific disease processes and appropriate diagnostic procedures.

COLLAPSE IN HORSES: SYNCOPE, SEIZURES, AND SLEEP DISORDERS

Collapse is characterized by a loss of postural tone with or without progression to recumbency and with or without loss

of consciousness. Collapse in horses is uncommon, but it has serious implications for both horse welfare and human safety. In horses, it appears that collapse most often occurs at rest, but episodes can occur during exercise.[348]

Collapse can be categorized as syncopal or nonsyncopal. Syncopal collapse, which is sometimes referred to as *fainting,* is a self-limiting loss of consciousness and postural tone resulting from cerebral hypoperfusion.[349,350] Nonsyncopal collapse includes a number of disorders that can be further subdivided into those that are associated with some degree of loss of consciousness, including seizures, sleep disorders, and hypoglycemia, and those with no loss of consciousness, including musculoskeletal and metabolic problems, such as hyperkalemic periodic paralysis.

Mechanisms of Collapse

Syncope

Syncope is defined as a temporary interruption of cerebral perfusion resulting in a sudden and transient loss of consciousness and postural tone.[349,350] The brain has a high metabolic demand and is highly sensitive to changes in perfusion. Normally cerebral blood flow is tightly regulated by a complex system of cerebral autoregulation involving metabolic, myogenic, and neurologic components. This system maintains cerebral blood flow despite changes in blood pressure, and syncope can occur when this system fails. As syncope is uncommon in horses, much of the information regarding syncope is extrapolated from other species.

The causes of syncope can be broadly classified as cardiovascular, noncardiovascular, and unknown.[350,351] Cardiovascular syncope is due to reduced cardiac output and has been associated with structural heart disease, arrhythmias, and, in people, coronary heart disease. Causes of noncardiovascular syncope include primarily neurologic and metabolic disorders. One cause of noncardiogenic syncope in people is orthostatic or postural hypotension, which is defined as a decrease of 20 mm Hg in systolic blood pressure or 10 mm Hg in diastolic blood pressure within 3 minutes of changing position from sitting or supine to standing.[350-352] It results from an inadequate physiologic response to postural changes and has been associated with an impairment of peripheral vasoconstriction or reduction of intravascular volume. Specific causes of syncope related to orthostatic hypotension include dehydration or blood loss, as well as a variety of neurologic, cardiovascular, and endocrine disorders. Another type of noncardiogenic syncope is neurally mediated syncope, which is associated with disturbances of reflex cardiovascular control.[350,351,353,354] Some cases of neurally mediated syncope are associated with pain, stresss, or specific triggers. Although the pathogenesis of this phenomenon is not fully understood, it is characterized by peripheral vasodilation and/or transient bradycardia that is associated with inappropriate triggering of neural reflexes. In some but not all cases, neurally mediated syncope is associated with concurrent cardiac disease. The most common form of neurally mediated syncope is neurocardiogenic or vasovagal syncope, in which there is an increase in vagal parasympathetic tone and a decrease in sympathetic tone that results in bradycardia and hypotension associated with peripheral vasodilation.[353,354] In two cases of presumptive neurocardiogenic syncope in horses, no bradycardia was noted before collapse, suggesting a purely vasodepressor response in those cases.[348] Some other forms of neurally mediated syncope that have been recognized in people include carotid sinus syndrome, postmicturition syncope, and swallow syncope.

Syncope is common in people, with approximately one third of the population experiencing syncope at least once during their lifetime.[350,351] In humans, presyncopal signs such as weakness, blurred vision, and nausea frequently precede the collapse. Recovery is spontaneous, and following the episode people can experience persistent drowsiness, dizziness, headache, or nausea but typically not confusion. In horses, signs such as stumbling, head elevation, or anxiousness can precede collapse, but in most cases there are little or no premonitory warning signs.[355] The collapse is associated with a transient comatose state followed by recovery. Horses may struggle during recovery but are normal thereafter unless they sustain significant trauma during the episode. A syndrome of convulsive syncope that is difficult to differentiate from seizure activity has been described in people, but it is uncertain if this occurs in horses.[356,357]

Seizures

Seizures are the manifestation of the excessive and/or hypersynchronous discharge of neurons in the cerebral cortex that leads to voluntary alterations of motor activity, consciousness, and autonomic or sensory functions.[349,355,358-360] Normal neuronal function reflects a balance between excitatory and inhibitory activity. When intracranial neurons experience either excessive excitation or loss of inhibition (disinhibition) the resulting excessive depolarization can result in seizure activity. The seizure threshold reflects the level of neuronal inhibition that must be exceeded for uncontrolled discharge of a population of neurons to occur.

Normally there are sporadic low-frequency spontaneous depolarizations within the brain that are contained by a process known as *surround inhibition*. However, in some cases, groups of cells will depolarize with recurrent high-frequency bursts of action potentials that can manifest as focal seizure activity. Depolarizations of sufficient magnitude can overcome the surrounding inhibitory zone and be conducted to a more widespread area via normal anatomic connections between neurons, thus propagating seizure activity and potentially involving the entire cortex. Although occasionally depolarizations in the brainstem and thalamus can result in seizures, these depolarizations are projected to the cortex. The mechanisms of seizure termination are not fully understood, but factors that may be involved include metabolic exhaustion of neurons and the activity of extracortical inhibitory centers within the cerebellum. Other regions of the brain, such as the caudate and reticular formation, may also affect seizure activity.

Multiple factors may trigger the uncontrolled synchronous neuronal activity involved in the generation of seizures, reflecting the complexity of the neuronal environment.[358-361] Among the factors influencing this environment are the neuronal lipoprotein cell membrane with its associated ion channels and enzymes. Also, neuronal function is influenced by the ionic environment, including concentrations of sodium, chloride, calcium, and potassium. A variety of neurotransmitters are present, including both excitatory neurotransmitters such as glutamate, aspartate, and acetylcholine, and also inhibitory neurotransmitters such as γ-aminobutyric acid, glycine, taurine, and norepinephrine. Several hormones and neurosteroids can influence epileptogenesis, having variable effects depending on the substance.[361] Any alterations in the complex neuronal environment can potentiate seizures. For

example, hypoglycemia can result in a loss of energy substrate for the Na^+-K^+ ATPase pump, causing cells to move toward lower positivity and allowing excessive excitation. In hepatoencephalopathy, there may be a decrease in the function of inhibitory neurotransmitters, resulting in a lack of inhibition and unregulated depolarization. Multiple factors contribute to the development of seizures associated with traumatic brain injury, infection, or neoplasia including neuronal loss, altered cellular metabolism and blood flow, and neuroinflammation, among others.[358-362]

Seizures can present with a variety of forms and severities, and the classification and terminology can be confusing. In humans, the Commission on Classification and Terminology of the International League Against Epilepsy has developed a comprehensive scheme for the classification of seizures to more accurately describe seizures and develop a systematic approach to their diagnosis and treatment.[363] Efforts have been made to similarly classify seizures in horses.[364,365] The term *epilepsy* is defined as two or more seizures that occur in more than 24 hours regardless of the cause. Seizures can be described as either focal or generalized, both of which have been described in horses. Focal seizures, which have previously been referred to as partial, represent a focal area of abnormal discharge within the brain and result in localized motor signs or sensations. Focal seizures can be further categorized as simple, if alertness and normal mentation are maintained, and complex, if impairment of consciousness is present. Generalized seizures involve the entire cerebral cortex and typically result in generalized bilateral motor activity and loss of consciousness. Generalized seizures can be primary, meaning they are generalized from the outset, or secondary, meaning they progress from a focal seizure. Seizures can also be classified by the cause. Reactive seizures are those in which the seizure is a result of a temporary systemic disease with normal brain function such as seizures seen in association with acute hemorrhage or hypoglycemia. Other causes of seizures have been grouped as follows: (1) symptomatic, in which there is a documented structural brain disorder such as brain damage from trauma or hypoxia, congenital anomalies, neoplasia, and infection, including meningitis, encephalitis, and abscessation; (2) cryptogenic, in which symptomatic causes are suspected but cannot be documented; and (3) idiopathic, in which there are no underlying structural or metabolic abnormalities and there is a suspected genetic predisposition.

The clinical presentation of seizures in horses is similar to that seen in other species.[355,364] In a study of 104 horses over 3 weeks of age with seizures, precipitating factors were identified in approximately 11% of cases and included xylazine, noise, trimming the mane, touching the neck, and estrus.[364] Prodromal or preictal signs are not consistently recognized but can be seen in some horses with either focal or generalized seizures and include anxious behavior, isolation from other horses, standing in a corner, swishing of the tail, and changes in personality. Focal seizures may involve the face or body and some of the more common signs include ear or lip twitching, tongue prolapse, opening and closing of jaw, compulsive kicking, head turning to one side, and tremors.[364] In some cases, impaired consciousness and behavior changes have also been reported. Generalized seizures are typically characterized by tonic-clonic motor activity. Eye globe deviation and nystagmus are common. Vocalization and autonomic disturbances such as mydriasis, urination, defecation, and profuse sweating have also been reported. Affected horses may have generalized rigidity or a loss of muscle tone. Postictal signs have also been reported in horses. In the study of 104 horses with seizures, 31% of horses affected by complex focal or generalized seizures had postictal signs typically lasting from minutes to hours.[364] These signs included ataxia, disorientation, lethargy, agitation, blindness, hypersensitivity, and shallow breathing.

Sleep Disorders

Sleep is defined as unconsciousness from which one can be aroused by sensory or other stimuli.[349,355] Sleep has been investigated in domestic horses, and four stages of vigilance have been identified: wakefulness, drowsiness, slow wave sleep (SWS), and rapid eye movement (REM) sleep, also known as *paradoxic* or *desynchronized sleep*.[366-369] REM sleep appears to be an important regenerative part of the sleep cycle. Adult horses typically require 3 to 5 hours per day of sleep with approximately 0.5 hour per day of that being REM sleep. The majority of REM sleep in horses appears to occur during recumbency, although occasionally REM sleep has been observed in standing horses that are not habituated to their environment.[368]

One cause of excessive drowsiness and possible collapse in horses is recumbent sleep deprivation. The level of tolerance for sleep deprivation among individual horses appears to vary widely, with some horses being able to tolerate weeks of being unable to lie down to sleep whereas others will show signs of sleep deprivation after just several days.[355,368,370]

Narcolepsy is a sleep disorder that is primarily characterized by excessive drowsiness and sleep attacks with or without cataplexy, which is a sudden loss of muscle tone and somatic areflexia.[355,371,372] In people, disturbed nocturnal sleep, hypnagogic hallucinations, and sleep paralysis can also be seen in association with narcolepsy. The sleep cycle is disrupted, and people with narcolepsy frequently enter REM sleep at the onset of sleep rather than later in the sleep cycle. Both sporadic and familial forms of narcolepsy have been identified in humans, dogs, and horses.[370-379] The pathophysiology of narcolepsy remains unclear and may vary among species and individuals. It appears to be a complex biochemical disorder affecting several regions of the brain (brainstem, hypothalamus, limbic system, and possibly the striatum and cortex) with dysfunction of dopaminergic, cholinergic, and noradrenergic neurotransmitters.[372,381] Defective hypocretin signaling has been described in both familial and sporadic narcolepsy in some species.[371-373,382] Hypocretin 1 and 2, also known as *orexins,* are neuropeptides that appear to be specifically expressed in certain hypothalamic neurons. They appear to have an important role in the regulation of sleep and arousal states, as well as appetite. In some dog breeds, a familial form of narcolepsy has been identified in association with a mutation in hypocretin-2 receptor gene.[374] In these dogs, hypocretin concentration in the cerebrospinal fluid (CSF) is normal. In humans, narcolepsy is only rarely associated with mutations in the hypocretin receptor gene. In both humans and dogs, the sporadic form of narcolepsy has been associated with decreased hypocretin concentration in the CSF. Many cases of narcolepsy in people are linked to the human leukocyte antigen, and an autoimmune component may play a role in the development of disease. It has been postulated that there is an immune-mediated destruction of hypothalamic neurons producing hypocretin, resulting in a progressive decline in the concentration of hypocretin. The role of hypocretin in equine narcolepsy is currently uncertain. The concentration of hypocretin in the CSF of an

Icelandic foal with narcolepsy without cataplexy was similar to controls, although it was speculated that concentrations could decrease over time.[377] Occasionally secondary narcolepsy may develop after disease or organic insult to the brain, such as following traumatic brain injury.[383,384]

Most cases of narcolepsy in horses have been diagnosed in foals, but sporadic cases have been seen in adults.[355,374-380] Given the difficulties in diagnosing narcolepsy, some of these cases may represent recumbent sleep deprivation or idiopathic hypersomnia, which is another disorder of the central nervous system characterized by excessive sleepiness. Better characterization of sleep disorders in horses is needed.

Sleep disorders in horses are often characterized by drowsiness, with gradual lowering of head and buckling, which most often occurs in the forward direction. In some cases there is complete collapse. In cases of narcolepsy with cataplexy there will be limb atonia and areflexia. Occasionally swaying and stumbling when walking have been described in narcoleptic horses. In cases of narcolepsy in other species, cataplexy can sometimes be induced by play or feeding, and similar triggers have been described occasionally in equine cases of narcolepsy. Many normal newborn foals can be induced into a sleeplike cataplectic state by firm, whole-body restraint or squeezing.[355]

Conditions Causing Collapse

Several conditions have been reported in association with collapse in horses, but information is somewhat limited (Box 7.7). It can be challenging to make a definitive diagnosis for the cause of collapse. In a retrospective study of 25 horses with episodic collapse, a final diagnosis was established in 11 cases and a presumptive diagnosis was made in 8, with 6 being undiagnosed.[348] Overall, the most common cause of collapse in this series of cases was syncope, which accounted for 63% of the cases in which a definitive or presumptive diagnosis was made. In the 11 horses with a specific final diagnosis, causes included cardiac disease (5 of 11), generalized seizures (2 of 11), hypoglycemia secondary to neoplasia (2 of 11), and sleep disorders (2 of 11). In the 8 horses with a presumptive diagnosis, causes included neurocardiogenic syncope (5 of 8), syncope associated with severe EIPH (2 of 8), and seizures (1 of 8).

Syncope

Syncope in horses has been associated with cardiovascular, noncardiovascular, and unexplained causes, with cardiovascular and presumed neurocardiogenic syncope being the most common. Specific cardiovascular problems that have been reported in association with syncope in horses include cardiac arrhythmias, including third-degree atrioventricular (AV) block, atrial tachycardia with advanced second-degree AV block, and atrial fibrillation.[348,355,385,386] Right-sided heart failure, ruptured chordae tendineae, myocardial infarction, myocardial fibrosis, aortic endocarditis, and pericarditis have also been associated with syncope.[355,385,386] In some cases, a definitive cardiac disease can be hard to confirm. Depending on the underlying problem some horses with cardiovascular syncope may have other signs of cardiac failure, but this is not consistent. Presumptive neurocardiogenic syncope has been diagnosed in horses in which there are no abnormal findings on clinical, neurologic, or cardiac examinations.[348,355] In general, collapse was reported to occur without warning at rest, and horses were described to sink abruptly or to raise their heads and fall backward to the ground. Confirmation of neurocardiogenic syncope would require ECG and blood pressure monitoring. Polycythemia and upper airway obstruction have also been reported to cause syncopal episodes.[387,388]

Seizures

A number of disorders have been associated with seizures in horses. The clinical presentation of the seizure appears to be

BOX 7.7 Causes of Collapse

SYNCOPE

Cardiovascular
- Arrhythmia
  - 3° atrioventricular (AV) block
  - Atrial tachycardia with 2° AV block
  - Atrial fibrillation
  - Other
- Right-sided heart failure
- Ruptured chordae tendinae
- Myocardial infarction, myocardial fibrosis
- Endocarditis
- Pericarditis

Noncardiovascular
- Neurocardiogenic (vasovagal) syncope
- Polycythemia
- Airway obstruction

Undetermined

SEIZURES

Reactive (no structural brain lesion)
- Hepatoencephalopathy
- Hemorrhage
- Electrolyte abnormalities
- Hypoglycemia

Symptomatic
- Traumatic brain injury (skull fracture, cerebral hemorrhage)
- Cerebral edema
- Neonatal encephalopathy
- Neoplasia
- Cholesterol granuloma (can be incidental)
- Vasculitis
- Viral, bacterial, or verminous meningoencephalitis
- Abscessation
- Equine protozoal myeloencephalitis
- Intracranial vascular events
- Leukoencephalomalacia
- Congenital anomalies
- Ear ticks

Cryptogenic
- Lesion suspected but cannot be identified

Idiopathic
- Juvenile idiopathic epilepsy of Arabian foals

SLEEP DISORDERS

Recumbent sleep deprivation
Narcolepsy

OTHER

Hyperkalemic periodic paralysis
Hypoglycemia
Hyperthermia
Undetermined

independent of the underlying cause, reflecting the area and extent of the cerebral cortex involved.[364] In the study evaluating 104 horses with seizures, 2 horses were found to have reactive seizures not associated with abnormal brain function. These horses were diagnosed with liver failure and severe acute systemic hemorrhage. The remaining 102 horses were felt to have underlying brain disease, although a specific diagnosis was not always possible. Of these, 28% had a single seizure episode and 70% had two or more seizures and were diagnosed with epilepsy. Of those horses with a single seizure episode, an underlying structural brain lesion was confirmed or suspected in 16 of 29 horses, with acute head trauma being the most common (6 of 16). In those horses with epilepsy, the condition was categorized as symptomatic in 35.6% of cases and cryptogenic in 54.8%, and 2 foals were diagnosed with idiopathic epilepsy. Overall there was no breed, age, or gender association in horses with epilepsy, although juvenile idiopathic epilepsy is seen in Arabian foals. Specific causes of symptomatic seizures that were identified included skull fracture, cerebral hemorrhage, cerebral edema, neoplasia, cholesterol granuloma, vasculitis, meningoencephalitis, abscessation, intracranial vascular events, leukoencephalomalacia, congenital abnormalities, and equine protozoal myeloencephalitis (EPM). The presence of ear ticks has rarely been associated with seizures.[355] Meningoencephalitis due to infection with the nematode *Halicephalobus gingivalis* has been associated with multiple neurologic deficits, including seizures.[389] Neonatal foals have a lower seizure threshold than adults, and seizures have been reported in association with sepsis, neonatal encephalopathy, and electrolyte abnormalities, including hyponatremia.[355,390-392] Hypoglycemia may cause seizures but is more often associated with weakness and lethargy. Hyperbilirubinemic encephalopathy (kernicterus) may rarely occur in foals.

Sleep Disorders

Sleep deprivation can be induced by preventing horses from being able to lie down, such as when horses are kept on a tie-line to prevent them from exacerbating a musculoskeletal injury by getting up and down.[355,370] Other conditions in which horses do not lie down to sleep include musculoskeletal, abdominal, thoracic, or neurologic problems that either create pain or mechanical difficulties on attempt at recumbency or rising to stand. Environmental insecurity, including such things as herd dynamics, stall size, and excessive noise, may prevent horses from feeling comfortable enough to lie down. It has also been proposed that monotony, such as being in crossties for an extended time, may cause horses to exhibit drowsiness, with the head lowering to the point of near collapse as the horse begins to transition from SWS to REM sleep.

Familial narcolepsy has been identified in American Miniature Horses, Shetland Ponies, and Lipizzaners.[355,375,376,378] At this time the precise genetics have not been determined. Sporadic narcolepsy, generally without cataplexy, has been identified in several breeds including Warmbloods, Icelandic Horses, and Thoroughbreds.[355,378]

Other

A number of other disorders can occasionally result in collapse. Hyperkalemic periodic paralysis can cause weakness, muscle fasciculations, and collapse without alterations in consciousness.[302] Other electrolyte abnormalities in addition to hyperkalemia may result in collapse including hypocalcemia, hyponatremia, and hypokalemia.[355] Hypoglycemia can be associated with weakness and collapse, and in some cases seizures may occur. Some other disorders that can be result in collapse include trauma to the motor pathways, botulism, and hyperthermia.[355]

Diagnostic Approach to Collapse

The diagnosis of the cause of collapse can be challenging, and in many cases a definitive cause is not determined. Often the clinician is unable to witness the episode, and although accounts by the owner can be helpful, they can also be inaccurate and may omit key information if the owner is unaware of the significance. A final diagnosis was found to be more likely in horses that experienced multiple episodes of collapse than in horses that were observed to collapse only once.[348] This may be because they may be more likely to have ongoing signs of disease and also because the sensitivity of diagnostic procedures may be improved by carrying them out either during or immediately after a collapsing episode. For example, some cardiac arrhythmias are paroxysmal and may not be present between episodes.

Signalment and History

There are some age, breed, and sex associations with some causes of collapse. In general, neonatal foals are more susceptible to seizures than adult horses and may seize in response to a number of metabolic and systemic diseases.[355,390-392] Juvenile idiopathic epilepsy is a disease of Egyptian Arabian foals with an age of onset ranging from 2 days to 6 months.[355,393] Familial forms of narcolepsy have been identified in American Miniature Horses, Shetland Ponies, and Lipizzaners.[355,375,376,378] Hyperkalemic periodic paralysis should be considered as a possible cause of collapse in Quarter Horses and related breeds.[302] In the study of 104 horses with seizures, seizure type was significantly associated with gender, with females being more prone to generalized seizures and one mare demonstrating generalized seizures during estrus.[364] Estrogen and progesterone concentrations are related to alterations in seizure threshold in women and female dogs, and a similar risk factor may be present in horses.[361,394]

A detailed history should be obtained, including a performance history and the occurrence of any other problems, such as EIPH or lameness. With regard to the episodes of collapse, the onset and duration as well as any specific triggers and the features of the episode should be determined. Possible reasons for recumbent sleep deprivation should be investigated, including underlying medical problems and management changes such as moving the horse to a new environment with different horses, excessive noise, or limited space.

Physical Examination

A thorough physical examination should be performed. In some cases, additional clinical signs may be present depending on the underlying disease. For example, fever and lethargy may be present in horses with viral or bacterial encephalitis and icterus, and weight loss may be seen in horses with hepatoencephalopathy. Horses with sleep disorders may have abrasions on the fetlocks from repeatedly buckling forward. Particular attention should be focused on the cardiovascular and neurologic systems. In some cases of potential cardiac disease, evaluating the horse after exercise may be useful.

Video surveillance may be needed to allow observation of the actual episode of collapse. Although differentiation of the conditions can be difficult, clinical features can vary among syncope, seizures, and sleep disorders. Generalized seizures generally differ from syncope in that they involve tonic-clonic

convulsive activity and may be associated with opisthotonos or nystagmus, as well as urination and defecation. Seizures are also often followed by a postictal phase that is not seen in syncope or narcolepsy. In horses with sleep disorders, the collapse is often preceded by a gradual lowering of the head, and the horse most often falls forward. Eye movement may be seen in association with REM sleep during a sleep attack, but this appears to be uncommon in horses.

Ancillary Diagnostic Aids

Clinical Pathology. A CBC, fibrinogen, and serum chemistry can be helpful in identifying metabolic or systemic abnormalities, such as sepsis, liver disease, or electrolyte abnormalities. In some horses, such as those with hyperkalemic periodic paralysis (HYPP), the abnormality may only be present during the episode. Measurement of cardiac troponin can be useful to identify cardiac disease.[395,396] Analysis of CSF and testing for EPM can provide useful information.

Electrodiagnostic Testing. An electrocardiogram (ECG) is valuable in evaluating the cardiac rhythm in horses with episodes of collapse. As some arrhythmias are intermittent, continuous ECG monitoring may be necessary to identify the arrhythmia. This is most often done with a 24-hour Holter monitor. An insertable cardiac monitor, also known as *insertable* or *implantable loop recorder,* has been used in horses to record an ECG during the collapse episodes and can improve the diagnostic yield.[348] Blood pressure monitoring during an episode could be useful but has not been done in horses.

An electroencephalogram (EEG) assesses electrical brain activity and can be helpful in the identification of seizures. However, due to the paroxysmal nature of epileptiform activity, a normal EEG does not rule out the presence of seizures, especially if performed during the interictal period. In Arabian foals with juvenile idiopathic epilepsy, epileptiform activity was found on EEG in 9 of 13 foals.[393] Continuous EEG monitoring improves the chance of detecting abnormal brain activity. A device for ambulatory EEG has been used in horses for long-duration EEG recording and has been shown to identify abnormal brain acitivity.[397,398] EEG can also evaluate electrical activity in the sleep cycle and may be useful in the assessment of narcolepsy.

Diagnostic Imaging. Echocardiography can be useful in the evaluation of cardiac disease. It can also be used to evaluate the liver in horses with suspected hepatic disease and hepatoencephalopathy.

Radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) can all be useful in the diagnostic evaluation of horses with collapse, especially with suspected seizure activity.[348,364,399,400] Skull radiographs and CT are particularly useful in horses with skull trauma.[400] CT can be used to identify other lesions as well but has some limitations in identifying inflammatory disease and small or diffuse parenchymal lesions. MRI has been shown to be a valuable diagnostic tool, especially in the evaluation of symptomatic epilepsy.[364,399] There has been a good correlation between MRI findings and intraoperative or postmortem results. It is important to remember, however, that it is not uncommon for seizures to occur in the absence of a structural brain lesion.

Additional Testing. Challenge testing has been used in the assessment of possible narcolepsy in horses, but results have not been consistent.[374-377] Physostigmine may induce narcoleptic episodes, and atropine may eliminate signs. In humans and dogs, hypocretin concentration in CSF can be used in the evaluation of narcolepsy, but at this time the value of hypocretin testing in horses is uncertain.[377,382]

DYSPHAGIA

Dysphagia is defined as difficulty swallowing. Normal swallowing, or deglutition, occurs as a complex sequence of events with three phases: oral, pharyngeal, and esophageal.[401] In equine medicine, dysphagia is often used in the broad sense to include any difficulty in the prehension and uptake of feed, as well as in actual swallowing. The clinical signs of dysphagia vary depending on the cause but frequently include dropping feed or packing feed between the cheek teeth and buccal mucosa, ptyalism, extension of the neck, gagging, coughing, and the presence of feed-tinged nasal discharge. Dysphagia can be a significant problem for the patient due to the risk of aspiration and the potential compromise in nutritional and hydration status.

Mechanisms of Dysphagia

Normal eating and drinking are complex neuromuscular activities that are initiated with the uptake of material into the oral cavity.[401-403] The process of swallowing allows the transport of this material from the oral cavity to the stomach while protecting the airway. The initial stage of swallowing is the oral phase, which encompasses the formation and positioning of a feed bolus, which is defined as feed that is of suitable size and consistency to be swallowed. Mastication and moistening by saliva lead to formation of the bolus and also initiate digestion by mechanical breakdown of the feed and addition of digestive enzymes from saliva. The bolus is moved to the base of the tongue, where coordinated movements of the tongue and pharynx initiate the pharyngeal phase of swallowing. The oropharynx relaxes and the soft palate elevates to seal the palatopharyngeal arch and nasopharynx. As the bolus enters the oropharynx, the hyoid apparatus moves rostrodorsally, drawing the larynx and common pharynx forward while at the same time the epiglottis tips caudally to prevent the bolus from entering the larynx. The bolus is moved through the pharynx by sequential contraction of the pharyngeal constrictor muscles along with some driving force from the tongue. The lower portion of the inferior pharyngeal constrictor muscle, known as the *cricopharyngeus,* is the major muscle in the upper esophageal sphincter. At the end of the pharyngeal stage of the swallow, this muscle relaxes, allowing the bolus to enter the esophagus, and then contracts to prevent oroesophageal reflux and aerophagia. As the bolus enters the esophagus, the esophagus, including the lower esophageal sphincter, relaxes and the bolus is propelled toward the stomach by primary peristaltic waves. Gravity can assist in moving a liquid bolus toward the stomach. After the bolus enters the stomach, the lower esophageal sphincter contracts to prevent gastroesophageal reflux. Any minor reflux that does occur is typically cleared by secondary peristaltic waves, which are waves that occur in the thoracic esophagus without an associated pharyngeal contraction. Active antiperistalsis does not normally occur in horses, and thus horses generally do not actively vomit. All of the activity involved in swallowing occurs relatively rapidly. In herbivores, breathing can continue uninterrupted during swallowing.

Several anatomic structures and at least 30 muscles, including both striated and smooth muscles, are involved in the process of eating and drinking.[401,402] Among the muscles used

are the masseter, temporalis, and medial and lateral pterygoid muscles, often referred to as the *muscles of mastication*. Also muscles within the lips, oral cavity, pharynx, larynx, and esophagus are involved. Sophisticated integration among these muscles and the peripheral and central nervous systems is required for normal swallowing to occur.

Each phase of swallowing is under complex neurologic control, with both voluntary (somatic) and involuntary (autonomic) input into the process.[401-403] Cranial nerves (CNs) that play a major role in prehension and swallowing include the trigeminal (CN V), facial (CN VII), glossopharyngeal (CN IX), vagus (CN X), spinal accessory (CN XI), and hypoglossal (CN XII). The activity of these six CNs is mediated centrally via the medulla oblongata of the brainstem, where a network of sensory and motor nuclei and interneurons form the swallowing center. In addition to the brainstem, the cortical and subcortical regions of the brain play an integral part in mediating the swallow, especially the oral phase.

Both sensory and motor function play a role in the uptake of feed, as well as throughout swallowing.[403] With regard to the uptake of feed, sensory input from the olfactory and optic nerves is important in providing smell and sight while the trigeminal nerve provides sensation to the rostral oral mucosa and lips. Once feed is in the oral cavity and oropharynx, peripheral receptors stimulate the trigeminal, facial, and glossopharyngeal nerves providing sensory input to the brainstem, which leads to activation of the swallowing reflex. Patterned discharges of excitation and inhibition are sent from neurons in the swallowing center to motor nuclei of the cranial nerves, resulting in swallowing. Swallowing can also be initiated by stimulation of cortical neurons, and often cortical and peripheral inputs act together in eliciting swallowing. Once swallowing is initiated, continuing sensory input modulates motor activity.

A variety of problems, either congenital or acquired, can disrupt swallowing.[404-406] Problems causing dysphagia may be grouped by the anatomic location as oral, pharyngeal, or esophageal. Also, general mechanisms of dysphagia may be classified as either morphologic or functional. Morphologic causes include pain and inflammatory conditions, as well as mechanical problems, such as anatomic abnormalities and obstruction. Functional causes include a variety of neurologic, neuromuscular, and muscular disorders that can interfere with the highly regulated activity of swallowing. Functional disorders may affect any phase in the process of eating and drinking, but most often affect the oral and pharyngeal phases of swallowing. Some disorders, such as guttural pouch empyema, have the potential to cause both physical obstruction and neurologic impairment.

BOX 7.8 Morphologic Causes of Dysphagia

- Anatomic abnormalities
  - Cleft palate
  - Wry nose, severe malocclusions
  - Branchial remnant cysts
  - Subepiglottic cysts
- Dental conditions
  - Points, hooks
  - Retained deciduous premolars
  - Wave, step, or shear mouth
  - Periodontitis
  - Fractured teeth
  - Equine odontoclastic tooth resorption and hypercementosis
  - Other
- Temporomandibular joint disease
- Oral ulceration
  - Dental problems
  - Vesicular stomatitis virus
  - Plant awns
  - Caustic substances, medications
  - Cantharidin toxicosis
- Trauma
  - Fractures of skull, mandible, or maxilla
  - Tongue lacerations
- Foreign bodies
- Neoplasia
  - Oral, esophageal—squamous cell carcinoma, dental
- Epiglottitis
- Retropharyngeal masses causing compression
  - Abscesses
  - Guttural pouch enlargement
  - Empyema, mycosis
  - Tympany
  - Hemorrhage associated with rupture of the longus capitus
  - Neoplasia
  - Septic sialoadenitis
- Esophageal disorders
  - Obstruction (choke)
  - Esophagitis
  - Perforation, fistula
  - Stricture
  - Diverticula, megaesophagus
  - Congenital abnormalities—cysts
  - Neoplasia
- Snakebite

Conditions Associated with Dysphagia

Morphologic Causes

Several morphologic causes of dysphagia have been identified in horses (Box 7.8). Anatomic abnormalities that have been recognized in association with dysphagia include a cleft palate, wry nose, branchial remnant cysts, and subepiglottic cysts.[405-408] Pain and inflammation from a number of underlying causes often contribute to dysphagia. Dental problems can cause both pain and mechanical problems with mastication.[409,410] Some painful dental conditions include ulcerations from points or hooks, periodontitis, infundibular caries, fractured teeth, and equine odontoclastic tooth resorption and hypercementosis syndrome (EOTRH). Problems such as retained deciduous premolars, as well as a wave, step, or shear mouth, and occasionally severe malocclusions may make it mechanically difficult to chew effectively. Oral ulceration causing discomfort may be seen with plant awns, vesicular stomatitis virus, cantharidin toxicosis, and exposure to caustic substances or some medications, such as phenylbutazone or enrofloxacin.[404-406] Dysphagia has been reported in a foal with equine herpesvirus 2–associated oral and esophageal ulceration.[411] Other painful conditions include epiglottitis, foreign bodies, temporomandibular joint disease, mandibular or maxillary fractures, and other traumatic injuries, such as hyoid bone injury or tongue

lacerations.[405,406,412,413] Although uncommon, septic sialoadenitis involving either the parotid or mandibular salivary gland can be a significant cause of pain, inappetance, and dysphagia.[414]

The most common obstructive problem causing dysphagia is esophageal obstruction, or choke.[404-406,415] This most often results from a feed impaction, although esophageal foreign bodies may occur as well. In addition to obstruction, other esophageal conditions that can result in dysphagia include esophagitis, esophageal rupture, fistula, strictures, diverticula, megaesophagus, and congenital disorders, such as esophageal cysts.[415,416] Esophageal tumors are uncommon, but primary esophageal squamous cell carcinoma has been reported.[415,417-419] Both squamous cell carcinoma and leiomyosarcoma have been seen to extend from the stomach into the esophagus. Idiopathic muscular hypertrophy of the distal esophagus has been recognized but in many cases is of no clinical significance.[420]

External compression of the pharynx or esophagus may also result in obstruction. Pharyngeal collapse may be seen with enlargement of the retropharyngeal lymph nodes, most often due to abscessation associated with *Streptococcus equi* subspecies *equi,* as well as with severe guttural pouch disease, including empyema, mycosis, or tympany, and occasionally neoplasia.[405,406,421-424] Pharyngeal collapse is often associated with dyspnea, as well as dysphagia. Oral neoplasms of either dental or nondental origin are relatively uncommon but can cause pain or act as a space-occupying mass resulting in dysphagia.[405,406,425,426] A number of dental tumors, as well as osteogenic tumors of nondental origin, such as osteomas, ossifying fibromas, and osteochondromas, have been described. Squamous cell carcinoma is the most common soft tissue neoplasm reported in the oral cavity, but others have been identified, including melanoma and lymphosarcoma. Adenocarcinoma of the tongue and epiglottis has been reported as a cause of severe dysphagia in a horse.[427] Snakebite may cause severe edema of the head and dysphagia.[347,428]

Functional Causes

Guttural pouch diseases affecting the cranial nerves within the pouch are one of the more common functional problems causing dysphagia[404-406,424,429-431] (Box 7.9). The dorsolateral wall of the medial compartment of the guttural pouch contains several nerves, including the glossopharyngeal (IX); branches of the vagus (X), spinal accessory (XI), and hypoglossal nerves (XII); and the cranial cervical ganglion. In addition, a small portion of the facial nerve (VII) is located in the dorsal wall of the lateral compartment. Thus guttural pouch disease can result in pharyngeal dysfunction, dysphagia, and occasionally other neurologic signs such as laryngeal paralysis, Horner's syndrome, and facial paralysis.[404-406,424,429-431] Important diseases of the guttural pouch causing dysphagia include guttural pouch empyema and guttural pouch mycosis. Skull trauma resulting in rupture of the longus capitus muscle at the site of attachment to the basisphenoid bone may result in significant hemorrhage into the pouch, potentially affecting the cranial nerves.[429] Occasionally flushing of the guttural pouch and surgical correction of guttural pouch tympany results in damage to the cranial nerves coursing through the pouch with consequent neurologic dysfunction.[405,406,431] Although temporohyoid osteoarthropathy most often results in deficits of the facial (CN VII) and vestibulocochlear (CN VIII) nerves, occasionally deficits of the glossopharyngeal (CN IX) and vagus (X) nerves occur, resulting in dysphagia.[432,433] Lead toxicity may result in a peripheral neuropathy with dysphagia.[434] Some horses with polyneuritis equi, an inflammatory condition affecting primarily the cauda equina, will have involvement of the cranial nerves and present with cranial nerve signs including dysphagia, occasionally even before the development of signs related to cauda equina dysfunction.[435,436]

Central neurologic diseases and neuromuscular or muscle disorders that can result in dysphagia often have other concurrent signs in addition to problems eating. Some important central neurologic diseases that can be associated with dysphagia include viral encephalitis (rabies, eastern and western encephalitis, West Nile virus, equine herpesvirus), equine protozoal myeloencephalitis, toxic neuropathies (leukoencephalomalacia and nigropallidal encephalomalacia), tetanus, cerebral trauma, and rarely migrating parasites.[404-406,437-441] Dysphagia is a relatively common finding in horses affected with rabies.[404] Horses with nigropallidal encephalomalacia have lesions of the basal ganglia and can swallow but are unable to prehend

BOX 7.9 Functional Causes of Dysphagia

PERIPHERAL NERVE DISEASE
- Guttural pouch disease affecting the cranial nerves
  - Empyema, mycosis
  - Tympany
  - Hemorrhage associated with rupture of the longus capitus
  - Neoplasia
- Temporohyoid osteoarthropathy
- Lead poisoning
- Polyneuritis equi

CENTRAL NEUROLOGIC DISEASE
- Viral encephalitis/encephalomyelitis
  - Rabies
  - Eastern, western, and Venezuelan encephalitis (EEE, WEE, VEE)
  - West Nile virus (WNV)
  - Equine herpes myeloencephalopathy
- Equine protozoal myeloencephalitis
- Toxicity
  - Nigropallidal encephalomalacia
  - Leukoencephalomalacia
- Trauma
- Tetanus
- Migrating parasites
- Equine grass sickness
  - Affects central, peripheral, and enteric nervous systems
- Pharyngeal dysfunction in neonatal foals

NEUROMUSCULAR DISEASE
- Botulism
- Tetanus
- Organophosphate toxicity
  - Primarily acute cholinergic signs, dysphagia rare
- Tick paralysis

MUSCLE DISEASE
- Nutritional myodegeneration (white muscle disease)
- Hyperkalemic periodic paralysis

feed as they lack coordination of the lips and tongue. Tetanus toxin acts at several sites within the nervous system, including the inhibitory interneurons in the central nervous system and the neuromuscular junction, causing muscle paralysis.[442] It typically results in increased tonus of the masticatory muscles, known as *trismus,* and dysphagia. The mouth may be difficult to open, thus the term *lockjaw.* Some cases of marked hypocalcemia may result in tetany and dysphagia. A syndrome of dysphagia related to presumed pharyngeal dysfunction has been reported in neonatal foals.[443] Although the pathogenesis is not fully understood, some affected foals were premature and/or diagnosed with neonatal encephalopathy. Other central neurologic problems that may potentially cause dysphagia include bacterial or fungal meningitis and intracranial masses.

Neuromuscular problems that can result in dysphagia include organophosphate toxicity, tick paralysis, botulism, and to some extent tetanus, which also has a central component.[404-406,442,444,445] One of the early signs of botulism can be that the horse eats slowly. Equine grass sickness (EGS), also referred to as *equine dysautonomia,* is a largely fatal neurodegenerative disease affecting the peripheral, central, and enteric nervous systems of grazing equids.[446-448] The gastrointestinal tract is the most severely affected body system, with the predominant clinical signs being colic, weight loss, and dysphagia. Although the disease primarily occurs within Great Britain, cases have been identified in regions of mainland Europe and rarely in other locations including the United States. A possible link to *Clostridium botulinum* types C and D has been proposed, but the cause of EGS remains unclear.[446]

The primary muscle disease resulting in dysphagia is nutritional myodegeneration (nutritional muscular dystrophy, white muscle disease) associated with selenium deficiency.[449-451] Although reported more frequently in foals, nutritional myodegeneration can affect horses of any age. Although multiple muscles can be affected, myodegeneration may be limited to the masseter muscle and/or tongue in some cases, making dysphagia the predominant sign. Foals affected with HYPP may have dysphagia, particularly when they are homozygous.[302]

Diagnostic Approach to Dysphagia

The evaluation of dysphagia focuses on determining whether morphologic and/or functional abnormalities are present. The initial assessment should include consideration of the signalment and history and a thorough physical examination, including observation of the horse eating. Additional tests such as a neurologic examination and ancillary diagnostic aids are often indicated.

Signalment and History

Some age and breed associations have been associated with dysphagia. Anatomic abnormalities such as a cleft palate or wry nose are generally apparent at an early age. Some dental disorders can be age related.[409,410] The deciduous premolars are lost between 2 and 5 years of age and may be retained as caps. Older horses are more are more likely to have a severe wave mouth, missing teeth, or EOTRH and can be at increased risk of esophageal obstruction. Dysphagia associated with pharyngeal dysfunction may be seen in neonatal foals, sometimes in association with prematurity or neonatal encephalopathy.[443] In foals with Quarter Horse breeding, HYPP can be a cause of dysphagia.[302] Friesian horses have an increased prevalence of esophageal disorders, specifically megaesophagus.[452]

A thorough general history is important in the evaluation of dysphagia. The history may help to differentiate dysphagia from a decrease in appetite. The diet, dental history, and any recent disease and treatment should be determined. A history of dropping feed during mastication, or *quidding,* may suggest dental disease. The potential for exposure to toxins such as lead, organophosphates, or yellow star thistle and Russian knapweed should be assessed. The vaccination status of the horse should be established, especially with regard to tetanus, West Nile virus, eastern equine encephalitis virus (EEE), western equine encephalitis virus (WEE), equine herpesvirus, and rabies. It should be determined whether other animals on the farm are having problems as certain conditions, such as strangles and botulism, may affect more than one individual. Trauma is often associated with a history of an acute onset of dysphagia. In some cases there is a known history of a traumatic event such as a fall or kick, but in other cases the cause of the trauma in unknown. Occasionally trauma may occur during the administration of medication or passage of a nasogastric tube. In addition, a history of flushing the guttural pouch can be of significance as the procedure may rarely cause inflammation and tissue damage.

Physical Examination

Biosecurity procedures should be followed during the initial assessment of horses with dysphagia as rabies is a potential differential. Ideally, veterinarians and assistants should have an adequate rabies antibody titer.

A complete physical examination should be performed. The presence of a fever suggests an infectious or inflammatory process. Observing the horse while eating, and if possible drinking, can be valuable. Some horses can continue to drink despite difficulty swallowing feed whereas others cannot. Offering feed may help distinguish dysphagia from anorexia. Depending on the underlying cause, many dysphagic horses are hungry and will attempt to eat. Some horses, such as those with retropharyngeal abscessation due to strangles, may have both dysphagia and a decreased appetite. Observation of eating can also help determine the phase of eating affected, which can help in prioritizing differentials. In cases where prehension is primarily affected, nigropallidal encephalomalacia should be considered in areas where yellow star thistle or Russian knapweed is present. Dropping feed while chewing is consistent with abnormal mastication, which is often associated with dental disease. The regurgitation of feed through the nares while eating is generally associated with pharyngeal or esophageal disorders rather than oral cavity problems. Those horses with feed in the nares are at increased risk of aspiration of feed material, and coughing or increased respiratory rate and effort may be seen. Careful auscultation of the thorax, including a rebreathing evaluation, should be performed.

A thorough oral examination using a mouth speculum is usually indicated. The teeth should be examined for the presence of problems such as retained deciduous caps, sharp points or hooks, wave mouth or step mouth, missing teeth, diastema, periodontitis, infundibular caries, dental fractures, and EOTRH.[409,410] The oral cavity and tongue should be examined for the presence of ulcers or other abnormalities, such as lacerations, foreign bodies, and masses. Foreign bodies may become wedged between the molars or under the tongue, and wire foreign bodies or awns may become embedded in the tissue. The submandibular and throat latch area should

be examined for evidence of lymphadenopathy or guttural pouch enlargement. Occasionally an esophageal obstruction can be palpated in the neck. An esophageal perforation should be considered if there is heat or swelling in the neck. If ptyalism is observed without dysphagia, ingestion of clover that is contaminated with *Rhizoctonia leguminicola,* a fungus that produces the mycotoxin *slaframine,* should be considered.[453] Excess salivation stops once the horse is no longer exposed to the toxin.

Nasogastric Intubation

A complete esophageal obstruction can be ruled out if a nasogastric tube can be passed into the stomach. Common sites for esophageal obstruction to occur are the proximal esophagus just distal to the larynx, at the thoracic inlet, and at the base of the heart.

Neurologic Examination

A complete neurologic examination is often indicated in the evaluation of dysphagia, especially when morphologic causes have been ruled out. The neurologic examination helps establish a neuroanatomic localization. In general, horses with dysphagia due to peripheral neurologic disease may exhibit only dysphagia, whereas those with central neurologic or neuromuscular disease tend to have additional deficits. For example, the presence of generalized weakness in association with dysphagia often suggests a neuromuscular problem, such as botulism or organophosphate toxicity.[404-406,444,445] Equine motor neuron disease results in generalized weakness and muscle atrophy; however, affected horses do not exhibit cranial nerve deficits and are not dysphagic.[454] Tetanus causes spastic paralysis and can present with a variety of signs, including dysphagia, hyperesthesia, and prolapse of third eyelid, in addition to a stiff gait, which may progress to recumbency.[442] Spinal ataxia associated with dysphagia suggests a diffuse or multifocal disease affecting the spinal cord and brainstem, such as equine protozoal myelitis, rabies, equine herpes myeloencephalopathy, or a migrating parasite.[437-440] Viral encephalitis should be considered in dysphagic horses with mentation changes, especially if the horse is febrile. Horses with polyneuritis equi occasionally have cranial nerve involvement in addition to the classic signs of cauda equina involvement, which include slowly progressive paralysis of the tail, rectum, anus, and bladder.[435,436] Affected horses may also have ataxia and weakness of the hindlimbs.

Ancillary Diagnostic Aids

Clinical Pathology/Laboratory Testing. A CBC, fibrinogen, and serum chemistry may be helpful in documenting an inflammatory process. In cases of suspected nutritional myodegeneration, measurement of selenium and glutathione peroxidase can help in evaluating the selenium status of the patient.

Further diagnostic tests are often indicated in cases of suspected neurologic disease. These may include an evaluation of CSF for cytologic and biochemical abnormalities, as well as specific testing for antibodies to *Sarcocystis neurona* or *Neospora hughsei.*[440] In cases of suspected West Nile virus infection, the immunoglobulin M (IgM) capture ELISA can be used. Cranial nerve involvement is infrequent with equine herpesvirus myeloencephalopathy, but testing by PCR or virus isolation on nasal swabs and/or blood should be considered if appropriate.[438,439] Botulism can be a difficult disease to diagnose, and diagnosis is often based on the history and clinical signs along with the exclusion of other diseases.[444,445] Several tests are available for definitive diagnosis, including testing for toxin by mouse bioassay or PCR in feed, manure, gastrointestinal contents, serum, or wound exudate. The antemortem diagnosis of polyneuritis equi can be difficult, but a biopsy of skeletal muscle innervated by nerves arising from the cauda equina may demonstrate extensive cellular infiltrates in intramuscular nerve fibers.[435,436]

Endoscopy. Endoscopic examination allows visualization of the nasal passageways, nasopharynx, pharynx, larynx, and guttural pouches. Pharyngeal and laryngeal function can be assessed, although the use of sedation should be taken into account as it may affect function. Endoscopic examination of the guttural pouch can identify the presence of empyema or guttural pouch mycosis, as well as other less common conditions such as trauma-related hemorrhage and neoplasia. The stylohyoid bone should be carefully evaluated. In temporohyoid osteoarthropathy there is often osseous proliferation primarily affecting the proximal portion of the stylohyoid.[432,433] Depending on the length of the endoscope, the esophagus may also be evaluated for evidence of esophagitis, obstruction, strictures, diverticula, perforations, or other abnormalities.

Diagnostic Imaging. Diagnostic imaging can provide useful information in the evaluation of dysphagia. Skull radiographs, CT, or MRI can help in the diagnosis of fractures, dental disease, temporohyoid osteoarthropathy, temporomandibular joint disease, guttural pouch disease, and retropharyngeal masses.[405,406,409,410,412,421] Radiopaque foreign bodies, such as a wire in the oral cavity, pharynx, or esophagus, can be identified on radiographs.[413] In cases of esophageal perforation, extraluminal radiolucencies consistent with subcutaneous air may be visualized. Contrast radiography with the use of barium sulfate can be useful in the diagnosis of certain esophageal disorders such as strictures, diverticula, or megaesophagus.[415] Due to the risk of aspiration in horses with dysphagia, radiographs and ultrasound of the thorax are often indicated, especially in horses with abnormal thoracic auscultation, nasal discharge, cough, increased respiratory rate, or increased respiratory effort as evidenced by increased abdominal effort or nasal flare. Ultrasound may also be useful in the detection of foreign bodies and in evaluation of swelling in the throatlatch region.

COLIC

Colic is defined as the manifestation of abdominal pain. In horses colic is a serious medical and economic problem worldwide. In the United States the annual incidence of equine colic has been reported to be anywhere between 3.5% and 26%.[455-458] A study performed by the National Animal Health Monitoring System in 1998 assessed the annual incidence of colic to be 4.2% with an estimated total cost of approximately $115 million.[455] In this study only 1.4% of colic episodes resulted in surgery, but the overall fatality rate for all colic was 11%. When evaluating general causes of mortality in horses over 6 months of age, including euthanasia, colic was found to be responsible for 22.2% of equine deaths in 1998 and 15.2% in 2005.[459] This makes colic among the most common causes of death in horses along with old age (24.8% and 30.4% of deaths) and injury (12.7% and 16.0% of deaths). Even in less serious cases, colic can be associated with a significant loss of use. In a study of working horses in Egypt, the prevalence of colic was found to be 54.6%.[460] These numbers illustrate the enormous impact that colic has on the equine population.

Horses express clinical signs of colic in a variety of ways.[461,462] Often the first sign recognized by owners is inappetence, but other early signs may include general restlessness and extended periods of lying down. More overt signs, such as kicking or biting at the abdomen, pawing, and stretching out as if to urinate, may also be observed. Bruxism is occasionally seen. As the level of discomfort increases, horses may repeatedly get up and down and try to roll, sometimes violently.[461] In some cases, the horse may acutely have much pain. The level of stoicism varies widely among individual horses, and the severity of signs does not always correlate to the severity of the lesion.

Mechanisms of Colic

The precise pathophysiologic mechanisms involved in cases of colic can vary because of the myriad causes for colic in the horse. Most cases of colic, sometimes referred to as "true" colics, are gastrointestinal in origin. However, disorders of other body systems, such as cholelithiasis and uterine torsion, may also manifest as colic. True colic can be classified on the basis of small intestinal versus large intestinal disorders, physical versus functional disorders, obstructive versus nonobstructive lesions, and strangulating versus nonstrangulating lesions. In all of these colic classifications, the simplest basic etiologies for damage to the gastrointestinal tract are inflammation and ischemia.[462-464] Gastrointestinal distention, ileus, mesenteric tension, and endotoxemia also play a role in the development of disease in many cases.

Ischemia of the intestine can result from a strangulating lesion or even from a simple obstruction. Strangulating lesions cause acute direct occlusion of vessels leading to rapid tissue hypoxia, ischemia, and ultimately necrosis. With obstructions significant pressure within the distended intestine may lead to venous collapse, which over time may result in ischemia as the intestinal vasculature becomes increasingly compromised.[462-464] The mucosa is the layer most sensitive to hypoxia because of its high metabolic activity. Damage to the mucosa can be assessed on a scale of Grade I through Grade V, with Grade V being the most severe.[462] The villous tips are especially sensitive to ischemia, and damage typically begins there. Crypt cells are affected later as the ischemia becomes more complete and longer in duration. In the equine colon complete ischemia leads to necrosis and detachment of surface epithelial cells and most likely to capillary thrombosis and occlusion.[462] Smooth muscle is less sensitive to hypoxia, and therefore it is destruction of the mucosa that is the main factor leading to the pathologic changes associated with colic.

Prolonged intestinal distention proximal to an obstructive lesion can eventually lead to tissue ischemia. Distention also results in edema and additional secretion of fluid into the lumen of the gut as venous collapse occurs.[462-464] As veins are occluded, hydrostatic pressure within the capillaries increases, causing increased filtration. Lymphatic drainage is also often impaired, and the resultant excess fluid becomes edema and secreted intestinal fluid. Distention is one of the main causes of pain associated with colic, as stretch pain receptors are triggered within the wall of the intestine.[462]

Inflammation plays a major role in almost every type of colic and often occurs secondary to ischemia. The inflammatory response is generally meant to protect the intestine against long-term damage. The pathophysiology of inflammation is complex and beyond the scope of this section, but the basic process in the gastrointestinal tract is similar to that of other body systems. Almost all cells in the intestine can play a role in the development of inflammation by either cytokine production or cell activation. Some specific cell types involved in the initiation of intestinal inflammation include mucosal cells, endothelial cells, fibroblasts, neutrophils, macrophages, neurons, eosinophils, and mast cells.[463] Cytokines, growth factors, and adhesion molecules produced by these cells are important in the initiation of inflammation. Some important cytokines include IL-1, TNF-α, platelet activating factor, complement, interferon, and histamine.[463]

Endothelial cells are stimulated by ischemia or macrophage cytokines to attract neutrophils, which subsequently migrate to the affected tissue facilitated by adhesion molecules. Vascular permeability is also increased, resulting in the formation of edema and facilitating the migration of inflammatory cells. Neurons, fibroblasts, and muscle cells detect and release other cytokines, leading to the activation of many effector cell types.[463,464]

Eventually the intestinal barrier is compromised to the extent that endotoxin begins to leak into systemic circulation. Endotoxemia (discussed in detail in Chapter 12) is most common with colitis and to a lesser extent with strangulating lesions. The response to endotoxin is complex, involving a massive release of cytokines and mediators that results in systemic inflammation and fever. Classical endotoxemia has more recently been described as *systemic inflammatory response syndrome (SIRS),* because it likely involves more than just endotoxin as an initiating factor.[463] The result is hemodynamic responses that include both vasodilation and vasoconstriction, platelet aggregation, and eventual development of a hypercoagulable state and consumptive coagulopathy.[462,463]

Finally, ileus should be addressed as an important component of the pathophysiology of colic. Ischemic bowel has decreased motility, although bowel more proximal to the lesion tends to have an increase in motility until it becomes so distended that it can no longer contract normally. Postoperative ileus appears to involve both dopaminergic and adrenergic stimulation. It has also been suggested that prostaglandins E_1 and E_2, as well as nitric oxide, play a role in disrupting intestinal motility patterns.[462]

Owners often question why horses have colic, and several studies have attempted to identify risk factors for colic with varying results.[465-473] Some factors that may increase the risk of colic in horses include stall confinement, feeding of excessive concentrate, infrequent large meals, recent feed changes, decreased water consumption or lack of access to water even during turnout, feeding of Coastal Bermuda grass hay, and off-the-ground feeding. Other risk factors include inadequate deworming or dentistry, exposure to sand, transport, changes in activity, previous colic episodes, and the use of nonsteroidal antiinflammatory drugs (NSAIDs). Colic has also been linked to stereotypic behaviors such as crib-biting, which has been shown in some studies to be associated with an increased risk of both colic in general and epiploic foramen entrapment.[470,474-476] It is important to remember that colic can occur regardless of management practices.

Conditions Associated with Colic

Colic encompasses a wide variety of conditions, both gastrointestinal and nongastrointestinal in origin (Table 7.4). The actual incidence of specific disorders causing colic in the general

TABLE **7.4 Gastrointestinal Causes of Colic**

Gas and spasmodic	
Impactions	Pelvic flexure
Feed	Large colon
Sand (primarily pelvic flexure, large colon)	Cecum
	Small colon
Other intraluminal obstructions	Ileal
	Gastric
	Meconium impaction (foals)
	Enteroliths
	Fecaliths
	Foreign body
Large colon displacements	Right dorsal displacement
	Left dorsal displacement (nephrosplenic entrapment)
	Other
Large colon torsion and volvulus	
Small intestinal volvulus	
Strangulating lipoma	
Entrapment of small intestine	Epiploic foramen
	Mesenteric rent
Intussusception	
Ulceration	Gastric
	Right dorsal colitis
Enteritis/colitis	Duodenitis/proximal jejunitis (anterior enteritis)
Inflammatory bowel disease	Colitis
Parasites	Ascarid impactions
	Tapeworms
	Strongylus vulgaris
	Cyathostomes
Herniation	Inguinal
	Umbilical
	Diaphragmatic
Peritonitis	
Abdominal abscessation	
Hemoperitoneum	
Toxins	Cantharidin
	Monensin
	Other
Other	Ileus
	Overo lethal white syndrome
	Congenital anomalies
	Neoplasia

equine population is not known, partially because a definitive diagnosis is not always established. In general, most colics are gastrointestinal in origin, with simple gas or spasmodic colics being most common.[456,477-479] Other common causes include large colon impaction and large colon displacement. In one study of 604 horses that were *referred* for evaluation of colic, 327 cases were medical (54.1%) and 277 cases were surgical (45.9%).[479] Of the medical cases, the most common problems were large colon impaction (39.6%) and spasmodic colic (20.8%). Of the surgical cases, the most common problems were large colon displacement (24.5%), followed by large colon torsion (14.3%) and strangulating lipoma (13.5%).[479]

Disorders of several body systems other than the gastrointestinal tract can present with signs of colic.[480-484] Causes of colic involving the reproductive tract include uterine torsion or tears in mares and testicular torsion in stallions. Occasionally ovarian activity may cause transient colic in mares. Some other potential nongastrointestinal causes of colic include cholelithiasis, liver lobe torsion, urolithiasis, and pheochromocytoma.

Diagnostic Approach to Colic

Colic can be caused by a number of different conditions. Several other clinical problems may be confused with colic, such as pleuritis, exertional rhabdomyolysis, laminitis, hyperkalemic periodic paralysis, renal disease, and even neurologic abnormalities.[485] When a horse presents with colic, it is important to determine that the horse is exhibiting signs of abdominal pain and then arrive at a specific diagnosis if possible. In some cases the evaluation of a horse with colic may be straightforward, but other cases may be more challenging. Fortunately, although a specific diagnosis may not be made, many cases of colic either resolve spontaneously or with minimal intervention. However, in some horses, the condition can be life threatening, and a delay in surgical exploration can result in increased mortality. Thus the initial goal in the assessment of a horse with colic is often to determine whether the case is an uncomplicated one, such as a gas or spasmodic colic, rather than one requiring either extensive medical management or surgical exploration. Signalment, history, physical examination, clinicopathologic data, imaging findings, and endoscopy may all contribute to the evaluation of a patient with colic.[485,486] A number of studies have focused on identifying means to aid in the early classification of colic cases as medical or surgical and to determine a prognosis. Most of these studies have assessed a number of physical examination and laboratory variables.[486-492]

Signalment and History

The signalment of the horse can provide information that may increase the degree of suspicion for a specific cause of colic. Weanling-age foals are more prone to ascarid impactions, whereas younger foals are at higher risk for small intestinal volvulus or intussusception.[485,486,493,494] Older horses have a far greater likelihood of developing strangulating lipomas.[462,477]

Colic may affect horses of any breed, but some breed predispositions have been recognized. An increased incidence of colic has been recognized in Arabians and Thoroughbreds.[455,457,485,495] Arabians are specifically predisposed to ileal impaction, small colon impaction, and enterolith formation. Miniature horses, especially when young, are prone to small colon impactions and fecaliths.[462,485] Standardbred, Tennessee Walking Horse, and Warmblood stallions have a higher risk of developing inguinal hernias than stallions of other breeds, which is felt to be related to increased size of the inguinal rings.[462,485] Overo lethal white syndrome is a fatal, recessive genetic condition that causes ileocolonic aganglionosis in neonatal foals.[496] Affected foals are white or predominantly white with small dark markings and generally develop signs of colic shortly after birth. The defective gene is found predominantly in American Paint Horses but has also been found in horses of other breeds with overo coloring, such as American Miniature Horses and half-Arabians.

Gender is also important to consider in cases of colic. In addition to inguinal hernias, testicular torsion can be a cause

of colic in stallions.[462] Postpartum mares are predisposed to torsion of the large colon, whereas colic in a late-gestation mare may be associated with normal parturition or dystocia.[462,485] Pregnant mares exhibit signs of colic with uterine torsion.[480,485] Nonpregnant mares can have mild transient signs of colic associated with ovarian activity.

The history of the patient can provide vital clues as to the severity and possible etiology of the colic.[485,486] With regard to the current episode, it is important to determine the duration and severity of pain, recent defecation and character of feces, appetite, previous treatment, and response to treatment. Previous history of colic, including colic surgery, history of other surgeries, recent management changes, geographic area, breeding history, and pregnancy status, are all important components in the medical history of a colicky horse. Additionally, specific details as to feed, access to sand, water source, deworming, dentistry, history of medications (e.g., NSAIDs, antibiotics), activity level, and stereotypic behavior such as crib-biting/windsucking may also provide valuable diagnostic information.

Physical Examination

A thorough physical examination is essential to the evaluation of colic. It is important to assess the degree of pain, and in some cases the horse may be so uncomfortable initially that sedation will be necessary for safe completion of the examination. If possible, heart rate, respiratory rate, and auscultation of gut sounds should be evaluated before sedation because these can change significantly in response to sedation.[497,498] Because rectal temperature can also be significantly decreased after rectal palpation, it is advisable to obtain the body temperature before palpation.[461] A finding of pyrexia may increase suspicion of colitis, enteritis, peritonitis, or intraabdominal abscessation in the patient, although previous administration of an NSAID may mask this clinical finding.[462,485,486] Tachycardia can be an indicator of pain, hypovolemia, tachyarrhythmia, or endotoxemia, and rates of greater than 80 beats per minute generally indicate serious disease.[462,485,486] During auscultation the patient should be evaluated for the presence of any cardiac abnormalities that would put the horse at increased risk under sedation. Respiratory rate may be increased in horses with colic as a response to some combination of pain, fever, and/or metabolic acidosis. Mucous membranes and capillary refill time (CRT) give a rough assessment of cardiovascular status and peripheral perfusion. Normal mucous membranes should be pink and moist with a CRT of less than 2 seconds. Tacky mucous membranes are generally observed with dehydration of at least 5% to 7%.[485,486] Prolonged CRT and either grayish or dark red mucous membranes indicate impaired cardiovascular status and poor perfusion. With poor perfusion, there may also be cool extremities and reduced jugular fill. Significant changes in mucous membrane color, often with a dark "toxic" line adjacent to the teeth, may accompany endotoxemia, which is common in gastrointestinal disease, particularly in horses with colitis, proximal enteritis, and strangulating lesions. Icterus is relatively common in horses that have been off feed for more than 48 hours due to equine fasting hyperbilirubinemia. However, icterus may also be seen with hepatobiliary disease or hemolysis. Other important considerations during the physical examination include assessment of hydration status, attitude, abdominal distention, and the presence of injuries that indicate self-trauma, which often reflects the degree of pain. As previously mentioned, in stallions careful palpation of the inguinal region must be performed to identify an inguinal hernia or testicular torsion. Severe abdominal distention may markedly increase the respiratory effort and eventually lead to respiratory distress. Auscultation of abdominal quadrants (left dorsal, left ventral, right dorsal, right ventral) can give an estimation of gastrointestinal motility.[485,486] Assessing the abdomen for pings can help to localize gas. Auscultation of the most ventral part of the abdomen should also be performed to assess for the presence of sand.[499] Although not always present, a characteristic "waves on the beach" sound can sometimes be heard, indicating the presence of sand in the colon. If feces can be collected from the horse, it can be useful to evaluate for the presence of sand. A simple way to do this is to mix a few fecal balls with warm water in a rectal sleeve and hang the sleeve with the fingers down. After about 5 minutes any sand in the feces should sediment into the ends of the glove fingers.[485]

Additional diagnostics for horses with colic include rectal palpation, nasogastric intubation, and, in many cases, abdominocentesis. Adequate restraint is important for these procedures because not only is the veterinarian at increased risk of injury with an uncooperative horse, but the horse also is at increased risk of rectal tears, significant epistaxis, and abdominocentesis complications such as enterocentesis or contamination of the collection site. The most appropriate means of restraint is dependent on the individual patient and may include sedation and/or the application of a nose twitch. When selecting the method of restraint the safety of the examiner and the horse must be considered, while at the same time it is important to not further compromise an unstable patient or dramatically affect assessment of the horse's level of pain. Use of xylazine hydrochloride intravenously at 0.2 to 0.5 mg/kg (typically 100–250 mg for a 500-kg horse) is often adequate, but butorphanol tartrate at 0.01 to 0.08 mg/kg intravenously can be added when necessary.[461] Use of detomidine is usually discouraged in the initial management of colic because of its long duration of action and heightened ability to mask more significant pain that may affect determination of the horse's treatment.[465,466] However, if indicated, detomidine can be administered at 0.01 to 0.04 mg/kg intravenously or intramuscularly.[461] It is most commonly used when a longer duration of sedation is required to keep a horse quiet during transport to a referral center.

Nasogastric intubation should be performed as a part of a complete colic examination. If a horse is exhibiting significant pain or has a heart rate greater than 60 beats per minute on initial evaluation, nasogastric intubation should be performed before other diagnostic procedures because it may have both diagnostic and therapeutic value. If a horse has significant gastric distention, gastric decompression may help prevent gastric rupture and decrease pain, allowing for a more thorough physical examination. The nasogastric tube can be left in place if a significant amount of net reflux is obtained to allow for repeated decompression. If no reflux is obtained and a simple colic is suspected, oral fluids with or without electrolytes or magnesium sulfate (Epsom salt) can be administered via the tube. Although mineral oil has long been considered a part of standard colic treatment, its use is controversial. Mineral oil may be valuable as a diagnostic tool, providing an estimate of gastrointestinal transit time. In a normal horse mineral oil can be observed in the feces and on the perineum and tail in 12 to 24 hours.[500] The absence of mineral oil after this period may indicate delayed gastrointestinal transit. However, mineral

oil can sometimes pass around an impaction that is present, thereby falsely suggesting adequate gastrointestinal transit when in fact digesta is not moving normally.[500] In addition, if a horse ultimately requires abdominal surgery, the presence of mineral oil can complicate an enterotomy.[501]

Palpation per rectum can be important in the assessment of colic. Even with the use of appropriate sedation, some horses remain resistant to rectal examination, placing them at increased risk for rectal tears. To potentially improve the quality and safety of palpation per rectum, intravenous administration of *N*-butylscopolammonium can help to decrease rectal pressure and peristalsis.[502] Application of lidocaine within the rectal lumen has also been used to facilitate palpation. Although rectal palpation can provide valuable diagnostic information, the presence or absence of a particular lesion cannot always be definitively determined. For instance, although a pelvic flexure or cecal impaction may be palpable, if no impaction is palpated, it cannot be ruled out. Additionally, gas distention might be palpable in gas colic, but it may also reflect a more serious problem, such as a displacement or torsion. Rectal palpation therefore can provide evidence to support a diagnosis but is often not diagnostic in itself. Nephrosplenic entrapment may be suspected if the spleen is displaced medially or the gut is palpated between the spleen and kidney.[485,486] Another useful finding is the identification of distended small intestine. Although small intestinal distention may occasionally occur secondary to a large intestinal problem such as a displacement, it is most often an indication of small intestinal disease. Although rectal palpation cannot differentiate a surgical small intestinal problem such as a strangulating lesion from a medical problem such as proximal enteritis, small intestinal disease is almost always an indication for referral.[485,486,503] Therefore palpable loops of distended small intestine are a significant finding on rectal examination. Rectal palpation can also be useful for identifying masses in the abdomen, which may be a cause of chronic colic.

Ancillary Diagnostic Tests

Clinical Pathology. A packed cell volume (PCV) and total protein should ideally be evaluated to assist with assessment of hydration status and possible protein loss. These values can be affected by stress, which can increase the PCV, anemia, protein loss, or hyperproteinemia, confounding the effects of dehydration.[462,504] Therefore these values must be evaluated in the context of the history and physical examination of the patient, as well as their relationship to each other. In general, the greatest negative indicator is a significantly increased PCV (i.e., greater than 65%) coupled with a significantly low plasma protein concentration (i.e., less than 4 g/dL), especially if serial values are trending toward these extremes.[462,485,486,504]

Although further blood work usually is not performed on a standard simple colic, a CBC and serum chemistry can provide valuable information if a colic goes beyond simple treatment and requires more advanced care.[504,505] In acute colic CBC values will typically be normal or reflect stress, but in more chronic conditions nonspecific signs of inflammation such as leukocytosis and hyperfibrinogenemia can develop, as well as a possible normochromic normocytic anemia of inflammation and chronic disease. If significant colon wall compromise occurs, leukopenia with neutropenia and a left shift with toxic changes can occur as a result of endotoxemia.[461,485,504] Thrombocytopenia may also be present with endotoxemia.

Electrolyte abnormalities, especially hypokalemia and hypocalcemia, are relatively common abnormalities observed on a chemistry panel in horses with colic.[505] Anorexia, dehydration, diarrhea, and excessive nasogastric reflux can all contribute to derangement of electrolytes. In addition to calcium and potassium, sodium, chloride, magnesium, and bicarbonate can be lost with diarrhea or significant gastric reflux.[472] Leakage from damaged cells may result in elevated serum phosphate. Metabolic acidosis caused by elevation of lactate, loss of bicarbonate, or both may also be observed. Hyperglycemia is relatively common in horses with acute gastrointestinal disease in association with dysregulation of glucose homeostasis. Significant elevations in glucose have been associated with a worse prognosis for hospital discharge.[506] Occasionally, hepatic enzyme activities are increased, especially γ-glutamyltransferase (GGT). This most commonly occurs with right dorsal displacement of the large colon or proximal enteritis.[507,508] In a study of horses with large colon displacements, 49% of horses with right dorsal displacements had concentrations of GGT above the reference range compared with 1% of horses with left dorsal displacements.[508] Dehydration often results in elevations in creatinine and serum urea nitrogen, and these parameters should be monitored, especially when NSAIDs or aminoglycoside antibiotics are used. Elevations in muscle enzymes are common in horses with colic. In a study of horses undergoing celiotomy for acute gastrointestinal pain, elevations in creatine kinase (CK) and aspartate aminotransferase (AST) activity were significantly associated with the presence of lesions resulting in intestinal ischemia.[509]

Abdominocentesis can be performed both in the field and in a referral setting. Most often the procedure is performed with either an 18-g, 1.5-inch needle or a teat cannula for the collection of fluid. The typical location in which the procedure is performed is to the right of midline (to avoid splenocentesis) on the most ventral point of the abdomen at least several inches caudal to the xiphoid.[462,485] However, occasionally other locations, such as on the ventral midline, will be used. Also, ultrasound of the abdomen can be used to identify pockets of fluid, but it should be remembered that fluid can often still be obtained even when a significant volume of fluid is not apparent on ultrasound. If severe gas distention or small intestinal distention is present, or if a sand enterocolitis is suspected, it may be advisable to forego abdominocentesis to avoid puncture of a distended compromised viscus or a heavy sand-filled viscus that is sitting flush with the ventral body wall. Although a practitioner may not have access to a full fluid analysis and cytology, a basic assessment of abdominal fluid can be made by visual evaluation for color and clarity, and total protein can be evaluated with a refractometer. Normal fluid should be odorless, nonturbid, and a clear to pale yellow color.[462,510,511] Increased turbidity can indicate increased protein, increased total nucleated cell count, or both. Total protein should be less than 2.5 g/dL. A normal cell count is typically less than 5000 cells/μL, although it may be normal up to 10,000/μL.[458,475] Serosanguineous fluid usually reflects a strangulating obstruction or significant compromise to the bowel wall. With a ruptured gastrointestinal structure, the fluid is generally dark and smells of ingesta. These results should be confirmed, however, because an accidental enterocentesis will appear the same.[462] If the spleen is accidentally punctured, the fluid will look like frank blood and will usually have a PCV equal to or greater than the peripheral PCV.[511]

Measurement of lactate concentrations in both the circulation and peritoneal fluid is useful in the assessment of colic.[512-516] Several point-of-care analyzers are available, making measurement of lactate practical.[516,517] In general, in horses with colic, an elevation in lactate concentration in either the circulation or peritoneal fluid suggests intestinal hypoperfusion and correlates with more severe disease. Elevations in peritoneal fluid lactate, especially if higher than the simultaneously measured blood lactate, as well as increases in peritoneal fluid lactate over time, are predictors of intestinal ischemia secondary to a strangulating obstruction.[512,515,516] There is some evidence that pony and miniature breeds presenting for gastrointestinal disease have higher blood lactate concentrations compared with large-breed horses, suggesting that different cutoff values should be used when determining the necessity of surgery and the prognosis in these breeds.[518]

Diagnostic Imaging. Ultrasound examination of the abdomen is often useful in the evaluation of horses with colic.[519-525] Adequate transabdominal ultrasound examination is most easily performed with a 2.5- to 5-MHz curved linear transducer; however, an examination can also be performed using a transrectal probe.[519,520,525] A protocol for fast localized abdominal sonography of horses admitted for colic (FLASH) has been developed.[524] This protocol allows for rapid evaluation of specific abdominal regions of particular importance in the assessment of colic. On the left side of the horse the regions evaluated include the ventral abdomen, gastric window, splenorenal window, and left middle third of the abdomen, and on the right side the regions evaluated include the duodenal window, right middle third of the abdomen, and cranial ventral thorax.

Ultrasonography is particularly valuable in the evaluation of small intestinal distention and motility.[519,520,522,524] Small intestine can most reliably be found in the inguinal region or on the ventral abdomen, and it should normally be collapsed or have a very small diameter with frequent peristalsis. Small intestine can be evaluated for dilation, motility, and thickening of the intestinal wall. The presence of dilated turgid small intestinal loops is highly sensitive and specific (80% and 96.15%) for small intestinal obstruction, although enteritis cannot entirely be ruled out. An intussusception may be identified as a target-shaped lesion on cross-sectional view.[519,520,526] Ultrasound can also be used to identify a left dorsal displacement of the large colon, also referred to as a nephrosplenic entrapment.[519,520,527] With this condition, the spleen cannot be visualized against the body wall, or the kidney cannot be visualized on the left side because of the interference of large colon. Visualization of colonic mesenteric vasculature on the right side of the abdomen can be a predictor of right dorsal displacement of the large colon, a 180° large colon volvulus, or both, although this change is not present in all cases.[528] Ultrasonographic assessment of peritoneal fluid volume and character may be useful in assessing the patient and in identifying pockets of representative fluid for abdominocentesis.[519,520] The thickness of intestinal wall should be evaluated at numerous locations, especially the right dorsal colon, which may be extraordinarily thickened with right dorsal colitis.[519,520] Investigation for abdominal masses also is often undertaken using ultrasound, coupled with rectal palpation.

A study comparing the findings of rectal examination and ultrasonographic findings in horses with colic demonstrated that ultrasonography was a more sensitive diagnostic technique than rectal examination in horses with small intestinal obstruction, left dorsal displacement of the large colon (nephrosplenic entrapment), and large colon torsion in the long axis, but was less sensitive than rectal examination in horses with impactions and most large colon displacements.[521] It was concluded that although ultrasonography is advisable in evaluation of the equine acute abdomen, it should not replace traditional rectal palpation.

Radiographs of the abdomen are of limited usefulness but may be diagnostic for two problems associated with colic in the adult horse: sand accumulation and enterolithiasis.[529,530] Sand is usually visualized best in the ventral large colon. It is important to keep in mind that some sand can be visualized in many normal horses, so the presence of sand in and of itself has no diagnostic relevance. Radiographs may, however, provide some information as to the volume of sand present.[504] Enteroliths represent the other main lesion identifiable by radiographs, although, depending on the location, they may be difficult to visualize. In a study of 141 horses evaluated for enterolithiasis, abdominal radiography had a sensitivity of 76.9% and a specificity of 94.4%.[530] The abdomen can be more thoroughly assessed via radiography in a neonate as opposed to an adult horse, although results still cannot be considered conclusively diagnostic. Radiographs of a foal's abdomen can identify gas distention of the stomach, small intestine, or large colon, which are nonspecific but generally pathologic findings.[494,531] Radiographs can aid in the diagnosis of meconium impaction. A radiographic pattern known as *pneumatosis intestinalis,* characterized by linear radiolucencies within the bowel wall, is typical for necrotizing enterocolitis.[494] Excessive peritoneal fluid and pneumoperitoneum can also be identified.

Endoscopy/Other. Gastroscopy is important in cases of colic where equine gastric ulcer syndrome is suspected. Ideally the squamous and glandular regions of the stomach, as well as the pyloric antrum, should be examined.

Evaluation for parasites may be indicated for some patients. Ideally both fecal flotation and a fecal egg count should be performed. Because standard flotation and fecal egg count methods are unreliable in the diagnosis of tapeworm infestation, however, a tapeworm ELISA, which detects antibody to tapeworms, should be considered.

An underlying cause is not found in some horses with chronic colic after routine diagnostic evaluation. In these cases, an exploratory laparotomy or laparoscopy may be indicated.

Referral Indications

Referral to a secondary care center is indicated when there is a strong likelihood that the horse will require surgery or more extensive medical care is necessary. The most common basis for referral is severe or persistent pain with a lack of response to analgesics.[485,486,503] If a horse demonstrates intractable pain or requires repeated doses of analgesics to remain comfortable, referral is warranted. Referral is also indicated when a horse has not resolved the signs of colic in 24 to 48 hours after onset, or if a 1.1-mg/kg dose of flunixin meglumine does not maintain comfort for at least 8 to 12 hours.[503] A persistently elevated heart rate can be a good indicator of pain or endotoxemia and necessitates referral. Other indications of endotoxemia or impaired cardiovascular status include weak pulses, abnormal mucous membrane color (pale, hyperemic, injected, purple, or cyanotic), and delayed capillary refill time. Rectal palpation of a potentially surgical lesion or small intestinal distention, an abnormal abdominocentesis, net nasogastric reflux of greater than 2 to 3 L, or significant depression are

all findings that would also support referral.[485,486,503] In addition, significant dehydration may require extensive treatment with intravenous or oral fluids or both because dehydration has the potential to exacerbate even apparently simple colic problems and affects the patient's systemic health. Dehydration can result in worsening of an impaction that is already present or contribute to development of an impaction when coupled with ileus and an inciting primary colic problem such as colonic displacement.

DIARRHEA

Diarrhea, defined as an increase in the fluidity, frequency, or volume of feces, is a commonly encountered clinical problem in the horse. It is often the result of a primary gastrointestinal disease but may also occur as a secondary response to another disease process, such as sepsis, endotoxemia, or hepatic disease. In some cases, diarrhea may rapidly develop into a life-threatening condition.

The function of the equine gastrointestinal tract is complex and involves maintenance of normal fluid balance and digestion and absorption.[532-534] As a result of dietary intake and endogenous secretions, a large volume of fluid normally enters the gastrointestinal tract, most of which is reabsorbed. In the adult horse absorption occurs predominantly in the large bowel, where a volume of water approximately equal to the total extracellular fluid volume of the animal, or about 100 L, is recovered during the course of the day. Because the large colon is the primary site of water resorption, most significant diarrheal disease in the adult horse involves the colon. In young foals, however, small intestinal disorders such as rotaviral infection also may result in diarrhea.[535]

A second critical function of the large bowel is that of microbial digestion of carbohydrates and, to some extent, protein or nonprotein nitrogen.[532-534] Microbial fermentation of carbohydrates in the cecum and colon results primarily in the production of volatile fatty acids (VFAs), which are absorbed readily, providing up to 75% of the energy requirement of the horse. The intestinal microbiome is a complex polymicrobial ecosystem that appears to play an important role in the maintenance of health.[534,536,537] Therefore maintaining a stable environment for the microbial population is important. In general, efficient function of the large bowel requires mechanisms that limit the rate of digesta passage, provide optimal conditions for microbial digestion, and allow for efficient transport of solutes and water.

The characteristics of normal equine feces and the frequency of defecation can vary somewhat with diet, age, and sex.[538] On average, adult horses defecate approximately 8 to 10 times daily. The frequency of defecation tends to be slightly higher in stallions and foals. Generally, equine feces are tan, brown, or greenish, and, although approximately 75% water, they are well formed. An average size adult horse on a typical diet of grass hay and grain produces about 20 to 28 g of feces per kilogram of body weight per day, or about 11 to 13 kg of feces per day.[538] In cases of diarrhea the amount of feces may increase up to tenfold, with some horses producing more than 200 g/kg/day, which can equate to more than 90 L of diarrhea. As a result, diarrhea can cause significant losses of electrolytes and water. Especially in cases of acute diarrhea, these losses may result in severe dehydration, electrolyte imbalances, and acid-base abnormalities. However, horses with chronic diarrhea seldom develop these abnormalities as they are often able to compensate for increased fecal losses. Protein loss may be seen with both acute and chronic diarrhea.

Mechanisms of Diarrhea

Several basic mechanisms of diarrhea have been described, and in many diarrheal diseases more than one mechanism is involved. Inflammation within the bowel often plays a central role in the pathogenesis of diarrhea and may contribute to diarrhea via multiple mechanisms. Basic mechanisms of diarrhea include the following:

1. *Malabsorption:* Malabsorption results from a decrease in the functional absorptive surface area of the gastrointestinal tract. In the small intestine, villus atrophy, such as that seen with rotaviral enteritis, equine proliferative enteropathy *(Lawsonia intracellularis),* and infiltrative bowel disease, can result in malabsorption because of the loss of functional epithelium and maldigestion caused by decreased production of digestive enzymes.[142,535,539-577] In the colon, a number of insults can result in inflammation and disruption of absorptive cells and tight junctions, leading to decreased absorptive capacity and decreased ability to retain absorbed fluid (i.e., increased loss). Several inflammatory mediators, such as TNF-α, histamines, and prostaglandins, can contribute to the colonic inflammation. These mediators are produced primarily by inflammatory cells in the lamina propria and inhibit absorption through a variety of mechanisms.[542-546]
2. *Increased secretion:* The increased secretion of solutes and water by the inflamed colon can contribute significantly to the development of diarrhea. Although the precise mechanisms of secretion in the equine colon are not understood fully, active secretion and passive fluid loss occur.[542-549] Control of active secretion is complex, involving two primary pathways: first, the activation of adenyl cyclase, resulting in an increase of intracellular cyclic adenosine monophosphate concentrations, and second, the activation of calcium channels, leading to increased intracellular calcium concentrations.[547,548] Cyclic adenosine monophosphate and calcium stimulate specific secretory activities, primarily through chloride channels. In some cases of diarrhea, bacterial enterotoxins such as those produced by certain strains of *Escherichia coli* and *Salmonella* spp. stimulate adenyl cyclase activity, thus increasing active secretion. This is true hypersecretory diarrhea. Also, a number of inflammatory mediators produced by the inflamed colon, particularly prostaglandin E_2, increase intracellular concentrations of cyclic adenosine monophosphate and to some extent calcium, thereby increasing active secretion by mucosal cells.[547-549] Inflammation also enhances passive fluid loss through a number of factors, such as changes in hydrostatic pressure in the colonic capillaries, mucosal damage, and loss of tight junctions. In horses with severe mucosal injury, the loss of protein can decrease vascular oncotic pressure and further potentiate fluid exchange across the endothelium.
3. *Decreased transit time (abnormal motility):* Sufficient retention time and thorough mixing are required for digestion and absorption of nutrients and fluid to occur, and thus decreased intestinal transit time can contribute to diarrhea.[532-534,550] Primary motility disorders causing diarrhea are not well recognized, although diarrhea associated with stress or excitement may represent this phenomenon. However, it appears that secondary motility disorders are

common in response to a variety of gastrointestinal problems, although the exact role that these changes in motility play in the pathogenesis of diarrhea is not entirely clear. Both inflammatory and infectious conditions may influence motility in addition to potentially altering absorption and secretion. Absorption of endotoxin and the release of inflammatory mediators, including prostaglandins, disrupts normal motility patterns.[551] In general, these changes result in hypermotility and decreased intestinal transit time, although hypomotility has been recognized as well. Some progressive motility must be present for diarrhea to occur. In some cases of acute colitis, a period of ileus may occur without diarrhea. This is usually transient and diarrhea develops, although occasionally ileus may persist. With diarrheal diseases, the elimination of gastrointestinal contents is part of the normal host defense mechanism, and thus treatments specifically aimed at decreasing motility are not indicated in most cases.

4. *Osmotic overload:* Any increase in osmotically active particles within the intestinal lumen can result in diarrhea. The increase can be associated with the administration or ingestion of osmotically active substances such as magnesium sulfate. The increase also may be associated with overloading of the intestine with carbohydrates or occasionally lipids beyond the amount that can be digested and absorbed. Therefore sudden dietary changes that result in significant shifts in gut flora and changes in fermentation or gastrointestinal diseases that result in malabsorption or maldigestion also may result in an osmotic diarrhea. In foals the loss of villous epithelial cells in the small intestine associated with disorders such as rotavirus infection and clostridiosis may lead not only to malabsorption but also to maldigestion caused by the decreased production of lactase and secondary lactose intolerance.[535,539,552] Although uncommon, primary lactose intolerance has also been reported in foals.[553] Lactose intolerance allows excess lactose to enter the large intestine, increasing the osmotic load.
5. *Increased hydraulic pressure from the blood to the lumen:* The pressure change may result in increased fluid movement to the lumen and decreased net fluid absorption. This mechanism of diarrhea is more common in chronic conditions, such as congestive heart failure or inflammatory bowel disease. The condition may result from decreased oncotic pressure associated with hypoproteinemia, increased capillary hydrostatic pressure (as in heart failure), or decreased lymphatic drainage associated with inflammation of lymphatics and lymph nodes.

The normal equine fecal microbiota is very complex. In horses with diarrhea, the bacterial diversity of the gut microbiota may be lower than in horses with normal feces.[537] This microbial imbalance, referred to as *microbiome dysbiosis,* may be both a result and a cause of intestinal disease and diarrhea. Characterization of the microbiome and its role in health and disease is a very active area of research.

Understanding the mechanisms of diarrhea can be helpful in directing therapy. It is important to remember that most disorders that cause diarrhea, whether infectious or noninfectious, do so through inflammatory mechanisms resulting in multiple functional alterations.

Conditions Associated with Diarrhea

Diarrhea is a common, and sometimes fatal, clinical problem of adult horses and foals. A number of specific causes for acute and chronic diarrhea have been identified (Tables 7.5, 7.6, and 7.7). In some cases, rapid dietary changes or stress can result in diarrhea that is generally mild and transient. Also, although sand ingestion is frequently associated with impactions, it may also result in diarrhea due to mechanical irritation to the gastrointestinal tract.

TABLE **7.5 Differential Diagnoses for Acute Diarrhea in Adult Horses**

Common Causes	Major Diagnostic Test(s)
Salmonellosis	Fecal culture or polymerase chain reaction (PCR), culture of rectal mucosal biopsy
Potomac horse fever *(Neorickettsia risticii)*	PCR (feces, peripheral blood), paired serologic tests
Clostridiosis *(Clostridium difficile, C. perfringens)*	Fecal culture, toxin analysis
Antibiotic-associated diarrhea	History
Nonsteroidal antiinflammatory toxicity (primarily right dorsal colitis)	History and supportive clinicopathologic findings, ultrasonography, exploratory surgery with biopsy
Undiagnosed	Other conditions ruled out
Less Common	
Cantharidin toxicity	
Parasitism (strongylosis, cyathostomiasis, other)	
Aeromonas, Campylobacter spp.	
Sand	
Carbohydrate overload	
Arsenic toxicity, other toxicities	
Thromboembolic disease	
Anaphylaxis	

Several infectious agents are associated with diarrhea in horses. *Salmonella* and *Clostridium* species are among the most common causes of infectious diarrhea in horses of any age.[554,555] *Salmonella* is of particular importance because under certain circumstances it can be highly contagious, leading to significant outbreaks of disease, especially in hospitalized patients.[556] *Clostridium difficile* and *Clostridium perfringens* are the most common clostridia associated with colitis in horses, although occasionally other species may be involved.[552,557-561] In certain geographic areas equine neorickettsiosis (Potomac horse fever) caused by *Neorickettsia risticii* is also common.[562] *Lawsonia intracellularis* can cause equine proliferative enteropathy resulting in diarrhea, colic, edema, and weight loss.[335,601-565] *Lawsonia intracellularis* can potentially affect horses of any age, but it is most common in weanling-age foals. Although primarily a respiratory pathogen, *Rhodococcus equi* also can cause diarrhea, particularly in foals 2 to 4 months of age.[566] *Escherichia coli* is an uncommon cause of diarrhea in foals, unlike in calves and piglets. However, enterotoxigenic strains, characterized by the presence of virulence factors, have been identified in foals.[567] Other, less common bacterial agents potentially associated with diarrhea include *Campylobacter* spp. and *Aeromonas* spp.[568,569]

Both equine rotavirus and coronavirus can be important enteropathogens. Rotaviral infection is a common cause of

TABLE **7.6 Differential Diagnoses for Chronic Diarrhea in Adult Horses**

Cause of Diarrhea	Major Diagnostic Test(s)
Chronic salmonellosis	Fecal culture or polymerase chain reaction, culture
Sand	Fecal sedimentation
Parasitism (strongylosis, cyathostomiasis)	Fecal egg count, empirical deworming
Nonsteroidal antiinflammatory toxicity (primarily right dorsal colitis)	History and supportive clinicopathologic findings, ultrasonography, exploratory surgery with biopsy
Inflammatory or infiltrative disorders	Histopathologic examination, absorption tests (supportive but nonspecific)
Inflammatory bowel disease (granulomatous, lymphocytic-plasmacytic, or eosinophilic enterocolitis)	
Mucosal lymphosarcoma	
Amyloidosis	
Dietary: abnormal fermentation	History
Neoplasms: lymphosarcoma, squamous cell carcinoma	Histopathologic examination
Peritonitis, abdominal abscessation	Peritoneal fluid analysis, ultrasound, exploratory surgery
Nongastrointestinal causes (chronic liver disease, congestive heart failure, renal disease)	Physical examination, clinicopathologic findings

TABLE **7.7 Differential Diagnoses for Diarrhea in Foals**

Cause of Diarrhea	Major Diagnostic Test(s)
Salmonellosis	Fecal culture or PCR
Clostridiosis *(Clostridium difficile, C. perfringens)*	Fecal culture, toxin analysis
Endotoxemia, gram-negative septicemia	Blood culture, physical examination, complete blood count, sepsis score
Antibiotic-associated diarrhea	History
Foal heat diarrhea	History, physical examination
Viral: rotavirus; rarely coronavirus or adenovirus	Electron microscopy, enzyme immunoassay
Protozoan: cryptosporidiosis	Fecal analysis
Secondary lactose intolerance therapy	Oral lactose tolerance test, response to
Rhodococcus equi	Culture, PCR
Lawsonia intracellulare	Fecal PCR, serologic testing
Gastric ulcer disease syndrome	Gastric endoscopy
Strongyloides westeri	Fecal egg count
Sand	Fecal sedimentation

PCR, Polymerase chain reaction.

diarrhea in foals and is most often recognized in foals from 1 to 4 weeks of age.[535,539,570,571] Equine coronavirus, also sometimes referred to as equine enteric coronavirus, has been recognized in both foals and adult horses.[571-575] Since 2011 several outbreaks of equine coronavirus have been identified in adult horses, causing it to be named as an emerging pathogen. The most common signs include anorexia, lethargy, and fever; diarrhea and colic are less common.

The signs associated with internal parasites can vary depending on the type and severity of infestation, but diarrhea may occur. Often it is a chronic diarrhea, but acute diarrhea may be seen. Encysted cyathosomin larvae are ubiquitous in grazing horses, but large numbers of encysted larvae place the horse at risk for developing larval cyathostominosis.[576,577] This condition occurs when there is a mass emergence of the larvae, resulting in acute typhlocolitis. The inflammatory responses trigger diarrhea, especially in individuals with high parasite burdens. The case fatality rate may be as high as 50%. The majority of infections with *Strongyloides westeri* are subclinical, but occasionally diarrhea can occur in foals with high worm burdens.[578,579] A 2014 study in Thoroughbred foals in central Kentucky found a mean prevalence of *S. westeri* infection of 30%, which was greater than previous reports from the area.[579] *Cryptosporidium* spp. are coccidian parasites that have been linked to diarrhea in foals and occasionally adult horses.[580-582]

Medications may be involved in the pathogenesis of diarrhea, with the two classes of drugs most commonly incriminated being antibiotics and NSAIDs. Potentially any systemic antibiotic may cause diarrhea, but the risk appears to be higher with certain antibiotics such as trimethoprim-potentiated sulfonamides and erythromycin.[28,583,584] Although the mechanisms of antibiotic-associated diarrhea may be multifactorial, an important factor is that the use of systemic antimicrobials leads to changes in the intestinal microbiota.[585,586] The use of NSAIDs has been linked to adverse gastrointestinal effects including gastric ulcers, right dorsal colitis, and inhibition of mucosal barrier healing.[336,587,588,589,626] Phenylbutazone causes changes in right dorsal colon arterial blood flow and changes in VFA production.[589]

Diarrhea is a component of the clinical syndrome associated with several toxins. Cantharidin (blister beetle toxin) can cause severe colitis in horses.[590] Some plants associated with diarrhea include alfalfa dodder *(Cuscuta campestris),* acorns, and oleander.[591-593] Other toxins that may result in diarrhea include lead, selenium, and arsenic.[594,595]

Cellular infiltrative disorders such as inflammatory bowel disease and neoplasia can cause diarrhea, which is generally chronic in nature. Alimentary lymphosarcoma is the most common intestinal neoplasia of horses, and it can cause significant cellular infiltration of the intestine and associated lymph nodes.[596] It has been recognized across a broad age range, including relatively young horses. Several inflammatory bowel diseases have been recognized in horses, including granulomatous enteritis, lymphocytic-plasmacytic enterocolitis, eosinophilic enterocolitis, and multisystemic eosinophilic epitheliotropic disease.[142]

Some additional causes of diarrhea occur in neonatal foals. Foal heat diarrhea is a normal physiologic diarrhea that occurs typically between 5 and 15 days of age.[597] Foals are otherwise healthy and the diarrhea is generally mild and self-limiting. With respect to infectious agents, coinfections appear to be

BOX 7.10 Outline of Diagnostic Approach to Diarrhea

I. SIGNALMENT, HISTORY, AND PHYSICAL EXAMINATION

II. CLINICAL PATHOLOGY

1. Minimum database: complete blood count, fibrinogen, and serum chemistry profile
   a. Assess hydration, acid-base status, electrolyte abnormalities, and protein status
   b. Assess renal and hepatic function
   c. Assess endotoxemia
2. Serum protein electrophoresis and immunoglobulin quantitation
3. Serologic testing: *Neorickettsia risticii* and *Lawsonia intracellulare*
4. Peritoneal fluid analysis

III. EVALUATION OF FECES

1. Gross appearance: severity, hemorrhage, odor, and presence of sand
2. Direct smear: evaluation of protozoan populations and presence of leukocytes and epithelial cells
3. Parasite evaluation: including evaluation for *Cryptosporidium parvum,* especially in foals
4. Evaluation of bacterial pathogens
   a. Gram stain and spore stain
   b. Aerobic and anaerobic culture (culture of multiple samples or rectal mucosal biopsy for *Salmonella* spp.)
   c. Clostridial toxin analysis
   d. Polymerase chain reaction: *Salmonella* spp., *N. risticii,* and *L. intracellulare*
5. Foals: evaluation of viral pathogens, primarily rotavirus (electron microscopy and enzyme immunoassay)

IV. DIAGNOSTIC IMAGING: RADIOGRAPHY AND ULTRASONOGRAPHY

V. ENDOSCOPIC EXAMINATION: STOMACH, RECTUM, AND DESCENDING COLON

VI. ABSORPTION TESTS (GLUCOSE OR XYLOSE ABSORPTION): PRIMARILY FOR CHRONIC PROTEIN-LOSING ENTEROPATHY

VII. HISTOPATHOLOGIC EXAMINATION

VIII. TOXIN EVALUATION: CANTHARIDIN IN URINE OR GASTROINTESTINAL CONTENTS, ARSENIC IN LIVER, OR OTHER

IX. RESPONSE TO THERAPY

common in neonatal foals.[571] Secondary lactose intolerance has been documented in foals with gastrointestinal infections, and primary lactose intolerance has been reported as well.[539,552,553] Diarrhea has been seen in neonatal foals in association with hypoxic-ischemic gastrointestinal damage, sepsis, and rarely acute pancreatitis.[598]

Diagnostic Approach to Diarrhea

A comprehensive evaluation may help in establishing a diagnosis and developing a treatment plan in cases of diarrhea (Box 7.10). However, even in severe cases a definitive diagnosis often is not made, making the problem particularly frustrating.[554,555,568,571,599]

Signalment and History

The veterinarian should consider the signalment and history carefully when evaluating a patient with diarrhea. Age is particularly important because several disorders, such as foal heat diarrhea, rotaviral diarrhea, and equine proliferative enteropathy, are age related. The genetic background also may be significant because diarrhea has been associated with certain heritable immunodeficiencies, and granulomatous bowel disease has been identified in three sibling horses.[600-602] Establishing whether the diarrhea is acute or chronic is important. Other historical questions of particular relevance include the type and source of feed, as well as any dietary changes; deworming program; involvement of single versus multiple animals; exposure to sand; and the use of medications, especially antibiotics and NSAIDs. Other concurrent diseases, stress, possible exposure to toxins, weight loss, water consumption, and salt availability also may be significant. The information obtained helps the veterinarian prioritize differential diagnoses and direct further testing.

Physical Examination

The clinician should perform a complete physical examination. Attention should be given to good biosecurity measures, especially as some causes of equine diarrhea are potentially zoonotic in addition to being transmissible among horses. The body condition of the horse and the presence of any edema should be noted. The presence of fever, dehydration, or signs of endotoxemia may help in assessing the severity of the disease and differentiating the cause because some causes of diarrhea are not typically associated with systemic signs of illness. The presence of oral ulcers and synchronous diaphragmatic flutter increase the likelihood of cantharidin toxicity especially in horses being fed alfalfa.[590] In horses presented for diarrhea with a concurrent arrhythmia, oleander toxicity should be considered if exposure is possible.[593] Careful evaluation of the abdomen should be performed. Visible abdominal distention is often an indication of large intestinal distention, which may occur in association with acute colitis. However, distention also may be visible with extreme dilation of multiple loops of small intestine. Careful auscultation of the abdomen can be useful in assessing motility. Although the frequency of borborygmi in horses is variable, horses with normal motility generally have 1 to 3 borborygmi in a 60-second time period. Auscultation behind the xiphoid process may help identify the presence of sand or gravel if particles can be heard grinding together during contractions of the colon.[499] Percussion of the abdomen while ausculting may help to identify high-pitched resonant sounds associated with gas-distended bowel. Particularly in foals, transabdominal palpation and ballottement may be useful to identify increased abdominal fluid or large masses near the body wall. Transrectal palpation can be helpful in assessing the size of intestinal segments, consistency of contents, and wall thickness, as well as in identifying masses, enlarged lymph nodes, or mesenteric arteritis.

Ancillary Diagnostic Tests

Clinical Pathology. Routine analysis of blood work typically does not identify a specific cause of diarrhea, although occasionally *N. risticii* can be found in circulating monocytes. However, blood work is often important in directing appropriate supportive care and may help to establish whether

diarrhea is caused by another condition, such as hepatic or renal disease. Some important parameters to evaluate include the presence of leukopenia, particularly neutropenia with a left shift, and toxic changes in the white blood cells. These abnormalities suggest a systemic inflammatory response, often associated with endotoxemia. Thrombocytopenia and coagulopathies may also be present. The clinician also should evaluate the concentration of protein, as well as the albumin-to-globulin ratio. Both acute and chronic diarrhea can cause significant protein loss, resulting in hypoproteinemia and particularly hypoalbuminemia. Hyperglobulinemia may indicate a chronic inflammatory condition. Disturbances in acid-base balance, especially metabolic acidosis, and electrolyte abnormalities frequently occur in horses with acute diarrhea but are uncommon with chronic diarrhea. Although hypocalcemia is relatively common in horses with colitis, marked hypocalcemia may be suggestive of possible cantharidin toxicity.[63] Because of the dehydration frequently seen with acute diarrhea, prerenal azotemia is common and is important to recognize because some therapies, especially NSAIDs, may worsen the condition. In a study of 122 horses with acute diarrhea, horses with azotemia and clinicopathologic findings consistent with hemoconcentration and hypoproteinemia were less likely to survive.[599]

The diagnostic and prognostic value of serum protein electrophoresis has been evaluated in horses with chronic diarrhea.[603] Significantly higher levels of β_1-globulin were found in horses with larval cyathostominosis than in other horses, and such values in conjunction with a decreased albumin were helpful in diagnosing intestinal parasitism. However, a normal β_1-globulin concentration was not a reliable indicator of the absence of the disease. Significantly lower albumin concentrations and significantly higher α_2-globulin concentrations were found in horses that did not survive, suggesting that these parameters are nonspecific indicators of the severity of inflammatory changes within the intestinal wall. Parasitic infections, particularly strongylosis, also may be associated with elevated serum concentrations of the immunoglobulin G (IgG) isotype IgG(T).[604]

Because immunodeficiencies are infrequently associated with diarrhea,[600,601] further evaluation of immune status may be indicated in some horses. This evaluation may include specific immunoglobulin quantitation, evaluation of specific lymphocyte subsets, or functional assays. The clinician should consider genetic testing for severe combined immunodeficiency in sick foals of Arabian breeding.

Analysis of peritoneal fluid may be useful in some horses with diarrhea. Abnormalities in the peritoneal fluid may reflect the severity of inflammation and in some cases may help to establish a specific diagnosis. Increases in protein and sometimes nucleated cell count may be seen in association with ulcerative colitis. In horses with bacterial peritonitis, the veterinarian may find organisms on cytologic examination or culture. Occasionally, the veterinarian may identify neoplastic cells in the peritoneal fluid, although their absence does not rule out the presence of neoplasia.

Evaluation of Feces. Evaluation of the feces may yield important information in horses with diarrhea. Even the gross appearance of the feces can be helpful. For example, profuse, watery diarrhea is not generally consistent with a diagnosis of right dorsal colitis, which is most often associated with soft, poorly formed feces. Frank blood in the feces suggests bleeding into the distal colon from mucosal damage. Hemorrhagic, foul-smelling feces often are seen in association with clostridial diarrhea. The clinician also can assess the feces for the presence of occult blood, which indicates bleeding from any source. Although excess sand in the feces is readily apparent in some cases, other cases require mixing the feces in a rectal sleeve with water and allowing the sand to settle. Acorn husks may be present in the feces of horses with acorn toxicity. Less commonly used tests include evaluation of fecal osmolality and electrolyte concentrations (sodium and potassium). If the concentration of sodium plus potassium is much less than the osmolality, the result indicates the presence of osmotically active nonelectrolytes, confirming an osmotic diarrhea.

Microscopic examination of the feces for evidence of parasitism and evaluation of viable protozoal populations also may be useful. A direct smear of fresh feces allows for observation of the motility of ciliates and can be used as a screen for the presence of ova and oocysts. Ideally evaluation of parasitism should include fecal flotation and a quantitative method that allows for estimation of the number of eggs per gram of feces, such as McMaster's or Stolley's. Cryptosporidial oocysts are typically difficult to identify on routine fecal flotation, but detection can be improved by acid-fast or acridine orange staining as well as immunofluorescent staining or flow cytometry.[579-582] It is important to remember that fecal examination for parasites sometimes can be misleading, giving false-negative results.

Fecal samples also can be examined microscopically for leukocytes and epithelial cells. In general, the cellularity increases with the severity of diarrhea. Fecal leukocytes and epithelial cells are increased in salmonellosis but are not specific for this disorder.[605] The presence of more than 10 leukocytes per high-power field has been associated with salmonellosis.

Evaluation of the feces for infectious agents is essential in the diagnostic evaluation of horses with diarrhea. Gram stain and spore stain of fecal smears can help to identify and quantitate the bacterial populations present, particularly clostridial species. However, although large numbers of gram-positive rods or spores have been identified in horses with clostridial enterocolitis, the results of direct staining may be misleading.[557-561] *Clostridium perfringens* has been cultured from 59% of samples in which no gram-positive rods were visible. Some clostridial strains also are likely parts of the normal microflora.[561,606] Large numbers of yeast in the feces should alert the clinician to the possibility of candidiasis, especially in compromised neonatal foals.

Fecal culture is used commonly to establish a diagnosis in horses with bacterial diarrhea. When culturing feces, especially if an outside laboratory is used, the clinician must consider proper sample handling, particularly for anaerobic clostridia.[607] *Salmonella* spp. are one of the most significant bacterial pathogens in equine feces.[556] Although the number of *Salmonella* organisms isolated from the feces of horses with clinical salmonellosis is generally greater than from horses with asymptomatic infections, the volume of feces in horses with profuse diarrhea may decrease the likelihood of positive culture. Culture of multiple fecal samples, typically five, is recommended to increase the sensitivity.[608] Culture of a rectal mucosal biopsy or rectal scraping is an alternative to fecal cultures and may increase sensitivity because *Salmonella* spp. are intracellular organisms. Identifying clostridial species requires anaerobic culture. However, evaluating the presence of toxin in cases of suspected clostridial diarrhea also is critical because *Clostridium* spp., particularly *C. perfringens* type A, may be present in normal equine feces.[557-561,606] Depending on the clostridial species and the laboratory, toxin can be assessed by detecting preformed toxin in the feces, toxin being produced by the isolate in culture, or the toxin gene in the isolate.

An increasing number of polymerase chain reaction (PCR) assays are available for detecting causative agents of equine diarrhea. In comparing a PCR with microbial culture for detection of salmonellae in equine feces and environmental samples, the PCR method was found to be more sensitive and more rapid and required submission of fewer samples.[609,610] For diagnosis of equine neorickettsiosis (Potomac horse fever), PCR is currently recommended for detection of *Neorickettsia risticii* in feces and peripheral blood.[562,611,612] Fecal PCR analysis is also useful in documenting *Clostridium, Lawsonia intracellularis,* and *Cryptosporidium* spp., as well as both equine rotavirus and equine coronavirus.[335,539,563,572,613,614] Both rotavirus and coronavirus can also be identified in the feces by electron microscopy.[539,572,615] A number of commercial assays are also available for the detection of rotavirus antigen.[539,616]

Serologic methods, evaluating the presence of antibodies, have been used in the diagnosis of *Neorickettsia risticii* and *Lawsonia intracellularis.*[562-564,612,614] In the case of *N. risticii,* the serologic tests are of limited value in the diagnosis of disease.[562] For *L. intracellularis,* it is recommended to use both PCR and serologic diagnostic testing as these assays have high analytic specificity but variable sensitivity depending on the circumstances.[563,614]

Coinfections have been documented in both adult horses and foals with diarrhea. In a study of neonatal foals, coinfections were significantly associated with the risk of gastrointestinal disease.[571] The use of diagnostic panels rather than individual tests in combination with quantitative toxin gene analysis may be helpful in the diagnosis of coinfections.

Diagnostic Imaging. Diagnostic imaging, although particularly useful in foals, also can be valuable in adult horses. In foals radiographs can detect gas distention in the lumen of the gastrointestinal tract, and the gas pattern may help to differentiate ileus from mechanical obstruction. Occasionally, gas may be seen within the bowel wall in severe cases of clostridial necrotizing enterocolitis. In adult horses abdominal radiography is limited somewhat by having the proper facilities and equipment to perform the procedure safely. However, radiographs can be effective in identifying radiodense material, such as enteroliths and sand. Ultrasonography can be used in horses of all ages to evaluate the amount and character of the peritoneal fluid, masses, small intestinal motility, intestinal distention, and wall thickness. In horses with right dorsal colitis the diagnosis has been supported by ultrasonographic evidence of an increase in mural thickness of the right dorsal colon.[617] The right dorsal colon may have a prominent hypoechoic layer most likely associated with submucosal edema and inflammatory infiltrates. Although isotope-labeled white blood cell scintigraphic scans also may help identify colonic ulcerations, the availability and sensitivity of the procedure are limited.[618] In cases of *L. intracellularis,* ultrasonography may reveal thickened small intestinal loops and possibly excess free abdominal fluid.[335,563]

Endoscopy. Endoscopic examination of the stomach and proximal duodenum may reveal the presence of neoplasms or ulceration. Diarrhea and inappetence can be seen in symptomatic foals with ulceration of the squamous gastric mucosa. Endoscopy also can be used for inspection of the mucosa of the rectum and descending colon, allowing for evaluation of mural masses or mucosal inflammation.

Additional Diagnostic Tests. Absorption tests are used primarily in horses with chronic diarrhea or weight loss to evaluate the small intestinal absorptive capacity. Oral glucose and oral xylose absorption tests have been used.[160,619] Although the plasma concentration of glucose may reflect glucose metabolism as well as absorption from the gastrointestinal tract, the assay is reliable in the diagnosis of significant malabsorptive conditions. Xylose is influenced less by the metabolic status of the horse, but the compound is more expensive than glucose, and the assay is not available in many laboratories. Results of both assays are nonspecific, but abnormal results support malabsorption and may indicate the necessity of biopsy.

Diagnosing neoplasms and chronic inflammatory or infiltrative disorders often requires histopathologic examination. A rectal mucosal biopsy is easy to collect and can be cultured, but the area that can be reached for biopsy is limited. Laparoscopy allows for visualization of the abdomen and certain biopsies. The veterinarian can obtain a full-thickness intestinal biopsy during exploratory celiotomy.

The diagnosis of cantharidin toxicity can be made in suspect cases by the identification of blister beetles in the feed source and detection of cantharidin in urine or gastrointestinal contents.[590] If a heavy metal or trace mineral toxicity is suspected, lead and selenium can be measured in the blood and liver or arsenic can be measured in the blood, urine, liver, or kidney as appropriate.[594,595] Oleandrin is detectable in urine and gastrointestinal contents.[593]

Evaluation of Response to Therapy

Evaluating the response to empirical therapy may be helpful in some horses with undiagnosed diarrhea, especially in chronic cases. Dietary changes may decrease diarrhea in some cases, and often a diet of grass hay alone is recommended. In cases in which right dorsal colitis is suspected but cannot be confirmed, using pelleted feed and the addition of psyllium mucilloid and corn oil to the diet may be beneficial. Psyllium mucilloid also has been used for treatment of horses in which sand was suspected as contributing to the diarrhea. Any medications that the horse has been receiving, especially NSAIDs or antibiotics, should be discontinued in case they are contributing to the diarrhea.

Fecal microbiota transplant (FMT), also known as *transfaunation,* can be used in an attempt to restore normal flora.[620] Although not a new concept, there has been renewed interest in FMT due in part to increased awareness of the importance of the microbiota and the success of FMT in the management of *Clostridium difficile* infection in humans. Currently, data regarding FMT in horses are limited. Some guidelines for the use of FMT in horses, including case selection and FMT procedure, have been proposed.[620] Several commercial prebiotics and probiotics are available, and their efficacy is under investigation.[621] The yeast *Saccharomyces boulardii* may decrease the severity and duration of clinical signs in horses with acute enterocolitis.[622]

A course of corticosteroids can be tried in cases of chronic diarrhea in which infectious causes have been ruled out. Treatment with a larvicidal anthelmintic may be beneficial in some cases and sometimes is used with corticosteroids. Some horses with chronic diarrhea have responded to iodochlorhydroxyquin (10 g/450 kg/day for 2 weeks). This drug sometimes has been used concurrently with trimethoprim-sulfa. Occasionally, transfusion with plasma seems to suppress diarrhea in young horses.

POLYURIA AND POLYDIPSIA

Polyuria and polydipsia are infrequently reported clinical problems in the horse that can be a source of inconvenience to owners, may indicate a major abnormality in the mechanisms controlling water balance, and can be associated with significant disease. As water intake and urine output are closely

linked, polydipsia and polyuria generally occur together. Establishing whether the primary problem is polyuria or polydipsia can be helpful in developing a management strategy and providing an accurate prognosis.

Normal fluid intake and urine production in horses are influenced by a number of factors, including age, diet, physiologic demands such as exercise or lactation, environmental temperature and humidity, and gastrointestinal water absorption.[623-630] In adult horses, water requirements range from 25 to 70 mL/kg per day. These requirements are proportional to metabolic body size rather than body mass, with larger horses requiring less water per kilogram than smaller horses or ponies. Because fat is low in water content compared with lean body tissue, horses with significant body fat require less water than lean horses. Fluid requirements are higher in neonatal foals than adult horses due to their high total body water.

Water is obtained from three sources: drinking water, water in feed, and metabolic water from the catabolism of fats, carbohydrates, and protein. Water is lost in urine and feces as well as through evaporation across the skin and respiratory tract. In adult horses, normal water intake through drinking is approximately 50 to 60 mL/kg per day (20–30 L/day for an average adult horse) and normal urine production is approximately 15 to 30 mL/kg per day (5–15 L/day for an average adult horse).[623-627] Diet is a major influence on drinking and urine output. In neonatal foals on a milk diet, fluid intake is approximately 250 mL/kg per day to meet their caloric needs.[631-633] As a result, the kidneys actively excrete water and the urine output approaches 148 mL/kg per day, which is almost 5 times that of adults. In adult horses, water intake correlates with dry matter intake.[628,629] Depending on weather conditions, water consumption may be minimal in horses on good quality pasture due to the high moisture content of grass. Water requirements are higher for horses consuming hay compared with pasture or grain-based rations and vary with the type of hay. Horses on legume hay have significantly higher urine production than those on grass hay. Voluntary water intake is also affected by ambient temperature, increasing when temperatures are high and water losses in sweat are increased[623,625,634,635] (Table 7.8). Water consumption may increase significantly in heavily exercised horses such as endurance horses to replace the additional fluid lost in sweat.[634,635] Horses with diarrhea may also have significantly increased water consumption.

Polyuria and polydipsia may be clearly evident in some affected horses but in others may be more subtle. The conditions are sometimes hard for owners to recognize, particularly in horses housed at pasture and especially if they are with other horses. Some owners may misinterpret frequent urination, or pollakiuria, as polyuria. Objective documentation of polyuria and polydipsia requires measurement of water consumption and 12- to 24-hour urine production. In adult horses, polydipsia has been defined as water intake greater than 100 mL/kg per day and polyuria as urine output greater than 50 mL/kg per day. Consideration of factors that can influence water consumption and urine production, such as diet, climatic conditions, and level of exercise, should be taken into consideration when documenting polyuria and polydipsia.

TABLE **7.8 Causes of Polyuria and Polydipsia**

SOLUTE DIURESIS
Primary renal insufficiency or failure
Glucosuria (PPID)
Psychogenic salt consumption
Diabetes mellitus
Postobstructive diuresis
WATER DIURESIS
Insufficient antidiuretic hormone (central diabetes insipidus)
PPID
Head trauma
(Potassium depletion)[a]
Insufficient response of collecting ducts to antidiuretic hormone
Acquired nephrogenic diabetes insipidus
Hyperadrenocorticism (glucocorticoid excess with PPID)
Endotoxemia
(Drugs: gentamicin, lithium, methoxyflurane, amphotericin B, propoxyphene, etc.)
(Congenital nephrogenic diabetes insipidus)
Renal medullary solute washout
Chronic diuresis of any cause
Inappropriate renal tubular sodium handling
Apparent psychogenic polydipsia
(Chronic liver disease)
(Polycythemia)
(Pyometra)
(Hypercalcemia)
(Potassium depletion)
IATROGENIC
Intravenous fluid therapy
Excess dietary salt
Drugs
Diuretics
Glucocorticoids
(Drugs causing acquired diabetes insipidus)

Mechanisms of Polyuria and Polydipsia

Maintenance of Normal Water Balance

The maintenance of adequate body water that has a relatively constant concentration of electrolytes and other solutes is essential for normal cellular function. Under normal conditions, plasma osmolality remains relatively constant, varying only by approximately 2%.[636] Body water is controlled by two general mechanisms: (1) fluid intake, which is regulated by factors that influence thirst, and (2) renal excretion of water, which is regulated by factors that affect glomerular filtration and tubular reabsorption. In normal horses, glomerular filtration exceeds 1000 L/day, but 99% is reabsorbed in the renal tubules and collecting ducts. Normal urine is 3 to 4 times more concentrated than plasma with an osmolality of 900 to 1200 mOsm/kg and a specific gravity of 1.025 to 1.050. The ability to concentrate urine is dependent primarily on three factors: (1) the production of arginine vasopressin (AVP), also known as *antidiuretic hormone (ADH);* (2) the presence of a sufficient number of nephrons that are sensitive to AVP; and (3) the presence of a hyperosmotic renal medullary interstitium.[636,637]

Role of Arginine Vasopressin. Arginine vasopressin is an important peptide hormone that is highly conserved among species.[636-639] Initially, AVP was recognized as having two functions, antidiuresis and vasoconstriction. It is

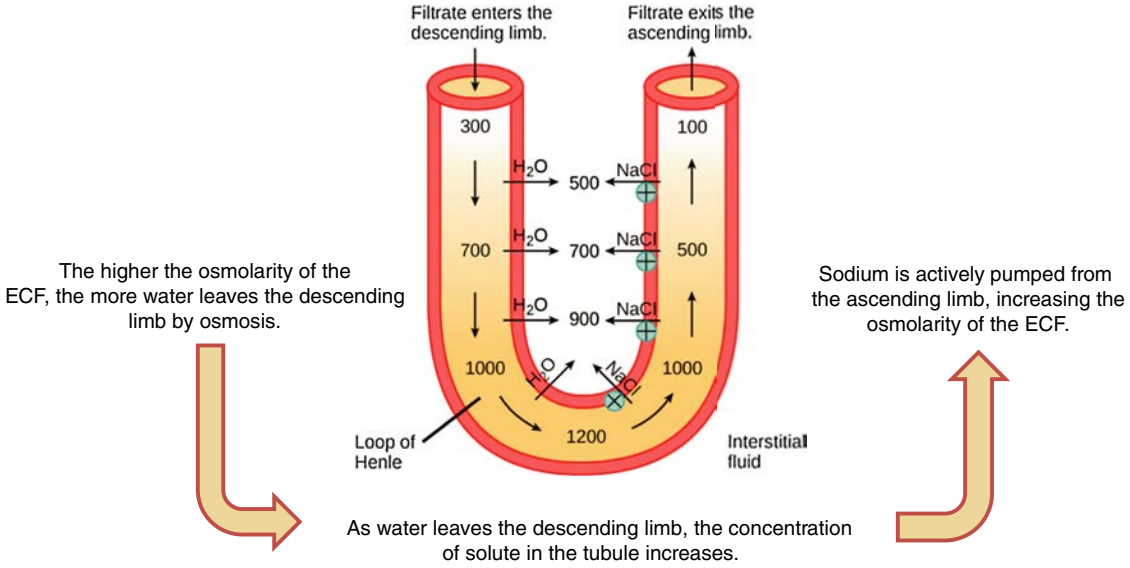

FIG. **7.6** Simplified schematic of the countercurrent multiplier in the loop of Henle. *ECF,* Extracellular fluid, concentrations in mOsm/L.

now known to have diverse effects, some of which include modulation of pituitary functions, as well as immune responses and behavior. A small peptide of nine amino acids, AVP is synthesized primarily in the supraoptic and paraventricular nuclei of the hypothalamus, with smaller quantities produced by various tissues outside the hypothalamus. It is produced as a precursor, prepro-vasopressin, which is packaged into neurosecretory granules and transported axonally via the pituitary stalk (infundibulum) to the posterior pituitary (neurohypophysis). During transport, prepro-vasopressin is processed into the active hormone, which is stored for secretion in the posterior pituitary.

AVP is primarily released in response to signals from osmoreceptors located in the anterior hypothalamus near the supraoptic nuclei and in the anteroventral region of the third ventricle.[636-639] These osmoreceptors rapidly respond to small increases in the osmolarity of the extracellular fluid, which is primarily determined by the sodium concentration. Once stimulated, osmoreceptors send signals to nerve cells in the supraoptic nuclei, which relay the signals down the pituitary stalk to the posterior pituitary stimulating the release of AVP from secretory granules in the nerve endings. Although the exact threshold for AVP release in the horse is unknown, in healthy ponies, an increase of approximately 8 mOsm/kg in plasma osmolality (about 3%) following water deprivation was associated with an increase in plasma AVP concentration from 1.53 ± 0.36 pg/mL to 4.32 ± 1.12 pg/mL.[640] When the extracellular fluid becomes hypo-osmolar, less AVP is released, causing less water to be reabsorbed. Although changes in osmolarity are the major stimulus for AVP release, the stimulation of arterial and cardiopulmonary baroreceptors by a reduction in circulating volume and hypotension can also result in AVP release.[636,638] Other stimuli for AVP release that have been reported in some species include stress, pain, nausea, hypoglycemia, and certain drugs such as morphine.

There are three different receptors for AVP, V1a, V1b, and V2, with V2 being the receptor found on the epithelial cells of the distal convoluted tubule and collecting duct of the kidney.[638] Extrarenal V2 receptors are present in the endothelium. Within the kidney, one mechanism of action of AVP is to influence aquaporins, which are integral membrane proteins that can form pores in the cell membrane that act primarily as water channels. Binding of AVP to the renal V2 receptor increases aquaporin-2 synthesis and leads to aquaporin-2 water channel insertion into the apical membrane. This aquaporin channel then allows water to move down the osmotic gradient and out of the nephron, increasing water reabsorption by the kidney. AVP also acts to increase urea permeability in the terminal inner medullary collecting duct by regulating urea transporters, increasing the concentration of urea in the medullary interstitium.[641] Also, the V2 receptors are active in the loop of Henle, where activation stimulates the reabsorption of sodium.

Role of the Renal Hyperosmotic Medullary Interstitium. The osmolarity of the interstitial fluid in the medulla of the kidney is approximately 1200 to 1400 mOsm/L compared with about 300 mOsm/L for interstitial fluid in other locations. This high osmolarity of the renal medullary interstitium surrounding the collecting ducts provides the osmotic gradient necessary for water reabsorption to occur when AVP concentrations are high. The primary mechanism maintaining the hyperosmolar interstitium is countercurrent multiplication, which depends on the structure and function of the loop of Henle[636] (Fig. 7.6). Essentially, the ongoing active reabsorption of ions from the thick ascending loop of Henle combined with the continued flow of new ions into the loop of Henle ultimately multiplies the medullary solute concentration. Due to the presence of aquaporin channels, the descending loop of Henle is permeable to water, but it is relatively impermeable to solute. Thus as tubular fluid enters the descending loop and moves toward the inner medulla, it gradually becomes more hypertonic as water moves out into the interstitium. In the thin ascending loop of Henle, ions begin to move into the interstitium by passive diffusion. Once fluid enters the thick ascending loop of Henle, sodium, potassium, and chloride are actively reabsorbed via the apical $Na^+/K^+/2Cl^-$ cotransporter. This active transport of ions, combined with the

impermeability of this section to water, results in an increased osmolarity in the renal medullary interstitium. This creates an osmotic pressure gradient, drawing water from the descending limb and increasing the osmolarity of the tubular fluid. This process is repeated as fluid continues to flow through the tubules, with the net effect of continuing to add sodium to the medullary interstitium until the osmolarity reaches 1200 to 1400 mOsm/L. The collecting ducts also contribute to the hyperosmolar interstitium through the active transport of ions and the facilitated diffusion of urea into the interstitium. The relatively low blood flow in the renal medulla and the unique characteristics of the vasa recta help to maintain the hyperosmolar interstitium.

Countercurrent multiplication and maintenance of the hyperosmolar interstitium play important roles in the concentration of urine. When luminal fluid enters the thick ascending loop of Henle, approximately 80% of the glomerular filtrate has been reabsorbed. The active resorption of NaCl in the thick ascending loop of Henle, which is impermeable to water, causes the fluid entering the distal tubule in the renal cortex to be hypotonic. Water is then reabsorbed from the distal tubules and cortical portions of the collecting ducts under the action of AVP. Reabsorbed water is transported rapidly out of the interstitium by the extensive cortical capillary network, and interstitial hypertonicity is preserved.

Thirst. Adequate fluid intake, which is regulated by thirst, contributes to the maintenance of water balance along with the renal excretion of water.[630,634,636,642] The thirst center in the hypothalamus consists of osmoreceptors in the anteroventral wall of the third ventricle and anterolateral preoptic nucleus that are in close proximity to those that regulate AVP secretion. A major stimulus for thirst is increased osmolarity of the extracellular fluid, which causes intracellular dehydration in the thirst centers, stimulating the sensation of thirst. In human beings the threshold for stimulation of thirst is approximately 2 to 5 mOsm/kg greater than that for stimulation of AVP release. Also, decreases in extracellular fluid volume and arterial pressure can stimulate thirst via mechanisms that are distinct from osmolarity. These mechanisms include neural input from cardiopulmonary and systemic baroreceptors and the release of angiotensin II, which can both stimulate thirst and decrease renal fluid excretion. Peripherally, mechanoreceptors in the oropharynx can sense dryness of the mouth, stimulating thirst. Following experimental water deprivation, ponies drank when their plasma osmolalities increased by 3%, when plasma Na concentrations increased by approximately 5%, and after induction of a plasma volume deficit of 6%.[8]

General Mechanisms of Polyuria and Polydipsia

General mechanisms of polyuria and polydipsia include water or solute diuresis, and in some cases both mechanisms may contribute.[625,630,634,636] Water diuresis is caused by either decreased water absorption in the collecting tubules or excessive voluntary water intake. In water diuresis, either polyuria or polydipsia may be primary. Solute diuresis is caused by excessive renal excretion of a nonreabsorbed solute such as glucose or sodium, resulting in primary polyuria.

Polydipsia as the Primary Problem. Excessive water intake results in water diuresis.[636] By expanding the extracellular fluid volume and decreasing plasma osmolarity, excessive fluid intake causes a suppression of AVP secretion. This then makes the collecting ducts less permeable to water, increasing urine output.

Polyuria as the Primary Problem. Polyuria can result from renal disease or several systemic disorders. Although polyuria is commonly associated with renal failure, the precise mechanisms are not fully understood and are most likely multiple.[643] With primary renal insufficiency or failure, there is a decrease in functional nephrons. This can result in solute diuresis, as increasing amounts of glomerular filtrate are presented to the remaining tubules, often exceeding their reasborptive capacity. The resultant increase in urinary solute is accompanied by an increase in water loss. Also, the increased tubular flow rate in the remaining tubules may simply allow less time for the reabsorption of water. In addition, diuresis may result from decreased hypertonicity of the medullary interstitium associated with decreased transport of sodium and chloride out of the loop of Henle when there is renal compromise. Another factor that may contribute to polyuria in renal failure is acquired nephrogenic diabetes insipidus due to an inability of the diseased collecting ducts to respond to AVP.

The syndrome of diabetes insipidus, which is characterized by the excretion of large volumes of dilute urine associated with abnormalities related to AVP, has several fundamental causes.[644,645] In primary polydipsia, AVP secretion is suppressed by excessive fluid intake. Also, in human patients, gestational diabetes insipidus can occur due to degradation of AVP by a placental enzyme. Central or neurogenic diabetes insipidus occurs when there is inadequate production or secretion of AVP. This form of diabetes, or inflammatory disease involves the hypothalamus or posterior pituitary. In nephrogenic diabetes insipidus there is insensitivity of the renal collecting duct epithelial cells to AVP, and the condition may be primary or acquired. Primary nephrogenic diabetes insipidus implies isolated dysfunction of the response to AVP not associated with actual structural or metabolic problems of the kidney. In people this occurs as a familial disorder with an X-linked autosomal semirecessive mode of inheritance, and there is some evidence this may occur as a familial problem in horses as well. Acquired nephrogenic diabetes insipidus can be associated with renal disease or altered sensitivity of nephrons to AVP due to endotoxemia or cortisol excess. Also, in some species, hypercalcemia, potassium depletion, and the administration of certain drugs such as gentamicin have been reported to cause insensitivity of the collecting duct receptors to AVP.

Renal medullary washout is a syndrome in which the relative hypertonicity of the renal medulla is reduced, typically from prolonged diuresis of any cause.[636,643] The increased tubular flow rates during diuresis may result in an inability to resorb sufficient sodium and urea from the tubular lumen. The resulting decrease in medullary hypertonicity leads to impairment of renal concentrating ability and polyuria with secondary polydipsia. Enhanced medullary blood flow may deplete medullary solute further.

Polyuria as a result of solute diuresis can occur in association with excessive salt consumption and hyperglycemia in addition to renal failure.[643,646-649] When blood glucose concentrations increase above the renal threshold of approximately 150 to 200 mg/dL in the horse, the resultant glucosuria results in increased urine flow. Solute diuresis may also occur following obstructive urinary tract disease, but this is not commonly reported in horses.

Conditions Associated with Polyuria and Polydipsia

There are several potential specific causes of polyuria and polydipsia in horses.[650,651] The most common causes include renal failure, PPID, and primary psychogenic polydipsia. Other less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus, and diabetes mellitus. Polyuria and polydipsia may also occur secondary to sepsis and endotoxemia or may be iatrogenic following the use of α_2-agonists, corticosteroids, or diuretics.[650-652]

Polydipsia

The most common reason for excessive water intake in horses is psychogenic water drinking. The extent of polydipsia and therefore polyuria seen with psychogenic water drinking can be substantial. Psychogenic water drinking can be a stable vice associated with confinement and boredom.[642,653] The behavior has also been associated with changes in environmental conditions, stabling, and diet. It has been suggested that primary polydipsia is particularly common in horses residing in the southern United States when ambient temperature and humidity are high.

Excessive salt consumption may also result in increased thirst, although a significant amount of salt needs to be consumed to stimulate thirst in horses.[648] In human patients, polydipsia has been reported in association with conditions affecting the osmoreceptors involved in the regulation of thirst, such as neurologic disease affecting the hypothalamic thirst center.[654,655] This could potentially occur in horses. For example, the enlarged pituitary gland in horses with PPID could compress the hypothalamus.

The ability to concentrate urine is retained in cases of primary polydipsia. However, occasionally the long-standing diuresis can result in medullary washout and a decrease in concentrating ability.

Polyuria

Important causes of primary polyuria in horses include renal failure and pituitary pars intermedia dysfunction.[650,651] Diabetes insipidus and diabetes mellitus are less common causes.

Renal Failure. In the acute stage of renal failure there is frequently a period of oliguria or anuria, which is then followed by polyuria.[643,646] The repair of tubules following an acute insult may take several weeks, and in some cases the repair may not be complete, resulting in chronic renal failure and persistently diminished concentrating ability.[643,647] Some potential causes of renal failure in horses include failure to recover from ischemic renal damage, pigmenturia, chronic infection, urinary obstruction, and exposure to nephrotoxins such as nonsteroidal antiinflammory drugs, gentamicin, and polymixin.[646,647,656,657] Other possible causes include immune-mediated disease, glomerulonephritis, congenital abnormalities, renal helminthiasis, and amyloidosis. In some horses, the inciting cause of chronic renal failure may be hard to identify.

Pituitary Pars Intermedia Dysfunction. Polyuria and polydipsia are recognized in approximately 30% of horses with *pituitary pars intermedia dysfunction* (PPID), although numbers vary among studies.[658-660] Other clinical signs that are commonly associated with PPID include hypertrichosis, laminitis, muscle atrophy, abnormal fat deposition, and recurrent infections. The pathogenesis of polyuria and polydipsia in PPID is not completely understood and most likely involves multiple factors. As some horses with PPID are hyperglycemic, osmotic diuresis associated with glucosuria may play a role. Although it has not been documented, the enlarged pars intermedia may impinge on the posterior pituitary and/or hypothalamus, potentially causing secondary neurogenic diabetes insipidus by interfering either with the production or release of AVP or possibly with osmoreceptors involved in thirst. Also, an increase in plasma cortisol associated with PPID may result in antagonism of the action of AVP at the renal tubule.

Diabetes Insipidus. Neurogenic diabetes insipidus appears to be rare in the horse, with two cases reported in the literature.[661,662] In both cases, the horses were unable to concentrate urine in response to water deprivation but responded to the administration of exogenous vasopressin with a decrease in urine volume and increase in urine concentration. In one case the condition was felt to be idiopathic, and in the other it was felt to be acquired secondary to encephalitis.

Primary nephrogenic diabetes insipidus also appears to be rare in horses, having been reported in three colts and a 14-year-old gelding.[663-665] Two of the colts were sibling Thoroughbreds, suggesting that an inherited form of nephrogenic diabetes insipidus similar to what is seen in people may occur in horses.[664] In addition to signs of polyuria and polydipsia, two of the three colts were underweight. Following water deprivation, affected colts could not increase urine concentration although plasma AVP concentrations increased. In addition, affected horses had minimal response to the administration of exogenous vasopressin, confirming resistance of the collecting ducts to the antidiuretic action of vasopressin.

Nephrogenic diabetes insidipus has been recognized in horses with some frequency as a secondary problem in which there is an acquired decrease in renal responsiveness to AVP.[645] This acquired nephrogenic diabetes insipidus has been associated with a variety of conditions, including renal disease. It has also been described following drug therapy, as well as with a variety of endocrine, metabolic, infectious, neoplastic, and postobstructive disorders.

Diabetes Mellitus. Diabetes mellitus is characterized by chronic hyperglycemia. In type 1 or insulin-dependent diabetes mellitus, there is a lack of insulin, whereas in type 2 or non–insulin-dependent diabetes mellitus, insulin is adequate but tissue sensitivity to insulin is impaired. Although it is a relatively common cause of hyperglycemia and glucosuria in other species, type 1 diabetes mellitus has been infrequently diagnosed in the horse.[152, 666-671] Type 2 diabetes mellitus has been recognized in horses in association with several conditions, especially PPID and equine metabolic syndrome.[80, 672-676] Diabetes mellitus has also been reported in a horse with bilateral granulosa cell tumors.[672]

Other. Medullary washout may result from chronic diuresis of any cause and may be a more common complication of primary diseases and their therapy in horses than has been reported to date. Polyuria and polydipsia have occasionally been reported in association with sepsis and endotoxemia in multiple species, including horses. The mechanisms are unclear but may involve endotoxin-induced production of PGE_2, which can cause renal vasodilation and inhibit the actions of AVP. Although infrequently reported in horses, polyuria and polydipsia have been recognized in association with severe liver disease. Some conditions that have been associated with polyuria and polydipsia in other

species include primary polycythemia, hypercalcemia, and potassium depletion.

Diagnostic Approach to Polyuria and Polydipsia

Signalment and History

The signalment and history can be valuable in the assessment of polyuria and polydipsia. Congenital problems such as renal anomalies are generally recognized in young animals, whereas PPID increases in prevalence with age. Primary nephrogenic diabetes insipidus has been described in two related Thoroughbred colts. A detailed history should be obtained with particular emphasis on the duration of signs, any management changes, diet including any supplements, and any current or previous medication use. In some horses, iatrogenic causes of polyuria and polydipsia can be ruled out by assessment of the history and return to normal urine output and water intake after discontinuing medications, intravenous fluids, or excess dietary salt.

Physical Examination

A complete physical examination should be performed with careful attention to hydration status. Palpation per rectum can be useful in evaluation of the urinary tract. Horses with psychogenic polydipsia are generally normal on physical examination. Chronic renal insufficiency is often associated with a poor body condition, and in some cases, appetite may be decreased. The clinical signs of PPID can be quite variable depending on the individual and the stage of disease, but commonly recognized signs include hypertrichosis, muscle atrophy, abnormal fat deposition, chronic infections, and laminitis.

Measurement of Water Intake and Urine Volume

The measurement of 24-hour water intake and urine production can be helpful in confirming the problem, especially in those cases in which polyuria and polydipsia are less obvious.[677-680] It can also establish the severity, which can help to prioritize differentials. In general, the degree of polydipsia and polyuria tends to be more pronounced with psychogenic polydipsia and diabetes insipidus than with renal failure or PPID. Several means of urine collection have been devised. Generally close observation and cross-tying are required to ensure the device stays in place and measurements are accurate. In general water intake over 100 mL/kg per day and urine output over 50 mL/kg per day are consistent with polydipsia and polyuria in adult horses. Factors that can influence water intake and urine production, such as diet and environmental conditions, should be taken into consideration. When measuring water consumption, behavioral tendencies to spill or play in the water should be taken into account.

Ancillary Diagnostic Aids

Clinical Pathology. A hemogram, serum biochemistries, and urinalysis should be assessed in horses presented for polyuria and polydipsia. Urine specific gravity (USG) is decreased in horses with polyuria and polydipsia. The extent of the decrease in USG, along with the presence or absence of other abnormalities on laboratory tests, can help prioritize differential diagnoses and may direct additional testing. Horses with psychogenic polydipsia tend to present with hyposthenuria (USG less than 1.008 and osmolality less than 260 mOsm/kg) without other laboratory abnormalities. As hyposthenuria indicates that renal diluting ability is intact, horses with renal failure or complete medullary washout are unlikely to have hyposthenuria, although it may occasionally be present in horses recovering from acute renal failure. Chronic renal failure is suggested by the presence of isothenuria (USG 1.008–1.014 and osmolality 260–300 mOsm/kg) with concurrent azotemia.[681-683] Other laboratory abnormalities that may be seen with chronic renal failure include mild anemia, hypoalbuminemia, hyponatremia, hypochloridemia, hyperkalemia, hypercalcemia, and hypophosphatemia. Some additional laboratory tests that may be used to assess renal function include fractional excretion of electrolytes, urinary protein–to–urinary creatinine ratio, creatinine clearance, and measurement of urinary enzymes. Measurement of glomerular filtration rate is a sensitive indicator of renal dysfunction but is infrequently performed primarily for practical reasons. Measurement of symmetric dimethylarginine, a methylated form of arginine that is eliminated primarily by renal excretion, is useful in the evaluation of renal function in small animals and is under investigation in horses.[684]

There are no consistent laboratory abnormalities in horses with PPID, although neutrophilia, lymphopenia, hyperglycemia, and glucosuria may be present.[658-660] Additional endocrine testing is required to confirm the presence of PPID. Some recommended tests include measurement of baseline ACTH concentration, measurement of ACTH concentration following the administration of thyrotropin-releasing hormone, or a low-dose dexamethasone suppression test. Hyperglycemia and glucosuria may also be seen with equine metabolic syndrome, underlying systemic disease and diabetes mellitus.

Water Deprivation Testing. Water deprivation evaluates the ability to conserve water and is most often used to differentiate psychogenic polydipsia from diabetes insipidus.[624,685,686] It is most clearly indicated in horses that are hyposthenuric rather than isosssthenuric. Water deprivation testing is contraindicated in horses that are dehydrated or azotemic. In normal animals, the increase in plasma osmolality that occurs with water deprivation results in the release of AVP, which acts on the renal tubules and collecting ducts to conserve water, increasing USG. Before initiating the test, baseline values for USG, serum urea nitrogen, creatinine, and body weight should be obtained and the bladder emptied by catheterization. After water is removed, USG and body weight should be monitored every 6 to 12 hours. Serum urea nitrogen and creatinine may be monitored as well. In response to 24 to 72 hours of water deprivation, normal horses will increase their USG over 1.045 with an osmolality over 1500 mOsm/kg. For practical purposes, if USG increases above 1.025 within 24 hours or by the time that 5% of body weight is lost, concentrating ability is adequate and the test can be discontinued. The test should be terminated if there is a loss of more than 5% of the body weight or if clinical signs of dehydration or azotemia develop. Typically, horses with psychogenic polydipsia can concentrate their urine in response to water deprivation whereas those with diabetes insipidus cannot. Occasionally horses with psychogenic polydipsia will have incomplete concentrating ability due to medullary washout and loss of the medullary interstitial osmotic gradient. These horses may respond to a modified water deprivation test where water intake is gradually restricted for several

days allowing for restoration of the medullary interstitial osmotic gradient.[687] Horses with either central or nephrogenic diabetes insipidus cannot effectively concentrate their urine in response to water deprivation, and to distinguish these conditions additional testing such as measurement of endogenous AVP concentrations and evaluation of the response to exogenous AVP is indicated.

Measurement of Arginine Vasopressin and Response to Exogenous Arginine Vasopressin or Analogs. The plasma concentration of AVP can be measured during water deprivation testing or following the administration of 7.5% sodium chloride solution to increase plasma osmolality. In normal ponies, AVP concentrations increased from baseline values of 1.53 ± 0.36 pg/mL to 4.32 ± 1.12 pg/mL after 24 hours of water deprivation.[13] Plasma concentrations of AVP will increase in horses with psychogenic polydipsia or nephrogenic diabetes insipidus, but any increase will be minimal with central diabetes insipidus. In nephrogenic diabetes insipidus, the elevation in AVP is not accompanied by an increase in USG.

The ability of renal tubules to respond to AVP can be assessed by a challenge test.[688] USG is monitored following the administration of either exogenous synthetic vasopressin or desmopressin acetate, a synthetic vasopressin analog. USG is expected to increase over 1.020, and failure to do so is consistent with a diagnosis of nephrogenic diabetes insipidus if medullary washout is not present.

Diagnostic Imaging

Transabdominal and transrectal ultrasound examination can be useful in evaluation of the urinary tract. Although not consistent, changes in the size and/or architecture of the kidneys may be present in both acute and chronic renal failure. Ultrasound can also be helpful in the diagnosis of urolithiasis.

POOR PERFORMANCE

Poor performance is the inability of an individual to perform at a level that can be reasonably expected based on the individual's physical characteristics, level of training, and/or previous performance. Any decrease in performance may be critical to the equine athlete. In some cases, poor performance may be easily documented, such as when the problem is severe or when there is a drop in performance that can be objectively measured (e.g., in a discipline such as racing). However, in other cases, poor performance may be subtle and difficult to document.

Mechanisms Affecting Performance

Numerous factors influence performance, including genetics, training, desire, body composition, and overall health. Peak athletic performance requires optimal function of all body systems, particularly those involved in locomotion and oxygen transport.

Genetic Factors

Genetic factors play a role in several aspects of performance. In multiple species, genetics are known to influence athletic potential. As the knowledge of equine genomics expands, understanding of the heritability of specific traits associated with elite athletic performance will increase.[689-691] For example, variation at the myostatin gene locus has been found to be associated with a horse's best racing distance.[690] In addition to influencing inherent athletic ability, genetic traits can potentially impair performance either by direct effects on the individual's health or by increasing the likelihood of the individual developing secondary problems. For example, heritable muscle disorders can directly affect performance, and poor structural conformation can increase the risk of injury.[3,4] Similarly, it has been suggested that Warmblood horses that must work in top gear to achieve the speeds required for upper levels of 3-day eventing are more prone to injury.[692]

Locomotion

Movement is a key component of athletic performance, and therefore musculoskeletal, neurologic, and neuromuscular disorders can all have a negative impact on performance.[691-695] The mechanisms by which they affect performance are multiple and include pain, mechanical restrictions, incoordination, and weakness. Pain can make the horse reluctant to exercise and can also limit the amount of training so that the horse is unable to achieve the level of fitness required for optimal performance. Any gait deficit can potentially make efficient movement mechanically difficult. Also, lameness at one site can contribute to the development of secondary problems such as back pain or chronic myopathy that can further impair performance. Neurologic disease can cause ataxia and weakness, adversely affecting performance.

Physical activity requires muscles to generate and sustain the power for movement. Horses are generally considered to be a highly athletic species, and there are several adaptations in equine skeletal muscle that contribute to this athletic ability, including an increased muscle mass relative to body weight, high locomotor efficiency based on muscle-tendon architecture, high intrinsic shortening velocities, and efficient muscle energetics.[696,697] In horses, muscle tissue comprises about 45% of body weight in most equine breeds and up to 55% of body weight in Thoroughbreds, compared with 30% to 40% in many other species. Horses that have the ability to run fast tend to have a large overall skeletal muscle mass, longer muscle fascicles, a high percentage of fast-twitch muscle fibers, and a low percentage of body fat.[90] Any change in muscle mass, architecture, or function can have a profound impact on performance. If muscle fatigues prematurely or is painful, such as with rhabdomyolysis, the horse may not be able to generate the necessary power for efficient movement.

Oxygen Uptake and Transport

Any process that impairs the uptake or transport of oxygen can limit the ability to produce the energy required for optimal performance. Thus diseases of both the upper and lower respiratory tract, and less frequently the cardiovascular system, are important causes of poor performance. A number of upper airway obstructive disorders have been recognized that restrict the movement of air into and/or out of the lung.[301,698-,699-702,739] Disease of the lower respiratory tract may increase the work of breathing and impede normal gas exchange in the lung. For example, inflammatory airway disease (IAD) has been shown to alter pulmonary mechanics through changes in lung compliance, greater viscous lung resistance, and rate of dynamic work of breathing.[703] Due to the increase in ventilatory load, the energy required for breathing is significantly higher in affected horses, which may limit their performance. Also, a higher neutrophil percentage in the bronchoalveolar lavage fluid of horses with poor racing performance has been correlated with significantly lower relative gas flows during inspiration and expiration.[704]

Although the effects of exercise-induced pulmonary hemorrhage (EIPH) on performance are not entirely clear, in a study of 132 horses with a history of poor performance, exercise-induced hypoxemia was seen in horses with IAD and EIPH.[705] Gas exchange was most significantly impaired in those horses with concurrent EIPH and upper airway obstruction. Once oxygen is taken up into the circulation from the lung, it must be delivered to the tissue, especially working muscle, for optimal performance. Thus cardiovascular disease can impair performance by decreasing the effectiveness of oxygen delivery to the tissues.

Other

Almost any systemic disease or source of pain has the potential to make the horse reluctant to work. For example, poor performance has been reported in association with equine gastric ulcer syndrome and possibly dental disease.[700,706,707] Also, in horses with anhidrosis, their decreased ability to maintain normal body temperature can limit performance in warm environmental conditions.[708]

Conditions Associated with Poor Performance

It is not possible to list all potential causes of poor performance as so many factors influence performance (Box 7.11). Certainly almost any systemic disease, as well as desire and training, can affect performance. When evaluating horses presented specifically for the complaint of poor performance, the conditions most often identified have been abnormalities of the respiratory and musculoskeletal systems.[695,699,700,709,710] It is not uncommon for multiple problems to occur concurrently. In a study of 275 racehorses with a history of poor racing performance, 84% were found to have more than one abnormality.[699] Similarly, in a study of 27 endurance horses with poor performance, 66.7% had multiple concomitant disorders.[710]

Locomotor Disorders

A surprising number of horses presented for poor performance are found to be lame even when lameness has not been reported by the owner or trainer.[692,695,699,700,709,710] Although some horses may compete successfully with low-grade lameness, any degree of lameness has the potential to impair performance. A wide variety of musculoskeletal conditions have been identified in association with poor performance.[692,695,699,700,709-712] In addition to those horses with forelimb or hindlimb lameness, horses with other sites of musculoskeletal pain, such as neck, back, or sacroiliac joint pain, may also have poor performance.[693,694,712] Neurologic deficits also have the potential to adversely affect performance.

Several muscle disorders have been linked to poor performance, including both sporadic and recurrent rhabdomyolysis (tying-up).[698,700,713,714] In many cases, affected horses do not exhibit the classic clinical signs of rhabdomyolysis but have increased muscle enzymes in response to exercise. In one study, 53 of 348 horses examined for poor performance had this form of subclinical myopathy identified only by increased creatine kinase concentrations after exercise, and 10 of 348 had clinical exertional rhabdomyolysis.[700]

Polysaccharide storage myopathy (PSSM) is an inherited glycogen storage disorder that is an important cause of muscle disease in a number of breeds, including Quarter Horses and related breeds, many draft and Warmblood breeds, and others.[714] Clinical signs vary depending on the individual and breed, and the clinical presentation of affected horses ranges from being asymptomatic to exhibiting muscle atrophy and progressive weakness, muscle soreness, and gait abnormalities, or acute rhabdomyolysis. In Quarter Horses and related breeds it appears there is a second mutation, malignant hyperthermia, that potentially worsens the signs of PSSM in affected horses.[24]

MUSCULOSKELETAL

Lameness
Back pain
Neck pain
Muscle disorders
- Sporadic exertional rhabdomyolysis
- Subclinical exertional rhabdomyolysis
- Polysaccharide storage myopathy
- Recurrent exertional rhabdomyolysis
- Vitamin E myopathy
- Muscle injury/strain
- Mitochondrial myopathy
- Myofibrillar myopathy

NEUROLOGIC DISEASE

RESPIRATORY TRACT DISEASE

Upper airway obstruction
- Dorsal displacement of the soft palate
- Recurrent laryngeal neuropathy
- Axial deviation of the aryepiglottic folds
- Dynamic pharyngeal collapse
- Epiglottic entrapment
- Subepiglottic cyst
- Rostral displacement of the palatopharyngeal arch
- Redundant alar folds

Lower airway disease
- Inflammatory airway disease; recurrent airway obstruction
- Exercise-induced pulmonary hemorrhage

CARDIOVASCULAR DISEASE

Cardiac arrhythmia
Myocardial dysfunction
Murmurs (often not clinically significant)

OTHER

Dental disorders
Equine gastric ulcer syndrome
Anhidrosis
Saddle fit; horse-saddle-rider interaction
Disease in early neonatal period

Several other muscle disorders have been identified in horses. Recurrent exertional rhabdomyolysis (RER) is a heritable abnormality of intramuscular calcium regulation seen primarily in Thoroughbreds and to a lesser extent in Standardbreds and possibly Arabians.[715] A skeletal muscle mitochondrial myopathy has been described in an Arabian in association with impaired oxidative energy metabolism; muscle stiffness and exercise intolerance due to a suspected myofibrillar myopathy have also been reported in Arabian horses.[716,717] Vitamin E deficiency has been associated with several clinical problems, one of which is a myopathy.[718] Horses affected with myopathy related to vitamin E deficiency may present with signs of muscle atrophy, weakness, toe dragging, and muscle fasciculations, as well as poor performance.

Muscle strain or soreness can also be a cause of decreased performance.[698] Equine activities can often be athletically challenging and may require either high intensity or prolonged effort. Some disciplines require a combination of activities and may require sudden moves or maintaining a precise body position. In some cases, the horse is not adequately conditioned, making the risk of muscle injury greater. Any muscle group may be affected, and clinical signs vary depending on the muscle involved and the severity of the injury.

Respiratory Disorders

Respiratory disease has been the most common cause of poor performance in several studies. Among the most common respiratory problems associated with poor performance in the equine athlete is dynamic airway obstruction, affecting both racing and nonracing performance horses.[300,699,700,702,709,719] In the study of 275 racehorses evaluated for poor performance, 110 (40%) were found to have dynamic airway obstruction.[699] Similarly, in the study of 348 racehorses and show horses with poor performance, 148 (42.6%) had dynamic airway obstruction.[700] Of these 148 affected horses, 39 were found to have multiple airway abnormalities, and an additional 22 were found to have a concurrent cardiac arrhythmia. The most common conditions causing airway obstruction include dorsal displacement of the soft palate and idiopathic left laryngeal hemiplegia with arytenoid collapse, also referred to as recurrent laryngeal neuropathy. Other conditions diagnosed have included axial deviation of the aryepiglottic folds, dynamic pharyngeal collapse, epiglottic entrapment, subepiglottic cyst, fourth branchial arch defect (rostral displacement of the palatopharyngeal arch, laryngeal dysplasia), and redundant alar folds. Horses of Quarter Horse breeding with hyperkalemic periodic paralysis (HYPP) may suffer dynamic collapse of the airway when exercising.[720]

Disease of the lower respiratory tract is also a common cause of decreased performance.[227,251,755,710,721,722] In the study of 27 endurance horses with poor performance, respiratory tract abnormalities, specifically tracheal fluid neutrophilia and IAD, were the most commonly identified problems.[710] IAD was identified in 70% of national hunt horses presented for poor athletic performance.[721] Excess mucus accumulation in the airway has been associated with poor willingness to perform in sport horses.[251,721] In addition to IAD, other subtypes of equine asthma, including recurrent airway obstruction (RAO) and summer-pasture–associated obstructive pulmonary disease, can limit athletic performance. The effects of EIPH on performance have been difficult to measure because there are so many confounding factors, but current evidence suggests that moderate to severe EIPH adversely affects athletic capacity.[227,722] Clinical bacterial or viral respiratory tract infection significantly affects performance, but the role of subclinical infections is less clear. Studies in Standardbred trotters have not found an association between subclinical viral infection and poor performance.[723,724]

Cardiovascular Disorders

Cardiovascular disease can also cause poor performance, although it is less common than either musculoskeletal or respiratory disease.[699,700,709,710] The prevalence and clinical relevance of cardiac arrhythmias have varied between studies.[699,700,709,710,725-727] In the study of 348 horses evaluated for poor performance, a clinically significant cardiac arrhythmia was the sole abnormality found in 33 horses, and an arrhythmia in conjunction with dynamic airway obstruction was found in 22 horses.[700] The most frequent arrhythmias observed were atrial and ventricular premature depolarizations. However, in the study of 275 racehorses, arrhythmias were noted in just two horses.[699] Isolated premature depolarizations were common in a study of 88 Thoroughbreds with poor performance, with 55 horses having at least one premature ventricular or supraventricular premature depolarization.[727] The clinical significance of these depolarizations was uncertain. Ventricular tachycardia and paroxysmal atrial fibrillation have also been identified in horses with poor performance. Changes in the T wave, once thought to be related to poor performance, and second-degree atrioventricular block have been found to have no effect on exercise capacity.[728]

Many horses have murmurs that are of little clinical significance.[699,700,709,710,729,730] In the study of 348 horses with poor performance, 102 were found to have murmurs, the most common being mitral regurgitation.[700] In all cases the murmur was determined to be clinically unimportant. Similarly, in the study of endurance horses, neither the prevalence nor the grade of valvular regurgitation was significantly different between well-performing horses and those with a decreased performance level.[710] Although many murmurs appear to be clinically unimportant, in some individual cases a murmur may be associated with more significant cardiac disease and poor performance.

Echocardiography has been used to evaluate cardiac function in cases of poor performance. In the study of 348 horses, decreased fractional shortening indicating left ventricular myocardial dysfunction after exercise was found in 19 horses, only 8 of which had echocardiographic changes at rest.[700] Six of the 19 horses had what was felt to be a clinically significant ventricular arrhythmia.

Other

A wide variety of other disorders have been linked to poor performance. Body condition plays a role in performance, and horses that are both overconditioned and underconditioned may have suboptimal performance.[90,697,731,732] A study in endurance horses demonstrated that body condition score at the start of the ride had a significant effect on performance, with horses with lower scores being less likely to complete the ride.[732] Some other problems potentially associated with poor performance include dental disease, gastric ulcers, anhidrosis, and both undertraining and overtraining.[706-708,733] Poor saddle fit may cause focal areas of increased pressure resulting in an unwillingness to work. The dynamic interaction between the horse, saddle, and rider may not be optimal.[734] Some foals that were sick within the first 18 hours of birth may have decreased performance as an adult.[735]

Diagnostic Approach to Poor Performance

Determining the cause of poor performance in those horses without overt clinical disease often is challenging.[695,698,699-701] In the study of 348 cases of poor performance, a definitive diagnosis was established in 73.5% of cases after in-depth examination, which included the use of a high-speed treadmill.[700] Multiple factors can contribute to the difficulty in establishing a definitive diagnosis. First, it can even be hard to determine whether the horse has actual poor performance or if it is simply not performing up to expectations that are unrealistic for the individual's inherent ability or current level of training. Medical conditions can certainly influence the willingness to work, but there may also be a behavioral component that can be difficult to assess. The abnormalities that are sufficient to impair performance can be quite subtle and may be evident only during exercise. Multiple problems may be present concurrently, which can make it hard to determine the actual clinical significance of any given problem.

Equine athletes presented for poor performance should undergo a comprehensive evaluation, the basic components of which include a history, detailed physical examination, and laboratory screening. The clinician should emphasize examination of the respiratory, musculoskeletal, and cardiovascular systems because these systems most often are linked to performance problems. In many cases standardized exercise testing, generally on a high-speed treadmill, is critical in identifying the problem. Endoscopic examination of the upper airways during exercise has proven particularly useful. It may also be helpful to evaluate the horse while it's being ridden.

Signalment and History

The signalment may be helpful in the assessment of some cases of poor performance. Horses that present at a young age may be more likely to have a congenital or heritable condition or may have limited genetic potential. Diseases with a heritable basis are more often seen in certain breeds. PSSM is found in a wide variety of breeds but is common in Quarter Horses and related breeds as well as some draft horse and Warmblood breeds, whereas RER is primarily seen in Thoroughbreds and to a lesser extent Standardbreds and possibly Arabians.[713-715] RER is more common in females and in horses with a nervous temperament. Recurrent laryngeal neuropathy appears to be more common in large, long-necked horses especially of Thoroughbred or draft horse breeding.[736]

Obtaining a complete history is a fundamental part of evaluating poor performance. The clinician should establish the use of the horse, the time in training, and the specifics of the training program. Determining whether the horse has never performed as expected or has experienced a decline in the level of performance is crucial. If the horse has never performed as expected, the veterinarian should consider a lack of ability, congenital abnormalities, and training problems. A change in performance, either sudden or insidious, often is associated with an acquired problem. The clinician should characterize specifically the decline in performance, including the intensity of exercise at which signs are observed and whether performance is abnormal from the onset of exercise or declines during an exercise bout. In those cases in which performance drops off during exercise, the clinician should determine whether the decline is acute or gradual and whether any other signs, such as stridor, are associated with it.

Other elements of the history with particular relevance to athletic performance include any previous respiratory disease, respiratory noise, cough, or respiratory distress associated with exercise. Any change in gait also may be significant. Establishing the housing environment, feeding practices, changes in appetite or body condition, the type of tack used, and whether sweating is appropriate is important. The clinician should determine the response to any medications that have been used, such as phenylbutazone or furosemide. The information obtained in the history may help direct the investigation.

Physical Examination

The clinician should perform a complete physical examination in all cases. The body condition score should be determined. In-depth assessment of the gait, as well as the respiratory and cardiovascular systems, is generally indicated.

Respiratory Examination. The examination should include evaluation of air flow from the nares and percussion of the sinuses, as well as assessment of any cough or nasal discharge. Careful palpation of the larynx may reveal an increase in prominence of the muscular process of the left arytenoid cartilage resulting from a loss of mass of the left dorsal cricoarytenoid muscle associated with idiopathic hemiplegia. The clinician can use the laryngeal adductor response test, or slap test, to evaluate adduction of the arytenoid cartilages by slapping the withers during expiration and evaluating movement of the contralateral arytenoid by endoscopy or palpation. It is important to note that many of the horses with airway obstruction did not have a history of abnormal respiratory noise and did not have abnormalities at rest.[300,699,700,702,709,719] At the same time, not all abnormalities observed at rest caused obstruction. These findings emphasize the importance of videoendoscopy during exercise as a component of a performance evaluation.

Thorough auscultation of the trachea and lungs should be performed. Having the horse rebreathe from a plastic bag placed over the nostrils increases the respiratory rate and tidal volume, thus accentuating sounds. In addition to auscultation, the clinician should note the character and pattern of respiration, including the presence of any abdominal component, and the recovery time. Percussion of the thorax may be useful in establishing the lung border and any dull or hyperresonant areas, as well as in detecting pleural pain.

Cardiovascular Examination. Any decrease in cardiac output potentially can limit performance, making thorough evaluation of the cardiovascular system essential. On basic physical examination the clinician should evaluate the mucous membrane color, capillary refill time, and arterial and venous peripheral pulses, although finding abnormalities in these parameters in horses presented for decreased performance is uncommon. The clinician should perform careful auscultation of the heart on both sides of the thorax to evaluate the cardiac rhythm and murmurs. Electrocardiography can be used to further evaluate the cardiac rhythm and ideally should be performed before, during, and after exercise using radiotelemetry.

Musculoskeletal and Neurologic Examination. A lameness examination should be performed in all horses presented for evaluation of poor performance both because lameness is a common cause of poor performance and because it is important to establish that the horse is sound enough to safely perform an exercise test if indicated. In some horses presented for poor performance, the gait asymmetry may be subtle and only discernible at high speed, making diagnosis by traditional methods difficult. In these cases use of a sensor-based motion

analysis system, gait analysis on the treadmill, and advanced diagnostic techniques such as nuclear scintigraphy, thermography, and CT or MRI may be useful. In some cases it can be helpful to perform a ridden evaluation. Careful palpation of the muscles should be performed to identify any heat, swelling, or reactivity. In many cases a neurologic examination is indicated to identify any neurologic deficits that could contribute to poor performance.

Ancillary Diagnostic Aids

Clinical Pathology/Selected Laboratory Tests. Hematologic testing and a biochemical profile are indicated, although in most horses presented for poor performance without obvious clinical abnormalities, routine evaluation of a single sample is within normal limits. Because exercise can induce some changes in laboratory parameters, such as an increase in the packed cell volume and neutrophil count, considering the time of sample collection relative to exercise is important.[737-739] Potentially significant findings include changes consistent with chronic inflammation, such as anemia, hyperglobulinemia, and possibly hyperfibrinogenemia or thrombocytosis. Subclinical infections may have only slight alterations in the leukocyte count and differential. Viral infections, especially in the early stages, may be associated with a leukopenia and neutropenia. A decrease in the neutrophil-to-lymphocyte ratio has been associated with overtraining, although this is not a reliable correlation.[739] Changes in the hormonal response to exercise have been reported with overtraining, primarily a decrease in cortisol.[740]

Horses at rest normally maintain a significant proportion of red blood cells and hemoglobin in the splenic reserve.[737,738,741] Although total body hemoglobin increases in response to training and may correlate with performance, this cannot be determined from a resting sample. Special techniques must be used to document total red cell mass or hemoglobin.[741,792] Anemia can decrease the oxygen-carrying capacity during exercise, resulting in suboptimal performance.

Signs of organ dysfunction in horses presented for poor performance are not common findings but are occasionally present. Much attention has been paid to the importance of electrolytes and exercise; however, abnormalities seldom are found. In general, circulating electrolyte concentrations are regulated tightly and may not reflect closely the total body electrolyte status.[628] However, a concentration of potassium consistently below 3 mEq/L may suggest a potassium deficit. Performing renal fractional excretion of electrolytes can help in detecting chronic electrolyte deficiencies.

Myopathy can lead to decreased performance, and muscle enzymes may be elevated, although many cases of myopathy are subclinical and require evaluation of muscle enzymes after exercise.[700,713] Creatine kinase is measured before exercise and ideally 4 to 6 hours after an exercise bout consisting of 15 to 30 minutes at the trot. In normal horses this light exercise rarely causes more than a threefold increase in creatine kinase. An increase of fivefold or more indicates exertional rhabdomyolysis. Genetic testing, muscle biopsies, and measurement of vitamin E and selenium can also be helpful in defining myopathies.

Myocardial disease may contribute to left ventricular dysfunction and arrhythmias. Elevations in myocardial fractions of creatine kinase, lactate dehydrogenase, and troponin support myocardial disease but are not present in all cases.

Analysis of fluid from the lower airways is important in the diagnosis of lower airway disease. Although exact sampling techniques can vary, in most cases cytologic evaluation of bronchoalveolar lavage fluid is used to aid in the diagnosis of EIPH and forms of equine asthma such as IAD and RAO.

Endoscopy. Endoscopic examination of the upper airway is an important part of the evaluation of poor performance. As many of the abnormalities associated with poor performance are related to dynamic airway obstruction, either treadmill or overground videoendoscopy is generally indicated regardless of the history and physical examination findings.[300,719,743-745] Endoscopy also can be useful in identifying respiratory problems other than dynamic airway collapse. For example, the clinician can identify narrowing of the ventral nasal meatus associated with sinusitis, nasal masses, and pharyngitis. In some cases evidence of inflammation and retropharyngeal lymphadenopathy on endoscopic examination of the guttural pouches has been associated with dorsal displacement of the soft palate, which may result from neuropathy of the pharyngeal branch of the vagus nerve.[746]

Tracheal injury and secretions in the lower respiratory tract can be visualized if the endoscope is sufficiently long. Airway secretions may be sampled via the endoscope or via a bronchoalveolar lavage catheter. Endoscopy can also be useful in diagnosing equine gastric ulcer syndrome.

Diagnostic Imaging. Diagnostic imaging can be useful in the evaluation of horses with poor performance. Radiographs and ultrasound are routinely used in the evaluation of musculoskeletal problems. In some cases, additional imaging techniques may be indicated such as nuclear scintigraphy, thermography, CT, or MRI.

Radiographs and ultrasound can also be helpful in evaluation of the respiratory tract. Thoracic ultrasound and radiographs are often used in the evaluation of lower respiratory tract disease but may be normal in conditions commonly associated with poor performance such as IAD. Radiographs of the upper airways can allow for the evaluation of soft tissue masses or fluid accumulations. In addition, abnormalities of the pharyngeal and laryngeal structures such as thickening of the soft palate or hypoplasia of the epiglottis may be seen. Upper airway ultrasonography can also be helpful, particularly in the assessment of recurrent laryngeal neuropathy.[747] The denervated laryngeal muscles are hyperechoic and more homogeneous than normal muscle. Other conditions that can be diagnosed by ultrasound include arytenoid chondritis, laryngeal dysplasia, and congenital malformations of the larynx. CT and MRI have also been used to evaluate the upper airway.

Echocardiography can be used in addition to electrocardiography for further assessment of the heart.[698,748] In assessing cardiac function, it is ideal to measure indices such as percentage fractional shortening and wall motion indices, both before and after exercise. It should be taken into account that there is considerable normal variation in postexercise indices.[749]

Exercise Testing. Exercise testing provides a mechanism for evaluating a range of body systems under standard exercise conditions.[695,698,750,751] In particular, measurements of cardiorespiratory and metabolic function taken during an exercise test provide information about the capacity and efficiency of key body systems involved in energy production. From a clinical standpoint exercise testing is generally most useful in assessing the significance of abnormalities found on a physical examination; however, testing may also help to establish the reason for reduced athletic capacity in horses that have no abnormalities on basic examinations. Exercise testing can be

done in the field, which mimics the condition in which the horse actually performs. However, most testing is currently done on a treadmill, which provides more consistent conditions and an opportunity to perform a greater range of measurements. The specific protocol used for exercise testing may vary somewhat.[695,698,750-752] Occasionally a high-speed test is performed in which the horse is accelerated rapidly to maximal speed and run to fatigue. However, the most common type of test is an incremental test in which the speed increases every 1 to 2 minutes until the horse reaches fatigue, allowing for the generation of data during submaximal and maximal exercise. In most cases the test is performed with the treadmill at a slope of 10%. This slope is not so steep as to be completely unrepresentative of normal exercise, yet it ensures that maximum-intensity exercise can be performed without reaching speeds that may be too fast for horse safety. Some parameters that can be assessed in an exercise test include heart rate, blood lactate level, arterial blood gases, total red cell volume, stride length, and oxygen uptake. Various spirometers, which are masks for measuring pulmonary ventilation, can be used to measure parameters such as air flow rates, tidal volume, and the durations of phases of the respiratory cycle.[698] As previously discussed, treadmill videoendoscopy is often valuable.

Heart Rate during Exercise. Evaluation of the heart rate during exercise provides an indirect index of cardiovascular capacity and function. Several heart rate monitors are available.[753] Radiotelemetry also can be used to evaluate the heart rate and rhythm, particularly at the end of exercise. Because the stroke volume does not change greatly with increasing exercise speed, the heart rate provides a guide to changes in cardiac output. In general, a linear increase in heart rate occurs with increasing exercise speed up to the point at which the maximal heart rate is reached.[752,754-756] The maximal heart rate (HRmax) is identified when no further increase in heart rate occurs despite an increase in exercise speed. The HRmax does not change with training state, although the speed at which it is reached increases with increasing fitness.

One reference point for comparison of cardiovascular capacity is the treadmill speed at a heart rate of 200 beats per minute (V_{200}). At a heart rate of 200 beats per minute, most horses are close to the point of onset of blood lactate accumulation. The V_{200} can be calculated by linear regression analysis or plotted using measurements taken at three to four submaximal exercise speeds, without the horse reaching maximal exercise. The clinician should take care when using the V_{200} to assess exercise capacity because at a heart rate of 200 beats per minute, horses may be exercising at different proportions of their HRmax and therefore their maximal oxygen uptake (VO_{2max}). In general, however, horses with the highest cardiovascular and metabolic capacities have the highest V_{200} values; that is, the better horses reach a heart rate of 200 beats per minute at higher speeds than those with a lower exercise capacity. The V_{200} increases with training and can be useful for monitoring changes in fitness. The better quality Thoroughbreds have a V_{200} of 8 to 9 m/sec in an exercise test with the treadmill set at a 10% slope. Values less than 7 m/sec are abnormal and if found in a fit horse indicate decreased cardiac capacity.

Another measurement of cardiovascular capacity is the treadmill speed at which the horse reaches HRmax, known as V_{HRmax}. This value correlates with VO_{2max} and exercise capacity but requires the horse to exercise up to maximal speeds so that a plateau in heart rate can be identified.

Heart rate measurements are helpful in determining the actual significance of cardiac abnormalities such as murmurs and arrhythmias. In horses with functional cardiac disease, the reduced stroke volume necessitates higher heart rates to maintain adequate cardiac output. It should be taken into account that a high heart rate does not always indicate a cardiac problem. For example, studies in Standardbred racehorses have suggested that horses with musculoskeletal problems have an increased V_{200} and that monitoring the V_{200} may help to identify subclinical lameness.

Blood or Plasma Lactate Measurement. Exercising muscles produce lactate to some extent during all intensities of exercise, but production increases exponentially with the intensity of exercise.[756-758] As exercise becomes more intense, the aerobic energy contribution becomes insufficient to meet total energy requirements, and increased anaerobic metabolism results in increased lactate production. Lactate diffuses from muscle to blood, and therefore blood or plasma concentrations of lactate reflect muscle lactate. Some evidence suggests that whole blood concentrations most accurately measure lactate accumulation because red blood cells actively take up lactate.[758-761]

The rate of increase of lactate in the blood may be used as an indirect indicator of cardiovascular and metabolic capacity. Horses with the highest aerobic capacities because of a high maximal cardiac output tend to have lower lactate values at submaximal exercise intensities than those with lower aerobic capacities. Lactate values can be used to compare horses or to evaluate training in the same horse. The treadmill speed at which a plasma lactate of 4 mmol/L (V_{LA4}) is reached is one measure of lactate production, and a high value reflects good aerobic capacity. The V_{LA4} has been used to monitor changes in fitness. In fit Thoroughbred horses 3 years of age and older, values for V_{LA4} range from 8.0 to 9.5 m/sec. Horses that are not fit or that have respiratory disease have lower values. Another useful reference is the blood or plasma lactate at conclusion of the 10-m/sec exercise step of the incremental test, and highly fit, athletic horses usually have values below 5 mmol/L. High-quality sprint horses, which perform largely under anaerobic conditions and have a high anaerobic capacity, may have high peak lactate values.

Oxygen Uptake. The measurement of oxygen uptake (VO_2) is critical to assessing athletic performance.[754,755] The VO_{2max} has been used as a key indicator of exercise capacity in human athletes since the 1950s. As the VO_2 increases linearly with increasing treadmill speed, VO_{2max} can be identified when VO_2 reaches a plateau despite an increase in speed. The Thoroughbred horse has VO_{2max} values that are higher than those of many other mammalian species when expressed on a mass-specific basis. The major factor responsible for the high VO_{2max} in athletic horses is their high oxygen-carrying capacity, which arises from a high maximum stroke volume and to some extent a large arteriovenous oxygen content difference. The VO_{2max} is a good index of changes in fitness and a measurement of exercise capacity in performance horses.

Maximum Oxygen Pulse. The oxygen pulse is defined as the VO_2/heart rate and is expressed as mL/kg/beat. This value provides an indication of the maximum stroke volume, and in high-quality horses values range from 0.66 to 0.76 mL/kg/beat. Those horses with cardiac problems resulting in low cardiac outputs and individuals with low VO_{2max} values usually have values in the range of 0.5 to 0.56 mL/kg/beat. The maximum oxygen pulse also has been shown to correlate with treadmill total run time.

Arterial Blood Gas Analysis during Exercise. Arterial blood gas analysis during exercise may be indicated, especially in horses in which respiratory disorders are the suspected cause of poor performance. For an accurate blood gas analysis, the clinician should take into account the temperature of the blood because it may reach 42°C during maximal exercise. At exercise intensities above 65% VO_{2max}, athletic horses become hypoxemic, although the extent varies among individuals.[762-765] Horses with low VO_{2max} values do not necessarily have a significant decrease in arterial oxygen tension.

Additional Pulmonary Function Evaluation. Assessment of pulmonary ventilation can be facilitated by measurements of respiratory resistance, air flow rates, tidal volume, and the durations of phases of the respiratory cycle. Tests can be performed during and after exercise. This testing generally requires specialized equipment such as spirometers and ergospirometers, which may become more widely available for use.

Hematocrit and Total Red Cell Volume during Exercise. The total volume of red cells is a major determinant of oxygen-carrying capacity, and therefore measurement of red cell volume can give some index of exercise capacity. A postexercise packed cell volume test is not a reliable indicator of total red cell volume primarily because of plasma volume variations, but it does provide a rough estimate of total circulating red cells.

The clinician can make an accurate determination of red cell volume by techniques that use dye dilution after mobilization of the splenic erythrocyte pool to measure the plasma volume. Although total red cell volume increases with training, some evidence indicates that Standardbred racehorses with overtraining syndrome may develop an abnormal red cell hypervolemia that contributes to poor performance.[792]

Peak Running Speed and Total Run Time. The peak treadmill running speed and the total run time may indicate exercise capacity. In some studies of human athletes, the peak treadmill running speed during an exercise test was shown to be a predictor of performance. Athletic Thoroughbred racehorses can complete 60 seconds at 13 m/sec during an incremental exercise test at a 10% slope.

Stride Length. Athletic horses are thought to have better stride characteristics.[701,766] Some studies have shown a correlation between maximum stride length and the treadmill run time. An accelerometric device has been used to provide quantitative information about locomotor variables that may be useful in evaluating performance.[766]

It is important to remember that although exercise testing can be useful in the evaluation of poor performance, a diagnosis usually cannot be made based on a single measurement. An integrative approach taking into account the history, clinical findings, and all ancillary diagnostic testing is generally required.

PART 2

Disorders of Specific Body Systems

This page intentionally left blank

CHAPTER 8

Disorders of the Respiratory System

Elizabeth Davis*

Equine respiratory disease is the second most common disorder that limits performance in horses, ranked only behind musculoskeletal disease in importance.[1,2] Specifically, the metabolic requirements of the pulmonary system include the transfer of oxygen from inspired air to the arterial system for delivery to the tissues. Concurrently, the carbon dioxide generated during cellular metabolism must be delivered to the lungs by the venous system and exhaled. Pulmonary functional requirements increase dramatically during exercise, which is why horses are recognized as elite athletes, as evidenced by wide fluctuations in gas exchange capabilities during exercise. Even though the respiratory system is highly integrated with other body systems such as the musculoskeletal, central nervous, and endocrine systems, the respiratory system has been well recognized as the limiting factor in determining athletic performance. For this reason, even early, mild, or subclinical respiratory disease will reduce the performance capacity of horses. Therefore, it is ideal to identify horses that suffer from respiratory disease early in the course of events so that the clinician can provide specific and effective care that will enable a favorable prognosis to be given. This is facilitated by the fact that, from a diagnostic standpoint, many aspects of the equine respiratory tract are highly accessible and easily evaluated, and, when pathology is present, these conditions are often responsive to a variety of therapeutic modalities.

The primary defense of the respiratory tract includes a combination of nonspecific, generalized, and highly specialized protective mechanisms. Nonspecific protection is offered by anatomic organization, microbial, and nonspecific immunologic mechanisms. Anatomic protection is provided by the organization of the upper respiratory tract, nasal passages, lymphoid tissue, and pulmonary clearance mechanisms. For instance, when particulate material is inhaled, anatomic upper respiratory tract barriers provide a valuable mechanism for removal via local trapping at the level of the nasal respiratory mucosa. Particles that are suspended in the inhaled air are largely removed by turbulent air flow that redirects their movement toward the mucus-covered epithelial surface. Turbulence created in the airstream results from the conformation of the turbinates, trachea, and bronchi. The combination of turbulence and anatomic organization effectively removes particles as small as 5 μm, so that only particles less than this dimension reach the alveoli.

Once the material has passed this level of protection and has gained entrance to the proximal trachea the mucociliary escalator mechanism will offer protection through trapping, the coughing reflex, and expulsion of material from the airways. Respiratory system mucous secretion is a continual process that aids with the removal of airway debris and particles. Mucous flow moves from the bronchioles in a rostral direction toward the bronchi and trachea due to the wavelike motion of the ciliated respiratory epithelium, and a similar but opposite movement of material passes from the nasal passages toward the pharynx. The mucociliary escalator is highly effective based on the composition of the double layer of mucus that extends from the pharynx to the bronchioles. The particle-laden mucus is swallowed and presumably digested in the intestinal tract.

Respiratory mucous secretions are produced by airway goblet cells that line the airway mucosa. The mucous gel is highly effective at adsorption of soluble host molecules, which include host defensin peptides, cathelicidins, lactoferrin, lysozyme, and surfactant proteins.[3,4] The majority of microbial organisms that encounter this barrier are rapidly destroyed. Those particles that escape the mucociliary clearance mechanism will reach the alveoli and be cleared via phagocytosis by alveolar macrophages, which will also enter the mucociliary clearance mechanism.

There are four major surfactant proteins produced by alveolar type II cells in pulmonary fluid secretions: surfactant protein (SP)-A, SP-B, SP-C, and SP-D. SP-B and SP-C are highly hydrophobic, which provides for low surface tension within the alveoli, preventing lung collapse. In contrast, SP-A and SP-D are antimicrobial because of their hydrophilic nature. These proteins belong to the collectin family of antimicrobial peptides and provide an innate defense mechanism against pathogen challenge.[5] Their hydrophilic nature enables them to bind to the surface of pathogens via their carbohydrate moieties and act as opsonins. Additional immunologic properties provided by SP-A and SP-D include macrophage activation, facilitation of chemotaxis, enhancement of respiratory burst activity, and inflammatory cytokine expression. SPs facilitate apoptotic cell removal from lower airways, which is particularly important for the resolution of pulmonary inflammation. Failure of effective macrophage phagocytosis leads to the persistence of degraded or apoptotic neutrophils

* The editors and authors acknowledge and appreciate the contributions of Dorothy M. Ainsworth and Jonathan Cheetham as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

and cellular debris, which can serve as a nidus for persistent airway inflammation.

The respiratory tract contains an abundant arrangement of lymphoid structures with lymphocytes diffusely distributed throughout the lung and along the airways. Mucosa in the proximal larynx contains a large repertoire of T lymphocytes. Microfold (M) cells are located along lymphoid nodules as well as in association with nasal lymphoid tissues. The predominant immunoglobulin (Ig) molecule in this location is secretory IgA, with the greatest concentrations in the upper respiratory tract. Secretory IgA is bound to the mucous layer through the secretory component, which facilitates the clearance of adherent bacteria. More distal regions of the respiratory tract contain greater concentrations of IgG, particularly in the bronchioles and alveoli. An additional antibody molecule present in the upper respiratory tract includes IgE. Notably, IgA facilitates host protection through the process of immune exclusion, which prevents the entry of potential pathogens through the respiratory epithelium. In contrast, other antibodies typically provide effective immunity through the process of immune elimination, which aims to target the pathogen for destruction and removal through the process of opsonization.

Many resident cells can be found in the lower airways. In healthy horses approximately 50% of the cells in bronchoalveolar lavage fluid (BALF) are macrophages, whereas approximately 40% are lymphocytes and <5% are neutrophils. Based on this cellular composition (i.e., a preponderance of pulmonary T lymphocytes and alveolar macrophages), cell-mediated immune activation may be induced in the lower airways under certain stimulatory conditions. Also, horses are a species that expresses pulmonary intravascular macrophages (PIMs), which provide the equine host with the capacity for clearance of blood-borne pathogens, resulting in the lung potentially serving as a shock organ. For instance, if marked bacteremia or other pathogen challenges occur as blood passes through pulmonary capillary beds, PIM activation can contribute to marked systemic inflammatory response mechanisms.

Although the respiratory tract may be considered as a relatively sterile environment, in reality it contains abundant flora or a microbiome that provides an important endogenous protection barrier. Similar to other surfaces, the mucosa of the respiratory tract is far from a sterile surface because of the presence of the extensive microflora, which provides beneficial microbes aimed at maintaining microbial homeostasis. The symbiotic relationship provided by the diverse microflora or microbiota is well maintained in the healthy host. Disruption of this microbial population, damage to the normal clearance mechanisms, or mechanical epithelial damage may, however, result in altered microbial populations leading to pathogen proliferation or invasion.

The upper respiratory tract contains an abundant microflora of aerobic and anaerobic bacteria, which provides an essential competitive barrier to pathogen colonization.[3] When horses suffer from lower airway infection it is typically caused by colonization with an opportunistic organism from the upper airways. Bacterial isolates associated with the healthy flora of the upper respiratory tract include *Streptococcus* spp., *Pasteurella* spp., *Escherichia coli,* and *Actinomyces* spp. In addition to common aerobic isolates, anaerobic bacteria predominate in the healthy equine oral cavity, including *Bacteroides fragilis, Fusobacterium* spp., *Eubacterium* spp., *Clostridium* spp., *Veillonella* spp., and *Megasphaera* spp.[4] Although pathogenetic mechanisms associated with lower airway disease are complex and commonly multifactorial, risk factors that contribute to colonization of the lower airways with commensals from the upper respiratory tract and oral cavity include stress, long-distance transport, esophageal obstruction, and prolonged head elevation.[5-7]

FIG. **8.1** A 7-year-old Saddlebred mare presented for 2-year history of upper airway noise. Endoscopy revealed a subepiglottic cyst.

PATIENT ASSESSMENT

Signalment

Specific patient details may provide insightful information regarding the potential for certain diseases. Congenital or developmental disorders are more likely to manifest as clinical disorders in young animals. Examples of such congenital abnormalities include choanal atresia, subepiglottic cysts (Fig. 8.1), hypoplastic lungs, or expression of upper airway disorders associated with hyperkalemic periodic paralysis (HYPP). Acquired disorders such as infections with *Rhodococcus (Prescottia*[8]*) equi* or *S. equi* subsp. *zooepidemicus* are generally evident at 2 to 3 months of age.

Similarly, performance-associated disorders such as epistaxis with short-burst breezing or barrel racing may increase the index of suspicion for exercise-induced pulmonary hemorrhage (EIPH), whereas having historical information that includes awareness of indoor patient housing during adverse weather conditions in association with the development of cough in a riding horse will make allergic airway inflammation more likely.

Diagnostic Considerations

When the initial examination is conducted it is imperative that the clinician collect a complete and pertinent history, although there may be extraneous factors that influence the presenting complaint. Historical information combined with a thorough evaluation at the time of presentation should aid the clinician in determining the source of the problem. Diagnostic examination of the respiratory tract can be achieved with a variety of modalities that include (but are not limited

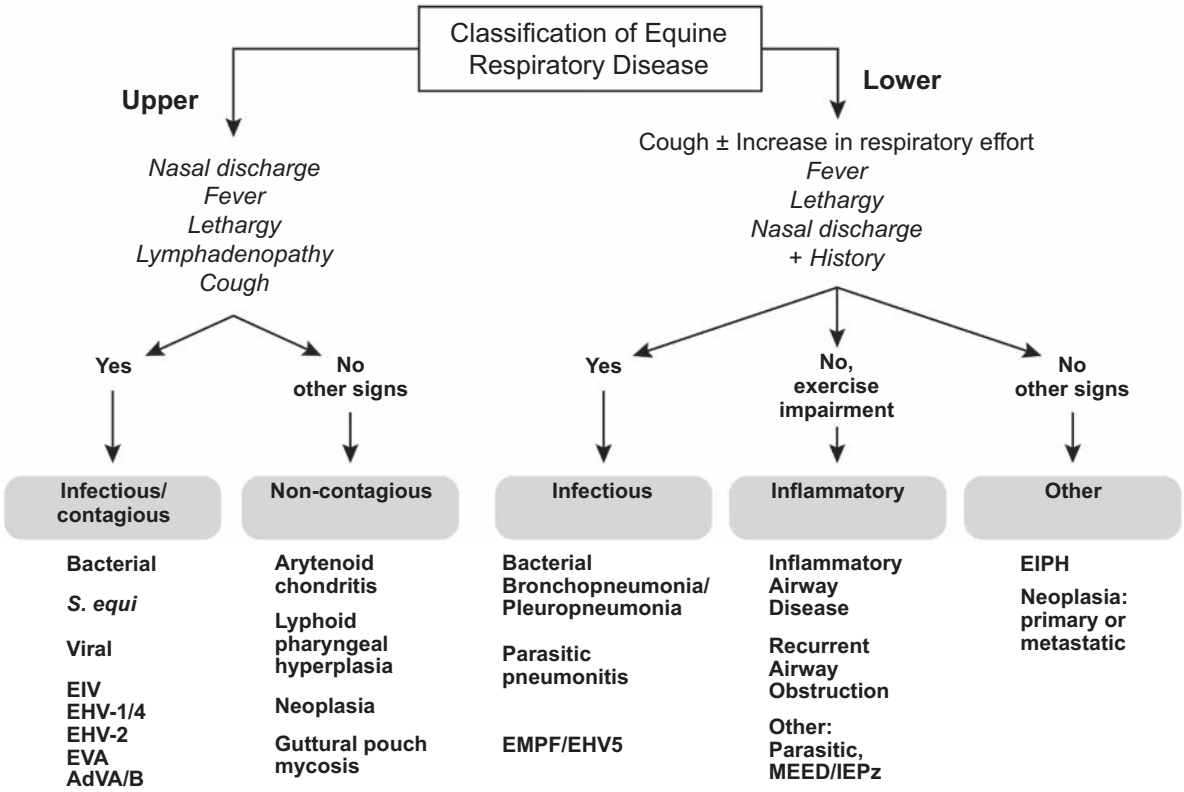

FIG. **8.2** Flowchart diagram differentiating various classifications of equine respiratory diseases. *EHV,* Equine herpesvirus; *EIV,* equine influenza virus; *EMPF,* equine multinodular pulmonary fibrosis; *EVA,* equine virus arteritis.

to) endoscopy, ultrasound, radiography, and respiratory secretion evaluation using transtracheal aspiration and/or bronchoalveolar lavage (BAL) for the collection of samples for culture or cellular analysis, respectively. Advanced imaging techniques include computed tomography (CT) or magnetic resonance imaging (MRI), which may be used for the examination of the upper respiratory tract in adult horses or the entire respiratory tract in small horses/ponies or foals.

Respiratory diseases in horses are typically categorized as upper or lower airway diseases and infectious or noninfectious. Some authors prefer to categorize these conditions according to those that are contagious and noncontagious, as well as infectious and inflammatory or other independent disorders. One way of classifying these disorders is reflected in Fig. 8.2.

Physical Examination

Physical examination should commence with the examination of respiratory rate, effort, and pattern at rest. The clinician should observe the horse in a natural, relaxed environment. It is ideal if the clinician can observe the horse from various angles to specifically observe the inspiratory and expiratory efforts, evidence of nostril flare, abdominal push, or other alteration from normal respiratory parameters. The normal respiratory rate is 8 to 12 breaths per minute. Anxiety, pain, acidosis, hyperthermia, and stress are among the more common reasons that horses can have an increase in respiratory rate. Therefore, the clinician must examine all facets of the patient's status before making the diagnosis of primary respiratory disease.

Clinical signs consistent with respiratory distress in horses include flared nostrils, anxious facial expression, and extended head and neck. The phase of respiration that is abnormal typically aids the clinician with insight into the origin of the respiratory tract disorder. Obstructive and restrictive airway diseases can generally be distinguished by differences in respiratory efforts. Marked inspiratory difficulty, particularly in combination with an audible noise, is consistent with obstructive upper airway disease. The very low airway pressure of the upper respiratory tract is exacerbated during inspiration, which is caused by the movement of soft tissue structures into the lumen in a dynamic manner, exacerbating airway obstruction of the upper respiratory tract. Conversely, a prolonged expiratory phase of respiration, combined with a marked expiratory respiratory effort, provides the clinician with evidence of lower airway obstruction. During expiration, intrathoracic pressure is positive, which narrows the diameter of small airways. If disease includes smooth muscle contraction, mucous production, and increased airway cellularity, these conditions collectively contribute to the development of lower airway obstruction.

Physical examination of the respiratory tract begins with the head. Observation of the character, frequency, and lateralization of nasal discharge may reflect the origin of the disease. Inspiratory noise is characteristic of upper airway obstruction. Maxillary sinusitis may present with unilateral discharge, facial deformity, and/or epiphora. Rostral components of the respiratory tract should be carefully examined for nostril flare, nasal discharge, and appropriate air flow. Nostril flare is not specific for any condition because it may be observed in association with either upper or lower airway disease. However, nostril flare observed in combination with prolonged inspiration and audible noise justifies concern regarding possible

upper airway obstruction. Sounds originating from the upper respiratory tract are classified as stridor, roar, or snore. Stridulous respiratory sounds are characterized by high-pitched inspiratory noise. Diseases characterized by inspiratory stridor include bilateral laryngeal paralysis, a marked pharyngeal or retropharyngeal mass or lymphadenopathy/abscess, arytenoid chondritis, and pharyngeal collapse as observed in cases of Quarter Horses with HYPP. Roaring is a very distinctive noise that occurs when exercising horses suffering from left laryngeal hemiplegia make a low-pitched noise. These horses do not make any audible noise at rest. Unilateral nasal passage obstructions lead to the development of snoring noise. On physical examination, these horses will be noted to have asymmetric airflow through their nostrils and accordingly develop a low-pitched noise that originates from the obstruction in the nasal passages. An exercise-associated low-pitched fluttering sound can be heard with dorsal displacement of the soft palate (DDSP). This might be associated with exercise intolerance, particularly in horses like Thoroughbreds that work at high speed. In the majority of cases, the origin of the airway noise can be successfully identified with standing and/or dynamic endoscopy.

EXAMINATION OF THE LOWER RESPIRATORY TRACT

Examine the horse during eupneic and hyperpneic (by use of a rebreathing bag) breathing. Normal breath sounds are those produced by turbulent air movement through the tracheobronchial tree and vary in intensity and quality depending on the portion of the lung field auscultated. Vesicular sounds, heard over the middle and diaphragmatic lung lobes, are the quietest. Bronchial sounds, which are audible over the trachea and the base of the lung, are the loudest. In the healthy horse, one can hear breath sounds more easily on the right side than on the left. Considerable variation exists among healthy patients in the intensity of the breath sounds. For example, vesicular sounds are often barely audible during normal breathing, whereas in the obese patient they have been described as soft rustling sounds. One may hear breath sounds more easily in a thin or young animal because of less attenuation of lung sounds by the chest wall. The intensity of breath sounds also increases with increased airflow. Thus breath sounds are accentuated in febrile or excited animals or in animals hyperpneic from a variety of causes (exercise, hypoxia, and pain). However, auscultatory findings do not always correlate well with the degree of alveolar ventilation.[9] For example, in horses with pulmonary consolidation, air movement through large airways adjacent to areas of pathology inappropriately gives the examiner the indication that a particular pulmonary region is well ventilated. Breath sounds also may become more difficult to hear in cases of alveolar overinflation in which the aerated tissue of the lung is a poor conduction medium for sound or pneumothorax and pleural effusions in which the sound is reflected at the pleural surface (acoustic impedance).[9] Adventitious pulmonary sounds are abnormal sounds superimposed on the normal breath sounds and are described as crackles or wheezes. Crackles are short, explosive, and discontinuous sounds that are consistent with the sound of cellophane being crumpled. They are usually of low intensity and are audible during the inspiratory phase of respiration. Their production has been attributed to the sudden equalization of pressure in two compartments after airways have reopened. Crackles are often audible in horses with pneumonia, pulmonary edema, or recurrent airway obstruction (RAO). Breathing 100% oxygen also may produce crackles because the nitrogen stent maintaining alveolar distention is eliminated.[10] Crackles are also audible in horses with subcutaneous emphysema. Wheezes are high-pitched musical sounds thought to arise from the vibration of airway walls or tissue masses in close contact with the airway walls and may be audible during inspiration or expiration. Pleuritic friction rubs are sandpaper-like sounds generated by visceral and parietal pleural movement. Percussion of the thorax is accomplished by evaluating the types of sounds produced as one systematically taps the intercostal spaces (ICS) of the thorax using a plexor and pleximeter (foals) or a large spoon and neurologic hammer (adults). Aerated tissues produce a resonant sound, whereas fluid-filled structures (bowel, heart, lung abscesses, and consolidated lung) produce a dull sound. The examiner should identify the transitional site in which the sound quality changes during percussion to establish the boundaries of lung fields. Defining caudal lung borders with thoracic percussion is consistent with limits identified by thoracic ultrasonography.[11] Under normal conditions performing thoracic percussion should not result in pain or discomfort to the patient; if the horse appears uncomfortable or distressed this may indicate pleural pain or the presence of rib fractures. Percussion that reveals ventral dullness suggests pleural effusion, pleural thickening, lung consolidation, masses, or pericardial effusion. Occasionally, caudal borders may be expanded, suggesting alveolar overinflation, which may accompany recurrent airway disease.

Endoscopy

Endoscopic examination is a cost -efficient diagnostic modality that enables the clinician to visualize many critical structures of the upper and lower respiratory tract. Horses are tolerant of endoscopic examination and in some instances do not require sedation, which may be highly desirable when examining laryngeal function. In some clinical settings light to moderate sedation provides the clinician with the ability to effectively complete a thorough endoscopic examination. Endoscopic examination of the respiratory tract provides a diagnostic tool that can be easily adapted to a variety of equine patients, regardless of size or age. The broad utility of endoscopy is extremely helpful to equine clinicians to diagnose DDSP, epiglottic entrapment, rostral displacement of the palatopharyngeal arches, arytenoid chondritis (Fig. 8.3), tracheal collapse or stenosis, and pharyngeal disease that may include narrowing (Fig. 8.4). Developmental or congenital abnormalities may be identified with upper airway endoscopy such as cleft palate, subepiglottic cyst (see Fig. 8.1), or choanal atresia. When exudate or hemorrhage is present, endoscopy can help determine its origin. Examples include guttural pouch mycosis, guttural pouch empyema, progressive ethmoidal hematoma, retropharyngeal lymphadenopathy, pulmonary hemorrhage (Fig. 8.5), or exudate or mucus (Fig. 8.6).

Examination should include tracheal examination and a thorough examination of the lower airways; particular areas of interest will include the mucosa and the presence of exudate or masses. Diagnostic sampling may include a collection of tracheal or bronchial secretions, depending on the purpose of sampling. Tracheal secretion collection is most appropriate for culture purposes, whereas BAL washing of distal airways can be performed for examination of lower airway cellularity.

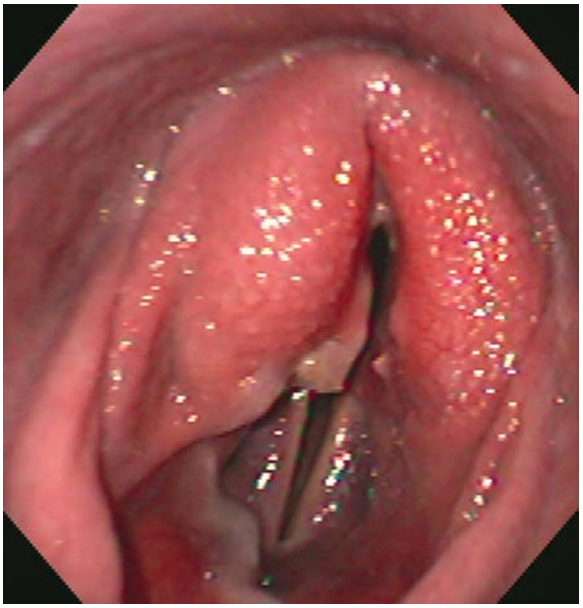

FIG. **8.3** A 24-year-old Paint mare presented for respiratory distress characterized by an increased inspiratory effort. Upper airway endoscopy revealed arytenoid chondritis. Right-sided chondritis is present with right-sided paralysis. Note the exudate exiting from the right arytenoid. Airway distress resulted from severe airway inflammation and near complete airway obstruction. (Video is available in this textbook's website video library.)

FIG. **8.4** Upper airway endoscopy of this 14-year-old Thoroughbred gelding presenting for abnormal whinny and roaring noise with exercise. Marked lymphoid hyperplasia was identified and determined to be caused by neoplastic lymphoid tissue diagnosed as B-cell lymphoma.

In instances where endoscope sterility is in question, transtracheal wash (TTW) is ideally performed using a midcervical, percutaneous approach to avoid the potential for inadvertent bacterial contamination (the TTW procedure is described later).

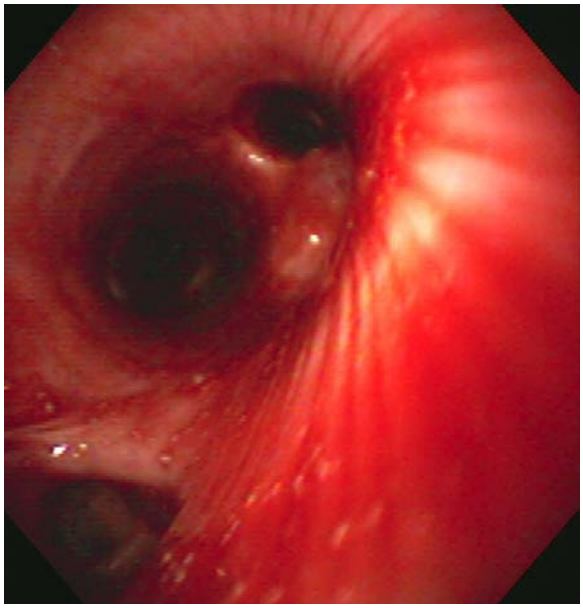

FIG. **8.5** Marked tracheal hemorrhage originating from the lower airway in a horse suffering from exercise-induced pulmonary hemorrhage.

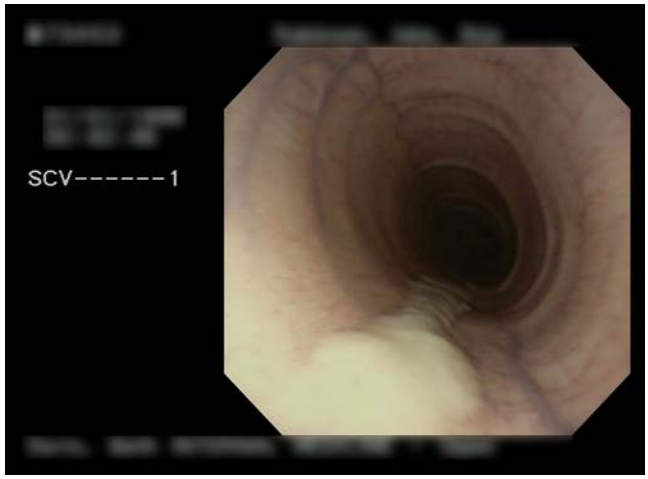

FIG. **8.6** A 5-year-old Holsteiner mare presented for the complaint of cough at the beginning of exercise. Airway endoscopy revealed marked tracheal exudate along the length of the trachea.

Videoendoscopic examination of the upper respiratory tract while on a high-speed treadmill and the use of dynamic endoscopy while the horse is ridden under saddle have become common methods to evaluate a variety of airway disorders. Although many abnormalities associated with the upper respiratory tract can be identified at rest, some conditions are ideally diagnosed with the use of dynamic evaluation while under saddle or on a high-speed treadmill.[12,13]

Radiography

Conventional radiography of the equine skull can be diagnostic under routine conditions of dental disease, the presence of a mass, fluid lines, or fracture. However, equine skull radiography may be challenging to interpret because of the multiple interfaces of radiographic densities and highly complex

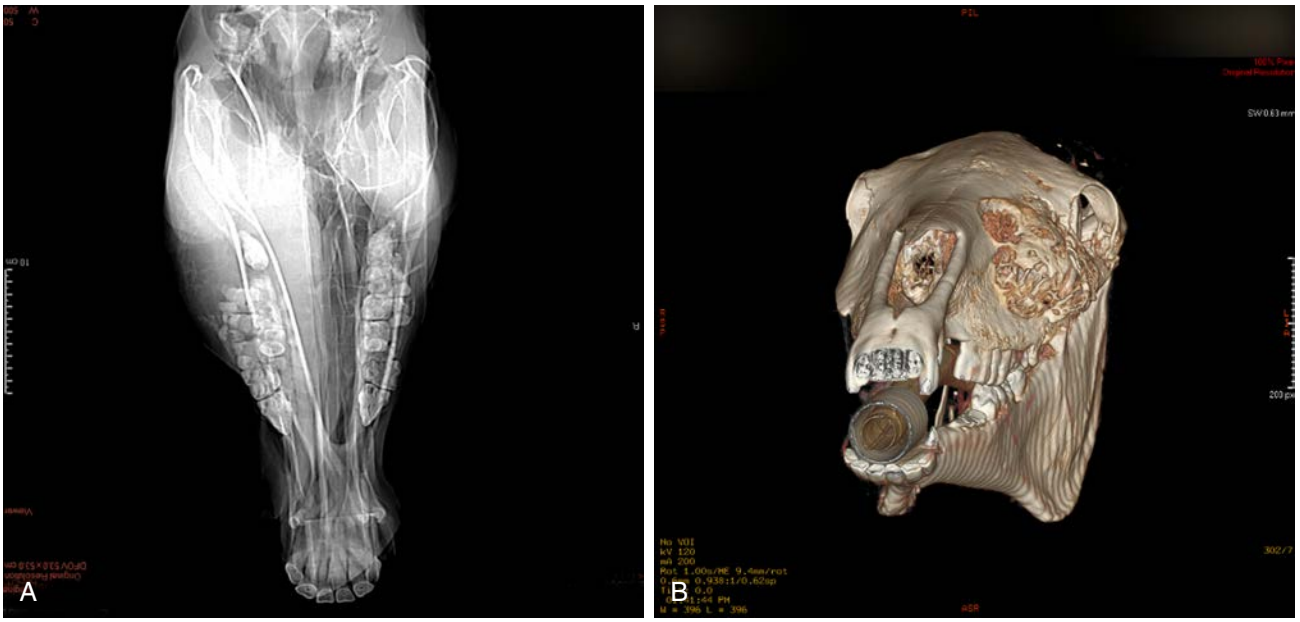

FIG. **8.7** A 31-year-old Arabian gelding presented for a left-sided mass that was rapidly progressive in nature. Although a dorsoventral radiographic imaging provides substantial evidence for a soft tissue mass (A), CT imaging with reconstruction provides remarkable detail regarding the nature and extent of the mass (B).

anatomy of detailed structures. Although examination and conventional radiography may provide some insight into disease origin, additional imaging modalities are often required to fully assess structures in the equine head. CT is a modality that lends itself to detailed imaging of complex structures, particularly when pathology is present.[14] From a methodological standpoint, CT uses a rotated highly collimated radiographic x-ray beam to generate digital cross-sectional images.[15] Collectively, these serial cross-sectional images provide the clinician with greater information and detail compared with conventional radiography alone (Fig. 8.7). (Note: Video is available of this series.) Some limitations of advanced imaging include cost and requirement for general anesthesia. However, CT imagining of the equine head continues to become more common, and in many instances the actual image capture time is shorter than compared with conventional radiographic imaging. Additional evidence to support the use of CT for the equine skull includes complex structures such as nasal turbinates, paranasal sinuses, dentition,[16] nasopharynx, larynx, and guttural pouches.

MRI is an additional imaging modality that can be used to investigate upper respiratory tract disorders. Magnetic resonance images represent a map of tissue protons that, under the influence of a magnetic field, are excited by brief pulses of radiofrequency waves.[15] As the magnetized excited protons relax back to their original magnetized state, a signal is emitted, the intensity of which is converted to a grayscale image. MRI provides excellent cross-sectional evaluations of soft tissue structures, although it also provides useful information about bony structures. Contrast enhancement can be achieved by injecting an intravenous (IV) derivative of gadolinium during the T1-weighted scans.[15] Recent evidence supports the utility of MRI for use in horses. There is a favorable correlation with imaging studies and those identified with surgery or postmortem examination. The increasing availability provides support for the application of this diagnostic modality in equine patients with structural diseases involving the head.[17]

LOWER RESPIRATORY TRACT DIAGNOSTIC SAMPLING

Tracheobronchial Aspiration

Transtracheal aspiration is a routine diagnostic procedure performed in equine respiratory disease workup. The primary indication for performing transtracheal aspiration is to identify pathogenic bacteria colonizing the airway in horses suffering from bronchopneumonia. Following routine sedation and sterile preparation, local subcutaneous anesthetic infiltration is administered to facilitate the procedure. A 3- to 5-mm stab incision is made vertically through the skin and subcutaneous tissue using a no. 15 surgical blade. A TTW trocar is inserted perpendicular to the skin between the tracheal rings, while manually stabilizing the trachea. After penetration of the tracheal lumen, the trocar is removed from the sheath, and the sheath is inserted down the trachea. A lavage catheter is introduced through the sheath into the airway to the level of the thoracic inlet. Approximately 30 to 50 mL of warmed, isotonic crystalline solution is instilled into the tracheal lumen and immediately aspirated. Samples can be used for Gram stains and prepared for aerobic and anaerobic culturing.

Bronchoalveolar Lavage Sampling

BAL can be performed through a 3-m endoscope or using a Bivona (equine BAL) cuffed tube designed specifically to sample the equine lower airway. Routine sedation is administered in combination with appropriate restraint procedures. The BAL tube is initially primed with sterile 0.9% saline containing 2% lidocaine. After entering the nasal passage, the BAL tube is placed in the ventral meatus and moved caudally into the trachea and passed to the lower airways until it is wedged into place at approximately the third- to fourth-generation bronchi. Once wedged into the third- to fourth-generation bronchi, the cuff is fully inflated and the tube is instilled with 200 to

TABLE **8.1 Differential Counts in Bronchoalveolar Lavage Fluid***

500 mL of sterile, physiologic solution. After instillation, fluid is aspirated with gentle but constant pressure. Marked suction should be avoided to minimize the chance for iatrogenic trauma and associated blood contamination, because blood contamination into the BAL fluid can complicate cytologic interpretation. In addition, horses with marked lower airway inflammation will be more likely to collapse their bronchi; thus care should be taken to avoid exuberant aspiration.[18,19] After completion of the sample collection (approximately 50%–70% recovery of instilled fluid) the cuff is deflated and the tube removed. Sample collection of BALF provides valuable diagnostic information in horses suffering from lower airway inflammation. Representative cytologic findings from bronchoalveolar lavage studies of normal horses are shown in Table 8.1

Thoracocentesis

Pleural fluid accumulation occurs in horses with pleuropneumonia, penetrating wounds that enter into the thoracic cavity, thoracic neoplasia, and hydatid cysts.[20] Percutaneous sampling of pleural fluid is performed for diagnostic and therapeutic purposes. Ideally the anatomic location selected for thoracocentesis is based on ultrasonographic identification of the largest and most ventral location of pleural fluid accumulation. Ventral location is particularly important when an indwelling thoracic drain is being placed, so that the greatest volume of fluid can be evacuated from the pleural space. Care should be taken to identify the location of the diaphragm and heart, noting that large-volume fluid can sometime result in caudal displacement of the heart. Skin preparation generally involves routine clipping and aseptic preparation. The skin and periosteum of the rib are locally blocked with 2% lidocaine. A small stab incision is made for placement of a teat cannula or indwelling thoracic drain. Following placement of the stab incision, a thoracic tube with trocar can be placed to facilitate drainage of pleural fluid. When fluid is drained from the pleural space, large-volume fluid should be removed slowly with concurrent administration of IV, isotonic fluid therapy. Rapid and large-volume pleural fluid drainage may lead to patient decompensation caused by re-expansion hypotension and potential development of pulmonary edema.[21,22] Concurrent IV fluid therapy will aid with maintenance of physiologic status. If the patient appears weak or anxious, it is recommended to periodically clamp off the chest tube while continuing to administer IV fluids to facilitate a stable patient status. When evacuating pleural fluid early in the course of disease or in conditions with low fibrin accumulation, fluid may be removed unilaterally yet effectively from both hemithoraces because horses do not have a complete mediastinum. However, with marked fibrin accumulation, it is unlikely that fluid evacuation from an individual side will successfully remove fluid from the contralateral hemithorax, necessitating bilateral indwelling thoracic tube placement. Ultrasonographic examination will enable the clinician to determine the necessity and frequency of fluid evacuation and thoracic tube placement. Once the indwelling thoracic tube has been placed, a one-way (Heimlich) valve can be placed on the end to facilitate one-way flow of fluid from the pleural space with protection to avoid ascending introduction of microorganisms into the pleural space (Fig. 8.8).

FIG. **8.8** The use of a one-way Heimlich valve placed on the end of an indwelling thoracotomy tube to provide effective elimination of pleural fluid while concurrently avoiding ascending contamination of the pleural space with room air or microbial contaminants.

If ultrasound imaging is not available and a blind approach to thoracocentesis is selected, landmarks should include the sixth or seventh ICS on the right hemithorax and the seventh

or eighth ICS on the left hemithorax. Sampling should be performed approximately 10 cm dorsal to the olecranon, dorsal to the location of the costochondral junction.

Thoracic Ultrasonographic Examination

Ultrasonographic imaging of the equine thorax is a routine diagnostic procedure. Thoracic ultrasonography reveals valuable information about the lung and pleural cavity. Examination will aid the clinician with the assessment for potential pulmonary consolidation, atelectasis, pleuropneumonia, abscess formation, masses, and integrity of the diaphragm.

Patient preparation should include cleaning the surface of the hair coat; ideally the area to be imaged should be shaved with surgical no. 40 clipper blades.[23] In some instances this is not conducive to patient management or the horse may have a very fine hair coat, and application of coupling gel or topical isopropyl alcohol will be sufficient to allow image acquisition.

In a healthy horse, pulmonary fields can be imaged from both sides of the thorax from just below the epaxial musculature to the area in which the lung fields join the diaphragm. The ventral border of the lung field is usually identified as a sloping line that originates at the level of the tuber coxae at the 17th ICS, then at the level of the ischial tuberosity at the 15th ICS, and at approximately the level of the point of the olecranon at the 5th ICS.[24] Lung fields can easily be imaged from the 5th to the 16th to the 17th ICS, bilaterally. Pulmonary fields can also be imaged in the more cranial lung fields at the third and fourth ICS, but in these locations the triceps musculature is superficial to the lung fields, so probe depth must be adjusted to account for the focal point of interest. The initial lung scan should be performed with a 5-mHz probe, with the depth set at approximately 10 to 15 cm.[25] If more superficial imaging is required, then a 7.5- to 10-mHz probe is indicated to improve image clarity. The depth setting for a higher frequency probe will need to be adjusted to approximately 5 to 10 cm. Higher frequency probes are most appropriate for imaging the foal thorax, including young neonates through weanling-aged individuals.[26] Adult full-sized horses with a particularly thick body wall may require a lower frequency setting to obtain a diagnostic quality image, and probe selection settings may be ideal at the 2.5- to 3.5-mHz range. Additionally, horses with severe pulmonary disease, such as a marked pleuropneumonia, may require an increased depth setting at 25 to 35 cm so that the full area of pathology can be effectively examined. Typically sector scanners will provide optimal imaging ability, because the head of the transducer is small and can be placed in the ICS of most horses. Limitations exist when using linear-array transducers because the depth is fixed at 10 cm with some instruments and the entire probe is not in contact with the skin surface, limiting the quality of the examination. The lung fields should be scanned in the 3rd (right side) or 4th (left side) through the 17th ICS, moving in a dorsal to ventral direction and moving cranial to caudal to ensure that all areas of the lung fields have been examined thoroughly.[26] The probe should be carefully placed in the ICS to avoid inadvertent acoustic shadowing from ribs as this will impair image assessment.

Thoracic Radiography

Thoracic radiography is a valuable component of patient evaluation often used in combination with other diagnostic modalities such as thoracic ultrasound. Standard thoracic radiography will require a 1000-mA, 150-kV unit to successfully obtain diagnostic-quality images.[27] A series of three to four overlapping lateral projections are generally required to successfully obtain the entire thorax. The routine focal spot to film distance is approximately 100 cm. The thoracic cavity of foals may be successfully imaged with portable radiographic equipment. Thoracic radiography provides superior diagnostic information compared with ultrasound when the aim of diagnostic testing is to examine pulmonary parenchymal lesions, mediastinal structures, and thoracic wall abnormalities. Specific clinical indications for thoracic radiographic imaging include patients with pulmonary disease that is not responsive to standard therapy; severe respiratory distress; thoracic trauma; respiratory disease in combination with weight loss, aspiration, or other forms of bronchopneumonia; intrathoracic esophageal disease; or suspected diaphragmatic rupture.[27] Pulmonary abscesses, pulmonary consolidation, interstitial pneumonia, pneumothorax, mediastinal lymphadenopathy, and pulmonary fibrosis are conditions in which thoracic radiography is indicated and will provide additive diagnostic information when combined with thoracic ultrasonography.[26,27] Structures located deeper than the superficial pulmonary surface and those that involve the pulmonary parenchyma cannot be examined in complete detail with ultrasound alone.

Four radiographic patterns are described for thoracic radiographic imaging and include interstitial, alveolar, bronchiolar, and vascular. Although classification of radiographic pattern can provide the clinician with insight as to the primary disease etiology, none of the radiographic patterns are pathognomonic for specific disease, and many times overlapping patterns are observed. Finding characteristic radiographic changes will aid in formulating and possibly narrowing the list of differential possibilities. Among the patterns observed in equine patients, similar to other species, the interstitial pattern is the most commonly identified. Changes within the interstitial tissue lead to an increased background opacity identified on radiographs. Although an increased interstitial pattern is characteristic for older horses and for this reason is sometimes considered a normal finding, marked change or interstitial disease in a young horse is abnormal. An interstitial pattern is often identified in the early course of disease and is very non-specific. Interstitial changes may be observed early in the course of infectious pneumonia, pulmonary neoplasia, cardiogenic-associated pulmonary disease, and allergic airway diseases. Nodular interstitial disease represents cellular infiltrative disease, with the most severe form represented by metastatic neoplasia or fungal pneumonia (Fig. 8.9). An alveolar radiographic pattern is seen as patchy and often with soft tissue dense areas that impair the ability to see vascular structures and airways. The characteristic feature of the alveolar pattern is the presence of air bronchogram(s), which characterize small airways. An air bronchogram is seen as a branching lucency in which the airway walls are not visible, yet the pulmonary fields are opaque because of the presence of fluid-filled alveoli. Air bronchograms are observed in patients with pulmonary edema, hemorrhage, consolidation, or atelectasis. Identification of an air bronchogram in a particular distribution will aid in establishing the differential diagnosis with a cranioventral distribution identified in association with bronchopneumonia (Fig. 8.10), whereas a caudodorsal distribution may represent cardiogenic pulmonary edema, hemorrhagic disease, or hematogenous dissemination and

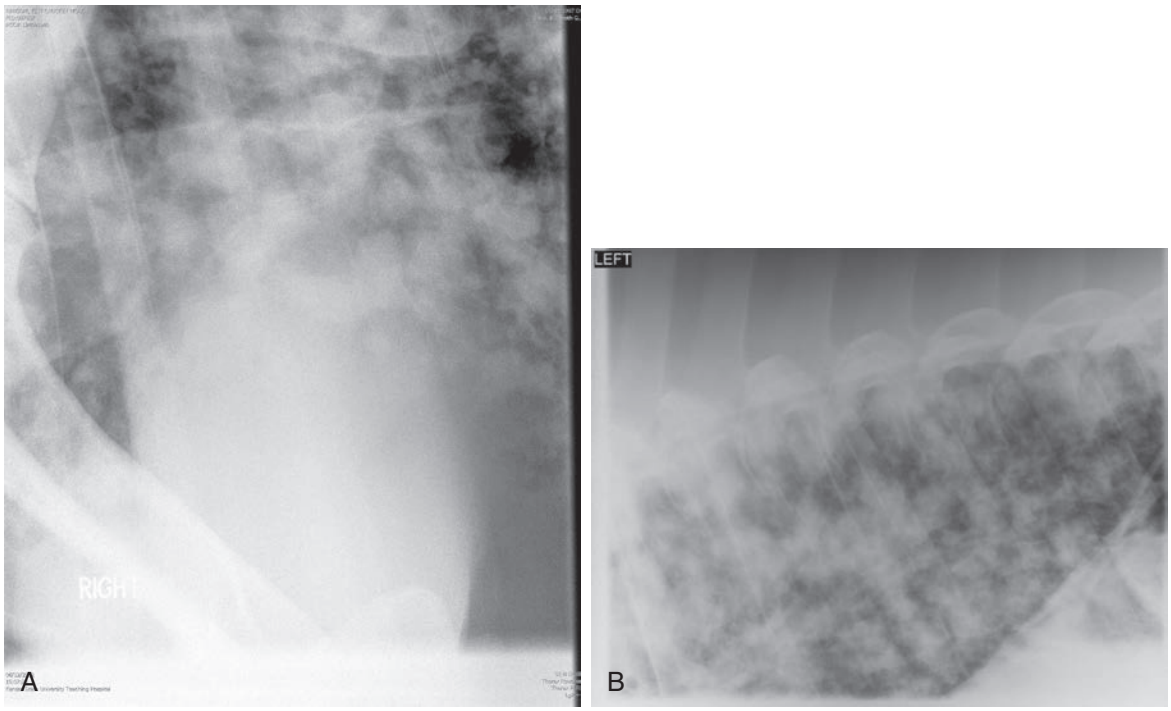

FIG. **8.9** A 15-year-old Thoroughbred gelding with the complaint of weight loss and the diagnosis of equine multinodular pulmonary fibrosis. (A) Nodular interstitial radiographic pattern in a ventral thoracic radiograph centered over the caudal cardiac silhouette. (B) Caudodorsal view of the nodular interstitial radiographic pattern.

FIG. **8.10** A 20-year-old Arabian gelding with the complaint of respiratory distress with acute onset following the administration of mineral oil for colic signs. Note the cranioventral alveolar pattern represented by air bronchograms caused by marked pulmonary fluid accumulation in association with severe mineral oil aspiration pneumonia.

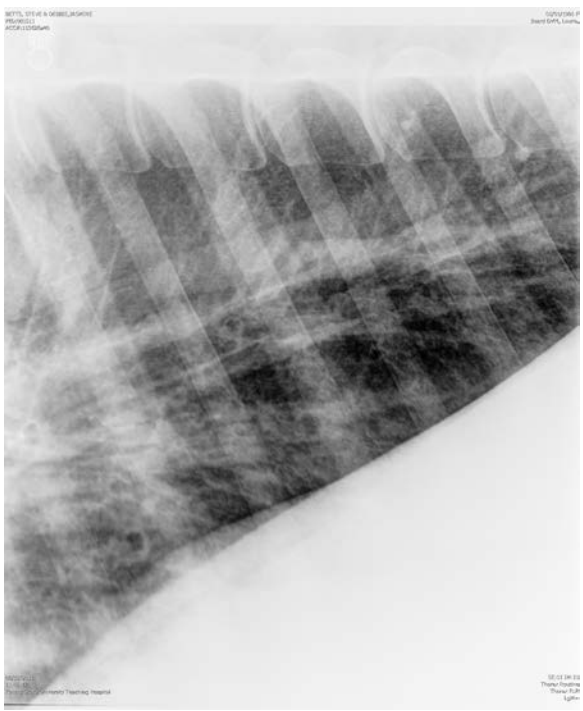

FIG. **8.11** A 15-year-old Arabian mare with the complaint of respiratory distress evidenced by nasal flare and increased expiratory effort. Note the marked bronchointerstitial pattern diffusely present in all lung fields. A marked bronchiolar component is consistent with the presence of chronic peribronchiolar inflammation in association with recurrent airway obstruction.

sepsis. Thickening of the airway results in the identification of a bronchiolar pattern (Fig. 8.11). This represents severe disease of the airways, resulting in thickening of the bronchiolar structures with increased visibility of the bronchi. Increased opacity of the bronchial walls may result from peribronchiolar infiltration or from intraluminal exudate, which is

sometimes referred to as a diphtheritic membrane. Classification of a bronchiolar pattern can be categorized based on sharply defined bronchi or more ill-defined thickened walls termed a *peribronchiolar pattern*. A bronchiolar pattern represents chronic disease with mineralized changes within the bronchiolar wall. In contrast, a peribronchiolar pattern indicates inflammatory disease that surrounds the bronchi, which may develop early in the course of bronchopneumonia or following chronic allergic airway disease such as RAO. The least common pattern is the vascular pattern characterized by a pronounced vascular pattern that mainly occurs following pulmonary overcirculation in association with a left-to-right shunt.

Pulmonary Function Testing

Measurements of mechanical properties of the respiratory system, airway reactivity, and arterial blood gas determinations have been used to determine pulmonary function in horses and are generally available only at select referral centers. Conventional techniques of pulmonary function testing require the horse to wear a breathing apparatus that measures airflow, and pleural pressure changes are measured by an esophageal balloon, which is connected to a pressure transducer. The integration of overall airflow as it relates to time provides a flow rate that aids in the measurement of inspiratory and expiratory volume. Additional parameters obtained using this method of pulmonary function assessment provide inspiratory and expiratory time, respiratory frequency, and peak airflow. From a practical standpoint, the simple measurement of tidal volume, breathing frequency, or minute volume (= tidal volume × breathing frequency) provides limited information regarding the pulmonary function because these values are extremely well maintained until severe respiratory disease leads to marked pulmonary impairment.[28,29]

Measurements of lung movement defined as compliance and airway obstruction characterized by pulmonary resistance provide meaningful information regarding overall pulmonary function. Dynamic compliance (C_{dyn}) is calculated by dividing the tidal volume by the change in pleural pressure occurring at the initiation and completion of inhalation. Pulmonary resistance can be measured by several different techniques, depending on whether the measurement is resistance at peak airflow or at specific ventilatory volumes (i.e., isovolumetric; e.g., 50% tidal volume), which is then divided by the change in pleural (esophageal balloon) pressure over the same interval. Changes in these measurements can provide information regarding the physiologic impact of the pulmonary disease. Horses that suffer from obstructive airway disease of the tracheobronchial tree have reduced dynamic compliance with increased pulmonary resistance. Reduced dynamic compliance without a change in pulmonary resistance indicates that the pulmonary parenchyma is stiffened by alveolar disease or by obstruction of the peripheral bronchioles. Notably, because of the marked surface area of peripheral bronchioles, there will be little change in overall lower airway function until severe, end-stage disease is present. The remarkably large cross-sectional area has minimal impact on the overall resistance of breathing until the disorder is well advanced. Conversely, increased pulmonary resistance without a change in dynamic compliance indicates that the obstruction exists in the respiratory tract, but is does not make a distinction between upper airway, trachea, or bronchus.[28]

An alternative and less invasive technique for measuring pulmonary function uses the forced-oscillation method (or its modification, the impulse-oscillation method). For this method of testing, the horse is fitted with an airtight face mask while an external test signal is imposed on the horse's breathing efforts that generate pressure-flow responses from the respiratory system. The mechanical properties derived from this technique over a wide range of frequencies include total respiratory system impedance (Z_{rs}), respiratory system resistance (R_{rs}), and respiratory system reactance (X_{rs}).[30,31] The impedance represents the *impediment* that the system presents to oscillatory flow and consists of R_{rs} (resistive properties of the respiratory system) and X_{rs} (elastic and inertive properties of the respiratory system).

Measurements of airway hyperresponsiveness are obtained in combination with pulmonary function testing.[32-35] This technique uses a dose of a nebulized bronchoconstrictor agent, such as histamine or methacholine, which causes a 35% increase in baseline R_{rs} or a 35% decrease in baseline lung compliance. The dose to achieve this value in a horse with inflammatory airway disease (IAD) or RAO is considerably less than the dose needed to induce airway reactivity in a healthy horse. Histamine bronchoprovocation testing requires that the horse be sedated and outfitted with an airtight breathing mask. Laboratory assistants must wear protective masks to prevent inadvertent inhalation of the bronchoconstricting agent, which could cause harm to personnel.

Pulmonary function testing of exercising horses and its use in assessing poor athletic performance remains a valuable diagnostic approach offered at select referral centers. With the availability of high-speed treadmills and the ability to measure airflow during exercise,[36] analysis of tidal volume, breathing frequency, dynamic compliance, lung resistance, end-expiratory lung volume, and flow-volume and pressure-volume loops continue to provide additional insights into the cause of the poor performance, the recognition of expiratory flow limitation, and the influence of EIPH on respiratory mechanics.

Lung Biopsy

A histopathologic diagnosis may prove useful in the therapeutic management of certain lung disorders. Percutaneous lung biopsy has been used to investigate disorders characterized radiographically by a pulmonary miliary pattern and disorders for which radiographic or ultrasonographic results are compatible with pulmonary neoplasia or granuloma. A percutaneous approach was originally described,[37] although methods used have been modified because of the routine use of ultrasound during sample collection. Following routine sedation biopsy locations are selected after ultrasonographic confirmation of landmarks (heart and diaphragm) and assessment of tissue accessibility. The biopsy instrument is aseptically advanced through the ICS (cranial to the rib) to the depth of the desired tissues, and samples are obtained for culture and for fixation in 10% formalin. In a study comparing biopsy instruments (manual Tru-Cut versus automated biopsy needle), the investigators found airway bleeding developed in approximately one third of the cases sampled with the manual device and one tenth of the cases biopsied using the automated instrument.[38] This technique is not recommended in patients that are tachypneic, are in respiratory distress, exhibit uncontrollable coughing, or have bleeding disorders. It is not indicated in horses with pulmonary

abscess formation, pleuropneumonia, or pneumonia.[39] In a review of percutaneous lung biopsies performed in 66 horses, this technique yielded a definitive antemortem histologic diagnosis of pulmonary disease in 82% of cases.[40] In the same study, no complications were recognized in 91% of horses sampled. The most common complications observed with lung biopsy are coughing, epistaxis, pulmonary hemorrhage, tachypnea, and respiratory distress. Hemothorax or accidental sampling of abdominal organs (liver and stomach) may occur.[38,40] When horses in respiratory distress are sampled using an automated instrument, epistaxis occurred in 13%, airway bleeding in 39%, and pneumothorax in 4% of patients.[38]

Thoracoscopy

Thoracoscopy or pleuroscopy is a diagnostic technique used in the standing sedated horse to visualize the intrathoracic structures that include the aorta, esophagus, intercostal vessels, sympathetic trunk, vagus nerves, lymph nodes, mainstem bronchi, pulmonary and azygous veins (right hemithorax), diaphragm, and dorsal and lateral surfaces of the lungs. The procedure is used to sample thoracic masses or nodules, to transect pleural adhesions, to place drains for the treatment of pleural abscesses, to repair diaphragmatic hernias, and to resect lung segments either for therapeutic or diagnostic purposes. Thoracoscopy provides a superior method to obtain larger biopsy samples and therefore more accurately assess parenchymal and peripheral airway morphology.

DISEASES OF THE UPPER RESPIRATORY TRACT

Sinusitis

Nasal airways can be infected with a variety of viral, bacterial, fungal, and parasitic agents with resultant sinusitis and/or rhinitis. Rhinitis is defined as infection of the nasal passage independent of the sinus. Infection may include the nasal concha but does not involve the conchal sinuses unless caused by viral agents. Specific viral agents include equine influenza virus (EIV), equine herpesvirus 1 and 4 (EHV-1 and EHV-4), equine rhinoviruses, and adenovirus. Bacterial rhinitis is not common and usually occurs secondary to trauma or foreign body. *Mycoplasma* spp. have been isolated at postmortem examination from horses with rhinitis.[41] A variety of mycotic agents such as *Aspergillus* spp., *Conidiobolus* spp. (usually *C. coronatus*), and *Cryptococcus neoformans* may cause rhinitis in horses.[42] The most common cause of parasitic rhinitis is myiasis caused by *Habronema; Draschia;* and the Russian gadfly, *Rhinoestrus purpureus.* Enzootic lymphangitis or glanders caused by *Burkholderia mallei* causes a specific granuloma within the sinus cavity.[43,44] Horses with sinusitis most commonly have unilateral disease unless the infection is viral or there is extensive involvement of the nasal septa. Most horses present with respiratory stridor and nasal discharge with diminished airflow on the affected side.[41,45-47] Therapy is usually aimed at surgical debridement, debulking of nasal granuloma, and local therapy for the specific agent.[47] Orally administered itraconazole has been described for treatment of recurrent nasal mycoses.[46] Although successful in this case, the pharmacokinetics of this agent are variable, suggesting that an antifungal agent with enhanced bioavailability such as fluconazole may be an appropriate consideration if the susceptibility profile indicates drug efficacy.

Sinonasal disease is very common in horses and likely results from the extensive network of six pairs of sinuses including the conchal sinuses that exchange air with the nasal airway. The frontal sinuses may be affected with granulomatous masses with fungal or parasitic etiologies or bacterial empyema. The most common bacterial isolates are *Streptococcus* spp., which include *S. equi* subsp. *zooepidemicus* and *S. equi* subsp. *equi. Staphylococcus* spp. are the next most frequent isolates.[48] Polymicrobial infection is also identified among sinus disease in horses. *C. neoformans* and *Coccidioides immitis* also may cause granuloma formation within the paranasal sinuses.[49,50] In a study of 277 horses with sinusitis, 24% of the horses had primary sinusitis with no history of predisposing trauma or dental infection.[51] Dental disease of the third to sixth maxillary cheek teeth was the most common predisposing factor for secondary sinusitis (22% of horses) followed by sinus cysts, neoplasia, progressive ethmoidal hematoma, trauma, mycotic infection, sinonasal polyps, and nasal epidermal inclusion cysts. Primary infection of a rostral maxillary cheek root infection was identified in only 4% of cases, although CT evaluation was not used for diagnosis of many of these cases. Nasal discharge (most commonly unilateral but occasionally bilateral) and facial swelling were the most common clinical signs associated with sinusitis in horses. Nasal discharge may be mucopurulent to serosanguineous. A fetid odor is often present and typically attributed to the presence of anaerobic bacteria. Clinical signs commonly persist over several weeks, an initial favorable response to broad-spectrum antibiotics is often only transient. Once antibiotic therapy is discontinued, clinical signs frequently return. Other signs of frontal and maxillary sinus involvement may include lacrimal discharge and exophthalmia. Headshaking syndrome is an uncommon clinical manifestation of fungal sinusitis in horses.[52]

Diagnostic techniques that may facilitate identification of the characterization of sinusitis in horses include endoscopy, radiography, CT, and MRI.[53-55] Endoscopy can detect changes in airway structure (84% of cases) and rule out ethmoidal hematoma.[51,56] Sinuscopy can also be performed through a space created in the skull by trephination in the standing horse.[44,51,56,57]

Radiography is essential for the identification of fluid and masses within sinuses and for preliminary assessment of dentition (Fig. 8.12). Currently available high-detail computed radiography images provide the clinician with a remarkable level of radiographic detail that may provide valuable diagnostic information for the identification of sinus or dental disease.[58] It is not uncommon that the first molar is involved in association with the development of sinusitis. CT and MRI[59] are exceptionally valuable for detection of tooth root involvement and boney changes, which often involve the maxillary bone and facial crest.

Appropriate and effective treatment of sinusitis requires that underlying or predisposing conditions be accurately identified and treated, that debris be removed from the sinus, and that associated infectious agents are properly identified. When fluid is present within a sinus, medical treatment with antibiotics alone is unlikely to be successful. Trephination and flushing or surgical debridement and drainage through a sinus flap are indicated.[60] Establishment of ventral

FIG. **8.12** Skull radiographs can be diagnostic for the identification of dental disease and associated potential sinus disease. This 5-year-old Quarter Horse mare presented with the complaint of facial deformity just rostral to the right facial crest. Radiography demonstrates evidence of periodontal disease, particularly in the region of the right fourth premolar.

drainage of the affected sinuses may be required. Local flushing is likely to be the most important component of therapy, although systemic antimicrobial therapy may be indicated for any horse with signs of osteomyelitis. Prognosis is guarded for complete resolution of clinical signs, especially when apical dental disease is present. Frequently, tooth removal is indicated. Recurrence is most common with ethmoidal hematoma and neoplasia.[61]

PROGRESSIVE ETHMOIDAL HEMATOMA

Definition and Epidemiology

Progressive ethmoidal hematoma (PEH) is characterized by encapsulated, expansive masses that usually arise from the submucosa of the ethmoidal labyrinth.[62,63] The mass is composed of blood and fibrous tissue, is encapsulated by respiratory epithelium, and may extend into the paranasal sinuses.[64]

This condition occurs in 4% to 6% of horses with diseases of the nose and sinus.[50,65] The inciting factor in their development is not known, although they have been hypothesized to be associated with repeated episodes of submucosal hemorrhage. PEH appears bilaterally in 50% of cases and is more prevalent in older horses.[66]

Clinical Signs

The most common clinical sign caused by PEH is intermittent, serosanguineous discharge from the affected nasal passage. Other clinical signs include facial swelling, halitosis, respiratory distress, and coughing.[58,64]

Diagnosis

Diagnosis is based on the clinical signs, endoscopic examination, radiographic evaluation,[51] and, in some cases, CT findings to determine the extent of the lesion.[67] Endoscopy reveals a variably green-colored, smooth glistening mass originating from the ethmoid region. The mass may protrude beyond the nasal septum (and in such cases may cause a bilateral nasal discharge). Radiographs reveal a space-occupying soft tissue density with smooth margins and may demonstrate extension into the paranasal sinuses. Confirmation of the diagnosis is by histopathologic study of the removed tissue,[58] although the clinical appearance is highly suggestive.

Treatment

Treatment options include formalin injection, surgical resection, and laser ablation. Smaller lesions (<10 cm in diameter) can be treated effectively by the intralesional injection of 4% to 10% formalin.[68] Most cases require multiple injections to achieve full resolution.[68a,68b] This procedure can be performed in the standing horse, has a low complication rate, and is associated with 60% resolution after a median of five injections.[64] However, severe neurologic complications can occur if the cribriform plate is fenestrated by the chronic pressure of a large PEH.[69] CT may be indicated to determine the extent of the lesion before treatment.[67]

Surgical removal via a frontal sinus flap is associated with extensive hemorrhage and may require preoperative or postoperative blood transfusions.[64,70] A preoperative crossmatch is warranted, and the horse may also require a postoperative tracheotomy if extensive packing of the nasal cavity is necessary to effect hemostasis. After surgical removal, approximately 20% to 50% of ethmoidal hematomas recur.[70,71] Postoperative complications may include facial incisional dehiscence, suture periostitis, facial bone sequestration, persistent nasal discharges, fungal sinus plaque formation, and encephalitis.[63,64] Laser excision has also been used to treat PEH, with a recurrence rate of 20% described in one report.[72] Recurrence is higher in bilateral PEH than other forms.

GUTTURAL POUCH ANATOMY

The paired guttural pouches are diverticula of the external auditory tubes. Some investigators have suggested that the pouches play a role in cooling the arterial blood supply to the brain.[73] Each pouch has a capacity of about 475 mL and is divided into medial and lateral compartments by the stylohyoid bone.[74] Each pouch fills on inspiration via the plica salpingopharyngeus. The mucosal lining of each pouch is secretory and covered by ciliated pseudostratified epithelium with goblet cells and glands.[74] The medial compartment is three times bigger than the lateral compartment and contains the internal carotid artery and a fold that encloses cranial nerves IX, XI, and XII. The pharyngeal branch of the vagus nerve (cranial nerve X) traverses the floor of the medial pouch, and the cranial sympathetic ganglia are also found within it. The rectus capitis ventralis and longus capitis muscle run just medially to the guttural pouch, and tearing of these muscles after a poll injury can be identified endoscopically as blood in the associated pouch. The lateral compartment of the guttural pouch contains the external carotid and maxillary artery. Branches of the facial nerve (VII), vestibulocochlear (VIII), and mandibular branch of the trigeminal nerve (V) run close to the wall of the lateral compartment.

Guttural Pouch Tympany

Guttural pouch tympany is defined as distention of the guttural pouches with pressurized air. In some instances air accumulation is accompanied by fluid accumulation. Most commonly the condition affects an individual pouch, but it may occur bilaterally. Several reports have described increased frequency of disease in fillies compared with colts.[75-78] Additionally, a breed predilection has been observed for Arabians and Paint foals.[76] Among the affected Arabian foals, many had close genetic relationships. Heritability testing revealed polygenic and mixed monogenic to polygenic models that best described the condition in Arabian foals.[79] Interestingly and consistent with these previous observations, whole genome-wide scanning for guttural pouch tympany in Arabian and German Warmblood horses revealed a gender-specific quantitative trait locus, which is completely consistent with the observation that fillies are more commonly affected than colts.[80]

Clinical Signs

Guttural pouch tympany is most commonly diagnosed in young foals, although it can occur at any time in the first year of life. Characteristic clinical findings include a markedly enlarged area in the throatlatch region. This area can be markedly enlarged and is most commonly unilateral, although bilateral involvement is possible. In cases with severe unilateral involvement, it may be somewhat challenging to determine whether one or both sides are involved because the area of enlargement can be large enough to cross the ventral midline, giving the impression of bilateral disease. The affected area is not painful to palpation, and additional clinical signs may not be apparent. In cases where severe guttural pouch enlargement is present, airway obstruction or dysphagia may be observed. When neurologic deficits are present (e.g., in cases of dysphagia) complete examination should be performed to determine whether evidence of aspiration pneumonia is present.

Pathogenesis

Although the exact etiopathogenesis is incompletely understood, anatomic and physiologic factors must be considered for disease development. It is thought that a mucosal flap (plica salpingopharyngeus) may serve as a one-way valve that prevents the release of air and/or fluid from the affected guttural pouch.[81] Other proposed etiologies include upper airway (viral or bacterial) infection, persistent coughing, or metabolic dysfunction.[82] In most cases there is no obvious anatomic abnormality that can be identified in association with the affected guttural pouch or opening.[76]

Diagnosis

Signalment, history, and clinical findings often provide strong evidence for the diagnosis of guttural pouch tympany in foals. Upper airway endoscopy will provide the clinician with the ability to thoroughly examine the upper airway, nasal passages, guttural pouches, and entire laryngeal region. Although the guttural pouch openings may appear normal, dorsal pharyngeal compression is commonly observed secondary to the trapping of air within the pouch. Additional diagnostic options include skull radiographs, which reveal an enlarged, gas-filled guttural pouch. Although radiographs may be difficult to interpret in foals with bilateral disease, the combination of endoscopy and radiographs will aid the clinician in making an accurate diagnosis.

Treatment

If upper airway inflammation is identified on endoscopy as lymphoid pharyngeal lymphoid hyperplasia, then medical therapy may be initially implemented as a conservative management scheme. Therapy may include nonsteroidal antiinflammatory therapy with flunixin meglumine combined with broad-spectrum antibiotic therapy, trimethoprim-sulfamethoxazole, doxycycline, or minocycline. Therapy should be maintained for 10 to 14 days. If unsuccessful or disease progression is observed, surgical options may be considered.

Surgical approaches include needle decompression and surgical fenestration. Regarding the intricate network of vasculature and nerves in the affected region, an experienced surgeon is best suited to manage affected patients.[81]

Overall, with surgical management, the prognosis remains favorable for recovery and return to function. In some cases, individual surgical decompression is not successful, and repeated surgery is indicated. Nonetheless, when properly applied, even if repeated surgery is required, the prognosis for recovery remains favorable.[76]

Medical conditions that may occur secondarily to the condition of guttural pouch tympany include guttural pouch empyema and aspiration pneumonia. Resolution of the primary condition of guttural pouch tympany is the central focus of disease resolution, but medical management with antibiotics and guttural pouch lavage may be required postoperatively. In some instances, the surgical procedure may result in permanent nerve damage resulting in aspiration caused by persistent dysphagia. In such cases, the prognosis for complete recovery is guarded.[75]

GUTTURAL POUCH MYCOSIS

Guttural pouch mycosis is a life-threatening disease that can lead to fatal hemorrhage in horses. Mycotic plaques are typically located on the roof of the medial compartment associated with the internal carotid artery, and are less commonly on the lateral wall of the lateral compartment of the pouch associated with the external carotid or external maxillary artery. There is no apparent age, gender, breed, or geographic predisposition to this condition. The etiopathogenesis of this disorder remains elusive, but *Aspergillus (Emericella) fumigatus* is the most frequently identified pathogen, which is more readily identified on biopsy versus fungal culture.[83] The fungal plaque is reported to contain a diphtheritic membrane that contains necrotic debris, a multitude of bacterial isolates, and fungal organisms. Although this is typically a condition of more intensely managed horses living in North America, guttural pouch mycosis has also been definitively diagnosed in horses living on pasture in the Southern Hemisphere.[84]

Clinical Signs

Horses most commonly present with the complaint of epistaxis, which may be severe. The hemorrhage originates from the site of fungal plaque localization, which is most commonly over the internal carotid artery, but may involve the maxillary artery in approximately one third of the cases.[73,85-88] Alternate clinical signs many include dysphagia evidenced by feed and saliva containing material exiting from the nostrils, recurrent laryngeal neuropathy (RLN) resulting in turbulent airflow and altered airway mechanics, Horner's syndrome, head extension, parotid enlargement, paralysis of cranial

nerve VII (facial), mycotic encephalitis, and atlantooccipital joint infections.[87,89-92] Even though guttural pouch mycosis is most commonly observed in adult horses, foals have also been reported to develop this disease.[93,94] Epistaxis may be recurrent in nature and can be fatal in approximately 48% of horses; therefore, immediate surgical management is indicated.[87,95]

Pathogenesis
