The etiopathogenesis of guttural pouch mycosis remains elusive. It has been postulated that aneurysmal dilations of the vasculature provide a suitable environment for fungal organisms to proliferate.[96] Fungal colonization of the guttural pouch mucosa and underlying vascular and neural structures results in marked inflammation, necrosis, and erosion, which leads to the clinical manifestation of hemorrhage and potential neuropathy. Clinical signs will reflect the severity of disease and specific anatomic structures that are colonized by the fungal organism.

Diagnosis

Diagnostic confirmation of guttural pouch mycosis is based on endoscopic observation of a fungal plaque within the appropriate anatomic location. Notably, in some cases complete examination of the guttural pouch may not be possible because of the severity of hemorrhage and obstruction of view. In such cases, endoscopic examination provides confirmatory diagnostic evidence regarding the area of hemorrhage, even though the exact site of the fungal plaque might not be observed upon initial examination. Based on clinical signs and endoscopic findings the diagnosis of guttural pouch hemorrhage can be established, which will allow a therapeutic plan to be established. An important consideration when performing endoscopy is to avoid dislodgement of an existing clot over a hemorrhagic lesion. For this reason, caution should be used when performing upper airway endoscopy in patients with suspected guttural pouch mycosis.[97]

Neuropathy may result in dysphagia or laryngeal paralysis. Fungal plaque formation involving the pharyngeal branches of the vagus and glossopharyngeal nerves results in dysphagia and potential aspiration pneumonia,[73,98] whereas a mycotic lesion located in the medial compartment of the guttural pouch may cause damage to the cranial cervical ganglion, which can lead to signs of Horner's syndrome on the ipsilateral side. Changes in vocalization or respiratory noise may result from RLN or pharyngeal paresis.[87] The presence of laryngeal paralysis or dysphagia should be documented at the initial examination because both are associated with a more guarded prognosis.[99] A more favorable prognosis is provided in horses that have evidence of dysphagia. Recovery has been observed to occur over a 6- to 18-month period. Horses may also recover from facial nerve paralysis and Horner's syndrome. Radiographs of the guttural pouch may show evidence of fluid accumulation or osteolytic changes in the stylohyoid bone or may suggest mycotic plaque formation.

Treatment

Current options for medical management of fungal disease in horses are hampered by not having a cost-effective, bioavailable drug that can be effectively administered. When hemorrhage is marked, having an efficient therapy is paramount. Regardless of the medical therapy selected, it generally requires weeks of therapy for treatment benefit to be achieved. For these reasons, medical therapy may not be the preferred therapeutic option for guttural pouch mycosis. Potential antifungal therapeutic protocols have been provided for select cases in which this therapy may be considered.[73] Amphotericin has been administered for up to 40 days, but lack of confirmed efficacy combined with safety concerns limit application of this therapy.[100,101] Itraconazole (5 mg/kg PO daily) can reach plasma concentrations greater than the minimum inhibitory concentration in horses and, although itraconazole has a similar spectrum of activity as fluconazole, it is effective against *Aspergillus* spp.[102] In a separate report, a combination of systemically administered itraconazole in combination with topical enilconazole (60 mL of 33.3 mg/mL solution daily flush) provided successful therapy in an individual case of guttural pouch mycosis.[103] Ketoconazole and fluconazole have been considered as potential therapeutic options, but because of a lack of efficacy and absorption, respectively, these drugs are not recommended for the treatment of guttural pouch mycosis. In a separate report of topical therapy, guttural pouch lavage with 0.08% clotrimazole emulsion in 500 mL water for 14 days prevented recurrence of a solitary lesion in an individual report. It has been suggested that a 3-day depot treatment of clotrimazole providing residual antimycotic activity within the pouch may be a superior option.

Additional medical therapy must also include patient needs. Complete assessment for severity of anemia, hydration status, and degree of discomfort must be addressed accordingly. Patients that are dysphagic will require nutritional support. An indwelling feeding tube may be required to provide support until disease resolution is sufficient to result in improved neurologic function.

Surgical Therapy

Commonly, guttural pouch mycosis is only effectively managed with intensive medical therapy to address blood loss and systemic disease manifestation in combination with surgical occlusion of the affected vessel or vessels. Current interventional therapies of choice use a coil or nitinol plug to occlude arterial flow proximal and distal to the fungal lesion.[81] The placement of transarterial coils, via an incision in the common carotid artery under fluoroscopic guidance, is associated with 84% survival and 71% return to performance.[99,99a] Historically, fluoroscopic guidance has been an important procedural component to ensure accurate coil placement. More recent reports describe transarterial coil embolization in standing horses with the use of fluoroscopy.[104] An increased risk of complication is associated with the presence of aberrant vessels, and for this reason fluoroscopic guidance provides the optimal imaging capability when vascular occlusion is performed.[105,106] Correct placement can be difficult in the presence of aberrant vessels.[105,106]

Prognosis

Horses that present with moderate to severe hemorrhage and receive occlusional procedures are likely to have an improved prognosis for survival. Although original reports suggested an approximate 50% survival rate, this was reported before the application of widespread and routine application of interventional therapies.[73] Recovery from guttural pouch mycosis is typically prolonged, and for this reason deficits may persist for extended periods and in some cases may be permanent. Laryngeal paralysis is commonly a residual complication of this disease,[99] but it has been reported to resolve in some cases.[89]

Dysphagia is one of the more serious long-term complicating factors, and, although some horses partially improve, the final outcome may not be apparent for up to 18 months.[87,89] Neuropathy that involves the facial nerve or cranial cervical ganglion leading to facial nerve paralysis or Horner's syndrome, respectively, often resolves completely.[73,107]

GUTTURAL POUCH EMPYEMA

Guttural pouch empyema results from accumulation of purulent material within one or both guttural pouches. Accumulated exudate can accumulate and become inspissated and form chondroids.[108] Most commonly empyema results following upper airway infection with *S. equi* subsp. *equi.* Abscess formation of the retropharyngeal lymph nodes leads to rupture and drainage into one or both guttural pouches. Persistence of purulent material may lead to the development of chondroids, which occurs in approximately 20% of horses that develop guttural pouch empyema.[108] Less commonly, empyema may be a complicating factor resulting from traumatic injury to the stylohyoid bone, potentially resulting in fracture. Iatrogenic infusion of irritating materials or trauma secondary to inadvertent placement of a nasoesophageal tube may result in trauma to the guttural pouch. Rarely, congenital or acquired stenosis of the guttural pouch opening may lead to impaired drainage, resulting in fluid and exudate accumulation.[82,109]

Clinical Signs

Horses with guttural pouch empyema often have intermittent, chronic nasal discharge.[108] Additionally, submandibular lymphadenopathy and parotid enlargement may be observed. Increased respiratory noise is commonly heard resulting from increased upper airway resistance caused by pharyngeal compression. Neuropathy and dysphagia are uncommon but may develop if guttural pouch inflammation is severe. Occasionally hemorrhage or serosanguineous discharge will accompany guttural pouch empyema.[73]

Diagnosis

Upper airway endoscopy will provide diagnostic confirmation for the presence of exudate within the guttural pouches. Examination will enable the clinician to determine the extent of fluid and exudate accumulation and definitively determine whether disease is unilateral or bilateral. Diagnostic testing on samples collected endoscopically generally includes microbiological culture and polymerase chain reaction (PCR) testing for the presence of *S. equi* subsp. *equi.* Radiography will also provide the clinician with diagnostic examination of other structures in the upper airway. Fluid lines within the guttural pouch suggest the presence of fluid and exudate within the guttural pouch. Ultrasonographic examination can provide additional diagnostic evaluation of peripheral soft tissue structures and the extent of lymph node enlargement.

Treatment

Based on the likelihood that *S. equi* subsp. *equi* is associated with the development of guttural pouch empyema, appropriate biosecurity protocols should be adopted to reduce the risk of bacterial dissemination to instruments or personnel. Specific management protocols generally include medical therapy for the physical removal of exudate, preferably while material is liquid rather than when firm mucoid accumulations have developed into chondroids. The horse should be routinely sedated to facilitate a low head position, which will improve drainage of lavage fluid. In acute cases, daily lavage with sterile physiologic or 0.9% saline is generally effective for removal of exudate.[108] Administration of local penicillin may improve treatment success.[110] A gelatin-penicillin mixture can be instilled through a catheter inserted either through an endoscope or using endoscopic guidance into the guttural pouch.[111] A 50-mL mixture is prepared by first heat dissolving 2 g of gelatin in 40 mL of sterile water and then cooling to 45°C to 50°C. Then add 10 million units of sodium benzylpenicillin that have been reconstituted with 10 mL of sterile water. The mixture is ideally stored overnight at 4°C to allow the gel to set. Approximately 25 mL of the mixture is instilled for each pouch that requires treatment.

When chondroids are present, their removal may be attempted with an endoscopic snare, which prevents the risk of surgical complications and minimizes treatment costs. However, complete removal of chondroids can be challenging, particularly if they are numerous.[111,112] When endoscopic removal is unsuccessful or chondroids are numerous, surgical removal may be performed through a modified Whitehouse approach or by using a transendoscopic laser to establish a permanent pharyngeal fistula into the guttural pouch.[81,113,114]

PHARYNGEAL LYMPHOID HYPERPLASIA

Pharyngeal lymphoid hyperplasia is a common condition involving the upper respiratory tract of 2- and 3-year-old racehorses. Most mild cases respond favorably to reduced athletic activity in combination with systemic and topical antiinflammatory therapy. Dexamethasone can be administered at a dose of 0.02 to 0.05 mg/kg orally daily for 1 week, followed by half of the original dose given orally for 1 week, then the same dose administered orally every other day for an additional week. A throat spray comprised of nitrofurazone, dexamethasone, and dimethyl sulfoxide is reported to be of benefit when administered topically.[115] Systemic immune modulation is reported to be effective for the treatment of horses with lower airway inflammation and may also have some benefit in horses suffering from upper airway inflammation.[115-117] Occasionally, chronic disease occurs; reports have suggested that these horses may respond favorably to cautery of the dorsal roof of the pharynx.[118]

Organisms associated with a more prolonged course of pharyngeal hyperplasia include *S. equi* subsp. *equi;* equine influenza; and EHV-1, EHV-2, and EHV-4. The condition is thought to result from chronic inflammation of the localized lymphoid tissues, particularly because these structures have a diffuse distribution within the mucosa in this species. Although some investigators have cultured the oropharynx of affected horses, no consistent etiologic agent has been identified. Normal inhabitants of the equine upper respiratory tract such as *S. equi* subsp. *zooepidemicus, Bordetella bronchiseptica,* and *Moraxella* have been isolated; however, the direct association with the condition has not been determined. A grading system has been established for this condition (Table 8.2). Horses with more severe inflammation have greater numbers of bacterial organisms isolated from their upper respiratory tract.[119]

TABLE **8.2 Grading Scheme for Pharyngeal Lymphoid Hyperplasia**

GRADE 1: Small number of inactive white follicles scattered over the dorsal pharyngeal wall. The follicles are small and inactive; this appearance is normal in horses of all ages.
GRADE 2: Many small inactive white follicles over the dorsal and lateral walls of the pharynx to the level of the guttural pouches. Numerous follicles are larger, pink, edematous and interspersed throughout.
GRADE 3: Many large pink follicles and some shrunken white follicles are distributed over the dorsal and lateral walls of the pharynx. In some individuals the follicles extend onto the dorsal surface of the soft palate and into the dorsal pharyngeal diverticula.
GRADE 4: More numerous pink and edematous follicles packed close together covering the entire pharynx, the dorsal surface of the soft palate, epiglottis, and lining the guttural pouches. Large accumulations appear as polyps.

TABLE **8.3 Function and Innervation of Muscles Controlling the Tone of the Equine Soft Palate**

Muscle	Function	Innervation
Tensor veli palatini	Tenses the rostral aspect of the soft palate	Mandibular branch of the trigeminal nerve
Levator veli palatini	Elevates the palate during swallowing and closes the nasopharynx	Pharyngeal branch of the vagus
Palatinus	Shortens and depresses the palate	Pharyngeal branch of the vagus
Palatopharyngeus	Shortens and depresses the palate	Pharyngeal branch of the vagus

DORSAL DISPLACEMENT OF THE SOFT PALATE

DDSP results in an upper airway expiratory obstruction with exercise. It is a common cause of poor performance in racehorses and has a prevalence of 10% to 20%.[120-123] Most affected horses make a loud, vibratory respiratory noise, known as *choking down,*[124,125] although a proportion are silent during displacement.[11,125] Endoscopic examination of the upper airway at rest is a poor predictor of DDSP.[126] A definitive diagnosis is made, during high-speed treadmill examination, if the caudal border of the soft palate is seen dorsal to the epiglottis for more than 8 seconds.[127]

Anatomy

The horse is an obligate intranasal breather, and the epiglottis is usually positioned dorsal to the caudal border of the soft palate. A common analogy is a *button through a buttonhole.*[128] The anatomy of this area is complex. The larynx is suspended from the petrous part of the temporal bone by a chain of paired hyoid bones, the stylohyoid, ceratohyoid, single basihyoid bone, and thyrohyoid, which articulates with the rostral aspect of the thyroid cartilage. The strap muscles (sternohyoid, sternothyroid, and omohyoid) contract during exercise and pull the larynx caudally. Similarly, the genioglossus, geniohyoid, and styloglossus muscles (through their direct or indirect attachments to the hyoid apparatus) pull the larynx rostrally.[129,130] The tone of the soft palate is determined by four pairs of muscles (Table 8.3). The stylopharyngeus muscle is innervated by the glossopharyngeal nerve and tenses the dorsal wall of the nasopharynx.[131]

Etiology

The etiologic factors of DDSP are not completely understood and can be divided into intrinsic and extrinsic causes. Intrinsic dysfunctions are seen with decreased tone in muscles of the palate. Dysfunction of the palatinus and palatopharyngeus muscles results in DDSP.[132] This cause is closely linked to pharyngeal lymphoid hyperplasia in young horses because the pharyngeal branch of the vagus nerve runs through the floor of the guttural pouch, which is also the roof of the pharynx. Transection of the tensor veli palatini tendon alone destabilizes the rostral aspect of the soft palate, leading to inspiratory airway obstruction but not DDSP.[133] Dysfunction of the caudal stylopharyngeus muscle destabilizes the nasopharynx but does not cause DDSP.[131]

Extrinsic causes are related to the musculature that controls the position of the larynx and hyoid apparatus. Transection of the paired thyrohyoid muscles produces DDSP[134] presumably because these muscles, innervated by the hypoglossal nerve, prevent caudal retraction of the larynx at exercise. Partial resection of the sternothyroid and sternohyoid tendons produces an inspiratory airway obstruction but not DDSP.[135]

Investigation targeting the role of the rostral hyoid muscles (geniohyoid, stylohyoid, and styloglossus) in horses is lacking, but in humans these muscles are critical to pharyngeal stability.[136,137] Indirectly, tongue-tie devices, which are designed to prevent caudal retraction of the hyoid apparatus at exercise, have been shown to prevent DDSP in some horses.[138] In addition to these neuromuscular dysfunctions, structural abnormalities such as masses or granulomas associated with the epiglottic cartilage or the soft palate can induce DDSP.[139]

Treatment

Surgical techniques aimed at preventing caudal retraction of the larynx, such as strap muscle resection and the Llewellyn procedure (transection of the tendon of insertion of the sternothyroid muscle), are associated with success rates ranging between 58% and 73%.[125,140,141] Treatments aimed at intrinsic causes include staphylectomy[141] and soft tissue stiffening techniques such as rostral palatoplasty.[142] Conservative management of DDSP, incorporating rest, improvement of fitness, use of a tongue tie, or any combination, has also been reported, with a success rate of up to 61%.[138,143] A case-controlled study demonstrated that composite surgery including staphylectomy, sternothyrohyoideus myectomy, and ventriculocordectomy produced increased race earnings in 60% of horses compared with 40% in controls.[124]

Surgical advancement of the larynx (laryngeal tie-forward procedure) demonstrated a success rate of 80% to 82% in

TABLE **8.4 Grading System for Laryngeal Function Performed in the Standing Unsedated Horse**[152]

Grade	Description
I	All arytenoid cartilage movements are synchronous and symmetrical, and full arytenoid abduction can be achieved and maintained.
II	Arytenoid cartilage movements are asynchronous at times, but full arytenoid abduction can be achieved and maintained.
III	Arytenoid cartilage movements are asynchronous or asymmetrical (or both). Full arytenoid cartilage abduction *cannot* be achieved and maintained.
IV	Immobility of the arytenoid cartilage and vocal fold is complete.

Grades II and III contain several subgrades. Readers should consult the referenced monograph[152] for further information.

TABLE **8.5 Grading System for Laryngeal Function Performed During Treadmill Endoscopy**[153]

Grade	Description
A	Full abduction of the arytenoid cartilages during inspiration
B	Partial abduction of the left arytenoid cartilage (between full abduction and the resting position)
C	Abduction less than resting position, including collapse into the contralateral half of the rima glottidis during inspiration

racehorses.[144] The proposed mechanism of this procedure is that it replaces the action of the thyrohyoid muscles and prevents ventral descent and caudal retraction of the larynx during exercise. This procedure is well described elsewhere.[144] Horses undergoing this procedure are as likely to race postoperatively as matched controls. The procedure restores race earnings to preoperative baseline levels and to those of matched controls.

In addition, an external device (Cornell Collar, Vet-Aire, Inc., Ithaca, NY) that applies forward and upward pressure to the hyoid apparatus and incorporates a figure-eight noseband also prevents experimentally induced DDSP during strenuous exercise.[145]

RECURRENT LARYNGEAL NEUROPATHY

RLN is a major cause of poor performance in racehorses and affects 1.6% to 8% of Thoroughbreds.[146-149] The prevalence in draft horses is nearly 42%,[150] and the risk of RLN increases with increasing height in Belgians and Percherons but not in Clydesdales.[150] Horses as young as 6 months may be affected.[151] The condition produces an inspiratory noise at exercise, which has been described as both *roaring* and *sawing*. The term *recurrent laryngeal neuropathy* is preferred to idiopathic laryngeal hemiplegia.[152]

Diagnosis

A diagnosis can be made in most horses based on a resting endoscopic examination of the arytenoid cartilages. Some confusion has arisen from different grading systems used to diagnose the degree of arytenoid dysfunction present at this examination. A recent meeting of investigators reached a consensus on a four-level grading system (Table 8.4).[152] This resting grading system is most useful in its ability to predict arytenoid function at high-speed exercise. Arytenoid position at exercise is shown in Table 8.5.[153]

All grade 1 horses are normal (grade A) at exercise, and all grade 4 horses show dynamic collapse (grade C).[154] During exercise, 4% of grade 3 horses are normal (grade A), 19% are grade B, and 77% are grade C.[155] For grade 2 horses, 4% are grade B or C at exercise.[154] Recently a technique for examining the lateral cricoarytenoid muscle using ultrasound has been described, and this technique is a good predictor of arytenoid function at exercise.[156] It is especially useful if a high-speed treadmill examination cannot be performed.

Anatomy and Etiology

The left recurrent laryngeal nerve curves medially around the aortic arch during development and is approximately 1 m long.[157] In contrast, the right recurrent laryngeal nerve courses around the right subclavian artery and is approximately 25% shorter.[157] The high prevalence of chronic demyelinating peripheral neuropathy in the left recurrent laryngeal nerve has been attributed to its length.[158,159] The myelin loss is most severe distally[160,161] and is associated with axonal loss.[161a,161b] RLN results in progressive atrophy of the left dorsal cricoarytenoid muscle and associated loss of arytenoid cartilage abduction.[158,160,162] The right recurrent laryngeal nerve is rarely affected, although direct trauma to the nerve can induce dysfunction.

During exercise, arytenoid dysfunction narrows the rima glottidis and increases inspiratory impedance and noise.[163,164] This circumstance, in turn, results in airflow limitation and increased driving pressure during inhalation, leading to severe exercise-induced hypoxemia and decreased performance.[163,165-167]

Treatment

The current gold standard for treatment of RLN in horses is prosthetic laryngoplasty, with or without vocal cordectomy or ventriculectomy.[168-171] This technique involves the placement of a nonabsorbable suture to create arytenoid abduction. One limitation of this technique is the frequent and significant loss of abduction of the arytenoid cartilage seen in the immediate postsurgical period.[171,172] This loss of abduction leads to a reduction in the cross-sectional area of the rima glottidis and the return of exercise intolerance and abnormal respiratory noise.[171-173] Loss of abduction may also contribute to the modest postoperative success rate of 48% to 68% observed in racehorses.[168,169,174-177] A much higher success rate (73%–91%) is reported in horses performing at submaximal exercise.[171]

In draft breeds, the degree of abduction required at laryngoplasty is lower than that for a racehorse, given that the goal is to prevent dynamic collapse of the arytenoid rather than to achieve a normal cross-sectional area of the rima glottidis. Some clinicians recommend vocal cordectomy alone for draft breeds. For racehorses and nonracehorses, the major complications are exercise intolerance, respiratory noise, and coughing.[169,170,177]

Restoration of physiologic function through reinnervation and nerve–muscle pedicle transplant techniques has also produced positive results,[178-180] although a delay of several months occurs before any improvement in arytenoid function is seen.

Partial arytenoidectomy is associated with a fair prognosis for the treatment of RLN in horses[174,181] and is not generally recommended as a first-line surgical option.

EPIGLOTTIC ENTRAPMENT

The aryepiglottic fold is the mucous membrane that extends from the lateral aspect of the arytenoid cartilages to the ventrolateral aspect of the epiglottis, where it blends with the subepiglottic mucosa and the glossoepiglottic fold. In epiglottic entrapment, this membrane envelops the free border of the epiglottis.[182] Billowing of the entrapping membranes during respiration decreases the cross-sectional area of the pharynx and effectively obstructs the airflow, particularly during expiration.

The cause of epiglottic entrapment is not understood completely. In most cases, the epiglottic cartilage and associated soft tissues appear normal. In occasional cases, congenital epiglottic hypoplasia or inflammation of the upper respiratory tract structures appears to contribute to entrapment. Epiglottic entrapment is responsible for 1% to 3% of upper airway obstructive problems in horses.[121,149]

Clinical Signs

Most horses exhibit exercise intolerance and respiratory stertor. Horses may occasionally cough during exercise or while eating.

Diagnosis

The diagnosis is based on endoscopic examination. The membrane obscures the normal serrated margin of the epiglottis and its dorsal vasculature. In contrast to DDSP, the shape of the epiglottis can still be seen. Ulceration of the free margin of the fold and erosion of the entrapped epiglottis may be apparent.[183]

Treatment

Entrapment requires surgical correction. Several different approaches have been used and include transoral[182,184-186] or transnasal[187] axial division with a hooked bistoury and transendoscopic division with a laser.[188-190] The prognosis is good after surgery, although re-entrapment and DDSP may occur after surgery.[182,190,191]

ARYTENOID CHONDRITIS

Arytenoid chondritis is a progressive inflammatory condition of the arytenoid cartilages in adult horses, originating as an infectious condition. Most commonly, upper airway dysfunction is reflected in poor athletic performance and respiratory stridor. Diagnosis is based on upper airway endoscopy. One manifestation of chondritis is the development of granulomas on the axial surface of the arytenoid cartilages. Clinical management of affected patients involves medical or surgical therapy. Although broad-spectrum antibiotic therapy has been attempted in many cases, it is rarely curative. Also of importance in management of some of these cases is placement of a tracheostomy tube. Several techniques are described for placement of a permanent tracheostomy.[192]

ROSTRAL DISPLACEMENT OF THE PALATOPHARYNGEAL ARCH

In the horse, the soft palate terminates caudally at the confluence of the caudal pillars to form the palatopharyngeal arch that covers the esophageal orifice.[193] With rostral displacement of the palatopharyngeal arch, this fold of tissue appears to be displaced forward, overlying the apices of the arytenoid cartilages. The condition is uncommon, with a number of small case series and individual cases being reported.[120,194-197] The displacement of the palatopharyngeal arch may be associated with malformation of the laryngeal cartilages and the cricopharyngeal and cricothyroid muscles.[120] The condition may be present from birth. In most cases, abnormal respiratory noise and poor athletic performance are the presenting complaints. Abnormal pharyngeal conformation prevents normal deglutition, predisposing horses to develop aspiration pneumonia. In severe cases, horses may exhibit dysphagia, nasal discharge of food material, and persistent coughing.[128,196] The diagnosis is based on the clinical signs and history and confirmed with endoscopic examination. The rostrally displaced palatopharyngeal arch obscures the normal view of the apices of the arytenoid cartilages. Rostral displacement of the palatopharyngeal arch represents a major deformation of the laryngeal structures and is associated with a guarded prognosis. Resection of the arch by conventional surgery or laser surgery has not enabled successful athletic performance.[194]

NASOPHARYNGEAL CICATRIX

Nasopharyngeal cicatrix is a condition of upper airway inflammation and subsequent scarring of the pharynx. Additional structures that are commonly affected include the openings to the guttural pouches, the epiglottis, and the arytenoid cartilages. A very specific geographic region is associated with the development of this condition, specifically in the Gulf Coast region of central and southeastern Texas.[198-201] The disease has also been reported in Mississippi, Louisiana, and Florida, but rarely.[183,198] This is an upper airway condition that has been recognized for approximately three decades, but for equine referral clinics this condition has become one of the most commonly diagnosed disorders among horses requiring permanent tracheostomy.[200] Clinical signs commonly include upper respiratory noise, exercise intolerance, and rarely, dysphagia. During acute stages of disease, nasal discharge may be observed.[202] Horses that present with the complaint of respiratory distress are more likely to be in the acute stages of disease. Airway obstruction of >50% leads to marked increase in airway resistance, which increases by 16-fold (or more) depending on the severity of scarring and pharyngeal narrowing. Consistent with the fact that disease is localized to the upper airway and dysphagia is uncommon, coughing is not usually reported in association with nasopharyngeal cicatrix.[202]

Upper airway endoscopy will provide a confirmatory diagnosis. Early diagnosis is important so that environmental factors can be modified to limit disease progression. Removal from pasture and movement to a stall or dry lot is associated with limited disease progression. Although various surgical procedures have been used to remove scar tissue formation, the currently recommended procedure is permanent tracheostomy.[199]

A recent retrospective case-control investigation aimed at determining risk factors for the development of nasopharyngeal cicatrix evaluated 242 horses, 121 with nasopharyngeal cicatrix and 121 control horses. In toto, 1236 horses were examined with the reported affected and control horses meeting inclusion criteria for investigation. Risk factors associated with disease development included horses living on pasture exclusively or access to pasture and age of the horse.[202] There was no breed or gender association with disease development, which was in contrast to a previous investigation that suggested mares may have an increased risk of disease.[198] The age-associated component of disease development is believed to be associated with chronic progression of the disease or that the disease results from repeated bouts of exposure to an allergen or irritant located in the pasture. The repeated bouts of exposure are believed to result in continued bouts of inflammation and fibrous remodeling of the upper airway of affected horses.[202] Based on the available published data reporting this disease, it appears that the proportion of cases have remained steady since the original reports were provided, with the overall proportion being 0.64% of the cases seen in high-risk geographic regions.[198,202] Disease was recognized to have a seasonality, with affected horses presented for examination in summer months. Acute flare-up of disease was more likely to occur in the spring, summer, or fall months, suggesting that exposure to an irritant such as pollen or algal toxin was more likely to occur during warmer months.

Overall, it appears that this condition is more likely to occur in older horses that live predominantly on pasture, particularly during warmer months in southeastern and central Texas. The exact etiology remains elusive, which makes prevention challenging. In horses diagnosed with nasopharyngeal cicatrix resulting in marked airway narrowing and distress, permanent tracheostomy is the treatment of choice, with a favorable prognosis (89%) for outcome and return to function.[200]

STREPTOCOCCUS EQUI SUBSP. *EQUI* INFECTION (STRANGLES)

Bacterial infections involving the upper respiratory tract commonly involve *S. equi* subsp. *equi. S. equi* subsp. *equi* is a gram-positive β-hemolytic coccoid bacterium that is categorized within Lancefield group C and has been responsible for causing primary respiratory disease in horses for centuries.[203] *S. equi* is a highly contagious primary upper respiratory tract bacterial pathogen and is the causative agent of strangles, which is one of the most common infectious diseases of horses. *S. equi* is easily grown on blood agar and produces mucoid, nonpigmented (honeydew) colonies that appear in pairs or chains that are surrounded by a prominent zone of β-hemolysis. Although highly similar genetically, this organism is distinct from *S. equi* subsp. *zooepidemicus,* which is a normal inhabitant of the upper respiratory tract of healthy horses. Although colony morphology may be indistinguishable, *S. equi* is typically differentiated from *S. zooepidemicus* by its inability to ferment carbohydrate sugars, specifically lactose, sorbitol, or trehalose.[204] Typical *S. equi* isolates fail to ferment sugars, whereas atypical *S. equi* isolates may ferment lactose or trehalose but not sorbitol.[205] In addition to biochemical characteristics, DNA-based tests that discriminate between these organisms can provide diagnostic information regarding DNA sequence data that are unique to *S. equi,* which provides the clinician with improved diagnostic sensitivity.[110] Ideally, PCR testing should be performed using primers based on the nucleotide sequence of the gene encoding the *S. equi* M-like (SeM) protein.[205]

Molecular evaluation with multilocus enzyme electrophoresis has confirmed a strong genetic relationship of *S. equi* subsp. *equi* and *S. equi* subsp. *zooepidemicus,* indicating that the former is actually a clone derived from the more genetically diverse *S. equi* subsp. *zooepidemicus.*[206] This finding has led to the recommendation that *S. equi* subsp. *equi* be reclassified as a biovar of *S. equi* subsp. *zooepidemicus.*[207] Even though isolates of these two organisms show greater than 92% DNA homology (similarity), immunity is species specific; immunization with *S. equi* subsp. *zooepidemicus* does not protect against challenge by *S. equi* subsp. *equi.* However, from an immunologic perspective, host response to this pathogen may be complex because of antigen cross-reactivity against these two very similar bacterial organisms.

Because *S. equi* is a primary pathogen of the equine upper respiratory tract, unlike *S. zooepidemicus,* which is pathologic only as a secondary invader, *S. equi* does not require airway epithelial disruption or prior viral infection for effective bacterial colonization and subsequent infection.[208] Three colony types exist for *S. equi,* with morphologic differences directly associated with bacterial virulence. The most widely recognized strain that demonstrates marked pathogenicity in horses produces colonies that are heavily encapsulated and light golden color on blood agar, whereas atypical *S. equi* colonies exhibit a matt appearance within 24 hours of incubation in culture conditions and are nonencapsulated colonies that are dry and small.[209] Morphologic differences are observed among *S. equi* strains as a result of variability in the hyaluronic acid content of the bacterial capsule.

Epidemiology

Infection with *S. equi* is most commonly observed in young horses, typically aged from 1 to 5 years of age, but can occur in horses of any age, particularly if antigen-specific immunity is not present or challenge is marked. Foals up to 3 months of age born from immune mares are known to be resistant to the development of strangles.[210] Therefore in endemic areas foals will have increased susceptibility to infection after waning of maternal antibodies, generally at the time of weaning or later in the first year of life. Immunologically naive individuals are highly susceptible to infection with morbidity rates of approximately 100%, whereas mortality is low (up to 10%).[211] It has been estimated that following infection approximately 75% of horses maintain protective immunity against challenge for greater than 5 years.[212,213] Interestingly, however, the remaining 25% of these horses fail to maintain pathogen-specific immunity; therefore, they are susceptible to reinfection within months of challenge, which may represent a failure to produce or maintain an adequate level of protective mucosal and systemic antibodies.[213] In one study of young horses that had been affected with clinical strangles as foals, researchers found that 83% were resistant to comingling exposure 6 months later.[214] As would be expected, however, immunity is not lifelong. Historical epidemiologic studies report attack rates in horses greater than 3 years of age at 18, 29, and 35%.[211,215,216]

FIG. **8.13** A 12-year-old Quarter Horse gelding with the history of *Streptococcus equi* infection approximately 6 months previously. Intermittent unilateral mucopurulent nasal discharge was observed since the original infection. Upper airway endoscopy revealed marked chondroid development in the left guttural pouch.

S. equi subsp. *equi* can be transmitted by direct contact with an infected horse with purulent discharge associated with disease or via contamination of fomites such as horse handlers, grooming equipment, tack, feed areas, water sources, or other items that may be contaminated with bacterial-laden mucous secretions from an infected horse. Not uncommonly, introduction of a horse that is recovering from infection into a group of naive horses can lead to an outbreak. Although horses can resolve the clinical manifestation of disease in approximately 14 days, bacterial shedding typically continues for 4 to 6 weeks. In some instances, disease outbreak can occur as a result of an apparently healthy horse serving as an asymptomatic chronic carrier animal. Horses can maintain the organism within the guttural pouches for extended periods within inspissated purulent material in the form of chondroids (Fig. 8.13). In a recent report it was recommended that guttural pouch endoscopy may provide the clinician with the most efficient and accurate method of diagnosis in an inapparent carrier horse. This case-control study included 8308 horses over an 8-year period that were examined by the ambulatory service of a major teaching hospital. Overall there were 108 (1.3%) strangles cases, and 215 (2.6%) of the horses presented with pyrexia but did not suffer from *S. equi* infection and therefore served as control animals. The study confirmed previous observations[217-219] that horses with bilateral mucopurulent nasal discharge (Fig. 8.14A–B) and external abscess formation in the pharyngeal region were likely suffering from *S. equi* infection.[220] Additionally it was determined that not all horses demonstrated clinical evidence to support *S. equi* infection and that on examination of suspect horses upper airway endoscopy may provide a more efficient and accurate method for examination of the upper airway and sample collection for microbial culture and molecular diagnostic testing. Previous reports have provided evidence that horses may harbor the organism in the guttural pouches for extended periods, with one report indicating 39 months in the absence of clinical signs.[216,221] The etiopathogenesis of the carrier state for horses with chondroids is incompletely understood but is believed to develop as a result of incomplete drainage of mucoid material from the guttural pouches. It has been proposed that incomplete emptying of the guttural pouches leads to retention of material that develops into chondroid material; the persistent presence of this material in the guttural pouch may maintain a perpetual cycle of inflammation in a relatively closed-off anatomic site. Carrier animals maintained in the general population play a critical role in harboring the bacteria between apparent disease outbreaks.[222] Identification of the carrier animal is paramount to abate future disease outbreak.

Although large-scale controlled field studies aimed at documenting survivability of environmental *S. equi* have not been conducted, there has been a long-standing suspicion that *S. equi* may persist in the environment for extended periods of time.[223] Recommendations for the management of contaminated environments were based on original investigations aimed at determining survival of environmental *S. equi* that suggested that long-term bacterial persistence may be a substantial risk for up to 63 days.[224] However, and in contrast to these original observations, more contemporary evidence suggests more limited survival of *S. equi* in an outdoor environment.[225] In this study, sunlight was associated with survival of less than 24 hours, whereas overall survival was less than 72 hours.[225] The implications from this investigation should not be overinterpreted; however, it is noteworthy than in an outdoor environment, particularly in which ample sunlight exists, long-term sequestering of facilities is unlikely to be necessary. When cleansing of nonporous surfaces is implemented, the organism is susceptible to a 1:200 dilution of phenol, and disinfectants such as povidone-iodine, chlorhexidine, and glutaraldehyde kill the organism within 90 minutes.

S. equi has traditionally been defined as a pathogen restricted to the equine host. However, fatal pneumonia attributed to the organism was reported and characterized at the molecular level in a dromedary camel.[226,227] Although *S. equi* infection may occur in humans and descriptions of *S. equi* bacteremia and meningitis exist, infections in humans are rare and may be associated with overwhelming challenge or impaired host immunity.[228]

Pathogenesis

After infective droplets are inhaled or ingested, the organism adheres to the epithelial cells of the buccal and nasal mucosa of the horse, but it does not colonize the mucosal surface of tonsillar tissues of the nasopharynx. The incubation period for bacterial exposure to clinical manifestation of lymph node abscess formation is approximately 10 to 14 days. Interestingly, *S. equi* cannot be detected by bacterial culture or nasopharyngeal swabs obtained 24 hours after infection or challenge. The mechanism of bacterial adherence remains incompletely understood but may involve exposed bacterial surface proteins such as SzPSe, Se73.0, and Se51.9.[223] What makes *S. equi* unique when compared with *S. zooepidemicus* has been suggested to relate to the genetic sequence of *S. equi,* which results in the ability of this bacterial organism to rapidly translocate the mucosal epithelium and create marked lymph node abscess formation. Of particular relevance to the molecular structure of *S. equi* is the fact that the genome encodes 29 surface proteins that are characterized by the presence of a specific LPXTG motif, which under the influence of sortase enzymes results in the attachment of this protein to the peptidoglycan cell wall.[222,229] Similarly, *S. zooepidemicus* also encodes sortase processed proteins with

FIG. **8.14** Yearling Quarter Horse cross filly with evidence of submandibular lymphadenopathy and bilateral mucopurulent nasal discharge consistent with microbiological culture of *Streptococcus equi* subsp. *equi* (A). (B) Subsequent rupture of submandibular lymph nodes.

one strain, termed *H70*, which encodes 39 proteins. These proteins are defined as pili loci; pili are hairlike projections that extend from the bacterial surface and are believed to play an important role regarding epithelial attachment to host tissues.[222] Because *S. equi* expresses a more limited repertoire of these proteins, this may limit the diversity of host attachments by this bacterial strain, leading to more rapid epithelial translocation.

Among the characteristics of *S. equi* is the ability of this bacteria to evade host defense mechanisms. The sortase-processed M protein of streptococci confer antiphagocytic properties. Specifically, acid-resistant fibrillar molecules that project from the bacterial surface are expressed in pairs that twine around one another into a tight surface coil structure. *S. equi* subsp. *equi*–expressed M proteins are approximately 58 kDa in size. The C-terminal region of SeM is predicted to have an α-helical coiled-coil structure with a high degree of sequence similarity to SzM expressed by *S. zooepidemicus.* In contrast, however, the N-terminal portion of SeM is not coiled, and single strands are expressed that are unique to *S. equi.* Regarding evasion of host immunity, antiphagocytic activity is associated with the fibrinogen binding capacity of these individual protein moieties in addition to the binding capacity with Ig isotypes, IgG4 and IgG7. With the presence of fibrinogen and Ig binding on the bacterial surface C3b-binding sites are blocked, which inhibits the activity of the alternate complement cascade of C3 and C5 convertases. There is a large degree of diversity of this region of SeM.

Although it is recognized that there are many differences among *S. equi* and *S. zooepidemicus,* one of the major differences pertains to fermentation of carbohydrates—namely, ribose, lactose, and sorbitol.[204,222] Mucosal colonization is directly related to carbohydrate metabolism, and it is believed that although *S. zooepidemicus* has maintained this capacity, *S. equi* has lost this through the process of evolution.

Similar to many strains of bacteria, *S. equi* produces a hyaluronic acid capsule. This capsule provides the bacteria with an immune evasion mechanism that limits host destruction of bacterial challenge. This capsule mimics the host molecule that is present in mammalian tissues, conferring a protective shield for the bacterial organism. Nonencapsulated *S. equi* has been compared with a medium capsule-producing strain referred to as the matt strain in addition to a heavily encapsulated or mucoid strain. When compared in vitro, the strains were similar with respect to their M-protein expression, cytotoxin activity, and mitogen expression. However, the nonencapsulated strain did not demonstrate any resistance to in vitro phagocytosis by neutrophils, independent of the presence of opsonins. In contrast, strains with matt or mucoid levels of capsule formation demonstrated near-complete resistance to phagocytosis. In addition, when considering the influence of the capsule on pathogenicity in the equine host, the nonencapsulated strain did not result in clinical disease following challenge, yet seroconversion was observed, whereas encapsulated strains of *S. equi* repeatedly resulted in disease consistent with *S. equi* infection.[230]

Within hours of adhesion, the organism translocates below the mucosa to gain access to the local lymphatics and lymph nodes, in which replication occurs extracellulary.[222,231] Complement-derived chemotactic factors generated after interaction of C1 with bacterial peptidoglycan attract large numbers of neutrophils that contribute to the lymphadenitis

and abscess formation.[213] Metastatic bacterial spread to sites other than the upper respiratory tract lymphoid tissue may occur by hematogenous or lymphatic pathways. Although uncommon and reported in an isolated investigation, *S. equi* may be cultured from the blood 6 to 12 days after intranasal inoculation.[232]

Numerous virulence factors of *S. equi* contribute to its pathogenicity, a few of which include the hyaluronic acid capsule, the SeM protein, an antiphagocytic protein (Se18.9), a leukocidal toxin (streptolysin S–like [SLS] toxin), and cell membrane lipoproteins.[205,232a-c,] Synthesis of the hyaluronic acid capsule is controlled by the *has* operon, which consists of *hasA* (encodes hyaluronate synthase), *hasB* (encodes UDP-glucose dehydrogenase), and *hasC* (encodes UDP-glucose pyrophosphorylase). The capsule is antiphagocytic, ultimately reducing the number of bacteria that are subsequently ingested and killed. The capsule, by virtue of its negative charge and hydrophilicity, also produces a localized reducing environment that protects the activity of oxygen-labile proteases and toxins (SLS). Finally, the capsule is required for the activity of SeM. In nonencapsulated strains of *S. equi,* SeM aggregate and fail to achieve the three-dimensional structure required for their function.[213] Although nonencapsulated strains of *S. equi* are able to colonize the surface of the upper respiratory tract and stimulate production of the serum antibody, they are unable to induce detectable pathologic changes in the retropharyngeal and mandibular lymph nodes. The second virulence factor, the SeM protein, is a 58-kDa cell wall antigen that is also antiphagocytic. At its N-terminal end, SeM binds to fibrinogen; at its central region, it binds to IgG. In doing so, it masks the C3b binding surface on the bacterial cell wall and inhibits the alternative C3 and classical C5 convertase.[213] Sequencing of the SeM gene between codons 38 and 143 from 142 *S. equi* strains has identified 43 alleles of SeM, with each allele characteristic of a particular outbreak in a geographic location.[232d] Thus SeM sequence analysis can be used to complement epidemiologic investigations of strangles outbreaks. The loss of SeM expression leads to a loss of virulence but not to a decrease in the infectivity of the organism. Another M-like protein of *S. equi,* SzPSe, exhibits antigenic cross reactivity with the M-like proteins of *S. zooepidemicus,* but its contribution to the virulence of *S. equi* is unknown.[206] Recently, a protein unique to *S. equi,* Se18.9, was found to also possess antiphagocytic properties.[232c] The net effect of Se18.9 is to decrease deposition of C3 (and hence opsonic C3b) on the bacterial surface, reducing phagocytosis. SLS protein is thought to represent a fourth virulence factor by its cytotoxic properties. It damages host macrophages and neutrophils enabling immune evasion, as well as access to released essential nutrients.[205] A fifth virulence factor resides in the lipoprotein components of the *S. equi* cell membrane. When mutants of a specific lipoprotein are synthesized (PrtM) and the organisms are administered to susceptible ponies, clinical signs are markedly attenuated (0 of 5 infected ponies developed signs compared with controls). These data suggest that this lipoprotein is an important virulence factor and might be targeted for vaccine development.[232b] Additional factors that contribute to the pathogenicity of *S. equi* include extracellular proteins or exotoxins that are mitogenic for peripheral blood mononuclear cells.[230] These mitogenic factors (SePE-H, SePE-I, SePE-K, and SePE-L) bind simultaneously to class II major histocompatibility complex (MHC) molecules on antigen-presenting cells and to the T-cell receptor of T cells to induce nonspecific T-cell stimulation, proliferation, and cytokine release. As a result, an acute phase response ensues, characterized by release of interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), and IL-6 from mononuclear cells that contribute to the production of fever, malaise, neutrophilia, and hyperfibri-nogenemia.[213,232a]

Humoral immune responses to many of these virulence factors are apparent in infected horses. During the initial stages of infection, serum IgGa to the SeM protein is induced, followed by the appearance of IgA and IgGb to SeM on the mucosal surfaces.[232e] During convalescence, strong IgGb responses appear to SeM, as well as to other surface-exposed proteins (Se44.2, Se46.8, Se45.5, and Se42.0).[213]

Clinical Signs

The incubation period for typical *S. equi* infection ranges between 2 and 12 days. Generally, horses are febrile (103°F or higher), exhibit lethargy, may have reduced appetite, and, although initially have serous nasal discharge, with the disease progressing, the material becomes mucopurulent. Ocular and nasal mucosal membranes are commonly hyperemic, and a mucopurulent ocular discharge may ensue. Mandibular and retropharyngeal lymph nodes are initially firm but become fluctuant before rupturing 7 to 14 days after the onset of signs. Retropharyngeal lymph nodes may rupture into the guttural pouches, causing neuropathy (dysphagia), empyema, and chondroid formation. Lymphadenopathy, one of the major signs of *S. equi* infections, may be asymmetric and may become so severe that dysphagia, stridor, and respiratory distress ensue. Swelling of the throatlatch area or of Viborg's triangle may be apparent, and palpation of this area may elicit pain. The affected horse may stand with its neck stretched out and be reluctant to swallow. A soft moist cough may be heard. The average course of the syndrome is 23 days.[208] In atypical *S. equi* infections, a mild inflammation of the upper respiratory tract occurs and is characterized by a slight nasal discharge, cough, and fever. Lymph node abscess formation occurs only in a small number of the cases.[209,233,234] In the majority of horses, clinical signs resolve, and bacterial shedding ceases by 4 to 6 weeks. In an estimated 10% of affected horses, continued intermittent shedding of *S. equi* may occur for several additional weeks.

Clinical Pathology

Neutrophilic leukocytosis, hyperfibrinogenemia, hyperglobulinemia, and anemia of chronic infection are characteristic findings with typical strangles cases. In cases complicated by concurrent pneumonia (aspiration), a left shift and the presence of neutrophils with toxic signs may be noted. In horses with purpura hemorrhagica, moderate to marked elevations in muscle enzymes occur. Horses that suffer from infarctive purpura hemorrhagica may have marked elevations of muscle enzymes.[235]

Diagnosis

Diagnosis of strangles in an equine patient is based on clinical signs and the isolation (culture) or detection (via PCR) of *S. equi* from a lymph node, nasal passage swab, nasopharyngeal lavage, or lavage fluid from the guttural pouches. Identification of *S. equi* via culture or PCR testing can generally be achieved 2 to 3 days after the onset of fever. Bacterial shedding can typically be detected for several weeks, often even following resolution of clinical signs. Because *S. equi* does

not colonize the upper airway mucosa culture, PCR testing of an acutely affected horse may initially be negative.[110] Nasopharyngeal lavage samples are more likely to yield positive results compared with swab samples. The lavage fluid will contact an increased surface area, increasing the likelihood of detecting bacteria if present. Following routine sedation, the wash is accomplished by instilling approximately 50 mL of warmed, 0.9% sterile saline into the nasal cavity via a 15-cm soft rubber tubing that has been inserted to the level of the medial canthus. Fluid is collected by gravity, placed into a 50-mL conical tube, and centrifuged; the pellet can be used for culture. Guttural pouch lavage is ideally performed endoscopically, allowing inspection of the medial and lateral compartments for evidence of lymphadenopathy, empyema, or (in more chronic infections) chondroid formation. For the lavage, approximately 50 mL of warmed, sterile 0.9% saline is instilled through the biopsy chamber and gently aspirated for culture, PCR, or (commonly) both. When endoscopy is not feasible, a guttural pouch lavage may yet be possible by advancing a Chambers catheter blindly into the guttural pouch of the sedated horse and lavaging the compartments. In unusual instances blood cultures may become positive for *S. equi* on days 6 to 12 after infection.[232] PCR testing is based on the SeM DNA sequence and is used in conjunction with bacterial culture in diagnostic workups. PCR has greater diagnostic sensitivity compared with bacterial culture and may detect SeM DNA for weeks in guttural pouch lavages after the disappearance of live organisms.[236] Upper airway endoscopy has become commonplace in field settings and may provide superior diagnostic capability for examination and sample collection, particularly when the goal is to identify carrier animals.[220] It is useful in detecting asymptomatic carriers, in establishing *S. equi* infection status before or after transport or commingling, and in establishing success of treatment.[223]

Screening of horses suspected to be suffering from complications of *S. equi* infection includes serologic assessment of the SeM-specific antibody. Horses identified to have an SeM titer in excess of 1:12,800 are suspected to suffer from complicating factors of *S. equi* infection, such as purpura hemorrhagica or metastatic dissemination of *S. equi*.[223] Serologic testing can also be helpful in determining the need for vaccination or in identifying horses that may be hyperresponders and predisposed to the development of purpura hemorrhagica (SeM-specific antibodies >1:1600). An enzyme-linked immunosorbent assay (ELISA) based on SeM-specific antibodies is commercially available through two commercial laboratories (Equine Diagnostic Solutions [EDS] Lexington, KY, and IDEXX Laboratories, Westbrook, ME). Serology may not reliably detect subclinical carriers because of the overlap in the breakpoints between normal and convalescent horses.[237,238]

Upper airway endoscopy is an important component of the examination of horses suffering from *S. equi* infection. Visual inspection of the guttural pouches will provide the clinician with the opportunity to identify evidence of lymphadenopathy, empyema, or chondroids, which can be instrumental in the diagnosis of *S. equi* infections. It can also aid in the identification of asymptomatic carriers, given that endoscopic abnormalities are often still present in these horses.[220,221] Notably, the absence of visible pathology in an asymptomatic carrier emphasizes the need to still obtain samples for concurrent culture and standard (direct) PCR analysis.[110,220,239]

Treatment

In most cases of *S. equi* infection supportive care provided by soft palatable feed, NSAID therapy, and maintenance of hydration will be all the medical care that is required. However, there are some differences of opinion regarding the administration of antibiotics in horses with strangles.[223] Treatment is a function of the stage of the disease, and the general recommendations listed here are those included in the American College of Veterinary Internal Medicine (ACVIM) Consensus Statement.[223] The reader is referred to this excellent review. In treating horses with *S. equi,* penicillin is the drug of choice, although the organism is sensitive to oxytetracycline and the potentiated sulfonamides.[211,231]

Clinical Management of *Streptococcus equi*–Infected Horses and Prevention of Disease Progression

Horses exhibiting early clinical signs of infection (initial fever spike and lethargy) in the absence of lymph node abscess formation should receive penicillin G therapy for 5 days, which can arrest the progression of the disease. One should isolate the horses during their treatment protocol. Treated horses are likely to remain susceptible to infection because sufficient bacterial antigen to elicit a protective immune response may not have been produced as a result of treatment. No evidence has been found that the use of antibiotics during this stage will promote the development of metastatic strangles.[240]

For alert and otherwise clinically stable horses exhibiting lymph node abscess formation, administration of penicillin slows the progression of lymph node abscess formation and is generally contraindicated. Hot-packing the area or areas promotes maturation of the abscess. Once achieved, the clinician should lance the abscess and flush it with a 3% to 5% povidone-iodine solution and, if desirable, then institute antibiotic therapy. Horses may benefit from phenylbutazone or flunixin meglumine administration, which will reduce fever, lessen pharyngeal discomfort associated with the lymphadenitis, and improve demeanor. Horses with *S. equi* infection should be maintained in an isolation area with strict adherence to biosecurity.

Horses that are systemically ill or that develop complications such as dysphagia, aspiration pneumonia, or respiratory distress (particularly if tracheostomy is needed), require supportive care in addition to high levels of IV penicillin and broad-spectrum antimicrobials effective against gram-negative organisms (aminoglycosides) and/or anaerobes (metronidazole). Horses may also require IV fluid therapy, nonsteroidal antiinflammatory drugs, and enteral nutritional support.

Sequelae

The overall complication rate in horses with strangles is estimated to be 20%; most frequently, complications result from metastasis of the organism to other organ systems with the formation of purulent foci.[241] Complications are detailed in the following sections.

Internal Abscessation of the Mesentery or of Parenchymatous Organs

The exact pathogenesis for the development of internal abscess formation is not known.[242] Although anecdotal reports suggest that antibiotic therapy early in the course of infection may predispose horses to the development of metastatic disease,

there is no evidence to support this suggestion. Additionally, because the treatment protocols for horses that suffer from internal abscess formation include long-term and in some cases high-dose antibiotic therapy, it is counterintuitive to consider that antibiotics are a risk factor for the development of metastatic disease. The prevalence of metastatic abscess formation is low, with estimates of 28% based on outbreaks on two farms.[243]

Purpura Hemorrhagica

Immune-mediated type III hypersensitivity leading to vasculitis may occur after re-exposure to *S. equi* by natural infection or following vaccination. Most commonly, purpura hemorrhagica develops during the recovery phase of the disease, 2 to 4 weeks following severe disease manifestation. Immune complex deposition of the vascular intima results in marked edema and necrosis. Clinical manifestation of purpura hemorrhagica involves the development of ventral edema that may be asymmetric in origin. The prevalence of this disorder after natural outbreaks is not known. In a retrospective study of 53 horses diagnosed with purpura hemorrhagica at a university teaching hospital,[244] 17 horses had confirmed exposure or infection with *S. equi,* and 5 had been vaccinated with SeM protein. Horses that are hypersensitive to *S. equi* are at greater risk for developing purpura hemorrhagica defined as having an SeM protein titer of >1:1600.[110] Specifically, the deposition of IgA-containing immune complexes is associated with clinical manifestation of purpura hemorrhagica, whereas an increase in *S. equi*–specific IgG was observed in the clinical recovery stage of purpura hemorrhagica in one report.[171,172] Horses with clinical evidence of purpura hemorrhagica demonstrated markedly elevated IgA titers against SeM-like proteins and culture supernatant compared with IgA titers in horses with uncomplicated strangles.[245] The isolation of immune complexes consisting of IgA and SeM-like proteins in the sera of horses with purpura hemorrhagica has led to the suggestion that IgA is directly involved in the development of purpura.[245,246] The immunologic basis for the increase in serum IgA levels is not known, but possible explanations include clonal expansion of *S. equi*–specific IgA secreting plasma cell populations, impaired IgG production, neutralization, or IgG utilization. Equine purpura hemorrhagica has some similarity with pathogenesis and disease manifestation and is therefore sometimes compared with Henoch-Schönlein purpura, an IgA-mediated immune complex–mediated disease of people.[246]

Guttural Pouch Empyema and Chondroids

This has been described earlier (see page 327).

Septicemia and the Development of Infectious Arthritis and Pneumonia

These conditions warrant a poor prognosis.[247]

Retropharyngeal Abscess Formation

Bacterial translocation across the pharyngeal epithelium with *S. equi* results in lymphadenitis and abscess formation of a variety of regional lymph nodes. Involvement of the retropharyngeal lymph nodes can result in marked pharyngeal compression and airway obstruction. Lymphadenopathy and inflammation in the guttural pouches may result in neuropathy and associated dysphagia, potentially with aspiration. Upper airway endoscopy will reveal nasopharyngeal collapse, which is a deviation of the larynx potentially with drainage of purulent material into the nasopharynx when external pressure is applied to the parotid region.[248] Skull radiographs typically demonstrate a soft tissue opacity in the retropharyngeal area; thickening of the roof of the pharynx; reduction in the diameter of the pharyngeal airway; and distortion or compression of the guttural pouches, pharynx, and trachea.[249] Ultrasonographic evaluation of the affected region caudal to the mandible, dorsal to the trachea, and between the linguofacial vein and maxillary vein can be used to identify the position of the abscessed retropharyngeal lymph nodes.[250,251] Abscess maturation and rupture will occur into the pharynx, which may result in secondary pneumonia, or abscess rupture may occur dorsally into the guttural pouches, which when associated with marked inflammation may lead to neuritis and subsequent dysphagia.[241,248,249]

Abscess Formation Resulting in Respiratory and Systemic Complications

Laryngeal hemiplegia has been reported to occur when abscessed lymph nodes impair normal conduction of the recurrent laryngeal nerve resulting in laryngeal paralysis.[252] In the same report an additional complicating factor involved tracheal compression caused by abscess formation in the region of the cranial mediastinal lymph nodes.[252]

Other Complications

Other complications of *S. equi* infection can also include endocarditis, myocarditis, or cardiac conduction abnormalities. These conditions may result from primary colonization or secondary immune-mediated, inflammatory disorders. An additional complication that can occur in periparturient mares is a condition of agalactia. Although not a result of primary bacterial infection, systemic illness and negative energy balance may play a role for mares reducing or eliminating their lactogenic capacity. Brood mares suffering from *S. equi* infection, that are intended to be raising a foal, should be monitored closely for proper lactation so that foals can be appropriately nutritionally supplemented, as indicated.

Central Nervous System Disease Disorder[243,253,254]

Clinical manifestation of CNS disease will depend on the location of *S. equi* abscess formation. Cerebral cortical lesions may present with the clinical complaint of circling, altered behavior, cortical blindness, marked lethargy, and/or reduced feed intake. Patients presenting with clinical signs that suggest CNS involvement may benefit from advanced imaging. In a previous report T2-weighted MRI images provided valuable diagnostic information regarding lesion location and severity. In addition to imaging acquisition in the cranium, imaging also defined lesion severity in the region of retropharyngeal lymph nodes and sinus involvement. The use of MRI in this report in two of four confirmed positive cases revealed high-quality images that involved soft tissue of the CNS. Lesions that were identified with MRI correlated well with lesions identified at postmortem. MRI is an excellent diagnostic tool that may be considered for the characterization of lesions in affected patients.[243] In a case of *S. equi* meningoencephalomyelitis in a 4-month-old foal, cerebrospinal fluid (CSF) analysis revealed marked elevated total nucleated cell count and total protein concentration and was PCR positive for *S. equi.*[254]

***Streptococcus*-Associated Myopathy.** Myositis may develop as a complication of *S. equi* infection. A serious and potentially fatal form of myositis has been called infarctive purpura hemorrhagica. In this disease horses may initially demonstrate clinical signs of purpura hemorrhagica, but in addition to lethargy, fever, and asymmetric edema, clinical signs of pain evidenced by reluctance to move, marked ventral edema, and colic signs often develop. Complete blood count and serum chemistry analysis reveals neutrophilic leukocytosis with left shift, and hyperproteinemia and hypoalbuminemia are characteristic findings. Most notably marked elevation of creatine (phospho)kinase and aspartate aminotransferase are identified on serum chemistry evaluation. When clinical presentation is consistent with infarctive purpura hemorrhagica and marked muscle involvement is identified, these findings should alert the clinician to the likelihood of extensive muscle damage and necrosis. Postmortem examination reveals muscle infarctions, as well as infarcts in the skin, gastrointestinal tract, pancreas, and pulmonary thromboembolism of the lungs; collectively all findings are compatible with infarctive purpura hemorrhagica. The prognosis is guarded, and affected horses require intense medical management: pain management, IV fluids, penicillin, and high-dose corticosteroid therapy.[235]

Immune-mediated myositis has been reported to occur in horses.[255] Among horses diagnosed with this disease the most common breed included Quarter Horses or closely related breeds.[255] The presenting complaint for affected horses is rapid with marked muscle atrophy (usually symmetric), particularly over the epaxial and gluteal muscles. Additional clinical signs include lethargy, reluctance to move, weakness, and fever. Muscle enzymes creatine kinase and aspartate aminotransferase are typically elevated. Histopathologic evaluation of affected muscle groups reveals macrophages and lymphocytes within myofibers. Phenotypic classification of lymphocytes revealed them to predominantly be CD4+ cells with few B cells, plasma cells, and CD8+ lymphocytes. Although 39% of the horses in the original report had recent exposure to *Streptococcus* spp. organisms, a specific trigger was not determined in all cases.[255] The diagnosis of immune-mediated myositis is based on characteristic clinical findings of marked muscle atrophy in combination with supportive histopathologic findings of lymphocytic myositis obtained from affected muscle tissue. Treatment involves a combination therapy of penicillin and corticosteroid therapy. Response to therapy is rapid and marked in most cases, but a tapering dose of corticosteroids may be needed for several weeks to achieve complete resolution in lymphocytic infiltrates within muscle tissue. Rarely, a poor or incomplete response to therapy is observed.[255]

Outbreak Management

The primary goal when managing an outbreak of *S. equi* is to effectively manage affected horses and minimize disease spread to naive individuals in an effort to minimize the risk of further disease outbreak and potential complicating factors.[223,256] The reader is referred to the ACVIM[223] consensus statement for complete management guidelines, but a summary of outbreak management is provided here:

1. Immediate quarantine of premises that halts equine transport on or off the affected premises to eliminate further disease spread.
   - Horses that are identified to have confirmed *S. equi* disease must be located in an isolation area that is properly designated as such ("dirty" or "strangles cases"). This will allow caregivers to have major areas for horse handling and "clean" and "affected" areas.
2. Determine whether recovering horses are infectious.
   - Three nasopharyngeal lavages (preferably) collected at weekly intervals for 3 weeks; samples should be tested using microbiological culture and PCR testing.
   - Test-negative horses are "clean" of infection.
3. Determine whether apparently healthy horses are *S. equi* positive.
   - Upper airway endoscopy to determine whether there is the presence of disease.
4. Eliminate *S. equi* from guttural pouches of affected horses.
   - Endoscopically guided guttural pouch lavage with isotonic, sterile fluid to remove mucous or chondroid accumulation; manual removal of chondroids may be required if lavage alone is unsuccessful.
   - Systemic and local antibiotic therapy to eliminate *S. equi* infection.
5. Establishment of an isolation area and protocols to prevent indirect cross-infection of *S. equi* to clean areas.
   - Caretakers should have dedicated barrier clothing and instruments. Avoid simultaneous contact with horses. Manage affected horses after clean horses and clean areas.
   - After removal of organic debris, all areas should be cleaned and disinfected.
   - Manure and general waste should be composted in an isolated area.
   - Water troughs should be cleaned daily.
   - Horse transportation vehicles should be cleaned after every use.

Disease Prevention

Among the currently manufactured vaccines there is an inactivated M-protein subunit vaccine and an attenuated live *S. equi* vaccine. The subunit vaccine is a protein-rich acid- and enzyme-extract product that is administered parenterally (e.g., Strepvax II, BIVI). The attenuated live *S. equi* vaccine is administered intranasally (Pinnacle I.N., Zoetis Inc.). In Europe, deletion mutant vaccine is approved as a submucosally administered vaccine. Injection is recommended in the upper lip (Equilis StrepE, Intervet). Among the currently available vaccines, there is no guarantee for the prevention of strangles in vaccinated horses.

Parenterally administered inactivated vaccines induce serum bactericidal activity, but circulating antibodies are not necessarily protective because local mucosal immunity plays a significant role in the resistance to infection.[256] Naive adult horses and foals should receive two to three vaccine doses at 2- to 3-week intervals, followed by annual boosters while they remain at risk for *S. equi* exposure. Vaccine administration is not recommended in horses with high SeM titers (>1:1600) because of the potential for an adverse event such as the development of purpura hemorrhagica.[223]

The attenuated live intranasally administered *S. equi* vaccine is aimed at mimicking the natural exposure to *S. equi,* inducing endogenous local immunity with systemic and locally produced immunoglobulins, notably IgA, aimed at this problematic pathogen. Vaccine manufacturer claims report a significant reduction in the number of horses developing clinical signs of disease following challenge when vaccinates are compared with control animals. Approximately

40% of vaccinees develop clinical signs of strangles, whereas approximately 60% of nonvaccinated control animals develop disease. Although intranasal vaccines are expected to produce fewer adverse reactions than parenteral vaccines, lethargy, inappetence, fever, lymphadenopathy, lymph node abscess formation, purpura hemorrhagica, and intramuscular abscesses have occurred after vaccination.[213] Additionally, clinicians may consider whether to administer the attenuated live vaccine to young horses (<1 year of age). In one report it was suggested that in this age group the potential for disease manifestation exists following vaccination and was observed, yet it should be noted that the sample size was small in this investigation.[257]

Submucosal vaccines have also been associated with the production of adverse reactions, including neck and mandibular lymph node abscess formation.[258]

Attenuated live vaccines should be administered to healthy afebrile animals free of evidence of disease. For the intranasal vaccine, it is recommended that two doses at 2-week intervals followed by an annual booster be administered. Foal vaccination should be considered in light of the mare's vaccine status at the time of parturition. In foals born to unvaccinated mares that are in high-risk situations vaccination may be initiated at 1 to 2 months of age, but the risk of vaccination is that disease-like manifestations may occur.

For the submucosal vaccine available in Europe (Equilis StrepE), two doses (0.2 mL) of vaccine are injected at 4-week intervals in healthy horses older than 4 months of age. Because the duration of immunity by the submucosal vaccine is limited, it is recommended that high-risk horses receive a booster every 3 months, although boosting of horses vaccinated up to 6 months previously in the setting of an outbreak was suggested in one report.[237]

When administering any form of an attenuated live vaccine (intranasal or submucosal vaccines) caution should be used regarding health status and any invasive procedures implemented at the time of *S. equi* vaccination. Specifically, care should be implemented if other vaccines are concurrently administered because potential abscess formation at the site of concurrent intramuscular vaccines may occur. Handling the vaccine should be followed by thorough hygiene measures that include careful handwashing to minimize the transfer of bacteria to other sites or instruments.

Additional areas of concern regarding *S. equi* vaccination include the risk of complications such as purpura hemorrhagica. For this reason, vaccination at the time of disease outbreak is controversial and should be carefully considered. The only horses that should be vaccinated are those that have not had a chance for bacterial exposure and those with an SeM titer of <1:1600. An appropriate amnestic immune response requires approximately 10 days to occur, so exposure to at-risk individuals should not occur before this immunity is expected to be present. No *S. equi* vaccines have any claim to provide protection against *S. zooepidemicus*–associated respiratory (or otherwise) disease.

General Control Measures

Introduction of new arrivals to an equine establishment should include careful biosecurity protocols that include a quarantine period of 3 to 4 weeks. Quarantine areas should be designed so that there is no direct contact of new arrivals with resident horses and that personnel use proper hygiene after working with new arrivals. During this period of quarantine new arrivals should be monitored for any evidence of contagious infectious disease, which includes overall health status, presence of nasal discharge, lymphadenopathy, and rectal temperature monitoring one to two times daily. Comprehensive monitoring of potential *S. equi* carriers should include upper airway endoscopy with guttural pouch lavage. Collection of fluid for *S. equi* PCR testing will aid with the determination of *S. equi* carrier horses. Measures should be implemented to prevent animal or personnel contact between the new additions and resident horses.

Although previous reports have provided suggestions that *S. equi* is a pathogen that may be eradicated, this has not been successfully achieved. Factors that favor eradication include an individual host for infection, poor survival in the environment, minimal antigenic variability, PCR diagnostic availability, and low level of carrier individuals.[259] The primary caveat is that although *S. equi* vaccines are available they are not universally protective. It is anticipated that with the advent of more efficacious vaccine(s), eradication of the serious bacterial pathogen may be achievable. If successful, strangles would become a reportable disease with stringent regulatory control measures implemented to prevent the reintroduction of this pathogen.

EQUINE INFLUENZA (EIV)

EIV is classified as an orthomyxovirus with a single-stranded segmented RNA genome.[260] Influenza viruses are classified on the basis of surface and internal protein antigens into three types (A, B, and C); only type A influenza is reported to infect horses. Major viral antigens include neuraminidase and hemagglutinin (HA). Two type A viral subtypes are known to cause disease in horses: H7N7 and H3N8.[260] The strain H7N7 was initially isolated in 1956 in Prague and designated A/equine/Prague/56. This H7N7 variant, termed equine-1 influenza, has not been isolated since 1980 and is believed to have disappeared from the equine population.[119] The H3N8 EIV, called equine-2, is a strain that was initially isolated in Miami in 1963 and designated A/equine/Miami/63.[261-263] Antigenic drift has subsequently resulted in many subtypes of variant equine-2 among horses, including A/equine/Fontainebleau/79, A/equine/Kentucky/81, A/equine/Saskatoon/90, and A/equine/Newmarket 2/93. Although antigenic drift has been observed for many years, a larger scale change in the antigenic nature of the EIVs has not been documented.

Equine influenza is endemic in Europe, North and South America, North Africa, the Middle East, and Asia. Because of the highly contagious nature of this virus, susceptible equine populations are at risk for major outbreaks if virus is introduced. This scenario occurred in 2007 when breeding stallions from Japan were introduced into Australia and were infected with a Florida Clade I lineage H3N8 equine influenza strain of the virus.[264,265] Australia was influenza free at the time of introduction, and disease outbreak resulted in 76,000 horses developing the viral infection. The outbreak occurred over an 18-week period. Rapid control measures were implemented, including vaccination; the outbreak was successfully managed; and Australia is once again influenza negative.

Influenza is most common in horses commingled under stressful conditions such as race training. Viral spread occurs through aerosolization of viral particles from a contaminated horse to susceptible individuals. Fomites can play a role as well; contamination of personnel can also contribute to viral

spread.[266] Infection occurs via inhalation of viral particles. The virus infects respiratory ciliated epithelium, leading to loss of the mucociliary escalator for pathogen and particle clearance. Therefore, viral infection predisposes affected individuals to secondary bacterial infection.

Clinical Signs

Clinical characteristics of equine influenza include a short incubation period of 1 to 3 days, high fever, depression, and paroxysmal coughing, which can be severe. Nasal discharge may begin as serous fluid and change to a more mucopurulent character with disease progression and bacterial contamination. Submandibular lymphadenopathy is commonly associated with viral disease. Myositis, anorexia, and persistent cough are not uncommon signs observed in association with influenza infection. Immune status and previous vaccination will directly influence disease course; unvaccinated horses or those not previously exposed to the virus typically demonstrate the most severe clinical evidence of disease. Horses with influenza are at risk of secondary bacterial infection that may progress to bronchopneumonia and/or pleuropneumonia.

Diagnosis and Treatment

The recognition of a rapidly spreading respiratory infection in a group of horses is characterized by rapid onset, high fever, depression, and particularly cough, which is strongly presumptive of the equine influenza infection.[267] Vaccinated horses may not demonstrate clinical manifestation of disease, which was illustrated with an outbreak of racehorses in Hong Kong that displayed a variety of clinical signs that delayed definitive diagnosis in this group of horses.[268,269] Additionally, based on experimental challenge data, there is an inverse relationship regarding the level of challenge and time course for clinical manifestation of disease.[270] Collectively, a variety of factors that include host immunity and health, pathogen-specific immunity, and pathogen dose can impact the presence and severity of clinical manifestation of the disease. For these reasons, all factors should be considered when evaluating a potential outbreak with appropriate diagnostic testing performed to determine the specific etiologic agent responsible for disease outbreak.

A variety of diagnostic tests have been developed to determine the presence of this virus in the equine host and include virus isolation, influenza A antigen detection, HA inhibition (paired baseline and convalescent), and real-time quantitative PCR (qPCR). Definitive diagnosis in an outbreak is based on viral detection with nasopharyngeal secretions or by an increasing virus neutralization (VN) titer. Notably, evidence supports that optimal sample collection with improved test sensitivity should be based on nasopharyngeal lavage sampling rather than just nasal swab sampling, particularly in surveillance situations that will lead to quarantine of test-positive individuals.[271] Sample collection with a synthetic swab submitted for PCR testing provides a cost-effective and efficient method of diagnostic testing under most routine clinical settings.[268,272]

Even though specific antiviral treatment for the management of influenza-positive humans has become commonplace, the same cannot be said for equine patients. The primary goal of prevention through application of effective biosecurity measures and vaccine strategies remains the focus for disease avoidance in horses. Among the American Association of Equine Practitioners risk-based vaccine guidelines, vaccination for the prevention of influenza is an achievable goal in many settings. Commercially available vaccines include live attenuated, cold-adapted, inactivated, and recombinant vectored vaccines. The majority of investigation into vaccine efficacy is based on relatively small-scale investigations that consistently identify a correlation between protection from disease and antibody levels, particularly when there is strong similarity between vaccine strain and challenge isolate. In most performance horse populations, regardless of discipline, vaccination practices are applied to aid with enhanced host immunity. In some instances, racing authorities have mandated vaccine protocols aimed at providing support for vaccination to enhance immunity. A recent investigation aimed at determining the optimal vaccine administration interval compared different intervals aimed at stimulating protocols established by various racing authorities. It was concluded that longer vaccine intervals may result in periods of susceptibility, in which vaccine-induced immunity may not be protective, but when needed shortened intervals may be protective when risk of exposure is high.[273] At the time of this writing, the United States Equine Federation has implemented a requirement for all horses competing in sanctioned events or shows to demonstrate proof of vaccination for EIV and EHV in the previous 6 months. Accelerated vaccine protocols with the recombinant canary pox–vectored influenza vaccine have been demonstrated to increase serum antibody levels using the single radial hemolysis assay. In this investigation, time from initial vaccine to second dose was 14 days, followed by a booster vaccine at 105 days.[274] In situations where an accelerated vaccine protocol is needed to enhance viral-specific immunity, accelerated protocols should be considered. Implementation of a protocol with the canary pox–vectored vaccine during the Australian outbreak not only provided enhanced host protection, but this strategy used a vaccine with differentiation of infected and vaccinated individual capacity, which is an added advantage to this protocol in this setting.[268]

EQUINE HERPESVIRUS INFECTION

Herpesviruses are enveloped, double-stranded DNA viruses that are ubiquitous in nature and are well recognized for infecting a variety of hosts. Equids have been reported to have the potential to be infected with nine different herpesviruses.[275] Among the viruses with clinical relevance to the equine host are alphaherpesviruses (EHV-1, EHV-3, and EHV-4) and gammaherpesviruses (EHV-2 and -5).

Among alphaherpesviruses EHV-1 and EHV-4 are most widely recognized for morbidity in horses.[276] Both EHV-1 and EHV-4 are well recognized for induction of upper respiratory disease in horses, whereas EHV-1 is also associated with abortion and in rare instances may induce severe neurologic disease. EHV-1 viral infection is associated with cell-associated viremia, in which infected host leukocytes effectively disseminate virus throughout the infected horse. Differences in these somewhat similar viruses are believed to influence clinical manifestation of the disease. Although both are capable of viral replication in the upper respiratory tract, EHV-1 is well adapted to translocate across the respiratory epithelium, whereas EHV-4 appears to be restricted to the upper airways supported by an airway explant model system,[277] which is believed to have a direct influence on this virus being restricted in anatomic location resulting in rhinopharyngitis and/or tracheobronchitis.[268] However, as a result of viral

dissemination, EHV-1 is recognized for not only upper respiratory disease but also abortion, neonatal illness, and neurologic disease.[278,279] Abortion and myelitis are a direct result of vasculitis that is induced by systemic spread of the virus. Because EHV is neurotropic, latency is likely and associated with the trigeminal (cranial nerve V) ganglion or lymphoid tissue.[280] During times of severe stress or immune suppression disease viral recrudescence and shedding are possible when latent virus is reactivated. Although EHV-1–associated disease has been reported in a variety of situations that include western performance events and a racetrack setting, horses evaluated in a veterinary hospital setting for the potential of EHV-1 viral shedding were not found to be shedding virus.[281]

Pathogenesis

Herpesviruses are well recognized for viral maintenance within the host as a latent virus, and this holds true for EHV-1/4.[282] A continued cycle of viral latency and recrudescence likely plays an important role in the viral maintenance within groups of horses. Immunosuppression is associated with attenuated cell-mediated immunity, which leads to viral shedding among latently infected individuals.[283,284] Horses that are latently infected are viral carriers for life.[268] In a small-scale investigation aimed at viral detection in a group of experimentally infected horses, it was determined that horses challenged 5 years previously were later determined to have maintained the same viral strain as the primary challenge strain.[285]

Clinical Signs

Clinical signs of disease associated with EHV-1/4 typically include pyrexia, marked serous nasal discharge, and occasionally cough. Secondary bacterial colonization will result in nasal secretions changing from mucoid to mucopurulent in nature. Lymphadenopathy and serous ocular discharge may also be observed in association with EHV-1/4 infection. Disease spread is typically not as rapid as with equine influenza, but morbidity among susceptible horses can be very high.[286,287] Clinical manifestation of respiratory disease tends to be worse in younger horses compared with mature adults, with reports commonly including disease outbreak in recently weaned foals. This may in part be influenced by the level of immunity in young horse populations. Diagnosis in affected horses more commonly reveals EHV-4 as the primary pathogen associated with disease.[276,288] EHV-1/4 is well recognized to cause respiratory disease in adult horses. One report described an EHV-1 outbreak among a group of racehorses in training during the winter months, whereas EHV-4 did not have an apparent age or season association with disease outbreak.[289]

When pregnant mares are infected, abortion occurs approximately 2 to 12 weeks following infection, typically during the final months of gestation. Aborted fetuses are typically fresh or demonstrate minimal autolysis while the placenta is passed shortly after abortion. Mares that are infected with EHV-1 rarely demonstrate clinical evidence of illness, particularly before expulsion of the fetus. There is no evidence of damage to the reproductive tract of the mare and no problems with subsequent fertility. Abortions may be individual cases or observed as an abortion storm within a herd. Mares that are virally infected during late gestation might successfully deliver a live foal, yet the foal will have marked disease caused by viral infection. Clinical signs observed in EHV–infected foals may include severe pneumonitis, icterus in association with hepatic involvement, and commonly marked neutropenia as a reflection of severe bone marrow necrosis and destruction.

Among the viral strains of EHV-1 that have been identified, in some instances there is a mutation in the open reading frame for the DNA polymerase (DNApol) gene. Specifically, the mutation has been identified as a single nucleotide polymorphism (SNP) at the nucleotide level (A2254 > G2254),[290] which is associated with increased virulence and the potential for neurologic disease manifestation.[291] Following signs of upper respiratory disease and fever, affected horses may progress with signs of mild incoordination, posterior paresis, posterior paralysis, and recumbency. Commonly clinical signs will include urinary emptying defects that result in marked urine dribbling. Attenuated sensation in the perineal region may also be present. Prognosis is influenced by disease severity and progression to recumbency.

Postmortem examination on foals from aborted mares reveals interlobar pulmonary edema, pleural effusion, and necrosis of lymphoreticular tissues that includes liver, bone marrow, and thymus. Petechiation of the myocardium, adrenal glands, and spleen are commonly observed lesions. Histopathologic examination will reveal intranuclear inclusions, particularly from the liver, lung, and adrenal glands.

Adult horses that succumb to EHV-1–associated myelitis may have no apparent gross lesions, or they may have mild hemorrhage in the meninges, brain, and spinal cord. Histopathology will reveal lymphocytic vasculitis with endothelial damage and perivascular cuffing, thrombus formation, hemorrhage, and possibly malacia. Lesions are most commonly observed in the spinal cord but may be observed in the brain and brainstem.

Diagnosis and Treatment

Horses suffering from contagious infectious respiratory disease should be maintained in an isolation-type environment. In most cases diagnostic confirmation requires days or longer. Because of the inherent nature of respiratory pathogens, horses should be restricted from contact with other horses, particularly in a hospital environment or farm with high-risk individuals such as breeding animals and animals that are traveling frequently for performance-related activities. Because of the similarity in clinical signs, viral respiratory disease requires diagnostic confirmation for pathogen identification. Serologic testing for virus-neutralizing antibodies collected during the acute and convalescent (4 weeks) sampling with a fourfold rise in antibody supports the diagnosis of recent EHV infection. However, when considering the frequency of latently infected adult horses, serologic testing can be challenging to interpret. Additionally, mares that abort their fetus have had a serologic response to viral infection long before delivery of the fetus, further complicating this diagnostic method. Definitive diagnosis (gold standard) is based on virus isolation from samples obtained from upper respiratory nasopharyngeal lavage sampling or leukocyte buffy coat isolation early in the course of infection. PCR testing has become the diagnostic test of choice because of its high analytic sensitivity and specificity. Positive PCR test results may be obtained when culture techniques are not successful because of low-level viral shedding. Samples can be collected from that respiratory tract and include nasal swab sampling or nasopharyngeal lavage collection. Additionally, because of the leukocyte-associated nature of the virus,

whole blood (anticoagulated) buffy coat sampling will provide an additional sample for viral PCR testing. In index cases, nasal swab and whole blood samples should be tested simultaneously (in parallel) to further enhance diagnostic sensitivity.[292] Nasal swab sampling is recommended over pharyngeal lavage sampling because of greater diagnostic sensitivity.[293] Contemporary molecular diagnostic tests have been designed to test for the presence of EHV-1 and the presence of the DNApol SNP at the amino acid level (D752/N752), with D752 more commonly associated with neurologic disease manifestation.[290] Diagnostic testing requires careful interpretation as outlined in the 2009 ACVIM consensus statement on this pathogen and disease process, and the interested reader is referred to this particularly valuable reference for a more detailed diagnostic outline.[292] Careful patient examination is the initial step to determine the course of diagnostic evaluation. In patients suspected to suffer from EHV-1–associated disease, appropriate diagnostic samples should be collected for PCR analysis. In samples that test positive for the EHV-1 sequence, an additional step in molecular characterization will be determining the presence of the mutated EHV-1 biovar. If present in the appropriate clinical setting, proper biosecurity and quarantine measures should be implemented immediately. In contrast, identification of this EHV-1 D752 biovar in an asymptomatic individual (healthy horse with no signs of respiratory or other disease) should not be overinterpreted. Recall that horses are often latently infected with EHV-1, and simply identifying this virus in an otherwise healthy horse does not confirm the presence of future disease manifestation, particularly neurologic disease. There is insufficient evidence to determine the subsequent implications of an individual being infected with this virus. Additionally, the absence of EHV-1 D752 does not preclude the development of equine herpesvirus myeloencephalopathy (EHM) in a horse that has clinical signs of respiratory or neurologic disease. Recommendations regarding diagnostic testing for horses that demonstrate clinical signs suggesting EHV-1 and provided in the EHV-1 ACVIM consensus statement include[292]:

- Uncoagulated (ethylenediaminetetraacetic acid) whole blood sample and nasal swab (synthetic material) for quantitative real-time PCR testing.
- Uncoagulated blood and nasal swab for virus isolation of EHV-1 when strongly suspect disease-positive horse based on clinical signs and PCR testing.
- Paired serum samples collected 12 to 21 days apart for VN and ELISA for specific virus antigen when possible.
- *Avoid* diagnostic testing in healthy horses that have no risk for disease manifestation; screening in healthy horses is not recommended.

There is no specific antiviral treatment recommended for the treatment of horses with respiratory disease associated with EHV-1/4 infection. Rest and proper nursing supportive care are indicated to facilitate disease recovery. High-quality, palatable feeds are recommended to facilitate proper nutritional intake. Horses should be maintained in a comfortable, sheltered environment to minimize the risk of secondary disease manifestation such as bacterial colonization. Horses that demonstrate marked pyrexia, fever >103°F will benefit from the administration of nonsteroidal antiinflammatory therapy in the euhydrated individual. Antibiotic therapy is indicated if clinical signs are consistent with bacterial colonization such as mucopurulent oculonasal discharge or pulmonary disease is evident.

Foals infected in utero with EHV-1 are unlikely to survive despite intensive care therapy. Antiviral therapy with acyclovir or valacyclovir may be considered for virally infected foals. Adult horses that demonstrate clinical manifestation of neurologic disease consistent with EHM are appropriate candidates for antiviral therapy with valacyclovir. Additional nursing care for EHM-affected horses often requires intensive nursing care that may include indwelling urinary catheter placement to avoid urinary bladder rupture. Satisfactory recovery can be achieved although mild persistent neurologic deficits might still be discernible 6 to 12 months later. Even so, these horses are often capable of competitive activity. Horses that remain recumbent for extended periods of time have a more guarded prognosis for survival.

Gammaherpesviruses

EHV-2 is ubiquitous among the equine population even though the exact significance of this virus as a primary respiratory pathogen remains to be fully elucidated. Select clinical signs and conditions that have been implicated with EHV-2 infection include pulmonary inflammation, keratoconjunctivitis, fever, pharyngitis, inappetence, immunosuppression, lymphoma. and lymphadenopathy.[294,295] EHV-2 has been identified within circulating leukocytes, nasal secretions and nasopharyngeal swabs, kidney, bone marrow, spleen, and reproductive and ocular tissues.[296-298] In addition, EHV-2 has been positively identified in lymphoid and neural tissue collected from naturally infected horses. In one investigation of equine respiratory disease tracheal aspirates were infrequently positive for EHV-2 (1/20 foals; 5%) when collected from healthy horses compared with those with clinical respiratory disease (20/30; 67%).[299] Notably, in the same investigation EHV-2 was identified within circulating leukocytes collected from both groups of foals. A subsequent investigation aimed at demonstrating a causal relationship of this viral agent and disease used respiratory secretions collected from a clinically affected EHV-2–infected horse. These were then administered to two immunosuppressed ponies that subsequently developed respiratory disease (coughing and nasal secretions), conjunctivitis, viral shedding, and a demonstrable humoral antibody response to EHV-2.[296] In addition to primary respiratory disease, it has been suggested that EHV-2 may play an important role regarding the disease pathogenesis of other respiratory pathogens, such as EHV-1. It is plausible that altered immune function infection induced by EHV-2 infection may promote recrudescence of EHV-1, resulting in notable clinical respiratory disease.[298]

Equine Herpesvirus-5 and Equine Multinodular Pulmonary Fibrosis

Initial investigations into the relevance of EHV-5 in association with interstitial pneumonia in adult horses resulted from the identification of asinine herpesvirus-5 (AHV-5) and AHV-2 in cases of interstitial pneumonia in donkeys.[300] In addition to the identification of AHV-2/5 in donkeys suffering from pulmonary inflammation and fibrosis, adult horses suffering from poor exercise tolerance and multinodular pulmonary fibrosis have been identified to harbor EHV-5.[301] Subsequent to initial observations, numerous reports support the finding that in nearly all cases of equine multinodular pulmonary fibrosis (EMPF) EHV-5 has been identified. In addition to the identification of EHV-5 in EMPF-affected horses,

Williams et al. administered EHV-5 via bronchial instillation to six healthy horses that subsequently demonstrated an increase in total lung collagen and the appearance of myofibroblasts, which supported the suggestion that EHV-5 is the causative agent for EMPF.[302] It is possible that infection with EHV-5 independently results in the development of pulmonary fibrosis, although it is also reasonable to consider that a synergistic effect may occur in horses that are coinfected with EHV-5 and EHV-2 or AHV-5. Further support regarding the synergism of EHV-2/5 comes from the observation that both gammaherpesviruses have been identified in approximately 30% of the cases of EMPF.[298]

Equine patients that suffer from EMPF are typically adult-aged horses (Fig. 8.15A). Clinical signs often include weight loss, poor overall condition, and increased respiratory rate and effort. Physical examination will localize disease to the respiratory tract characterized by fever, abnormal pulmonary sounds including tracheal rattle, and increased bronchovesicular sounds with wheezes. Additional clinical signs include lymphadenopathy, reluctance to ambulate normally (pain), oral cavity ulcerations, and keratoconjunctivitis.[303-305] Hematologic examination will often reveal leukocytosis, neutrophilia, lymphopenia, anemia, hyperfibrinogenemia, hypoxemia, and hypoalbuminemia.[302] Consistent with the pronounced inflammatory response in affected individuals, elevation of serum amyloid A can also be expected in EMPF patients. A number of investigators suspect that in some cases of infection there is an immune-mediated destruction of mature cells in the peripheral circulation and possible destruction of hematopoietic precursors located within the bone marrow, which can result in notable cytopenia.[306] Although this mechanism remains to be fully elucidated, this author has most commonly observed elevation of leukocyte cell counts in EMPF cases, although in rare individuals marked cytopenia has been observed. EHV-5 has been conclusively identified in the bone marrow of one affected individual that had pancytopenia.[306]

Diagnosis

Diagnostic evaluation of suspect EHV-5 cases should include a complete evaluation of the respiratory tract. Physical examination followed by thoracic ultrasound will provide the clinician with evidence of primary pulmonary disease. Severity of ultrasonographic abnormalities will relate to chronicity of pulmonary disease demonstrated by pleural irregularity and thickening, peripheral nodules, and abscess that can often be visualized in non-acute cases (Fig. 8.15B). Subsequent respiratory system examination will often include thoracic radiographs, which reveal moderate to severe interstitial pulmonary nodules (Fig. 8.15C). Radiographic appearance of pulmonary nodules may resemble those resulting from metastatic neoplasia or fungal granulomas; therefore, additional diagnostic testing will be needed to definitively diagnose EMPF. Additional diagnostic testing includes BAL, which will allow the clinician to examine pulmonary cellularity of the lower airways. Characteristic findings include neutrophilic inflammation with marked mucous accumulation. In some instances, the cytologic characteristics may resemble RAO (heaves). Clinical distinction of the conditions is important. EMPF should be suspected in an equine patient diagnosed with RAO that does not respond to appropriate therapy and environmental management. In addition, EMPF-affected horses have chronic progressive disease, systemic inflammation, and a poor or incomplete response to corticosteroid therapy.

Postmortem examination of EMPF-affected horses reveals evidence of primary pulmonary disease characterized by enlarged lungs that fail to collapse, diffuse pleural thickening, and the presence of numerous fibrous nodules of variable size, in some cases up to 5 cm (or more) in diameter. Bronchial and mediastinal lymphadenopathy is commonly associated with the presence of pulmonary granulomas (Fig. 8.15D–E). There have been two types of pulmonary granulomas described in EMPF patients based on lesion size and distribution. The more common form is referred to as a disseminated nodular form in which multifocal, coalescing fibrotic nodules are present throughout all lung fields with lesions ranging from 1 to 5 cm. In this form of EMPF there is often minimal healthy pulmonary parenchyma present, and approximately 80% of the lungs are composed of fibrous granulomas. Alternatively, a discrete nodular form has been described in which large discreet nodules are separated by normal-appearing pulmonary parenchyma. The nodules in this form of disease are much larger, sometimes measuring 8 to 10 cm in diameter. Regardless of the form of disease on histologic examination, the lesions are characterized by marked interstitial fibrosis with type 2 pneumocyte hyperplasia. Alveoli are often filled with neutrophils, fewer alveolar macrophages, multinucleated giant cells, and eosinophilic proteinaceous material. Intranuclear inclusions, consistent with herpes viral infection, may be observed within macrophages and/or epithelial cells.[302,307]

Definitive diagnosis of EMPF is based on histopathologic evidence of pulmonary tissue obtained by lung biopsy or sample collection at postmortem. Diagnosis is often strongly suspected based on clinical history, ultrasonographic evaluation, thoracic radiographic findings, and pulmonary airway cytology, particularly if cells with intranuclear inclusions are identified. Additional supportive evidence for the diagnosis of EMPF is based on the presence of EHV-5 detected with molecular testing such as PCR and preferably with the qPCR method. Ideal samples for testing include BAL fluid and/or lung tissue. Additional samples that should be tested in parallel include peripheral blood (leukocytes) and nasal swab secretions (synthetic, nylon or Dacron swab). Testing should also include evaluation for additional viruses such as EHV-2 and AHV-5. Although they may not serve a primary role, their presence may potentiate disease development in affected horses.

Treatment

Therapeutic management of EMPF patients is targeted at clearance of pathogen challenge and provision of appropriate supportive care. Specifically, therapy should include broad-spectrum antimicrobials, antiinflammatories that include dexamethasone, and intranasal oxygen therapy in hypoxic individuals. Antiviral therapy is recommended as a component of therapy; although acyclovir[308] has poor bioavailability, valacyclovir has been demonstrated to have improved plasma levels following oral administration.[309] The dosing protocol should be at the higher end of the dosing range, based on limited evidence for successful management of such cases. Valacyclovir should be administered at 30 to 40 mg/kg PO three times daily.[310] Although this treatment protocol remains

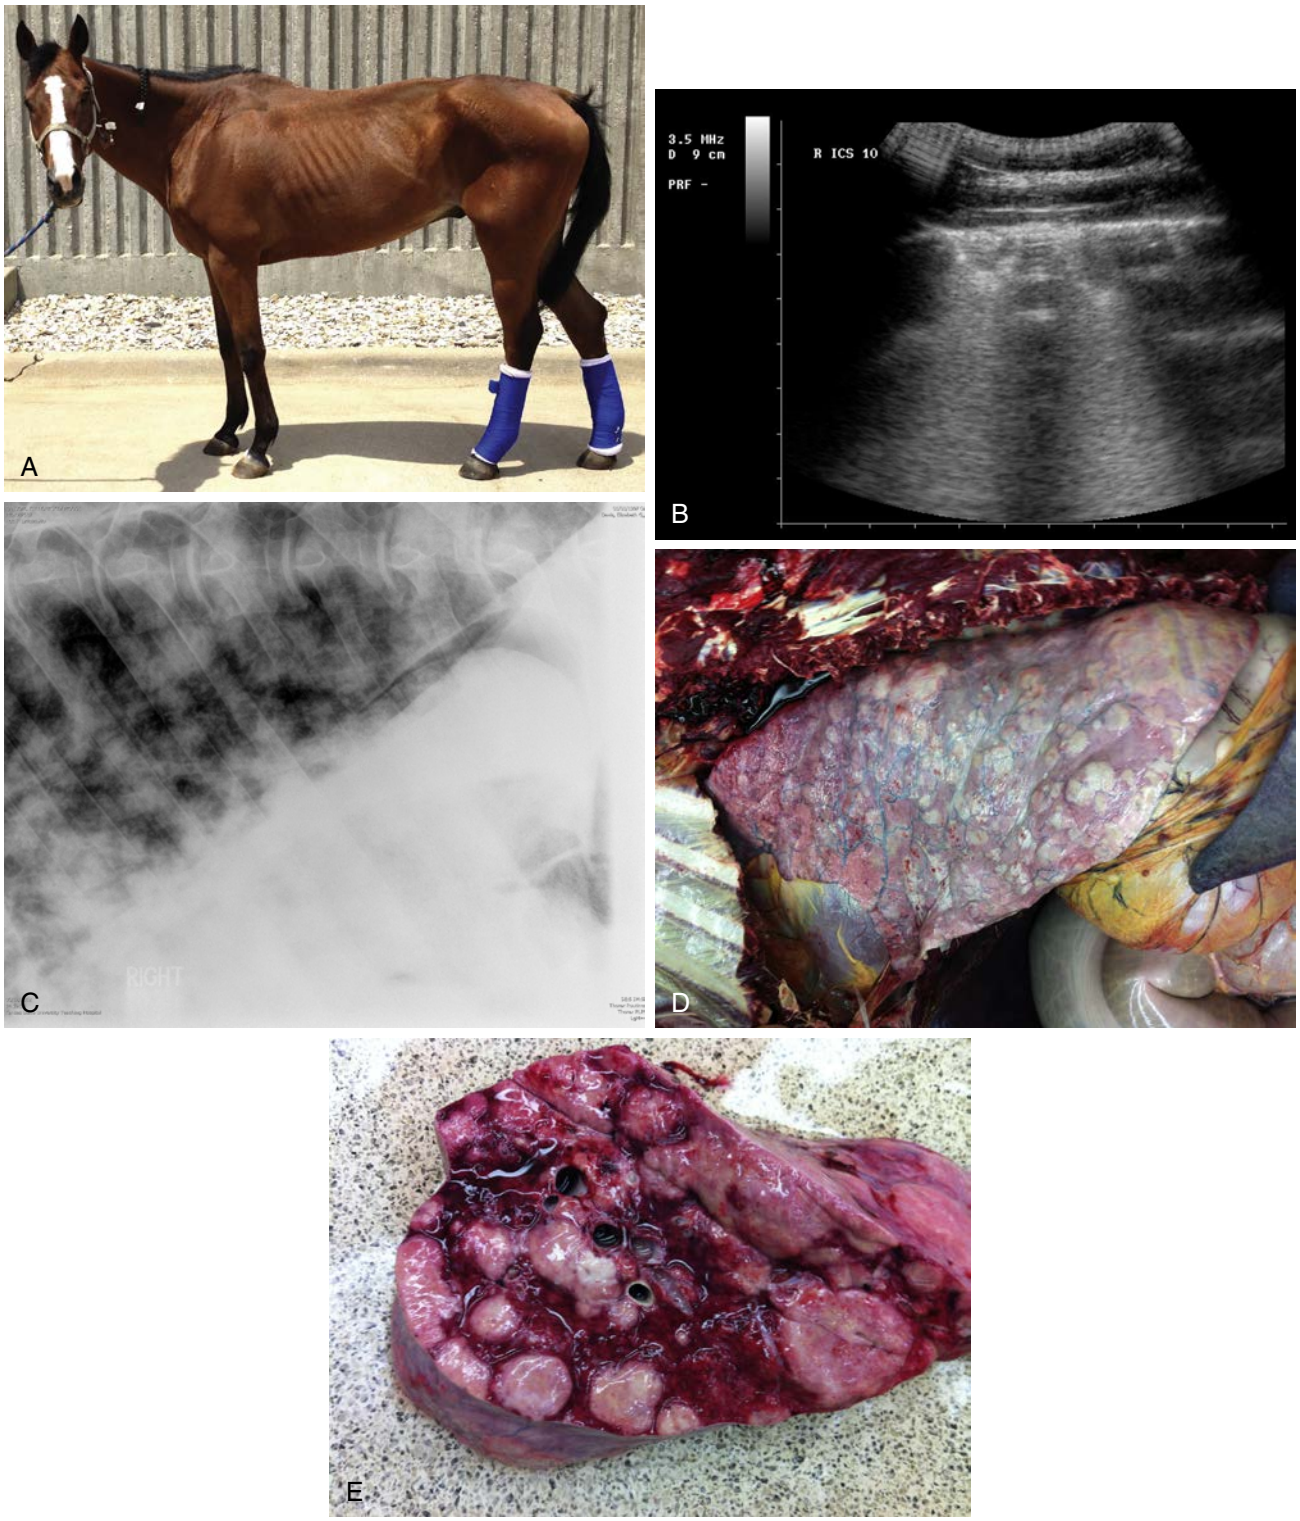

FIG. **8.15** (A) A 15-year-old Thoroughbred gelding presenting for weight loss and poor appetite was diagnosed with equine herpesvirus 5 (EHV-5) associated equine multinodular pulmonary fibrosis. (B) Thoracic ultrasound revealed multiple peripherally located nodular lesions ranging from approximately 2 to 4 cm in diameter. (C) Thoracic radiographs confirmed the presence of a diffuse nodular interstitial radiographic pattern. (D) Failure to respond to therapy necessitated euthanasia, which revealed gross pulmonary changes consistent with those identified antemortem on thoracic ultrasound and radiograph. (E) Cross section of nodular pulmonary fibrosis associated with EHV-5 infection.

under investigation for this particular viral infection, there is evidence to support this dose for this particular condition. A serious and potentially fatal complicating factor for horses suffering from EMPF includes the development of pulmonary hypertension, which may be suspected based on ultrasonographic and radiographic evaluation. The presence of pulmonary hypertension is considered a poor prognostic indicator for EMPF-affected horses and was observed postmortem in one EMPF-affected horse.[311]

In cases suspected to have elevated pulmonary arterial pressure, pulmonary artery diameter should be measured and compared with aortic diameter during echocardiographic evaluation to aid in the establishment of pulmonary hypertension.[311] In addition, pulmonary artery pressure should be measured in such cases whenever possible. An individual report of management of an EMPF-affected horse with associated pulmonary hypertension involved administration of the phosphodiesterase type V inhibitor sildenafil with furosemide.[312] Additional therapies that have been included in the treatment protocol for EMPF include nebulized *N*-acetylcysteine, pentoxifylline, and doxycycline.

Based on the current body of literature regarding EHV-5 in horses, this appears to be an important pathogen that at least in part plays a role in the development of pulmonary fibrosis in horses, whereas AHV-5 appears to play a similar role in disease development among donkeys. EMPF is a distinct disease process that results in nodular pulmonary disease of equids; there is marked remodeling of the pulmonary architecture with eosinophilic intranuclear viral inclusion bodies that may be present within intraluminal macrophages.[304] Early diagnosis and aggressive therapeutic management provide the most favorable prognosis. When severe or advanced, EMPF remains a serious infectious disease of horses.

EQUINE ARTERITIS VIRUS INFECTION

Although most commonly recognized for its association with the equine reproductive tract, equine arteritis virus (EAV) causes a mild to moderate vasculitis and associated respiratory disease termed *equine viral arteritis* (EVA). The virus is maintained in equine populations in carrier stallions because testosterone is required for persistence and maintenance of the virus in vivo. Carrier stallions maintain the virus within the ampulla and vas deferens.

Clinical Signs and Viral Transmission

Clinical manifestations of EVA are similar to those of other viral respiratory tract diseases. Variations in the severity of clinical signs result from strain differences in virulence, pathogen dose, and host immune function. Incubation requires several days to 2 weeks, with a more rapid course of disease after venereal transmission. Clinical signs associated with respiratory tract infection include serous nasal discharge, submandibular lymphadenopathy, mild to moderate cough, and ventral edema. Vasculitis is evident based on clinical signs of edema and occurs secondary to viral damage of the tunica media of small arteries and venules. Edema of the prepuce, scrotum, and limbs is commonly observed. The two most important consequences of EVA infection include abortion of the pregnant mare and induction of the carrier status in a breeding stallion. Clinical signs may persist for 2 to 9 days. Most infections are self-limiting, although edema may be severe and respiratory distress evident. Abortion typically occurs within a month of exposure and occurs during late clinical disease or early convalescence. Typically the fetus is nonviable at the time of abortion and is autolyzed by the time of expulsion. Rarely, neonatal foals infected with the virus demonstrate respiratory difficulty and rarely recover from viral infection.[313-315] Hematologic evidence of EVA includes leukopenia characterized by a lymphopenia, and thrombocytopenia, which may be severe.

EAV is spread by aerosolization of respiratory secretions and venereal transmission. Virus-laden droplets can be disseminated in the environment for up to 2 weeks following recovery from disease. Immunologically naive intact stallions exposed to the virus following sexual maturity maintain the virus in the ampulla of the vas deferens. Carrier stallions remain seropositive, and their semen contains live virus whether used for natural breeding, artificial insemination, or frozen semen. The virus can be maintained for many years in frozen semen with little negative influence on fertility.

Susceptible mares bred to EAV-positive stallions commonly develop respiratory disease (80%–100% cases) and suffer from early embryonic death but do not sustain a persistent EVA infection. Most cases of EVA are self-limiting with low risk of complicating factors. Standardbred horses have a high frequency for seropositivity and carrier infection compared with other horse breeds.

Prevention

The greatest challenge for disease prevention is the presence of a persistently infected stallion. Prevention from infection and induction of the carrier state can be achieved through careful vaccination. Once determined to be serologically negative (requirement for international equine transport), stallions can be successfully vaccinated with the commercially available MLV vaccine to prevent the carrier state. Colts should be vaccinated <280 days of age and isolated for approximately 21 days to minimize the risk of viral shedding in the vaccinated individual and to allow for immunity to develop and prevent viral exposure before the immunity is maximally induced. All vaccinated horses should be separated from nonvaccinated horses for approximately 21 days following vaccination. Infected horses should be separated from herdmates for approximately 3 weeks following infection to reduce the risk of viral spread. Similarly, any individual that has been infected with the virus should not have contact with young horses or broodmares. All at-risk individuals should be vaccinated annually to minimize the risk of disease. Broodmares should be vaccinated before breeding; the modified live vaccine is not recommended to be administered to pregnant broodmares.

EQUINE PICORNAVIRUS INFECTION

The equine picornaviruses are categorized into two serogroups: equine rhinitis virus A and B (ERAV and ERBV). Former classification referred to these viruses as rhinoviruses. ERAV (formerly equine rhinovirus 1) is grouped in the *Aphthovirus* genus based on genotype and similarity with other members of this genus, such as foot and mouth virus, as well as the characteristic viremia and persistent shedding that occurs following infection with the virus.[316,317] Equine rhinitis B virus ERBV1 (formerly equine rhinovirus 2), ERBV2 (formerly equine rhinovirus 3), and ERBV3 (formerly acid-stable picornavirus) are members of the genus

Erbovirus.[318,319] Both ERAV and ERBV have been implicated in association with respiratory disease in horses.[268,320,321] Most recent investigations have provided evidence for the virus-neutralizing capability of antibodies against these viruses and their impact on clinical respiratory disease in horses.[322] Persistent shedding has been identified in respiratory and urinary secretions.[323]

Viral detection of picornaviruses has been identified in horses with respiratory disease and healthy horses.[324,325] It has been suggested that infection happens early in life via aerosol transmission. Notably ERAV is shed in respiratory secretions and urine,[326] whereas ERAB1 and ERAB2 appear to be restricted to the respiratory tract (secretions) only. Experimentally induced respiratory disease with ERAV resulted in upper and lower airway disease and viremia, which lasted 4 to 5 days.[268] Additional clinical signs following experimental challenge included pyrexia, lymphadenopathy, changes on thoracic auscultation, evidence of airway inflammation with mucosal hyperemia, and tracheal mucous accumulation that persisted for 21 days.[327]

Clinical manifestations of disease typically include pyrexia, serous to seromucous nasal discharge, coughing, depression, anorexia, pharyngitis, and submandibular lymphadenopathy.[327] Mild lymphopenia and increased plasma fibrinogen concentrations have been reported in affected horses.[319,328]

Diagnosis is based on serology or molecular detection of the virus. The application of PCR and real-time PCR have become more commonplace because of the variability in serologic titers and prolonged turnaround time for virus isolation.

Preventative strategies have primarily focused on hygiene and overall health maintenance. Recently, a commercially available ERAV vaccine was approved for use in horses and may be considered for high-risk situations.

AFRICAN HORSE SICKNESS

African horse sickness (AHS) is a foreign animal disease that has never been reported in the United States. From a global perspective the disease has major implications on the equine industry. Historically this is a viral disease affecting horses in Sub-Saharan Africa, but outbreaks in India and the Middle East were reported in the mid-1950s,[329] and cases in Spain were reported in the 1980s.[330]

The primary vector for viral transmission is *Culicoides imicola.* This is a serious worldwide pathogen because morbidity and mortality remain high in naive equine populations. Disease manifestation ranges from fulminant pulmonary edema, subcutaneous edema, and myocardial failure to horse sickness depending on the level of host immunity at the time of viral challenge.

There are four clinical syndromes: peracute, acute, subacute, and mild. AHS is caused by a virus within the family Reoviridae, genus *Orbivirus* (double-stranded RNA virus), and is related to the causative agent of bluetongue.

Although endemic in parts of Africa, all equidae are susceptible, with horses having the greatest sensitivity to the virus, followed by mules, donkeys, and zebras.[331]

Viral spread is directly influenced by the insect vector *C. imicola.* This biting midge prefers claylike moisture-retaining soils. In years with abundant rainfall midge numbers increase dramatically. The vector is moving northward, which is why there has been movement into the Middle East and parts of Europe.

As stated previously, disease manifestation is a reflection of host immunity. The peracute syndrome is the pulmonary form with a mortality rate of approximately 95%. With this, there is a brief incubation period that may last up to 5 days. Clinical signs include fever and hemorrhagic pulmonary fluid exudate characteristic of pulmonary edema. Postmortem examination reveals evidence of marked pulmonary edema and hydrothorax. Acute or mixed AHS is a more common manifestation with pulmonary and cardiac abnormalities. The incubation period is slightly longer and may be up to 7 days. Mortality for the acute form is 50% to 95%. Clinical signs reveal a combination of cardiac (edema of head and neck) and pulmonary disease (cough, respiratory distress, and pulmonary edema) manifestations. Postmortem examination reveals marked subcutaneous edema of the head and neck. Subacute AHS demonstrates clinical signs of myocardial dysfunction, fever, edema, and lethargy. Edema of the supraorbital fossa is highly characteristic of AHS. Incubation of the subacute form is 50%. Horse sickness fever is the mildest form of the disease, and this manifestation is displayed by horses with preexisting immunity and those species with inherent resistance to disease such as donkeys and zebras. Mortality tends to be low for this form of the disease.

Diagnosis is based on serology and virus isolation.[332] An inactivated vaccine is available and is used in endemic regions to minimize loss in high-risk regions.[333] During an epidemic, the primary goal is to eradicate disease though implementation of quarantine, vector control,[334] and euthanasia of exposed horses. If these efforts fail, perimeter vaccination is implemented to limit the spread of the disease.[13]

HENDRA VIRUS INFECTION

Hendra virus, formerly referred to as equine morbillivirus, was first identified in Hendra, Australia, in 1995 and was recognized as a zoonotic disease of horses.[335] Hendra virus causes fatal pneumonia and encephalitis in horses and humans.[336] Clinical signs of Hendra virus are similar to AHS. Fruit bats are the reservoir of infection. Disease transmission requires close contact with infected horses or bat excrement. Hendra virus is classified as a Hazard Group 4 pathogen, which requires the highest level of biosecurity procedures.

In an initial outbreak involving Hendra virus, 14 of 21 horses died.[337] Two primary caregivers for the horses became ill, and one did not survive.[338] Morbillivirus was identified from renal tissue from one of the nonsurviving humans, which was identical to the virus cultured from the lungs of five affected horses.[339] All human cases have been reported in association with equine cases. Although Hendra virus is not considered directly contagious, very close contact with horses, particularly in the environment in which they were infected, increases the risk of human disease. Among 157 humans that had casual contact with infected horses and humans, there was no evidence of seroconversion. Gray-headed fruit bats seroconvert and demonstrate mild clinical disease when experimentally infected.[340] However, subclinical disease or seroconversion have not been identified in horses exposed to the virus. Horse are exposed via the upper respiratory or oral cavity and once infected will excrete virus in their urine, saliva, and respiratory secretions.[341] The virions are highly labile and can be destroyed by heat, lipid solvents, detergents, formaldehydes, and oxidizing agents.

Horses that are infected with virus develop severe and typically fatal respiratory disease that is characterized by dyspnea, vasculitis, and severe pulmonary edema. Nonspecific signs include lethargy, anorexia, fever, respiratory distress, ataxia, tachycardia, and frothy nasal discharge. Encephalitic and marked subcutaneous edema may be observed in some cases. The incubation period is 8 to 12 days, with clinical progression characterized as peracute. Death typically occurs 1 to 3 days after the onset of clinical signs. Clinical manifestation is similar to AHS, and diagnosis is based on serology aimed at detecting virus-neutralizing antibodies and immunofluorescence. Virus isolation is performed in Vero cell culture with immunofluorescence used to detect viral antigens within infected tissues. Because of the extreme danger and zoonotic potential of this virus, sample collection should be performed under Biosafety Level (BSL)-4 conditions; this is the highest level of biosecurity implementation.

BACTERIAL PNEUMONIA AND PLEUROPNEUMONIA

Bacterial pneumonia is not usually a spontaneous disease in adult horses. Most often it is a primary disease or risk factor that leads to bronchopneumonia in the adult horse. Events that lead to suppressed endogenous immunity may result in bacterial colonization of the lower respiratory tract. A primary viral upper respiratory tract infection may lead to loss of the mucociliary clearance mechanism leading to bacterial colonization of the lower airways or marked aspiration, potentially in combination with some of the previously mentioned mechanisms. General anesthesia may contribute to immunosuppression and in some cases may result in low-grade (or marked) aspiration. Long-distance transport, particularly with head elevation for extended periods of time or esophageal obstruction can all result in various levels of aspiration into the lower airways. Although anatomic and immunoprotective mechanisms are likely to aid in protection from lower airway colonization, in some instances bacterial challenge overwhelms the host protective mechanisms, and bronchopneumonia may result.

The importance of risk factors cannot be overemphasized because bacterial pathogens isolated from the lower respiratory tract are opportunistic, environmental, or commensal organisms that are unable to initiate primary invasion. The most frequently isolated organism from horses suffering from primary pneumonia is *S. equi* subsp. *zooepidemicus*. Initial colonization involves the primary airways, resulting in bronchitis, whereas disease progression leads to extension beyond the airways to the surrounding pulmonary parenchyma. Further disease dissolution leads to the most advanced progression of bacterial colonization with extension to the pleural space and associated structures and is termed *pleuropneumonia*. In mild or early cases of airway colonization, frequently disease resolution can be achieved with broad-spectrum antibiotic administration and general supportive care to facilitate optimal immune function. However, when disease is severe or chronic or involves marked immunosuppression the prognosis may be guarded. Identification of risk factors and severity of disease will aid the clinician in determining the ideal diagnostic and therapeutic options.

Primary pleuritis is a rare event in horses. Traumatic penetrating wounds that contaminate the pleural cavity commonly result in septic pleuritis. Pneumonia is not a common secondary event to traumatic wounds but may occur in the event that the primary pleuritis is not effectively managed. The clinical approach to equine patients with marked pleural effusion should include consideration for septic, traumatic (hemorrhage), neoplastic causes; secondary to congestive heart failure; and parasitic disease (hydatid cyst). In North America, pleuropneumonia remains the most common cause of pleuropneumonia, whereas in other parts of the world reduced frequency of this disease is observed. Notably, in the UK, some reports indicate that pleuropneumonia only makes up approximately 30% of the cases of infectious lower airway disease.

At the time of diagnosis of pneumonia or pleuropneumonia, relevant history includes information that may support the primary etiology, such as recent viral respiratory infection, long-distance transport, strenuous exercise, immunosuppressive therapy, exercise-induced pulmonary hemorrhage, severe esophageal obstruction, or marked age. Endogenous pulmonary defense mechanisms include cough, mucociliary clearance, respiratory (or bronchial)-associated lymphoid tissue, and alveolar macrophages.

The mucociliary escalator provides an active mechanism for removal of particulate material from the respiratory tract and is an important component of the nonspecific endogenous host mechanisms for clearance of pathogen challenge. The mucociliary escalator is present from the level of the pharynx to the respiratory bronchioles. Particles that accumulate on the epithelial surface are moved in an oral direction under the action of ciliary waves moving the double layer of superficial sol-gel mucus. Once in the pharynx the constituents are swallowed. Anatomic airway division or size impacts respiratory clearance efficiency as ciliary beating frequency is greater in the larger airways compared with the lower bronchioles; host benefit from this effect is prevention of excessive mucous accumulation in the trachea and larger conducting airways. This also contributes to the impact of head position on mucous clearance; prolonged head elevation is a known impediment to respiratory clearance mechanisms primarily mediated by the mucociliary escalator. In the larger airways mucus originates from goblet cells, whereas in the bronchioles mucus is produced in the nonciliated Clara cells. In the bronchi, submucosal bronchial glands produce serous and mucous secretions. Mucous secretion is under autonomic regulation; importantly, transepithelial water and electrolyte constituents may fluctuate, resulting in changes in mucus composition. Changes in volume and composition of mucus can lead to respiratory disease or may be the result of pathogen or toxin exposure. Cough is an important clearance mechanism mediated in part by stimulation of the subepithelial irritant or stretch receptors, which are located with the greatest density in the larger bronchi. Cough is an effective way to clear mucoid secretions from the intrathoracic trachea and large bronchi but not from peripheral bronchi and bronchioles. Alveolar macrophages provide an essential layer of protection within the alveoli. Alveolar macrophages will either move up the mucociliary system or leave the alveoli and enter lymphatics. Once in lymphoid tissues, these macrophages play an important role in antigen presentation. Physiologic factors that impair macrophage function include a hypoxic environment brought about by disease or reduced Fc receptor expression and subsequent phagocytosis secondary to therapeutically administered corticosteroids. Alveolar function is suppressed by viral infection. Therefore, in addition to viral respiratory disease leading to impaired mucociliary clearance mechanisms, viral challenge also impairs direct killing by alveolar macrophages and antigen presentation.

Etiologic Agents

Because the majority of cases of equine bacterial pneumonia result from aspiration, the bacterial flora of the upper respiratory tract is commonly involved with lower airway colonization. Notably, *S. equi* subsp. *zooepidemicus* remains the leading bacterial pathogen of the lower airways of adult horses suffering from pneumonia.[342,343] In addition to *S. equi* subsp. *zooepidemicus,* other pathogens may co-colonize the lower airways. As mentioned previously, a variety of stress and physiology factors may put horses at risk for lower airway infection.

Classification of pathogens that may colonize the lower airways include gram-positive and gram-negative aerobes and anaerobes. In addition to *S. equi* subsp. *zooepidemicus, Staphylococcus* spp. may lead to bronchopneumonia. In rare instances, typically in association with immunodeficiency, *Rhodococcus equi* may be identified. Human pathogens are uncommonly identified in the airways of horses, with *Streptococcus pneumoniae* more commonly being identified among racehorses in the UK and occasionally in the United States.[344,345] Because of the pathogenesis of equine bronchopneumonia, aspiration may result in the colonization with mixed isolates. Anaerobic bacteria may include *Bacteroides fragilis, Prevotella heparinolytica, Clostridium* spp., *Peptostreptococcus* spp., and *Fusobacterium* spp. Historically, anaerobic bacteria have been reported to compose approximately 30% of the isolates identified in horses with pneumonia.[346,347] Identification of the bacterial population present can provide prognostic information, with the identification of anaerobes yielding a higher overall mortality, particularly if there has been a delay from the onset of disease to the time of diagnosis and treatment.[348]

Clinical Manifestation of Disease

Clinical manifestation of lower airway infection frequently indicates severe systemic infection. Although somewhat nonspecific, when combined with relevant history, signalment, and examination findings, the diagnosis is generally not overwhelmingly challenging. Clinical signs often include lethargic attitude, reduced appetite, fever, and increased respiratory effort. Cough may be present but may be blunted as a result of the thoracic pain experienced on induction of the cough reflex.

Diagnosis

Equine patients suffering from pleuropneumonia commonly have a fever and lethargic mentation. Variation in clinical signs at presentation will be influenced by severity and chronicity of disease. Early in the course of infection, in addition to pyrexia and lethargy, horses may experience pleural pain demonstrated by forelimb abduction at the level of the elbow. Physical examination should include complete thoracic auscultation, and particular attention should focus on the identification of breath sounds in all lung fields. If lung sounds are attenuated, particularly in ventral pulmonary fields, examination should include thoracic ultrasonography. Although rebreathing examination may be a reasonable approach, the procedure is contraindicated if there is any evidence of respiratory distress or impairment.

Thoracic ultrasonography should be performed in a thorough and comprehensive manner with particular attention paid to the evaluation of the entire thorax, bilaterally. Examination should be performed from dorsal to ventral either cranial to caudal or vice versa. The region of the mediastinum can be imaged through the triceps and is an important aspect to examine, particularly if abundant fluid and fibrin are identified on ultrasound examination. Advantages of ultrasonography are that location and approximate quantity (depth) of pleural fluid can be identified. Additionally, ultrasonography provides the clinician with the ability to thoroughly examine peripheral lung fields. If fluid is present, once the pleural fluid has been removed thoracic radiography will provide additional imaging information to aid with patient assessment of disease severity. Axial disease, such as abscess formation or lymphadenopathy, will not be apparent with ultrasonography alone.

Thoracic ultrasound will enable identification of not only fluid accumulation but also gas echoes, fibrin, loculation, or highly cellular fluid, which will provide prognostic information regarding the severity of disease. Pleural fluid with high protein content and low cellularity will appear anechoic (Fig. 8.16), whereas fluid containing greater cellularity will have a greater degree of echogenicity. The identification of gas echoes within the pleural space may be identified in patients with anaerobic-containing fluid, rupture of a bronchopleural fistula, or following iatrogenic introduction of air, which may result during thoracocentesis. Pulmonary atelectasis, consolidation, or abscess formation may be identified if located in peripheral lung fields. Ultrasound waves are unable to penetrate gas; therefore, air-filled lung or lung overlapping areas of disease will not be visible with ultrasound imaging alone. Marked pulmonary consolidation identified in combination with serosanguineous pleural fluid, particularly when combined with the identification of epistaxis, suggests the presence of pulmonary infarction, which carries a guarded prognosis.[349] Added benefits of thoracic ultrasound include the ability to determine whether pleural adhesions are present. The clinical importance of identifying where adhesions are located is so they can be avoided if thoracentesis is performed or if indwelling thoracic drains are going to be placed. Pneumothorax can be diagnosed with thoracic ultrasonography, but the extent of disease cannot be fully determined. Once the diagnosis of pneumothorax is made with ultrasound, further patient assessment should be completed with thoracic radiography. Cranial thoracic imaging should be completed to determine whether mediastinal fluid or abscess formation are present. Imaging through the triceps can be performed with most 3- to 5-mHz imaging probes. When examination of the equine patient with pleuropneumonia is

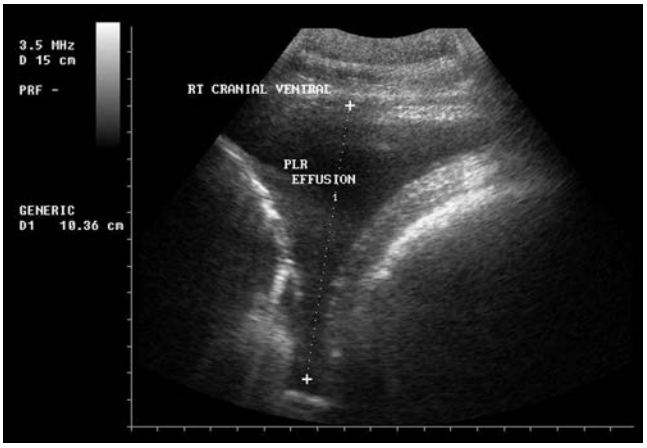

FIG. **8.16** A 25-year-old Arabian gelding with severe pleuropneumonia following esophageal obstruction and associated aspiration pneumonia. Thoracic ultrasound examination with a 3.5-mHz probe revealed the presence of marked anechoic pleural effusion that surrounds consolidated pulmonary parenchyma measuring greater than 10 cm in depth.

completed, the advantage of ultrasound is to not only determine the presence and character of pleural fluid but also to determine the ideal location for performing pleurocentesis and potential indwelling chest tube placement. The goal of sample collection and tube placement is to determine the area of greatest depth (volume) and a safe location that will minimize the potential for adverse outcome such as diaphragmatic or cardiac puncture. Subsequent to making the diagnosis of pleuropneumonia and evacuation of pleural fluid, daily thoracic ultrasound is a mainstay of patient monitoring. Daily ultrasound examinations will allow the clinician to determine evidence of disease progression or resolution, based on volume of fluid present, effectiveness of indwelling thoracic tubes, the presence and extent of pleural fibrin production, and the assessment of peripheral pulmonary parenchymal disease.

Once fluid has been identified within the pleural space, if the volume measures greater than 3 cm in depth, then thoracocentesis is indicated for therapeutic and diagnostic purposes (Fig. 8.17). Location for fluid collection should be determined based on the most ventrally accessible location. Anatomic locations may be altered by large-volume fluid accumulation, and this should be considered when planning the site for thoracocentesis or tube placement. The procedure for thoracocentesis should be performed using sterile technique. Once the location has been determined, subcutaneous infiltration of 2% lidocaine is performed. A no. 15 blade is an ideal choice for making a small skin incision, which is generally 0.5 cm in length. A blunt teat cannula is an ideal instrument for fluid collection. If large-volume fluid is present an indwelling thoracic tube can be placed, which is generally sized between 16 and 32 Fr. Pleural fluid collection will provide a diagnostic sample for Gram stain and aerobic and anaerobic culture. If an indwelling tube is placed, fluid evacuation provides improved patient stability in addition to diagnostic sample collection (Fig. 8.18). Large-volume fluid removal should be completed with caution over a period of 30 to 45 minutes with concurrent isotonic crystalloid fluid administration. Rapid fluid removal from the pleural space can lead to re-expansion pulmonary edema and hypotension.

Normal equine pleural fluid is transparent with a clear to pale yellow color. It is odorless and has a protein concentration of <2.5 g/dL with a nucleated cell count of <8000/μL.[350] Bacterial pleuropneumonia commonly leads to an increase in protein concentration and nucleated cell concentration. As previously mentioned, pulmonary infarction results in serosanguineous pleural fluid. Cytologic examination of pleural fluid is typically represented by a large percentage (>80%) of neutrophils, which are characterized by degenerate changes. Often intracellular and extracellular bacteria are visible. Additional evidence for septic disease will include an elevated pleural fluid lactate concentration (greater than found in circulation), pH <7.1, and low glucose concentration (<40 mg/dL). Pleural fluid with a fetid odor often suggests the presence of anaerobic bacteria. A recent report that described five cases of intrathoracic esophageal rupture leading to the development of severe fibrinous pleuropneumonia[351] highlights the importance of a thorough examination of pleural fluid cytology. The presence of feed material in pleural fluid is not a normal

FIG. **8.17** Teat cannula placement with a polyethylene extension set for evacuation of purulent pleural fluid associated with pleuropneumonia that developed in a 13-year-old Arabian mare that had recently been transported over approximately 1600 miles.

FIG. **8.18** Indwelling thoracic tube placement should be determined with ultrasound as indicated by tube placement in this individual with a dorsally located loculated pocket of pleural fluid accumulation. Note the unusually dorsal location of tube placement in this individual. Abundant septic pleural fluid can be observed to fill this thoracic tube.

finding and should alert the clinician to potential esophageal damage and rupture. Particular case details that may provide the clinician with evidence to support a possible esophageal rupture includes a history inconsistent with the development of pleuropneumonia, such as a horse that has not had recent long-distance transport or esophageal obstruction. Examination of pleural fluid should also include Gram stain, which is beneficial to determine the class of bacterial organisms present, which can direct initial therapeutic strategies until bacterial culture results are available.

In addition to pleural fluid culture for aerobic and anaerobic bacterial pathogens, percutaneous transtracheal aspiration should be performed. Although pleural fluid is a readily accessible sample, based on the pathogenesis of disease resulting from aspiration, sampling from the primary site is likely to provide superior diagnostic information, which may differ from pleural fluid analysis.[13] Cytologic examination will provide supportive evidence of septic inflammation characterized by a predominance of degenerate neutrophils. Gram stain evaluation will provide diagnostic information that may aid with therapeutic decision making while waiting for final culture results to be returned.

Etiologic agents associated with equine pleuropneumonia commonly originate from the upper respiratory tract, with polymicrobial infection as a predominant and consistent feature of equine pneumonia.[280,342,348,352] Although the most common isolate remains *S. equi* subsp. *zooepidemicus,* gram-negative pathogens such as *Escherichia coli* are also recognized.[353] When a *Klebsiella* spp. is isolated from the lower airways of adult horses with pneumonia, a particularly guarded prognosis may be indicated and likely reflects the high degree of antibiotic resistance that has been reported.[354] Obligate anaerobes are normal inhabitants of the oral cavity and intestinal tract of horses and for this reason may be isolated from the lower airways of horses with aspiration pneumonia. A recent investigation that used a novel molecular method of detection (referred to as the 16S rRNA gene sequencing) recognized that *Bacteroides* spp. and *Prevotella* spp. are dominant anaerobes of the lower airways with antibiotic susceptibility patterns that include metronidazole, imipenem, and clindamycin.[355]

Pleuropneumonia may be effectively managed with evacuation of the pleural space via teat cannula placement followed by primary closure of the entrance made into the thoracic cavity. Alternatively and particularly with large-volume pleural fluid, indwelling thoracic drains are commonly left in place until marked improvement or complete resolution of the septic process. Once placed the chest tube can be maintained in place by using a snare-type suture pattern along the 3 to 5 cm of thoracic tube that is exiting from the body wall. A one-way (Heimlich) valve is required to provide a mechanism for fluid evacuation and reduce the potential for introduction of air or additional pathogens into the pleural space. Patient assessment should include daily thoracic ultrasound examination to determine the effectiveness of pleural drainage and identify any changes that may develop, such as the production of fibrin accumulation within the pleural cavity. Loculated parapneumonic effusion with fibrin deposition has been reported to have a more guarded prognosis in horses with pleuropneumonia and is an important characteristic that should be carefully monitored through the course of disease management.[356] A sampling of pleural fluid should be cultured every 10 to 14 days to identify changes in microbial populations and associated antimicrobial susceptibility patterns. Fibrin and cellular debris may occlude the end of the thoracic drainage tube, and ultrasound can aid in determining the efficacy of thoracic tube drainage based on the amount of fluid exiting the tube and the amount of fluid remaining in the pleural space. If needed, a 60-mL catheter-tip syringe can be used in a sterile fashion to remove debris from the indwelling tube. In addition sterile isotonic fluid can be introduced into the thoracic tube to lavage the pleural space. Approximately 5 to 10 L of warm sterile fluid can be introduced and removed by gravity flow. When fluid is introduced patient monitoring should be continued throughout instillation. If at any time the patient appears uncomfortable or anxious the fluid should be allowed to drain and relieve any built-up pressure. If during the instillation of fluid any fluid is noted to exit from the nostrils, coughing observed, or pleural fluid exiting from the nostrils, lavage should be immediately discontinued, and consideration should be given to the presence of a bronchopleural fistula. Continued pleural lavage in the presence of a bronchopleural fistula can lead to dissemination of septic material to previously healthy regions of lung. If suspected, a bronchopleural fistula can be confirmed by the instillation of fluorescein dye into the pleural space. The presence of dye at the level of the nostrils will confirm open communication between the septic pleural space and the central airways. Additional complications that may develop include kinking of the indwelling tube or cellulitis surrounding the site in which the tube is located. In instances where cellulitis develops locally, applied warm compress material can aid with reduced swelling and inflammation. Marked pain or swelling indicate more severe disease necessitating tube removal.

Thoracic ultrasonography is an essential diagnostic modality for the ongoing management of an equine patient with pleuropneumonia. In addition to establishing a diagnosis, determining an optimal site(s) for pleural drainage by thoracic ultrasound is essential for the ongoing evaluation and assessment of patient progress and response to therapy. In addition to thoracic ultrasound thoracic radiography is an important imaging modality for determining disease severity. It is paramount that pleural fluid is drained effectively before thoracic radiography so there is optimal visualization of pulmonary parenchymal disease. Thoracic radiography will provide additional information to patient assessment because radiographs are better able to detect central disease such as mediastinal lymphadenopathy or abscess formation, deep parenchymal lesions, mediastinal disease, and the presence and severity of pneumothorax. Serial imaging studies will provide the clinician with diagnostic information regarding response to therapy and disease progression. Disease distribution will differ based on the etiology of pneumonia because most cases of bronchopneumonia are a consequence of aspiration. Cranioventral pulmonary alveolarization is typically identified. In contrast, disease that resulted from hematogenous delivery will be evidenced by a caudodorsal pulmonary distribution.

Treatment

Clinical management of pleuropneumonia requires effective antibiotic therapy, pleural drainage, ideal supportive patient management, and in some cases surgical intervention for the removal of necrotic pulmonary foci.

Broad-spectrum antibiotic therapy is the mainstay of patient management because of the frequency of polymicrobial infection. In addition to antimicrobial therapy frequent patient monitoring is essential to determine patient status

and response to therapy. Patient status is typically dynamic, particularly early in the course of disease. For this reason changes in patient status should be addressed quickly to minimize further complications and morbidity. In many instances fibrin deposition will lead to marked flocculation of pleural fluid. Thoracocentesis may be efficacious in particular regions of disease and should be modified to address current patient status. It is not uncommon that several thoracic drains may be required to effectively drain an individual hemithorax caused by the presence of fibrin loculations and the organization of numerous fluid pockets. In addition to antibiotic therapy and effective pleural drainage, it is paramount that the clinician provide excellent supportive care in the form of maintenance of euhydration with IV fluid therapy, assessment of acid-base status, supplemental oxygen therapy in severe cases, provision of adequate nutritional support, and analgesic antiinflammatory therapy commonly through the judicious administration of NSAIDs. In cases where medical management alone provides incomplete disease resolution, surgical intervention may be indicated for the removal of necrotic pulmonary tissue as well as to facilitate drainage that may be impaired by the use of thoracic tubes alone.

When horses suffering from pleuropneumonia are identified and properly diagnosed early in the course of the disease, effective therapeutic management may lead to disease resolution with limited or individual thoracocentesis to facilitate pleural drainage. More commonly, disease progression is present at the time of presentation, and pleural drainage is required multiple times for management of an individual or multiples, and at times bilateral indwelling thoracic drainage tubes are required.

Combined thoracic drainage and systemic antibiotic therapy are the mainstay treatments required for the resolution of pleuropneumonia in horses. Effective medical therapy for the management of pleuropneumonia required knowledge about the microorganism(s) present and susceptibility to various antimicrobial agents. Broad-spectrum antibiotic coverage is required for the various classes of bacterial pathogens that may be present. A rational approach for initial treatment includes the combination of penicillin (or other β-lactam agent), gentamicin, and metronidazole. This combination will provide a broad level of antibiotic protection against gram-positive (e.g., *Streptococcus* spp.), gram-negative enteric organisms, and anaerobic bacteria, respectively. Although penicillin has good efficacy against many anaerobic organisms, the synthesis of β-lactamase by *Bacteroides* spp. warrants the addition of metronidazole for more complete coverage. Adverse events or reduced patient stability may require modification to this initial protocol. Once bacterial isolate(s) have been identified and antibiotic susceptibility profiles provided, informed changes in antibiotic coverage can be made (Table 8.6).

An essential adjunct therapy in horses suffering from pleuropneumonia involves analgesic and antiinflammatory therapy. In the early stages of disease management, NSAID therapy is indicated to address the issues of systemic inflammation and fever, pain of disease and thoracic tube placement, and endotoxemia that may ensue because of infection with gram-negative pathogens and subsequent lipopolysaccharide (LPS) liberation. Commonly selected NSAID agents aimed at providing analgesia in horses with pleuropneumonia include flunixin meglumine, phenylbutazone, firocoxib, and meloxicam (Table 8.7).[357-361] Caution should be exercised in horses that have evidence of hypovolemia, renal impairment, or loss of gastrointestinal epithelial integrity. Even though NSAIDs are a mainstay of clinical management of equine patients suffering from a variety of inflammatory and painful disorders, the risk for an adverse drug event should be recognized. Renal papillary necrosis, gastric ulceration, and right dorsal ulcerative colitis have been well reported as consequent events that can develop in equine patients.[362] Particular attention should be paid to medications that may have been administered before veterinary evaluation to minimize the potential for concurrent NSAID agent administration, which could potentiate adverse events.[363,364]

Nutritional support should be carefully monitored in horses suffering from marked pleuropneumonia. It is not uncommon for horses that suffer from pain and sepsis to enter into a negative energy balance, which can be potentiated with reduced feed intake. Monitoring body weight at routine intervals will aid the clinician to determine a decline in condition. In addition, monitoring certain clinical

TABLE **8.6** **Antibiotic Therapy**

Antimicrobial	Dose
Amikacin	10–185 mg/kg, IV, q 24 h
Ampicillin sodium	11–22 mg/kg, IV or IM, q 6–8 h
Ceftiofur sodium	2.2 mg/kg, IV or IM, q 12 h
Ceftiofur crystalline-free acid	6.6 mg/kg IM, q 96 h
Chloramphenicol	50 mg/kg, PO, q 6 h
Doxycycline	10 mg/kg, PO, q 12 h
Enrofloxacin	7.5 mg/kg, PO or IV, q 24 h 5.0 mg/kg, PO or IV, q 12 h
Gentamicin	6.6 mg/kg, IV or IM, q 24 h
Metronidazole	15–25 mg/kg, PO, q 6–8 h
Minocycline	4 mg/kg, PO, q 12 h
Oxytetracycline	6.6 mg/kg, IV, q 12–24 h
Potassium penicillin G	22,000 IU/kg, IV, q 6 h
Procaine penicillin G	22,000 IU/kg, IM, q 12 h
Rifampin	5–10 mg/kg, PO, q 12 h
Sodium penicillin G	22,000 IU/kg, IV, q 6 h
Trimethoprim-sulfonamide	15–30 mg/kg, PO or IV, q 12 h

IM, Intramuscularly; *IV,* intravenous; *PO,* orally; *q,* every.

Flunixin meglumine	0.5-1.1 mg/kg, IV or PO, q 12-24 hr
Phenylbutazone	2.2-4.4 mg/kg, IV or PO, q 12-24 hr
Selective COX-2 specific inhibitors	
Firocoxib	0.1 mg/kg, IV, q 24 hr
Meloxicam	0.6 mg/kg, PO, q 24 h

Dosages of non-steroidal antiinflammatory drugs (NSAID) used in the treatment of pleuropneumonia and other severe pulmonary infections in which the administration of corticosteroids might be contraindicated.

chemistry parameters can also aid with the determination of overall nutritional status. Monitoring of blood glucose, electrolyte concentrations, and serum triglyceride levels will help determine whether the horse is entering into a negative energy balance. Particular attention should be paid to horses that are among breeds at risk for lipid mobilization such as ponies, Miniature horses, or those with evidence (or risk) of insulin resistance or pituitary pars intermedia dysfunction. Palatable feeds and fresh grass can often help to encourage feed intake in sick horses. When indicated additional nutritional supplementation can be achieved with the addition of dextrose to IV fluids or the introduction of parenteral nutrition (partial or complete). Enteral nutrition can be achieved by offering commercial supplementation with high-protein amino acid products (Purina Well Gel, Purina Mills, Inc. St. Louis, MO).

Complicated, refractory disease often requires surgical thoracotomy to facilitate removal of fibrinous material and necrotic lung to facilitate pleural drainage. Evidence that a horse is suffering from refractory disease includes lack of pleural fluid resolution over the course of several weeks despite appropriate antimicrobial therapy and repeated pleural drainage. Case selection for thoracotomy is a critical component of case outcome. Timing for thoracotomy in equine pleuropneumonia cases was reported to have a mean time of 60 days since disease development in one report. Surgical intervention too early in the course of disease may result in complications that include bilateral pneumothorax, hemorrhage, and/removal of viable lung, which can result in catastrophic case outcome. When case selection is made, timing for thoracotomy should be based on several factors that include patient stability and approximately 45 to 60 days of medical therapy. In an ideal setting pleural abscess will become walled off so that a pleural to parietal pocket is completely formed and separate from other regions of the thorax. At a minimum, it is important to determine that the mediastinum is complete based on the ability of the patient to handle air introduction into the proposed surgical hemithorax. The indwelling thoracic drain should be left open without a one-way valve for a minimum of 2 hours to determine whether the patient is able to physiologically handle a unilateral pneumothorax. If the patient is noted to become anxious and have altered respiratory rate and pattern or other signs of distress the site should be closed, air removed, and the procedure delayed until the patient is anatomically prepared with a closed mediastinum for the surgical intervention.

The procedure for thoracostomy can be performed using two different methods: an intercostal approach that opens an area in an ICS or a partial rib resection, which removes a section of rib adjacent to the abscessed material. An intercostal approach has the advantage of using a smaller window of approach, which limits postoperative discomfort. In mild cases intercostal thoracotomy can provide a functional area for pleural drainage and removal of fibrin and necrotic pulmonary tissue. In more severe cases, partial rib resection has the advantage of a larger surgical window in which larger, more advanced necrotic lung and debris can be removed. Patient recovery in the postoperative period is further delayed with rib resection because of the size and extent of tissue removal, which delays wound healing. In the immediate postoperative period daily lavage should be performed with warmed sterile isotonic fluids. Lavage will help facilitate the removal of debris and blood clots following surgery. After tissue granulation has been established (by 7–10 days) postoperatively nonsterile fluids (tap water) can be used for ongoing pleural drainage. Drainage should continue until sepsis is resolved and the surgical site has closed. The convalescent period following surgery will depend on the surgical procedure selected and degree of ongoing sepsis at the time of surgery. Generally, horses complete tissue healing and resolution of sepsis within 60 days of thoracotomy.

Complicating factors may prolong or prevent disease resolution. Primary pulmonary conditions that may complicate disease management include the development of pneumothorax, pleural adhesions, pulmonary abscess formation, pulmonary infarction, bronchopleural fistula, or cranial mediastinal abscess formation. Pneumothorax is a relatively common complication that develops with pleuropneumonia. Causes include iatrogenic introduction of air at the time of thoracocentesis or indwelling chest tube placement or secondary to development of a bronchopleural fistula. Mild pneumothorax is commonly well tolerated and may not have clinical consequences. However, more severe pneumothorax requires air evacuation to reestablish adequate pulmonary function and oxygen delivery. Clinical signs that support the necessity of air evacuation in a patient with pneumothorax include respiratory distress and elevated respiratory rate and effort. Placement of an indwelling thoracic tube in the caudodorsal lung field following the confirmation of pneumothorax via radiography will provide the clinician with the ability to remove pleural air to reestablish negative intrathoracic pressure. Pulmonary infarction has been reported to occur following strenuous exercise and is associated with severe pulmonary disease characterized by epistaxis, pulmonary consolidation, and fetid serosanguineous pleural fluid.[349] Bronchopleural fistulae can develop in horses with extensive pulmonary necrosis, which result in an open communication between the pleural cavity and central airways. The presence of a bronchopleural fistula does not impair the prognosis for survival, but it will prevent thoracic lavage and may impact future athletic performance. Occasionally septic pleural disease can have cranial dissemination leading to the organization of a mediastinal abscess. Clinical signs that suggest a mediastinal abscess may be present include apparent preference to stand with forelimbs in a pointed position, evidence of jugular vein occlusion with pronounced jugular pulsation, and marked pectoral edema. Imaging with ultrasound and thoracic radiography may provide additional evidence of mediastinal abscess based on cranial fluid accumulation located cranial to the heart. In such cases, there is also evidence of caudal displacement of the cardiac silhouette. Mediastinal abscess formation can be particularly challenging to manage, often requiring general anesthesia to facilitate effective drainage cranial to the heart.

Extrathoracic complications can develop in association with pleuropneumonia and include laminitis, jugular vein thrombophlebitis, and antibiotic-associated colitis. Similar to other manifestations of laminitis, depending of the severity of laminar damage, recovery may be prolonged and athletic performance limited following recovery despite resolution of pulmonary disease. Horses suffering from pleuropneumonia are commonly critically ill at the time of diagnosis, and hematologic parameters may indicate the onset of disseminated intravascular coagulopathy (DIC). Whether clinical or subclinical, DIC will place patients at greater risk for thrombophlebitis. In some cases catheter site cellulitis may progress

to thrombophlebitis, and for these reasons catheter selection should be aimed at materials with a low likelihood of thrombogenicity with placement and maintenance a clinical priority. Inadvertent or frequent jugular venipuncture should be avoided in horses at high risk for thrombotic disorders. In most instances, if a timely identification of jugular vein disease is established recovery can be favorable with an alternate placement site, and thrombosis is not severe. Antibiotic-associated colitis is an ever-present potential in horses receiving antibiotic therapy. Based on the nature and severity of disease, this should be monitored throughout the course of therapy. If evidence of gastrointestinal disturbance is noted, hydration, acid-base status, and electrolyte concentrations should be corrected. Antibiotic therapy will be required throughout the course of management for pleuropneumonia, so alternate therapy should be selected to target the primary pulmonary pathogen(s).

Prognosis and Outcome

The overall prognosis for horses to recover and resume athletic performance has improved over the past three decades. Evidence to suggest a more guarded prognosis includes the presence of marked fibrin accumulation with an overall survival of 68%. In horses that did not have fibrin accumulation survival was 100%, whereas horses that had fibrinous accumulation survival was only 62%.[21] It was noted that in this population, the nonfibrinous group only had 18% of the patients identified as having necrotic pulmonary parenchyma, whereas 60% of the patients with fibrinous disease exhibited necrotic pulmonary parenchyma. Bacterial isolates in this report were similar to previous reports, with the most common pathogen being *S. equi* subsp. *zooepidemicus* followed by *E. coli, Actinobacillus equuli, Enterococcus,* and *Klebsiella.* The most common anaerobes were *Prevotella* spp. and *Bacteroides* spp.[21] In a previous report, horses that had pleuropneumonia or pneumonia had an overall survival rate of 75%.[342] In that report 38% of the horses with anaerobic bacteria cultured from the lower airways survived, which is similar to 35% survival in the recent report, regardless of the presence of marked fibrin accumulation.[21,346] In a report that looked at pneumonia as secondary to penetrating thoracic wounds, the association of reduced survival with the presence of anaerobic bacteria was not found. This finding may have resulted, in part, because of the different pathogenesis of disease rather than the lack of association with anaerobic bacteria, resulting in a more guarded prognosis.[365] Among the published reports regarding the prognosis for horses with pleuropneumonia the range is 43.3% to 95.7%.[353,366,367] Not only is there a favorable overall prognosis for the horse to survive pleuropneumonia, the likelihood of returning to the previous performance level is also favorable. With appropriate treatment the prognosis is approximately 90% with about 60% returning to performance. As mentioned previously a delay in therapy, the presence of anaerobic bacteria, and the presence of marked fibrin loculations are associated with a more guarded prognosis. Horses that are at risk for the development of lower airway disease and bacterial colonization should be treated appropriately with antimicrobial therapy, monitored closely, and have therapy modified as indicated by the bacteria isolated from the lower airways. Complicating factors such as pneumothorax, laminitis, or colitis may prolong hospitalization and owner expense, which may also limit the ability of the horse to recover from its primary disease.

PULMONARY ABSCESS FORMATION

Pulmonary abscess formation most commonly occurs in weanling age foals in association with *R. equi* infection (Chapter 20). *S. equi* subsp. *zooepidemicus* is the organism most commonly cultured from the lungs of horses with generalized pneumonia and rarely results in abscess formation. Complications from *S. equi* infection include metastatic spread to various organs including possible pulmonary abscess formation. Aspiration is another cause of focal pulmonary infection and abscessation. Aspiration pneumonia is a potential complication of esophageal obstruction or dysphagia in horses. Neonatal foals may suffer from dysphagia in association with hypoxic ischemic encephalopathy or nutritional muscular dystrophy, whereas adult horses may develop aspiration pneumonia after complete esophageal obstruction.

INTERSTITIAL PULMONARY DISEASE

Interstitial pneumonia is a pulmonary disorder that may affect horses of various age groups. Adult horses with interstitial pneumonia have a more guarded prognosis for recovery and survival[280] compared with foals and weanlings. Horses less than a year of age that are provided with appropriate therapy and supportive care tend to have a favorable prognosis for complete recovery.[368]

Etiology

Some cases of interstitial pneumonia result from a primary toxic or infectious insult, but at the time of presentation determination of the exact etiology can be challenging.[300,368-370] Toxic pulmonary disease has been associated with ingestion of crofton weed, pyrrolizidine alkaloids (*Crotalaria, Trichodesma,* and *Senecio*), perilla ketones, silicosis, and prolonged oxygen therapy. Hepatic metabolites of pyrrolizidine alkaloids cause cellular damage and death in the pulmonary endothelium.[370,371] Inhaled irritants or toxins may contribute to direct pulmonary damage such as occurs after inhalation of smoke or agrichemicals.[372-374] Silicosis is a highly specific chronic granulomatous pneumonia of horses and should be considered in horses with compatible clinical signs that originate from the Carmel Valley in California.[280]

The most recent evidence for an infectious etiology associated with interstitial disease in horses is EHV-5–associated multinodular pulmonary fibrosis. Supportive evidence for the association was recently described in which investigators characterized findings of 24 adult horses that suffered from progressive nodular fibrotic lung disease associated with EHV-5.[302] Herpes viral DNA was identified in 79.2% of affected individuals compared with 8.7% of the control animals.[302] Similarly, a case series of five horses suffering from respiratory distress with clinical evidence of interstitial disease were all confirmed to have EHV-5 in pulmonary tissue or secretions, supporting previous findings associated with this disorder and multinodular pulmonary fibrosis secondary to viral disease.[311] An additional report of two horses also confirmed similar clinical manifestation of disease, radiographic and histopathologic evidence of multinodular granulomatous disease, and the presence of EHV-5.[304] It should be noted that the exact association of viral involvement remains speculative in some circumstances. In a prospective investigation of mares and foals in central Kentucky, up to 88% of the foals were positive for the virus in peripheral blood yet they

remained clinically healthy.[375] Although EHV-5 has been isolated from the upper respiratory tract of horses with respiratory disease, similar to a related gammaherpesvirus EHV-2, clinical disease associated with EHV-5 has been suggested to result in lymphadenopathy, immunosuppression, depression, and primary respiratory tract disease. Adult onset of severe respiratory disease characterized by multinodular granulomatous pulmonary lesions should be strongly suspected to be associated with EHV-5 infection.

The initial infectious or toxic agent causes alveolar damage resulting in cell death and increased permeability at the level of the alveoli. Pulmonary congestion, interstitial edema, erythrocyte extravasation, and alveolar edema occur during the exudative phase of the disease. Subsequently, alveolar infiltrates with inflammatory leukocytes and fibrin and increased permeability lead to fluid accumulation, impairing normal gas exchange mechanisms, hyaline membrane formation, and clinical respiratory distress. Acutely affected patients typically demonstrate respiratory distress, injected mucous membranes, and impaired pulmonary function. Subacute to chronic disease results in alveolar regeneration with alveolar type II pneumocyte proliferation to replace damaged type I pneumocytes. Fibroplasia leads to cellular proliferation and septal thickening, fibrous development, and ultimately to reduced pulmonary compliance.

Clinical Findings

Horses presenting with interstitial pneumonia are typically in severe respiratory distress with labored breathing, dark mucous membranes, poor pulse quality, and tachycardia. Some patients are mistakenly considered to have an obstructive disease like heaves, yet interstitial pneumonia is characterized by a restrictive rapid, shallow breathing pattern. Additional clinical features of disease include hypoxemia, a stress or inflammatory leukogram, hyperfibrinogenemia, and hypoxemia that may be severe. More chronic disease may be observed in mildly affected individuals with exercise intolerance and chronic cough.

Diagnosis

Definitive diagnosis of interstitial pneumonia in horses is based on histopathologic evaluation of a pulmonary biopsy. Examination for EHV-5 viral DNA can be performed on a tissue sample or BALF. Thoracic radiographs can be helpful in establishing a preliminary diagnosis of interstitial pneumonia. Two patterns of interstitial disease have been described in horses with interstitial pneumonia: as discrete or diffuse nodules suggestive of neoplasia or mycotic disease or as a diffuse increase in radiographic interstitial pattern (Fig. 8.19). Serum titers may indicate recent exposure or infection with viral respiratory disease. Histopathologic evaluation of lung biopsies or specimens obtained at postmortem will confirm the diagnosis of interstitial pneumonia. If silicosis remains a differential, diagnosis is based on x-ray diffraction techniques on lung tissue preparations.[280]

Treatment

The prognosis for adult horses with interstitial pneumonia remains guarded. In horses that present with mild to moderate disease, treatment should be aimed at improving oxygenation. Intranasal insufflation of oxygen is warranted for patients that are severely hypoxemic. Antiinflammatory therapy should initially include systemic corticosteroids

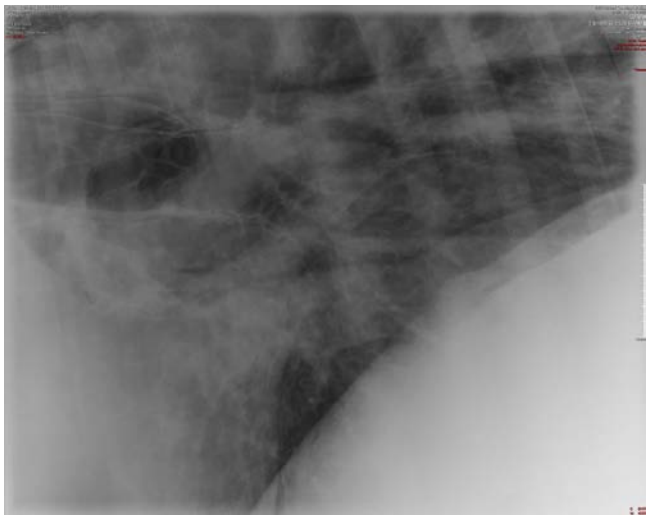

FIG. **8.19** A 19-year-old Quarter Horse mare presented with a 5-day history of fever, anorexia, and respiratory distress. The mare failed to respond to antibiotic and nonsteroidal antiinflammatory drug therapy. Thoracic radiographs were diagnostic for generalized interstitial pneumonia.

(dexamethasone 0.05–0.1 mg/kg IV daily), with transition to aerosolized corticosteroids (beclomethasone 1500 µg intranasally three times a day to twice a day)[376] as clinical improvement is observed. Corticosteroid therapy should be continued until clinical resolution is observed or no further improvement is noted with therapy. Prolonged corticosteroid therapy of several weeks to months should be anticipated because of the severity of lower airway inflammation associated with this condition. Bronchodilator therapy is indicated when severe bronchoconstriction exists. β_2-adrenergic receptor agonists are the drugs of choice for immediate bronchodilation and subsequent improvement of air movement to the lower airways (albuterol 360–720 mg/kg every 3–12 hours).[377,378] Enteral bronchodilator therapy with clenbuterol 0.8 to 3.0 µg/kg orally every 12 hours (Ventipulmin, BIVI) can provide additional support in cases with marked bronchoconstriction. Following initial stabilization, an additional therapeutic option is the use of a combined parasympatholytic agent (ipratropium 360–470 µg/kg every 6–12 hours)[379] with a β_2-adrenergic receptor agonist (albuterol; Combivent, 3M Pharmaceuticals, and Boehringer Ingelheim) to improve oxygen delivery to the lower airways with the added advantage of having an increased half-life compared with β_2-adrenergic agonist therapy alone.

In addition to supportive care and antiinflammatory therapy, specific antiviral therapy may be selected for cases of EHV-5–associated multinodular pulmonary fibrosis, typically in combination with antiinflammatory therapy. Valacyclovir has the greatest oral bioavailability with a protocol that includes 27 mg/kg orally every 8 hours for 48 hours followed by 20 mg/kg every 12 hours thereafter.[309,380,381] Duration of therapy should be based on clinical response to treatment. In some circumstances, this therapeutic protocol may be cost prohibitive or only possible for a limited time. Investigations are ongoing regarding the optimization of antiviral therapeutic protocols for horses that suffer from herpes viral infection. Supportive evidence is provided by the use of such agents in human patients that are at risk for serious cytomegalovirus infection post organ transplantation.[382,383]

Prognosis

The prognosis for return to function is guarded for adult horses and favorable for foals that are managed appropriately. Supportive and antiinflammatory therapy may improve clinical status, yet high-level athletic activity may be impaired.

FUNGAL PNEUMONIA

Respiratory fungal disease is most commonly a result of inhalation of aerosolized fungal pathogens. After inhalation the causative organisms are able to penetrate into the lower pulmonary airways and alveoli as a result of their small particle size. Interestingly, more than 90% of the particles present in stable air samples that are visible with light microscopy are spores of fungi or *Actinomyces*.[384,385] However, in some cases of fungal pneumonia penetration may occur through a compromised gastrointestinal tract in an immunocompromised patient. In one report 86% of the horses diagnosed with mycotic pneumonia developed disease secondary to gastrointestinal disease with disruption of epithelial integrity.[386] For this reason, in addition to horses that demonstrate evidence of pulmonary disease and have appropriate risk factors such as gastrointestinal disease, particularly if immunocompromised (marked neutropenia is present), fungal pneumonia should be considered.

The most common isolate from horses with fungal pneumonia is *Aspergillus* spp., which are commonly present in the equine environment,[387] particularly in moldy feed and bedding materials, such as straw. Predisposing factors that lead to disease development in horses include immunosuppression because *Aspergillus* spp. are opportunistic pathogens. Adequate anatomic and immunologic function provides the healthy individual with effective protection against colonization and disease. Immunosuppression may result from endogenous disease that alters effective immunity or is secondary to the administration of immunosuppressive therapy.[388-392]

Pathogenesis

Enteritis, colitis, and typhlocolitis are proposed to predispose horses to the development of systemic fungal dissemination. Gastrointestinal inflammation results in the disruption of the epithelial barrier, allowing for translocation of fungal organisms and subsequent systemic dissemination. Lesions have been described to center around large blood vessels, which then lead to systemic spread of organisms. Among the reported retrospective cases of invasive pulmonary aspergillosis nearly 84% were associated with enterocolitis.[388,392] Hematogenous dissemination leads to fungal deposition in the lung.

Among the risk factors for mycotic distribution from the gastrointestinal tract, NSAID therapy may contribute to epithelial disruption, enhancing mucosal permeability to luminal microorganisms. Additionally, neutropenia is an important risk factor for humans to develop mycotic pneumonia. Similarly in horses, the majority of cases are reported to suffer from neutropenia even though the exact role that neutropenia plays regarding disease manifestation is not fully elucidated. Dissemination of disease is an important component of disease pathogenesis; 40% of the horses with fungal pneumonia have evidence of invasive fungal disease in other organs including the kidney and brain.[347,388]

Overwhelming exposure to inhaled spores may result in pulmonary fungal disease, particularly in immunosuppressed individuals. Altered immunity may result from iatrogenic administration of corticosteroid therapy, pituitary pars intermedia dysfunction, or other overwhelmingly debilitating disease. Some invasive fungal pathogens may cause primary disease and do not require a predisposing host factor as a precedent for colonization, which includes *Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum,* and *Cryptococcus neoformans.*

Direct inhalation of *B. dermatitidis* conidia can result in pulmonary colonization. These are dimorphic saprophytic fungi that can be detected on cytologic examination of airway secretions. Infection has been reported to result in pulmonary abscess formation, peritonitis, subcutaneous abscesses, and mastitis.[393-395] *Histoplasma capsulatum* is most commonly associated with moist regions, particularly those contaminated with bird or bat fecal waste. The characteristic appearance of yeast includes a 2- to 4-μm organism with a definitive circular halo surrounding the centrally located crescent-shaped cytoplasm. Although horses are considered resistant to infection, disease associated with *H. capsulatum* has included pulmonary granuloma,[396] pneumonia, and abortion.[397] Coccidioidomycosis is an uncommon pathogen of horses, but among horses that live in regions of sandy, alkaline soils disease may occur following inhalation. Marked pulmonary inflammation develops initially, followed by pulmonary and lymphoid localization. Nonspecific clinical signs may involve multiple organ systems including liver, lung, kidney, or spleen and warrant a particularly guarded prognosis. Horses with severe pulmonary disease associated with *C. immitis* similarly are unlikely to survive.

Immunosuppressed Patients

Candida albicans is an uncommon opportunistic pathogen that has been observed as a complicating factor in septic neonatal foals, which rarely can be identified on diagnostic evaluation of the respiratory tract. In suspect cases, fungal culture of transtracheal aspirate samples may be indicated. *Pneumocystis jirovecii* is currently classified as a saprophytic fungus based on the DNA sequence information from the 16S-like ribosomal subunit. Clinical signs of *P. jirovecii* infection typically include an interstitial pneumonia that fails to respond to conventional therapeutics. Historical reports have described Arabian foals with severe combined immunodeficiency as the most likely to succumb to infection. Similarly, in humans, this is a disease of immunosuppressed individuals that commonly suffer from HIV infection that have progressed to develop AIDS. Diagnosis is based on cytologic examination of lower airway secretions obtained by BAL sampling. This organism cannot be cultured.

Clinical Signs

Clinical signs of equine fungal pneumonia include tachypnea, fever, nasal discharge, epistaxis, nasal plaques or erosions, abnormal lung sounds, and pleural friction rubs. Most horses have a history of progression of respiratory disease despite aggressive antimicrobial therapy. Inspection of the nasal passages may reveal nasal plaque formation or ulceration. Although these lesions may be detected in the minority of cases, estimated in 10% of horses, this is highly predictive of concomitant or subsequent invasive pulmonary aspergillosis.

Diagnosis

Low-volume pleural effusion may be detected by thoracic ultrasound, and fibrin plaques may occur on visceral and parietal pleural surfaces. If pleural effusion is identified, pleural

fluid samples should be submitted for cytologic evaluation and culture. Observation of fungal spores on cytologic evaluation and/or culture of fungal elements from transtracheal aspirate samples are not strong indicators of a diagnosis of fungal pneumonia in horses. Culture and histologic evaluation of lung biopsy samples provide definitive evidence of fungal pneumonia and differentiation from neoplasia. Fungal mediastinal granuloma appears similar to mediastinal lymphoma on radiographic examination.[398] The site is difficult to biopsy percutaneously and is best identified via thoracoscopy.

The radiographic appearance of fungal pneumonia can be similar to disseminated pulmonary neoplasia. A miliary or reticulonodular interstitial pattern is common with multifocal, coalescing nodules visualized in peripheral lung fields in both fungal pneumonia and metastatic neoplasia (see Fig. 8.9).

Patient examination will provide the clinician with the opportunity to determine optimal sample collection for diagnostic examination. Thoracocentesis may be performed in cases with evidence of pleural fluid. However, in cases of lower airway disease, with an absence of pleural fluid accumulation, transtracheal aspiration will be a preferred diagnostic sample for collection. Cytologic examination of pleural fluid or tracheal aspirate reveals the presence of fungal organisms. *Aspergillus* spp. are characterized by having broad septate hyphae with parallel sides and discrete 90-degree branches that can be identified on cytologic or histopathologic examination. Sample collection should include fungal culture analysis in suspect cases. Serologic assessment may provide supportive evidence, but specificity is influenced by the frequency of fungal exposure among horses. Sample staining may provide more efficient diagnostic evidence; immunohistochemistry and immunofluorescence are available diagnostic options.

Lesions involving the upper respiratory tract may be sampled using standard biopsy techniques. Uterine biopsy instruments are useful tools for sample acquisition because in some cases sample size can make definitive diagnosis challenging. For lesions involving sinus structures, sample acquisition is generally accomplished with a sinus flap. Fungal pneumonia may be diagnosed via TTW or BAL sampling or lung biopsy acquisition. Risk of pulmonary vascular damage is a potential risk associated with biopsy collection and should be carefully monitored with ultrasound and physical examination (epistaxis) to determine whether hemorrhage is present.[385] Routine staining with hematoxylin and eosin may not provide diagnostic information for all fungal organisms, particularly when chronic lesions contain marked fibrosis; therefore, in suspect cases special staining for fungal organisms should be requested. Staining techniques may include periodic acid–Schiff, Gridley fungus stain, and Grocott-Gomori methenamine silver nitrate staining.[385]

The presence of fungal elements may be identified in cytologic fluid samples or impression smears obtained from tissue biopsy samples, although interpretation of such findings should be carefully considered. The direct association of fungal elements in biologic samples should correlate with the presenting complaint and patient status. Tracheal aspirate and lower airway samples commonly contain *Alternaria* spp. (nonpathogenic *barn fungus*), yet this does not correlate with clinical disease, and they are found in combination with normal cytologic findings in healthy horses.[399] If diagnosis is based on cytologic examination, ideally this finding should be based on clinical pathologic findings of abundant fungal organisms in the presence of marked inflammation characterized by abundant (>20%) and typically degenerate neutrophils present. Clinically relevant findings typically also include intracellular and extracellular organisms in the presence of marked inflammation.

In vitro growth of fungal organisms can be lengthy because of their naturally fastidious growth kinetics. Suspect samples should be applied to prepared culture media and transported to a microbiology laboratory at room temperature. Routine culture media includes Sabouraud dextrose agar, inhibitory mold agar, or a mycobiotic containing cycloheximide and chloramphenicol, which enhance the potential for positive fungal growth. Test interpretation should carefully consider patient status because of the frequency of fungal organisms in the equine environment. Similar to airway cytology findings test specificity is reduced and false positive samples can occur.[385,400]

Serologic diagnostic testing can provide the clinician with valuable diagnostic information and the opportunity to monitor disease progression and response to antifungal therapy. Currently available options include immunodiffusions, radioimmunoassays, complement fixation, and ELISA testing. These tests will aid with the quantification of circulating antifungal antibody titers. For this reason they have diagnostic and patient-monitoring benefits. Immunohistochemistry, fluorescence in situ hybridization, and DNA probes are antigen-detection testing methods. Additionally, a commercial comprehensive real-time PCR assay can be used to detect fungal DNA in biological samples. This can be followed by a species-specific real-time PCR test to determine the particular inciting pathogen.[401]

Although not all fungal pathogens are opportunistic in nature, based on the potential for attenuation of endogenous immune activity, suspect cases that fail to demonstrate an appropriate risk for fungal disease may benefit from immune assessment testing. Overall lymphocyte concentrations can be ascertained on compete blood count analysis, but lymphocyte subset testing and functional analysis can provide the clinician with an improve assessment of host immune function. Testing should include lymphocyte subset immunophenotyping and immunoglobulin concentration assessment.[402-407]

Treatment and Prognosis

Amphotericin B deoxycholate is a polyene antibiotic that combines with ergosterol in the fungal cell wall to enhance membrane permeability. The hazards of drug administration are numerous, and caution should be exercised when administering to equine patients. When administered intravenously the drug is nephrotoxic and quite irritating, potentially leading to phlebitis. Additional adverse events may include anorexia, anemia, cardiac arrhythmias, hepatic dysfunction, and hypersensitivity reactions.[408] Despite the potential for adverse events in some instances, this is considered a reasonable treatment choice and has been used with success to treat systemic diseases such as histoplasmosis, pulmonary aspergillosis, cryptococcosis, and topically for nasal *Conidiobolus coronatus*.[100,387,409-412]

Benzimidazole derivative drugs classified among the azoles provide an effective antimicrobial therapy against fungal pathogens by inhibiting ergosterol synthesis in the cell membrane. These drugs have been used with success topically and as systemically administered drugs (Table 8.8).

TABLE **8.8 Antifungal Agents for Consideration in Equine Patients**

Drug	Dose	Comments
Amphotericin B	0.3–0.6 mg/kg in 1 L 5% dextrose[1]	Nephrotoxicity, phlebitis, hypersensitivity Use caution
AZOLE DRUGS		
Miconazole 2% topical	Topical[2]	Guttural pouch mycosis
Enilconazole	Topical[3]	Guttural pouch mycosis Nebulization for fungal pneumonia, *Scopulariopsis* spp.
Ketoconazole	30 mg/kg NG tube, daily[4,5]	Acidify with 0.2 N HCl
Itraconazole (Sporonox)	5 mg/kg PO, daily[6]	*Aspergillus* spp., *Histoplasma* spp., *Blastomyces* spp. Compounded formulation not recommended
Fluconazole	Load 14 mg/kg PO	Not effective against *Aspergillus* spp. and *Fusarium* spp.
	Then 5 mg/kg PO, daily[7–9]	Compounded formulation is stable
Voriconazole	4 mg/kg PO, daily[10]	Drug of choice for human invasive *Aspergillus* spp. pneumonia
IODIDE THERAPY		Do not administer to pregnant mares, congenital hypothyroidism
Sodium iodide (20%)	20–40 mg/kg/day 7–10 days[11–13]	Monitor for signs of iodonism: lacrimation, dermatitis
Oral formulations		
Inorganic potassium iodide	10–40 mg/kg/day [12,13]	Chemical grade only, unstable in light, heat, humidity
Organic ethylenediamine dihydriodide	0.86–1.72 mg/kg/day[13]	Commercially available

NG, Nasogastric; *PO,* orally.

Although iodide-containing agents have limited evidence to demonstrate efficacy against fungal pathogens, they have apparent effectiveness against some granulomatous diseases and are thought to provide benefit through antiinflammatory properties. Advantages of iodide therapy include that these are cost-effective agents and for this reason are often administered to equine patients with fungal disease, commonly in combination with other therapies (Table 8.8).

The overall prognosis for horses suffering from fungal disease involving the respiratory system is dependent on a variety of factors that include infecting agent, host immune status, primary disease process, the stage of the disease at the time of diagnosis, and owner commitment to invest in newer generation antifungal agents when indicated. Collectively, in some instances horses suffering from mycotic pulmonary disease may demonstrate a positive response to appropriate therapeutics, but because of the multitude of factors that may be involved with host status these must also be considered. In cases where disease is advanced, complicating factors are marked and/or therapeutic options are limited, prognosis for disease resolution may be more guarded.

PARASITIC PNEUMONITIS

Parasitic pneumonia is a condition that may affect foals or adult horses. Parasites associated with this condition include *Parascaris equorum* larvae or the adults of *Dictyocaulus arnfieldi.* Clinically affected horses have obvious evidence of respiratory disease that includes exercise intolerance and coughing that may be accompanied by nasal discharge, fever,

and depression, particularly when secondary bacterial infection has occurred. *P. equorum* infection is most common in foals and weanlings, particularly those raised on breeding farms in which the parasite resides in the environment and soil. *Dictyocaulus* infection may occur in horses of any age, but this parasite requires a donkey as a primary host to complete its life cycle.

Clinical Findings

Chronic coughing, mucoid to mucopurulent nasal discharge, respiratory distress, and poor overall body condition provide nonspecific evidence of parasitic disease in foals. Poor body condition, abnormal pulmonary sounds represented by increased bronchovesicular sounds, crackles, and wheezes are common findings on thoracic auscultation of horses with parasitic pneumonia. Poor body condition is a common finding because of intestinal involvement of parasitic infection. Colic may be a component of the history or may result following therapeutic anthelmintic treatment in severely affected individuals. Frequently the history also includes a poor response to appropriate antimicrobial therapy for suspected bronchopneumonia.

Diagnosis

Hematologic evaluation commonly reveals an inflammatory leukogram consisting of a mature neutrophilia, hyperfibrinogenemia, and hyperglobulinemia. In some instances, particularly early in the course of disease, hematologic evaluation may reveal few abnormalities. Hepatic parasitic migration (*P. equorum*) may result in mild to moderate hepatic enzyme elevation.[413] Thoracic radiography is a useful diagnostic test in affected individuals. A moderate to severe bronchointerstitial pattern is a common finding, whereas granuloma or abscess formation may be detected by radiographs with advanced disease. Thoracic ultrasonographic examination will allow the clinician to detect the presence of pleural fluid or peripheral pulmonary consolidation.

Cytologic examination of a sterile tracheobronchial aspirate will often reveal abundant eosinophils (5–50%, normal <2%), and neutrophilic inflammation may exist concurrently, particularly when secondary bacterial infection is present. Microorganisms are apparent with significant bacterial infection; culture is recommended to determine the presence of bacterial infection and to determine the antimicrobial sensitivity pattern for pathogens of concern. Fecal flotation is indicated to determine the presence of parasite ova being shed from the host. *D. arnfieldi* requires a donkey or mule host for life cycle completion; therefore, parasite eggs will only infrequently be detected in adult horses with lungworm infection. It is difficult to diagnose *P. equorum* infection on fecal flotation because tissue migration occurs during the prepatent period. Therefore, diagnosis is based on clinical signs, lack of evidence of bacterial infection, and tracheal wash cytology indicating eosinophilic pneumonitis. Response to therapy is supportive of the diagnosis, although antibiotic therapy may be required in combination with anthelmintic therapy.

Therapy

Severely hypoxemic patients may require oxygen insufflation. Severe pulmonary inflammation is induced by eosinophilic infiltrates necessitating bronchodilator and potentially aerosolized corticosteroid therapy (see previous recommendations on aerosol therapy). Oral anthelmintics used to treat *P. equorum* infection include an initial low dose of fenbendazole (5 mg/kg). Careful monitoring for approximately 24 hours is recommended to observe the foal for evidence of deterioration or gastrointestinal distress. Laxative therapy may be required if gastrointestinal ascarid impaction is suspected. After the foal has received an initial low dose of fenbendazole without complication, the dose can be increased (10 mg/kg PO daily) and this therapy can be repeated daily for 5 days. This therapy will be effective in killing adult and migrating larvae. Because this is a farm problem, other individuals on the same property of similar age should be managed appropriately, even if clinical evidence of disease is not apparent. Other anthelmintics that have been used include pyrantel pamoate (6.6 mg/kg) and ivermectin (200 μg/kg). *D. arnfieldi* infection can be successfully treated with ivermectin (200 μg/kg), moxidectin (adult horses only, 400 μg/kg), thiabendazole 440 (mg/kg/day twice), or levamisole (10 mg/kg).

Benzimidazole anthelmintic agents inhibit microtubule formation, which impairs the parasite's ability to move and ingest food. Energy metabolism is also impaired because of the inhibition of fumarate reductase.[414] Although many benzimidazoles are efficacious against intestinal larvae, they are not uniformly effective at killing migrating parasite larvae; however, at higher doses fenbendazole is safe and effective at killing intestinal and tissue larvae. Anecdotal and personal observations have suggested this anthelmintic to be highly efficacious, particularly in cases where ivermectin resistance is suspected.

Pyrantel pamoate is an acetylcholine agonist that results in parasite paralysis.[415] At the recommended dose this agent is effective at killing intestinal larvae but not migrating larvae.[413,414] Avermectins are effective because they bind glutamate-gated chloride channels, and this class is effective against both *P. equorum* and *D. arnfieldi* adults and migrating larvae. Ivermectin has a reported efficacy of 76.9% for removal of intestinal *P. equorum* and is 100% effective for removal of pneumonic larvae.[414,416] Overall, ivermectin and moxidectin have similar efficacy as effective anthelmintics in horses for many gastrointestinal parasites other than *Anoplocephala perfoliata*.[417] Based on these reports regarding anthelmintic efficacy, recommendations include combining therapeutic agents to maintain maximal efficacy. Initial treatment with fenbendazole (10 mg/kg orally daily for 5 days) followed in 14 days with an avermectin product at the appropriate dose should clear the individual of both intestinal and pneumonic parasites.

Prognosis

Foals or adult horses with primary parasitic pneumonia and secondary bacterial infection will require concurrent antibiotic and anthelmintic therapy. The prognosis is excellent for recovery from parasitic pneumonitis. It is important to emphasize the need for complete deworming, including donkeys and mules, because they harbor the adult *Dictyocaulus* parasites that serve as a source for parasite contamination and infection of horses in the immediate environment.

RECURRENT AIRWAY OBSTRUCTION

Clinical Presentation

Equine RAO (heaves and severe equine asthma[418]) causes a reproducible series of clinical signs in affected horses. RAO is a common cause of performance impairment characterized by

a chronic cough, serous to mucoid nasal discharge, and episodic respiratory distress. Clinical signs are often seasonal and more intense when horses are housed indoors and exposed to dust, poor-quality hay, ammonia fumes, fungal spores, and other nonspecific stimuli.[418-420] Horses with RAO are typically mature adults, and the average age of horses with RAO is >7 years of age.[421]

There is no breed or gender predilection, but there is an apparent heritable component to disease development, particularly in certain lines of breeds such as Warmblood horses in Europe.[422-424] Although these studies have demonstrated that in some lines the heritability of RAO is more clearly defined, the overall mode of inheritance for RAO is not completely understood and is presumed to be complex. A question that has challenged equine clinicians for many years has involved the potential relationship between pulmonary inflammation in the form of IAD leading to the subsequent development of RAO. Additional information that may contribute to the complexity and understanding of these conditions relates to the current terminology of equine airway inflammation classified as mild to moderate asthma in horses suffering from IAD and severe equine asthma in horses with RAO. An incomplete understanding of disease pathophysiology may lead an individual to assume that these conditions are directly linked. In reality, there is insufficient evidence to provide a direct relationship that a horse with IAD will develop RAO in later life. Current evidence supports that horses with cough associated with pulmonary mucus and inflammatory cell accumulation are at risk for the development of RAO,[425] and there is insufficient evidence to demonstrate that there is a clear transition from IAD to RAO.[418] Summer pasture-associated obstructive pulmonary disease (SPAOPD) is a syndrome similar to heaves or severe equine asthma; however, the clinical signs are triggered by exposure to late summer pollens in the southeastern United States. The primary difference between heaves and summer-associated disease is the local climate with exposure to specific allergens that induce clinical signs of airway obstruction. The presenting complaint for horses with severe equine asthma varies but often includes a chronic cough. Exercise intolerance, respiratory distress, mucopurulent nasal discharge, abnormal pulmonary sounds, and an enlarged field of percussion may also be identified.

Diagnosis

Typically the diagnosis of RAO is based on supportive historical information and physical examination findings. Complete blood count and serum chemistry analysis are generally unremarkable in horses without comorbid disease. Thoracic radiography is not indicated for routine diagnosis of heaves, but if a horse fails to demonstrate expected clinical improvement to appropriate pharmacologic therapy and environmental modification, then additional diagnostics should include thoracic radiography. Thoracic radiography is an important diagnostic modality to determine whether marked interstitial disease exists. Therefore, in horses suspected to have bronchointerstitial pneumonia or multinodular pulmonary fibrosis, thoracic radiography is indicated. Characteristics of the respiratory pattern should provide the clinician with evidence of marked fibrosis or interstitial disease resulting in restrictive pulmonary disease, which would be characterized by marked inspiratory distress compared with the RAO-affected horse that demonstrates marked expiratory effort caused by air trapping and expanded pulmonary fields.

BAL cytology will provide diagnostic confirmation of pulmonary inflammation in horses with mild to moderate disease. BAL is recommended as the appropriate diagnostic method to obtain samples for cytologic analysis. Compared with samples obtained with TTW aspiration, BAL sampling provides more representative diagnostic information regarding the status of cellular infiltrate into the lower airway secretions. There is poor correlation using the criteria for RAO diagnosis of >5% neutrophils in a BAL sample compared with >20% neutrophils in a tracheal aspirate sample. It is well recognized that a great deal of variability can be identified in the cellular composition of tracheal fluid, which is in contrast to samples from the lower airways obtained by BAL sampling.[426] When sampling is performed using the BAL protocol, specifically when marked inflammation is present, there may be a reduction in sample volume obtained resulting from airway collapse distal to the tube or endoscope.[17] In such instances, low aspiration pressures should be applied in an effort to reduce distal airway collapse. In addition to difficulty with sample collection, the quality of sample collected should be inspected. In horses where airway collapse has occurred the amount and quality of surfactant collected may be reduced. Interpretation of cytologic findings support RAO when neutrophilic inflammation (>5% neutrophils) is found on BALF cytology. Cellular morphology is generally normal and classified as nondegenerate without evidence of sepsis. Mucus is commonly abundant in cytologic analysis of horses suffering from RAO and deeply stained casts of inspissated mucus (classified as Curschmann's spirals) may be reported. However, mucus may be identified with other conditions that can lead to pulmonary inflammation, reducing the specificity of this independent finding. The diagnosis of RAO is more difficult when clinical signs are mild and exhibited by an occasional cough or minimal abdominal effort. Rebreathing is a simple procedure that will enhance pulmonary sounds on auscultation, but in horses with less severe disease, ancillary diagnostics are required. When pulmonary function testing is performed on horses with severe equine asthma, they typically demonstrate an increased change in pleural pressure ΔP_{Lmax} (>15 cm H_2O), increased pulmonary resistance (R_L), and decreased dynamic lung compliance (C_{dyn}).[427-430] Although standard pulmonary testing is not sensitive enough to detect mild airway obstruction when RAO patients are in remission, horses with RAO have histologic evidence of pulmonary disease. These findings indicate that although clinical signs are recurrent, and the patient may be in remission, pulmonary disease is permanent and pulmonary function is negatively impacted, particularly when exacerbation is present.

Therapeutic goals of horses suffering from RAO include improved pulmonary function through the attenuation of airway inflammation and bronchial wall hyperresponsiveness leading to marked bronchoconstriction. The central factor for disease control is environmental modification that limits (preferably eliminates) allergen exposure. The removal of the environmental allergen is a key feature to achieving disease remission in horses suffering from heaves. Medical therapy aimed at attenuation of clinical signs associated with pulmonary inflammation and bronchoconstriction will provide temporary clinical benefit. If environmental modification is insufficient, disease exacerbation will occur once drug dosages are reduced. Synthetic corticosteroid administration will aid with reduction in pulmonary inflammation, and

bronchodilator therapy will open airways, improving pulmonary function as a rescue therapy, and should be continued concurrently with corticosteroid therapy until bronchodilation is achieved.

The goal of therapy is to reduce airway inflammation and bronchoconstriction while enhancing mucociliary clearance mechanisms. Corticosteroids and bronchodilator therapy are used regularly for treatment of RAO. The most common environmental allergens leading to exacerbation of RAO signs include airborne particulate material that is in extraordinarily high concentrations in most stable environments. Apparently clean and fresh hay typically contains mold spores such as *Aspergillosis fumigatus, Faenia rectivirgula,* and *Thermoactinomyces vulgaris.*[419,431] In addition to environmental molds, environmental endotoxin and ammonia are recognized to contribute to induction of airway inflammation.[432,433] Round bale hay is exposed to repeated environmental moisture and contains high levels of airway allergens when fed to RAO-affected horses maintained on pasture. Horses that are stabled will have an improved local environment if provided with ample ventilation, a clean stall with low-dust bedding material, and commercial pelleted feed (low dust) that contains minimal allergens and particulate materials. Moistened hay pellets, cubes, or silage may provide alternate roughage sources for horses with airway-related inflammation. Commercial roughage products such as hydration hay are becoming increasingly available with the advent of small-sized baled hay that can be soaked and fed from a 5-gallon bucket. These products have the advantage of high-quality roughage with the introduction of limited allergens and airborne particles. Soaking of long-stem hay is an option for management of mildly affected horses but will not provide sufficient reduction of allergen exposure for highly sensitive individuals. Management of heaves-affected horses should take into account all triggers. Although dust particles are not a specific allergen, horses with airway inflammation will benefit from a low-particle environment.[434] Avoidance of indoor arenas, housing near a rock or dirt road, or maintenance in a dry lot pen should be avoided in an effort to remove all particles from the breathing zone of affected horses.

Antiinflammatory Therapy

The cornerstone of remission of clinical signs in horses suffering from RAO is reduced inflammation. It is well recognized that the inflammatory cytokines released by activated T lymphocytes increase the pulmonary concentration of IL-4 and IL-8.[435,436] The recruitment of neutrophils, particularly in response to the potent chemokine IL-8, maintains a heightened level of immune reactivity in this environment, contributing to enhanced mucous production, bronchospasm, and coughing. Corticosteroids act as direct inhibitors of this inflammatory cycle, resulting in improved clinical signs. The combination of corticosteroids with bronchodilator therapy is the most effective method to induce disease remission. It is important to consider that long-acting potent corticosteroids are more likely to produce detrimental effects such as laminitis and immunosuppression. Therefore, therapeutic recommendations include using the lowest effective dose and avoiding prolonged therapeutic administration. In many cases, a course of therapy for approximately 2 weeks is sufficient to induce clinical remission.

Systemic administration of potent corticosteroids improves clinical signs, reduces airway inflammation, and improves pulmonary function in horses with RAO. Triamcinolone acetonide (0.09 mg/kg intramuscularly) as a single dose relieves lower airway obstruction for up to 4 weeks. However, this protocol also results in adrenal suppression for up to 4 weeks.[437] Triamcinolone has also been demonstrated to induce hyperglycemia and hypertriglyceridemia for up to 4 days following drug administration.[438] Dexamethasone (0.1 mg/kg IV q 24 h) reduces airway obstruction and inflammation within 3 to 7 days with clinical benefit evident for up to 7 days.[439] Administration of dexamethasone also produces adrenal suppression; however, this effect lasts for approximately 3 days after discontinuation of treatment.[18] Oral prednisolone has favorable bioavailability and improves clinical signs of airway inflammation, but compared with IV dexamethasone does not provide the same antiinflammatory effect based on BALF cytologic examination.[440] Oral prednisone demonstrates limited efficacy for resolution of clinical signs associated with RAO. Nor does this therapy reduce pulmonary inflammation in horses with moderate to severe disease.[441] NSAIDs and antihistamines are ineffective for treatment of RAO.[442]

Inhaled corticosteroids provide an effective treatment alternative for mild to moderately affected RAO horses. Beclomethasone (500–1500 µg b.i.d.) reduces pulmonary inflammation, improves pulmonary function, and improves ventilation imaging of horses suffering from RAO.[443] In contrast to rescue bronchodilator therapy, no immediate drug effect is observed with aerosolized corticosteroids.[18] Aerosolized medications can effectively be administered with a spacer device such as the Equine Haler (Jorgensen Labs, Inc.) or the AeroHippus (Trudell Medical International). Investigations aimed at comparison of delivery systems have revealed similar efficacy.[444] Clinical improvement is apparent approximately 24 hours following initiation of therapy. Administration of beclomethasone (3200 µg b.i.d.) using the Equine Haler device improves parameters of pulmonary function and arterial oxygen tension approximately 3 to 4 days after initiation of therapy.[1] Among the variety of available inhaled corticosteroid preparations, fluticasone is the most potent with the advantage of lowest adrenosuppressive effects.[9,11,13] Reduced pulmonary neutrophilia, improved pulmonary function, and reduced airway hyperresponsiveness are significantly improved following fluticasone administration (2000 µg t.i.d.).[445-447] Although inhaled corticosteroids are particularly useful for resolution of airway obstruction, unless environmental modification is implemented, clinical signs of obstructive disease will return within 2 to 4 days after discontinuation of therapy.

Aerosolized corticosteroids are effective in horses with mild to moderate airway obstruction, with clinical signs ranging from exercise intolerance to respiratory distress while at rest. Aerosolized drugs provide the benefit of drug delivery directly to the respiratory tract but represent a more substantial financial investment and may be reserved for valuable or performance horses. Currently, there are three aerosolized corticosteroid preparations available in metered dose inhaler preparations: beclomethasone dipropionate, fluticasone propionate, and flunisolide. The relative potency of these surface-acting corticosteroids are fluticasone > beclomethasone > flunisolide = triamcinolone. When considering dexamethasone as a standard of 1, flunisolide = 1.9, triamcinolone = 2.0, beclomethasone = 13.5, and fluticasone = 18.0. When comparing the commercially available corticosteroid products,

fluticasone is the most potent and the most expensive. Fluticasone is highly lipophilic, which results in the longest pulmonary residence time. Because fluticasone has extremely low oral bioavailability (<2%) and extensive first pass metabolism (99%), fluticasone has the advantage of the least potential for adverse systemic side effects and the most favorable therapeutic index of the commercially available aerosolized corticosteroids. Horses suffering from RAO and receiving fluticasone (2000 μg t.i.d.) demonstrate reduced pulmonary neutrophilia, improved pulmonary function assessment, and reduced responsiveness to histamine challenge during episodes of airway obstruction.[29] When healthy horses are evaluated following administration of fluticasone, serum cortisol levels are reduced by 40% following 1 day of therapy and 65% following 1 week of treatment. Serum cortisol concentrations return to pretreatment levels approximately 24 to 48 hours following discontinuation of drug therapy. Beclomethasone is the first line of aerosolized corticosteroid therapy for moderate to severe allergic airway disease in human patients. Beclomethasone (500–1500 μg t.i.d.) results in reduced pulmonary inflammation, improved parameters of pulmonary function, and improved ventilation imaging of horses with RAO.[1,11,13,18] Although immediate effects are not observed following administration of beclomethasone, clinical signs and pulmonary function begin to improve within 24 hours of administration. Administration of beclomethasone (3750 μg t.i.d.) improves pulmonary function and arterial oxygen tension for about 2 weeks. When housed in an allergen-rich environment, pulmonary function parameters return to pretreatment values within 3 to 7 days following discontinuation of drug therapy.[18] Subsequently, it can be concluded that if environmental management is not addressed, clinical resolution will not be maintained when beclomethasone treatment is used without environmental modification.

Despite the fact that human asthma patients remain on inhaled corticosteroids for extended periods without the detriment of adrenosuppression, horses have increased sensitivity to the adrenosuppressive effects of inhaled corticosteroids. Endogenous cortisol production is reduced in horses treated with beclomethasone (>1000 μg b.i.d.)[18] or fluticasone (2000 μg b.i.d.)[29] with the threshold for beclomethasone of approximately 500 μg b.i.d. The adrenosuppressive effects have been observed to last for approximately 2 days following discontinuation of drug therapy. Interestingly, the therapeutic efficacy of beclomethasone (500 μg b.i.d.) is approximately equal to larger doses, suggesting that horses can be treated at an effective dose with the least adrenal suppression being induced when environmental modification is implemented.[18]

Bronchodilator Therapy

Pulmonary bronchoconstriction associated with RAO requires specific therapy for immediate relief of smooth muscle contraction in the lower airways. Symptomatic bronchodilator therapy will improve clinical signs; however, lower airway inflammation is not altered by bronchodilator administration. Bronchodilator therapy is primarily indicated for immediate relief of bronchoconstriction (rescue therapy).[2,5,19,24] The rapid onset of action of an aerosolized bronchodilator consistently provides immediate relief of bronchoconstriction. The most effective agents available for bronchodilation are β_2-adrenergic agonists and parasympatholytic agents.

Clinical improvement associated with bronchodilator treatment is characterized by reduced pulmonary resistance, increased pulmonary compliance, and decreased maximal change in pleural pressure observed in heaves-affected horses treated with bronchodilator therapy.[2,5,19] The most consistently effective bronchodilators are β_2-adrenergic agonists and anticholinergic agents. Methylxanthines are less reliable for providing positive results and have a narrow therapeutic index. Heaves-affected horses stabled in a dust-free environment demonstrate a positive response to bronchodilator therapy, suggesting that environmental management alone will not completely resolve the bronchoconstrictive component of heaves.[15]

The pathogenesis of bronchospasm in horses with recurrent airway disease appears to be primarily vagally mediated and may involve soluble mediators such as serotonin, histamine, and leukotriene D4.[12,15] Defective inhibitory pathways of airway smooth muscle have been suggested to play a role in the development of bronchospasm. β-Adrenergic agonists serve as inhibitors of smooth muscle contraction through the release of nitric oxide from inhibitory nonadrenergic noncholinergic (iNANC) nerves and release of inhibitory prostanoids such as prostaglandin 2 (PGE_2) from the airway mucosa. During episodes of acute RAO, iNANC-mediated relaxation is not present, and the prostanoid profile shifts from an inhibitory one to a stimulatory one.[15]

Smooth muscle contraction, smooth muscle hypertrophy, and mucosal thickness all contribute to airway narrowing and subsequent air trapping. Pulmonary remodeling in heaves-affected horses includes mucous cell hyperplasia and metaplasia that contributes to the cascade of smooth muscle contraction leading to luminal contraction and narrowing. Bronchodilator therapy has remained a mainstay of heaves treatment, and resolution of severe airway distress requires administration of rapid-acting bronchodilators.[9,11,13]

Increasing luminal diameter should not be the only focus of therapy. Antiinflammatory therapy is required to reduce exudate and prevent bronchoconstriction. Inflammation is recognized to be the underlying pathophysiological process in all cases of bronchoconstriction, and daily antiinflammatory therapy will mitigate potential disease exacerbation and reduce the requirements for bronchodilator therapy. Corticosteroids are recognized to be the only drug class to demonstrate substantial modification of allergic airway disease in human asthmatic patients. Chronic administration of β_2-adrenergic agonists alone produce deterioration in pulmonary function, increased airway responsiveness, and more frequent exacerbations of bronchoconstriction.

Aerosolized, short-acting β_2-adrenergic agonists (albuterol, pirbuterol, and fenoterol) are rapidly effective bronchodilators indicated for "rescue therapy" for horses demonstrating respiratory difficulty at rest.[2,5,19,24] Albuterol sulfate (360 μg) improves pulmonary function by 70% within 5 minutes of administration.[5,19] When severe airway obstruction is present, drug administration at 15-minute increments for up to 2 hours may be implemented for sequential bronchodilation. Beneficial effects from short-acting β_2-adrenergic agonists last approximately 1 hour in severely affected horses, resulting in the need for longer acting preparations. Combination therapy with corticosteroids will reduce the tolerance that develops to these agents in addition to enhancing β_2-adrenergic receptor protein expression.[11,13,18]

Long-acting bronchodilator preparations are ineffective for use as rescue treatment in patients suffering from severe airway obstruction caused by delayed onset of activity and slightly reduced peak activity compared with albuterol sulfate.[10,20] Salmeterol xinafoate is a chemical analog of albuterol

with an elongated side chain providing a longer duration of action. Salmeterol xinafoate (210 μg) improves pulmonary function by 55% within 60 minutes of administration with efficacy lasting for up to 8 hours, even in severely affected horses.[10,11] Ipratropium bromide is a surface-acting antimuscarinic agent that exhibits little to no systemic absorption (quaternary ammonium structure) from the respiratory or gastrointestinal system. Ipratropium (90–180 μg) improves pulmonary function by 50% within 1 hour, and the duration of the effect is approximately 4 to 6 hours in severely affected patients. Oral clenbuterol (0.8 μg/kg, PO, b.i.d.) is a systemic alternative to the aerosolized, long-acting bronchodilators for management of RAO-affected horses. Clenbuterol is prepared for oral administration as a syrup (Ventipulmin, BIVI). A significant advantage to clenbuterol is a longer duration of action (12 hours). Clenbuterol is approved by the Food and Drug Administration (FDA) in the United States for use in horses with airway constriction. It should be noted that clenbuterol is illegal for use in food-producing animals.[1,2] Dosing protocols for clenbuterol should be followed carefully and in accordance with manufacturer recommendations. Initial therapy at the lower end of the dosing range is generally well tolerated, and incremental dose increases may be tolerated. However, inadvertent initial high-dose therapy (3.2 μg/kg) may result in tachycardia, tremors, sweating, and apparent anxiety. Clenbuterol administration is indicated for temporary smooth muscle airway relaxation in association with airway disease; prolonged therapy is not indicated and may result in adverse effects.

Alternate Bronchodilatory Options

N-butylscopolammonium bromide (NBB; Buscopan) is a quaternary ammonium that serves as a peripherally acting antimuscarinic, anticholinergic agent similar in action to atropine. This formulation is marketed by BIVI as Buscopan for administration to horses. NBB is FDA approved in the United States for use in horses that demonstrate colic signs resulting from gas, spasms, or mild impactions. Recent work has focused on the potential utility of NBB administration for the treatment of marked airway obstruction that may occur with conditions of airway inflammation such as RAO. Current evidence provides support for the use of NBB as an immediate bronchodilator.[429,448] Although tachycardia and reduced gastrointestinal motility are valid considerations, based on the short duration of activity and evidence to support improved ventilatory function it is considered an appropriate therapeutic option when managing equine patients with severe airway obstruction. Additional evidence to support the use of NBB in horses suffering from airway obstruction is supported be a crossover investigation in RAO-affected horses in which atropine and NBB provided similar bronchodilatory effects, yet the systemic effects, such as pupillary dilation and one horse developing colic signs, were only observed following atropine administration.[449] From this study it was concluded that NBB bromide was associated with fewer systemic side effects and is therefore a preferred treatment for reversible airway obstruction in horses. Atropine (0.005–0.01 mg/kg horse, IV) is a rapid and powerful bronchodilator in horses suffering from heaves. Because several adverse effects (ileus, CNS toxicity, tachycardia, increased viscosity of mucous secretions, and impaired mucociliary clearance) may develop following the administration of atropine, use of this agent is recommended as a rescue therapy for severe and life-threatening airway obstruction.

SPAOPD is a condition similar to RAO regarding clinical signs and management; however, a marked difference in disease development involves the triggering aeroallergen involving molds and pollens from pasture grasses. Disease development of SPAOPD is similar with respect to the development of hypersensitivity; however, the antigenic stimulus involves pasture forage pollens that have been recognized in the Gulf Coast states in the United States and in England.[450,451] Weather conditions that favor exacerbation for sensitized horses include hot, humid weather that most commonly occurs in late summer.[452,453] Evidence has demonstrated that specific environmental conditions that contribute to the exacerbation of SPAOPD include not only temperature but also humidity, which affect concentration of fungal spores, seasonal vegetative growth, and pollination of plants in the pasture environment.[453,454]

Bronchodilator and antiinflammatory therapy are recommended in combination with relocation to a clean, low-dust environment. Eliminating or reducing access to an antigen commonly requires a well-ventilated stable environment. Clinical signs are similar to those associated with traditional RAO. The clinical management of SPAOPD involves removal from pasture, whereas in traditional RAO the preferred environment is full-time pasture access. Interestingly, some horses manifest airway obstruction under specific environmental conditions such as traditional RAO in which a closed barn environment favors disease exacerbation, whereas in the southeastern United States a warm humid outdoor environment results in clinical signs of respiratory distress. The particularly challenging component of managing any horse with allergic airway disease is to specifically determine the inciting cause of disease so antigen avoidance can be used. In horses that react to a multitude of environments with clinical signs of airway obstruction, maintaining a horse in a state of consistent disease remission can be particularly challenging. The similarity among disease development and the recognition that SPAOPD may also demonstrate sensitivity to allergens in a confined environment such as hay and straw dust and molds support the suggestion that minimizing these exposures should also be avoided.

INFLAMMATORY AIRWAY DISEASE

Clinical Presentation

IAD (mild to moderate equine asthma[418]) can develop in horses of all ages. In contrast to RAO, clinical signs of IAD are typically subtle, particularly at rest. Horses with IAD tend to be younger horses compared with horses that suffer from RAO, but clinical signs of IAD are dependent on the extent of physiologic exertion. The presenting complaint may include poor performance, particularly at exertion, with occasional cough. Frequency of cough in horses with IAD is variable. In some reports cough has been used as a measure of inclusion criteria,[455] which complicates the determination of the overall frequency of cough in horses with confirmed IAD.[419] At rest, horses with IAD do not demonstrate any discernable evidence of respiratory dysfunction. Pulmonary inflammation in horses that suffer from IAD is mild, requiring advanced pulmonary function testing to detect alteration in gas exchange mechanisms. However, similar to RAO, horses with IAD typically have airway mucus accumulation, which can be marked in severe cases. Current recommendations have focused on

the identification of lower airway cytologic characteristics that define the inflammatory milieu of the lower airway in combination with pulmonary function testing.[418] Collectively these criteria provide the clinician with direct evidence with respect to the origin of reduced exercise performance.[32,456-458] Different phenotypes of airway inflammation have been described for horses with IAD and have apparent correlation with disease severity. Mast cell inflammation has been observed in association with airway hyperreactivity[459] and subclinical airway obstruction, whereas airway neutrophilia has been observed in association with cough and airway mucus accumulation.[418,459]

Diagnosis

Diagnosis of IAD (mild to moderate equine asthma) is based on clinical signs, airway inflammation with excess mucus, abnormal lower airway cytologic evaluation, or abnormal pulmonary function. It must be confirmed that horses with IAD do not suffer from RAO or infectious pulmonary disease. Identification of clinical signs consistent with lower airway inflammation are characterized by reduced athletic performance and mild cough and airway mucus identified on endoscopy (Table 8.9). Other consideration should be given to causes for poor performance such as upper airway disease or musculoskeletal disease or injury.

BALF cytology is the diagnostic test sampling procedure of choice for a confirmatory diagnosis of IAD. Although the cytologic profile of BALF analysis in horses with RAO is markedly neutrophilic, horses with IAD typically have a cytologic profile characterized by mild to moderate increase in neutrophil, eosinophil, and/or mast cell percentages.[418,457,460] Variability among sampling techniques and instrumentation prevents the application of universal cutoff limits for the classification of IAD. Based on the availably body of literature, when 250 mL of sterile saline is infused the approximate findings should include a total cell count of ≤530 cell/μL, neutrophils ≤5%, eosinophils ≤1%, and metachromatic (mast) cells ≤2%. When interpretation of cytologic values are based on total percentages, regardless of volume of fluid instilled, findings consistent with IAD include neutrophils >10%, mast cells >5%, and eosinophils >5%.[418,460-463] Collectively the interpretation of BALF cytology needs to be based on the patient history, clinical signs, physical examination, and findings on airway endoscopic examination in combination with the cytologic analysis.

It is important to note that the interpretation of cytologic findings should be carefully considered in association with the patient. It has been long recognized that age, vocation, and environment can play a role regarding cellular changes in the respiratory tract. In a recent study young horses transitioning to a race-training environment were recognized to have abnormal BALF cytologic analysis after 4 weeks in race training.[433] Although the horses were not tested for pulmonary function changes, the actual clinical implications for these cellular changes cannot be made. This investigation highlights the importance of environment, particularly in young horses entering race training that may not have any measurable changes in training performance but may have cytologic changes occurring in their lower airways. In other words, looking at lower airway BALF cytology independent of other factors may lead to overinterpretation of clinical association. Sample collection is also an important consideration, which has been well reported in the literature. When examination of a suspect IAD horse is performed, sample collection must be restricted to the use of BALF analysis. Although in some settings collection of a transtracheal aspirate may provide greater ease and efficiency of collection, based on the lack of correlation between TTW and BALF cytology,[426,464,465] TTW sample collection for cytologic analysis for the diagnosis of IAD is not recommended.[418]

Additional diagnostics that may be completed for a horse with suspect IAD may include complete hematologic and serum chemistry profile analysis, pulmonary function testing, and thoracic imaging to include ultrasound and radiography. Hematologic changes are rarely abnormal in horses with IAD with the exception of horses suffering from eosinophilic IAD, which may also be associated with peripheral eosinophilia,[466] particularly if the horse is suffering from idiopathic eosinophilic pneumonia, although circulating changes in eosinophilic concentrations are not always present in horses with airway eosinophilia.[433] Sensitive pulmonary function testing that includes forced expiration and impulse oscillometry provides evidence that horses with IAD suffer from airway obstruction.[33,460] Because advanced pulmonary function testing requires specialized instrumentation and training, diagnostic testing is limited to specialty services that provide such testing. Reproducible characteristics of eosinophilic and mast cell–associated IAD include clinical evidence of airway hyperresponsiveness to airway particles. Clinical manifestation of airway reactivity includes bronchoconstriction, airway reactivity, and cough, which represent the physiologic response to irritants that alter pulmonary homeostasis, resulting in reduced pulmonary function, particularly at speed. Based on the recognition that there are similarities and differences between IAD and RAO, clinically practical observations can be made to aid the clinicianin discriminating between these two airway disorders.[418] Specifically, a horse with evidence of airway disease can be placed in a challenge environment of moldy hay and observed for evidence of respiratory distress or difficulty. Although horses that suffer from IAD will have cytologic changes and increased mucous production in their lower airways, they will not demonstrate evidence of respiratory distress. In contrast, a horse that suffers from severe equine asthma will demonstrate increased expiratory effort, cough, and nostril flare when placed in the challenge environment.

TABLE **8.9 Tracheal Mucus Grading Scale**[1,2]

Grade	Mucus Accumulation
0	None
1	Multiple small
2	Moderate larger, non-confluent
3	Marked mucus
	Marked - confluent
	Marked - stream forming
4	Large pool-forming
5	Extreme, profuse amounts

Treatment

Clinical management of horses suffering from IAD has some similarities to the management of horses with RAO. Interestingly, published evidence to support therapeutic protocols are more limited when demonstrated efficacy for the management of IAD is compared with the efficacy of therapy for RAO.[418,419] As stated, IAD is a milder condition; horses do not demonstrate respiratory distress and appear normal at rest. For these reasons disease characterization can be more challenging; therefore, objective measures that define disease outcome and response to therapy are limited. Nonetheless, clinical management is aimed at reducing pulmonary inflammation through the use of antiinflammatory therapy and environmental management.

Once the diagnosis of IAD has been established, antiinflammatory therapy combined with environmental management[467] is aimed at reducing pulmonary cellular infiltrates and airway hyperresponsiveness.[467]

Treatment goals of horses suffering from IAD include immediate control of horses that demonstrate evidence of bronchoconstriction and cough that impairs performance, reduced mucous production and associated airway obstruction, and sustained pulmonary quiescence to allow for continued athletic performance. Despite the limited evidence to support the efficacy of corticosteroids for improvement of IAD in horses, anecdotal reports support recommendations that antiinflammatory therapy is an important component of therapy in horses with performance limitation caused by IAD. Systemically administered corticosteroids have a profound and global effect on inflammation and associated eicosanoid expression. The decision for route of drug delivery for systemically administered drug compared with aerosolized medication is based on factors that include severity of disease and financial availability, because aerosolized medications can be cost prohibitive in some settings. Additionally, potential consequences associated with corticosteroid administration must be factored into the decision-making process. Systemic responses following corticosteroid administration include some degree of immunosuppression, altered protein synthesis, and reduced adrenal responsiveness. Unpredictable idiosyncratic reactions may have deleterious patient effects, such as the development of laminitis.

Using RAO as a model to determine drug efficacy, several studies have been designed to assess drug efficacy based on clinical signs, BALF cytology, and pulmonary function. Systemically administered dexamethasone appears to provide superior antiinflammatory effects as evidenced by improvement in pulmonary cellular infiltrate compared with prednisolone[468] in an antigen-controlled investigation. In an independent investigation aimed at determining drug efficacy in an antigen-rich environment, oral prednisolone and dexamethasone were compared with improved clinical signs observed in all treated horses; however, dexamethasone-treated horses demonstrated improvement in pulmonary function. Although prednisolone has historically been a treatment of choice because of the ease of oral administration, response to therapy has not been consistently observed and likely relates to variability in bioavailability among horses. Adverse events appear to be more common with systemically administered triamcinolone, and for this reason this agent is not recommended for the management of airway inflammation. An investigation that demonstrated similar clinical efficacy when dexamethasone was compared with isoflupredone also demonstrated hypokalemia, making this a less than ideal drug selection as well.[469]

Use of aerosolized corticosteroids has become commonplace for the management of equine patients with lower airway inflammation (Table 8.10). In most clinical settings when treating a patient for airway inflammation associated with IAD (similar to the management of RAO), in all but the most mild of cases initial therapy will include systemically administered medication; once airway inflammation is believed to be reduced drug administration will typically include aerosolized therapy. As stated, finances may impact the ability of the clinician to use the airway for drug delivery. Options for the administration of synthetic corticosteroid delivery are beclomethasone and fluticasone. Available spacer devices include the AeroHippus and Equine Haler devices, with drug delivery and efficacy among the two devices being similar.[444]

Efficacy of aerosolized corticosteroid therapy in horses with RAO was evidenced by the administration of fluticasone propionate (2000 µg q 12 h) with improvement of clinical signs and pulmonary function without evidence of impairment of immune system function.[446] Beclomethasone when administered at moderate dosages (≥500 µg) results in adrenosuppression.[470] Similarly, fluticasone (1500 µg b.i.d.) administration

attenuated serum cortisol concentrations following 1 week of therapy.[471] Notably, there are no reports that describe clinical manifestation of Addisonian crisis or evidence of adrenal dysfunction in horses following treatment, but it should be advised that because of systemic effects judicious drug administration should implemented.

Current protocol recommendations from a recent review suggest that treatment is ideally initiated with systemically administered corticosteroid therapy using a tapering dose protocol for approximately 4 weeks.[419] Drug dosages are typically reduced at 25% increments at weekly intervals or as clinical response to therapy is observed. Clinical improvement of

IAD can subjectively be difficult to determine because clinical signs are typically mild, particularly at rest. Therefore, a protocol aimed at systemically administered corticosteroids tapered over 4 weeks and followed by aerosolized therapy is a rational approach aimed at improved pulmonary inflammation. Transition from systemically administered medications to fluticasone or beclomethasone is determined by disease severity and response to therapy. Some individuals apparently respond more favorably to one preparation over another, and this factor should be considered with drug selection and follow-up examination to determine response to therapy.

The overall goal of therapy for horses suffering from airway hyperresponsiveness is the reduction in pulmonary inflammation as well as attenuation of tissue airway remodeling, which is a consequence of chronic airway inflammation. Application of environmental modification used in combination with anti-inflammatory therapy with fluticasone in combination will provide the greatest likelihood of achieving these therapeutic goals.

Bronchodilator therapy is aimed at improving airway mechanics and airflow, particularly with severe airway obstruction. Therapeutic agents available to provide benefit include β-adrenergic type 2 receptor agonists and parasympatholytic agents. Among the β-adrenergic receptor type 2 agonists, aerosolized albuterol, and oral clenbuterol syrup (Ventipulmin, BIVI) are the agents of preference. Among drugs that target muscarinic receptors, aerosolized ipratropium or IV NBB[429,449] (Buscopan, BIVI) are the agents of preference. Atropine used at low dosages provides bronchodilation but carries the potential risk of iatrogenically induced ileus, and for that reason it is not recommended for routine use. Albuterol is indicated for immediate rescue treatment of bronchoconstriction, whereas clenbuterol is indicated for prolonged bronchodilation. Chronically administered clenbuterol (0.8 μg/kg, PO, b.i.d.) was reported to lead to tachyphylaxis evidenced by an investigation that determined 21 days of clenbuterol therapy resulted in increased airway hypersensitivity and impaired bronchodilatory activity.[472] As stated, clenbuterol administration is indicated for temporary bronchodilation; prolonged therapy is not recommended.

Aerosolized albuterol is indicated for bronchoconstriction observed in horses with severe airway disease. Although rescue therapy is not commonly required for the management of patients with IAD, in some instances airway obstruction may benefit from bronchodilatory therapy. In addition to bronchodilation, therapeutic strategies must also incorporate corticosteroid therapy and environmental modification to reduce dust and aeroallergen materials. Albuterol is generally cost-effective and is readily available for use in equine patients. Uncommon events such as paradoxical bronchoconstriction may result in patient responsiveness to the racemic mixture of albuterol preparations. In instances where an alternate approach is desired, the (R)-enantiomer can be administered solely in the form of levalbuterol. Although levalbuterol has historically been cost prohibitive for use in equine patients, current costs have come down considerably. Longer acting β_2-adrenergic agonist therapy is available in the form of salmeterol. With a modification of molecular design, this agonist can sustain longer activity compared with albuterol. Frequency of administration is approximately every 8 hours.[473] Additional classes of aerosolized bronchodilator therapy may provide added benefit for patients that have diminished sensitivity to β_2-adrenergic receptor agonists. Ipratropium is a surface-acting parasympatholytic agent that has similar activity to atropine. Low to negligible bioavailability provides the advantage of not inducing unwanted side effects of systemically administered parasympatholytic agents. Horses suffering from mast cell IAD may benefit from the administration of sodium cromoglycate, which blocks calcium channels, resulting in mast cell stabilization rather than degranulation, inhibiting the release of histamine and tryptase, which potentiate leukotriene and PGE expression and bronchoconstriction. Client compliance is essential because the drug must be administered for 1 to 2 weeks to produce clinical benefit. For some caregivers this therapeutic protocol is not practical.

Although mild to moderate equine asthma is not nearly as debilitating as severe equine asthma, consideration must be made for environmental influences that may potentiate airway reactivity and hyperresponsiveness. Low-dust environments and avoidance of any feeding from hay nets or elevated mangers should be practiced. Areas in which dust is present should be wet down before cleaning and whenever possible, horses removed from the environment before cleaning. Use low-dust bedding material, avoid stabling in an area with an indoor arena, and avoid overhead storage of hay or straw.

EXERCISE-INDUCED PULMONARY HEMORRHAGE

Definition

EIPH is defined as the presence of blood in the airways following strenuous exercise. Hemorrhage originates from the pulmonary capillary vasculature into the alveolar spaces. The predominant regions of hemorrhage are localized in the caudodorsal lung fields. At the microscopic level, tissue changes include edema, pulmonary capillary hemorrhage, and alveolar hemorrhage.

Blood may be identified by gross examination with airway tracheobronchoscopy or by the identification of erythrocytes or hemosiderophages on tracheal or BAL cytologic examination. EIPH may result in occult hemorrhage, in which blood is not obviously visible on examination but can be identified with airway endoscopy or may be evidenced by epistaxis following exertional exercise. A recent systematic review was compiled on this subject and published as an ACVIM consensus statement and serves as a valuable reference on this particular disease process.[474]

Epidemiology

EIPH is a disease the affects all disciplines of horses that work at intensity. The characterization of the frequency of EIPH among performance horses is somewhat hindered by the use of different criteria to define the disease. When the diagnosis was made with tracheobronchoscopy within 2 hours of racing, approximately 43% to 75% of racing Thoroughbreds were identified with blood within the tracheal lumen.[475-478] However, when horses have been repeatedly examined the frequency of disease increases to 85%.[478,479] The dramatic changes in pulmonary pressure are a direct effect of cardiac output generated during the high-intensity exercise of athletic horses. Performance events other than racing have variable prevalence of disease ranging from 10% to 70%, with the greatest frequency in horses that work at speed such as racing Quarter Horses and those with the lowest frequency on horses that work at lesser intensity such as pleasure ponies. The relevance of use is

associated with the intensity of exercise rather than the duration of work. In one investigation, polo ponies were examined for the presence of tracheal hemorrhage, with approximately 11% to 46% of the horses demonstrating evidence of pulmonary hemorrhage.[480] The primary lesion associated with pulmonary hemorrhage is pulmonary capillary stress failure. More severe grades (3–4) of EIPH are associated with reduced racing career length.

Pathogenesis

The pathophysiologic mechanism leading to stress failure is a result of high pulmonary capillary pressure and very low inspiratory alveolar pressures that occur during intense exercise.[481] Consequently, the pulmonary capillary transmural pressure is extreme at times of intense, strenuous exercise leading to tissue failure and hemorrhage. Pulmonary capillary pressure at rest is very low, yet with high-intensity exercise pressures may exceed 95 mm Hg during maximal exercise.[482,483] The critical point at which stress failure occurs appears to be when capillary pressure exceeds 75 to 100 mm Hg. There is good indirect evidence that these numbers are exceeded by most galloping horses.[484] Ultrastructural pulmonary capillary stress failure and changes have been identified in horses tested using a treadmill challenge and in a perfused lung model system. Characteristic changes that are identified in association with EIPH include disruption of the capillary endothelium and alveolar epithelium, with resulting erythrocytes within the alveoli and pulmonary interstitial spaces and subsequent erythrocytes, platelets, and macrophages in the region of tissue failure. A characteristic change occurring in some horses that suffer from EIPH involves the development of venoocclusive remodeling associated with pulmonary veins. This remodeling takes place in the intralobar pulmonary veins with the presence of collagen deposition, smooth muscle hypertrophy, and intimal hyperplasia within the pulmonary veins. The end result of this venoocclusive remodeling is increased stiffness with reduced vascular compliance. It is believed that these changes are the physiologic consequence to repeated bouts of strenuous exercise. The pathologic effect on the horse with continued high-intensity exercise is that with increased cardiac output and continued high pressure from the pulmonary arterial vasculature, tissue failure can continue and potentially worsen over time, leading to propagation of tissue failure and hemorrhage into the alveolar spaces and surrounding interstitium. Evidence to support this postulated series of events is in part a reflection of the finding that racehorses that have suffered from EIPH can have increased fibrosis in their caudodorsal lung fields.[485] The specific amount of exercise required to lead to these tissue changes has not been defined. The complete understanding of the impact that venoocclusive remodeling has on the development and propagation of EIPH continues to be under investigation.

Among the historical proposed risk factors for the development of EIPH, lower airway inflammation has been suggested to play a role in disease development. The suggested pathway has included persistent pulmonary inflammation with associated bronchoconstriction leading to increased negative alveolar pressure that would further potentiate pulmonary hemorrhage.[486,487] More recent investigations, however, do not support this suggestion,[488] and airway inflammation as a proposed mechanism for EIPH disease development is not supported. Although it is clear that following an episode of pulmonary hemorrhage there is an indication and recruitment for leukocyte infiltration, specifically macrophages that will provide the phagocytic capacity needed for clearance of erythrocytic debris, there is no evidence to demonstrate that this inflammation was the proximal mediator in the cascade that induced the primary event of hemorrhage. Instillation of whole blood into the airways will consistently induce inflammation and associated alveolar macrophage activation to clear erythrocyte byproducts evidenced by the presence of hemosiderophages, which will clear the region of hemorrhage within 14 days.[489,490] Further supportive evidence for the lack of primary inflammation serving as an initiating factor for the development of EIPH is based on the recognition that when a model system using the instillation of blood to determine clearance mechanisms was investigated, not only was there efficient and effective removal of blood, there were no caudodorsal pulmonary lesions characteristic of horses with EIPH.[491,492] Although some investigations have examined the role of experimentally induced airway inflammation with the propensity for pulmonary hemorrhage to occur, there is insufficient evidence from larger scale investigations that have examined racehorses to make a direct correlation between cough as a measure of inflammation and the presence of hemosiderophages[493] or between endoscopic scoring of tracheal mucus and tracheal hemorrhage.[494] Collectively, when considering pathogenic events that my lead a horse to experience pulmonary hemorrhage with intense exercise, the current understanding is that the level of evidence to support inflammation of the airways or pulmonary parenchyma as a cause of EIPH is low.[474]

Clinical Signs

Identification of a horse that has suffered a bout of EIPH will most consistently be determined with airway endoscopy. In a small proportion of racehorses (approximately 5%) epistaxis may be observed.[475,476,495,496] Physical examination of horses with EIPH is within normal limits for most parameters evaluated; in one small-scale investigation (n = 10) there were changes identified with thoracic percussion in 50% of the horses with EIPH but no auscultable abnormalities in the caudodorsal lung fields.[497] The recent systematic review provided that there was no evidence of changes in examination parameters, such as changes in respiratory rate, respiratory effort, or evidence of distress, or changes in behavior to provide clinical evidence of EIPH following exercise. The quality of evidence suggesting that consistent clinical abnormalities can be detected in horses with EIPH (with the exception of epistaxis following exercise) is also low.[474]

Although epistaxis is an uncommon finding, when present it is an indication of the severity of hemorrhage. The clinician may consider differential possibilities for the presence of epistaxis following exercise, but current evidence supports the suggestion that when epistaxis is observed soon after exercise, EIPH is the likely cause.[474] Several retrospective studies have further characterized the frequency of epistaxis among performance horses with EIPH. In Japan, when horses were examined 30 minutes following race completion that included both flat and steeplechase racehorses, epistaxis was identified in 0.13% of the Thoroughbreds examined and 0.10% of Anglo-Arabs.[498] A similar frequency of epistaxis has been identified in South African Thoroughbred racehorses.[499] Once a horse suffers from epistaxis, the recurrence rate was reported to be 13%, supporting the persistent nature of the disease. In one study, there was an apparent association with horses that were

TABLE **8.11 Grading Scale for EIPH Endoscopic Examination**[1]

0	No blood in pharynx, larynx or anywhere along the tracheal lumen
1	Few specs of blood, fever than 2 short areas
2	Specs throughout, < 10% tracheal surface stream
3	Multiple distinct streams, covers > 30% tracheal surface, but not pooling at thoracic inlet
4	Multiple coalescing streams, covers > 90% tracheal surface with obvious pooling at thoracic inlet

1. Hinchcliff KW, Jackson MA, Brown JA, et al., Tracheobronchoscopic assessment of exercise-induced pulmonary hemorrhage in horses, *Am J Vet Res.* 2005;66:596-598.

older and that raced over jumps. The evidence to support an age-associated phenomenon is lacking. Although age may play a role with the development of disease, the number of races that horses have competed in needs to be recognized because this directly impacts the number of high-intensity events that a horse has endured and therefore, the degree of pulmonary vasculature remodeling that exists.

Some early indicators suggested that acute death may be associated with EIPH in racehorses. However, the overall frequency of EIPH is notably high among racehorses at 85% or higher in some populations. In contrast, the development of acute death among racehorses is remarkably low at 0.08 to 0.29 horses per 1000 starts.[500] Although some reports suggest that pulmonary hemorrhage may account for up to 35% of acute deaths in which postmortem was successful with the confirmatory cause of death,[501] other reports do not consistently provide evidence to support this finding. Currently, the level of evidence to support that EIPH is causally associated with acute death in racehorses is low.[474]

The overall influence of EIPH on the performance level of horses has long been questioned. Although the standards for athletic performance differ among breeds, when racehorses are examined for their racing career longevity the evidence demonstrates that horses with low to moderate (grades 1–3/4) level EIPH do not have shortened race careers.[502] In contrast, racehorses with severe EIPH are likely to have shortened race careers.[474] When considering the impact that EPIH has on racing performance using finishing position as a measure of racing performance,[477,503] horses that are EIPH grade 1 or less (no blood) as defined by endoscopic examination are more likely to win or at least finish in the top three finishing positions.[504] With the currently available and analyzed evidence, the consensus is that horses with more severe EIPH will have inferior performance compared with horses that have minimal to no pulmonary hemorrhage.[474] Horses with more severe forms of EIPH have reduced career utility compared with horses that have lower levels of hemorrhage associated with EIPH.

Diagnosis

The diagnosis of EIPH is based on the identification of hemorrhage within the airways. Although tracheobronchial endoscopy can be performed between 30 and 90 minutes following exertional exercise and will identify frank hemorrhage in most EIPH-affected horses, BAL remains a valuable diagnostic technique. An endoscopic scoring system reflecting the presence of tracheal blood following exercise has been established (Table 8.11) and has consistent interpretation among observers.[477] Commonly, tracheobronchoscopic examination following intense exercise will provide confirmatory evidence of pulmonary hemorrhage. However, the absence of blood does not eliminate the possibility of pulmonary hemorrhage. The presence of hemorrhage will be evident following exercise, but the clearance of erythrocyte constituents may not be complete for up to 14 days. Because of this, BAL can be valuable for the diagnosis of EIPH.

BAL cytologic assessment can aid with the diagnosis of EIPH. Although total nucleated cell counts in BALF are similar among horses in race training and yearlings that have not entered training,[505] erythrocytes and hemosiderophages in the BALF are greater in horses in training compared with horses not being trained. Although the identification of erythrocytes within the BALF is used to provide the diagnosis of EIPH, variability among samples has led to the concern that enumeration of BALF erythrocytes alone may not provide accurate evidence to allow the clinician to classify the severity of EIPH.[506] When horses confirmed with EIPH are compared with healthy horses, total hemosiderin score (cytoplasmic calculation of iron within alveolar macrophages) correlates with EIPH status. Total hemosiderin score >75 has a reported sensitivity and specificity of 94% and 88%, respectively.[507] Notably, hemosiderin scores should be carefully interpreted because pulmonary hemorrhage, regardless of etiology, such as traumatic pneumonia/pleuropneumonia or abscess formation will increase the hemosiderin score.

Thoracic radiographs obtained from horses with EIPH will have characteristic changes in the caudodorsal pulmonary fields. Radiographic changes may include alveolar or mixed interstitial opacities in the caudodorsal lung fields. Clinical management of EIPH-affected horses is unlikely to be impacted by the identification of radiographic changes. Lesions can be identified with radiography and have been consistently identified in horses at postmortem.

Treatment

Furosemide is the recommended therapy for the prophylaxis of hemorrhage associated with EIPH. Although hemorrhage is not eliminated, it is evident that furosemide administration (0.5–1.0 mg/kg, IV) approximately 4 hours before exertion reduces the severity of pulmonary hemorrhage in racehorses.[477] Efficacy of furosemide to reduce the severity of pulmonary hemorrhage is believed to be an effect of reduced pulmonary arterial pressure and left atrial (pulmonary wedge) pressures.[508-515] The effect of lowering pulmonary arterial pressure is a reduction in capillary and transmural pressure during exercise, which reduces the impact on the capillary alveolar interface and associated tissue stress failure and disruption. There is strong evidence that furosemide is an effective mitigating therapy for horses that suffer from EIPH.

In addition to the administration of furosemide as a prophylactic treatment for the attenuation of pulmonary hemorrhage associated with EIPH, additional therapeutic agents have been tested for their efficacy as a prophylactic agent or treatment for pulmonary hemorrhage. Agents have included antiinflammatory therapeutics, bronchodilators, phosphodiesterase inhibitors, procoagulants (synthetic and herbal remedies), and application of nasal dilator strips.

Two independent investigations aimed to determine the effectiveness of aminocaproic acid for the treatment of EIPH. Both were randomized, controlled studies that used a treadmill model to induce high-intensity exercise. These

investigations failed to identify the difference between aminocaproic acid administration and saline placebo administration 2 to 4 hours before high-intensity exercise. No difference in BALF erythrocyte number was identified between treatment groups. These were low-powered investigations based on sample size and methods applied for outcome assessment.[516,517] There is insufficient evidence to support the recommendation for the use of aminocaproic acid in horses with EIPH.[474] Alternate agents that have been considered for the treatment of EIPH include bronchodilators for the potential of subclinical bronchoconstriction that may further reduce negative alveolar pressure. Clenbuterol administered independently (intravenously) or in combination with furosemide failed to influence hemodynamics among study subjects.[508,518] Additionally, clenbuterol was investigated for the potential beneficial effect of enhancing pulmonary clearance of red blood cell debris following experimental inoculation, but no benefit was observed in clenbuterol-treated horses.[519] Atropine and ipratropium have also been investigated for their potential benefit in EIPH patients, but no clear benefit has been identified.[520] Based on these investigations without any demonstrated benefit, bronchodilators are not recommended for the treatment of EIPH-affected horses. Among the potential treatments that may provide benefit, intuitively corticosteroids have been reasonably considered for the therapeutic benefit of reduced potential inflammation and subsequent remodeling that may contribute to the development of lower airway stiffness. Limited numbers of studies have been undertaken to test dexamethasone, beclomethasone, or oral prednisolone, but among the outcomes examined there was no evidence of benefit or improvement of EIPH severity.[519,521] Nonsteroidal agents have similarly been investigated in small-scale treadmill investigations; neither phenylbutazone with furosemide nor flunixin meglumine has demonstrated any improvement with the presence of blood on endoscopic examination.[514,522] Vasodilator therapy and modification of erythrocyte rheologic properties have been postulated to potentially influence the severity of EIPH, resulting in two treadmill investigations testing the efficacy of pentoxifylline as a potential treatment strategy for EIPH. When administered alone or in combination with furosemide there was no evidence of change in pulmonary hemodynamics.[511,523] Using nasal dilator strips for the prevention of pulmonary hemorrhage has been tested in several investigations. One treadmill study found that there was no benefit from using nasal dilator strips on the amount of blood in the airways following exercise. Four additional investigations with a limited number of horses revealed that there was a reduction in the number of BALF erythrocytes following exercise with the application of nasal strips.[524-527] These data show low-quality evidence to support the efficacy of nasal dilator strips for the prevention of EIPH.[474]

TUMORS OF THE RESPIRATORY SYSTEM

Equine patients suffering from pulmonary neoplasia present with nonspecific signs that may not clearly indicate the primary disease process. Careful history and physical examination combined with thorough diagnostic assessment will enable the clinician to establish the diagnosis of pulmonary neoplasia.

Primary Thoracic Neoplasia

Primary lung tumors are less common than metastatic pulmonary neoplasms and constitute less than 10% of all pulmonary tumors.[528] Granular cell tumor is the most frequently reported primary pulmonary tumor of horses.[529] Despite being the most common type, only approximately 30 cases have been reported in the literature.[530-537] These tumors have been described as myoblastomas and appear to originate from Schwann cells.[538] They occur as single or multiple masses adjacent to the bronchi and bronchioles and are locally invasive with no reports of metastasis. The mass typically extends into a large-caliber airway, resulting in partial or complete occlusion of the lumen. Although some authors suggest an increased frequency for the right hemithorax, there is no apparent predisposition to right-sided or left-sided lesions.[537] Bilateral disease is uncommon and occurs in less than 20% of the case reports. There is no breed predilection, yet mares more commonly develop these tumors. Despite their size and propensity to occlude large airways, granular cell tumors may result in minimal clinical signs and represent an incidental necropsy finding in some horses.

In clinically affected horses, the presenting complaints are chronic cough, exercise intolerance, tachypnea, and weight loss. Horses with advanced disease demonstrate an increased effort of respiration during expiration. Depending on tumor size, auscultation may reveal decreased breath sounds over one hemithorax. Based on age (mean age at onset = 13 years old) and clinical signs, horses with granular cell tumor are often assigned a presumptive diagnosis of recurrent airway disease (heaves).[537] Failure to respond to appropriate therapy results in further diagnostic testing. Focal pneumonia may develop in the pulmonary parenchyma distal to the mass because of poor clearance of respiratory secretions and inhaled particulate material. Horses with focal pneumonia present with fever, depression, abnormal lung sounds, and leukocytosis, in addition to coughing. There are no reports of pleural effusion, epistaxis, or mediastinal lymphadenopathy in horses with granular cell tumor. Hypertrophic osteopathy (HO) has been reported as a paraneoplastic complication of granular cell tumor in some horses.[535,539-541]

Routine blood work provides little evidence to advance the diagnosis of granular cell tumor. Thoracic radiography identifies a single, large mass or multiple pulmonary masses near or caudal to the hilus.[529] Evaluation of magnification in left and right radiographic projections can identify the hemithorax affected by the tumor. Rarely, the tumor cannot be visualized via thoracic radiography. In some cases, the mass may be obscured by focal pneumonic lung. Focal pneumonia in an atypical pulmonary location (i.e., central or dorsal lung fields) should trigger a suspicion of tumor or inhaled foreign body. Using a tracheobronchial map of the lung,[542] the approximate location of the tumor in the pulmonary tree can be determined for endoscopic examination.

There is no report of visualization of the tumor mass via ultrasonographic examination; however, decreased movement of the pleural surface over the affected hemithorax has been reported in horses with large granular cell masses.[537]

Gross assessment of granular cell tumors reveals them to be smooth pink to white in color and occludes or nearly occludes a large-caliber airway. A mainstem bronchus is the most commonly affected airway.[543] Biopsy confirmation is difficult and may not be necessary because the endoscopic appearance of the tumor is distinctive. The external surface of the mass consists of normal respiratory epithelium; therefore, a

biopsy sample obtained via endoscopy may be non-diagnostic because of insufficient size and depth.[537,544] To obtain a larger tissue sample, with a greater chance of achieving a diagnosis, a biopsy instrument (such as uterine biopsy forceps) can be passed through a tracheotomy incision at the level of the thoracic inlet.[544]

On histopathological examination, neoplastic cells are benign and appear rounded to polyhedral with hyperchromatic nuclei, numerous eosinophilic cytoplasmic granules, and indistinct cytoplasmic margins.[537,543] Histochemical and immunohistochemical staining results of these tumors are well described and suggest they are composed primarily of neural crest cells, which are likely myelinating Schwann cells.[538] Morphologic features of the equine pulmonary granular cell tumors are similar to those of endobronchial granular cell tumors of humans.[538,543] In other species (dogs, cats, and humans), granular cell tumors are reported to occur at many other sites along with the thoracic cavity, including the oral cavity and CNS.

Granular cell tumors are presumably slow growing and may be an incidental finding at postmortem examinations. Conservative treatment may produce an acceptable clinical outcome for years in horses with stable clinical signs.[537] The presenting complaint for the horse is indicative of focal pneumonia and includes cough, fever, and depression. The granular cell tumor obscured a third-generation bronchus and compressed only a small portion of pulmonary parenchyma. The mare was treated with a 2-week course of broad-spectrum antibiotics and managed for several years with minimal clinical signs. Ohnesorge et al.[545] removed the intraluminal portion of a granular cell tumor mass via transendoscopic electrosurgery. The remaining tumor surface was irradiated using an Nd-YAG laser to coagulate and kill residual tumor cells. In most cases, the tumor observed in the airway represents only a small proportion of the total tumor mass. Horses with large tumor masses require more aggressive therapy. Facemire et al.[544] removed the entire right lung, which was affected by multiple large masses. In the reports by Ohnesorge et al.[545] and Facemire et al.,[544] there was no tumor recurrence after a 2-year period of follow-up.

Necropsy examination reveals a single large mass or, more commonly, a large mass with multiple small nodular masses, which compress the surrounding parenchyma and invade the lumen of a large airway. There are no reports of metastasis to other organs, primary neoplasia originating from other sites, metastasis to regional lymph nodes, or invasion of nonpulmonary tissue.[529]

Thymic Tumors

Thymic tumors are classified as benign or metastatic, based on evidence of tissue invasiveness, even though they uniformly appear benign histologically. These tumors are derived from epithelial reticular cells of the thymus. Tumor classification has historically included those with a lymphocytic component, epithelial, or mixed composition. More recently, the World Health Organization (WHO) has provided classification recommendations to include A, AB, B1, B2, and B3.[546] The equine case report that used this classification scheme describes a type A tumor characterized by the proliferation of spindle cells without nuclear atypia that contain no more than a few nonneoplastic lymphocytes and inconspicuous nuclei. [547] Thymic tumors are rare in horses. In an original report of two cases, they were described as incidental postmortem findings without evidence of metastasis.[548]

Malignant thymoma has rarely been reported to affect horses.[499,547,549] A mediastinal mass, associated lymphadenopathy, and marked pericardial involvement was reported in one case.[499] In addition to cranial thoracic disease, the affected Percheron mare had evidence of pulmonary lymph node involvement, extensive parenchymal pulmonary disease, and abdominal and retroperitoneal lesions. A separate report described a mixed-breed mare affected by a squamous cell thymoma that demonstrated a markedly more aggressive nature.[549] This latter report described the lesions to extend from the intermandibular space to the thoracic inlet. Postmortem examination revealed the mass to involve the mediastinum and pericardial sac. Pulmonary nodules were diffusely present and confirmed on histopathology.

A recent report describes an 18-year-old Tennessee Walking Horse that suffered from acute death during a trail ride.[547] Postmortem examination revealed that the pleural cavity and pericardial sac contained a combined volume of 300 to 500 mL of serosanguineous fluid. A large mass was found to occupy the cranial thoracic cavity and was adherent to the thoracic wall. The architecture of the right atrium was significantly distorted, which also involved the tricuspid valve. Histopathological evaluation of the mass revealed few characteristics of neoplasia consistent with previous reports of thymic tumors in horses. This tumor was classified in accordance with the WHO classification system as a type A thymoma with proliferation of spindle-shaped cells with oval to elongated nuclei, lack of nuclear atypia, and a lack of neoplastic lymphocytes with inconspicuous nuclei. A predominant feature of this neoplasm and the findings in this reported case is the lack of a neoplastic nature identified on histopathology, yet there was aggressive behavior of the tumor in the host. In the reported case, cardiac invasion was attributed to lymphatic drainage or direct local invasion, yet hematogenous spread was also considered a possibility.[547]

Other Tumor Types

Additional primary thoracic neoplasms originate from various pulmonary tissues and are primarily reported as single case reports: pulmonary and bronchial carcinoma and adenocarcinoma,[550-554] bronchogenic squamous cell carcinoma,[555] bronchial myxoma,[556] pulmonary chondrosarcoma,[557] pulmonary leiomyosarcoma,[558] and pleuropulmonary blastoma.[559]

Clinical signs of primary pulmonary neoplasms are dependent on the tumor type and location. Chronic cough, weight loss, anorexia, fever, and respiratory difficulty are common clinical findings in horses with pulmonary neoplasia regardless of the tissue of origin. Ventral edema, pleural effusion, and epistaxis are not unusual in horses with pulmonary neoplasia. Most case reports involve aged horses (>12 years of age), although pleuropulmonary blastoma has been reported in a neonate and a young adult horse.[559] Similar to humans, this tumor is characterized by mixed epithelial and mesenchymal elements and aggressive malignancy. The clinical presentation of pulmonary leiomyosarcoma is similar to granular cell tumor, with the exception of the presence of epistaxis.[558]

Mesothelioma is a rare primary pleural tumor arising from the mesothelium of the pleura, pericardium, and peritoneum. In humans, this malignancy is associated with asbestos exposure. The clinical presentation in horses includes weight loss, respiratory difficulty, and large-volume pleural effusion.

Differentiation of neoplastic mesothelial cells from reactive mesothelial cells can be challenging based on cytologic examination of pleural effusion. Ultrasonographically, the tumor is observed as multiple small nodules on a thick serosal surface, and pleural biopsy is diagnostic. There is no treatment and the prognosis is grave.[560-567]

Most cases of primary thoracic neoplasia have an extended history of cough and nonspecific signs of weight loss and anorexia.[529] The most common first-opinion diagnosis in horses with pulmonary neoplasia is heaves, followed by low-grade pneumonia and pleuropneumonia. In some cases, the definitive diagnosis is not identified for months to years. With the exception of granular cell tumor, there are limited options for therapeutic intervention, and the prognosis is grave at the time of diagnosis.[528]

Metastatic Pulmonary Neoplasia

Equine lymphoma is the most common hematopoietic neoplasm in horses and can present with a variety of the clinical signs that have been previously described.[554,568-573] Classification involves four main manifestations of lesions: mediastinal, multicentric, alimentary, and cutaneous. When present in the thoracic cavity, this manifestation of lymphoma is not considered a true primary neoplasm because it originates from an extrathoracic site.[554] Lymphoma is usually a disease of adult horses without a specific breed or gender predilection.[572]

Clinical signs of lymphoma typically relate to the primary organ system involvement. Common clinical features of the disease include chronic weight loss, lethargy, anorexia, subcutaneous edema, lymphadenopathy, colic, bleeding tendency, and diarrhea.[574-576] Although the disease has an insidious progression, it is not uncommon for cases to present with a relatively acute change or deterioration in condition. It is likely that the time of presentation relates to a stage of disease in which the clinical manifestation has become pronounced.

Ventral edema, particularly when in the pectoral region, is a common clinical finding in association with lymphoma, resulting from lymphatic obstruction. Coughing and labored respiratory effort are often apparent in individuals suffering from mediastinal masses. In such instances, pleural effusion may result in severe pulmonary atelectasis, and pulmonary function is significantly compromised.

Hematologic and serum biochemical testing are nonspecific regarding the provision of diagnostic evidence for the presence of thoracic lymphoma. Thoracic radiography may identify a pleural fluid line, and in some instances it reveals the presence of a mediastinal mass. Thoracic ultrasonography provides specific evidence regarding the presence, depth, and character of pleural fluid. Thoracocentesis is an important diagnostic procedure that will provide the clinician with evidence of the nature of fluid. Cytologic examination provides evidence of lymphoma, when the tumor is exfoliative. In some instances concurrent sepsis may be identified. Therefore, careful examination of lymphocyte morphology should be performed. When overlapping conditions exist, such as sepsis with mediastinal lymphoma, a lack of response to appropriate medical therapy should alert the clinician to the potential for complicating factors rather than a primary pleuropneumonia. Thoracoscopy may be particularly helpful in these cases. When enlarged peripheral lymph nodes are present, biopsy is strongly recommended to aid in diagnostic confirmation of lymphoma. Fine-needle aspirates typically do not provide diagnostic information regarding lymph node architecture and are difficult to cytologically differentiate from reactive lymph nodes.

Peripheral lymphadenopathy is an uncommon clinical feature of disease,[577] yet when lymphadenopathy develops, the prescapular or submandibular nodes are usually enlarged. Postmortem examination typically reveals conclusive evidence of lymphoid pathology. When examining a patient with suspected lymphoma, rectal palpation is an important component of the physical examination to determine whether abdominal lymphadenopathy is present. A recent report of lymphoma described an 18-year-old mare with a presenting complaint of severe pruritus, alopecia, pyrexia, mammary gland enlargement, and lymphadenopathy.[578] This mare was determined to be suffering from primary T-cell lymphoma that primarily affected the mammary gland. Hematologic dyscrasias that may be present in lymphoma cases include hyperglobulinemia, hypercalcemia, and anemia. Rarely leukemia may be identified, which typically represents bone marrow involvement. The mare of the previously mentioned report suffered from pyrexia and anemia, which resulted from paraneoplastic complications. Pruritus has been previously described to occur as a paraneoplastic condition in horses[579] and has been identified in approximately 25% of human patients suffering from Hodgkin's lymphoma.

A recent report described a mare with significant submandibular lymphadenopathy and respiratory distress that was later diagnosed with lymphomatoid granulomatosis.[580] Although the mare had clinical findings to suggest a more typical case of lymphoma, this mare had evidence of marked lymphocytosis on hematologic examination. Morphologic evaluation of these cells revealed that approximately 98% of the cells were classified as atypical T cells. Additional clinical findings included anemia and thrombocytopenia. On postmortem examination unencapsulated nodules were scattered throughout all the lung lobes, without obvious involvement of other organs. However, microscopic examination of the skin revealed perivascular and mural infiltrates of neoplastic mononuclear cells closely associated with an affinity for vascular elements. Neoplastic cells were characterized to have oval or cleaved nuclei with characteristics of neoplasia represented by multiple nucleoli and evidence of mitosis among cells. Lymphomatoid granulomatosis is a rare form of lymphoma that has been previously identified in humans,[581] dogs,[582-586] and cats.[587] The findings in this mare were supportive of this diagnosis for the first time in a horse. Interestingly, her lesions involved primarily the submandibular lymph nodes, pulmonary tissue, and skin. The leukemic nature of disease in this horse was believed to represent a consequence of the angioinvasive progression of the disease. This differential consideration should be considered for clinical disease that presents in a similar fashion with clinical and histopathologic findings to support this diagnosis.

Classification of tumor type has become a routine component of the clinical evaluation of lymphoma. Specifically, diagnostic modalities used for tumor classification include immunophenotypic examination with flow cytometry and immunohistochemical staining on tissue samples. Immunophenotypic evaluation of pleural fluid can be performed to determine lymphocyte surface marker expression, which can aid with the characteristic nature of neoplasia. Flow cytometry of fluid effusions is analyzed for surface expression of MHC II, CD4, CD5, CD8α, or CD8/α/β.[588] When tissue samples

are available, immunohistochemistry is used to establish cell-surface expression, which provides criteria for tumor classification.[577,589] Cellular staining provides diagnostic evidence for the distinction between T- and B-cell lineage neoplasms. Standard staining protocols involve identification of CD3 for T-cell lesions and CD20, CD21, and/or CD79α for B-lymphocyte surface marker. Several veterinary laboratories offer diagnostic services that can aid in the specific identification of tumor type. Examination of DNA ploidy may aid in characterization of neoplastic cell populations in some clinical investigations.[403,590]

Classification of equine lymphoma has been hindered by the documentation of relatively few cases. An original report examined 31 horses with diagnostic confirmation of lymphoma. Among these cases, 24 (77%) horses had lymphoma derived from B lymphocytes with an infiltration of nonneoplastic T lymphocytes and is termed *T-cell–rich B-cell lymphoma* (TCRBCL).[589] This investigation concluded that not all equine lymphomas can be classified; however, among equine tumors that can be classified, there is an apparent tendency toward TCRBCL.

In contrast, a more recent investigation that used immunophenotyping classified 37 cases of equine lymphoma.[577] Among all tumors, 34 (91%) of the neoplasms involved multiple lymphoid tissues in addition to abdominal or thoracic organs. Twenty-six (70%) of the cases were identified to be of T-cell origin, 7 cases B-cell origin, and 4 cases were not able to be classified. Immunophenotyping was performed on effusions and was found to be consistent with the immunohistochemical findings in six tumors.[577] The investigation of this population concluded that most horses had large T-cell tumors, a concurrent inflammatory response was common, and many horses had mediastinal masses. This population of affected horses was uncharacteristically young, less than 5 years old. Anemia was the most common cytopenia and was frequently associated with agglutination and hyperglobulinemia. Thrombocytopenia and neutropenia were identified in association with myelophthisis.[577] Although equine lymphoma is relatively uncommon, an effort to establish a diagnosis early in the course of disease would be expected to enhance the chance for a favorable case outcome should chemotherapy be a therapeutic option.

Postmortem examination typically reveals large-volume pleural effusion and associated ventral pulmonary atelectasis. Cranial mediastinal masses are commonly present and are often composed of coalescing enlarged lymph nodes. Such masses may occlude the thoracic inlet contributing to obstruction of blood flow and lymphatic drainage. Regional and local lymph nodes are commonly enlarged. In some instances, the pulmonary parenchyma may be infiltrated with neoplastic lesions as well as other organs that may be involved including liver, kidney, spleen, and potentially gastrointestinal tract.[554,591]

Hemangiosarcoma appears to be the second most common metastatic thoracic neoplasm in horses. In a series of 35 cases, pulmonary parenchyma and pleura were involved in 77% of the horses.[592] The age distribution of affected horses is clustered around middle-aged adults (mean age 12 years, range 3–27 years). Pulmonary hemangiosarcoma is not unusual in 6- to 7-year-old horses.[593-595] Disseminated hemangiosarcoma is aggressive and rapidly progressive. Most horses present in good body condition with an abbreviated history of anorexia and depression. The clinical presentation often includes tachypnea; pale or icteric mucous membranes; respiratory distress; epistaxis; and subcutaneous, cutaneous, or intramuscular masses.[596] Anemia, thrombocytopenia, and neutrophilia are the most common abnormalities on routine blood work.[592] A large volume of hemorrhagic pleural effusion is present in approximately 20% of the cases, accompanied by ventral edema and marked respiratory distress. Thoracocentesis provides relief for horses with large-volume pleural effusion. Pleural fluid is typically serosanguineous in color and may be characterized as hemothorax. Cytologic examination may or may not reveal neoplastic cells. Trauma is the most common first-opinion diagnosis in horses with hemothorax caused by hemangiosarcoma.[592]

Antemortem diagnosis is uncommon[592] but has been achieved via cytologic evaluation of pleural fluid and pleuroscopic-guided biopsy.[595] Biopsy of a hemangiosarcomatous mass can result in further hemorrhage. Plans to manage hemostasis should be considered before completing a biopsy in cases of suspected hemangiosarcoma. At postmortem examination, neoplastic tissue is widely distributed to many tissues including the heart, spleen, kidney, skeletal muscle, and CNS. The spleen is the most common organ of origin, although many other tissues have been reported to be the site of primary tumor formation. Occasionally, the thoracic cavity is considered the primary tumor with disseminated metastasis to distant sites.

Disseminated hemangiosarcoma should be differentiated from focal hemangiosarcoma of the distal limb in horses less than 3 years of age.[597] These tumors do not demonstrate the same aggressive biological activity and are unlikely to metastasize at the same rate. Surgical resection can be curative, and, in some cases, the tumor may resolve spontaneously.

Other tumor types that metastasize to the thoracic cavity include adenocarcinoma,[598,599] squamous cell carcinoma,[600] fibrosarcoma,[601] metastatic melanoma,[602,603] mastocytoma,[604] or undifferentiated sarcoma.[528,554] The clinical features of these tumors are generally nonspecific and often relate more to the primary site of tumor formation. Some metastatic tumors will produce neoplastic effusion and/or damage to intrathoracic structures.[601,602] Cytologic evaluation may or may not identify neoplastic cells. Thoracoscopy is an important diagnostic tool to obtain a tissue sample to confirm neoplasia and identify the tissue type.[605,606]

Paraneoplastic Disease

Paraneoplastic conditions develop in association with neoplasia yet are often unrelated to the primary site of tumor development. Recent reviews will provide the reader with a comprehensive understanding of this condition and specific manifestations in equine patients.[607]

Fever is a common paraneoplastic disorder observed in association with equine lymphoma resulting from cytokine production by the tumor. IL-1, IL-6, and TNF are pyrogens that are believed to increase PGE production by hypothalamic endothelial cells. When pyrexia is identified in combination with anemia, the differential list must include potential infectious etiologies such as equine infectious anemia and piroplasmosis. Immune-mediated disorders should also be considered as a primary disease or manifestation of paraneoplastic disease that may also involve intermittent or persistent fevers.

Pruritus has been clearly demonstrated to develop as a paraneoplastic condition associated with equine lymphoma.[579] Altered T-cell function is believed to result in modified cytokine synthesis and secretion. Additional etiologies for pruritus

include nerve entrapment or compression, tumor growth, and hepatic involvement leading to bile duct obstruction.[607]

Anemia may result from immune-mediated mechanisms or reduction of bone marrow production, such as with myelophthisis. Anemia of chronic disease is well recognized and occurs secondary to a variety of inflammatory conditions. Changes in bone marrow function occur secondary to altered cytokine synthesis. Cytokines that have been implicated in this mechanism include transforming growth factor B, IL-11, IL-6, and interferon gamma, which upregulate hepcidin synthesis. Hepcidin will antagonize gastrointestinal iron uptake and utilization. In addition, erythropoietin antagonism results from TNF affecting bone marrow production and function.[607]

Hypercalcemia (calcium >14 mg/dL) may result from a paraneoplastic syndrome, although the clinician should consider other differential possibilities as well such as chronic renal failure, iatrogenic hypervitaminosis D, consumption of wild or day-blooming jasmine *(Estrum diurnum)* particularly in the southeastern United States, rapid administration of calcium-containing solutions, laboratory error, and hyperparathyroidism.

The mechanisms of hypercalcemia occurring in patients suffering from neoplastic disease may include lytic bone metastases, malignant hyperparathyroidism, ectopic tumor production of parathyroid hormone-like hormone (PTHLH, PTHLP), tumor-produced PGEs (PGE_1 and PGE_2), and tumor-produced osteoclast activating factor.[608-610] The cDNA sequence for equine PTHLP has been reported (Accession NP_001157453). Although this protein has been clearly defined to result in hypercalcemia associated with canine tumors such as with lymphoma and anal sac adenocarcinoma,[611] further investigations are required to more clearly define the relationship of PTHLH in the horse. Reported cases of hypercalcemia in equine patients suffering from neoplasia are somewhat limited to include disseminated lymphoma and lymphoid leukemia.[579,612,613]

Hypertrophic osteopathy (aka Marie's disease) has been reported in domestic species and is most commonly associated with primary and metastatic pulmonary tumors.[614-616] The pathogenesis of HO remains incompletely understood. The primary syndrome involves periosteal proliferation on the cortices of long bones. The condition is classically described to occur secondary to an intrathoracic mass yet may develop secondary to extrathoracic lesions as well. Although HO is more common in humans and dogs, it also occurs in horses. In horses, it has been reported in association with a variety of pulmonary conditions including infection, neoplasia, and trauma.[540,617] Thoracic neoplasia is an uncommon disease in horses, with HO being rarely reported in affected individuals. This finding is in contrast to the findings in humans in which up to 10% of patients with thoracic neoplasia develop HO, often characterized by clubbing of the fingers, dermal changes, limb swelling, and arthropathy.[616] In canine patients suffering from HO, the most common predisposing factor is consistently pulmonary neoplasia.[614] The presence of HO in an equine patient should alert the clinician to be aware of the potential for intrathoracic disease.

Although HO is a relatively uncommon condition in horses, it has been described to occur in association with pulmonary and extrapulmonary disease. Previous retrospective reports that described HO in horses include a total of 42 cases.[540,617,618] These reports are divided among individual case reports that date back to 1944 and a more recent retrospective that describes the clinical features of 24 cases.[540] In this report, 71% of the horses were ultimately diagnosed with pulmonary disease. Among those with pulmonary lesions, 40% were neoplastic in origin. In cases with a treatable pulmonary condition, resolution of HO occurred following clearance of the primary pulmonary disease. Limb swellings were present on all four limbs and typically occurred in a bilaterally symmetric fashion. In some instances, the limbs were cool and comfortable, whereas in others they were warm and sensitive to palpation. Head lesions were present in two of the cases that involved the mandible and maxilla.[540] Stiffness and pain were commonly reported in affected individuals. When intrathoracic disease was present, clinical signs also included cough and dyspnea. The radiographic findings associated with HO included periosteal new bone formation in a palisade fashion. Similar to findings in humans and canine patients, in those individuals with a treatable condition, clinical signs resolved on resolution of the primary disorder. Interestingly, in this report three cases were not identified to have a primary disorder, yet clinical signs resolved following symptomatic therapy with phenylbutazone. In humans, indomethacin is an NSAID that has been reported to provide clinical benefit when used as the primary therapy for the management of HO.[619]

Other Considerations

Differentiating a thoracic tumor from a number of infectious conditions of the thorax can be surprisingly difficult. Middle-aged and aged horses with solid pulmonary tumors are often mistaken as affected with heaves. Hydatid cysts and fungal pneumonia are less common conditions that may mimic signs of thoracic neoplasia.

Equine cases of hydatid cyst may present with a large volume of pleural effusion. In Europe, hydatidosis *(Echinococcus equinus)* is generally well tolerated in horses, and cysts in the liver and lung may be an incidental finding at postmortem examination.[19] In the United States *Echinococcus* spp. and an unidentifiable aberrant, acephalic metacestode have been identified in the liver and lungs of horses. Occasionally the cyst will rupture, resulting in clinical respiratory difficulty caused by large-volume pleural effusion. In the United States, this clinical syndrome has been associated with the acephalic metacestode.

Affected horses may have intermittent fever, depression, rapid shallow respiration, pectoral edema, and nonspecific laboratory findings indicative of inflammation.[19] A large volume of pleural effusion is a consistent finding in horses with pulmonary and pleural metacestode infection. The effusion has low to moderate cellularity (5000–80,000 cells/μL), 20% to 80% neutrophils, and markedly increased protein concentration (5.0–8.0 g/dL) and may be difficult to differentiate from neoplastic effusion.[529] Bacterial and fungal culture of the pleural fluid is negative. Ultrasound examination may reveal a large fluid-filled cyst within the pulmonary parenchyma, on the surface of the diaphragm, and/or within the hepatic parenchyma. Metacestodes may be attached to a thickened pleural surface, or hypoechoic cysts (1 × 4 mm) may be seen floating within the pleural or peritoneal fluid.

Treatment of a horse with an unidentified aberrant, acephalic metacestode utilized albendazole (10 mg/kg, PO, s.i.d. × 30 days), thoracic drainage, and surgical debridement of the pleura and cyst (10 × 10 × 17) on the surface of the diaphragm. Disruption of a cyst by centesis or surgery may result in an anaphylactic reaction or seeding of daughter metacestodes

within the thoracic cavity. Surgical intervention was performed in this case after 2 weeks of antiparasitic therapy. The horse was asymptomatic 6 weeks after treatment and returned to athletic performance for several years.

CHAPTER 9

Disorders of the Cardiovascular System

Colin C. Schwarzwald*

Cardiovascular (CV) system function is critical to exercise, thermoregulation, and the blood flow–dependent functions of the brain, heart, lungs, kidneys, gut, and reproductive system. Heart and vascular diseases are common in horses, but fortunately the underlying lesion is often minor and well tolerated. However, clinically significant CV disease can develop in horses with clinical signs that can include arrhythmia, exercise intolerance, congestive heart failure, weakness or collapse, systemic infection, or sudden death.

The clinical evaluation of the equine CV system is often perplexing. Horses are renowned for a variety of physiologic murmurs and arrhythmias. Furthermore, the equine CV system has an enormous compensatory capacity, and the limits of normal CV function can only be reached by horses undergoing exercise at the highest levels. Clinical assessment is best served by an awareness of normal variation, the appreciation of relevant diseases, diagnostic studies and prognostic indicators, and an understanding of available management options. Communication of these issues constitutes the focus of this chapter.

Equine cardiology has advanced from a study of physiologic variation and speculation to one of accurate diagnosis and focused therapy, though many clinical issues are unresolved. Much of the important groundwork in clinical equine cardiology can be attributed to the studies of Detweiler and colleagues,[1-4] Hamlin, Smith, and Smetzer,[5-20] and Holmes and his trainees.[21-51] The initial information provided by these cardiologists regarding normal CV physiology, cardiac catheterization, pathology, cardiac auscultation, and electrocardiography was pivotal, and we still make clinical decisions based on data these groups provided. There has been steady progress in cardiac assessment by many other investigators over the past decades. Many of these advances relate to the various modalities of echocardiography, which (along with auscultation) is the most important of available diagnostic studies. Other examinations of importance to CV assessment include ambulatory electrocardiography, functional exercise testing, and biochemical tests of cardiac injury. Appropriate selection and interpretation of these tests allows the clinician to identify and quantify most diseases of the heart and circulation.

A variety of sources are available providing a comprehensive overview of the current knowledge of CV diseases in horses.[52-67] A recent consensus statement formulated by a group of experts in the field of equine CV medicine summarizes the current recommendations for management of equine athletes with CV abnormalities.[68] These recommendations are included in the respective sections later in this chapter.

Heart murmurs and arrhythmias are commonly detected in horses, even in the absence of clinical signs of CV disease.[69-82] A variety of studies describe the prevalence of CV disease in horses, indicating that mitral regurgitation, aortic regurgitation, tricuspid regurgitation, and atrial fibrillation are the most common cardiac abnormalities detected.[33,83,84] Else and Holmes noted myocardial fibrosis in 14.3% of horses examined at necropsy and evidence of chronic valvular disease in approximately 25% of the hearts examined.[27-29] Various CV lesions were considered important in 8.5% of 480 consecutive losses in a necropsy study conducted by Baker and Ellis.[85] Cardiovascular diseases are probably the third most common cause of poor performance following musculoskeletal and respiratory diseases.[86-90] Occult heart disease, cardiac arrhythmias, and vascular lesions are considered important reasons for unexplained sudden death.[85,91-106] Certainly, CV abnormalities are clinically relevant, and most clinicians encounter manifestations of CV disease or dysfunction on a regular basis.

The assessment of CV disease in a horse is predicated on a competent clinical examination, the clinician's knowledge, and the ability to order and evaluate diagnostic studies. Incomplete information may impede an accurate diagnosis, foster miscommunication of risks to the client, or delay the proper course of management. Fundamentals of CV anatomy, physiology, and electrophysiology are reviewed elsewhere.[9,20,53,57,107-117] This chapter offers a framework for understanding the lesions, pathophysiology, diagnosis, and management of important congenital and acquired conditions of the heart and major vessels. Clinical aspects of circulatory shock are described in this volume. The reader is referred elsewhere for the management of cardiopulmonary arrest.[58,118]

ANATOMIC CORRELATES OF CARDIOVASCULAR DISEASES

Most diagnostic techniques, including cardiac auscultation, electrocardiography, cardiac catheterization, and echocardiography, are predicated on an understanding of cardiac anatomy and physiology. The CV system is divided into two separate circulations—systemic and pulmonary. The systemic circulation has a greater venous capacitance, ventricular pumping

*The editors and authors acknowledge and appreciate the contributions of John D. Bonagura and Virginia B. Reef as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

pressure, arterial pressure, and vascular resistance.[57,110,112-114,116] Despite these differences, the functions of these two circulations are interdependent as the following examples illustrate. Systemic and pulmonary circulations are arranged in series; therefore cardiac output (CO) from the left ventricle (LV) and the right ventricle (RV) must be equivalent. Accordingly, failure of either ventricle limits CO. Isolated left ventricular failure, as with severe mitral regurgitation, can cause right-sided failure. This is explained by the increased pulmonary venous pressure causing pulmonary vascular remodeling and pulmonary hypertension and imparting a pressure load on the RV. A third example is the case of isolated RV failure with marked right ventricular dilation. Here the leftward bulging of the ventricular septum impairs filling of the LV. This last situation also can develop in chronic pericarditis. Arrhythmias also affect both sides of the heart, so that the development of atrial fibrillation (AF) in the setting of severe structural heart disease often promotes biventricular heart failure.

The heart consists of unique active and passive components, and different diagnostic methods are needed to evaluate these structures and associated functions. Normal heart action requires coordination of electrical activity, muscular contraction and relaxation, and valve motion. When reviewing heart anatomy, and subsequently cardiac pathology, it is useful to consider the anatomic integrity of the pericardium, myocardium, endocardium and valves, specialized impulse-forming and conduction systems, and blood vessels.[107,109,111] Using this approach, the causes of CV disease can be conveniently subdivided into anatomic, physiologic (functional), and etiologic diagnoses (Boxes 9.1 and 9.2).

Pericardial Disease

The pericardium limits cardiac dilation, acts as a barrier against contiguous infection, and contributes to the diastolic properties of the heart. The pericardial space is formed by the reflection of the two major pericardial membranes, the parietal pericardium and the visceral pericardium (epicardium), and normally contains such a small amount of serous fluid that it cannot be seen by echocardiography. Pericardial effusion leading to cardiac compression (tamponade) impairs ventricular filling and diastolic function, typically causing right-sided congestive heart failure (CHF). Some cases of pericarditis progress to constrictive pericardial disease, which severely limits ventricular filling.

Pericardial effusion can develop as a primary disorder or secondary to pleuropneumonia. Infective pericarditis can produce an effusion sufficient to cause cardiac tamponade or eventual constriction of the heart.[88,119-137] Sterile, idiopathic pericardial effusion also has been reported in horses. The volume of effusion can be substantial and can lead to cardiac decompensation.[126] Cardiac mass lesions and intrapericardial tumors have been reported sporadically.[128,131,138,139] Cranial mediastinal tumors (lymphosarcoma) or abscesses secondary to pleuropneumonia also can compress the heart and mimic pericardial disease.[140] Clinical aspects of pericardial disease are discussed later in this chapter.

Myocardial Disease

The myocardium forms the bulk of the atrial and ventricular muscular walls. The right atrium (RA) communicates with the RV inlet through the right atrioventricular (AV) or tricuspid valve. The RV appears crescent shaped on cross-sectional echocardiographic examination and is functionally U shaped. The RV inlet is located in the right hemithorax and the outlet, pulmonary valve, and main pulmonary artery (PA) on the left side of the chest. The left atrium (LA) is caudal to the RA and separated by the atrial septum. The LA is dorsal to the LV through which it communicates across the left AV (mitral) valve. The LV is circular in cross section when viewed by echocardiography and separated from the RV by the ventricular septum. The septum and free walls are thicker than the RV free wall (by approximately 2.5–3 times). Persistent embryologic openings in the cardiac septa are known as septal defects, with the ventricular septal defect (VSD) representing the most common cardiac anomaly in most equine practices (see Box 9.2). The LV is functionally V shaped, with an inlet and outlet separated by the cranioventral (septal or according to the human nomenclature "anterior") leaflet of the mitral valve (Fig. 9.1). The aorta originates in the LV outlet, continuous with the ventricular septum cranially and in fibrous continuity with the septal mitral leaflet caudally. This great vessel exits from near the center of the heart and to the right of the main PA.

The myocardium may dilate or hypertrophy in response to exercise,[141,142] in response to increased work caused by

BOX 9.1 Cardiac Diagnoses

ANATOMIC DIAGNOSIS
- Cardiac malformation
- Valvular (endocardial) disease
- Myocardial disease
- Pericardial disease
- Cor pulmonale (pulmonary disease leading to secondary heart disease)
- Disorder of the impulse-forming or conduction system
- Vascular disease

PHYSIOLOGIC DIAGNOSIS
- Systemic: pulmonary shunting
  - Left to right
  - Right to left
- Valvular insufficiency
- Valvular stenosis
- Myocardial (systolic) dysfunction
- Diastolic dysfunction
- Cardiac rhythm disturbance
- Cardiac-related syncope
- Heart insufficiency or failure (limited cardiac output)
- Congestive heart failure
- Shock
- Sudden cardiac death
- Cardiopulmonary arrest

ETIOLOGIC DIAGNOSIS
- Malformation (genetic)
- Degenerative disease
- Metabolic or endocrine disease
- Neoplasia
- Nutritional disorder
- Inflammatory disease
  - Infective or parasitic
  - Noninfective
    - Immune-mediated
    - Idiopathic
- Ischemic injury
- Idiopathic disorder
- Iatrogenic disease
- Toxic injury
- Traumatic injury

BOX 9.2 Causes of Cardiovascular Disease

CONGENITAL CARDIAC MALFORMATION

Simple systemic-to-pulmonary shunts (left to right)
- Atrial septal defect
- Ventricular septal defect
  - Paramembranous defect
  - Ventricular inlet defect
  - Subarterial (subpulmonic) defect
  - Muscular defect
- Patent ductus arteriosus

Patent foramen ovale (permitting right-to-left shunting)
Valvular dysplasia
- Mitral stenosis/atresia
- Pulmonary atresia (leading to a right-to-left shunt)
- Tricuspid stenosis/atresia (leading to a right-to-left shunt)
- Aortic stenosis/insufficiency (bicuspid or quadricuspid valve)

Subaortic rings with stenosis
Tetralogy of Fallot
Pulmonary atresia with ventricular septal defect (pseudotruncus arteriosus)
Double-outlet right ventricle
Subaortic stenosis
Hypoplastic left side of the heart
Other complex malformations

VALVULAR HEART DISEASE CAUSING VALVE INSUFFICIENCY OR STENOSIS

Congenital valve malformation
Semilunar valve fenestrations causing valve insufficiency
Degenerative (fibrosis) or myxomatous disease causing valve insufficiency
Valvular prolapse
Bacterial endocarditis causing valve insufficiency with or without stenosis
Rupture of a chorda tendinea causing mitral or tricuspid valve insufficiency
Rupture of a valve leaflet causing flail leaflet and valve insufficiency
Noninfective valvulitis
Valvular regurgitation following dilation of the heart or a great vessel
Papillary muscle dysfunction causing valvular insufficiency

MYOCARDIAL DISEASE

Idiopathic dilated cardiomyopathy: ventricular dilation and myocardial contractility failure
Myocarditis
Myocardial fibrosis
- Ischemic (embolic?) myocardial fibrosis
- Parasitic (*Strongylus*) embolization

Myocardial degeneration/necrosis
- Myocardial ischemia/hypoxia
- Toxic injury (e.g., ionophores, plant toxins, cantharidin, snake venom)
- Nutritional deficiencies (e.g., vitamin E, selenium)
- Atypical myopathy
- Trauma

Infiltrative myocardial disease (e.g., myocardial neoplasia, amyloidosis)
Tachycardia-induced cardiomyopathy
Chronic hypertension (e.g., chronic pain, laminitis, metabolic syndrome, chronic kidney disease)

PERICARDIAL DISEASE

Pericardial effusion with or without cardiac tamponade
- Infective: bacterial, viral, or fungal
- Immune-mediated
- Trauma
- Neoplasia
- Idiopathic pericardial effusion

Constrictive pericardial disease
Mass lesion (intrapericardial or extrapericardial) compressing the heart

PULMONARY HYPERTENSION AND COR PULMONALE

Pulmonary hypertension following left-sided heart disease
Pulmonary vascular disease following left-to-right shunt
Immature pulmonary circulation
Primary bronchopulmonary or pulmonary vascular disease
Alveolar hypoxia with reactive pulmonary arterial vasoconstriction
Severe acidosis
Pulmonary thromboembolism

CARDIAC ARRHYTHMIAS (see Box 9.12)

Atrial arrhythmias
Junctional (nodal) arrhythmias
Ventricular arrhythmias
Conduction disturbances

VASCULAR DISEASES

Congenital vascular lesions
Rupture of the aorta, pulmonary artery, or systemic artery
Aneurysm of the aortic sinus of Valsalva
Aortopulmonary fistula
Aortic or aortoiliac degenerative disease
Arteritis
- Infective
- Immune-mediated

(Jugular) venous thrombosis/thrombophlebitis
Pulmonary embolism
Mass lesion or tumor obstructing blood flow

structural cardiac disease, or as a consequence of a noncardiac disorder. Ventricular or atrial dilation is recognized echocardiographically or at necropsy by distention and rounding of the affected chambers, including a "double-apex" sign when there is marked RV enlargement. Lesions causing systolic pressure overload lead to concentric hypertrophy.[143] More common in horses are lesions such as incompetent valves or shunts that cause ventricular volume overload with dilation and eccentric ventricular hypertrophy. Increased cardiac work also occurs in response to exercise, severe anemia, and infections. In these situations, compensatory increases in CO, sympathetic activation, and peripheral vasodilation occur to maintain oxygen delivery to the tissues.[57,110,112-114,116,117,144]

The overall prevalence of myocardial disease is unknown; however, multifocal areas of fibrosis are commonly found at necropsy.[28,29,97,145-150] Whether these areas indicate prior inflammation, toxic injury, or ischemic necrosis caused by intramural coronary disease is uncertain. Cases of multifocal or diffuse

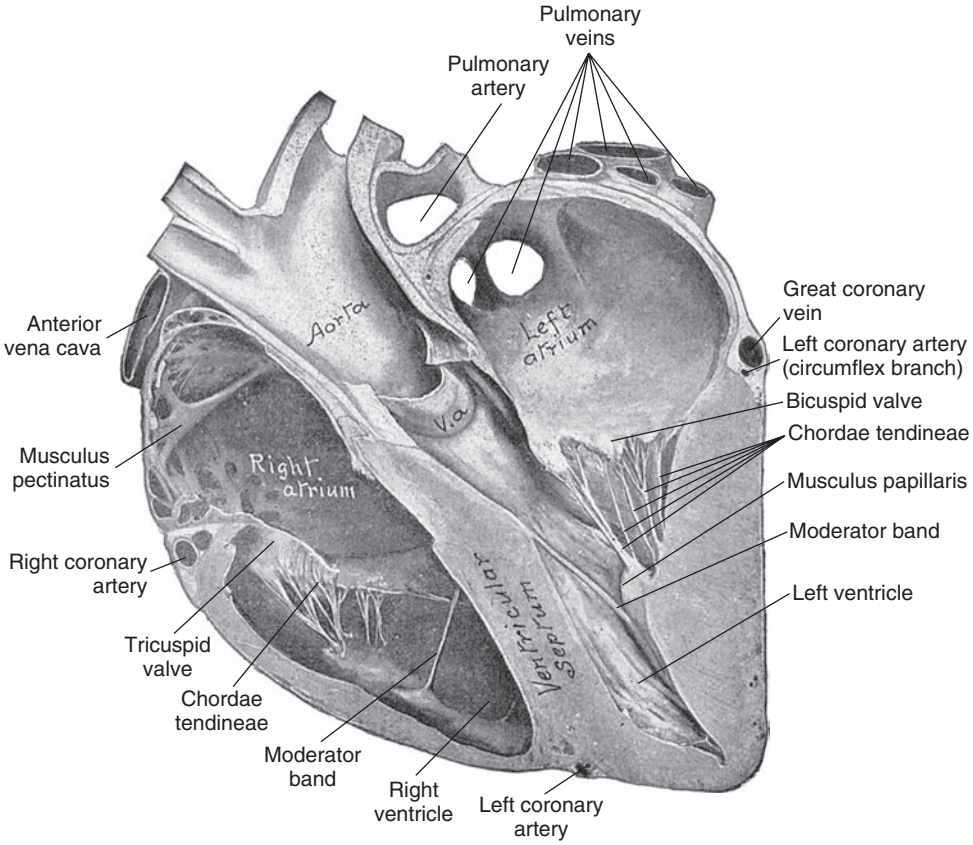

FIG. **9.1** Sagittal view of the equine heart. The thicknesses of the ventricles, the position of the atria relative to the ventricles, and the relationship of the left ventricular (LV) inlet and outlet are evident. The bicuspid valve referred to in this figure is the mitral valve. The circular appearance of the left atrium (LA) and the relationship of the septal cusp of the mitral valve to the LV inlets and outlets are notable. These aspects are important when examining the heart by echocardiography. *v.a.,* Segment of aortic valve. (From Sisson S, Grossman JD: *Anatomy of the domestic animals,* ed 4, Philadelphia, 1953, WB Saunders.)

myocarditis have been observed. Myocardial inflammation and myocardial failure can lead to cardiac arrhythmias and heart failure.[4,151,152] Idiopathic dilated cardiomyopathy develops sporadically and is recognized echocardiographically as a dilated, hypokinetic left or right ventricle.[129] As in other species, echocardiographic features of dilated cardiomyopathy can also be tachycardia induced and may resolve following successful control of heart rate (HR) and heart rhythm.[153] Ingestion of monensin or other ionophores can cause mild to severe myocardial injury.[154-163] Vitamin E and selenium deficiency have been described as causes of myocardial degeneration and dysfunction.[164,165] Neoplastic infiltration is considered rare.[93,138,139,166] Impaired myocardial function as a consequence of regional ischemia has been sought using stress echocardiography immediately following treadmill exercise or pharmacologic stress, but this diagnosis requires further definition[167,168] (see later discussion). Myocardial contraction is dictated by electrical activity of the myocardium; accordingly, cardiac arrhythmias—especially atrial fibrillation or ventricular tachycardia (VT)—can limit CO and cause exercise intolerance in performance animals (see later discussion). Clinical aspects of myocardial disease are discussed later in this chapter.

Valvular and Endocardial Diseases

The cardiac chambers are lined by the endocardium, which also covers the four cardiac valves and is continuous with the endothelium of the great vessels. Normal valves govern the one-way flow of blood through the heart by preventing significant regurgitation of blood from higher to lower pressure zones. The AV inlet valves—the tricuspid and the mitral—are anchored by the collagenous chordae tendineae and papillary muscles and are supported by a valve annulus and the caudal atrial walls (Fig. 9.2; also see Fig. 9.1).[107,109,111] The mitral valve consists of two major cusps and several accessory cusps.[45] The tricuspid valve is the largest valve and consists of three well-defined leaflets. Lesions of any portion of the AV valve apparatus or dilation of the ventricle can lead to valvular insufficiency (see Box 9.2). The aortic and pulmonary valves each consist of three semilunar leaflets that close during diastole to protect the ventricles from the higher arterial blood pressure (BP). Aortic valvular tissue in horses is not simply passive, and it will contract in response to a number of adrenergic and vascular agonists, such as angiotensin II and endothelin.[169] The left and right main coronary arteries originate within the aortic valve sinuses (of Valsalva).

Valvular disorders in horses are common. Congenital valve stenosis, dysplasia, or atresia are recognized sporadically in foals.[4,151,170-190] Degenerative diseases of the aortic, mitral, and tricuspid valves are very common in mature horses,[4,123,148,151,191,192] and endocarditis can develop on any cardiac valve[4,31,129,151,191,193-206] (see Box 9.2). Valvular lesions of obscure etiology, including nonseptic valvulitis, have been recognized sporadically. Tricuspid and mitral regurgitation, of unspecified etiology, is often detected in high-performance animals, including Standardbred and National Hunt horses.[70,72,75,207-211] Mitral regurgitation

FIG. **9.2** Anatomy of the left atrioventricular (mitral) valve. Opened left atrium (LA) and LV viewed from the caudal perspective. The large anterior (cranioventral or septal) leaflet in the center of the figure is notable. Chordae tendineae attach the valve to the papillary muscles. The ventricle has been cut so that the multiple cusps of the posterior (caudodorsal or mural) leaflet are visible to the left and the right of the anterior leaflet.

(MR) due to rupture of a chorda tendineae is recognized in both foals and mature animals.[38,212-214] Clinical aspects of valvular heart disease are discussed later in this chapter.

Disease of the Impulse-Forming and Conduction Systems

The specialized cardiac tissues consist of the sinoatrial (SA) node, internodal pathways, AV node, bundle of His, bundle branches, fascicles, and Purkinje system (Fig. 9.3). The SA node, a relatively large, crescent-shaped structure, is located subepicardially at the junction of the right auricle and cranial vena cava. Well-documented sinus node disease, although suggested,[215] is rare; in contrast, vagally induced sinus arrhythmias are common.[9,215-217] The equine atrial muscle mass is large and predisposes the horse to development of reentrant rhythms and fibrillatory conduction.[218] The AV node, situated in the ventral atrial septum, and the bundle of His, which continues on into the bundle branches, are sites for AV block, both physiologic (vagal) and, infrequently, pathologic in nature. Conduction is slow across the normal AV node.[112,219-221] The His-Purkinje system in the ventricular septum and ventricular myocardium can act as substrates for junctional and ventricular ectopic impulses and tachycardias. Because the horse has relatively complete penetration of Purkinje fibers in the ventricles—except for a small portion of the LV free wall—the substantial equine ventricles are electrically activated in a relatively short time (approximately 110 msec).[7]

The autonomic nervous system extensively innervates the heart and influences cardiac rhythms.[4,151,222-227] Interplay between the sympathetic and parasympathetic branches normally controls HR and heart rhythm in response to changes in arterial BP.[9,228] The vagus innervates supraventricular tissues extensively and probably affects proximal ventricular tissues to

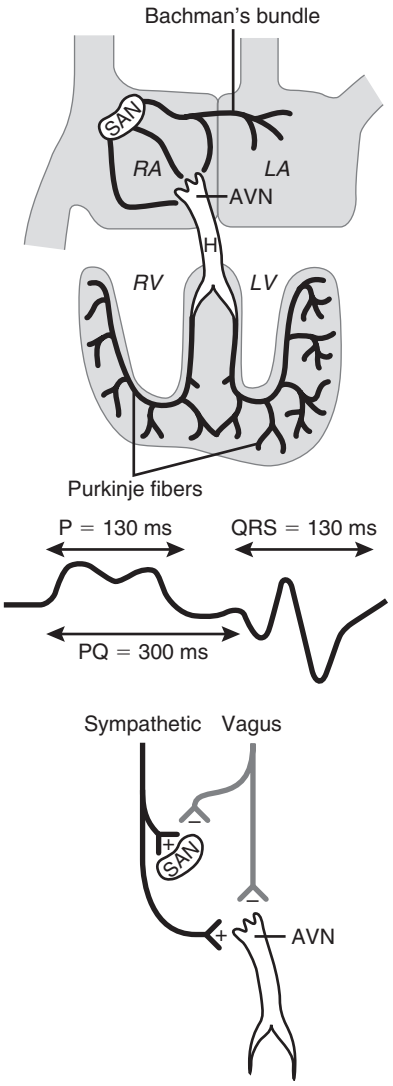

FIG. **9.3** Impulse-forming and conduction systems of the heart. The impulse originates in the sinoatrial node (SAN) and is propagated across the right atrium (RA) and left atrium (LA), generating the P wave. Specialized internodal and interatrial (Bachmann''s bundle) pathways facilitate impulse conduction. The impulse is delayed in the atrioventricular node (AVN) and rapidly conducted through the bundle of His (H), bundle branches and Purkinje network *(top).* Electrical activation of ventricular myocytes generates the QRS complex. The automaticity of the SA node and conduction across the AV node are modulated by the autonomic nervous system *(bottom).* (Courtesy Dr. Robert L. Hamlin. From Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JA, editors: *Equine anesthesia: monitoring and emergency therapy,* ed 2, St. Louis, 2009, WB Saunders.)

a minor extent. Vagal influence generally depresses HR (chronotropism), AV conduction (dromotropism), excitability (bathmotropism), and myocardial contractile state (inotropism). However, because vagotonia also shortens the action potential and refractory period of atrial myocytes, high vagal activity is a predisposing factor in the development of AF.[112,229] Innervation of the stimulatory sympathetic nervous system is extensive throughout the heart and has effects generally opposite to those of the parasympathetic system. β_1-Adrenergic receptors dominate in the equine heart,[230] but presumably there are other autonomic subtype receptors, including α-adrenergic receptors and small numbers of β_2-adrenoceptors.[112,231] The notable increase in HR that attends exercise is related to increased

sympathetic efferent activity and withdrawal of parasympathetic tone.[9] Increases in HR to 220 to 240 beats/min are not uncommon with maximal exercise.[232-236] The exact role of dysautonomia in the genesis of cardiac arrhythmias has not been determined; however, infusion of autonomic receptor agonists and antagonists can be associated with direct or baroreceptor-induced changes in HR and rhythm.[237-247] Cardiac arrhythmias are discussed later in this chapter.

Vascular Diseases

There are three major subdivisions of the circulation: systemic, coronary, and pulmonary. The arteries and veins consist of three layers: adventitia, media, and intima. The overall structure and function of each layer vary with the vessel and location. Vascular receptors[20,112,114,116] and anatomic lesions influence vascular resistance and blood flow. α-Adrenoceptors dominate in the systemic vasculature, and BP is generally raised by vasoconstriction following stimulation of postsynaptic α-adrenergic receptors by norepinephrine, epinephrine, or infused α-adrenergic receptor agonists such as phenylephrine.[246,248-254] The presence of vasodilator β_2-adrenergic receptors is clinically relevant, insofar as infused β_2-agonists cause vasodilation in circulatory beds that contain high β-agonist adrenergic receptor density. Many vascular beds also dilate following the production of local vasodilator substances, such as nitric oxide, released during exercise, stress, or metabolic activity.[112,114,116] Dopaminergic receptors, when present in vascular walls, may be stimulated, causing vasodilation, provided vasoconstricting α-adrenergic activity does not dominate. Stimulation of histamine (H_1) receptors or serotonin (5-HT) receptors causes arteriolar dilation, venular constriction, and increased capillary permeability.[112,114,116] Infusion of endothelin[255-257] or of calcium salts causes arterial vasoconstriction,[258] whereas administration of calcium channel antagonists (e.g., verapamil, diltiazem) causes vasodilation of vascular smooth muscle.[259]

Various vascular lesions have been reported in horses (see Box 9.2). Rupture of the aorta, PA, or middle uterine artery is devastating and often lethal.[4,34,92,151,260-262] The aorta may also rupture into the heart, creating an aortic to cardiac fistula.[263,264] Aortopulmonary fistulation in conjunction with aortic rupture is relatively common in Friesians, possibly caused by a connective tissue disorder.[265,266] Although parasitic arteritis may predispose to vascular injury, the cause of most vascular lesions, including aortoiliac thrombosis, is unknown.[267-272] Causes of vasculitis include *Strongylus vulgaris* infestation of the cranial mesenteric artery, infective thrombophlebitis of the jugular veins, equine viral arteritis, and suspected immune-mediated disease.[145,147,273] Neoplasms can obstruct blood flow by external compression or through invasion, more often affecting the right side of the circulation. Examples include obstruction of the PA by a lung tumor and obstruction of venous return by neoplastic compression or invasion of the vena cava. Clinical features of vascular disease are discussed later in this chapter.

CLINICAL CARDIOVASCULAR PHYSIOLOGY

The clinician must appreciate elementary aspects of normal heart function in order to perform a clinical CV examination and understand the abnormalities associated with heart disease and CHF. Central to this are the electrical-mechanical correlates of Wiggers' cardiac cycle.

Cardiac Cycle

The association between electrical and mechanical events of the heart first described by Wiggers has been reviewed in standard physiology textbooks (Fig. 9.4).[57,110,112-115] From a study of this cycle, it is evident that cardiac electrical activity precedes pressure and volume changes; therefore arrhythmias can exert deleterious hemodynamic effects, especially during exercise, illness, or anesthesia. Relevant aspects of this cycle are now considered.

The P wave of the electrocardiogram (ECG) stems from electrical activation of the atria, late in ventricular diastole, and after the ventricles have been largely filled. During the ensuing atrial contraction the *atrial sound* (fourth heart sound or S_4) is generated and the ventricle is filled to its end-diastolic volume. The increase in atrial pressure, the atrial *a wave,* is reflected as a normal *jugular pulse* in the ventral cervical region. The magnitude of the atrial contribution to ventricular filling generally placed at 15% to 20% at rest but increases dramatically during high HRs. Therefore atrial tachyarrhythmias such as AF have the greatest impact on CO during exercise or tachycardia.

The QRS complex heralds ventricular systole. After depolarization of the ventricular myocytes, calcium enters the cell to trigger release of calcium stores in the sarcoplasmic reticulum. Increased cytosolic calcium interacts with the cardiac troponin complex on actin and myosin filaments to shorten the myofilaments and develop tension. These events are enhanced by sympathetic activity or drugs such as digoxin or dobutamine and depressed by anesthetics and drugs that impair calcium entry into cells. The abrupt increase in ventricular wall tension and chamber pressure closes the AV valves (coinciding with the vibrations of the *first heart sound;* S_1) and increases intraventricular pressure *(isovolumic period)* until the semilunar valves open.[23,25] At this instant the ventricular walls move inward and blood is ejected into the great vessel as the ventricular pressure increases to peak value and creates a similar peak arterial BP (Figs. 9.4A, 9.5C and D, and 9.6). The contracting heart twists during systole, and the left ventricle strikes the chest wall caudal to the left olecranon causing the *cardiac impulse* or *apex beat.* This early systolic movement, coincident with opening of the aortic valve, is a useful timing clue for cardiac auscultation and for identifying the mitral valve area for auscultation. The delay between the onset of the QRS and the opening of the semilunar valves, termed the *preejection period,* can be measured by Doppler echocardiography and is an index of ventricular myocardial contractility such that sympathetic activation and positive inotropic drugs shorten the preejection period.[46,241,274-279] Blood is ejected into the aorta and PA with an initial velocity that generally peaks near 1 m/sec and can be measured by Doppler echocardiography (see Fig. 9.5D).[280,281] The aortic ejection time usually exceeds 400 msec in a horse at rest, and reductions of either ejection velocity or ejection time are suggestive of reduced LV function. A *functional systolic ejection murmur* is often heard during ejection (Fig. 9.4A). Such murmurs, by definition, must begin after the first sound and end before the second sound. The difference between the diastolic and systolic pressure (pulse pressure) and rate of rise of pressure contribute to a palpable *arterial pulse* during midsystole (see Figs. 9.4A and 9.6). The precise timing of the pulse depends on the proximity of the palpation site relative to the heart. At the end of the *ejection period,* as ventricular pressures fall below those of the corresponding arteries, the semilunar valves close coincident with the high-frequency *second heart sound* (S_2) and the incisura of the arterial pressure curves (see Figs. 9.4A and 9.6).[19,23,25] The pulmonary valve may close either after or before the aortic valve.[3,4,282] Asynchronous valve closure may lead to

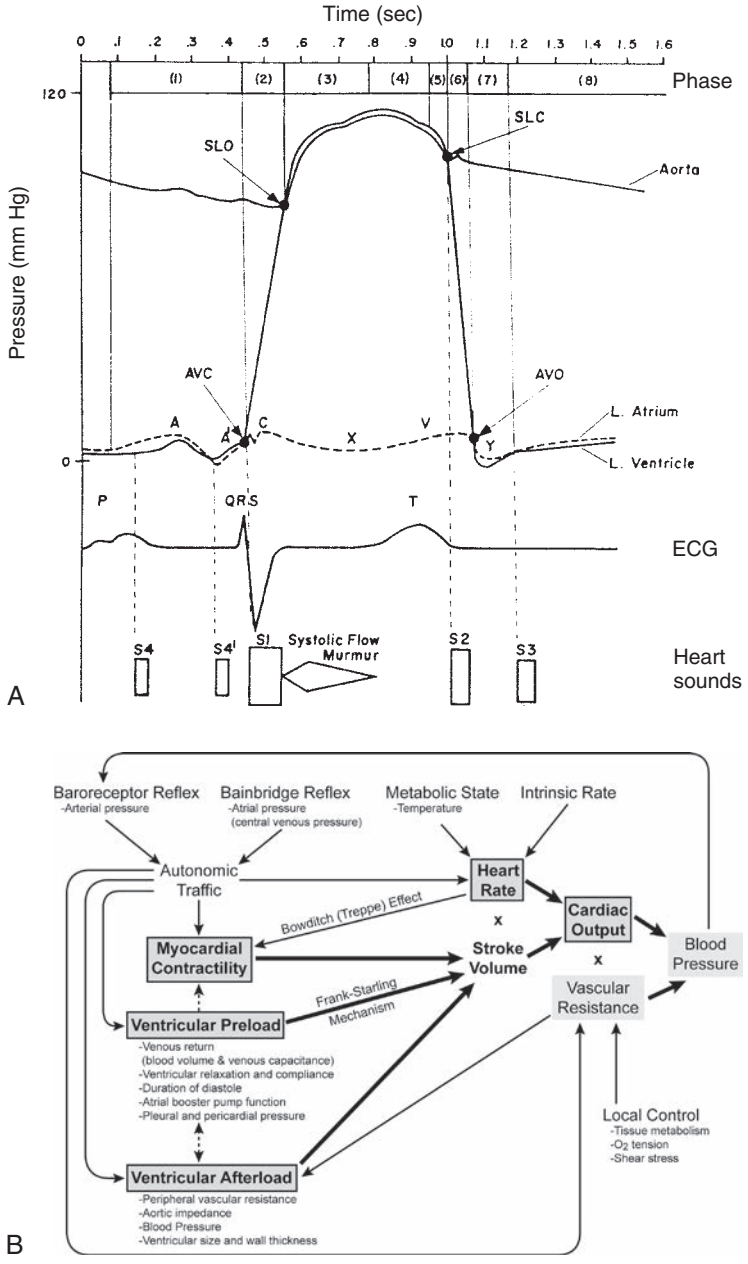

FIG. **9.4** A, The cardiac (Wiggers) cycle of the horse. This drawing integrates the electrical, pressure, mechanical, and flow events of diastole and systole and demonstrates the origins of the heart sounds. Electrical activity precedes mechanical events. See the text for a full description. *AVC,* Closure of the mitral (atrioventricular) valve; *AVO,* opening of the mitral (atrioventricular) valve; *SLO,* opening of the aortic (semilunar) valve; *SLC,* closure of the aortic (semilunar) valve. B, Determinants of cardiac output (CO) and blood pressure (BP). (A, Modified from Detweiler DK, Patterson DF: The cardiovascular system. In Cattcott EJ, Smithcors JF, editors: *Equine medicine and surgery,* ed 2, Santa Barbara, CA, 1972, American Veterinary Publications. audible splitting of S_2, which is normal but can be extreme in some horses with lung disease and pulmonary hypertension. During the ejection period the ventricular volume is markedly reduced from the end-diastolic volume: this volume ejected is defined as the *stroke volume.* The ratio of the stroke volume to the end-diastolic volume is the *ejection fraction,* a commonly used index of systolic heart function and correlated to the often-used *shortening fraction* of the M-mode echocardiogram (see Fig. 9.5C). Contraction of the ventricles causes the AV valves to bulge toward the atrium, leading to the early-systolic positive *c wave* of the atrial pressure curve, and is accompanied by a downward motion of the mitral and tricuspid annulus toward the apex, causing the subsequent *x descent* of the atrial pressure curve and a brief systolic collapse of the jugular vein. Subsequent to atrial filling during ventricular systole, a positive pressure wave, the *v wave,* occurs in the atrial and venous pressure curves. Severe TR accentuates this wave and may lead to pathologic systolic pulsations extending up the jugular furrow. Finally there is a decline in ventricular pressure *(isovolumic relaxation)* related to off-loading of calcium from the troponin apparatus

FIG. **9.5** Ventricular function and echocardiography. A, Derivation of the M-mode echocardiogram. The lines demonstrate typical paths of M-mode recording planes (*1,* ventricular/papillary muscle; *2,* chordae tendineae; *3,* anterior mitral valve [AMV]; *4,* aortic root and left atrium [LA]/auricle; *TW,* thoracic wall; *RVW,* right ventricular wall; *RV,* right ventricle; *S,* septum; *LV,* left ventricle; *AV,* aortic valve; *AO,* aortic outflow tract; *LVW,* left ventricular wall; *PMV,* posterior mitral valve; *LA,* left atrium). B, The drawing demonstrates the appearance of the M-mode echocardiogram at each level (*PER,* pericardium; *RS, LS,* right and left sides of the ventricular septum; *EN,* endocardium). C, M-mode echocardiogram demonstrating the method of measuring left ventricular shortening fraction (LVSF), in which *D* is diastolic dimension and *S* is systolic dimension (LVSF = D – S/D). The prominent thickening of the walls during systole is notable. The end-systolic excursion of the LV wall is visible *(arrow).* In practice, the systolic dimensions of the ventricular septum and the LV wall generally are measured along the same line as demonstrated for the LV lumen in systole *(S)* (*W,* LV wall; *VS,* ventricular septum). D, *Left:* Doppler echocardiographic recordings of LV filling *(left)* and ejection *(right).* Transmitral inflow is characterized by an early diastolic rapid-filling wave *(E),* low-velocity middiastolic filling (diastasis), and a presystolic atrial filling wave *(A). Right:* The velocity profile of aortic ejection is characterized by a roughly triangular appearance with rapid acceleration of blood flow into the ascending aorta in early to midsystole and termination of flow at the time of aortic valve closure. The area under the velocity spectrum curve (velocity-time-integral) correlates directly with ventricular stroke volume. The preejection period (the time between the start of the QRS and beginning of ejection) and the ejection times *(ET, arrows)* are load-dependent indices of LV function.

and resequestration into the sarcoplasmic reticulum. This active ventricular relaxation is associated initially with closure of the semilunar valves and eventually by opening of the AV valves (see Fig. 9.4A). Relaxation in healthy hearts is enhanced by sympathetic activity. Conversely, myocardial ischemia can impair active relaxation, and it is likely that subendocardial ischemia combined with reduced diastolic filling time contributes to the marked elevations in left atrial pressures observed during galloping or other high-intensity exercise.[283,284]

Ventricular filling commences just as the AV valves open. As shown in Fig. 9.5D, ventricular diastole can be subdivided into three general phases: rapid ventricular filling, diastasis, and atrial contraction.[110,112,113,115] These phases are readily observed using pulsed-wave Doppler echocardiography or Doppler tissue imaging.[168,285-287] Once the ventricles have relaxed and the atrial pressure exceeds the corresponding ventricular pressure, the AV valves open. At that instant, rapid filling ensues, with a peak velocity of about 0.5 to 1 m/sec but varying directly with the HR.[280] The ventricular pressures increase only slightly during this phase, whereas the ventricular volume curves change dramatically from the venous return. Rapid filling may be associated with a *functional protodiastolic murmur,* which is concluded by the *third heart sound* (S_3), the low-frequency vibrations occurring near the termination of rapid ventricular filling (see Fig. 9.4A). The loss of atrial volume and corresponding decline in the atrial pressure (the *y descent*) is reflected in the jugular furrow as the vein collapses. Following rapid filling, a period of greatly reduced low-velocity filling, diastasis, ensues. This period may last for seconds during vagal arrhythmias such as sinus bradycardia, pronounced sinus arrhythmia, or second-degree AV block. With markedly exaggerated pauses, the jugular vein may begin to fill prominently. The last phase of diastole is the contribution to ventricular filling caused by the atrial contraction. A functional *presystolic murmur* has been associated with this period between the fourth and first heart sounds.

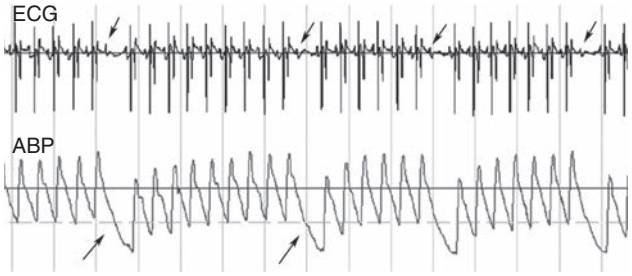

FIG. **9.6** Compressed electrocardiogram (ECG) with simultaneous arterial blood pressure (ABP) recording in a horse with second-degree atrioventricular block. The progressive increase in ABP triggers a baroreceptor reflex leading to atrioventricular conduction block *(upper arrows)* and a corresponding fall in the ABP *(lower arrows)*. Presumably this mechanism, along with sinus arrhythmia and sinus arrest, represents vagally induced mechanisms for controlling ABP in the standing horse.

During the cardiac cycle the atrium functions as a reservoir for blood (ventricular systole), a conduit for venous return (early to middiastole), and as a pressure pump (atrial systole).[288] Mechanical atrial function of the LA can be studied using two-dimensional (2D) echocardiography and advanced Doppler echocardiographic methods. Impaired electrical and mechanical function of the atria may predispose to recurrent atrial arrhythmias such as AF.[218,287,289-291]

Ventricular Function

The ability of the ventricles to eject blood depends on both systolic and diastolic ventricular function as well as HR and heart rhythm (Box 9.3; see also Fig. 9.4B). The most commonly used

BOX 9.3 Determinants of Cardiac Function

SYSTOLIC FUNCTION: DETERMINANTS OF VENTRICULAR STROKE VOLUME (see also Fig. 9.4B)

Preload [+]—ventricular end-diastolic volume
- Plasma (blood) volume
- Determinants of diastolic function (see below)

Contractility [+]—intrinsic myocardial ability to contract
- Sympathetic activity
- Loading conditions
- Myocardial perfusion (ischemia)
- Myocardial disease
- Drugs (positive or negative inotropic agents)

Afterload [–]—wall tension required to eject blood
- Aortic impedance
- Vascular resistance
- Ventricular volume (tension increases with dilation)
- Ventricular wall thickness (thin walls have higher tension)

Cardiac lesions increasing workload [–]
- Valvular regurgitation (common)
- Valvular stenosis (rare)
- Septal defects and shunts

DIASTOLIC FUNCTION: DETERMINANTS OF VENTRICULAR FILLING

Pleural/mediastinal factors
- Intrapleural pressure (ventilation, effusion)
- Mass lesions

Pericardial function
- Intrapericardial pressure (effusion)
- Constriction

Myocardial recoil (passive elastic properties)

Myocardial relaxation (active process)
- Myocardial perfusion (ischemia)

Ventricular wall distensibility (chamber and myocyte compliance)

Venous pressure and venous return (must be matched with compliance)
- Plasma volume
- Venous capacitance

Diastolic filling time
- Heart rate

Atrial contribution to filling (“booster pump”)
- Heart rate
- Cardiac arrhythmias (atrial fibrillation)

Atrioventricular contraction sequencing
- Cardiac arrhythmias

Atrioventricular valve function
- Stenosis

measurements of overall ventricular performance and circulatory function are HR, invasively or noninvasively determined arterial BP, rate of ventricular pressure change (dp/dt), cardiac output (CO), stroke volume (SV), LV ejection fraction, LV shortening fraction, systolic time intervals, central venous pressure, PA and pulmonary capillary wedge pressures, and arteriovenous oxygen difference (A-V DO_2).[57]

Cardiac output, the amount of blood pumped by the left (or right) ventricle in 1 minute (L/min), is the product of ventricular SV (mL/beat) multiplied by HR (beats/min) (see Fig. 9.4B). Cardiac index refers to the CO divided by (indexed to) the body surface area (or body mass). Cardiac output coupled to systemic vascular resistance determines the mean arterial BP; an increase in either variable raises mean arterial pressure. Values for CO vary widely with the size and activity of the horse and are often influenced by drug therapy or anesthesia.[292,293] Ventricular *stroke volume* depends on myocardial contractility, preload, and afterload (see Fig. 9.4B and Box 9.3).[24,26,110,112-115] Although traditionally considered independent determinants of myocardial function, these three variables are all interconnected and influence force, velocity, and duration of ventricular contraction and thereby SV.[110,112,114] Invasive and noninvasive estimates of SV and CO can be obtained in standing and anesthetized horses using a large variety of methodologies.[276,294-318] In clinics, SV is often estimated noninvasively by 2D and Doppler echocardiography (see later discussion).[168,297,306,307,309,311-313]

Myocardial *contractility (inotropy)* is defined as the maximum velocity of fiber shortening at zero load.[110,112-115] Ultimately, it is determined by the availability of calcium to the sarcomere and the sensitivity of troponin C for calcium, which are modulated by the autonomic input, the initial myocardial stretch (preload; see later discussion), and the HR (Bowditch "treppe" effect) (see Fig. 9.4B). Contractility is increased by catecholamines, calcium, digitalis glycosides, and phosphodiesterase inhibitors.* True contractility is difficult to measure in the clinical setting because of the influence of HR and loading conditions on clinical measurements of systolic ventricular function. Overall systolic ventricular function can be estimated noninvasively by observing directional changes in load-dependent preejection or ejection phase indices of ventricular function. These include LV shortening and ejection fractions by M-mode and 2D echocardiography; preejection period, ejection time, flow acceleration, velocity time integral of aortic or pulmonic ejection, and peak myocardial velocity by tissue Doppler echocardiography; and myocardial deformation (strain) or strain rate by computerized analysis of 2D echocardiograms or tissue Doppler studies (see Fig. 9.5).† Measured variables will be influenced by physiologic state, altered mildly by day-to-day variation[350,351] or sedatives,[274] and affected markedly by exercise[168] and general anesthesia.[292]

Ventricular sarcomere length before contraction or *preload* is a positive determinant of ventricular systolic function that depends on ventricular filling (Box 9.3). The healthy ventricle is highly preload dependent such that increases in preload increase SV. This ability of the heart to change its force of contraction and therefore SV in response to changes in preload is called the *Frank-Starling mechanism* (or Starling's law of the heart).[110,112-115] Dehydration, venous pooling, impairment of ventricular relaxation and compliance, increased intrapleural or intrapericardial pressures, loss of atrial booster pump function (e.g., with AF or atrial stunning after AF) and certain tachyarrhythmias (by shortening filling time and disturbing the atrioventricular conduction sequence) all reduce ventricular filling and decrease SV. Increased preload can be observed in horses with heart disease as a consequence of impaired pump function and fluid retention secondary to activation of the renin-angiotensin-aldosterone system.[117] Moderate to severe valvular insufficiency increases ventricular filling pressures and preload.[144,352-355] The increased ventricular diastolic dimensions serve as a compensatory mechanism that maintains forward stroke volume in the early setting of a failing ventricle or regurgitant heart valve. Ventricular preload can be estimated by determining ventricular end-diastolic dimensions (volume, area, or diameter) using echocardiography[168,344,345,355] or by measuring venous filling pressures using intracardiac catheters.[353,354] The measurement of venous filling pressures (central venous pressure, pulmonary diastolic, or pulmonary capillary wedge pressure)[353-358] provides an accurate gauge of preload provided that HR and ventricular compliance (distensibility) are normal and ventilation is relatively stable. Myocardial ischemia, which impairs myocardial relaxation, and pericardial diseases, which constrict the ventricles, both reduce ventricular compliance; in such cases, the venous filling pressures may not accurately reflect chronic changes in ventricular preload.

Ventricular *afterload* relates to the forces impeding ejection of blood and is closely related to the aortic pressure.[110,112-115] Vascular impedance during ejection is determined by the elastic, resistive, and dynamic properties of the connected great vessel and vascular tree. However, afterload is not solely determined by blood pressure. Ejection against a pressure load causes wall stress, which according to Laplace's law is proportionate to pressure (P) × radius (r) and inversely proportionate to wall thickness (h). Afterload can be expressed as LV wall stress during ejection. While the exact equation depends on cardiac chamber shape, which is subject to changes during the cardiac cycle, the above simplified relationship highlights how pressure, radius, and wall thickness contribute to afterload. Peak wall stress occurs immediately before aortic valve opening. Afterload is difficult to measure clinically, and although BP is not identical to afterload, it may be used to estimate directional changes in afterload. Additionally, relative LV wall thickness can be measured by echocardiography and should be taken into account.[168,344] Increases in ventricular chamber size, thinning of ventricular walls, aortic stenosis, arterial stiffness or resistance (leading to increased pressures), as well as marked increases in hematocrit, increase the impedance to ventricular ejection and reduce SV. Ventricular hypertrophy, by increasing relative wall thickness, can be thought of as a mechanism that reduces wall stress at a given pressure and radius.[114] The failing heart is characterized by poor myocardial contractility, an exhausted preload reserve, and an increased sensitivity to ventricular afterload. Arterial vasodilators such as acepromazine, hydralazine, and angiotensin-converting enzyme inhibitors decrease afterload and are important components of heart failure treatment.[55,58,359-363]

Ventricular *synergy* refers to the normal method of ventricular activation and contraction. Normal electrical activation causes a burst of activation of great mechanical advantage. Cardiac arrhythmias, especially ventricular rhythm disturbances, can cause dyssynergy (dyssynchrony) with a resultant decrease in SV. Coronary occlusions leading to transient myocardial ischemia or ischemic myocardial necrosis also cause dyssynergy but are considered relatively rare.[91,147,364]

Structural and functional *competency of the cardiac valves and the ventricular septa* influence ventricular systolic function.

* References 237, 238, 241, 246, 249-251, 253, 258, 277, 319-339.

† References 49-51, 56, 168, 279, 286, 340-349.

Valvular insufficiency (or the rare stenosis) reduces ventricular stroke volume unless there is adequate compensation from ventricular dilation and hypertrophy. Ventricular remodeling, combined with HR reserve, often allows small septal defects or mild to moderate valvular lesions to be well tolerated even during exercise. However, large defects or severe valvular lesions can create significant volume overload of the left side of the heart, progressive myocardial dysfunction, and heart failure. Development of CHF is particularly likely when an arrhythmia such as AF is superimposed on a serious structural lesion.

Ventricular *diastolic function* determines ventricular filling and preload.[110,112-115] Factors that affect diastolic function are indicated in Box 9.3. When diastolic function is abnormal, there is often greater HR and higher venous pressure dependencies for maintenance of CO. A well-recognized cause of diastolic dysfunction is constriction or compression of the heart due to pericardial disease. Marked ventricular chamber dilation or hypertrophy also decreases ventricular compliance and requires higher ventricular distending pressures for filling. Left ventricular diastolic dysfunction as a consequence of severe RV dilation or hypertrophy can be explained by bulging of the ventricular septum into the left ventricle, which impedes left-sided filling. This impact of *ventricular interdependence* is observed clinically with chronic pericardial disease and severe pulmonary hypertension. Ventricular diastolic function also is affected by arrhythmias. Persistent tachycardia shortens diastole, cardiac filling time, and coronary perfusion. With AF, the atrial contribution to filling is lost. Junctional and ventricular arrhythmias lead to AV dissociation preventing normal AV sequencing and can also create marked dyssynchrony of ventricular contraction. Objective measures of diastolic function are very complicated, and no good clinical indicator of diastolic function is currently available for horses. However, diastolic dysfunction may be assumed when one of the aforementioned conditions is recognized. It is possible to measure transmitral and tricuspid inflow using Doppler techniques, but these methods are unreliable, are crude, and also depend on atrial pressure.[280,281,287,344,365] Assessment of diastolic wall motion velocities by tissue Doppler imaging also may provide more insight into diastolic cardiac function.[161,164,286,349,366]

Imbalance between *myocardial oxygen demand* and delivery can reduce both ventricular systolic and diastolic function and may affect cardiac rhythm as well. This relationship is also relevant when there is airway obstruction or bronchopulmonary disease, which can reduce arterial oxygenation.[90] Myocardial oxygen demand is augmented by increasing myocardial inotropic state, HR, and ventricular wall stress (related to preload and afterload).[110,112-115] Oxygen delivery depends on coronary anatomy and vasomotion (degree of vessel constriction), diastolic arterial BP, diastolic (coronary perfusion) time, and metabolic activity of the myocardium.[10,367-373] Normal coronary flow is highest to the LV myocardium in the ventricular septum and LV wall.[373] The immediate subendocardial layer of myocardium is probably most vulnerable to ischemic injury,[367] and altered ventricular depolarization may develop secondary to an imbalance in oxygen delivery. This probably accounts in part for the ST-T depression and changes in the T waves observed in hypotensive animals and in normal horses during sinus tachycardia. Coronary vasomotion is effective in augmenting coronary perfusion even at high HRs (up to 200/min in ponies); however, coronary autoregulation is not as effective if diastolic perfusing pressure decreases in the aorta.[368,369] The clinician may use the "double product" of arterial BP × HR as a general estimate of myocardial oxygen demand.[112] Persistent ST-segment depression or elevation, especially at rest and normal HRs, suggests deficient myocardial perfusion. However, marked ST-segment and T-wave changes are normal in horses examined during treadmill exercise and are therefore difficult to interpret.

CARDIOVASCULAR EXAMINATION OF THE HORSE

General Approach

A general approach to the recognition and diagnosis of heart disease and an assessment of its severity is summarized in Box 9.4.[61,62] Undoubtedly, history and physical examination are the most important initial evaluation procedures in the CV examination of the horse. With the exception of mild abnormalities in cardiac structure and function, normal physical examination and cardiac auscultation in a horse with good exercise tolerance practically precludes clinically relevant heart disease. The initial CV physical examination should include recording of an accurate resting HR and respiratory rate, evaluation of the arterial pulses (head and limbs), inspection of the veins (mostly jugular veins), evaluation of the mucous membranes for pallor, refill time, and cyanosis (which may develop secondary to a right-to-left cardiac shunt or severe respiratory disease), evaluation for abnormal fluid accumulation, inspection for abnormal ventilatory patterns, palpation of the precordium, a thorough auscultation of the heart at all valve areas, and auscultation of both lung fields. Noninvasive BP measurement can serve to objectify palpatory findings on arterial pulses and identify widening of pulse pressure.[52,68]

It is worth emphasizing that most *serious* cardiac disorders can be detected initially by physical examination and a stethoscope. The presence of a cardiac murmur is the essential finding that leads one to suspect degenerative or infective valvular disease or a congenital heart malformation. Sustained or recurrent cardiac arrhythmias are easily discovered through cardiac auscultation and palpation of the arterial pulse. Pericarditis and cardiac tamponade are characterized by muffled heart sounds or pericardial friction rubs, jugular distention, and often RV failure. Significant myocardial disease is usually associated with heart failure, arrhythmias, or a cardiac murmur, especially when ventricular dilation or dysfunction causes insufficiency of the mitral or tricuspid valves. Mild, subtle, or occult CV disease may be subclinical at rest and require a detailed examination, including exercise testing, before abnormalities can be objectively detected. Laboratory studies, electrocardiography, echocardiography, and cardiac catheterization are additional tests that are particularly useful in recognizing or confirming the underlying basis of CV disease and assessing its severity.

History

CV disease may be suspected from the history or a serendipitous finding during the course of a routine examination. The horse with CHF may be presented for generalized venous distention, jugular pulsations, edema, or rarely, in the case of acute left-sided heart failure, respiratory distress and pulmonary edema.[148,374] Conversely, other cardiac problems such as arrhythmias or murmurs can be incidental findings, detected during a routine physical, prepurchase, or insurance examination. The horse with clinically apparent CV disease may have subtle performance problems that are only apparent at peak performance levels. In many cases, performance

BOX 9.4 Diagnostic Studies for the Evaluation of Heart Disease

HISTORY[a]

- Signalment, presenting complaints, general medical history, past illnesses, past and current medications, weight loss, work history, and exercise tolerance

PHYSICAL EXAMINATION[a]

- Body condition
- Heart rate and rhythm
- Arterial and venous pulses, venous distention, venous refill
- Mucous membrane color and capillary refill time
- Evaluation for abnormal fluid accumulation: subcutaneous edema, pleural effusion (by thoracic percussion)
- Auscultation of the heart (heart sounds, heart murmurs, rhythm) and lungs
- Measurement of arterial blood pressure and pulse pressure (noninvasive)

ELECTROCARDIOGRAPHY

- Resting electrocardiogram—heart rate, rhythm, P-QRS-T configuration, conduction sequence, association of P and QRS-T, ECG time intervals, and electrical axis (axis has limited value in horses)
- Exercise and postexercise electrocardiography[b]
- 24-Hour ambulatory (Holter) electrocardiography[b]

ECHOCARDIOGRAPHY

- Two-dimensional echocardiography—cardiac anatomy, chamber size, and vessel dimensions; valve anatomy and motion; systolic atrial and ventricular function; identification of cardiac lesions or free fluid; estimation of cardiac output
- M-mode echocardiography—ventricular dimensions and systolic ventricular function; cardiac anatomy and valve motion; estimation of cardiac output
- Doppler echocardiography—identification of normal and abnormal flow; estimation of intracardiac pressures and pressure gradients; estimation of cardiac output; assessment of systolic and diastolic ventricular function
- Postexercise echocardiography[c]—identification of regional or global wall dysfunction or valve dysfunction exacerbated by exercise

THORACIC RADIOGRAPHY

- Evaluation of pleural space, pulmonary parenchyma, lung vascularity
- Estimation of heart size

THORACIC AND ABDOMINAL ULTRASONOGRAPHY

- Evaluation of abnormal fluid accumulation: pleural effusion, ascites

CLINICAL LABORATORY TESTS

- Complete blood count, serum amyloid A (SAA), and fibrinogen to identify anemia and inflammation
- Serum biochemical tests including electrolytes (particularly K^+, Mg^{2+}, Ca^{2+}), renal function tests, and muscle enzymes: these studies can be useful for assessment of arrhythmias, identification of low cardiac output (azotemia), and recognition of myocardial cell injury (CK and AST, unspecific)
- Cardiac troponin T or I (cTnT, cTnI): Can be measured at rest and after exercise testing to identify myocardial damage
- Serum proteins to identify hypoalbuminemia and hyperglobulinemia
- Arterial blood gas analysis to evaluate pulmonary function (alternatively: pulse oximetry)
- Venous (or preferably mixed venous) blood gas analysis to assess acid-base status, oxygen delivery, and oxygen extraction in the tissues
- Blood lactate to identify anaerobic metabolism associated with poor tissue oxygenation or impaired oxygen utilization in the tissues
- Blood cultures in cases of thrombophlebitis or suspected endocarditis
- Cytology and culture of pericardial effusates
- Urinalysis to identify renal injury from heart failure or endocarditis
- Serum/plasma assays for digoxin, quinidine, and other cardioactive drugs (therapeutic drug monitoring)

CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY[c]

- Diagnosis of abnormal blood flow and identification of abnormal intracardiac and intravascular pressures

RADIONUCLIDE STUDIES[c]

- Detection of abnormal blood flow or lung perfusion; assessment of ventricular function

[a] Most important part of the cardiac evaluation.
[b] May be needed to identify paroxysmal arrhythmias.
[c] Not routinely performed.

may only deteriorate slightly. In other horses, particularly in cases of AF, racing performance may decline greatly by 20 to 30 seconds or more throughout a race. Horses with sudden-onset AF or with malignant ventricular tachycardia (VT) may stop abruptly or even fall. Horses with CV disease also may demonstrate excessively high heart and respiratory rates during and after exercise or may take a longer than normal time to return to a resting rate (or "cool out"). Coughing, either at rest or during exercise, tachypnea, and exercise-induced pulmonary hemorrhage are respiratory signs reported in some horses with heart disease. Cardiovascular disease must always be considered along with musculoskeletal, respiratory, metabolic, and neurologic problems in the differential diagnosis of poor performance (Box 9.5).[87-90,375-377] Other performance-related problems with CV disease can include weakness, ataxia, collapse, and sudden death (Box 9.6).[85,91-106,261]

Once an abnormality has been found, a complete CV examination is aimed at determining the lesion and the clinical relevance of disease in terms of horse and rider safety, performance capabilities, and expected longevity.

BOX 9.5 Cardiovascular Disorders Associated With Poor Performance

ARRHYTHMIAS
Atrial premature complexes
Ventricular premature complexes
Atrial fibrillation
Supraventricular tachycardia
Ventricular tachycardia
Advanced second-degree atrioventricular block
Complete third-degree atrioventricular block

CONGENITAL, VALVULAR, MYOCARDIAL, OR PERICARDIAL HEART DISEASES ASSOCIATED WITH MURMURS
Ventricular septal defects or other congenital malformations
Mitral regurgitation
Tricuspid regurgitation
Aortic regurgitation
Cardiomyopathy with secondary atrioventricular valvular regurgitation
Pericardial disease causing friction rubs

OCCULT HEART DISEASE
Pericardial disease
Myocardial disease

VASCULAR DISORDERS
Aortoiliac thrombosis
Jugular vein thrombosis/thrombophlebitis (bilateral)
Aortic root rupture (aortocardiac fistula)
Peripheral vein thrombosis/thrombophlebitis

BOX 9.6 Causes of Sudden Cardiovascular Death

DISORDERS OF THE HEART (ARRHYTHMIAS)
Ventricular tachycardia, flutter, or fibrillation
Complete atrioventricular block
Asystole

HEMORRHAGE
Rupture of the heart (with cardiac tamponade)
Rupture of the aorta or pulmonary artery (with or without cardiac tamponade)
Arterial rupture
Middle uterine artery
Mesenteric, omental, or other large arteries
Severe pulmonary hemorrhage
Rupture of the spleen or liver
Brain hemorrhage

ACUTE MYOCARDIAL FAILURE
Acute decompensation of chronic heart failure
Acute onset of severe valvular insufficiency
Acute myocardial ischemia/necrosis (rare)

TOXIC INJURY TO THE HEART
Drug- or toxin-induced arrhythmia
Anesthetics
Toxic plants
Myocardial toxins
Systemic toxin secondarily affecting the heart

CARDIAC TAMPONADE
Bacterial pericarditis
Idiopathic pericarditis
Viral pericarditis
Trauma

EMBOLISM
Carotid air embolism
Coronary embolism or thrombosis

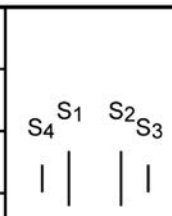
ELECTROCUTION
Lightning
Alternating current electrocution

CARDIAC TRAUMA
Cardiac catheterization or needle puncture of a ventricle leading to ventricular fibrillation
Penetrating thoracic wound

Auscultation

Clinical Method

Cardiac auscultation is the systemic examination of the heart using a stethoscope. Auscultation is expedient and relatively sensitive for detection of serious heart disease when performed by a knowledgeable and experienced examiner. It provides information about HR, persistent arrhythmias, and presence or absence of congenital and acquired heart diseases. Auscultation should be conducted within the context of a medical history and general physical examination.



Effective auscultation requires an understanding of anatomy, physiology, pathophysiology, and sound. There is extensive clinical experience regarding cardiac auscultation in the horse,* and experience with Doppler echocardiography has refined the clinician's understanding of heart sounds and murmurs.[71,208,209,211,390,391] Experience and training are also significant factors in effective cardiac auscultation,[392,393] and this examination method should be considered an acquired skill that can be constantly honed. The overall sensitivity of auscultation is high for identification of congenital heart diseases, *significant* valvular disease, and *persistent* cardiac arrhythmias. Sensitivity is lower for primary myocardial or pericardial diseases, unless there are obvious associated abnormalities such as a murmur, arrhythmia, or prominent friction rub. The specificity of auscultation in the horse (e.g., the ability to distinguish a functional from a pathologic murmur or identify a specific flow disturbance) has not been sufficiently studied, but most certainly depends on the clinician's knowledge and experience,[392] as well as one's opinion related to the physiologic versus pathologic nature of valvular regurgitation in some high-performance horses.

A prerequisite for auscultation is an appreciation of the normal heart sounds, the genesis of which has already been described (see Clinical Cardiovascular Physiology). The examiner must be familiar with the causes and clinical features of arrhythmias and murmurs (Tables 9.1 through 9.3) and the areas for auscultation (Fig. 9.7).* Auscultation is best

TABLE **9.1** **Identification of Heart Sounds and Common Cardiac Murmurs**

Auscultatory finding	Timing°		Point of maximal intensity (valve area)*
Normal Heart Sounds			
First heart sound (S_1)	Onset S		Left apex (mitral valve)
Second heart sound (S_2)	End S		Left base (aortic valve)
Pulmonic component	End S		Left base (pulmonic valve)
Third heart sound (S_3)	Early D		Left apex (mitral valve)
Fourth (atrial) sound (S_4)	Late D		Ventricular inlet or base (Left)
Functional Murmurs†			
Systolic ejection murmur	S		Left base (Aortic/pulmonary valves)
Early (proto-)diastolic	D		Ventricular inlets (Left/Right)‡
Late diastolic (presystolic)	D		Ventricular inlets (Left/Right)‡
Valvular Regurgitation§			
Mitral regurgitation	S		Left apex (mitral valve)
Tricuspid regurgitation	S		Right hemithorax (tricuspid valve)
Aortic regurgitation	D		Left base (aortic valve)
Pulmonary insufficiency	D		Left base (pulmonic valve)
Ventricular Septal Defect ‖	S		Right sternal border/left cardiac base
Patent Ductus Arteriosus	S + D		Dorsal left base over pulmonary artery

°S—systole, the interval between S_1 and S_2; D—diastole, the interval between S_2 and S_1 (see Figs. 9.8 and 9.9).
*Only typical features are considered; "apex" refers to the ventral part of the heart, at the point of the palpable cardiac impulse (apex beat); "base" refers to the craniodorsal part of the heart over the outlet valves (aortic, pulmonic) where the second heart sound is most intense (see Fig. 9.7).
†The exact causes of functional (flow) murmurs have not been proven. The systolic ejection murmur, which begins after the first heart sound and ends before the second heart sound, is the most commonly identified murmur in the horse; the protodiastolic murmur extends from the second to the third heart sound; the presystolic murmur is quite short, spanning the fourth and first heart sounds. Functional murmurs may be musical.
‡Ventricular inlets refer to the parts of the thorax overlying the ventricular inflow tracts. These include the areas just dorsal to the mitral and tricuspid valve areas and extend ventrally to the apical regions of the ventricles.
§Murmurs of AV valve insufficiency are generally heard over the affected valve, project prominently toward the respective ventricular apex, and also radiate dorsally, following the regurgitant jet into the atrium. Occasionally, murmurs of tricuspid valve disease are prominent at the extreme left, cranial heart border. Valve regurgitation murmurs are evident throughout systole or diastole and extend into the second heart sound (holosystolic or pansystolic) or first heart sound (holodiastolic or pandiastolic); however, late systolic murmurs, which may be related to valve prolapse, have been identified with mitral or tricuspid valve insufficiency, and the murmur of aortic insufficiency may not always be holodiastolic. Documented reports of valve stenosis are quite rare.
‖Murmurs caused by defects in the right ventricular inlet septum (paramembranous VSD, common) are heard best above the right sternal border; murmurs from defects in the RV outlet septum (subpulmonic VSD, rare) may be loudest over the pulmonic valve; increased flow across the pulmonic valve can cause left-basilar systolic murmurs of relative pulmonic stenosis in the absence of pulmonic valve pathology; flow across very large nonrestrictive defects can be relatively soft.
From Schwarzwald, C.C., Bonagura, J.D., and Muir, W.W.: The cardiovascular system. In: *Equine Anesthesia—Monitoring and Emergency Therapy* (Ed. W.W. Muir), 2nd ed. Saunders Elsevier, p. 65.

carried out in a very quiet area because extraneous noise makes detection of soft to moderate murmurs quite difficult. The horse or foal should be sufficiently restrained so the examiner can concentrate on listening. The venous pulse should be inspected and then the arterial pulse and the precordium palpated before commencing auscultation. Although uncommonly used today, percussion of precordial area to identify the region of cardiac dullness can be used effectively by practiced examiners to identify heart size.[395]

The stethoscope examination generally commences on the left side. Both stethoscope chest pieces—the diaphragm (applied tightly, for high-frequency sounds and murmurs) and the bell (applied lightly, for low-frequency sounds and murmurs)—should be used. When using a single-piece tunable

TABLE **9.2** **Auscultation of Cardiac Arrhythmias**

Rhythm	Heart Rate per Minute	Heart Sounds[a]	Auscultation
SINUS RHYTHMS			
Sinus rhythm	Variable	S_4–S_1–S_2 (S_3)	Rate and rhythm dependent on autonomic tone
Sinus arrest/block	<26	S_4–S_1–S_2 (S_3)	Irregular, long pauses
Sinus bradycardia	<26	S_4–S_1–S_2 (S_3)	Generally regular unless escape rhythm develops
Sinus arrhythmia	25–50	S_4–S_1–S_2 (S_3)	Irregular, cyclic change in heart rate; often interval varying between S_4 and S_1; often associated with second-degree atrioventricular block or sinus bradycardia
Sinus tachycardia	>50	S_4–S_1–S_2 (S_3)	Typically regular, but second-degree atrioventricular block may develop if sympathetic tone decreases (e.g., during recovery from exercise)
SUSTAINED ATRIAL TACHYARRHYTHMIAS			
Atrial tachycardia and atrial flutter	>30	S_1–S_2 (S_3)	Ventricular regularity and rate dependent on atrioventricular conduction sequence and sympathetic tone; consistent S_4 absent; variable-intensity S_1; may detect independent atrial sounds
Atrial fibrillation	>30	S_1–S_2 (S_3)	Ventricular response irregular; rate related to sympathetic tone; heart rates consistently above 60 beats/min suggestive of significant underlying heart disease or heart failure; absence of consistent S_4
ECTOPIC RHYTHMS			
Junctional rhythm	26–200	S_1–S_2 (S_3)	Heart rate usually regular with idionodal rhythms or junctional tachycardia; heart rate dependent on the mechanism and sympathetic tone; inconsistent independent S_4 at lower rates possibly audible
Ventricular rhythm	26–200	S_1–S_2 (S_3)	Heart rate possibly regular during monomorphic, uniform ectopic rhythm or irregular during polymorphic or multiform ectopic activity; heart rate dependent on the mechanism (e.g., escape rhythm versus ventricular tachycardia); variable intensity and split heart sounds possibly audible
Premature atrial and junctional beats	Varies	Early S_1–S_2	Intensity of S_1 may be louder or softer than normal; the sounds are not usually split; less than compensatory pause often follows premature beat; nonconducted atrial premature complexes result in pauses but not premature first heart sounds
Premature ventricular beats	Varies	Early S_1–S_2	Intensity of S_1 often variable and ventricular beats possibly softer than normal; heart sounds possibly split from asynchronous ventricular activation heart sounds; compensatory pause typically following a premature beat
ATRIOVENTRICULAR BLOCKS			
Incomplete (first- and second-degree block)	<50	S_4–S_1–S_2 (S_3) Isolated S_4	Heart rate variable; cyclic arrhythmia, variable S_4–S_1 interval; some variation in heart sounds; isolated S4 with second-degree AV block
Complete (third-degree block)	<26	S_4/S_1–S_2 (S_3)	Ventricular escape rhythm, usually regular; independent atrial (S_4) sounds; variable-intensity heart sounds

[a]Heart sounds in parentheses may not be audible.

TABLE **9.3** **Causes of Cardiac Murmurs**

Cardiac Murmur	Lesion Identified by Echocardiography, Cardiac Catheterization, or Necropsy
Functional murmurs[a]	No identifiable lesions; occasionally markedly turbulent systolic blood flow identified in great vessels on color Doppler echocardiography
Congenital heart disease murmurs	Defect(s) in the atrial or ventricular septa; patent ductus arteriosus; atresia/stenosis of tricuspid or pulmonic valve; valve stenosis; complex malformations of the heart
Mitral regurgitation[b]	No identifiable lesion (high-level training); degenerative thickening of the valve; bacterial endocarditis; mitral valve prolapse into left atrium; rupture of a chorda tendinea; dilated, hypokinetic ventricle (dilated cardiomyopathy, severe aortic regurgitation); papillary muscle lesion or dysfunction; noninfective valvulitis; malformation

Continued

TABLE **9.3** **Causes of Cardiac Murmurs—cont'd**

Cardiac Murmur	Lesion Identified by Echocardiography, Cardiac Catheterization, or Necropsy
Tricuspid regurgitation[b]	Same as mitral regurgitation; also pulmonary hypertension from severe left-sided heart failure or chronic respiratory disease
Aortic regurgitation[b]	Degenerative thickening and/or prolapse of the valve; congenital fenestration of the valve; bacterial endocarditis[c]; aortic prolapse into a ventricular septal defect; flail aortic valve leaflet; noninfective valvulitis; malformation; ruptured aorta or aortic sinus of Valsalva
Pulmonary regurgitation[b]	No identifiable lesion; bacterial endocarditis[c]; pulmonary hypertension; flail pulmonary leaflet; noninfective valvulitis; malformation; rupture of the pulmonary artery

[a]Functional murmurs may be innocent (unknown cause) or physiologic (suspected physiologic cause); functional murmurs are very common in foals, trained athletes (athletic murmur), and horses with high sympathetic nervous system activity (pain, stress, sepsis); are associated with fever; and are often heard in anemic horses. Functional murmurs are very dependent on physiologic state and can be altered (accentuated or abated) by changing the heart rate. Such dynamic auscultation is very useful in detecting functional murmurs.
[b]"Silent" trivial or mild regurgitation across right-sided (most common) or left-sided (less common) cardiac valves can be identified in some horses by Doppler echocardiography; this is probably a normal finding of no clinical relevance provided that no other findings indicate the presence of cardiac disease. Pulmonary insufficiency is often silent. Many trained athletes have audible murmurs of tricuspid and/or mitral regurgitation that are not associated with poor performance or signs of heart disease (by physical examination and echocardiography) and are not considered clinically relevant.
[c]Large vegetations may result in anatomic stenosis causing a systolic murmur, which is usually associated with a diastolic murmur of valve insufficiency; increased flow across a normal valve may generate a murmur of relative valve stenosis (e.g., with aortic regurgitation, there may be a systolic ejection murmur resulting from an increased stroke volume).

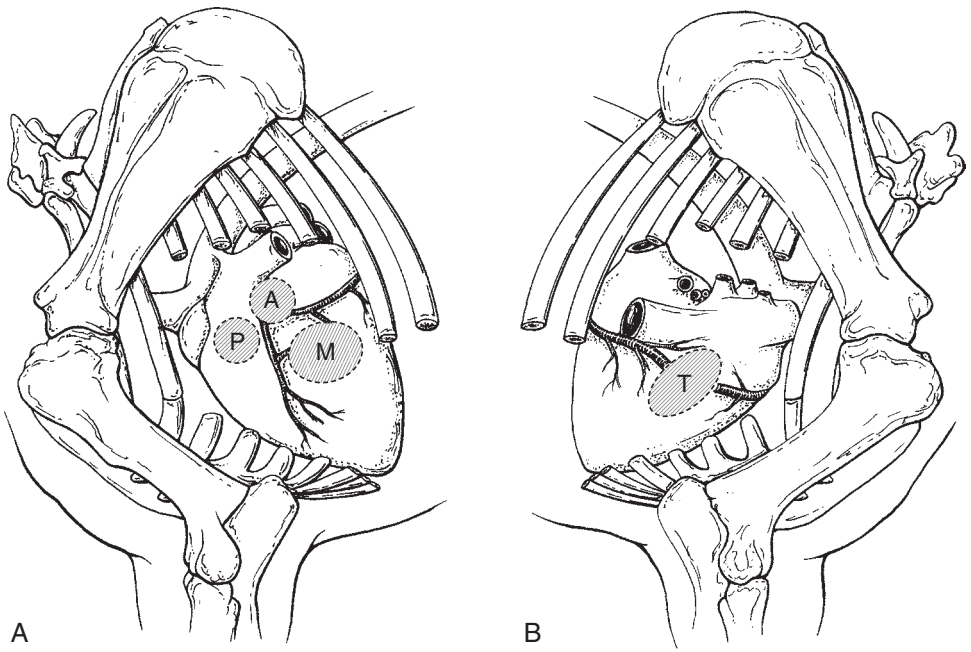

FIG. **9.7** Cardiac auscultation areas in the horse from the left (A) and the right (B) side of the thorax. Note the size and anatomic position of the heart within the thorax. The cardiac apex (apical area) is usually located slightly above the level of the olecranon and can be identified by palpation of the apical beat. The cardiac base (basilar area) is located more cranially and at the level of the scapulohumeral joint. The shaded areas represent the respective valve areas (*P,* pulmonic; *A,* aortic; *M,* mitral; *T,* tricuspid). The right atrium (RA) *(above T),* tricuspid valve, and right ventricular (RV) inlet (inflow region, *below T*) are located on the right side of the thorax. Paramembranous ventricular septal defects (VSDs) that communicate with the RV inlet (below the tricuspid valve) are usually heard best along the lower right hemithorax *(below T)* and typically radiate from the right ventricle (RV) into the pulmonary artery (left hemithorax). Most (but not all) murmurs of tricuspid valve disease are heard best over the right chest wall, usually heard best more dorsally as they radiate into the RA *(above T).* The RV outlet projects to the left side of the thorax and continues into the pulmonary artery, which is located at the left dorsal cardiac base *(above P).* Thus murmurs originating in the RV outlet (e.g., murmurs from subpulmonic VSDs), systolic murmurs of relative pulmonic stenosis (from cardiac shunting), murmurs of pulmonic insufficiency (rare), and functional pulmonary arterial murmurs are heard best over the left chest wall *(P).* The aortic valve is located centrally, and diastolic murmurs of aortic insufficiency may be heard at either hemithorax, although they are usually loudest on the left *(A).* Functional murmurs generated in the ascending aorta are heard over the cranial basilar region of the heart. The systolic murmur of mitral regurgitation (MR) radiates to the left apex and is usually heard across the left ventricular (LV) inlet (area caudoventral of *M*). The regurgitant mitral jet can be directed craniodorsal or caudodorsal into the left atrium (LA) and can account for variability in murmur radiation. The functional protodiastolic murmurs associated with ventricular filling are usually evident over the ventricular inlets and may be heard on either side of the thorax. (From Reef VB: Cardiovascular system. In Orsini JA, Divers TJ, editors: *Manual of equine emergencies: treatment and procedures,* ed 2, Philadelphia, 2003, WB Saunders.)

diaphragm, the pressure on the chest piece should be gradually increased to optimize the sounds of interest. A variety of digital stethoscopes are available today that are able to amplify heart sounds and murmurs across selected frequency ranges, reduce or eliminate external noise and artifacts, record sound, and display phonocardiograms on a computer or a smartphone. These devices can be helpful for diagnostic and teaching purposes. However, the clinician should be aware that digitally processed sound quality is different compared with traditional stethoscopes. The diagnostic agreement may only be moderate, and the sensitivity to detect abnormal sounds and murmurs may not necessarily be improved with digital techniques.[396,397] It is therefore advisable to use digital stethoscopes complementary to and not in place of conventional stethoscopes.

All auscultatory areas should be examined (see Fig. 9.7). The locations of the cardiac valve areas can be identified using the following method:

- The left apical impulse located at the left thoracic wall is adjacent to or under the olecranon near the fifth intercostal space; this location identifies the ventral region of the LV inlet. The mitral valve is dorsal to the cardiac impulse, but mitral sounds and murmurs often project well to the apex while also radiating dorsally into the left atrium. The first heart sound (S_1) is best heard at this location and the ventricular filling or third heart sound (S_3) is also heard well over this point.
- The aortic valve area is located one (or two) intercostal spaces cranially and is dorsal to the left apical impulse. The second sound (S_2) is loudest at this point, and aortic valve murmurs are heard best over this valve. The murmur of mitral regurgitation may also radiate dorsally and cranially to this area. Because of the central location of the aortic valve and the orientation of the ascending aorta to the right, aortic flow murmurs and the murmur of aortic regurgitation generally can be heard bilaterally, just medial to the triceps muscles.
- The pulmonic valve is located slightly cranioventral (generally one intercostal space) to the aortic valve, and the pulmonary component of S_2 is loudest at this point. This is also the location where splitting of the second sound is most obvious. The main PA extends dorsally from the pulmonic valve, high on the left-cranial base. Murmurs that radiate into the PA are heard best at this location, including some functional murmurs and the murmur of patent ductus arteriosus. The murmur associated with a subarterial (subpulmonic) VSD, as well as the rare murmurs of an atrial septal defect or pulmonic stenosis, are typically loudest over the pulmonary valve and PA.
- The tricuspid valve area is located over a wide area on the right hemithorax, dorsal to the sternum and just cranial to the mitral valve; sounds and murmurs associated with tricuspid valve disease are usually heard best over the right hemithorax. Murmurs of paramembranous VSDs are often detected ventral and slightly cranial to the tricuspid valve area, dorsal to the sternum.

It is worthwhile to concentrate first on the individual heart sounds when assessing the heart rhythm, because the generation of cardiac sounds depends on the underlying electrical rhythm and heart murmurs are timed relative to the heart sounds (Fig. 9.8). The atrial sound (S_4) is heard after the P wave. The first and second heart sounds (S_1 and S_2) encompass systole, indicating the presence of a QRS complex. A murmur detected between the first and second sounds is termed *systolic*. In contrast, a murmur heard after S_2 is designated as *diastolic*. The distinctive atrial sound (S_4) is absent in AF. Normal variation in the PR interval causes gradual changes in the S_4–S_1 interval. Absence of a QRS complex, which occurs with second-degree AV block and with nonconducted atrial premature complexes, causes a pause in which the first and second heart sounds are absent. The heart sounds and precordial movements often can be palpated, especially over the left thoracic wall. Frequently the cardiac movements and low-frequency vibrations corresponding to the atrial contraction (S_4), onset of ventricular contraction (S_1), and closure of the semilunar valves (S_2) can be detected. With ventricular volume overloading or vigorous normal filling, an accentuated apex beat and third sound (S_3) will be palpable. Cardiac enlargement or displacement of the heart by an intrathoracic mass may lead to an abnormal location of the cardiac impulse. A loud cardiac murmur is often associated with a palpable vibration or *precordial thrill*.

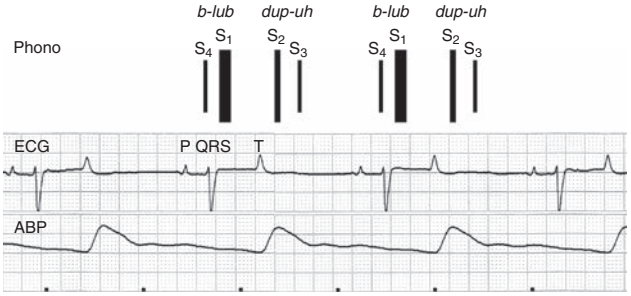

FIG. **9.8** Schematic diagram of the normal heart sounds (Phono) in relation to a surface electrocardiogram (ECG) and an arterial blood pressure tracing (ABP) recorded from the transverse facial artery. S_1, First (systolic) heart sound; S_2, second (diastolic) heart sound; S_3, third heart sound; S_4, fourth (atrial) heart sound. *B-lub dup-uh* describes the sounds heard on auscultation. Note the timing of the heart sounds and the (peripheral) pulse pressure wave relative to the ECG. (From Orsini JA, Divers TJ, editors: Manual of equine emergencies: treatment and procedures, ed. 2, Philadelphia, 2003, Saunders.)

Heart Sounds

Heart sounds should be readily heard on each side of the thorax, although there is some variability based on body type, and sounds are louder over the left thoracic wall. All four heart sounds can be detected in healthy horses, but all may not be present or evident at the same location (Figs. 9.8 and 9.9; see Table 9.1).[3,23,25,382] The intensity of the heart sounds should be consistent when the rhythm is regular, but variation of heart sound intensity occurs with arrhythmias (irregular cardiac filling). Muffled heart sounds are heard with pericardial effusions or pericardial abscesses (the muffling may only be on one side of the thorax) but also occur in some horses with large pleural effusions and cranial mediastinal masses. Accentuation of all heart sounds, especially the third sound, may be detected with volume-loaded ventricles or with marked sympathetic activity. Projection of heart sounds over a wider area is sometimes evident in cases of pleuropneumonia with pulmonary consolidation.

The first heart sound (S_1) varies with arrhythmias and often becomes louder (or sometimes softer) after prolonged diastolic periods. This in itself is not diagnostic of an abnormality. Splitting of the first heart sound, if pronounced, may indicate abnormal ventricular electrical activation or ventricular premature complexes.[3,282] Close splitting of the first sound may be more obvious when there is AF, and in the absence of an atrial sound (S_4), the split S_1 may be misinterpreted as a closely timed S_4–S_1 complex.

The second sound (S_2) is loudest normally over the aortic valve area and may be audibly split over the pulmonic valve

area.[3,282] This sound can be very soft or absent following a premature beat, and it may be obscured by a holosystolic murmur. Audible splitting of S_2 occurs commonly in normal horses, varies with HR or respiration, and only infrequently is associated with pulmonary hypertension. The relative closure of the semilunar valves probably varies with the HR and PA pressure,[3,282] although the pulmonic component is most often detected after the aortic component in the healthy, resting horse. If the pulmonic component of the second sound develops a tympanic quality, becoming equal to or louder than the aortic component of S_2, the clinician should suspect pulmonary hypertension. Identification of a loud pulmonic S_2 is a useful clinical finding in cases of right-sided heart failure because it often indicates that a lesion on the *left* side of the heart has led to pulmonary hypertension and right-sided CHF.

Diastolic transient sounds are normal.[3,16,17,19,387] The atrial sound (S_4) should be detected in virtually all horses, and this sound may be quite loud in some cases. Isolated atrial sounds are commonly auscultated at slow resting HRs due to second-degree AV block; however, multiple isolated S_4 sounds indicate high-grade AV block. The ventricular filling sound (S_3) is most localized and variable and may be difficult to detect unless the bell is placed lightly over the left apex. This sound is normal and has a low-pitched sound that often increases transiently when there is sinus tachycardia and enhanced rapid filling. This sound also achieves greater intensity when there is ventricular dilation and elevated filling pressures as with heart failure.

Other sounds may be detected with heart disease. Systolic clicks are uncommonly heard over the great vessels where they are thought to be benign. A systolic click loudest over the mitral area may be a marker for mitral valve disease or prolapse of the valve into the left atrium. Constrictive pericardial disease can create a loud early diastolic ventricular filling sound, a ventricular "knock," indicating abrupt termination of rapid filling under high venous pressures. In addition to muffling of sounds, pericarditis is often associated with a pericardial friction rub. These rubs are classically detected during three portions of the cardiac cycle (systole, early diastole, late diastole). These sounds must be distinguished from pleural friction rubs or respiratory mediated sounds, which are occasionally associated with the cardiac cycle. Pleural and pulmonary rubs tend to be heard only during one or two phases of the cardiac cycle and may not correlate closely.

Heart Rate and Rhythm

HR can change rapidly and dramatically, varying with autonomic efferent traffic and level of physical activity. Changes in the rate and rhythm are reflected in cardiac auscultation and palpation of the pulse (see Table 9.2). The normal arterial pulse and cardiac rhythm are regular or cyclically irregular. HR in mature horses varies between 28 and 44 beats/min, although slightly slower HRs can be detected in some very fit racehorses, and higher HRs are often present in foals,[386] yearlings, draft horses,[398] ponies,[399] and healthy but nervous horses. An elevated resting HR is commonly detected with late pregnancy, fever, pain, hypovolemia, severe anemia, infection, or shock. Persistent, otherwise unexplained tachycardia is also typical of heart failure wherein the standing HR usually exceeds 60 beats/min.

Physiologic arrhythmias associated with high resting vagal tone must be differentiated from pathologic arrhythmias. Vagal induced arrhythmias are most often observed in healthy relaxed

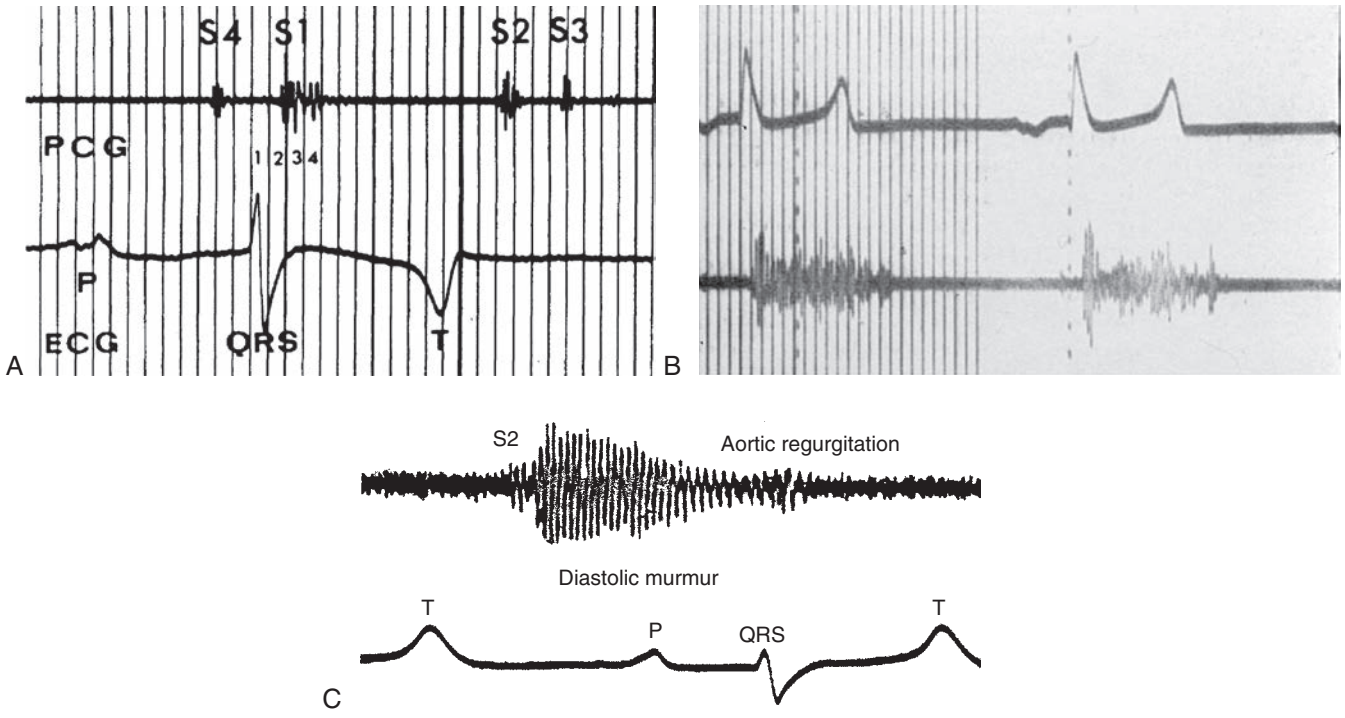

FIG. **9.9** Phonocardiograms (PCG). A, The four normal heart sounds (S_1 through S_4) are evident in this recording. (The numbers *1* through *4* indicate the various components of the first heart sound; *ECG,* electrocardiogram.) B, Systolic murmur recorded from a yearling with a ventricular septal defect (VSD) (P waves on the ECG are negative in this tracing). C, Decrescendo, musical, holodiastolic murmur recorded from a horse with aortic regurgitation (AR). The murmur begins in early diastole (after the T wave) and ends at the QRS complex. (*A,* Recording courtesy D. Smetzer, R.L. Hamlin, and C.R. Smith.)

horses. The most common of these are sinus arrhythmia and second-degree AV block (see Fig. 9.6), which is reported in 15% to 18% of normal horses at rest and has been detected in up to 44% of normal horses with 24-hour continuous electrocardiographic monitoring.[222,227,400] This arrhythmia is most common in fit racehorses or in other high-performance animals and disappears with stimulation of sympathetic nervous system activity. Sinus arrhythmia also occurs regularly in horses and is often associated with sinus bradycardia and resting HRs of 24 to 28 beats/min. Sinus arrhythmia may wax and wane with respiration; however, synchronization with ventilation is not a consistent finding in the horse, and it is more likely related to changes in baroreceptor activity. Sinoatrial block and SA arrest occur sporadically in fit horses. Because these physiologic arrhythmias are associated with high vagal tone, it is typical for the HR to range from a low-normal value to overt bradycardia. Maneuvers that reduce vagal activity and increase sympathetic tone can be undertaken to ensure that the rhythm becomes normal. Successful methods include leading the horse through three or four tight circles, jogging, or lunging. It should be recognized, however, that some horses redevelop physiologic AV block within 10 to 60 seconds following such maneuvers. If the arrhythmia persists after exercise, or if the auscultatory findings suggest another arrhythmia, an ECG should be obtained (Table 9.4; also see Table 9.2).

The arrhythmias associated with heart disease occur most often with normal to increased HRs, with the exception of advanced second-degree and complete (third-degree) AV block.[33,84,383,401,402] Atrial premature beats are characterized by a regular cardiac rhythm, which is suddenly interrupted by earlier than normal beats. Because the sinus node is reset during an atrial premature beat, the following pause is usually incomplete or less than compensatory (provided the underlying sinus rhythm is regular). Premature atrial beats can also be blocked in the AV node, leading to a sudden pause in the rhythm without a premature first heart sound. A ventricular premature beat is often followed by a fully compensatory pause unless the extrasystole is interpolated between two normal sinus beats. Pulse deficits (more first heart sounds than arterial pulses) are common with premature beats due to inadequate ventricular filling and subsequent low stroke volume.

Atrial fibrillation is characterized by an irregularly irregular pulse and ventricular rhythm, with some beats occurring sooner than expected, and with pauses in the rhythm demonstrating no consistent diastolic interval. The atrial contraction and hence the fourth sound (S_4) are absent in AF. Infrequently, AF develops with recurring periodicity of cycle lengths that can cause difficulty in distinguishing this from second-degree AV block.[219,221,229,403] At higher rates, such as during exercise or in a horse in heart failure, the cycle lengths shorten and the rhythm appears to become (more) regular. However, when listening carefully, an irregularly irregular rhythm is still evident, distinguishing AF from second-degree AV block. Another diagnostic pitfall can be the presence of a split first sound, because the clinician may mistake this for a closely timed S_4–S_1 complex.

Atrial tachycardia can be conducted with patterns leading to a rapid but regular heart rhythm. However, most horses with atrial tachycardia develop irregular rhythms owing to frequent block of atrial impulses in the AV node, especially at rest. HRs are usually higher than normal at rest. Auscultation of the horse in a quiet area may reveal isolated audible fourth heart sounds associated with the second-degree AV block.

Junctional or nodal tachycardia and ventricular tachycardia (VT) are usually manifested by a rapid regular rhythm, although some VTs (particularly polymorphic or multiform VT) cause an irregular rhythm. Owing to concomitant AV dissociation or abnormal ventricular activation, the heart sounds may sound split or variable in intensity.

Cardiac Murmurs

Cardiac murmurs are prolonged audible vibrations developing in a usually quiet portion of the cardiac cycle. In general, murmurs are manifestations of either normal (functional) or abnormal (pathologic) blood flow in the heart and blood vessels. Although many heart murmurs are functional (physiologic, athletic, innocent), other murmurs provide evidence of heart disease and may require further investigation (see Tables 9.1, 9.3, and 9.4). One of the challenges of physical diagnosis is determination of the cause and clinical relevance of a cardiac murmur. With knowledge and experience the clinician can accurately determine the *likelihood* that a murmur is physiologic or pathologic in origin, and efficiently select animals requiring additional studies. The clinician should describe the *timing, duration, quality or pitch, grade, point of maximal murmur intensity,* and *radiation* of a murmur (Box 9.7), as well as the effect of changing HR on the sounds. Determination of timing is made relative to the heart sounds so that murmurs are designated as systolic, diastolic, or continuous. When the overall timing is not obvious, the clinician can either palpate the apical impulse, which occurs in early systole, or the systolic pulse in the brachial or median artery to identify the timing of the murmur (consider the slight time delay between ventricular contraction and occurrence of a peripheral pulse wave). It is also helpful to remember that at a normal (low) HR, ventricular diastole (i.e., the time interval between S_2 and the following S_1) is markedly longer than ventricular systole (i.e., the time interval between S_1 and the following S_2) (see Fig. 9.8). Hence, long-lasting murmurs or brief murmurs occurring during the long S_2–S_1 interval are likely to be diastolic murmurs. Skilled auscultators subdivide the timing of murmurs into *proto-* (early), *meso-* (middle), or *tele-* (late) systole or diastole because the timing and duration of the murmur often correlate with specific flow disturbances. Shorter murmurs, especially those occurring in early systole or protodiastole, are more likely to be functional, although this is not always the case. Experience also teaches that relatively loud or long murmurs are more likely to be associated with cardiac pathology, but again there are exceptions. The pitch or quality of the murmur provides additional insight. For example, mixed frequency (harsh or blowing) murmurs are typical of cardiac disease. A brief vibratory or musical murmur is typically functional; however, a prolonged musical murmur is suggestive of a valvular lesion. Applying the characteristics of murmurs to the clinical setting requires study, an organized scheme (see Table 9.4), and practice.

Functional, innocent, or physiologic heart murmurs are very common and are not attributed to cardiac pathology. Such murmurs may be related to the large size and tremendous inflow and outflow volumes of the equine heart. They are caused by vibrations that attend the *ejection* of blood from the heart during systole or the *rapid filling* of the ventricles during early diastole.* Physiologic causes of functional murmurs include fever, high sympathetic activity (e.g., colic,

TABLE **9.4 Diagnostic Algorithm for Cardiac Auscultation in the Horse**

Auscultation		Considerations		Further Observations		Probable Assessment		Other Tests
Irregular rhythm	→	Vagally mediated or abnormal rhythm	⇒	Induce increased sympathetic tone[a] ⇓				
				↑ Rate and *regular* rhythm	→	Vagally mediated (physiologic) rhythm[b]	→	None
				↑ Rate and *irregular* rhythm	→	Abnormal cardiac rhythm (see Table 9.2 for details)	→	ECG, ± echo, electrolyes, cardiac troponin I (cTnI)
Regular tachycardia <90 beats/min[c]	→	Sympathetic activation (stress/anxiety, pain, volume depletion, infection, anemia, heart failure, etc.) or ectopic cardiac rhythm	⇒	Manage underlying disorder ⇓				
				Appropriate HR reduction with normal heart sounds	→	Physiologic sinus tachycardia	→	None
				Persistent tachycardia, abnormal heart sounds or murmurs	→	Persistent sinus or ectopic tachycardia,[d] underlying organic heart disease	→	ECG, ± echo, electrolyes, cardiac troponin I (cTnI)
Loud cardiac murmur with a precordial thrill	→	Organic heart disease	⇒	Determine timing and PMI (see below)	→	Congenital or acquired heart disease	→	Echo
Systolic murmur PMI: left thorax	→	Functional or organic	⇒	PMI: pulmonic or aortic valve Crescendo-decrescendo				
				Grade: 1–3/6[e]	→	Functional ejection murmur	→	None[g]
				Grade: 4–6/6	→	Congenital heart defect[f]	→	Echo
				PMI: mitral valve or left apex Any grade or configuration	→	Mitral regurgitation	→	Echo[g,h]
Systolic murmur PMI: right thorax	→	Organic murmur	⇒	PMI: tricuspid valve Any grade or configuration	→	Tricuspid regurgitation	→	Echo[g,h]
				PMI: cranioventral thorax Holosystolic	→	Ventricular septal defect (VSD)	→	Echo
Diastolic murmur PMI: left or right thorax	→	Functional or organic	⇒	Brief (protodiastolic or presystolic)	→	Functional murmur (or trivial AR)	→	None[g]

				PMI: aortic or pulmonic valve Holodiastolic	→	Aortic regurgitation (AR) or pulmonic regurgitation with pulmonary hypertension	→	Echo[g,h]
Continuous murmur PMI: left or right thorax	→	Organic murmur	⇒	PMI: pulmonary artery Foal or other signs of CHD	→	Patent ductus arteriosus (PDA) or a systemic to pulmonary shunt	→	Echo
				Mature horse	→	Aortic to cardiac fistula or aortic to pulmonary artery fistula	→	Echo
Pericardial friction rub[i]	→	Organic murmur	⇒	Systolic or multiphasic Distant (muffled) heart sounds Jugular venous distention	→	Pericarditis	→	Echo

[a]Endogenous sympathetic activity can be transiently increased by suddenly leading the horse in four or five tight circles or through trotting or lunging; the horse should be examined *immediately* after the activity has stopped.
[b]Vagally induced rhythms include sinus bradycardia, pause or arrest, sinoatrial block, sinus arrhythmia, and second-degree atrioventricular block.
[c]Resting tachycardia exceeding 90/min should be evaluated with an ECG to qualify the rhythm; the cutoff rate is arbitrary but clinically useful.
[d]Ectopic rhythms include ectopic atrial tachycardia, junctional (nodal) tachycardia, and ventricular tachycardia.
[e]Functional murmurs due to ejection of blood into the great vessels often become transiently louder following an increase in sympathetic activity.
[f]Loud ejection murmurs over the semilunar valves and great vessels may indicate pulmonic stenosis or complex defects such as tetralogy of Fallot.
[g]Judgment should be exercised regarding the need for echocardiography. An echocardiogram might be indicated in the prepurchase examination of any valuable foal or horse with a cardiac murmur; however, echocardiography may not be indicated in an older horse with a soft murmur of aortic regurgitation with normal arterial pulses or in a fit racehorse with a typical murmur of tricuspid regurgitation.
[h]According to the 2014 Joint ACVIM/ECEIM Consensus Statement on Recommendations for Management of Equine Athletes with Cardiovascular Abnormalities (Reef VB, et al., J Vet Intern Med 28:749-761, 2014), an echocardiogram is specifically indicated if a left-sided murmur compatible with mitral regurgitation or aortic regurgitation is of grade 3–6/6 or a right-sided systolic murmur compatible with tricuspid regurgitation is of grade 4–6/6.
[i]Classic pericardial friction rubs are heard during systole, early diastole, and late diastole. Occasionally a functional presystolic murmur exhibits a frequency quality similar to a brief friction rub.

Abbreviations and Terminology:

Configuration = the phonocardiographic "shape" of a murmur; for example, a "plateau-shaped" murmur that extends from the first sound through the second sound is termed *holosystolic* or *pansystolic* (e.g., MR or VSD); a "diamond-shaped" murmur is crescendo-decrescendo in configuration (e.g., functional ejection); a "blowing" murmur that starts suddenly but dissipates gradually is decrescendo (e.g., aortic regurgitation); and a murmur that becomes progressively louder and then stops is crescendo in configuration (e.g., MR from mitral valve prolapse)
ECG = perform an electrocardiogram to determine heart rhythm
Echo = perform an echocardiogram to identify abnormal structure, cardiac size, or function; Doppler studies are added to assess normal and abnormal blood flow patterns and are optimal for evaluating horses with cardiac murmurs; Doppler studies must be interpreted relative to auscultatory findings
Grade = intensity of the murmur on a 1 through 6 scale; in most systems a grade 5 or 6 murmur is accompanied by a precordial thrill
HR = heart rate
Organic = related to a structural lesion in the heart or great vessels
PMI = point of maximal murmur intensity
Precordial thrill = the palpable thoracic vibration associated with a loud cardiac murmur
Troponin I = serum/plasma concentration of inhibitory cardiac troponin or cTnI, a biomarker used to detect cardiomyocyte injury or necrosis
Valve = refers to the general valve area of auscultation (see text for details)

BOX 9.7 Characterization of Heart Murmurs

TIMING AND DURATION (see Figs. 9.8 and 9.9 and Tables 9.1 and 9.4)

- Systolic, diastolic, or continuous
- Early, mid, or late systolic or diastolic
- Holosystolic (S_1 to S_2), holodiastolic (S_2 to S_1)

QUALITY

- Frequency of sound—high pitch, low pitch, mixed-pitch
- Character of murmur—harsh, coarse, rumbling, musical, honking, blowing

GRADE

- Grade 1/6—very quiet, only heard over a very localized area after careful auscultation in quiet environment, may be inconsistent
- Grade 2/6—quiet, heard consistently over the point of maximal intensity
- Grade 3/6—moderately loud, heard immediately and consistently, small area of radiation
- Grade 4/6—loud, radiating over a wider area, no palpable thrill
- Grade 5/6—very loud, radiating over widespread area, palpable precordial thrill
- Grade 6/6—extremely loud, also heard with the stethoscope held just above the skin surface
- Variations in grade can be described as crescendo (increasing in grade), decrescendo (decreasing in grade), or crescendo-decrescendo ("diamond-shape")

POINT OF MAXIMAL INTENSITY

- Apical—location of the thoracic wall cardiac impulse (apical beat), approximately at or slightly above the level of the elbow (ventral region of the left ventricular inlet)
- Basilar—area above the elbow and slightly more cranial, below the triceps muscle (region of the ventricular outflow tracts, semilunar valves, and great vessels)
- Mitral, aortic, pulmonic, tricuspid valve area (see Fig. 9.7)

RADIATION

- Dorsal-ventral, cranial-caudal, left-right

exercise, pain), moderate to severe anemia, and peripheral vasodilation. These murmurs are typically soft (grades 1–3/6), localized, relatively short, crescendo-decrescendo in timing, and labile. Increasing HR usually increases the intensity and duration of a functional murmur, although in some horses the murmur becomes less intense. Functional murmurs are neither holosystolic nor holodiastolic, and therefore the heart sounds should still be evident.

The most common functional murmur is the systolic ejection murmur heard over the aortic and pulmonic valves and projecting into their respective arteries at the left cardiac base (see Fig. 9.7 and Table 9.1).[3] The functional ejection murmur is generated by flow into the great vessels and by definition must start after S_1 and end before S_2. Nonetheless, in some horses, the functional ejection murmur can achieve substantial intensity (rarely, a grade 4–5/6) and may seem holosystolic at higher HRs. At times there is a remarkable change in functional murmur intensity from one day to another. An example of this is the varying murmurs identified in some horses with emergent colic. Because a loud functional murmur can radiate caudally, it may be confused with mitral regurgitation. In terms of diagnostic considerations, the clinician should not mistake a functional ejection murmur for that of aortic or pulmonic stenosis. Pulmonic stenosis is rare in the horse and aortic stenosis even less common. Accordingly, these valvular malformations are rarely entertained in the differential diagnosis. The murmurs resulting from subpulmonic (subarterial) VSDs or the stenosis associated with tetralogy of Fallot may be loudest over the great vessels, but such murmurs are usually very loud and prompt echocardiographic investigation.

Functional diastolic murmurs are also common, especially in young horses and in the Thoroughbred breed. These murmurs are generally soft and are detected over the LV or RV inlets—from the dorsal atrium to the ventricular apex. The functional protodiastolic murmur is an early diastolic murmur detected between S_2 and S_3. The murmur may be musical, vibratory, or "squeaky" and typically accentuates with increased HR.[3] It most reasonably represents the rapid early filling of the ventricles. The presystolic functional murmur is heard between S_4 and S_1, and the vibrations may sound like a "rub" or long heart sound following the atrial contraction. It can be confused with an early systolic murmur or a friction rub.

Causes of *abnormal (pathologic) murmurs* include *structural or organic heart disease* such as incompetent cardiac valves, septal defects, vascular lesions, and (very rarely) valvular stenosis. The continuous murmur of patent ductus arteriosus is a normal finding in full-term foals for up to 3 days after parturition but occasionally persists for almost a week after foaling.[382,386,408,409] The most commonly detected pathologic murmurs in horses are those generated by tricuspid regurgitation, mitral regurgitation, aortic regurgitation, and ventricular septal defect. Typical causes and auscultatory features of these murmurs are indicated in Tables 9.1, 9.3, and 9.4 and described in detail later in this chapter.

When a murmur is believed to represent underlying cardiac pathology, further investigation is required. The overall relevance of the hemodynamic abnormality should include consideration of the work history, general physical examination, presence or absence of heart enlargement or cardiac failure, and results of ancillary tests such as echocardiography, electrocardiography, and exercise performance (or testing). Certainly, the history should be considered, because the horse with excellent performance and good exercise tolerance is unlikely to have serious heart disease. Auscultation, however, is insufficient to distinguish trivial from significant heart disease in the poorly performing horse or in a horse with a cardiac arrhythmia. Echocardiography is helpful in these cases to quantify heart size and objectively assess ventricular function. Underlying lesions such as a valve vegetation, a ruptured valve chorda tendineae, or dilated cardiomyopathy can be identified or discounted. Although there are no well-defined echocardiographic or Doppler correlates to functional heart murmurs, these studies can document abnormal blood flow and can pinpoint the cause of a pathologic murmur.

Pulmonary Auscultation

Auscultation of the lungs should reveal normal breath sounds with the horse at rest, while ventilating into a rebreathing bag, and after exercise. Decreased or absent airway sounds or large airway sounds in the ventral portions of the thorax indicate a pleural effusion, a common finding in biventricular or

FIG. **9.10** Peracute pulmonary edema in a horse with a ruptured chorda tendinea. The photo was taken immediately after euthanasia. An important note is that tracheal froth is often a postmortem artifact, particularly when observed hours after death.

right-sided heart failure. Moist or bubbling (fluid) sounds or crackles (i.e., rales) are uncommonly auscultated in the lungs of horses with pulmonary edema and left-sided heart failure. Instead, tachypnea associated with harsh bronchovesicular breath sounds is usually heard, as horses with chronic left-sided CHF seem to develop more interstitial than alveolar pulmonary edema. When alveolar edema does develop, respiratory distress may be severe, crackles may become evident, and free fluid may be auscultated in the trachea. On rare occasion, primarily with peracute left-sided heart failure, froth will be visible at the nares and the horse will cough and expel large quantities of pulmonary edema (Fig. 9.10). Such horses demonstrate severe respiratory distress (marked tachypnea and dyspnea), anxiety, and agitation.

Examination of the Peripheral Vasculature and Blood Pressure Measurement

An evaluation of the peripheral vasculature is part of a CV workup and should include examination of the arteries and veins in the head, forelimbs, and hindlimbs and assessment of the mucous membranes. When the equipment is available, arterial BP also should be measured. The genesis of the arterial and venous pulses has been described previously. The heart sounds should be correlated with both the jugular and arterial pulses.

Arterial Pulses and Blood Pressure Measurement

Normal quality *arterial pulses* should be palpable in the facial, median, carotid, great metatarsal, coccygeal, and digital arteries. The arterial pulse represents the pulse pressure (i.e., the difference between peak systolic and diastolic pressures), the rate of rise of arterial pressure, and the physical characteristics of the artery and surrounding tissues. HR and heart rhythm, as well as altered hemodynamic states, may be identified by palpating the facial artery pulse. The arterial pulse can be described as normal, hypokinetic (weak), hyperkinetic, or variable. Irregularity often indicates a cardiac arrhythmia.

Thready or hypokinetic arterial pulses are associated with reduced stroke volume and peripheral vasoconstriction and therefore may be detected in CHF and in diseases associated with volume depletion or profuse hemorrhage. Thready arterial pulses may also be detected only in the hindlimbs with aortoiliac thrombosis. The pulse in septic animals may be weak, owing to reduced pulse pressure, or normal to rapidly declining if there is peripheral vasodilation. Bounding, hyperkinetic arterial pulses are palpable with clinically relevant aortic regurgitation, patent ductus arteriosus, and aortic to pulmonary or aortic to right-sided heart fistulas. Marked variation in the intensity of the pulse usually occurs with arrhythmias, particularly AF and rapid or multiform VT. A pulse deficit (first heart sound without palpable pulse) occurs when developed LV pressure does not exceed aortic pressure. Deficits are likely to be palpated in association with pathologic arrhythmias, particularly premature beats or following very short diastolic periods of tachyarrhythmias when ventricular filling is insufficient to generate a significant stroke volume.

Arterial pressure is determined by the interplay among SV, HR, and vascular resistance (see Box 9.3 and Fig. 9.4B). Palpation of the arterial pulse mainly provides information on pulse pressure but cannot quantify the actual *arterial BP,* which (if required) must be measured directly by arterial puncture or cannulation (invasive blood pressure [IBP]) or indirectly using various auscultatory, Doppler, or oscillometric techniques (noninvasive blood pressure [NIBP]).[259,410-440] Percutaneous placement of an arterial catheter in the facial, transverse facial, transverse tibial, or metatarsal artery is frequently used to monitor pressure invasively in critically ill or anesthetized horses and foals. Indirect methods have been used successfully to monitor pressure in the coccygeal, metacarpal, metatarsal, and median artery. However, NIBP measurements are less reliable compared with IBP measurements. Although different study designs (including varying patient populations, hemodynamic interventions, devices, cuff sizes and placements, and correction factors) make direct comparison difficult, overall agreement between IBP and NIBP measurements tends to be better in anesthetized animals compared with standing conscious horses. The mean arterial pressure (MAP), which is derived from the maximum oscillation amplitude, is more accurately detected by oscillometric monitors than the algorithm-dependent systolic arterial pressure (SAP) and diastolic arterial pressure (DAP).[441,442] No information is available on the accuracy and reliability of noninvasive pulse pressure measurements, although in clinical practice quantification of pulse pressures is considered very useful to detect or confirm hyperkinetic pulses, particularly in horses with AR (see later discussion).[406]

Attention must be directed to placement and diameter of the occluding cuff when indirect methods are used.[427] A cuff width to tail circumference ratio of 0.4 to 0.6 is often recommended by the manufacturers and has been used in horses when measuring pressure in the middle coccygeal artery.[412,436,437,439,440] However, a large range of ratios from 0.2 to 0.9 have been described in the literature,[412,434-440,443] and some authors recommend an optimal cuff width between 0.2 to 0.35 of the circumference of the tail.[421,425,444] Generally, if wide cuffs tend to cause underestimation then small cuffs tend to cause overestimation of NIBP.[427,443]

The effect of gravity and the vertical distance between site of cuff placement and the heart base also need to be considered. Measurements of NIBP in standing horses using a tail cuff will underestimate true pressures because the coccygeal artery is located above the heart base. Generally, a correction

factor of 0.77 mm Hg/cm of vertical distance between the base of the tail and the point of the shoulder is applied or, if not, measurements should be described as "uncorrected" values.[427]

NIBP measurements may be less sensitive in hypotensive animals and may lag in response during rapid changes in BP.[413,415,417] The slow HR in horses may represent another source of inaccuracy for NIBP measurements, because the rate of the cuff deflation can be a source of error if the deflation rate is too rapid or the HR is too slow.[445] The arterial pulse wave itself varies, depending on the site of measurement, due to the wave reflection when the pulse wave is entering from central to the periphery. The distal arterial systolic pressure may be higher, and the diastolic pressure lower, than the corresponding central aortic pressures. However, due to compensation of the increase in peak systolic pressure by narrowing of the pressure wave, the MAP is usually unaffected by wave reflection.[444,446]

Arterial BP monitoring includes determination of SAP, DAP, MAP, and pulse pressures (difference between SAP and DAP). Normal reported values for NIBP in conscious standing adult horses (corrected for vertical distance of cuff position above heart base) are around 135 ± 15, 110 ± 15, and 90 ± 15 mm Hg (average ± standard deviation [SD]) for SAP, MAP, and DAP, respectively, with a calculated pulse pressure of approximately 45 ± 6 mm Hg.[423,431,436,439] BP is lowest in neonates and rises during the first month of life to the normal adult range.[409,415,426] There is some variation among breeds. Draft breeds tend to have lower pressures than racehorses, and Standardbreds have lower pressures than Thoroughbreds.[431] Posture imposes a significant influence on arterial pressure, because raising the head from the feeding position necessitates a higher aortic pressure to maintain cerebral perfusion. Obviously, when the head is lowered, the hydrostatic pressure imposed by an elevated head position is minimized. MAP measured in the middle coccygeal artery can vary approximately 20 mm Hg with the changing head position.[428] Marked increases in CO can lead to significant increases in arterial BP, with systolic pressures exceeding 200 mm Hg.[447-449] Sedatives, anesthetics, and adrenergic drugs cause significant dose- and time-dependent increases or decreases in systemic BPs.[292]

The *systolic arterial pressure* is generated by the left ventricle and is consequently affected by the interplay between the stroke volume, HR, aortic compliance, and previous diastolic BP.[46] Arterial *pulse pressure* is highly dependent on stroke volume and the peripheral arteriolar resistance that determines the runoff of diastolic pressure. Ventricular failure or reduced venous return reduces pulse pressure, creating a hypokinetic pulse, whereas abnormal diastolic runoff (aortic regurgitation, generalized vasodilation) widens the pulse pressure, producing a stronger peripheral pulse. *Diastolic and mean pressures* are better estimates of perfusion pressure in anesthetized or critical equine patients; these variables are increased by arteriolar vasoconstriction or by higher CO.[57] Arterial pressures fluctuate slightly with ventilation and significantly under positive pressure ventilation or during cyclic changes in HR (see Fig. 9.6) related to variation in ventricular filling. However, marked differences can be associated with cardiac tamponade, and the dramatic fall in pressure during inspiration is termed *pulsus paradoxus*.

Mucous Membranes

The color of the mucous membranes and the capillary refill time (CRT) are determined by cardiac output, systemic blood pressure, peripheral vasomotor tone, PCV and hemoglobin concentrations, and plasma bilirubin concentrations. Although assessment is largely subjective, normal mucous membranes should be moist and pink, with a CRT of less than 2 seconds. Dry, congested membranes suggest dehydration and CV disturbance. Pale membranes indicate anemia or poor peripheral perfusion and vasoconstriction, and dark red (injected) or gray-bluish membranes may indicate septicemia or endotoxemia and peripheral vasodilation or vasoconstriction, respectively. Capillary refill time is prolonged with poor CO, hypovolemia, hypotension, or peripheral vasoconstriction; conversely, it may be shortened when there is vasodilation. Cyanosis because of right-to-left cardiac or vascular shunting is a rare finding. It is important to realize that the detection of hypoxemia by inspection of the mucous membranes is influenced by the blood hemoglobin concentration, because the bluish color of the mucous membranes directly relates to the absolute concentration of deoxygenated hemoglobin. Hence, anemic horses may be hypoxemic without showing any cyanosis, whereas polycythemic horses might appear cyanotic without being markedly hypoxemic.

Peripheral Veins

The cutaneous veins should be examined for distensibility, refill, thrombosis, and estimated venous pressure. The jugular veins in normal horses are collapsed, but the veins of the limbs and torso are visible and somewhat filled. Venous pressure in the jugular vein is normally less than 10 cm of water above the phlebostatic point (i.e., 0 [zero] reference point, usually taken to be the right atrium), and *jugular pulsations* are normally confined to the thoracic inlet and the ventral one third (10 cm) of the neck. These pulsations are reflections of the right atrial pressure changes that range from positive to subatmospheric over the cardiac cycle (discussed previously). Pulsations are normally visible along the entire length of the jugular vein when the head is lowered below the level of the heart and should not be misinterpreted. A pathologic jugular pulse also can be misdiagnosed if there is transmission of carotid arterial pressure into the jugular furrow. Occluding the jugular vein ventrally can demonstrate if the pulses are actually originating within the right atrium or not, because venous pulse transmission, or prominent collapse, will be prevented by light digital pressure over the vein. Pronounced jugular pulsations are observed occasionally in excited but otherwise normal horses with high sympathetic tone. This might be due to either vigorous right atrial contraction. Alternatively, an exaggerated venous collapse can create a "jugular pulse" that is simply a reflection of normal venous refilling during periods of positive right atrial pressure. When there is doubt, this finding can be verified by simple ultrasound imaging of the ventral portion of the vein.

Jugular abnormalities include abnormal pulses or elevated venous pressure. An abnormal jugular pulse is one that extends proximally up the jugular vein for more than 10 cm in systole (with the horse's head held in a normal position) or that demonstrates retrograde filling from the heart when the vein is occluded dorsally. Duplex Doppler studies of the jugular vein can distinguish a prominent pulse caused by retrograde flow from an apparent pulse caused by prominent collapse and normal filling. Abnormal jugular pulses are observed with arrhythmias causing AV dissociation (nonconducted atrial premature beats, junctional tachycardia, VT); with diseases of the tricuspid valve (moderate to severe tricuspid regurgitation; tricuspid

stenosis); and with RV failure from any cause including cardiac tamponade or constrictive pericardial disease. Elevated jugular venous pressure generally indicates right-sided CHF, pericardial disease, or hypervolemia. Generalized venous distention, particularly when accompanied by subcutaneous edema, is characteristic of CHF (Figs. 9.11 and 9.12). Isolated distention of the veins cranial to the thoracic inlet is suggestive of a cranial mediastinal or pulmonary mass (or abscess) with obstruction of the cranial vena cava.[140] Prolonged refill of the saphenous vein indicates the possibility of aortoiliac thrombosis and decreased arterial supply to the affected limb.[267-272,450-455] A distended vein that is firm to palpation and associated with marked distention of associated veins indicates probable venous thrombus. Pain or heat associated with venous swelling is suggestive of thrombophlebitis.[456-458]

Diagnostic and Laboratory Studies

Exercise Testing

Because most horses function as athletes, exercise testing represents an important method for identifying CV and other disorders in horses with exercise intolerance or poor performance. In horses with clinically important structural lesions, intermittent premature complexes, or AF, exercise testing can determine whether the HR is appropriate for the work performed or if an arrhythmia deteriorates over the course of the test.[53,54,61,68,459] Exercise testing is also indicated during a prepurchase examination when a nonfunctional heart murmur or sporadic arrhythmia is identified. Having advanced this recommendation, it must be acknowledged that the reliability and overall sensitivity, specificity, and predictive values of exercise testing (as it pertains to detection of arrhythmia and organic heart disease) are incompletely defined, and more data and information are needed to establish the clinical value of such studies relative to CV disease. Contraindications for an exercise test include CHF; severe valvular regurgitation with secondary AF, PHT, or severely reduced systolic function; or presence of a ventricular arrhythmia of dangerous complexity.[68]

FIG. **9.11** Jugular venous distention in a Shire foal with biventricular congestive heart failure (CHF) caused by congenital heart disease.

FIG. **9.12** Ascites, ventral edema, and weight loss are evident in this mare with right-sided congestive heart failure (CHF). The distended lateral thoracic vein *(arrow)* is evident caudal to the triceps.

High-speed treadmill exercise and various forms of field exercise testing are increasingly used to detect subtle clinical abnormalities that limit peak performance or may lead to collapse, syncope, or sudden death.[53,460,461] Treadmill exercise is particularly useful when evaluating the horse at risk of collapse, because the cardiac response to exercise can be evaluated without risk to a rider. Although an exercise test at lower levels of work effort (e.g., lunging exercise) might still provide some valuable information, the work intensity during an exercise test should generally be at or slightly exceeding the horse's customary or anticipated activities. This is particularly important when the history indicates performance problems only at the peak of exercise. Some method of inducing unexpected sympathetic stimulation should be included in the exercise test to identify an inappropriate HR, aberrant conduction, or ectopy associated with adrenergic stimulation.[68] If the animal is too young to perform a regular exercise test, evaluation after a period of free exercise is recommended.

The exercise examination provides valuable information about musculoskeletal diseases, airway diseases, and cardiovascular disorders. There are a number of components to a standardized treadmill examination, which should include continuous recording of an ECG using a device that has permanent storage and playback capabilities.[54,68,462] Specific cardiac assessments include (1) the effects of exercise on auscultation (rate, rhythm, and murmurs); (2) peak HR during exercise; and (3) HR and heart rhythm during the different phases of the exercise test and during recovery. Optionally, echocardiography can be performed before and after exercise (stress echocardiogram). Additional tests that might be indicated are gait analyses, assessment of airway dynamics by videoendoscopy, evaluation of pulmonary function by arterial blood gas analyses, and clinical laboratory tests such as preexercise and postexercise serum creatine kinase (CK) activities to identify subclinical myopathy. The "standardized" exercise test may not be identical across equine medical centers so it may be difficult to compare results. The examiner's own reference for normal variation further qualifies the examination results.

Changes in HR and ECG with exercise have been well studied.* The normal horse develops sinus tachycardia, shortening of conduction intervals, and marked ST-T alterations associated with exercise. The maximal HR achieved depends

* References 53, 54, 61, 233, 448, 459-461, 463-471.

on the level of exercise performed. At HRs of less than 100 to 120 beats/min, SA node discharge is very labile and subject to psychological influences. Once exercise has commenced, the HR should accelerate and then stabilize at a level appropriate for the work being performed. As a general guideline: on the flat, HRs of 70 to 140 beats/min are normal at the trot, 120 to 160 beats/min at the canter, 150 to 180 beats/min at the gallop, and more than 180 beats/min when galloping hard. When exercising on slopes, the highest rates associated with each gait increase, and it is possible to approach maximal rates at the trot when on gradients of greater than 20%. The maximal HR for most horses is between 210 and 240 beats/min, although some younger horses develop higher rates, and aged horses can have maximum rates below 210 beats/min. There is a linear relationship between HR and the velocity or work effort of exercise when the HR is between 120 and 210 beats/min. HR usually recovers rapidly and falls to less than 100 beats/min within 2 to 5 minutes of cessation of exercise. The recovery of HR to the resting level is influenced by many factors, including the humidity, ambient temperature, training fitness, work performed, psychological factors, and state of CV health. After maximal work, such as a race, an hour may pass before the HR completely recovers to the resting rate. An inappropriately high HR for a given level of exercise may simply denote a healthy, but unfit, horse; however, this finding can also indicate the presence of pulmonary, musculoskeletal, or CV disease.[68,472] Information about the HR is particularly useful when a horse has the HR monitored routinely during exercise.

Exercise-induced arrhythmias may be observed during or after exercise. An exercising ECG is necessary to determine whether an arrhythmia is present during exercise. An HR monitor may provide some indication regarding arrhythmias during exercise; however, the detectable maximum HR (or shortest RR interval) might be limited by inherent filtering algorithms, and the detection of erratic heart "blips" or "beeps" does not adequately characterize the rhythm disturbance. Exercise may induce supraventricular premature complexes, AF, ventricular premature complexes, or VT. Exercise-induced (paroxysmal) AF should be included in the differential diagnosis of horses with poor performance during high-intensity exercise.[39,54,68,88,472-474] Exercise-induced ventricular arrhythmias (VAs) are a particular concern because ventricular rhythm disturbances can lead to poor performance, sudden stopping, or even falling and have been suspected as a common cause of sudden death.* Repetitive ventricular activity (paroxysmal ventricular tachycardia) with short R-R intervals or R-on-T phenomenon is particularly worrisome and may indicate preexisting myocardial disease or myocardial ischemia with altered cardiac electrical activity. Although AF per se is not a fatal rhythm, sudden-onset AF during maximal exercise may rarely cause a horse to collapse. One recent study further showed that the prevalence of QRS broadening and R-on-T phenomenon was high in horses with AF even at lower levels of exercise, indicating that some horses with AF might in fact be at risk for fatal ventricular rhythms.[472] AF associated with exercise-induced VA resulting in sudden cardiac death has been documented in at least one horse.[54]

Undoubtedly, CV disorders can be induced or worsened by the stress of exercise, and the likelihood of detecting disease is increased. However, there are challenges to this assessment because physiologic variability is also magnified. Horses demonstrate marked fluctuations in sympathetic and parasympathetic tone during the recovery period following exercise, often termed *autonomic instability*.[471,475-478] Arrhythmias are especially common during this time,* even if the resting and peak exercise heart rhythms were normal. Marked sinus arrhythmia, second-degree AV block, supraventricular ectopy, and ventricular premature complexes can be evident in the immediate postexercise period. With the exception of vagally mediated arrhythmias, postexercise arrhythmias should be considered suspicious. Atrial fibrillation, ectopic supraventricular tachycardias, and ventricular tachycardias are considered abnormal at any point in the exercise test. However, the importance of single (isolated) ectopic complexes identified only in the immediate postexercise phase is less certain,* which is not surprising considering similar issues persist in assessing human athletes. In assessing these horses, attention also should be directed to baseline auscultation and echocardiographic examinations, the heart rhythm during exercise, and measurements of plasma cardiac troponin I (cTnI) concentrations before and after exercise. The presence of coexisting respiratory disease and associated arterial hypoxemia needs to be considered, because it creates the potential for secondary rhythm disturbances, unrelated to primary cardiac disease.[90]

Echocardiography immediately following the stress of exercise (the so-called stress echo) may be used in an attempt to identify global and regional myocardial dysfunction.[90,167,168,459,480-482] This examination must occur within 2 to 3 minutes after high-intensity exercise and with the HR in excess of 100 beats/min.[168] However, the optimal HRs and the influence of rapidly decreasing HRs on echocardiographic measurements such as shortening fraction require better definition.[168] Dynamic changes can be viewed from the short-axis tomograms, and prominent thickening of the ventricular septum and LV free-wall identified from long-axis images. Persistent abnormalities in regional myocardial contraction are suggestive of vascular disease with ischemia, preexistent myocardial fibrosis, or a localized conduction disturbance. Left ventricular shortening fraction and LV fractional area change—two estimates of LV systolic function—are commonly measured during stress echocardiography but have recently been shown to poorly track stress-induced changes in LV function.[168] Errors in cursor placement (e.g., too dorsal) or inconsistent orientation of the M-mode cursor placement between examinations can produce misleading results. Volumetric estimates of stroke volume and LV ejection fraction by 2D echocardiography are more reliable to assess global LV systolic function after exercise.[168] Other methods used for stress echocardiographic assessment of LV function are the manual tracking of endocardial motion and subjective evaluation of regional wall motion. Newer echocardiographic modalities such as 2D strain imaging (2D speckle tracking) may have some advantages over conventional methods and could prove useful for quantitative assessment of regional and global LV function during stress echocardiography.[168] However, the quantitative and objective detection of stress-induced hypokinesia, akinesia, and dyssynchrony in diseased horses requires additional investigations, and more data and standardizations are needed before methods can be widely accepted. Finally, the assessment of cardiac valve function following exercise requires much better definition before any conclusions can be made.

Although the standardized treadmill examination is the most commonly used cardiac "stress test" at equine centers, some attention has been directed on performing pharmacologic stress testing. This examination involves increasing the HR and myocardial contractile force with dobutamine, either with or without atropine or glycopyrrolate, followed by echocardiographic assessment of ventricular contraction.[243,247,481,483,484] Pharmacologic stress echocardiography is used to identify regions of reduced myocardial perfusion or ischemic myocardial injury in human patients with coronary heart disease; the study is used in people who cannot perform physical exercise to stress the heart and increase myocardial oxygen demand. Whether this form of stress testing should be used in horses is subject to debate. First, it must be emphasized that there is no compelling evidence from pathology studies that horses develop significant coronary arterial disease. Admittedly, myocardial fibrosis is found in some horses at necropsy[29,485]; however, the pathogenesis or clinical relevance of these often microscopic lesions is unresolved. In human patients, the diagnostic target is well-defined extramural coronary artery disease, and stress echocardiography generally predicts normal or abnormal findings at coronary arteriography. There is no evidence at this time for a similar situation in horses, and this represents a major contextual issue when considering "stress echo" with either exercise- or pharmacologic-induced cardiac work. Furthermore, pharmacologic stress testing may not achieve the identical exercise endpoints in terms of HR or altered vascular resistances. The combination of dobutamine and atropine involves the use of proarrhythmic drugs, making the heart rhythm assessment—a pivotal component of the exercise test—quite problematic. Pharmacologic stress testing does not provide an opportunity for dynamic assessment of the gait and airways.[482] Last, assessment of left heart valve function is complicated by changes in systemic arterial BP that may develop during drug-induced tachycardia (but have been poorly characterized in studies thus far). Thus, although pharmacologic stress testing carries the benefit of a stationary diagnostic setup not requiring a treadmill, a number of outstanding issues must be addressed before this examination can be advocated for wider use.

Electrocardiography

Normal Cardiac Cell Electrical Activity. Cardiomyocytes are excitable and capable of responding to electrical stimuli regardless of extrinsic innervation. Specialized cardiac tissues such as those in the sinoatrial node and the His-Purkinje system demonstrate spontaneous depolarization and can serve as pacemakers for the heart. The electrical processes responsible for the ECG are caused by ion fluxes across the cell membrane (Fig. 9.13).[57,110,112-114,116] A general understanding of cellular activity, generation, and spread of the cardiac electrical impulse; effects of autonomic innervation; and electrocardiographic lead systems is required to interpret the equine ECG.

The partially selective nature of the cardiac cell membrane and the presence of various cell membrane pumps lead to an unequal partitioning of ions across the cell membrane.[57,110,112-114,116] This results in very high potassium and relatively low sodium concentrations intracellularly compared with the extracellular fluid. Other ions including chloride and magnesium, but most notably calcium, are important to cellular electrical activity. Calcium also is essential for contraction of the cardiomyocytes. Sudden changes in cardiac cell membrane permeability or conductance to sodium, calcium, potassium, and chloride are responsible for the processes of depolarization, muscular contraction, and repolarization (see Fig. 9.13). These processes, in turn, are affected by serum electrolyte concentration, acid-base status, autonomic traffic, myocardial perfusion and oxygenation, heart disease, and drugs. The basic processes of cell depolarization, calcium influx, and cell repolarization form the basis for, respectively, the P and QRS complexes of the ECG, myocardial contraction, and the ST-T wave of the ECG.

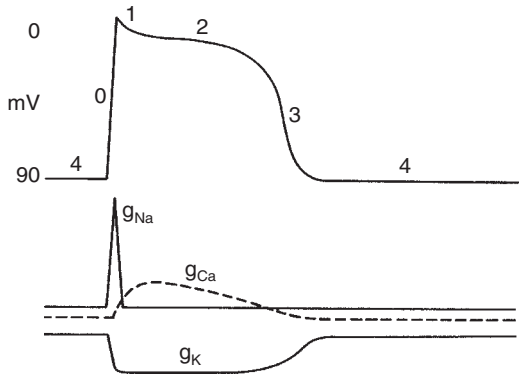

FIG. **9.13** The cardiac action potential. The diagram demonstrates the phases of depolarization and repolarization, as well as membrane conductance (g) to important ions (see the text for details). (From Berne RM, Levy MN: *Cardiovascular physiology,* St. Louis, 1986, CV Mosby.)

The resting membrane potential is determined primarily by the partitioning of potassium ions and proteins across the cell membrane and the relative impermeability of the membrane to sodium. *Depolarization* of atrial and ventricular myocytes and Purkinje fibers is caused by the rapid influx of extracellular sodium into the cell.[57,110,112-114,116] This current is represented by phase 0 of the cardiac cell action potential recording. Normal cardiac tissues depolarized in this manner conduct electrical impulses at high velocity. In contrast, the cells of the SA and AV nodes, as well as ischemic cells, demonstrate less negative diastolic membrane potentials. Nodal cells depend on a slow-inward current of depolarization that is carried mainly by calcium ions across the transient and long-lasting calcium channels. In ischemic cells, due to the less negative resting potential, some sodium channels remain in the inactivated state and thus are unavailable for activation and membrane depolarization during phase 0. Therefore cells in the SA node, AV node, and ischemic tissue conduct electrical impulses very slowly and can be involved in blocks, abnormal automatic mechanisms, or reentrant pathways that promote cardiac arrhythmias. Antiarrhythmic drugs and calcium channel blockers act differently on tissues that are "fast" versus "slow" current dependent (see Cardiac Arrhythmias later in this chapter).

The influx of extracellular calcium into the cell during the *plateau phase* (phase 2) of the action potential triggers the release of intracellular calcium from the sarcoplasmic reticulum. Increases in cytosolic calcium cause myocardial contraction. Hypoxia, acidosis, anesthetics, and many other drugs can affect myocardial contractility by interfering with calcium entry into cells, with the release of calcium from the sarcoplasmic reticulum, or with the binding of calcium to contractile filaments.[57,110,112-114,116] Conversely, digitalis glycosides and dobutamine increase calcium influx and myocardial contractility.

Cellular *repolarization* is initiated by decreases in the cell membrane conductance to sodium and to calcium coincident with increased conductance to potassium. As intracellular potassium moves out of the cell, along its concentration gradient, phase 3 of the cardiac action potential occurs. Repolarization is complex, involves a number of ion currents,[486] and is affected by genetics and drugs such as quinidine or amiodarone. Sympathetic stimulation may activate currents that facilitate repolarization at higher HRs, explaining the shortening of the action potential under sympathetic drive. Paradoxically, vagotonia also enhances repolarization by opening potassium channels, an effect that is very prominent in the atria and may predispose to development of AF. Hypoxia and abnormalities in serum potassium or calcium also alter repolarization. Hyperkalemia accelerates repolarization and shortens the ST-T wave of the ECG. This occurs because hyperkalemia *increases* membrane permeability to potassium, and the high intracellular potassium (exceeding 100 mmol/L) is more than adequate to drive potassium out of the cell (because extracellular potassium rarely exceeds 10 mmol/L).

Spontaneous depolarization or automaticity is a property of select cardiac tissues. Such activity is most prominent in the SA node but may also be encountered in cells around the AV node and in the His-Purkinje network. Normal automaticity is observed in these cells during phase 4 of the cardiac action potential. Spontaneous *pacemaker activity* is generated in normal pacemaker tissues by the background inward sodium current and a time-related decrease in membrane permeability to potassium ion efflux, and a transient inward calcium current.[57,110,112-114,116] Once membrane threshold is reached, ion flow across the long-lasting calcium channels ("slow current") predominates and leads to cell depolarization (phase 0). Spontaneous depolarization is modified markedly by autonomic traffic. Vagal activity opens potassium channels and hyperpolarizes the membrane, depressing automaticity. With sympathetic stimulation or membrane hyperpolarization, the depolarizing "funny current" (I_F) becomes activated, enhancing pacemaker activity.

Autonomic innervation has profound effects on electrical activity[9,217,487] but is not distributed equally through the heart. The right and left vagus have preferential innervation to SA and AV nodes, and parasympathetic traffic is more extensive in supraventricular than ventricular myocardium. Sympathetic activity derived from paired ganglia are also not bilaterally symmetric but do innervate both atria and ventricles extensively. Parasympathetic activity depresses SA nodal activity, enhances intraatrial conduction by shortening atrial action potential duration, and slows AV nodal conduction. Conversely, sympathetic efferent traffic increases HR and shortens AV conduction time.[112] Sympathetic activity also increases cellular excitability, predisposes to some cardiac arrhythmias, and increases myocardial oxygen consumption by augmenting the HR, force of myocardial contraction, and myocardial wall tension. Parasympathetic efferent traffic dominates in the resting, standing horse and frequently fluctuates with changes in BP. The pronounced sinus arrhythmia, sinoatrial block, and second-degree AV block so often encountered in the normal horse are caused by changing vagal tone and serve to regulate arterial BP at rest (see Fig. 9.6).[108]

Depression of normal SA automaticity or increased activity in other tissues in the atria, in the Purkinje system, or in cells around the AV node may lead to an abnormal or "ectopic" cardiac rhythm. This situation is often observed in healthy horses under general anesthesia. When the principal abnormality resides in depression of SA node function or blockage of the impulse in the AV node, the slow discharge of a subsidiary pacemaker is termed an *escape* mechanism. The purpose of these latent cardiac pacemakers is to rescue the heart from extreme bradycardia or asystole. However, ectopic pacemakers also can be enhanced abnormally by drugs, inflammatory mediators, abnormal sympathetic activity, electrolyte disturbances, or ischemia, leading to *ectopic* rhythms that manifest as premature complexes or tachycardias. Additional abnormal electrophysiologic mechanisms, including abnormal automaticity in tissues other than nodal and conduction tissues (i.e., ischemic myocardium), afterdepolarizations, and reentry account for the development of other arrhythmias.[57,110,112-114,116]

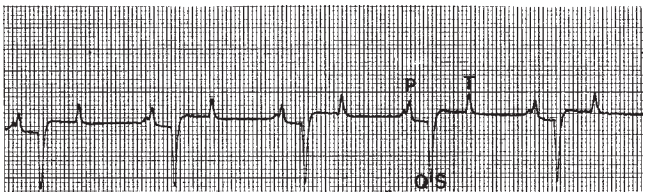

FIG. **9.14** A normal equine base-to-apex lead electrocardiogram (ECG) (25 mm/sec; 1 cm = 1 mV). The waveforms are indicated. The normal P wave in this lead is positive and notched (bifid), and a depression occurs in the baseline after the P wave that indicates atrial repolarization (Ta wave). The QRS complex often lacks an R wave in this lead (QS complex). The T wave is labile and may be negative, biphasic, or positive. Increases in heart rate or sympathetic tone usually lead to positive T waves in this lead.

Genesis of the Electrocardiogram. The SA node is located near the right auricle; therefore initial cardiac muscle depolarization crosses the right atrium (see Fig. 9.3). Activation waves spread through the atrial myocardial cells to the left atrium and also in the direction of the AV node. Specialized atrial muscle cells comprising internodal pathways and Bachman's bundle facilitate transmission of current across the atria.[8,488] These specialized pathways—as well as the SA node—are relatively resistant to high serum potassium concentrations and may function during hyperkalemia to cause a sinoventricular rhythm, even while normal atrial myocytes are inexcitable (atrial standstill).

Conduction continues across the AV tissues by first entering the AV node. Current transmission across the AV nodal cells is especially slow because this tissue depends on inward calcium currents and is subject to physiologic blockade from vagal efferent traffic.[220] Conduction proceeds at a greater velocity through the bundle of His and bundle branches. Propagation of the impulse through the ventricles is enhanced by a rapidly conducting Purkinje system that penetrates relatively completely through the ventricular myocardium.[6,7]

The ECG graphs the time-voltage activity of the heart. The average electrical potential generated by the heart muscle is recorded throughout the phases of the cardiac cycle with time displayed along the X-axis and electrical potential inscribed vertically (Fig. 9.14). The normal waveforms are the P wave (atrial depolarization), the PR (or PQ) interval that is due mostly to slow AV nodal conduction, the QRS complex (ventricular depolarization), and the ST-T wave (ventricular repolarization). A prominent atrial repolarization wave (Ta wave) is often noted in the PR segment of the equine ECG, particularly at faster HRs. The QT interval represents total electrical activation-repolarization time.

BOX 9.8 Electrocardiographic Leads

BASE-APEX MONITOR LEAD (MOST COMMONLY USED)

[+] Electrode over the left apex (left chest, at the level of the olecranon)
[–] Electrode over the right jugular furrow
The most common method to obtain the base-apex lead is to place the left arm (LA) electrode over the left apex, the right arm (RA) electrode over the jugular furrow, and select "lead I" on the electrocardiograph.
This lead is the preferred choice for monitoring cardiac rhythm.

BIPOLAR LEADS (EINTHOVEN)[a]

Lead I = Left foreleg (LA) [+] – Right foreleg (RA) [–]
Lead II = Left rear leg (LL) [+] – Right foreleg (RA) [–]
Lead III = Left rear leg (LL) [+] – Left foreleg (LA) [–]

UNIPOLAR AUGMENTED LIMB LEADS (GOLDBERGER)[a]

Lead aVR = Right foreleg [+] – Left foreleg and Left rear leg [–]
Lead aVL = Left foreleg [+] – Right foreleg and Left rear leg [–]
Lead aVF = Left rear leg [+] – Right foreleg and Left foreleg [–]

UNIPOLAR PRECORDIAL CHEST LEADS

[+] Electrode over selected precordial site
[–] Electrode composed of a compound electrode of left and right foreleg and left rear leg (Wilson central terminal)
The lead is named based on the location of the exploring (V or C) electrode.
V_{10} = [+] over the dorsal spine. Precordial leads other than V_{10} are not commonly used.

MODIFIED ORTHOGONAL LEAD SYSTEM

Lead X = Lead I, right [–] to left [+]
Lead Y = Lead aVF, cranial [–] to caudal [+]
Lead Z = Lead V_{10}, ventral [–] to dorsal [+]

[a] Frontal plane leads.

Clinical Electrocardiography. The clinical application of *electrocardiography* to the horse has been studied extensively.* The principles of recording and interpreting the equine ECG are similar to those used for humans, dogs, and other species. The lead systems employed are identical, although some modified leads, such as the base-to-apex lead, are most useful for monitoring the cardiac rhythm. A number of semiorthogonal lead systems have been evaluated experimentally but are rarely used in clinical practice. The modified Einthoven's lead system, consisting of leads frontal planes I, II, III, $_a$VR, $_a$VL, and $_a$VF, and the precordial lead V_{10}, is quite applicable for ECG studies of horses (Box 9.8). The base-apex lead or chest leads are most often used for rhythm analysis.

The value of continuous, *ambulatory (Holter) ECG* monitoring is obvious for identification of infrequent rhythm disturbances, quantifying the severity of an arrhythmia, or objectively evaluating drug therapy (Fig. 9.15). In one study it was observed that many horses that were historically and clinically without evidence of cardiac disease had supraventricular or (less often) ventricular arrhythmias on Holter ECG.[400,541] Ambulatory monitoring can be performed with self-adhesive contact electrodes using a bipolar lead system similar to that used for the equine HR monitors. Electrodes are often placed over the left saddle area (positive [right arm] electrode), sternum (negative [left arm] electrode), and right thorax (neutral [left leg] electrode), with the ground (right leg) electrode placed anywhere around the girth area. However, alternative electrode placements might be used to record an ambulatory ECG of diagnostic quality (e.g., right arm, right saddle area; left arm and left leg, left thorax 20 cm and 5 cm, respectively, above olecranon; right leg (neutral), left saddle area). To facilitate ECG pattern reading and optimize the ECG for automated processing using dedicated software, the electrode arrangement should provide an ECG with a distinct negative QRS complex and positive P and T waves (see Fig. 9.14). If ECG recordings are analyzed using human Holter analysis systems, it may be beneficial to record an ECG with positive QRS complexes. In any case, the T waves should not be bigger than the QRS complexes. Clipping may not be necessary as long as the hair coat is not too long and the self-adhesive electrodes can be kept moist (e.g., by additionally adding a drop of 0.9% saline or electrode contact gel onto the contact area) and in tight contact with the horse using a surcingle and padding material. This type of continuous 24-hour rhythm monitor can be useful to evaluate the horse with a history of syncope or an arrhythmia but in which an arrhythmia cannot be induced during resting, exercise, and postexercise ECG examinations. An alternative is an ECG event recorder that continuously records the rhythm and stores the ECG following an observed event, such as a sudden fall. These event recorders can be worn for longer periods of time.

Telemetry-based ECG recordings are commonly used in exercise testing (see Exercise Testing earlier in this chapter) and in monitoring of critical patients in hospital settings.[58,90,459,534] The lead systems used are often similar to those employed for Holter ECG recordings. However, the degree of artifact that occurs during exercise is considerable. Those interested in consistent

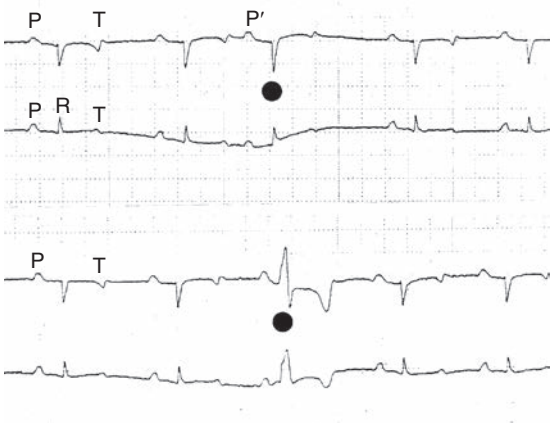

FIG. **9.15** Examples of extrasystoles. Atrial (P′ at *top*) and ventricular (at *bottom*) extrasystoles in a mare with heart failure, sinus tachycardia, and premature beats. The recordings are from a 24-hour tape-recorded (Holter) electrocardiogram (ECG). Two transthoracic leads recorded simultaneously. The waveforms are indicated. The dark circles indicate the premature complexes. The P-R interval of the APC is longer because of physiologic refractoriness in the atrioventricular node. The ventricular ectopic follows the sinus P wave (late diastolic) but discharges the ventricle before the sinus impulse can cause a normal QRS complex. The T wave of the ventricular extrasystole is abnormal (secondary T-wave change). Paper speed is 25 mm/sec.

- Calibration—standard: 1 cm/mV
- Lead(s)—see Box 9.8

ARTIFACTS
- Electrical, motion, twitching, muscle tremor, equipment (ventilator)

HEART RATE
- Atrial and ventricular rate

CARDIAC RHYTHM
- Regular, regularly irregular, irregularly irregular
- Atrial, AV conduction sequence, ventricular, ventricular conduction
- Arrhythmias
  - Site or chamber of abnormal impulse formation, myocardial fibrillation, or conduction disturbance
  - Rate of abnormal impulse formation
  - Conduction of abnormal impulses
  - Patterns or repeating cycles

WAVES AND COMPLEXES
- P wave—morphology, duration, amplitude, variation
- PQ (PR) interval—duration, variation, conduction block (of P wave)
- QRS—morphology, duration, amplitude, frontal plane mean electrical axis
- ST segment—depression or elevation
- T wave—changes in morphology or size
- QT interval—duration (consider heart rate)

MISCELLANEOUS
- Electrical alternans, synchronous diaphragmatic contraction

stress ECG recordings must experiment with various electrode positions and lead systems. One proven possibility is placement of the right arm and ground electrodes next to each other on the left dorsum above the scapula, cranial to the saddle or the lunging girth, and the left arm and left leg electrodes next to each other on the left ventral thorax, caudal to the saddle girth or lunging girth. The electrodes should be place sufficiently distant to the tack and the rider's legs to minimize motion artifacts.

The orientation, amplitude, and duration of the ECG waveforms depend on many factors, including the age and size of the horse,[386,399,519] the lead examined, the size of the cardiac chambers, the degree of training, and even the phase of ventilation.[492,493] The principal use of the ECG is to diagnose the heart rhythm, because in horses this examination is insensitive for detecting cardiomegaly, especially in horses with mild to moderate heart enlargement. A normal ECG does not exclude heart disease; moreover, the ECG is not a test of myocardial function. A systematic approach to ECG analysis should be undertaken (Box 9.9) and compared with reference values (see Table 9.5). Although the magnitude of absolute differences may be small, body weight needs to be considered when comparing HR and ECG time intervals to reference values, because small equine breeds have slightly faster HRs and shorter ECG time intervals (i.e., PR interval, QRS duration, QT interval) compared with larger equine breeds (Fig. 9.16).[399] Furthermore, the HR dependence of repolarization needs to be considered when measuring QT intervals,[399,536,537,539] acknowledging that the best method for QT correction in individual horses is ill defined.

Atrial depolarization generates the P wave. Normal activation proceeds from right to left and craniad to caudad, leading to positive P waves in left-right lead I and also in craniocaudal leads II and aVF.[8,11] The normal P wave is notched or bifid; however, single peaked, diphasic, and polyphasic P waves may be encountered in normal horses. A negative/positive P wave is often recorded if the focus of pacemaker activity shifts to the caudal right atrium near the coronary sinus (Fig. 9.17). The initial peak of the common bifid P wave is reportedly caused by depolarization of the middle and caudal one third of the right atrium.[6,8] The second peak represents activation of the atrial septum and the medial surface of the left atrium. The P wave peaks can be subdivided, with P_1 reported to be as

TABLE 9.5 Normal Heart Rates and ECG Time Intervals for Horses at Rest

Breed	HR (beats/min)	PQ (msec)[a]	QRS (msec)[b]	QT (msec)[c]
ADULTS[399,470,499,500,512,532,533]				
Large breeds	26–50	200–500	80–140	360–600
Small breeds, ponies	30–54	160–320	60–120	320–560
FOALS[426,519,546]				
Large breeds	100–140	100–180	50–80	200–350
1–7 d	80–130	100–190	60–80	230–350
14 d				
Ponies	70–145	90–130	25–70	180–370
1–30 d	60–95	110–150	30–70	220–420
60 d	50–85	130–170	50–80	310–390
90 d				

[a]Also termed PR, because the Q wave is often not visible. Interval varies with autonomic input, longer when vagal tone is high.
[b]QRS duration is often difficult to determine due to the normal slur in the ST segment. Duration can vary with size of the heart and lead positioning (often longer in the base-apex lead).
[c]Inversely related to heart rate.

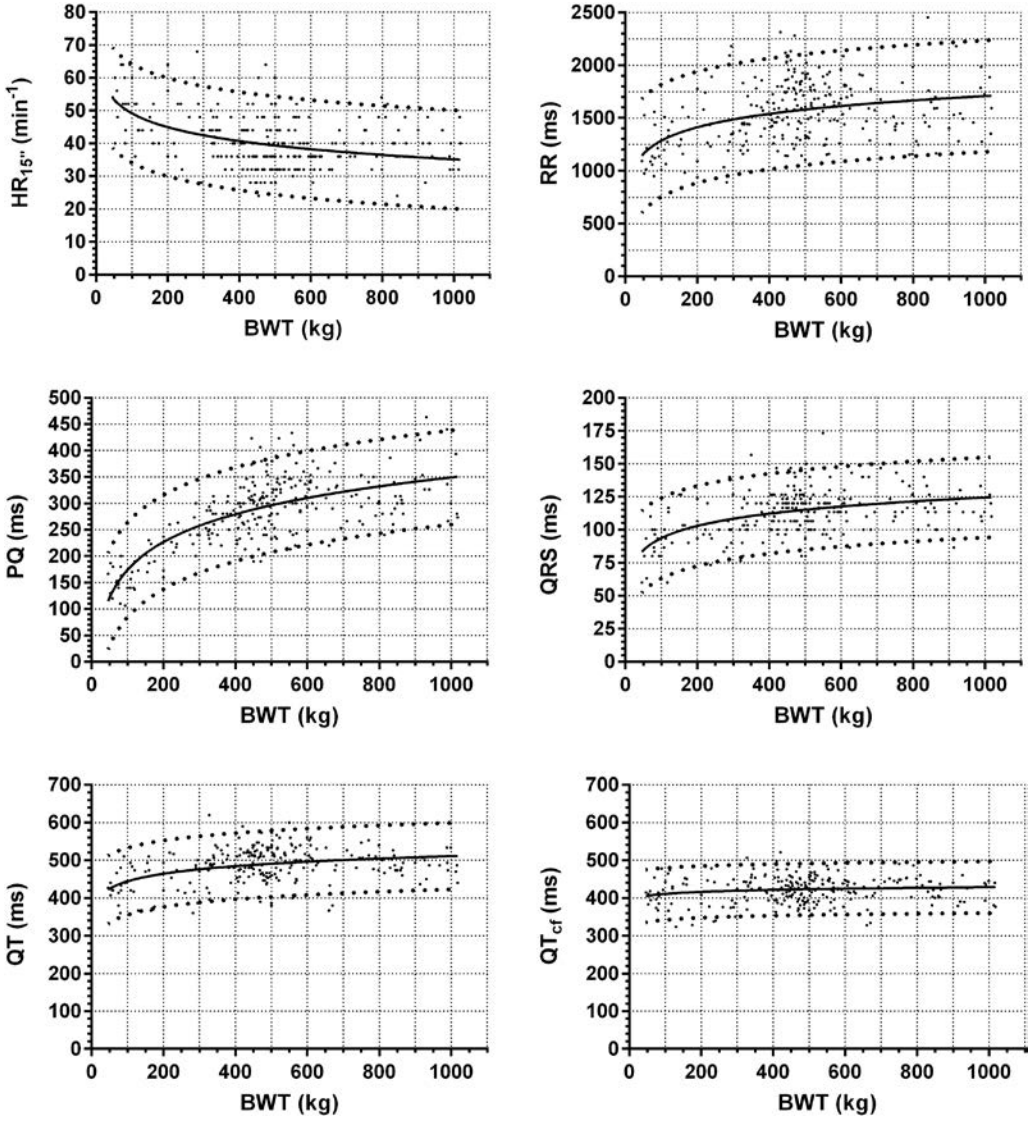

FIG. **9.16** Scatter plots showing the relationship between body weight (BWT), heart rate (HR), and ECG time intervals in healthy adult horses of different breeds (n = 250). Reference intervals for HR and ECG time intervals for a specific BWT can be estimated based on the prediction band (dotted line). $HR_{15"}$, mean HR calculated over 15 sec; *RR,* RR interval; *PQ,* PQ (PR) interval; *QRS,* QRS duration; *QT,* QT interval; QT_{cf}, rate-corrected QT interval, Fridericia's correction. (Modified from Schwarzwald CC, et al.: Relationship of heart rate and electrocardiographic time intervals to body mass in horses and ponies. *J Vet Cardiol* 2012, 14:343-350.)

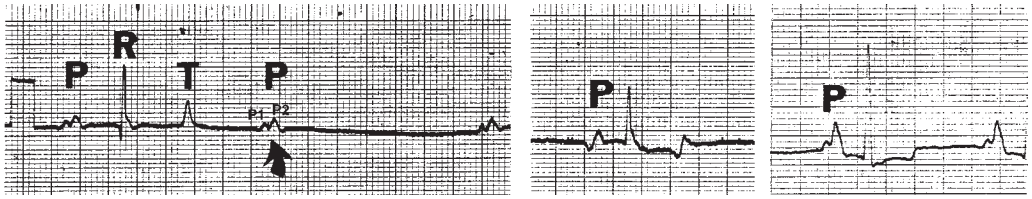

FIG. **9.17** P waves of the horse are demonstrated. On the left is a normal, bifid P wave morphology with two distinct peaks (designated as P_1 and P_2) and also a physiologic second-degree atrioventricular block *(arrow).* The center panel demonstrates a negative/positive P wave of coronary sinus origin. This is a normal variation. The right panel shows increased amplitude P waves recorded in a horse after conversion from atrial fibrillation (AF). The second peak is particularly large and may indicate atrial enlargement; however, such voltage criteria correlate poorly with cardiomegaly in horses. Echocardiography is a more accurate method for evaluating atrial size. Lead 2 paper speed is 25 mm/sec.

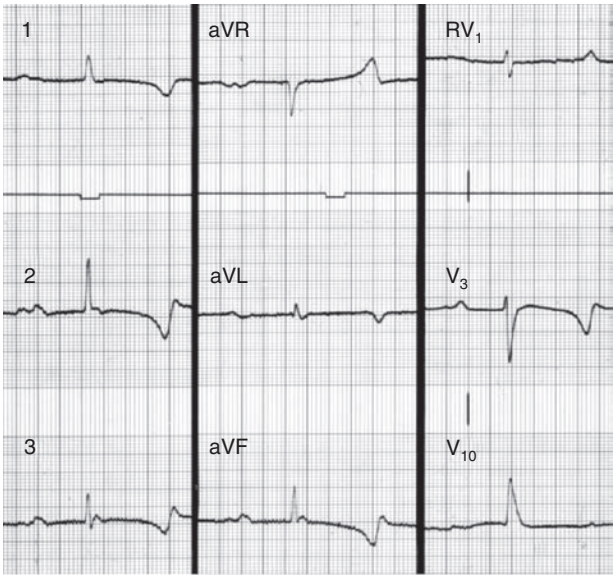

FIG. **9.18** Multiple lead recordings in a normal horse. The varying configuration of the P-QRS-T complexes across the leads is notable.

high as 0.25 mV (mean of 0.14 mV) and the second peak, P_2, reported to be as high as 0.5 mV (mean of 0.28 mV).[499] There are even subtle differences among breeds of horses. The P-wave morphology can change cyclically with waxing and waning of vagal tone during sinus arrhythmia. During tachycardia, the P wave shortens, becomes more peaked, and is followed by a prominent atrial repolarization (T_a) wave that deviates the PQ segment downward. Such features make the diagnosis of atrial enlargement by electrocardiography very difficult.

The time required for conduction across the AV node and His-Purkinje system is estimated by measuring the PR interval. Because physiologic AV block is so common, there is significant variation in the PR interval even within the same horse; thus, normal maximal values for the PR interval are difficult to state. Values that persistently exceed 0.5 seconds are probably abnormal (see Table 9.5). Variation in the PR interval is not usually related to changes in ventilation[42] but is often correlated with changes in BP and baroreceptor activation.[108]

The morphology of the QRS complex is variable. The relatively complete penetration of the conduction system into the free walls of the ventricle causes these chambers to be activated simultaneously with a burst of depolarization, which cancels much of the divergent electromotive forces.[6,7] Consequently, the normal electrical axis may vary, and the amplitude of the QRS complex can be quite small in the frontal plane leads. A substantial dorsally oriented vector causes a prominent positive terminal deflection in lead V_{10}, while the (– electrode) right base to (+ electrode) left apex lead exhibits a prominent S-wave (Figs. 9.14 and 9.18). The normal slur in the ST segment makes determination of QRS duration difficult in many horses.[6,35,542] The mean amplitude for the R wave in lead II for normal racehorses is about 0.8 to 1.1 mV.[1,4,151,499-501,522] Clinical experience suggests that R wave amplitudes exceeding 2.2 mV in lead II or 1.7 mV in lead I are often abnormal. But occasionally, the R wave amplitude in a normal horse exceeds even these limits. The frontal plane leads can be inspected to estimate the mean electrical axis of depolarization, the "average" wave of depolarization. Abnormal axis deviations have been observed with cardiomegaly, cor pulmonale, conduction disturbances, and electrolyte imbalance.[522]

Following ventricular activation, repolarization of the ventricles is recorded. This period is measured from the end of the QRS complex (the "J point") and extends to the end of the T wave.[35,505,543] The T wave vector is most often directed toward the right caudal quadrant, resulting in a positive T wave in lead III and a negative or isoelectric T wave in lead I in resting horses (Fig. 9.18).[499] Although some clinical surveys have suggested that abnormalities of the ST-T indicate cardiac dysfunction in performance animals, marked deviation of the ST segment and increased amplitude of the T wave are anticipated in healthy horses during exercise or even with excitement-induced tachycardia. There is simply no compelling evidence that T-wave abnormalities can be interpreted consistently. Progressive J-point or ST-segment deviation in the horse with hypovolemia or shock may indicate myocardial ischemia, whereas enlargement of the T wave may develop with myocardial hypoxia or hyperkalemia.

Diagnosis and management of cardiac arrhythmias are discussed later in this chapter.

Thoracic Radiography

There are severe limitations to the use of thoracic radiography in the evaluation of the equine heart because of the large size of the mature horse and the ability to obtain only a standing lateral thoracic radiograph in all except the smallest foals.[544] Although recumbent lateral and on occasion ventrodorsal or dorsoventral projections can be obtained on neonatal foals, the stress of restraint or requirement for heavy sedation can make such positioning contraindicated in foals with cardiac disease. Thoracic radiographs may be useful to identify areas of pulmonary or pleural disease and assist in the differential diagnosis of respiratory problems.

Gross changes in cardiac size and shape may be detected in a lateral thoracic radiograph of a foal or horse with significant cardiomegaly.[544-548] A normal thoracic radiograph does not necessarily indicate that the heart is normal in size. Mild to moderate increases in the size of the cardiac chambers may go undetected, particularly in adult horses. Generalized enlargement of the cardiac silhouette is observed in cases of significant pericardial effusion or with CHF (Fig. 9.19). Dorsal displacement of the trachea may be detected in some horses with left atrial (LA) and LV enlargement. In some horses with LA enlargement, the caudodorsal border of the cardiac silhouette bulges caudally. Increased contact between the ventral border of the heart and the sternum may be detected with RV enlargement but is usually difficult to appreciate. A 50% decrease in the spinotracheal angle (the angle between the dorsal border of the trachea and the ventral border of the adjacent thoracic vertebrae) was demonstrated in young horses with cardiomegaly caused by congenital cardiac disease.[544]

Evaluation of the pulmonary vasculature and pulmonary parenchyma is also difficult and very dependent on radiographic technique. Enlarged pulmonary vessels associated with pulmonary overcirculation can occasionally be observed in left-to-right shunts; the opposite is also true in congenital right-to-left shunts. Pulmonary edema causes generalized increased radiopacity, particularly in the hilar regions; the characteristic air bronchograms are more readily identified there when alveolar edema is present.

Angiocardiography is only practical in foals less than about 115 kg and usually requires general anesthesia, which may be contraindicated in the foal with a severely compromised cardiovascular system. Both selective and nonselective positive contrast angiocardiograms have been performed in foals and adult horses (see Fig. 9.19D),[171,545,549] but these techniques have been almost exclusively replaced by echocardiography.

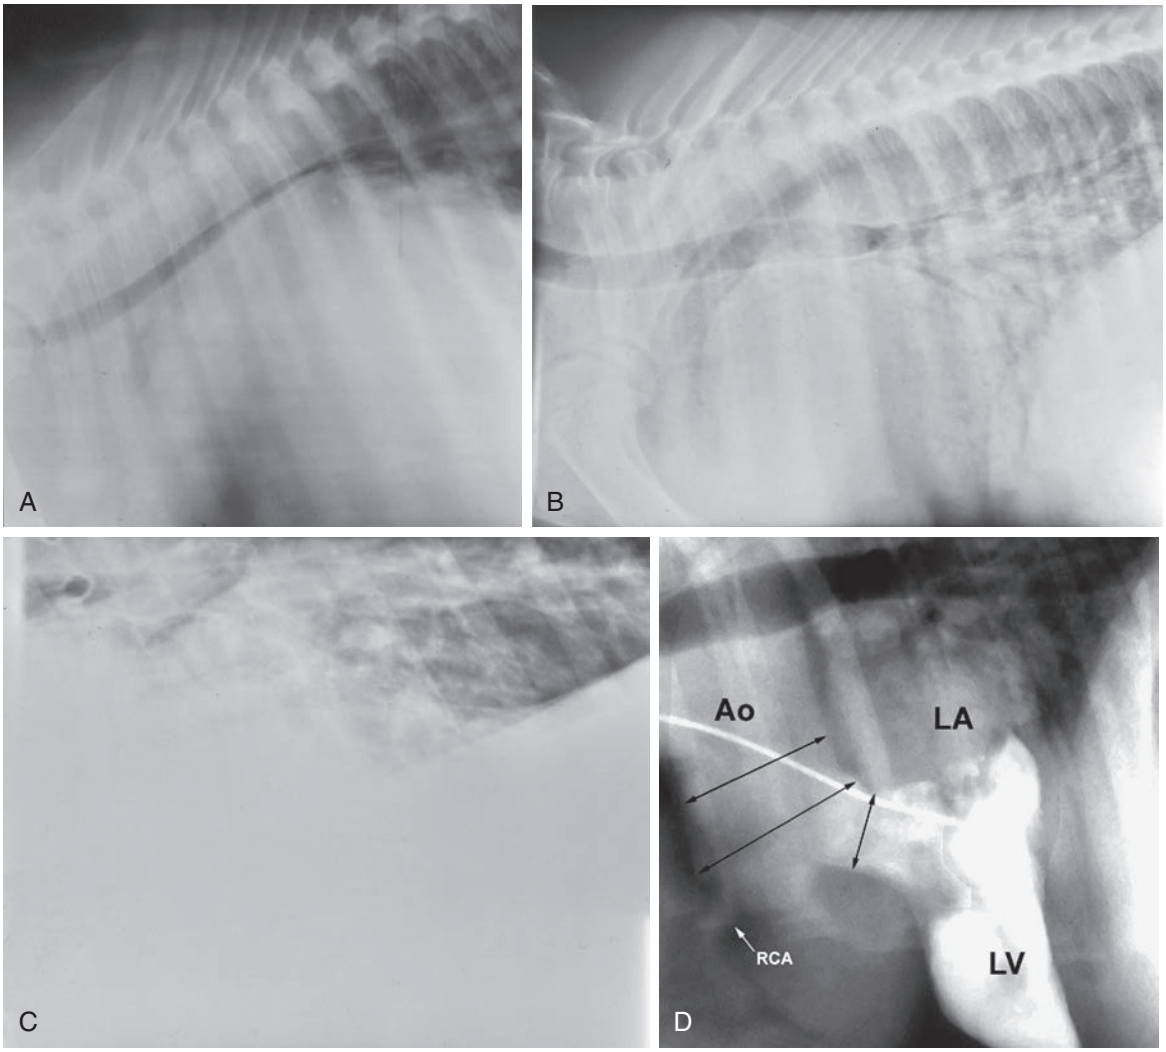

FIG. **9.19** Thoracic radiography. A, Significant cardiomegaly in a Quarter Horse foal with complex congenital heart disease, including multiple ventricular septal defects (VSDs). B, Cardiomegaly and alveolar pulmonary edema in a filly with mitral regurgitation (MR) and left-sided congestive heart failure (CHF). C, Increased pulmonary density and pleural effusion in a Standardbred gelding with atrial fibrillation (AF), atrioventricular valvular regurgitation, myocardial failure, and biventricular CHF. D, Angiocardiogram obtained from an Arabian foal with pulmonary atresia and a large VSD (pseudotruncus arteriosus). Contrast medium was injected in the left ventricle (LV), and this medium opacifies a dilated, overriding aorta. Right-to-left shunting across the VSD results in dilution of contrast medium. The right arrow shows the subaortic LV outflow tract; the widened aorta is delineated by the arrows at the left. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RCA,* right coronary artery.

Nuclear medicine imaging has been developed in some equine referral institutions and has been used to assess cardiac function. First-pass nuclear angiocardiography permits the visualization of the cardiac chambers during sequential phases of the cardiac cycle.[544] Application of first pass studies may be useful for identification of cardiac shunting, but again, this diagnosis is more simply attained by echocardiography.

Echocardiography

Over the past 35 years, echocardiography has evolved to become the most important diagnostic study currently available for evaluation of the equine heart. Transthoracic echocardiography, including 2D, M-mode, and Doppler studies, provides the basis for comprehensive evaluation of internal cardiac structures, chamber and vessel dimensions, blood flow characteristics, mechanical function of the heart, presence and nature of heart lesions, and the relevant hemodynamics of a cardiac lesion.* Transesophageal echocardiography (TEE) has been used in horses[241,276,277,309,312,566] but (except in foals) requires custom-made transducers and is only practical in anesthetized or heavily sedated horses due to the fragile (and expensive) nature of the TEE probe.

Despite the recent technical advances that allowed great improvement of image quality and temporal resolution of echocardiographic images, accurate and reliable assessment of chamber dimensions and mechanical function of the heart remains challenging and is limited by a variety of technical, anatomic, and physiologic issues that need to be considered

* References 14, 49, 51, 56, 70, 71, 74-76, 122, 124, 129, 130, 142, 148, 161, 167, 168, 209, 211, 243, 244, 274, 276, 280, 281, 285-287, 289, 297, 306, 311-313, 340-350, 365, 390, 391, 426, 481, 484, 550-593.

when performing echocardiographic examinations.[344,594,595] Knowledge of the technical principles of ultrasonography, technical skills with imaging and instrumentation, strict adherence to a routine protocol in order to obtain high-quality standard sonographic images, comprehensive knowledge of normal cardiac anatomy and physiology, and thorough appreciation of equine cardiac diseases are prerequisites to the successful use of echocardiography.

The echocardiographic examination should take place in a location where the horse can be safely restrained. If possible, the patient should not be sedated before the examination, because cardiac dimensions, indices of cardiac function, and color Doppler signals of regurgitant flow or shunt flow might be altered because of drug effects on preload, afterload, contractility, HR, and rhythm.[274,584,587,596] However, some horses do not tolerate the echocardiographic procedure and require sedation to allow conducting the examination safely, with sufficient quality, and at normal HRs.

Examination findings are relatively consistent when performed by experienced examiners, but there is day-to-day, subject, and examiner variation that can be significant (greater than 10%) for some variables and must be considered when performing serial examinations.* Unfortunately, an imaging standard for equine echocardiography that is unanimously acknowledged and followed by all centers and clinicians is currently lacking. Most clinicians follow some kind of standard, but the methods differ. Similarly, the methods described in the literature vary and are often not sufficiently described when it comes to technical details, machine settings, imaging planes, exact anatomic landmarks, and—importantly—timing of measurements. Reference values for echocardiographc measurements are often insufficiently defined and are based on individual papers or small studies in selected populations. Some representative data are provided in Table 9.6.

A recent survey showed that despite the large number of publications and the great amount of collective experience among experts, there is hardly anything in equine echocardiography everybody does entirely the same way when it comes to modalities, imaging planes, landmarks, timing, and scaling for differences in body mass.[597] It will be important in the near future to define standard imaging guidelines based on expert consensus, better characterize repeatability and reproducibility of echocardiographic methods and measurements, and provide normal reference intervals for echocardiographic measurements considering differences in breed, size, and body weight. This said, it is important to realize that despite the availability of quantitative imaging methods, subjective assessment of recordings is a cornerstone of echocardiography and must not be neglected. Finally, independent of the methods used, the findings obtained during echocardiography must be critically assessed in the light of medical history and clinical findings.

Indications and Clinical Use of Echocardiography in Horses. Echocardiography can be used to identify cardiac disorders, assess hemodynamic and structural consequences of disease, and monitor response to treatment and progression of disease. Echocardiography is primarily indicated in horses with heart murmurs and allows differentiation of physiologic flow murmurs from pathologic murmurs and assessment of their clinical relevance. However, there are other clinical situations when echocardiography also provides valuable information (Box 9.10).[68] Furthermore, ultrasound can also identify other lesions of the lung, pleural space, or mediastinum that may masquerade as heart disease.[140,598]

A complete echocardiographic study should address morphologic lesions, motion abnormalities, cardiac chamber and great vessel size, cardiac valve function, blood flow disturbances, global and regional ventricular systolic function, estimates of hemodynamic variables including pressure gradients and volumetric flow, and ventricular diastolic function and filling pressures (realizing that these two are challenging to measure in mature horses).[68] A normal echocardiogram and Doppler study in a horse with a cardiac murmur is a favorable finding, suggesting a functional basis for the murmur. Conversely, identification of an abnormal flow pattern with associated cardiomegaly or abnormal ventricular function may indicate a high risk or limitation for work. As with all diagnostic studies, there can be ambiguous results, particularly regarding the tricuspid valve, because physiologic tricuspid regurgitation, silent to auscultation, is detectable by Doppler studies in many clinically normal horses. Box 9.11 provides an overview on interpretation of echocardiographic and Doppler studies. Clinical applications of echocardiography are illustrated later in this chapter.

Technical Considerations. The ultrasonographic equipment should include a phased-array sector transducer working at frequencies between 1.5 and 3.5 MHz. Tissue harmonic imaging often improves the image quality, particularly in the far field and in large horses, by providing a higher signal-to-noise ratio, better contrast, and higher spatial resolution. The depth of penetration should reach at least 25 to 30 cm to scan the heart of an adult horse. The image is usually displayed, by convention, with that part of the heart closest to the transducer at the top of the screen. Simultaneous recording of a surface ECG is required and allows exact timing of flow events and echocardiographic measurements. Modern echocardiography systems offer digital raw data storage of still frames and cine loop recordings. This is extremely useful because it reduces the contact time with the patient and allows postprocessing and off-line analysis of the stored data.

Two imaging modalities, the motion-mode (M-mode) and two-dimensional (2D, B-mode, or cross-sectional) formats, are in widespread use. When Doppler studies or contrast echocardiography are added, blood flow can be detected relative to the 2D and M-mode images (Box 9.11, Figs. 9.20–9.25; see also Fig. 9.5).[56,344,590,591]

The *M-mode echocardiogram* is a single-crystal icepick image of the heart (see Figs. 9.5, 9.20, and 9.23).[56,344,590,591] The movement of the cardiac structures (vertical axis) is displayed over time along the horizontal axis. The ECG is recorded to provide a timing reference, and the depth of the cardiac structures from the transducer is displayed in centimeters. Visualization of the characteristic movements of cardiac structures permits the experienced viewer to evaluate and quantify cardiac anatomy and function. The high sampling rate of the M-mode study makes it excellent for visualizing rapidly vibrating structures, such as the oscillating mitral leaflet in aortic regurgitation (see Fig. 9.23D).[554]

The *two-dimensional echocardiogram (2DE)* generates an image by sweeping an ultrasound beam across the heart to produce sector frames (see Figs. 9.20–9.22).[56,344,590,591] In conventional transthoracic echocardiography, the operator hand-directs the imaging probe to achieve a suitable tomographic plane.

Note: This summary does not provide a systematic review of the current literature. It is intended to serve as a general guide for assessment of some of the most commonly used echocardiographic indices of cardiac dimensions and cardiac function in horses. Individual measurements may differ depending on echocardiographic techniques and breed, age, body weight, and athletic condition of the animal.

BOX 9.10 Indications for Echocardiography

EVALUATION OF HEART MURMURS

- Previously diagnosed "functional" murmur that is louder on serial examinations[a]
- Grade 3–6/6 left-sided murmur compatible with mitral regurgitation (MR) or aortic regurgitation (AR)[a]
- Grade 4–6/6 right-sided systolic murmur compatible with tricuspid regurgitation (TR)[a]
- Suspected ventricular septal defect (VSD) or other congenital heart lesion
- Continuous or combined systolic-diastolic murmurs
- Murmur associated with poor performance
- Murmur detected on prepurchase examination

EVALUATION OF ARRHYTHMIAS

- Clinically important arrhythmias, whether a murmur is present or not

OTHER INDICATIONS

- Suspected myocardial disease (unexplained tachycardia, supraventricular or ventricular ectopy, increased cardiac troponin I concentrations)
- Unexplained exercise intolerance, poor performance, collapse, or episodic weakness
- Fever of unknown origin or specific suspicion for endocarditis or pericarditis
- Muffled heart sounds (to detect effusion)
- Suspicion of CHF
- Severe respiratory disease (to detect pulmonary hypertension)

[a]Because of the high prevalence of heart murmurs in the healthy horse population, an echocardiographic examination is not strictly recommended in all horses with murmurs. Acknowledging the fact that murmur grade might not be directly related to clinical relevance or severity of disease, the current recommendations are based on murmur grades, on the assumption that murmurs of grade 1–2/6 are less likely to be clinically relevant. In case of doubt, an echocardiogram is always indicated in horses with murmurs.

The pie-shaped image obtained has both depth and breadth but has no significant thickness. Accordingly, different image planes must be used to interrogate the three-dimensional heart. These imaging planes are designated long-axis (sagittal), short-axis (coronal), apical (when the transducer is near the left apex), and angled (hybrid) views. Because of anatomic restrictions, apical images are difficult or impossible to obtain except in foals. By convention, in long-axis and short-axis recordings, the dorsal regions of the heart (atria, heart base) and the cranial regions of the heart (right ventricular outflow tract), respectively, are displayed to the right of the screen.

The 2D field is constantly updated to visualize cardiac motion in real time, and this is done at typical sampling rates (frame rates) of 20 to 40 frames/sec, with the update rate inversely related to penetration depth and angle of field. Fully digital echocardiographs can display much faster frame rates, often exceeding 60/sec. Newer applications such as 2DE-based anatomic M-mode[345] or 2D speckle tracking[161,168,346-348] demand a frame rate between 40 and 90 Hz to achieve sufficient temporal resolution. Human interpretation is generally limited to 32 frames/sec, so that recordings made at higher frame rates require slow motion playback for detailed analysis. 2D echocardiography allows assessment of cardiac anatomy, detection of macroscopic structural lesions, subjective evaluation and measurement of chamber and vessel dimensions, and evaluation of left atrial and left ventricular function.

Contrast echocardiography,[599] whereby saline is used to delineate the path of blood flow, is especially useful for the detection of right-to-left shunts in foals, including patent foramen ovale (see Fig. 9.24D).

Doppler echocardiography relies on the Doppler principle to measure the direction and velocity of red blood cells (RBCs) moving through the heart (see Figs. 9.5 and 9.25).* In Doppler echocardiography, a portion of the ultrasound emitted by the transducer strikes moving RBCs. These targets cause ultrasound to be reflected back to the transducer. Because the RBCs constitute a moving "source" of (reflected) ultrasound, the returning sound waves attain a frequency that is slightly different from that originally transmitted (the "carrier frequency"). When the echocardiograph unit records the Doppler frequency shift, calculation of RBC velocity and direction relative to the transducer is possible. The information is displayed as a Doppler spectrum showing time along the horizontal axis, flow direction relative to the transducer as above (toward) or below (away from) a zero baseline, and calculated RBC velocity along the vertical axis. Disturbed flow, as might be recorded across a regurgitant orifice or ventricular septal defect, results in a high-velocity and broadened velocity spectrum. With all Doppler modalities, parallel alignment with the direction movement of the target is crucial, because excessive angle of interrogation (i.e., greater than 20 degrees) will lead to an underestimation of velocities. Therefore technically, velocities can only be accurately measured for blood flowing parallel to the ultrasound beam (i.e., toward or away from the transducer) but not for blood moving perpendicular to the ultrasound beam. Most echocardiography units offer digital angle correction that can be applied live or during postprocessing to mathematically correct the measured velocities. However, this function should not be applied for Doppler measurements of intracardiac blood flow because the exact true direction of flow in the cardiac chambers is unknown and cannot be derived from the Doppler signals, and angle correction may lead to overestimation of true velocity and severity of the lesion.

Pulsed-wave (PW) Doppler methods measure direction and velocity of RBCs within a discrete area of the heart or circulation, which can be determined by the observer when placing the sample volume within the cardiac chambers or vessels. *Color-coded Doppler imaging* is a more refined example of pulsed-wave technology whereby flow toward the transducer is coded in red and flow away is represented in blue. Calculated velocity is displayed in relative shades of these colors, and green or yellow are added to the flow mapping to identify "turbulence." Color coding permits superimposition of flow information onto the 2D or M-mode image (see Fig. 9.25). Although there are substantial technical challenges in terms of penetration and frame rate, color Doppler imaging is useful in horses because a large area of the heart can be screened for flow disturbances; this is also called "color flow mapping" (CFM). For example, it is much easier to find a jet of mitral regurgitation using color Doppler imaging than with other Doppler

BOX 9.11 Interpretation of Echocardiographic and Doppler Studies

GENERAL PRINCIPLES OF INTERPRETATION

- Evaluate the electrocardiogram relative to cardiac motion and cardiac rhythm disturbances; arrhythmias can alter measures of ventricular function, cause aortic valvular regurgitation, and alter flow and pressure gradients.
- Remember that persistent tachyarrhythmias can lead to reversible form of dilated cardiomyopathy (tachycardia-induced cardiomyopathy).
- Determine the initial image planes needed for examination based on clinical examination and your standard operating procedures.
- Identify the general situs of the heart and cardiac structures; identify the atria, ventricles, cardiac septa, great vessels, and cardiac valves.
- Note any dilation, attenuation, or absence of the aorta or pulmonary artery, and identify their origins and relationships to the atrioventricular valves and to the ventricles.
- Note the presence of unanticipated or lack of expected structures.
- Identify pleural effusion.
- Rule out extrapericardial mass lesions of the lung or thorax.

PERICARDIUM AND PERICARDIAL SPACE

- Rule out pericardial effusion and pericardial mass lesion.
- Mixed echoic effusions or shaggy tags may indicate highly cellular or inflammatory effusate.
- In pericardial effusion: Identify diastolic collapse of the right atrium or right ventricle indicating cardiac tamponade or a large bilateral pleural effusion; protracted collapse or ventricular or atrial inversion are more reliable signs of tamponade. Exuberant swinging of heart may be seen.
- In pericardial effusion: Identify any heart-related lesions using multiple complementary planes.
- If there is concern about constrictive pericardial disease, evaluate the motion of the ventricular septum (for accentuated flutter or 'septal bounce'), and perform Doppler studies of the left and right sides of the ventricular inlets; large E waves with abrupt termination of filling may be observed; evaluate the effects of ventilation because marked variation may be observed in E waves; tissue Doppler may also be instructive in cases of constrictive disease.

LEFT ATRIUM, PULMONARY VEINS, AND ATRIAL SEPTUM

- Identify pulmonary veins and pulmonary venous entry.
- Examine for attenuation or small size: Rule out volume depletion, right-to-left shunt, or low cardiac output.
- Examine for enlargement or rounding/turgid appearance: Rule out left-to-right shunt, mitral valve disease, left ventricular systolic or diastolic failure, chronic arrhythmia (e.g., atrial fibrillation).
- Measure left atrial diameter and/or left atrial area by 2D imaging.
- Examine the atrial septum for abnormal bowing to the left or right atrium (high atrial pressure).
- Examine the atrial septum for septal defects or patent foramen ovale (perform Doppler and 'bubble' contrast studies if necessary).
- Examine the blood pool for spontaneous contrast.
- Examine the atrioventricular groove for dilated vascular structure: Rule out dilated coronary sinus and left cranial vena cava.
- 2D echocardiography and tissue Doppler can be used to evaluate atrial wall motion and function.

MITRAL VALVE

- Identify two valve leaflets and cusps in long- and short-axis planes; if evidence of mitral regurgitation, also examine mitral valve from left caudal imaging windows in two or more imaging planes.
- Observe motion during cardiac cycle by 2D and M-mode echocardiogram.
- Examine the support apparatus (chordae tendineae, papillary muscles).
- Increased valve echogenicity: Rule out degenerative thickening, valvulitis, vegetation (infective endocarditis), malformation (rare).
- Cleft or common septal leaflet: Rule out endocardial cushion defect/primum atrial septal defect (rare defects).
- M-mode: Reduced diastolic (E-F) slope suggests decreased transvalvular flow.
- Lack of diastolic separation or increased mitral E point to septal distance: Rule out aortic regurgitation (regurgitant jet impinging on the valve), left ventricular dilation with left ventricular failure (reduced transmitral flow), or mitral stenosis/tethering (rare defects or acquired from endocarditis).
- Prolapse of mitral leaflet into left atrium: Rule out degenerative disease, elongated or ruptured chordae tendineae, lesion of papillary muscle.
- Flail leaflet: Rule out ruptured chordae tendineae or avulsion of papillary muscle.
- Double line of mitral closure (mobile): Rule out ruptured chordae tendineae (flail leaflet).
- Diastolic mitral valve fluttering: Rule out aortic regurgitation.
- Systolic mitral fluttering: Rule out mitral regurgitation (musical).
- Chaotic valve motion: Rule out arrhythmia (atrial flutter, premature ventricular complexes), ruptured chordae tendineae.
- Premature (diastolic) closure: Rule out severe semilunar valve insufficiency, long P-R interval, or atrioventricular block.
- Delayed (systolic) closure (B-shoulder): Rule out left ventricular failure and elevated atrial pressure.
- Systolic anterior motion of the mitral valve (systolic anterior motion, systolic mitral–septal contact): Rule out dynamic left ventricular outflow tract obstruction due to valve malformation, subaortic stenosis, volume depletion, pulmonic stenosis, or hypertrophic or infiltrative cardiomyopathy (all very rare).
- Doppler studies can be used to interrogate the mitral valve for regurgitation or abnormal flow; multiple planes should be obtained including short-axis images at the level of the left atrium immediately dorsal to the mitral valve.
- Mitral regurgitation is common. Eccentric jets are often observed. Do not confuse 'backflow' color noise with true

Continued

BOX **9.11** **Interpretation of Echocardiographic and Doppler Studies—cont'd**

regurgitation. Horses can develop mid-to-late systolic mitral regurgitation (as with mitral prolapse). Multiple jets of mitral regurgitation are common.
- Always time flow events of mitral regurgitation (color M-mode and spectral Doppler); do not misdiagnose diastolic mitral regurgitation. Do not overemphasize receiving chamber color coding in mitral regurgitation because red blood cell entrainment and a 'spray effect' can result in overestimation of mitral regurgitation severity, whereas wall-hugging jets underestimate severity of mitral regurgitation. Attempt to measure jet width at origin and correlate to left atrial and left ventricular chamber size.

LEFT VENTRICLE
- Evaluate from long- and short-axis tomograms; inspect contour and walls; dorsal septum is normally slightly thicker than left ventricle free wall.
- Echogenic smoke/contrast: Some spontaneous contrast may be normal; rule out low output states, bradycardia, systemic inflammation (?).
- Evaluate left ventricle dimensions (internal dimensions, thickness of interventricular septum and free wall) and left ventricle systolic function (fractional shortening, ejection fraction) using M-mode or 2D imaging.
- Left ventricular dilation: Rule out causes of volume overload or left ventricular failure, including mitral or aortic valvular regurgitation, dilated cardiomyopathy, myocarditis, left-to-right shunt, persistent tachyarrhythmia.
- Left ventricular wall thinning: Rule out infarct, prior myocarditis, congenital aneurysm (rare).
- Left ventricular wall thickening: Consider "athletic heart"; rule out pseudohypertrophy from volume depletion, acute myocarditis (necrosis/edema; viral, bacterial, toxic, idiopathic), infiltrative cardiomyopathy (amyloid, lymphoma, other neoplasia), chronic systemic hypertension (chronic kidney disease, metabolic syndrome, laminitis, chronic pain), chronic digitalis (foxglove, oleander, yew) poisoning, or left ventricular outflow obstruction (very rare).
- Hyperkinesis of left ventricle: Rule out mitral or aortic insufficiency, bradycardia, sympathetic stimulation.
- Hypokinesis or dyskinesis of the left ventricle: Rule out cardiomyopathy or other myocardial disease, ischemia, infarct, arrhythmia, regional wall infiltration, or myocarditis.
- Hyperechoic myocardium or subendocardium: Rule out recurrent ischemia, fibrosis, infiltration, infarction, myocarditis, amyloidosis.
- Tissue Doppler and 2D speckle tracking (2D strain) may be used to evaluate regional and global left ventricular function; tissue Doppler (E_m/A_m ratio) is useful for assessment of left ventricular diastolic function; transmitral flow can also be obtained but is limited with respect to evaluation of left ventricular diastolic function.

LEFT VENTRICULAR OUTLET, AORTIC VALVE, AND AORTA
- Identify aortic valve leaflets and motion during cardiac cycle: Identify abnormal leaflet morphology (e.g., thickenings, fenestrations) or motion. Examine in both long-axis and short-axis image planes to see all leaflets.
- Thickened leaflets (diffuse or nodular): Rule out degeneration, endocarditis.
- Prolapse of aortic valve into the left ventricle: Rule out degenerative semilunar valve disease (common), ventricular septal defect, or bacterial endocarditis with torn leaflet.
- Diastolic fluttering of the aortic valve: Rule out aortic insufficiency.
- Systolic fluttering or the aortic valve: Normal or high flow state.
- Lack of systolic separation: Rule out valvular cardiac output, arrhythmia, stenosis (rare).
- Decreased aortic diameter: Low cardiac output, hypotension.
- Aortic dilation: Rule out aortic regurgitation tetralogy of Fallot, pulmonary artery atresia, truncus arteriosus, patent ductus arteriosus (rare).
- Aortic sinus of Valsalva aneurysm (focal dilation or ballooning of affected sinus): Evaluate for rupture into ventricular septum or right atrium.
- Doppler studies may be used to identify blood flow patterns in the left ventricle outflow tract, aortic regurgitation, paramembranous ventricular septal defect, and rare cases of aortic stenosis. Doppler studies also can identify abnormal blood flow paths in rare cases of aortic sinus ruptured into the heart.

VENTRICULAR SEPTUM
- Septal hyperkinesis: As per the left ventricle.
- Septal hypokinesis: As per left ventricle; also rule out right ventricular pressure or volume overload.
- Paradoxic ventricular septal motion: Rule out moderate to severe right ventricular volume overload such as atrial septal defect, severe tricuspid regurgitation, severe pulmonary hypertension with tricuspid regurgitation.
- Flat ventricular septum: Rule out right ventricular volume overload (diastolic flattening) or right ventricular pressure overload (systolic flattening).
- Exaggerated and disparate ventricular filling rates with diastolic septal fluttering: Rule out constrictive pericardial disease.
- Examine for ventricular septal defects in both long-axis and short-axis image planes (perform Doppler studies if necessary).
- Echocardiogram dropout or discontinuity of the ventricular septum: Rule out ventricular septal defect (peri/paramembranous adjacent to right/noncoronary cusps of the aortic valve and septal leaflet of tricuspid valve; inlet septal ventricular septal defect (ventral to tricuspid valve); muscular or trabecular ventricular septal defect; subpulmonic ventricular septal defect (also termed outlet, supracristal, subarterial, or doubly committed ventricular septal defect; directly underneath pulmonic and aortic valves); tetralogy of Fallot; pulmonary artery atresia; truncus arteriosus; or a false defect caused by angle of the ascending aorta or aortic dilation.
- Malalignment of the ventricular septum and anterior aortic root: Examine for tetralogy of Fallot, malalignment-type ventricular septal defect.
- Examine for dissection or "track" that may suggest rupture of the aorta into the ventricular septum with subsequent fistula.

BOX 9.11 Interpretation of Echocardiographic and Doppler Studies—cont'd

- High-frequency fluttering of the ventricular septum: Rule out aortic regurgitation.
- Doppler studies, especially color Doppler, are useful for recognizing ventricular septal defects; continuous-wave Doppler should be used to measure velocity across shunts to evaluate for "restrictive" versus unrestrictive septal defects. High-velocity flow across a ventricular septal defect (>4.5 m/sec) generally suggests a restrictive defect more likely to be well tolerated.

RIGHT ATRIUM AND ATRIAL SEPTUM

- Examine for attenuation: If small, rule out volume depletion, external compression, or mass lesion impairing venous return.
- Examine for enlargement: If enlarged, rule out tricuspid regurgitation, tricuspid stenosis or atresia (rare), right-sided heart failure, atrial septal defect, moderate to severe anemia, or chronic arrhythmia.
- Examine the atrial septum for abnormal bowing into the left or right atrium (high atrial pressure).
- Examine the atrial septum for septal defects or patent foramen ovale (double mobile lines in foals).
- Doppler studies can be used to identify atrial septal defect, but streaming of normal flow patterns (i.e., caudal vena cava flow) is confusing.
- "Bubble studies" (by injecting agitated normal saline into the jugular vein) should be used to identify right-to-left shunting of blood. *Caution:* Similar to Doppler studies, streaming of normal blood from the caudal vena cava may produce negative contrast in the right atrium, falsely suggesting left-to-right shunting of blood.

TRICUSPID VALVE

- Identify valve leaflets and cusps in long- and short-axis image planes.
- Observe motion during cardiac cycle.
- Identify support apparatus (chordae tendineae, papillary muscles).
- Increased valve echogenicity: Rule out degenerative thickening, vegetation, malformation, thrombus on valve.
- Common septal leaflet: Rule out endocardial cushion defect/primum atrial septal defect (rare).
- Flail leaflet: Rule out ruptured chordae tendineae or avulsion of papillary muscle; rule out infective endocarditis.
- Chaotic valve motion: Rule out arrhythmia, ruptured chordae tendineae.
- Premature (diastolic) closure: Rule out severe pulmonic insufficiency, long P-R interval, or atrioventricular block.
- Doppler studies can interrogate the tricuspid valve for abnormal flow or regurgitation; most horses have some small jets of tricuspid regurgitation by color Doppler evaluation; use color M-mode and spectral Doppler to evaluate timing and peak velocity. High-velocity tricuspid regurgitation (>3.2 m/sec): Also rule out pulmonary hypertension, large ventricular septal defect, right ventricular outflow obstruction.

RIGHT VENTRICLE

- Dilation: Rule out severe tricuspid insufficiency, chronic right ventricular pressure overload, biventricular congestive heart failure, atrial septal defect, large ventricular septal defect, severe pulmonary insufficiency, persistent tachyarrhythmia.
- Hypertrophy: Rule out large (unrestrictive) ventricular septal defect, pulmonary hypertension, pulmonic stenosis (rare), tetralogy of Fallot (rare), or complex congenital heart disease.
- Midventricular bands: Rule out double-chambered right ventricle (examine for ventricular septal defect); remember that the right ventricular moderator band can be very prominent in horses.
- Hyperechoic tissue: Rule out myocardial fibrosis.

RIGHT VENTRICULAR OUTLET, PULMONARY VALVE, AND PULMONARY ARTERY

- Identify valve leaflets and motion during cardiac cycle; if pulmonary valve lesion is suspected, also interrogate from a left cranial transducer position.
- Thick, fused, or hypoplastic leaflets: Rule out congenital stenosis or dysplasia (rare).
- Diastolic fluttering of pulmonic valve: Rule out valvar insufficiency.
- Systolic fluttering of pulmonic valve: Normal or high flow state.
- Lack of systolic separation of the pulmonic valve: Rule out low cardiac output, arrhythmia, stenosis.
- Pulmonary artery, absence or attenuation: Rule out pulmonary atresia or pulmonary artery hypoplasia.
- Pulmonary artery, dilation of: Rule out pulmonary hypertension, left-to-right shunt, poststenotic dilation of pulmonic stenosis (rare); rupture of the aorta into the right side of the heart or pulmonary artery (rare).
- Doppler studies can be used to identify abnormal flow in the pulmonary artery, including the rare pulmonic stenosis (high velocity), increased velocity flow from a left-to-right shunt, and patent ductus arteriosus in equine neonates. Pulmonary regurgitation is normal; high-velocity pulmonary regurgitation indicates pulmonary hypertension.

methods. A pivotal limitation of color Doppler regards temporal resolution. Depending on the system used, the frame rates of interrogation can be very slow (often less than 10/sec). Thus it is mandatory to time flow events using either spectral Doppler or by invoking the M-mode cursor and recording the event by color-M-mode echocardiography. In many cases, the color M-mode examination is simpler and provides excellent temporal resolution, reducing interpretation errors. This timing of blood flow prevents the clinician from misinterpreting normal "backflow" signals related to valve closure or diagnosing a diastolic flow event as systolic.

PW spectral and color Doppler techniques can provide accurate information about the location of flow disturbances but cannot measure high-velocity flow faithfully. High-velocity flow is encountered as RBCs are ejected from high to lower pressure zones across incompetent valves, stenotic valves, and intracardiac and extracardiac shunts (provided that there is a pressure difference across the defect). In general, once

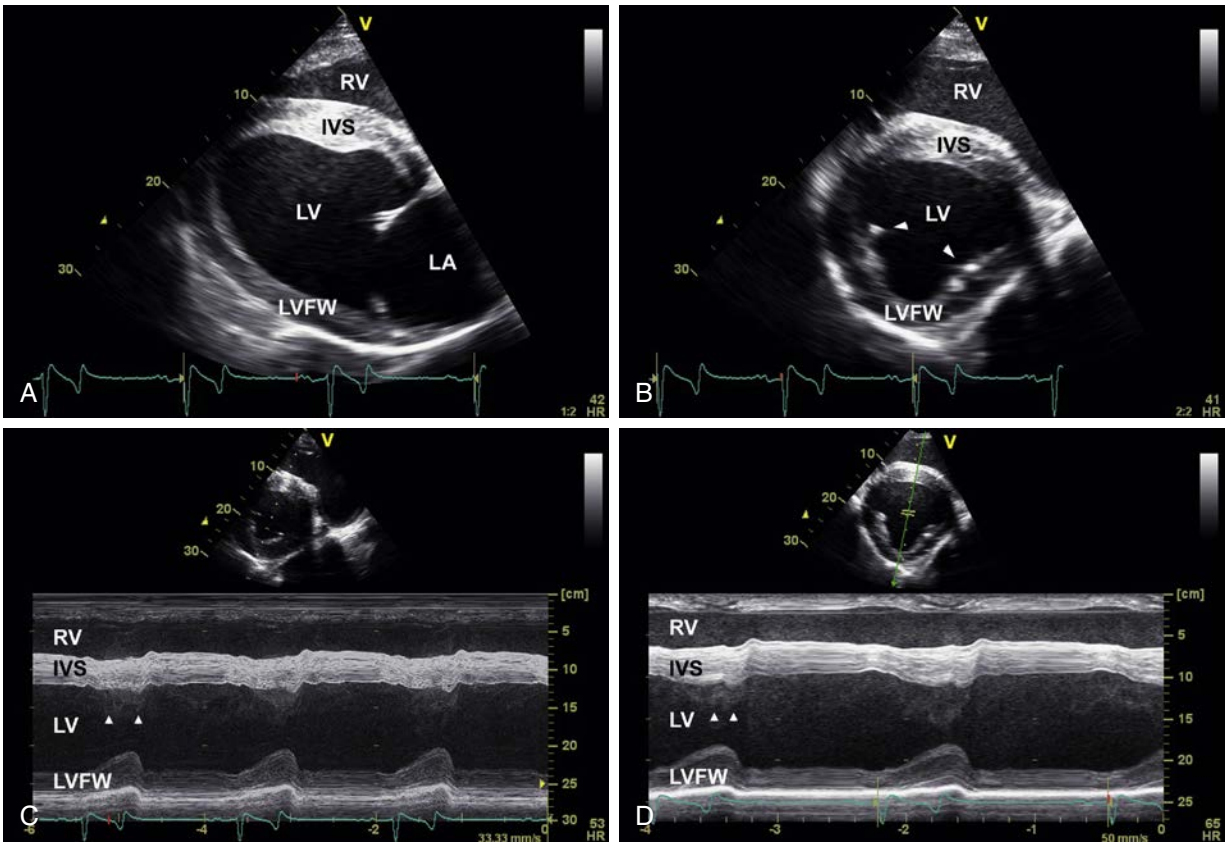

FIG. **9.20** Standard echocardiographic views for assessment of left ventricular size and function. A, Right-parasternal long-axis 4-chamber view centered on the left ventricle (LV). The transducer is positioned in the right 4th intercostal space at a level slightly above the olecranon, angled caudally and rotated clockwise to the 1 o'clock position. Slight changes in transducer placement may be necessary to optimize the image plane. This view is best suited to assess the structures, dimensions, and mechanical function of the LV. Because this image is centered on the LV, the left atrium (LA) may not be imaged in its entirety throughout the cardiac cycle. Assessment of the right side of the heart is limited due to its anatomic position, its complex geometry, and its visualization in the narrow near field of the imaging sector. B, Right-parasternal short-axis view of the LV at the level of the chordae tendineae *(arrowheads).* This view is obtained by rotating the transducer 90 degrees clockwise from a 4-chamber view. It is commonly used for measurement of the diameter and the area, respectively, of the LV and evaluation of LV systolic function. C, Right-parasternal short-axis view *(top)* and corresponding M-mode recording *(bottom)* of the LV at the chordal level. The motion of the interventricular septum (IVS) and the left-ventricular free wall (LVFW) is displayed over time. The right ventricle (RV) and the right-ventricular free wall are displayed in the near field. A small amount of spontaneous echo contrast is frequently seen in the ventricular lumen *(arrowheads).* Measurement of LV wall thickness and internal dimensions, evaluation of septal motion, and calculation of LV fractional shortening allow assessment of LV size and systolic function. D, Anatomic M-mode (AMM) image of the LV *(bottom),* reconstructed from a digitally stored 2D cineloop recording obtained from a right-parasternal short-axis view at the chordal level *(top).* Notice that the AMM cursor *(green line)* can be freely positioned on the 2D image, independent of the sector apex, to bisect the IVS, the LV cavity, and the LVPW into two equal parts throughout the cardiac cycle. (From Schwarzwald CC: Ultrasonography of the heart. In: Kidd JA, Lu KG, Frazer ML, et al.: *Atlas of equine ultrasonography,* Wiley, Oxford, UK, 2014. Reproduced with permission of John Wiley & Sons, Ltd.)

velocities exceed about 2.5 m/sec in either direction, part of the returning signal is displayed in the incorrect direction. This problem is called signal "aliasing" (see Fig. 9.25).[56,344,590,591] To quantify high-velocity flow, a third modality must be invoked, either *high pulse-repetition-frequency (HPRF) Doppler* or *continuous-wave (CW) Doppler.* Continuous-wave Doppler has virtually unlimited ability to record very high velocity but does not provide the spatial discrimination found in PW Doppler modalities.

In recent years, more advanced echocardiographic methods such as *tissue Doppler* imaging* and *2D speckle tracking (2D strain) imaging*[161,168,346-348,575,603] (which is based on conventional 2DE cineloop recordings and independent of the Doppler principle) have been investigated in horses to complement the traditional 2D, M-mode, and Doppler echocardiographic methods and to overcome some of their limitations.

FIG. **9.21** Standard echocardiographic views for assessment of left atrial size and function. A and B, Right-parasternal 4-chamber view centered on the left atrium (LA), to image the LA in its entirety throughout the cardiac cycle. At an imaging depth of 30 cm, this view is best suited to assess the mitral valve (MV) apparatus, LA dimensions, and LA mechanical function. Only in rare cases (e.g., giant draft breeds, horses with severe cardiomegaly) the LA cannot be displayed in its entirety from this window. A, Image recorded at the end of ventricular systole, 1 frame before opening of the MV, when the LA is at its maximum dimensions. Chordae tendineae are seen in the left ventricular (LV) cavity *(arrowheads).* B, Image recorded at the end of diastole, immediately after closure of the MV, when the LA is at its minimum dimensions. Note the obvious change in LA dimensions within a single cardiac cycle (i.e., between A and B), indicating that timing of measurements of LA dimensions is critical. Generally, LA dimensions should be assessed at the end of ventricular systole (A). C, Right-parasternal short-axis view at the level of the aortic valve. This view is obtained by rotating the transducer 90 degrees clockwise from a right-parasternal left-ventricular outflow tract view (Fig. 9.22A). In this view, the aortic valve (AV) with its three cusps is visible in the center of the image. The surrounding structures include right atrium (RA), tricuspid valve, right ventricle (RV), right-ventricular outflow tract (RVOT), LA, and left atrial appendage (LAA). The apparent triangular separation (at the 12 o'clock position) evident between the noncoronary cusp (NCC) and the right coronary cusp (RCC) is a normal finding and does not represent an anomaly. In this view, the end-systolic size of the LA and LAA can be measured and compared with the aortic area. D, Left-parasternal long-axis view of the LA, MV, and LV. The transducer is positioned in the 5th intercostal space slightly above the olecranon, oriented perpendicular to the chest wall and angled dorsally. This view has traditionally been used for assessment of LA dimensions. However, as opposed to the right-parasternal views (A, B), this view often does not allow imaging of the LA in its entirety due to interference with the ventral lung border. Nonetheless, imaging LA and MV from a left thoracic window provides additional information and should complement the right-parasternal views. *LCC,* Left-coronary cusp of the aortic valve; *PV,* pulmonary vein; *TV,* tricuspid valve. (From Schwarzwald CC: Ultrasonography of the heart. In: Kidd JA, Lu KG, Frazer ML, et al.: *Atlas of equine ultrasonography,* Wiley, Oxford, UK, 2014. Reproduced with permission of John Wiley & Sons, Ltd.)

These modalities allow quantitative assessment of myocardial motion velocity, deformation (strain), deformation rate (strain rate), displacement, and rotation in longitudinal, radial, and circumferential imaging planes and may provide more sensitive methods for assessing regional or global myocardial function in horses. Tissue Doppler imaging is a promising tool for assessment of LV diastolic function,[164,366,575] and 2D speckle tracking may be helpful for detection and quantification of LV systolic dysfunction in horses with myocardial disease (see Fig. 9.49 later in this chapter)[161,164,575] and for

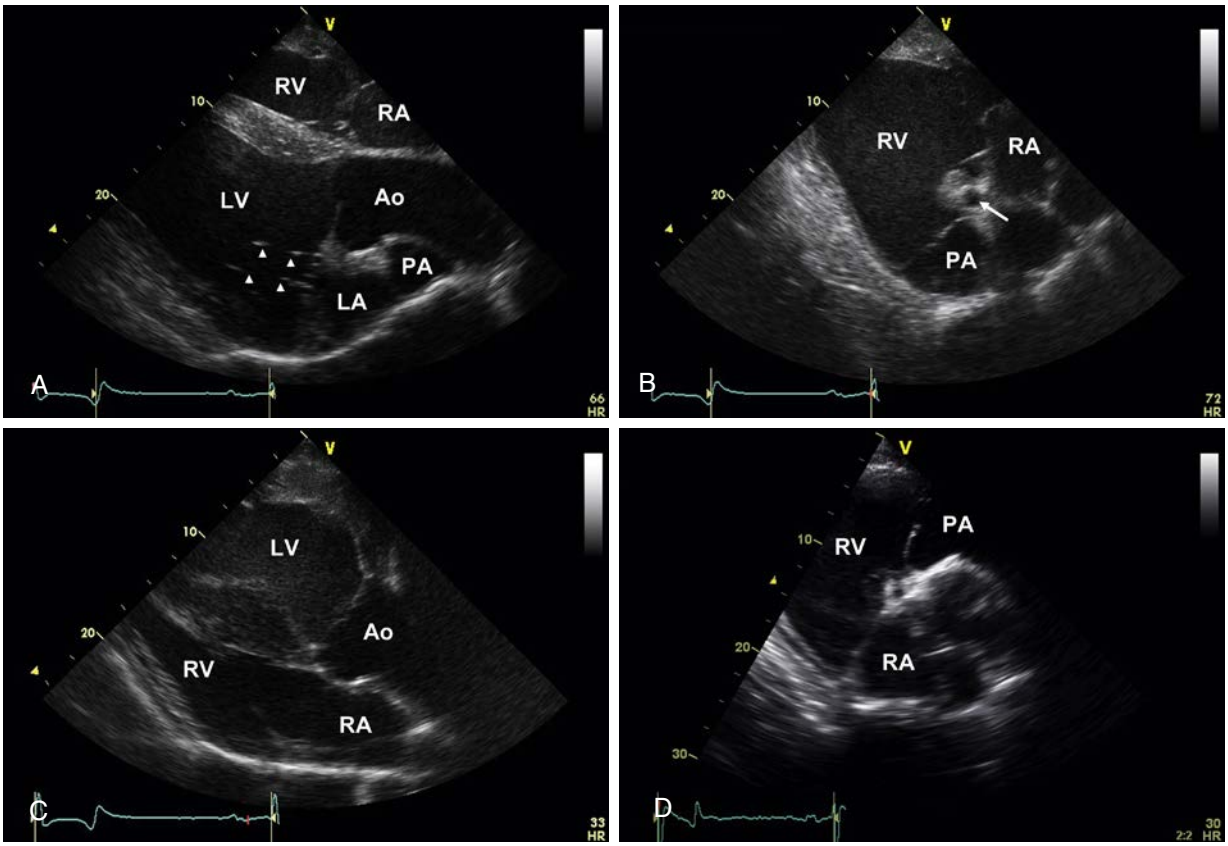

FIG. **9.22** Standard echocardiographic views for assessment of the great vessels. A, Right-parasternal long-axis view of the left ventricular outflow tract (LVOT). Starting from a 4-chamber view, the transducer is angled more cranially, tilted dorsally, and rotated to the 2 o'clock position to obtain this view. It is best suited to assess the structures, dimensions, and function of the aortic valve, the sinus of Valsalva, and the ascending aorta (Ao) and the pulmonary artery (PA). The size of the PA should be smaller than the diameter of the aorta. B, Right-parasternal long-axis view of the right ventricular outflow tract (RVOT). Starting from an LVOT view (A), the transducer is angled more cranially to obtain this view; occasionally the transducer will have to be moved one intercostal space more cranially. The right atrium (RA), the tricuspid valve, the right ventricle (RV), the RVOT, the pulmonic valve, the pulmonary artery (PA), and across section through the right coronary artery *(arrow)* can be visualized. C, Left-parasternal long-axis view of the LVOT. The transducer is positioned in the 5th or 4th intercostal space at a level slightly above the olecranon and angled slightly cranially. D, Left-parasternal long-axis view of the RVOT. Starting from the LVOT view (C), the transducer is moved one intercostal space more cranially to obtain this image. *LA,* Left atrium; *LV,* left ventricle. (From Schwarzwald CC: Ultrasonography of the heart. In: Kidd JA, Lu KG, Frazer ML, et al.: *Atlas of equine ultrasonography,* Wiley, Oxford, UK, 2014. Reproduced with permission of John Wiley & Sons, Ltd.)

quantification of stress echocardiograms.[168] However, clinical applications and the added value over traditional echocardiographic methods need further definition.

Assessment of Chamber Dimensions. One of the main goals of echocardiography is the detection of cardiac chamber dilation or hypertrophy and the grading of the enlargement (if present) as mild, moderate, or severe. Chamber dimensions provide important information on hemodynamics, chamber remodeling, and severity of cardiac disease. Assessment of left atrial (LA) and left ventricular (LV) dimensions should be based on an integrative approach combining subjective evaluation and assessment of multiple measurements based on 2D and M-mode echocardiography (see Figs. 9.20–9.23).*

Left-ventricular internal dimensions and LV wall thickness, respectively, are usually measured from a right-parasternal short-axis view or from a right-parasternal four-chamber view using 2DE or M-mode recordings (see Fig. 9.20).[344] Linear measurements of the LV minor dimension may not well describe true LV size and geometry, as asymmetric LV dilation and dimensional changes along the major axis of the ventricle are neglected. Similarly, linear measurement of wall thickness may not be accurate estimates of LV mass, particularly asymmetric thickening is present or if the M-mode cursor crosses a papillary muscle or fails to sample the thickest part of the wall. Furthermore, standardized placement of the M-mode cursor can be challenging and is difficult to verify in all three dimensions. This limitation may be partially overcome by use of anatomic M-mode technology, which allows free orientation of the cursor line within the imaging plane independent of the apex of the imaging sector (see Fig. 9.20D).[345] Measures that consider the short-axis area (instead of diameter) and the length of the LV (i.e., various

* References 168, 287, 289, 344, 345, 576, 591, 595.

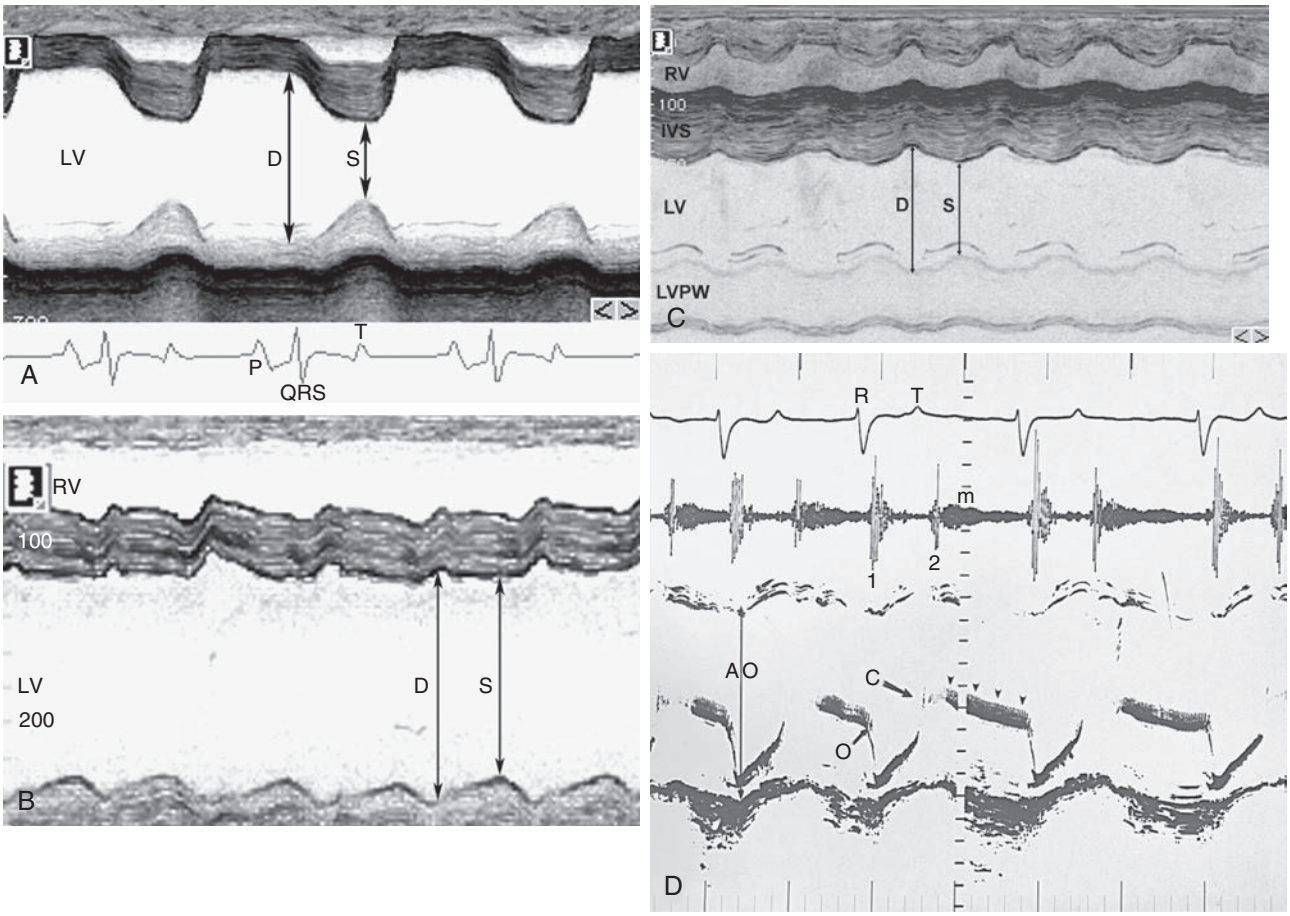

FIG. **9.23** M-mode echocardiography. A, M-mode tracing demonstrating a hyperdynamic left ventricle *(LV)* in a horse with acute mitral regurgitation (MR). The significant change in LV dimensions from diastole *(D)* to systole *(S)* is notable and is typical of volume overloading with preserved ventricular function. Furthermore, the reduced resistance to ejection of blood into the left atrium (LA) enhances ventricular shortening. Depth calibration in millimeters is shown on the left. B, Recording through the ventricles demonstrating decreased systolic function with a reduced LV shortening fraction. This pattern of contraction can be caused by myocarditis, myocardial injury (e.g., monensin), idiopathic dilated cardiomyopathy, chronic volume overload, protracted ventricular tachycardia (VT), or administration of negative inotropic drugs. Depth calibration in millimeters is shown on the left (*RV,* right ventricle). C, M-mode echocardiogram across the ventricles recorded from a horse with cardiac amyloidosis. Global LV systolic function is mildly reduced. The IVS and LVPW are thickened. The IVS also appears hyperechoic relative to the RV wall. The LVPW in the far field is less echogenic owing to attenuation of echoes in the far field. The right ventricle (RV) contained spontaneous echocontrast. Depth calibration in millimeters is shown on the left (*RV,* right ventricle; *IVS,* interventricular septum; *LV,* left ventricle; *LVPW,* left ventricular peripheral wall). D, Recording from a horse with aortic regurgitation (AR) and atrial fibrillation (AF), demonstrating fine diastolic fluttering of an aortic valve leaflet *(small arrows).* The aortic root *(AO),* valve opening *(O),* and valve closing *(C)* are indicated. The murmur *(m)* of AR is evident in the previous phonocardiogram. First *(1)* and second *(2)* heart sounds are labeled. Diastolic fluttering of the mitral valve (most common), aortic valve, ventricular septum, or walls of the aortic root may be observed in horses with this hemodynamic abnormality. The M-mode sampling rate (approximately 1000 pulses/sec) is ideal for detecting these high-frequency events.

area-length models and the Simpson's method of disks) may be more accurate estimates of internal LV dimensions and LV mass (see Fig. 9.20A and B).[168,297,306,344] The accuracy of these methods, on the other hand, is limited by the fact that true LV long axis may be difficult to measure by 2DE because of the LV shape and the translational motion of the LV during contraction and relaxation. Furthermore, all conventional volumetric indices are calculated based on several geometric assumptions and approximations and may therefore be prone to error. Nonetheless, in addition to conventional linear measurements one should consider using area measurements and volume estimates for quantification of chamber dimensions, particularly in cases where the subjective evaluation and conventional measurements provide equivocal results.

Assessment of LA size has traditionally been limited to subjective evaluation and measurement of the LA diameter from a left-parasternal long-axis view (see Fig. 9.21D). However, this view often does not allow imaging of the LA in its entirety due

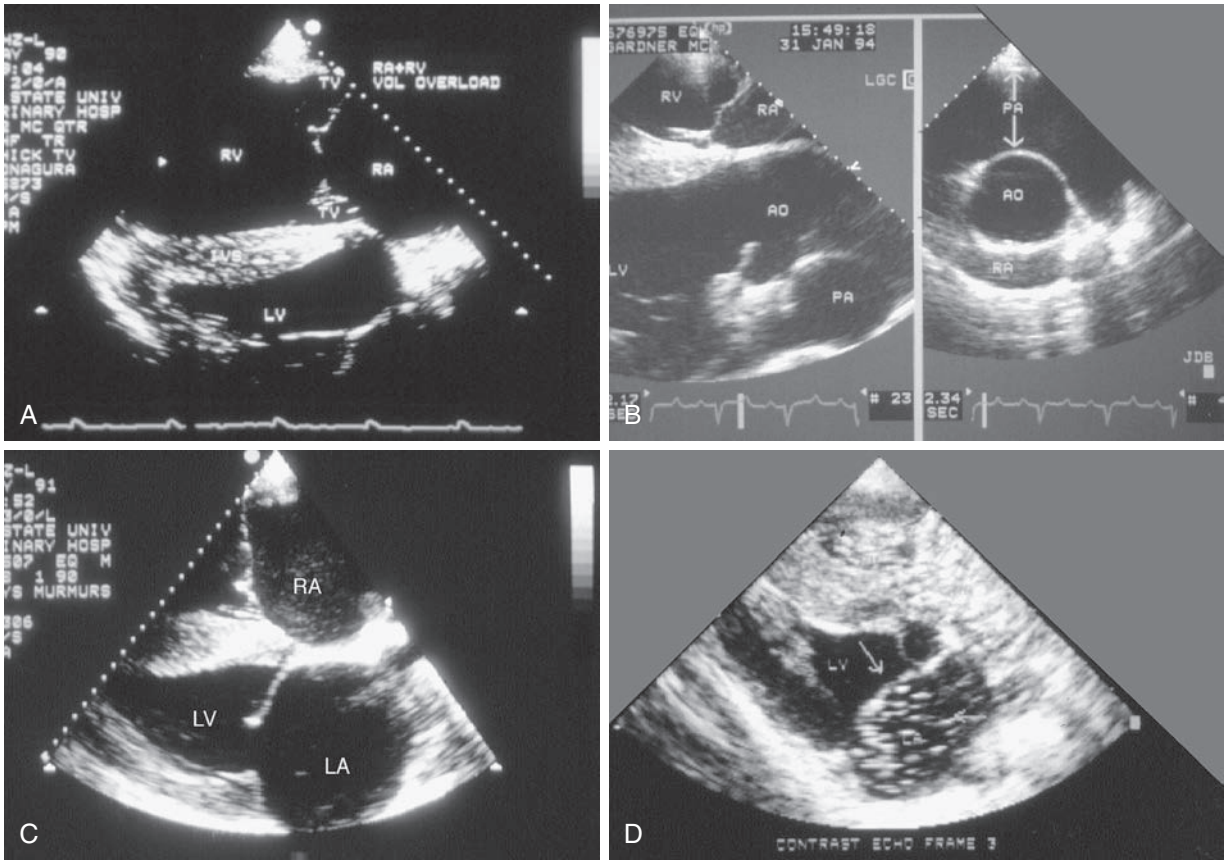

FIG. **9.24** Two-dimensional (2D) echocardiograms. A, Long-axis image from the right thorax in a 12-year-old Quarter Horse gelding demonstrating significant right ventricular (RV) and right atrial (RA) dilation after tricuspid regurgitation (TR) and elevated pulmonary artery pressure. In this case a tumor that obstructed flow in the main pulmonary artery caused the pulmonary hypertension. The ventricular septum is flat and bulges slightly into the left ventricle (LV). B, Images of the ascending aorta and pulmonary artery obtained from the right hemithorax *(left panel)* and left cranial hemithorax. An evaluation of the pulmonary artery diameter relative to the aorta is useful when identifying pulmonary hypertension. C, Biatrial dilation in a Thoroughbred colt with mitral regurgitation (MR), pulmonary hypertension, atrial fibrillation (AF), and congestive heart failure (CHF). Both atria are rounded and appear turgid. The cause of mitral disease in this case was idiopathic lymphocytic-plasmacytic mitral valvulitis (*RA,* right atrium; *LV,* left ventricle; *LA,* left atrium). D, Contrast echocardiogram demonstrating right-to-left shunting at the level of the foramen ovale in a foal with severe respiratory disease. The saline generates echocontrast, opacifies the right atrium (RA) and right ventricle (RV), and visibly fills the left atrium (LA) *(arrows),* although the LV has not yet been opacified. This technique is easy and practical for demonstrating right-to-left shunts across the cardiac septa.

to interference with the ventral lung border; this often results in measurements of the LA diameter that are not parallel to the mitral valve annulus or that are made too close to the annulus and thereby underestimate the true maximum atrial diameter. Also, the timing of LA measurements is often not specified in the equine literature, leading to uncertainties when comparing results from different studies. With contemporary echocardiographic systems, right-parasternal long-axis and short-axis views (Fig. 9.21A–C) are preferred because they allow visualization of the LA in its entirety and provide sufficient anatomic landmarks for consistent and reliable measurement of LA dimensions.[287,289,576] In addition to LA diameter, assessment of LA area should be considered because enlargement may not occur in a uniform fashion and LA geometry may change over time. The LA size is best measured at the end of the ventricular systole, one frame before mitral valve opening, when the LA chamber is at its greatest dimension.

Objective quantification of the right atrial (RA) and right ventricular (RV) dimensions is difficult, because the geometric shape of the right heart is complex and the internal dimensions of the RA and the RV cavity largely depend on transducer placement and imaging plane. Subjective assessment of the right heart chambers in multiple image planes is therefore important.

Assessment of Systolic Left Ventricular Function. The echocardiographic detection of myocardial failure and deterioration of systolic function has great prognostic implications. Most of the indices used in clinical practice serve to evaluate global systolic LV function. It is important to realize that the echocardiographic indices of systolic ventricular function generally do not reflect contractility per se but are (to a variable extent) influenced by preload, afterload, HR, and heart rhythm (see Fig. 9.4).[344 595] Generally, it is advised to use a variety of echocardiographic variables to assess LV systolic function and to interpret them in the context of the clinical findings.

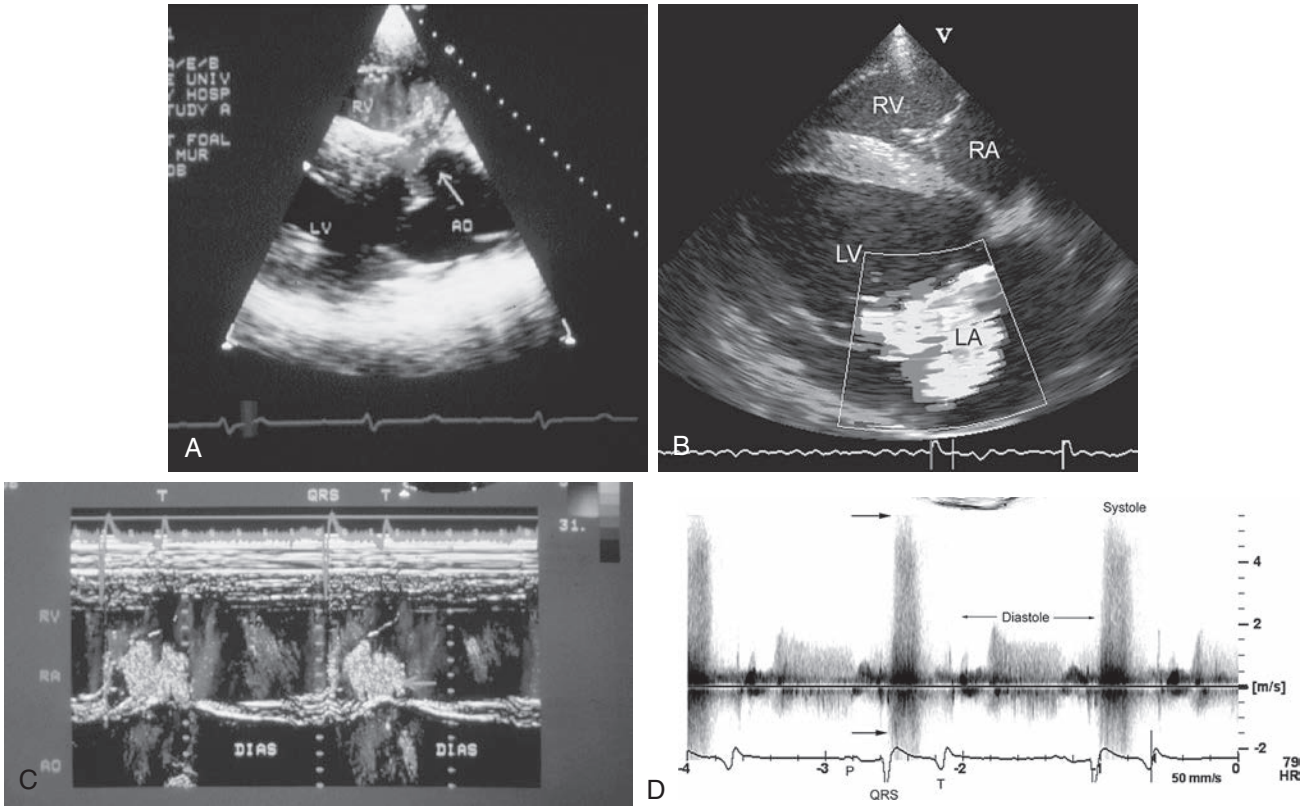

FIG. **9.25** A–C, Black-and-white representations of color Doppler echocardiograms demonstrating mapping of blood through the heart. A, Perimembranous ventricular septal defect (VSD) in a foal *(arrow).* The flow pattern was coded red and aliased as the velocity increased across the defect. B, Wide spray of mitral regurgitation (MR) with flow moving from left ventricle *(LV)* into the left atrium *(LA)* in a horse with mitral valve prolapse (*RV,* right ventricle; *RA,* right atrium). C, Color M-mode study from a horse with tricuspid regurgitation (TR). The bright systolic flow pattern, following the QRS of the electrocardiogram (ECG), was mapped as turbulence in the color study. This is an excellent method for timing abnormal flow events. D, Example of continuous-wave *(CW)* spectral Doppler echocardiogram obtained from a horse with a VSD and mild aortic regurgitation (AR). Time and the ECG waveforms are shown along the x-axis and velocity of flow along the y-axis with a meters per second scale (m/sec). Direction of flow relative to the transducer is also shown; flow toward the transducer is displayed as a positive signal (relative to the zero velocity baseline) and away from the transducer as a negative signal. A low-velocity flow pattern is evident in diastole related to diastolic shunting across the VSD, aortic regurgitant flow moving across the cursor line 'off angle' (with parallel alignment, the AR velocity would be higher [i.e., >3.75 m/sec]), or contaminated transtricuspid flow. In systole a high positive velocity signal is recorded (>5 m/sec) compatible with a small (restrictive) left-to-right shunting VSD. However, the maximum velocity is not evident because the signal reaches the upper limit of the velocity scale *(arrow).* The negative signal *(lower arrow)* is either an aliased signal (if antialiasing filters are off) or VSD turbulence in the other direction. Moving the baseline down or increasing the velocity scale would have allowed for faithful recording of the peak velocity.

The 2D ejection phase indices are based on measurements of LV dimensions. Left ventricular ejection fraction (LV EF = SV/LVEDV × 100, where SV is stroke volume and LVEDV is LV end-diastolic volume) is based on geometric estimates of LV volumes and has traditionally been the standard index of LV systolic function. The LV fractional shortening (LV FS = [LVIDd − LVIDs]/LVIDd × 100; where LVIDd and LVIDs are the LV internal short-axis diameters at end-diastole and at peak systole, respectively), is an approximation of the LV EF and is the most commonly used index of LV systolic function in horses. In fact, often it is the only one used in routine echocardiography, because it can be easily calculated from M-mode recordings (see Fig. 9.23).[306,344,595] However, reliance on this index as a single measurement of LV function may be problematic.[168] The LV FS actually represents the relative shortening of the LV short axis in only one single dimension, disregarding the fact that the LV contracts in all three dimensions. Also, it may lack accuracy when the IVS and the LVFW do not contract synchronously or when the cursor line is not placed optimally. In horses with mitral regurgitation and normal myocardial function, the LV FS can actually be increased due to the increased preload and decreased afterload. Conversely, a normal LV FS in the presence of severe MR may indicate (but does not necessarily prove) myocardial failure.

Area-based measurements such as the LV fractional area change (LV FAC) may be less sensitive to asynchronous wall

motion and allow assessment of shortening in two dimensions. Volume-based measurements (LV EF, stroke volume, cardiac output) can be calculated based on estimates of LV volume as described earlier.[168] They are generally considered more accurate and less affected by altered chamber geometry. However, there are differences and limitations related to the geometric model used.[297,306,344,595] As stated, area- and volume-based measurements of LV systolic function should be considered in cases where the subjective evaluation and conventional measurements give equivocal results.

Doppler-based estimates of stroke volume (SV) and cardiac output (CO) are also indices of global ventricular function. The SV is calculated by multiplying the velocity-time integral (VTI) of the aortic or pulmonic flow signal by the cross-sectional area of the respective vessel.[297,306,307,311,313,344] There are many limitations of this echocardiographic estimate of SV, including the angle-dependency of Doppler-based flow measurements, inaccuracies in the determination of the flow area, and uncertainties as where exactly to measure flow and cross-sectional area (or diameter) of the vessel.[311] In adult horses, adequate alignment of the Doppler beam with blood flow by transthoracic echocardiography is difficult, and Doppler estimates of SV are considered neither very accurate nor reliable. Transesophageal echocardiography (TEE) allows parallel alignment between Doppler beam and aortic blood flow in adult horses, and CO measurements by TEE in adult, anesthetized horses have been shown to be in better agreement with thermodilution CO than CO measurements by transthoracic echocardiography.[309,311,312] In foals, alignment of the ultrasound beam with blood flow can be achieved using apical imaging planes. Although this may improve the accuracy of CO measurements by Doppler echocardiography, volumetric 2DE measurements using the bullet method have been shown to provide better agreement with CO by lithium dilution than Doppler estimates of CO.[306] Generally, measurements of CO by echocardiography may be more accurate for detecting acute changes in CO over time than for obtaining absolute measurements of CO. Assessment of SV and CO by Doppler is not routinely performed in horses with cardiac disease. In fact, myocardial dysfunction generally must be severe for blood flow indices to be affected, because cardiac output is maintained in the failing heart until the compensatory mechanisms are overwhelmed. Therefore estimates of SV and CO may be of limited relevance in most horses with heart disease.

Systolic time intervals (STIs), including LV preejection period (PEP), LV ejection time (LVET), and LV preejection period-to-ejection time ratio (PEP/LVET), can be measured from M-mode images of aortic valve motion and from Doppler tracings of aortic blood flow, respectively.[344,605] The STIs may serve as alternative indicators of LV function that are independent of ventricular shape and geometry and that may be superior to the calculation of the LV FS. However, they are also variably influenced by HR and loading conditions.[344] Accurate time intervals may be difficult to obtain due to inability to clearly identify the onset and the end of ejection on M-mode or Doppler tracings. This limitation may be overcome by use of tissue Doppler imaging for measurement of STIs.[164,286] The clinical value of STIs has not been well established in horses with cardiovascular disease.

Assessment of Diastolic Function. Diastolic ventricular function is more complex than systolic function. Ventricular filling results from the dynamic interplay of active ventricular relaxation, ventricular compliance, filling pressures, pericardial restraint, ventricular interaction, and atrial function (see earlier discussion). Afterload and contractility will further influence diastolic function. Therefore the echocardiographic assessment of diastolic ventricular function and filling pressures (which are commonly assessed together) is difficult. In horses, diastolic ventricular dysfunction may certainly play a role in pericardial and myocardial disease,[161,164,366] but the clinical relevance of diastolic dysfunction in other types of cardiac diseases is not clear, and the prevalence of diastolic heart failure is unknown.

Doppler-derived transmitral flow velocities (E wave, A wave, E/A ratio, E-wave deceleration time and deceleration slope) are commonly used in humans and small animals for assessment of diastolic LV function and filling pressures. However, the usefulness of transmitral flow velocities is limited, because impaired relaxation coexisting with increased filling pressures may lead to "pseudonormalization" of filling patterns.[594] Furthermore, PW Doppler recordings of transmitral flow velocities strongly depend on alignment with blood flow and are sensitive to placement of the sample volume relative to the position of the mitral valve. Transmitral flow velocity profiles can be recorded in horses, but optimal alignment with blood flow from an apical window is not possible in adults. Transmitral flow velocity measurements in horses are relatively unreliable and may not be suitable to detect minor changes in diastolic LV function.[281,287,289] Nonetheless, if marked decrease or reversion of the E/A ratio is present, diastolic dysfunction must be suspected.[164] Tissue Doppler imaging may provide additional velocity-based and time interval–based indices that are easier to obtain and that can be helpful for assessment of LV diastolic function in horses.[161,164,286,366]

Assessment of Left Atrial Function. LA function is rarely considered during routine echocardiography, and the clinical relevance of LA dysfunction is not well known in horses. However, LA function is impaired in horses with atrial fibrillation (AF), and persistent LA contractile dysfunction can be detected in horses after conversion from AF to sinus rhythm, likely attributed to AF-induced atrial remodeling.[289-291] LA size and LA mechanical function can easily be assessed in horses by use of 2DE variables, including LA area and LA fractional area changes (see Fig. 9.21).[287,289-291]Additional studies will be required to determine the clinical relevance of LA mechanical dysfunction in the presence of cardiac disease in horses.[576]

Assessment of Valvular Regurgitation. The Doppler technology of current echocardiographic systems is very sensitive to detect valvular regurgitation, and care must be taken not to overinterpret the echo findings, particularly in otherwise healthy animals without abnormal clinical findings and in the absence of heart murmurs. Assessment of valvular regurgitation should be achieved using an integrated qualitative and quantitative approach, combining clinical examination (including auscultation of a typical murmur) and echocardiographic findings. Measurement of cardiac chamber dimensions provides information on the hemodynamic relevance of chronic valvular regurgitation. Abnormal timing and direction of transvalvular flow as well as flow turbulences can be detected by 2D color Doppler, color M-mode, and spectral Doppler echocardiography. The regurgitant signal in the "receiving chamber" can be interrogated in multiple imaging planes to identify origin, extent, timing, and duration of the regurgitation.[74] However, it is important to realize that

color Doppler echocardiography only describes blood flow direction and velocity but not absolute volumetric flow. The Doppler-derived regurgitant signal is largely influenced by gain settings, direction of flow, orifice size and shape, driving pressure, and characteristics of the receiving chamber. Quantification of regurgitation by assessing signal strength of the spectral Doppler regurgitant signal or measuring the area of regurgitation within the receiving chamber is therefore neither very accurate nor reliable.

Hemodynamic Assessment. The hemodynamic load placed on the heart by cardiac disorders can be estimated by combining echocardiographic information on chamber size, wall thickness, myocardial motion, LV systolic and diastolic function, and intracardiac blood flow. Doppler studies can be used to assess intracardiac pressures and pressure gradients. Normal pressure gradients driving blood flow through heart, valves, and large vessels range from 0.25 to 1.5 m/sec. Abnormally high velocities can be found in many cardiac conditions, including ventricular septal defects and valvular regurgitations, in which pressure gradients drive blood across a restrictive orifice. The pressure gradients are either reflections of normal intracardiac pressures or consequences of pathologically increased pressures. Pressure gradients can be estimated using Doppler echocardiography by employing the simplified Bernoulli equation ($dp = 4 \times v_{max}^2$, where dp is the pressure gradient in mm Hg and v_{max} is the peak velocity in m/sec). The main indications to measure pressure gradients in horses are the assessment of ventricular septal defects (by interrogation of shunt flow) and the diagnosis of pulmonary hypertension (by interrogation of regurgitant flow at the tricuspid valve and the pulmonic valve).

If, for example, a peak velocity of 4.8 m/sec is recorded across a ventricular septal defect, and if the systolic systemic arterial BP is determined noninvasively to be 125 mm Hg, the estimated RV systolic pressure would be calculated as follows:

- Pressure drop across defect = $4 \times 4.8^2 = 92$ mm Hg
- Estimated LV systolic pressure = 125 mm Hg
- Estimated RV systolic pressure = 125 − 92 = 33 mm Hg

These findings indicate a restrictive septal defect, a lesion unlikely to cause difficulties for the horse except at highest levels of performance.

A similar quantitative approach is used to estimate the presence or absence of pulmonary hypertension when tricuspid regurgitation is identified in the absence of right ventricular outflow tract obstruction (i.e., PA ejection velocity of less than 1.5 m/sec). Assuming the jet can be interrogated at nearly parallel to flow, peak regurgitant velocities exceeding 3.2 to 3.4 m/sec are suggestive of elevated PA systolic pressure. For this calculation, peak right atrial pressure must be estimated (around 10 mm Hg in horses without CHF). For example, a peak regurgitant velocity of 3.8 m/sec would results in calculated pressure drop from RV to RA of $4 \times 3.8^2 = 58$ mm Hg. When the RA pressure estimate (10 mm Hg) is added, estimated PA systolic pressure is 68 mm Hg. In cases of right-sided CHF, the RA pressure can be assumed to be at least 20 mm Hg or more accurately measured by a catheter.

Intravascular Pressures and Cardiac Catheterization

There is a large body of literature derived from catheterization studies of the healthy standing, exercising, and anesthetized horse and pony along with limited catheterization data derived from horses with heart disease.* Normal published data relate in part to population and study methods; accordingly, reference intervals vary considerably.[57] Normal values also depend on the head and body positions of the horse, the influence of administered tranquilizers, sedatives, or anesthetic agents, and the size of the animal. Hemodynamic variables that can be measured or calculated by catheterization techniques include systolic, diastolic, and mean BP in the systemic and pulmonary circulations, PA occlusion (or pulmonary capillary wedge) pressure, central venous pressure (in the venae cavae, near the right atrium), intracardiac (atrial and ventricular) pressures, CO, systemic and pulmonary vascular resistances, and arteriovenous oxygen difference.[633]

Cardiac catheterization in the clinical setting has largely been replaced by Doppler echocardiography. However, indications for cardiac catheterization persist, especially for research purposes or in clinical practice, when accurate measurement of PA pressure is needed, the origin of pulmonary hypertension cannot be determined, or the diagnosis of occult constrictive pericardial disease is entertained. Knowledge of the general principles of hemodynamics and catheterization data in health and disease creates a useful framework for understanding clinical assessment of the CV system.

Pressures on the left side of the circulation include systemic arterial, left ventricular, and left atrial pressures. Measurement of systemic arterial BP has been described earlier in this chapter. Left ventricular pressures can be measured by percutaneous retrograde catheterization of the LV via the carotid artery, aorta, and aortic valve.[47,259,449,634,635] Carotid catheterization can be facilitated using ultrasound guidance. For research purposes, subcutaneous translocation of the carotid artery has been described to allow for repeated catheter procedures.[636] Left ventricular pressures are typically measured using microtip pressure-sensing catheters to avoid artifacts that commonly arise when using fluid-filled catheter systems.[47,259,449,635] Left atrial pressure is rarely measured directly but can be estimated during right-sided heart catheterization by a pulmonary capillary wedge pressure as described later.

Systemic arterial pressure is related in a directly positive manner to left ventricular systolic function, impedance to blood flow in the aorta, systemic vascular resistance, and HR. Systolic pressures in the aorta and left ventricle in the standing horse generally peak at approximately 110 to 130 mm Hg (with individual variation).[57,259] Diastolic aortic pressure is usually near 75 mm Hg. An increase in HR as small as 10 beats per minute can increase systemic BP by 20 mm Hg or more over these values. A peak systolic pressure gradient between the LV and central aorta indicates an obstruction to left ventricular outflow, a very rare condition in horses. Left ventricular diastolic pressure reflects diastolic ventricular function and filling pressures as well as ventricular emptying during systole. The diastolic pressure most often reported is the LV end-diastolic pressure (LVEDP), which is higher than the early (often subatmospheric) minimal diastolic LV pressure. The LVEDP typically ranges between 12 and 24 mm Hg in standing horses and ponies and is higher than the LVEDP of either people or dogs.[21,24,57,259,449,615] Exercise increases both left atrial and ventricular end-diastolic pressures.[53,283,284,370,608,610,637] Pathologic elevation of resting LVEDP indicates either reduced myocardial contractility, ventricular failure, LV volume overload

*References 42, 46, 47, 248, 259, 298, 304, 308, 309, 311-314, 317, 318, 321, 352, 354, 355, 367-370, 409, 410, 414, 418, 419, 428, 561, 606-632.

(large VSD, mitral regurgitation, or aortic regurgitation), myocardial infiltration (lymphoma, amyloid), pericardial constraint, or increased ventricular wall stiffness.

Detailed computer-based analysis of a LV pressure tracing allows derivation of several indices of LV systolic and diastolic function. The maximum rate (i.e., the first derivative) of positive pressure change during isovolumetric contraction ($+dp/dt_{max}$) is a classical invasive index of ventricular systolic function. Similarly, the maximum rate of negative pressure change during the isovolumetric relaxation phase ($-dp/dt_{max}$) and the time constant of isovolumetric relaxation (τ) are considered the most reliable and least load-dependent indices of ventricular relaxation.[57,259,633,638] Although these indices are not routinely obtained in clinical cases, they are often used for research purposes.

A right-sided heart catheterization is easily performed in most horses using a percutaneous technique involving local anesthesia, placement of an 8-Fr introducer sheath into the jugular vein, and insertion of a 7-Fr balloon-tipped (Swan-Ganz) catheter of 110 to 120 cm in length through the jugular vein and the cranial vena cava into the RA, RV, and PA. Longer catheters are required to consistently measure pulmonary capillary wedge pressures in large-sized horses, but these have to be custom made for use in horses and are not commercially available on the market. Pressures within the RA, RV, and PA can be obtained by advancing the catheter slowly from the jugular vein into a lobar branch of the PA. This is typically performed in standing horses and guided by pressure measurements and sometimes with 2D ultrasound imaging. Catheter placement in the RV and the PA is considerably more difficult in recumbent (e.g., anesthetized) horses, and if intracardiac pressures are to be measured during anesthesia, it is advised to place all catheters before induction of anesthesia. Once the catheter tip is located in the PA, it may be possible to inflate the balloon tip briefly to occlude PA flow and "wedge" the distal catheter tip. This pulmonary capillary wedge pressure (PCWP, sometimes also referred to as pulmonary artery occlusion pressure) can be used to estimate LV filling pressures that are referred into the pulmonary veins and left atrium.[355,356,409,633,637,639]

Mean RA and central venous pressures estimate the pressures filling the RV and are influenced by plasma volume, venomotor tone, body position, and heart function. Central venous pressure is typically about 5 to 10 mm Hg but increases significantly in recumbent horses, especially during general anesthesia.[57,259] Values frequently double from the standing preanesthetic measurement, and central venous pressure determinations of 20 mm Hg are not uncommon.[612,640] A single measurement of the central venous pressure or of pressure in the RA is difficult to interpret unless the value is severely elevated. Trends are most important in assessment of plasma volume status and cardiac function. Markedly elevated RA pressures are observed with cardiac tamponade, constrictive pericardial disease (along with an abrupt "y" descent; see Fig. 9.4A), and in right-sided CHF. The "x" descent of the RA pressure waveform may be replaced by a positive "c-v" wave in the setting of severe tricuspid regurgitation; this pressure wave corresponds to a prominent jugular pulsation observed during inspection of the neck.

The peak RV systolic pressure is lower than that of the left ventricle and is usually around 40 mm Hg (to up to 60 mm Hg) in standing horses.[52,57,641] A small gradient (usually 10–15 mm Hg) may be measured between the ventricular apex and proximal pulmonary artery during systole in normal animals and relates in part to gravitational influences. The RV end-diastolic pressure is usually between 10 and 14 mm Hg, but values as high as 20 to 28 mm Hg have been reported.[52,57,484,585,642] Hydrostatic effects can affect the RA and the RV end-diastolic pressure if the horse's head is raised or lowered.[427] As with the left ventricle, depression of contractility reduces the rate of systolic pressure development ($+dp/dt_{max}$).[352] Elevated RV systolic pressure is recorded in pulmonary hypertension from any cause, with a large VSD, and with RV outflow obstruction as with pulmonic stenosis, tetralogy of Fallot, or obstructive pulmonary valve vegetation.[200] Pathologic elevations in RV diastolic pressure are encountered with pericardial disease, pulmonary hypertension, severe right-sided valvular disease, and CHF (Fig. 9.26).

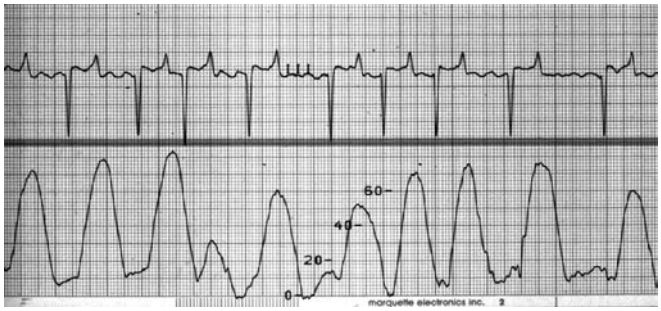

FIG. **9.26** Recording of intravascular pressure during cardiac catheterization. Right ventricular (RV) pressure recordings from a Thoroughbred yearling with atrial fibrillation (AF), pulmonary hypertension, and biventricular congestive heart failure (CHF). The pressure waveforms vary because of ventilation and the arrhythmia. Peak pressures exceed 70 mm Hg. In the absence of pulmonic stenosis or a large ventricular septal defect (VSD), this indicates pulmonary hypertension. The ventricular end diastolic pressure also is elevated and is compatible with heart failure.

Pulmonary artery pressures in standing mature horses are considerably lower than values recorded from the aorta because of the lower resistance encountered in the pulmonary vascular tree. The PA pressure is higher in the newborn foal and decreases significantly during the first 2 weeks of life as pulmonary arteriolar resistance falls.[409] Systolic PA pressures in healthy horses and ponies are approximately 35 to 45 mm Hg (but can be higher or lower depending on CO). Mean PA pressures range around 25 to 30 mm Hg, and diastolic PA pressures are approximately 20 to 25 mm Hg, but again showing some variation.[52,57,259] Pulmonary vascular pressures increase dramatically with increased CO as encountered during sinus tachycardia, and mean PAP can reach (or even exceed) 80 to 90 mm Hg during high-intensity exercise.* The pressure that is developed in the PA depends not only on CO and pulmonary arteriolar resistance but (unlike the systemic circulation) on the pulmonary capillary resistance and on the compliance and pressure in the left atrium. Pulmonary disease can influence these variables; in addition to structural vascular and parenchymal changes,[645] alveolar hypoxia and acidosis can induce reactive vasoconstriction, raising PA pressures.[646] Left ventricular function also directly influences PA pressures because elevation of LA and pulmonary venous pressure places a direct burden on the PA and right ventricle.[449] Left ventricular failure generally

* References 53, 414, 448, 608, 610, 637, 643, 644.

leads to secondary pulmonary hypertension that can be very severe. In other cases, the cause of pulmonary hypertension may not be evident.[647] Accordingly, elevated PA pressures must be assessed in light of HR, CO, and pulmonary capillary wedge, LA, or LV end-diastolic pressure.[352,353] When PA pressure is increased, RV systolic pressure is also elevated to meet the pressure load. If pulmonary hypertension is chronic, right sided cardiac enlargement, tricuspid regurgitation, and right-sided heart failure can ensue. Further details on pulmonary hypertension can be found later in this chapter.

The origin of pulmonary hypertension generally can be determined by conducting a thorough cardiorespiratory examination that includes echocardiographic and Doppler assessment of the left and right sides of the heart. However, catheterization of the PA can be instructive in confusing cases, especially if left-sided heart failure cannot be excluded. The PCWP estimates LV filling pressure and should approximate LVEDP, as long as there are no obstructions in the pulmonary veins or across the mitral valve. The PA diastolic pressure also can estimate PCWP, provided that HR is normal and pulmonary vascular resistance is not increased. Increases in PCWP (or pulmonary diastolic pressure) are measured during exercise as left atrial pressure increases,[283,356,637] in left-sided CHF,[353,639] with moderate to severe MR,[354,355] and in some horses with AF.[357] Overinfusion of crystalloid solutions or marked depression of LV function are other causes of elevated PCWP; conversely, the wedge pressure is reduced in hypovolemia. When pulmonary hypertension is not caused by left heart failure, a near-normal wedge pressure is recorded in the setting of elevated PA diastolic pressure. This indicates increased vascular resistance across the small arteries due to pulmonary vasoconstriction or pulmonary vascular lesions. One caveat is that a pressure gradient between the PA diastolic and PCWP may be observed in normal horses in the setting of resting tachycardia.

Cardiac output (CO) is the volume of blood pumped by the left (or right) ventricle in 1 minute. This can be divided by body weight or body surface area to calculate the cardiac index. The CO can be measured by thermodilution techniques, lithium dilution, arteriovenous oxygen difference (Fick methodology), 2D echocardiographic and Doppler studies (see earlier discussion), and other methods.[168,276,294-318,409,628] Cardiac output in standing adult average-size (500-kg) horses is around 30 to 40 L/min, with reported values for cardiac index in standing horses or ponies ranging between 60 and 80 mL/min/kg.[57] Measurement of CO is most often done clinically when monitoring the effects of anesthetic agents or during fluid and drug therapy of the circulation in critical care situations wherein CO relates to tissue oxygen delivery.[57] However, invasive methods involving cardiac catheterization are largely limited to research purposes. Traditionally, the thermodilution technique has been the most commonly used method for invasive measurement of cardiac output in horses.* Thereby, a thermistor-tipped Swan-Ganz catheter is placed in the pulmonary artery. A cold indicator solution is injected into the right atrium or vena cava either through the proximal injection port of the Swan-Ganz catheter (in foals) or through a second injection catheter placed through the jugular vein into the RA (in larger animals). The indicator solution is usually 5% dextrose or saline cooled to approximately 4°C or, in foals, at room temperature. The resultant change in blood temperature is detected by the thermistor downstream of the heart, and the CO can be calculated from the area under the curve of temperature change over time.

The PA catheter can also be used for sampling of mixed-venous blood. The mixed-venous oxygen content ($C\bar{v}O_2$ in mL oxygen/dL blood), which is determined by hemoglobin concentration (Hb), mixed-venous hemoglobin saturation ($S\bar{v}O_2$), and mixed-venous partial pressure of oxygen ($P\bar{v}O_2$), can be used as an indirect estimate of CO.[57,307,628,630] As CO increases, the tissues extract less oxygen from each aliquot of blood as it passes through the capillaries; consequently, the $C\bar{v}O_2$, $S\bar{v}O_2$, and $P\bar{v}O_2$ increase. As CO decreases, the tissue extraction of oxygen increases, $C\bar{v}O_2$, $S\bar{v}O_2$, and $P\bar{v}O_2$ decrease, and the systemic-to-venous O_2 difference widens.

Systemic and pulmonary vascular resistances strongly influence the mean pressures in their respective vascular systems. Vasoconstriction increases arterial BP. However, resistances cannot be measured directly in the intact animal and are generally calculated using a variation of Poiseuille's or Ohm's laws. The general formula for calculation of static vascular resistance is as follows: Vascular resistance = (Mean arterial pressure − Mean atrial pressure)/CO, where pressure is measured in mm Hg and CO is measured in mL/min. The pressures used are mean aortic pressure and mean right atrial pressure for calculation of systemic vascular resistance and mean PA pressure and mean pulmonary wedge pressure for calculation of pulmonary vascular resistance. The units for vascular resistance are mm Hg × min × mL^{-1}, sometimes abbreviated as peripheral resistance units (PRU). Alternatively, resistance is often expressed in centimeter-gram-second (cgs) units as dynes × sec × cm^{-5}, where 1 mm Hg = 1330 dynes/cm^2 and CO is expressed as cm^3/sec. The resistance value in PRU can be multiplied by 80 for conversion to a corresponding cgs value.[114] It is important to note that SVR can be calculated from pressures and CO, but it is not determined by either of these variables. Physiologically, SVR and CO are the independent variables, and MAP is the dependent variable.[114] Normal systemic vascular resistance in average-size (500-kg) adult horses averages about 265 dynes × sec × cm^{-5}. It is considerably higher in smaller horses, ponies, and foals, because the total length of the circulation and the total cross-sectional area of the resistance vessels, which according to Poiseuille's law determine vascular resistance, are directly related to body size.[57,259] This explains the fact that systemic blood pressures are largely independent of body size despite the differences in CO between larger and smaller individuals. Pulmonary vascular resistance should be about one fifth that of the systemic value, but reported values vary more widely than that.[57] Mechanisms that increase systemic vascular resistance include sympathetic activation, activation of the renin-angiotensin system, and the release of other vasoactive hormones into the blood, including arginine vasopressin (antidiuretic hormone) and epinephrine. The pulmonary vascular resistance is tied to pulmonary vascular anatomy, age, total lung capillary resistance, left atrial pressure, and degree of pulmonary vascular constriction. The latter is controlled by the tension of alveolar oxygen and local mediators, including nitric oxide and endothelin.[57,110,112-117,255-257]

Laboratory Studies

Cardiovascular disorders may develop as a consequence of systemic or metabolic diseases such as electrolyte disturbances or septicemia. Conversely, CV infections, myocardial damage, or

* References 259, 296, 301, 304, 307-309, 311, 312, 314, 317, 648.

circulatory failure may alter routine laboratory tests. Therefore laboratory studies might be indicated during the workup of horses with CV disorders. An overview of the laboratory studies useful in assessment and management of CV diseases is found in Box 9.4.

A complete blood count, measurement of SAA and fibrinogen concentrations, assessment of a biochemical profile, and urinalysis are indicated in horses with arrhythmias, heart failure, or when there is clinical evidence or suspicion of endocarditis, pericarditis, vasculitis, myocardial disease or pleural effusion. Prerenal azotemia and electrolyte disturbances (hyponatremia, hypokalemia, hypomagnesemia) may be detected in the horse with CHF, especially following diuretic therapy. Additional studies including arterial and venous blood gas tensions and oxygen saturation, blood lactate concentrations, blood cultures, and cytology and culture of pericardial effusates are indicated in selected cases. Monitoring of serum or plasma drug concentrations, especially quinidine and digoxin, are appropriate when these drugs are administered.

Cardiac troponins are sensitive and tissue-selective diagnostic biomarkers of myocardial damage in mammals.[649,650] Troponins may be released in the circulation from primary or secondary cardiac muscle injury, as might occur with myocardial infarction, myocarditis, cardiomyopathy, toxic or nutritional myocardial injury, mechanical or electrical myocardial damage, hypotension, ischemia, endothelial injury, DIC, endotoxemia, and septicemia.[161-164,575,651-668] High-intensity or prolonged exercise also induces a small rise in plasma cTnI but does not necessarily indicate underlying structural heart disease and can be observed in healthy horses.[355,484,669-673] Both cardiac troponin I (cTnI) and cardiac troponin T (cTnT) are useful for detection of myocardial injury in horses[674-677] and have replaced the less specific LDH and CK-MB isoenzymes in clinical practice. Troponin concentrations can be obtained from most commercial laboratories or using handheld point-of-care analyzers.[650,656] Normal plasma cardiac troponin concentrations vary depending on assay and laboratory but are often near or below the limit of detection of the respective assay.[656,674,676-679] The average half-life of cTnI in horses is less than 1 hour.[680] Failure to observe a decline in plasma cTnI concentrations over several hours therefore suggests ongoing myocardial damage as opposed to acute, transient myocardial injury.

Natriuretic peptides are released in the blood in response to a variety of stimuli, including myocardial stretch due to volume overload and increases in intracardiac pressures.[110,112-114,116,664,681] Plasma atrial natriuretic peptide (ANP) concentrations increase during exercise,[355,682-687] and they can be elevated in horses with cardiac disease, particularly in the presence of LA enlargement or LA dysfunction.[355,688-690] To date, no assays are available for accurate and reliable measurement of ANP in equine blood in routine clinical practice.[664,691] Therefore the use of ANP as a cardiac biomarker is currently limited to experimental settings, and more work needs to be done to elucidate its clinical value in horses with heart disease.

A variety of other cardiac biomarkers potentially indicating myocyte stress, myocyte injury, neurohormonal activation, myocardial remodeling, inflammation, or oxidative stress are known but are currently not used for routine diagnostic purposes in horses with heart disease.[664] Further application of laboratory studies is discussed under specific diseases later in this chapter.

PULMONARY HYPERTENSION AND COR PULMONALE

Pulmonary hypertension (PHT) is hemodynamically characterized by pulmonary artery pressures exceeding the upper normal limit by more than 10 mm Hg.[692] Current human classifications of pulmonary hypertension include (1) pulmonary arterial hypertension (including idiopathic, drug and toxin induced, and persistent PHT of the newborn); (2) PHT caused by left-sided heart disease (including congenital and acquired heart disease); (3) PHT caused by lung disease and/or hypoxia; (4) chronic thromboembolic PHT; and (5) PHT with unclear multifactorial mechanisms (including hematologic, systemic, metabolic, and other disorders).[693,694]

In horses, clinically relevant PHT most commonly results from severe mitral valve disease, pulmonary overcirculation caused by congenital left-to right shunts (e.g., VSD), or chronic left-sided heart failure. In these cases, PHT can be very severe, with systolic pulmonary artery pressures exceeding 80 mm Hg. Presumably, factors such as reactive vasoconstriction or anatomic changes (structural remodeling) in the pulmonary vascular tree must develop as a consequence of elevated left atrial pressures in order to sustain such high pressures at rest.

Pulmonary hypertension is occasionally diagnosed in foals and adult horses with severe respiratory disease.[695-699] In addition to structural vascular and parenchymal changes,[645] low alveolar oxygen tension is considered a very potent trigger of (reversible) pulmonary vasoconstriction leading to an increase in pulmonary vascular resistance.[700,701] Hypoxia was found to be a contributing factor leading to (relatively mild) pulmonary hypertension in horses with recurrent airway obstruction.[646,697-699] Hypoxic vasoconstriction may also be particularly important in newborn foals, in which vascular resistance is already high.[409]

Persistent pulmonary hypertension of the newborn foal (also called persistent fetal circulation or reversion to fetal circulation) results from failure to successfully make the cardiorespiratory transition to extrauterine life or from reversion to fetal circulatory patterns in response to hypoxia or acidosis.[609,702,703] The fetal circulatory pattern with PHT and right-to-left shunting of blood through the patent foramen ovale (PFO) and the ductus arteriosus are maintained in these cases, and affected foals are in hypoxemic respiratory failure. Factors contributing to persistent PHT in newborns are chronic in utero hypoxia or acidosis, asphyxia, and meconium aspiration, but often the precipitating trigger is unknown.[702]

Pulmonary thromboembolism is rarely diagnosed in horses,[193,704-709] but it is possible that the condition is in fact underrecognized in clinical practice and that its incidence might be higher than supposed.[705] Idiopathic pulmonary hypertension has been reported as a cause of AF in horses; however, left-sided heart dysfunction was not completely excluded in the reported cases.[96]

Exercise-induced PHT, with mean pulmonary artery pressures exceeding 80 to 90 mm Hg, is a unique feature in horses and ponies. It is likely caused by the massive (up to tenfold) increase in pulmonary blood flow, in association with high LV filling pressures (necessary to ensure rapid ventricular filling at maximal HRs), compression of pulmonary vessels during forced expiration and inspiration, greater blood viscosity related to the exercise-induced rise in packed cell volume, and possibly arteriolar vasoconstriction.* Elevated pulmonary

* References 53, 414, 448, 608, 610, 637, 643, 644, 710-716.

vascular pressures during strenuous exercise are thought to be one of the major factors contributing to capillary stress failure and the occurrence of exercise-induced pulmonary hemorrhage.[53,210,644,717]

Pulmonary hypertension increases afterload on the RV and results in elevated end-diastolic and central venous pressures. Acute PHT may result in RV dilation, because there is not enough time for adaptive mechanisms (e.g., RV hypertrophy) to develop. If pulmonary hypertension is chronic, RV hypertrophy will develop over time. Increased RV pressures and alterations in RV geometry often result in tricuspid regurgitation. In severe cases, the interventricular septum bulges into the LV, interfering with filling and thus causing diastolic LV dysfunction. Right-sided or biventricular heart failure can ensue.

Cor pulmonale is characterized by right ventricular enlargement secondary to PHT due to pulmonary parenchymal or vascular disease, in the absence of left ventricular failure, a congenital malformation (e.g., VSD), or an acquired valvular disorder. Diagnosis of cor pulmonale requires evidence of pulmonary hypertension and exclusion of a primary cardiac disease.[57,692] Cor pulmonale is uncommon in horses.[374,695,718-721] Although both acute and chronic airway obstruction can negatively affect right heart and overall cardiac function,[646,696,720,721] there is no compelling evidence at this time to incriminate cor pulmonale as a common cause of clinically important heart disease in horses.

On physical examination, a split-second heart sound with a loud pulmonic component and a right-sided systolic heart murmur consistent with TR may be detected in horses with pulmonary hypertension. In cases of severe PHT, signs of right-sided congestive heart failure including distended jugular veins and peripheral edema will be evident. Pulmonary artery pressures can be estimated echocardiographically by Doppler flow imaging of tricuspid or pulmonic regurgitation velocities. Enlargement of the pulmonary artery (exceeding the aortic root diameter) is considered a fairly specific (but not sensitive) indicator of pulmonary hypertension. Cardiac catheterization allows invasive measurement of pulmonary artery pressures and pulmonary capillary wedge pressures and may aid in the diagnosis of pulmonary hypertension and cor pulmonale. Further details on the diagnostic procedures required to diagnose PHT have been discussed earlier in this chapter.

Horses with PHT are considered unsafe to ride or drive.[68] Treatment of PHT should include alleviation of hypoxia and acidosis to minimize functional hypoxic vasoconstriction. Elimination of the underlying cause may be possible in horses and foals with severe but treatable lung disease. Horses with PHT secondary to severe left heart disease require symptomatic treatment of heart failure (see later discussion). Note that diuretics may be harmful in horses with cor pulmonale because small decreases in preload often worsen clinical signs. Nitric oxide (NO) is a potent, selective vasodilator of the pulmonary circulation, and inhaled NO may have value as a therapeutic agent in foals with PHT.[702,722] The use of other pulmonary vasodilators or of endothelin receptor blockers has not been established for treatment of PHT in horses.

CONGESTIVE HEART FAILURE

Heart failure is a clinical syndrome characterized by cardiac disease leading to systolic dysfunction, diastolic dysfunction,

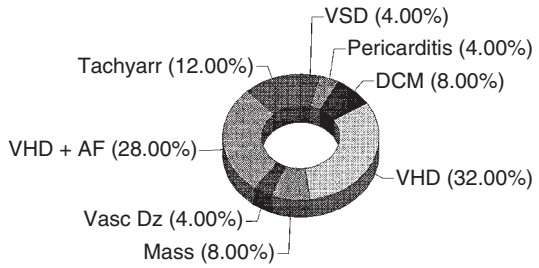

FIG. **9.27** Graph demonstrating the overall causes of congestive heart failure (CHF) in 25 horses at a referral teaching hospital as a percentage of the total number of cases of equine CHF. *Tachyarr,* Tachyarrhythmia; *VSD,* ventricular septal defect; *DCM,* dilated cardiomyopathy; *VHD,* valvular heart disease; *Mass,* mass lesion; *Vasc Dz,* vascular disease; *VHD + AF,* valvular heart disease and atrial fibrillation. Data from Ohio State University Veterinary Hospital.

or a combination of the two, limited CO in the setting of normal to high venous pressures, increased neurohormonal activity, renal sodium retention, accumulation of edema in tissues, and transudation of fluid into serous body cavities. The neurohormonal and renal abnormalities that characterize heart failure have not been extensively studied in horses but are probably similar to those reported in other species and include increase in sympathetic tone, activation of the renin-angiotensin-aldosterone system, and increased release of antidiuretic hormone (vasopressin) and atrial natriuretic peptide.* The most sensitive sign of heart failure is impaired exercise capacity, but this is hardly specific in horses. The most characteristic clinical features of heart failure are tachycardia, increased venous pressures, and fluid accumulation. The typical horse with cardiac failure is recognized in the overtly congested phase termed *congestive heart failure* (CHF) (see Figs. 9.11 and 9.12).

However, most cardiac lesions in horses are insufficient to cause CHF, and this syndrome is not common in equine practice. Nevertheless, CHF does develop in foals and mature horses as a consequence of diverse disorders, including the following: congenital malformation, severe degenerative valvular disease, chordal rupture, valvulitis, bacterial endocarditis, dilated or infiltrative cardiomyopathy, myocarditis, myocardial necrosis, pericardial disease, vascular rupture, pulmonary hypertension, artery obstruction, or persistent tachyarrhythmia.* The most common cause of CHF in horses is valvular heart disease—often complicated by atrial fibrillation, the onset of which can trigger transition from the compensated to the decompensated phase of heart failure (Fig. 9.27). In addition to structural lesions of the heart and blood vessels, primary electrical disturbances, particularly sustained AV dissociation caused by intractable junctional or ventricular tachycardia, can cause tachycardia-induced cardiomyopathy, reduce myocardial function, decrease CO, and lead to CHF.[736] This is especially likely when the HR exceeds 100 beats/min for many days. Resolution of CHF in such cases may be possible if antiarrhythmic therapy and rate control are successful.[153]

Clinical Recognition of Heart Failure

Congestive heart failure may develop suddenly or gradually. Peracute heart failure can occur following acute-onset mitral regurgitation due to chordal rupture or papillary muscle ischemia or infarction, consequent to acute endocarditis of a heart valve, or as a result of acute vascular rupture leading to an aortocardiac fistula.[262,265,374] Heart failure may progress rapidly in a foal with a large ventricular septal defect as the pulmonary vascular resistance falls in the weeks following birth.[117,728] Chronic valvular regurgitation can after many years lead to CHF, although only a small number of horses with degenerative valvular disease develop CHF.[583] Some lesions, which might otherwise be well tolerated, can cause heart failure if there are increased demands for CO. Examples include strenuous work, severe anemia, or persistent fever. Pregnancy is another example: the volume expansion and increased demands for CO in the latter stages of gestation may precipitate CHF in a mare with previously compensated heart disease. Development of AF in a horse with underlying structural disease, such as severe mitral or aortic regurgitation, can precipitate CHF. Such cases are distinguished from the more typical case of AF by the presence of persistent, resting tachycardia and identification of structural lesions and cardiomegaly during echocardiography.

The clinical features of CHF are easily recognized,[724] but determination of the underlying cause of heart disease may be more difficult. The etiology can be established if careful auscultation is combined with echocardiography, ECG, laboratory tests, and ultrasound examination of other body cavities.* Presenting clinical signs can vary but often include exercise intolerance, poor recovery after exercise, lethargy, anorexia, weight loss, loss of body condition, coughing, tachypnea, ventral edema, and colic-like signs.

The clinical features of right-sided CHF include resting tachycardia (generally at 60/min or greater) and prominent third (ventricular) sound along with generalized ventral, preputial, pectoral, and limb edema. Scrutiny of the jugular and other superficial veins generally makes the recognition of right-sided CHF straightforward, because affected horses demonstrate elevated venous pressure and pathologic jugular pulses and filling (see Figs. 9.11 and 9.12). Isolated limb edema, which is common in hospitalized horses, or ventral edema in the absence of generalized venous distention are not a sign of CHF and should prompt consideration of other disorders causing edema including hypoproteinemia, vasculitis, or severe pleural or abdominal effusion.

The most common causes of "isolated" right-sided CHF are tricuspid or pulmonic valve lesions as with valvular endocarditis, diffuse pulmonary vascular disease, and pericardial disease. In most cases a prominent murmur of tricuspid regurgitation will be evident over the right thorax. When there is pulmonary hypertension underlying right-sided failure, the tricuspid murmur may be especially loud and the pulmonic component of the second heart sound tympanic. Because right-sided heart failure often develops consequent to pulmonary hypertension caused by left-sided heart failure, concurrent left-sided murmurs are not uncommon. Another common association of right-sided CHF is persistent cardiac arrhythmia, such as AF, superimposed on structural heart disease of any form. Cranial mediastinal lymphoma and cranial thoracic masses including large pulmonary abscesses must be distinguished from RV failure.[140,737] Differential diagnosis is facilitated by examination with 2D echocardiography and thoracic ultrasonography.

The recognition of isolated left-sided heart failure, which causes pulmonary venous congestion and pulmonary interstitial or, uncommonly, alveolar edema, is more difficult in horses. Tachypnea and respiratory distress are predominant clinical signs. In these cases, heart sounds and murmurs may be difficult to identify owing to loud airway sounds or even pulmonary crackles. If a cardiac murmur is present but missed, an erroneous diagnosis of pneumonia or severe equine asthma (recurrent airway obstruction) may be entertained. Again, resting tachycardia and loud third heart sound are typical in these cases, and echocardiographic examination of the horse will be particularly useful. Typical findings in acute left-sided CHF are dilation and rounding of the left atrium and ventricle and often dilation of the PA caused by pulmonary hypertension. Careful examination may demonstrate anatomic lesions of the aortic root, ventricular septum, left heart valves, papillary muscles, or chordae tendineae. Fulminant left-sided CHF can lead to coughing and expectoration of edema—a grave sign in most horses (see Fig. 9.10).

Biventricular CHF is most commonly observed when severe left-sided disease results in chronic CHF and is complicated by AF. The clinical signs of advanced biventricular heart failure include resting tachycardia (usually >60 beats/min), loud ventricular filling sound, subcutaneous edema, tachypnea (from pulmonary congestion or pleural effusion), varying amounts of ascites and pleural effusion, a small pericardial effusion, jugular distention, and abnormal jugular pulsations. Chronic biventricular CHF is frequently characterized by lethargy and loss of body condition. In most cases there will be a left-sided heart murmur typical of mitral or aortic valve regurgitation and a murmur of tricuspid regurgitation on the right, which in advanced cases may become more prominent than the left-sided murmurs. Infrequently, biventricular CHF is due to congenital heart disease such as a VSD or a complex malformation.

It is important to understand that *chronic* left-sided CHF in the horse is likely to cause interstitial lung edema and pulmonary hypertension in the absence of overt clinical signs of left-sided heart failure. The magnitude of pulmonary hypertension is often impressive, with systolic PA pressures exceeding 80 mm Hg in many cases. The mechanisms by which the lung accommodates such severe and chronic elevations in pulmonary venous pressures without development of alveolar edema is speculative. It is likely that pulmonary arterial resistance increases, possibly related to remodeling in pulmonary arteries from chronic elevation of LA pressure. Chronic pulmonary hypertension subsequently leads to RV dilation and hypertrophy, tricuspid regurgitation, and RV failure, which limits CO and results in predominant clinical signs of right-sided CHF. Thus the clinician should anticipate signs of right-sided CHF even when the primary cardiac lesion is located on the left side of the heart. Clinical findings of severe pulmonary hypertension caused by left-sided CHF include a loud, tympanic, pulmonary component of the second heart sound (heard cranioventral to the aortic valve area), a systolic murmur and jugular pulse of tricuspid insufficiency, and dilation of the PA, which can be identified by 2D echocardiography. Thoracic radiographs may demonstrate increased pulmonary vascularity, pulmonary infiltration near the hilus, pleural

* References 83, 125-127, 144, 148, 152, 192, 204, 212, 213, 262, 265, 352, 374, 546, 563, 725-735.

effusion, and rounding or enlargement of the cardiac silhouette. Further scrutiny of the echocardiogram identifies LA dilation and lesions affecting the LV and usually the mitral valve, aortic valve, or aorta. Doppler echocardiography can document abnormal flow patterns such as valvular regurgitation and predict PA pressures (using the Bernoulli relationship discussed previously). An ECG is needed to evaluate cardiac arrhythmias.

Therapy for Congestive Heart Failure

Therapy for CHF is realistic for potentially reversible disorders such as acute papillary muscle ischemia/dysfunction, myocarditis, pericarditis or sustained ventricular tachyarrhythmia. It may also be feasible for valuable breeding stallions and mares, mares that develop CHF during gestation, or horses and ponies kept as pets.[724,727] The goal of treatment is to reduce the hemodynamic consequences of heart failure, restore cardiac output, and reduce congestion. Before therapy can commence, an accurate diagnosis is needed. For example, pericardiocentesis (not cardiac drugs) would be the appropriate initial management of cardiac tamponade; thereafter, surgical drainage of the effusion (using drainage tubes) or a pericardiectomy could be considered.[125-127,133,137,738-742] Antibiotics would be essential in the treatment of bacterial endocarditis or infective pericarditis. Sustained junctional and ventricular tachyarrhythmias may lead to low CO and a potentially reversible dilated cardiomyopathy. Antiarrhythmic therapy with lidocaine, magnesium sulfate solution, quinidine, procainamide, propafenone, sotalol, or amiodarone may be effective for treatment of some of these arrhythmias,[55,58] and with resumption of normal rhythm, CHF may be reversed.[153]

Horses in CHF should be brought to a quiet environment, and any type of stress should be avoided or at least minimized as much as possible. This also means that diagnostic interventions, although necessary, should be limited to those that are required to make an initial decision about the most appropriate initial treatment.

Diuretics are used in the treatment of CHF not associated with cardiac tamponade in order to reduce volume overload and edema and prevent their recurrence. Loop diuretics such as furosemide are preferred due to their superior fluid clearance and dose-dependent effects. They act by inhibiting the $Na^+/K^+/2\ Cl^-$ cotransporter in the ascending limb of the loop of Henle.[743] Furosemide is administered to horses with CHF at initial dosages of 1 to 2 mg/kg IV, given as repeated boluses to effect.[55,58,327,744-748] Because the site of action is reached intraluminally after excretion of furosemide by the proximal tubule, higher or more frequent doses might be required when renal function is impaired.[743] Bolus administration followed by constant rate infusion is thought to be more effective than intermittent bolus administration and can be chosen when profound diuresis is needed[747] (Table 9.7). Respiratory effort should improve when pulmonary edema is evident, and doses should be adapted as dictated by respiratory rate and effort.

TABLE **9.7** **Drug Therapy of Heart Disease**

Drug	Dose Recommendations	Comments Therapeutic Drug Monitoring Adverse/Toxic Effects	Indications (I) Contraindications (CI)
ANTIARRHYTHMICS			
Sodium Channel Blocker (Class I_A)			
Quinidine sulfate (PO) or gluconate (IV)	22 mg/kg quinidine sulfate PO by NGT q 2 h for 4 (–6) doses until converted, adverse or toxic effects, or plasma quinidine concentration >4 μg/mL. Do not exceed 6 doses PO q 2 h. Continue q 6 h until converted, adverse or toxic effects, or total dose of 180 mg/kg. 1–2.2 mg/kg quinidine gluconate IV q 10 min or 0.1–0.22 mg/kg/min CRI up to 12 (–24*) mg/kg total dose (*Caution: Can result in severe adverse effects!)	IV administration for AF of recent onset (<2 weeks) without underlying structural heart disease or AF occurring during anesthesia. PO administration preferred for long-standing AF (>2–4 weeks). Therapeutic drug monitoring: therapeutic range: 2–5 μg/mL [6.2–15.4 μmol/L] 1–2 h after PO administration. Adverse effects: Commonly depression, diarrhea, colic, nasal mucosal swelling, and ataxia. Rarely paraphimosis, urticaria, and laminitis. Cardiovascular effects include acceleration of AV conduction and tachycardia (most common), prolonged QRS and QT interval, VT or torsades de pointes, hypotension, neg. inotropism, exacerbation of heart failure, cardiovascular collapse, sudden death.	I: AF, SVT (ventricular arrhythmias). CI: Ventricular tachyarrhythmias, torsades de pointes, untreated heart failure, preexisting prolonged QRS or QT interval, complete AV block, digitalis intoxication. Use with caution in patients with uncorrected hypokalemia, hypomagnesemia, hypoxia, or acid-base disorders.
Procainamide	25–35 mg/kg PO q 8 h 1 mg/kg/min IV, up to 20 mg/kg total dose	Adverse effects: Hypotension, QRS and QT prolongation, neg. inotropism, arrhythmias, GI and neurologic disorders. Similar but generally less severe than with quinidine.	I: Ventricular and supraventricular arrhythmias. CI: See quinidine.

TABLE **9.7 Drug Therapy of Heart Disease—cont'd**

Drug	Dose Recommendations	Comments Therapeutic Drug Monitoring Adverse/Toxic Effects	Indications (I) Contraindications (CI)
Sodium Channel Blocker (Class I_B)			
Lidocaine	0.25–0.5 mg/kg slow IV, repeat in 5–10 min to effect, up to 1.5 mg/kg total dose; followed by 0.03–0.05 mg/kg/min CRI	Adverse effects: Low incidence at therapeutic doses. Occasionally depression and muscle fasciculations. Overdoses may lead to ataxia, CNS excitement, seizures, hypotension, VT, collapse, and sudden death.	I: Ventricular arrhythmias, (potentially vagally sustained AF). CI: SA, AV, or intraventricular block, bradycardia. Caution with hypovolemia, liver disease, shock, and heart failure.
Phenytoin	20 mg/kg PO q 12 h for 3–4 doses or until signs of sedation, followed by 10–15 mg/kg PO q 12 h maintenance dose 5–10 mg/kg IV, followed by 1–5 mg/kg IM q 12 h or 10–15 mg/kg PO q 12 h	Maintenance dose varies considerably. Therapeutic drug monitoring: therapeutic range 5–10 μg/mL [19.8–39.6 μmol/L]. Adverse effects: Sedation, lip and facial twitching, gait deficits, excitation seizures, arrhythmias. Hepatotoxicity with chronic therapy. Hypotension and respiratory depression at high doses.	I: Digoxin-induced arrhythmias, other ventricular arrhythmias. CI: SA or AV block, sinus bradycardia.
Sodium Channel Blocker (Class I_C)			
Flecainide	1–2 mg/kg IV, infused at a rate of 0.2 mg/kg/min 4 mg/kg PO q 2 h for 4–6 doses, followed by 4 mg/kg PO q 4 h; adjust dose intervals if signs of toxicity occur	Use with caution. Not generally recommended for treatment of AF. Not considered effective for chronic AF. Adverse effects: depression, colic, neurologic signs, negative inotropism, QRS and QT prolongation, severe ventricular arrhythmias, sudden death.	I: Acute AF, supraventricular and ventricular arrhythmias resistant to other treatments. CI: Structural heart disease, heart failure, SA or AV node dysfunction.
Propafenone	0.5–2.0 mg/kg in 5% dextrose slowly IV over 10–15 min 2 mg/kg PO q 8 h	Not commonly used. Adverse effects: GI and neurologic disorders, bronchospasm, negative inotropism, exacerbation of heart failure, AV block, QRS and QT prolongation, arrhythmias.	I: Supraventricular and ventricular arrhythmias resistant to other treatments. CI: Structural heart disease, heart failure, SA or AV node dysfunction.
β-Adrenoceptor Blocker (Class II)			
Propranolol	0.03–0.16 mg/kg slow IV q 12 h 0.38–0.78 mg/kg PO q 8 h	Unspecific β_1/β_2-blocker. Variable oral bioavailability. Dosage should be individually adjusted. Adverse effects: Depression, lethargy, weakness, bradycardia, AV block, hypotension, neg. inotropism, exacerbation of heart failure, bronchoconstriction (aggravation of recurrent airway obstruction).	I: SVT and AF (rate control, often in combination with digoxin), catecholamine-induced arrhythmias, unresponsive supraventricular and ventricular arrhythmias. CI: Bradycardia, high-degree AV block, untreated heart failure, bronchopulmonary disease.
Potassium Channel Blocker (Class III)			
Sotalol	1 mg/kg PO q 12 h for 1 d, continue at 2–3 mg/kg PO q 12 h	Also class II effects. Good oral bioavailability. Generally well tolerated, even with chronic oral administration. Dosage should be gradually reduced before discontinuing medication. Adverse effects: QT prolongation, ventricular arrhythmias.	I: Prevention of recurrent AF, supraventricular and ventricular arrhythmias CI: Preexisting QT prolongation. Use with caution in patients with uncorrected hypokalemia or hypomagnesemia.

TABLE **9.7 Drug Therapy of Heart Disease—cont'd**

Drug	Dose Recommendations	Comments Therapeutic Drug Monitoring Adverse/Toxic Effects	Indications (I) Contraindications (CI)
Amiodarone	5 mg/kg/h IV for 1 h, followed by 0.83 mg/kg/h for 23 h, and subsequently 1.9 mg/kg/h for 30 h or to effect	Also class I, II, and IV effects. Poor and variable oral bioavailability, long half-life (16 days). Adverse reactions: Hindlimb weakness, weight shifting, torsades de pointes (supposedly low incidence), SA and AV nodal inhibition, bradycardia, hypotension. Prolonged treatment may affect lungs, liver, heart, thyroid gland, GI tract, eyes, skin, and nerves.	I: AF, ventricular arrhythmias (not investigated). CI: Sinus node dysfunction, bradycardia, AV block, cardiogenic shock.
Bretylium tosylate	3–5 mg/kg IV, repeat up to 10 mg/kg	Also indirect antiadrenergic effects. Adverse effects: Excitement, GI disorders, hypotension, tachycardia, arrhythmias.	I: Refractory, life-threatening ventricular tachycardia, ventricular fibrillation.
Calcium Channel Blocker (Class IV)			
Diltiazem Verapamil	0.125 mg/kg over 2 min IV, repeated q 10 min to effect, up to 1.25 mg/kg total dose 0.025–0.05 mg/kg IV q 30 min, up to 0.2 mg/kg total dose	Titrate to effect. Use diltiazem doses >0.5–1.0 mg/kg with caution. Adverse effects: Hypotension, tachycardia, sinus arrhythmia, bradycardia, sinus arrest, high-grade AV block, negative inotropism, exacerbation of heart failure (unless secondary to SVT or AF with rapid ventricular response rate).	I: Supraventricular arrhythmias (ventricular rate control in AF and interruption of SA/AV nodal-dependent SVT). CI: Hypotension, bradycardia, SA or AV block, ventricular systolic dysfunction, severe heart failure, cardiogenic shock, β-blocker.
Physiologic Calcium Channel Blocker, Activator of Membrane Na^+/K^+-ATPase			
Magnesium sulfate	2–6 mg/kg/min IV to effect, up 55 (–100) mg/kg total dose	Adverse effects: Overdoses (rare) may lead to CNS depressant effects, weakness, trembling, bradycardia, hypotension. Very high doses lead to neuromuscular blockade with respiratory depression and cardiac arrest.	I: Ventricular arrhythmias (esp. torsades de pointes and refractory VT), hypomagnesemia associated with cardiovascular disease. CI: Bradycardia, SA and AV block, renal failure.
DIGITALIS GLYCOSIDES			
Digoxin	IV loading dose: 0.0022 mg/kg IV q 12 h, for 2 doses IV maintenance dose: 0.0022 mg/kg IV q 24 h PO maintenance dose: 0.011 mg/kg PO q 12 h	Therapeutic drug monitoring: peak (1–2 h) and trough (12h) concentrations at steady state should fall within 0.8–1.2 (2.0) ng/mL (1–1.5 [2.6] nmol/L). Adverse effects: Depression, anorexia, colic, diarrhea, sinus bradycardia, AV block, supraventricular and ventricular arrhythmias (bigeminy).	I: Heart failure, ventricular rate control in SVT or AF. CI: AV block, diastolic ventricular dysfunction, preexisting digitalis toxicity, myocarditis, ventricular arrhythmias.
ADRENERGIC (SYMPATHOMIMETIC) AGENTS			
Inotropes			
Dopamine	1–5 μg/kg/min CRI, titrate to effect or adverse reactions	β_1-adrenergic, also dose-dependent dopaminergic and α_1-adrenergic. Adverse reactions: Tachycardia, ventricular arrhythmias, vasoconstriction and hypertension can occur at doses >4–5 μg/kg/min.	I: Hypotension, acute heart failure, cardiogenic shock, noncardiogenic shock (after adequate fluid loading), sinus arrest, bradycardia, high-grade or complete AV block, vagally induced bradyarrhythmias. CI: Ventricular arrhythmias, tachycardia, atrial fibrillation (risk of severe tachycardia due to accelerated atrioventricular conduction).
Dobutamine	1–5 μg/kg/min CRI, titrate to effect or adverse reactions	β_1-adrenergic, also β_2- and α_1-adrenergic. Preferred over dopamine. Adverse reactions: Tachycardia, ventricular arrhythmias, vasoconstriction.

TABLE **9.7** **Drug Therapy of Heart Disease—cont'd**

Drug	Dose Recommendations	Comments Therapeutic Drug Monitoring Adverse/Toxic Effects	Indications (I) Contraindications (CI)
Epinephrine	0.01–0.05 mg/kg IV 0.1–0.5 mg/kg IT Note different concentrations: 1:1,000 = 1 mg/mL 1:10,000 = 0.1 mg/mL	β-adrenergic, α_1-adrenergic at higher doses. Adverse effects: Tremor, excitability, arrhythmias, ventricular fibrillation. Overdoses can lead to hypertension, arrhythmias, renal failure, pulmonary edema, cerebral hemorrhage.	I: Ventricular asystole, cardiopulmonary resuscitation. CI: Nonanaphylactic shock, arrhythmias, hypertension.
Vasopressors			
Norepinephrine	0.05–1 μg/kg/min CRI, titrate to effect	α_1-adrenergic, norepinephrine also exerts some β_1-adrenergic effects. Usually administered in conjunction with fluid therapy and dobutamine. Adverse effects: Hypertension, reflex bradycardia, reduction in cardiac output due to increased afterload, CNS effects (excitement, restlessness), rarely arrhythmias. Overdosage can lead to seizures, ventricular arrhythmias, cerebral hemorrhage.	I: Hypotension and shock associated with excessive peripheral vasodilation (i.e., septic or endotoxic shock, quinidine toxicity; after adequate volume loading). CI: Hypertension, bradycardia, poor cardiac output, cardiac disease, ventricular tachycardia.
Phenylephrine	0.1–1 μg/kg/min CRI, titrate to effect		
ANTICHOLINERGIC (VAGOLYTIC) AGENTS			
Atropine	0.01–0.02 mg/kg IV, IM	Adverse effects: Constipation, ileus, colic, bradycardia (initially or at very low doses), tachycardia, arrhythmias, CNS effects (stimulation, drowsiness, ataxia, seizures, respiratory depression). Glycopyrrolate is slightly less arrhythmogenic and rarely results in CNS effects.	I: Vagally induced bradyarrhythmias, sinus bradycardia, sinus arrest, high-grade or complete AV block. CI: Tachycardia, tachyarrhythmias, heart failure, GI disease, colic.
Glycopyrrolate	0.005–0.01 mg/kg IV		
ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS			
Benazepril	0.5–1.0 mg/kg PO q 24 h	Potential effects include vasodilation, reduction of volume overload, blunting of mechanism leading to diuretic resistance, cardioprotection by decreasing myocardial remodeling and fibrosis. Optimal doses, safety, and efficacy in horses largely unknown. Benazepril appears most effective at inhibiting serum ACE activity. Monitor renal function and serum potassium concentration. Adverse effects: Cough, impairment of renal function, hypotension, hyperkalemia.	I: Cardiovascular protection in cases with AR or MR, treatment of heart failure. CI: Severe renal failure, hyperkalemia, hypotension, pregnancy.
Ramipril	0.05–0.2 mg/kg PO q 24 h		
Quinapril	0.25 mg/kg PO q 24 h		
Enalapril	0.5 mg/kg PO q 12 h		
VASODILATORS AND INODILATORS			
Acepromazine	0.02–0.06 mg/kg IM q 6–8 h, titrate to effect 0.3–1.0 mg/kg PO q 12 h, titrate to effect	Sedative/tranquilizer, anxiolytic, antiarrhythmic, vasodilator (decreases afterload). Start at lower dose and titrate up to effect. Monitor systemic blood pressure. Adverse effects: Hypotension, protrusion of penis (very low risk of permanent penile dysfunction in intact male horses).	I: Management of CHF CI: Hypotension, hypovolemia, use cautiously and in smaller doses in animals with hepatic dysfunction.

TABLE **9.7 Drug Therapy of Heart Disease—cont'd**

Drug	Dose Recommendations	Comments Therapeutic Drug Monitoring Adverse/Toxic Effects	Indications (I) Contraindications (CI)
Hydralazine	0.5–1.5 mg/kg PO q 12 h 0.5 mg/kg IV q 12 h	Arterial vasodilator (reduces afterload). Adverse effects: Transient weakness, lethargy, hypotension, tachycardia, sodium/water retention (unless given with diuretics).	I: CHF, mitral regurgitation. CI: Hypotension, hypovolemia, severe renal disease.
Nitroglycerine	5–20 μg/kg/min CRI, titrate to effect	Venous vasodilator (reduces preload). Tolerance with long-term treatment (12–24 h). Adverse effects: Severe hypotension, reflex tachycardia, weakness.	I: Acute management of CHF. CI: Hypotension, hypovolemia.
Milrinone	0.2 μg/kg IV bolus, followed by 10 μg/kg/min CRI 0.5–1.0 mg/kg PO q 12 h	Phosphodiesterase inhibitor (inodilator). Adverse effects: Arrhythmias, hypotension, tachycardia, accelerated AV conduction.	I: Acute management of CHF. CI: Normal or low filling pressures, severe renal failure.
DIURETICS			
Furosemide	Initial dose for CHF: 1.0–3.0 mg/kg IV or IM q 8–12 h as needed to produce diuretic effect Alternatively: 1–2 mg/kg IV loading dose, followed by 0.12 mg/kg/h CRI Maintenance dose: 1 mg/kg IV or IM q 12 h	Start at higher/more frequent doses and reduce to minimal effective dose, as dictated by respiratory rate and effort. Oral administration not effective. Adverse effects: At high doses risk of hypovolemia, renal failure, electrolyte and acid-base imbalances.	I: Congestive heart failure, edema. CI: Dehydration, severe electrolyte disturbances.

AF, Atrial flutter/fibrillation; *AR,* aortic regurgitation; *AV,* atrioventricular; *CHF,* congestive heart failure; *CRI,* constant rate infusion; *HF,* heart failure; *IT,* intratracheal; *MR,* mitral regurgitation; *NGT,* nasogastric tube; *RAAS,* renin-angiotensin-aldosterone system; *SA,* sinoatrial; *SVT,* supraventricular tachycardia; *VT,* ventricular tachycardia.

Volume depletion, azotemia, and electrolyte imbalances are the most common adverse effects of furosemide treatment. Renal function should be followed and the dosage controlled to minimize prerenal azotemia. Diuretic therapy can eventually be discontinued in some horses, but others will require once- or twice-daily administration on the farm to prevent fluid retention. Systemic availability of orally administered furosemide is poor and variable,[745] and therefore oral treatment is not recommended. Prolonged diuresis may lead to loss of diuretic potency and diuretic resistance, which can potentially be counteracted by coadministration of angiotensin-converting enzyme inhibitors.[743]

Short-term therapy with intranasal oxygen therapy, if available, at a rate of 5 to 10 L/min using one or two nasal cannulas might be useful for horses with respiratory distress.

Horses in CHF can be cautiously sedated using acepromazine to minimize stress. In addition to its anxiolytic effects, acepromazine also acts as an antiarrhythmic and a potent vasodilator. As such, it reduces afterload, thereby decreasing valvular regurgitant fraction and facilitating ventricular ejection. Acepromazine should be titrated to effect, and if possible, systemic blood pressures should be monitored to avoid severe hypotension (see Table 9.7).[58] Note that α_2-adrenergic agonists such as xylazine and detomidine should not be used for sedation in horses with CHF, because they act as vasoconstrictors that increase afterload and result in increased regurgitant fraction and workload of the heart.

If acute positive inotropic support is required for stabilization of CHF or treatment of cardiogenic shock, dobutamine can be administered as a continuous rate infusion (CRI), taking its proarrhythmic and vasoconstrictive effects into account (see Table 9.7).[55,57,58,743] For chronic inotropic support, digoxin is commonly used. Digoxin therapy is indicated for CHF not associated with pericardial disease or serious ventricular ectopy. It is particularly beneficial when there is concurrent AF superimposed on structural valvular heart disease, because in addition to its inotropic effects it also causes baroreceptor sensitization and increases vagal tone, thereby reducing HR (negative chronotropic effects) and controlling ventricular response rate to AF (negative dromotropic effects).[743] Treatment is initiated by the intravenous route, with most (450–550 kg) horses receiving a total dose of about 1 mg IV (see Table 9.7). The reported elimination half-life of digoxin has not been consistent (7.2–28 hours) and probably relates to the clinical state of the animals studied.* Long-term digoxin therapy involves once- or twice-daily oral administration. Oral doses of digoxin are relatively higher because of lower bioavailability (20%).[320,330,331,334] Chronic digoxin therapy is monitored by measuring the serum digoxin concentration (drawn 8–12 hours after the previous dose). Target therapeutic values range between 0.8 and 1.2 (2.0) ng/mL (1–1.5 [2.6] nmol/L), depending on the time of the blood sample, and drug therapy achieving these serum concentrations is usually well tolerated in terms of appetite and heart rhythm. Periodic cardiac examinations, measurements of serum biochemistries (creatinine, electrolytes), and recordings of ECG

* References 319, 320, 322, 327, 328, 330-332, 334, 727, 749-752.

rhythm strips are warranted during any long-term course of therapy.

The use of acepromazine as a sedative and afterload reducer in horses with CHF has been described earlier in this chapter. There is limited published experience using other vasodilators in horses with CHF (see Table 9.7). Hydralazine[359,743] might be considered in the initial management of severe MR caused by ruptured chordae tendineae or endocarditis, because systemic arterial dilation can reduce the mitral regurgitant fraction. Nitroglycerin is a venous vasodilator that reduces preload and can be effective as an adjunctive treatment in hospital therapy of severe congestive heart failure and pulmonary edema.[743,753] However, clinical experience with the use of nitroglycerin in horses is limited, and the drug should be used with caution. Ointment, sublingual tablets, or transdermal patches have not been used in horses for treatment of heart failure to date. Milrinone is a phosphodiesterase III inhibitor that increases myocardial contractility and causes systemic vasodilation.[328,336,743] It can be used in the acute management of heart failure to provide inotropic support and reduce afterload. Although occasionally recommended for horses, its costs are often prohibitive and the pharmacology, effects, and adverse effects in horses with heart failure are not well studied.

Heart failure leads to an activation of the renin-angiotensin-aldosterone system (RAAS). Angiotensin-converting enzyme (ACE) inhibitors act on the RAAS by inhibiting the angiotensin-converting enzyme (ACE), which is responsible for conversion of angiotensin-I to angiotensin-II (AT-II). Therefore ACE inhibitors decrease renal sodium and water reabsorption, reduce volume overload, blunt the mechanisms leading to diuretic resistance, and cause vasodilation and decrease in myocardial oxygen demand. Furthermore, they are considered cardioprotective by decreasing myocardial remodeling and fibrosis.[743] In humans, ACE inhibitors have been shown to reduce mortality in heart failure. However, the benefits of ACE inhibitors have not been well studied in equine heart failure. There are some data available in horses regarding enalapril,[360,754-757] ramipril,[361,363,756,758,759] quinapril,[362,363,756,760] perindopril,[363] and benazepril (see Table 9.7).[363,756,761] Although effective intravenously,[360] oral enalapril at 0.5 mg/kg PO q 12 h does not demonstrate significant availability, pharmacodynamic effect, or suppression of ACE activity.[754-757] Ramipril administered at 0.1 to 0.3 mg/kg PO daily[363,756,758,759] and quinapril at doses ranging between 0.125 and 0.5 mg/kg PO[363,756,760] suppress ACE activity and reduce indirect BP in healthy horses at rest and during exercise. Ramipril has been used in a horse to treat CHF,[361] and an open-label clinical study of quinapril in horses with MR but without CHF showed some evidence for increased stroke volume and reduced regurgitation fraction.[362] The currently available data suggest that oral benazepril at doses of 0.5 to 1.0 mg/kg PO in healthy horses results in significantly greater serum ACE inhibition compared with the other ACE inhibitors.[363,756,761] Pharmacokinetics is not affected by feeding, and administration of multiple doses does not result in a cumulative effect of the drug on serum ACE inhibition. Unfortunately, the use of benazepril is cost-prohibitive in some countries. Additional studies will be required to assess the pharmacodynamics, clinical efficacy, and safety of benazepril and other ACE inhibitors in horses with volume overload or signs of CHF. Cough, impairment of renal function, hypotension, and hyperkalemia are potential adverse effects of ACE inhibitors that must be considered. Most ACE inhibitors are contraindicated in humans during pregnancy; therefore until appropriately studied, all ACE inhibitors should be considered as contraindicated in pregnant mares because of potential ill effects on the fetus.

Pimobendan is a calcium-sensitizing agent with phosphodiesterase inhibitory effects similar to milrinone. Owing to its positive inotropic and vasodilatory effects, it is increasingly used for treatment of heart failure in small animals.[762-767] A recent study in five healthy mature horses indicated that pimobendan administered intravenously at 0.25 mg/kg of body weight has positive chronotropic and inotropic effects without apparent adverse reactions. There are currently not enough data to allow the clinical use of pimobendan in horses, but this drug warrants further investigation for the treatment of heart failure in horses.[339]

For horses with valvular disease or cardiomyopathy, the development of AF may precipitate CHF. Furosemide and digoxin can effectively control CHF in many of these cases, with ACE inhibitors often being added to the treatment protocol. Quinidine is generally contraindicated in such cases, although horses may sometimes convert to sinus rhythm after the resolution of CHF by medical therapy. Reasonable long-term control of clinical signs may be achieved in some cases of chronic CHF, thus permitting a comfortable existence for the horse and—in the case of breeding animals—continued reproductive service.

Prognosis in CHF is at best guarded when irreversible structural heart disease is the cause of failure; thus the long-term outcome for life is poor. Of course, the horse with CHF requires rest to reduce demands on the heart and should never be worked or ridden owing to the risk of PA rupture, syncope, or fatal arrhythmia.[68] Valuable horses may be used for breeding; however, pregnant mares are likely to be difficult to control in the later stages of gestation related to the volume expansion that accompanies the latter stages of pregnancy.

CONGENITAL HEART DISEASE

The prevalence of congenital heart disease (CHD) in the overall equine population is unknown. In one survey of causes for neonatal death or euthanasia in 608 cases, the prevalence of congenital heart disease was 3.5%.[176] Congenital heart disease is often considered when a foal, weanling, or immature horse is identified with a prominent cardiac murmur, cyanosis, or signs of congestive heart failure.[405] Some defects are lethal to the neonate, whereas other malformations are compatible with life but limit performance or reproductive value.

A wide variety of cardiac malformations have been identified.* Theoretically, a great number of cardiac malformations could occur, including anomalies of (1) venous drainage, (2) atrial situs or septation, (3) atrioventricular connection, (4) atrial or ventricular development (including formation of the two atrioventricular valves and the septum), (5) ventricular outflow tracts, (6) semilunar valves, and (7) great vessels.[797-800] Furthermore, abnormal segmental connections might occur, leading to "discordance" in the path of systemic or pulmonary venous return relative to the pulmonary artery or aorta. These abnormalities include transposition of the great vessels and double-outlet ventricle, wherein both great vessels exit the right or left ventricular cavity.

* References 27, 28, 59, 170-186, 188, 408, 546, 552, 556, 563, 599, 728, 731-733, 768-796.

Hence, complex congenital malformations are often characterized by an unusual arrangement of the cardiac chambers and great arteries and by a markedly altered topographic cardiovascular anatomy. Echocardiographic diagnosis of complex congenital cardiac malformations is perceived as a difficult task by many clinicians and may be challenging even for the most experienced cardiologists. Even at necropsy, the correct and complete diagnosis of congenital heart disease often appears difficult and requires considerable effort. Sequential segmental analysis offers a systematic approach to complex congenital malformations of the heart, facilitating their in vivo diagnosis (using echocardiography, angiography, computed tomography, or magnetic resonance imaging) and postmortem description.[797,799-802]

Despite the wide variety of potential congenital defects, practically speaking, the most common cardiac malformations in horses involve shunting of blood at the atrial or ventricular levels, with the ventricular septal defect (VSD) most often recognized (Fig. 9.28). Isolated malformations leading to valvular stenosis or incompetency are uncommon. Rare lesions such as double-outlet right ventricle,[769,803,804] transposition of the great vessels,[173,182,805,806] persistent right aortic arch,[807-809] aorticopulmonary septal defect,[810] bicuspid pulmonary valve,[772] pulmonic stenosis,[173,184,188,772] subaortic stenosis,[780] mitral valve malformation,[187,793] persistent fetal circulation,[811] hypoplastic left heart syndrome,[174,175] endocardial fibroelastosis,[95,812] total anomalous pulmonary venous return,[813] aortic origin of the pulmonary artery,[731] double-inlet left ventricle,[814] and others have been reported but will not be discussed further. Some of the more frequently recognized defects[59,176,546] are described later in the chapter.

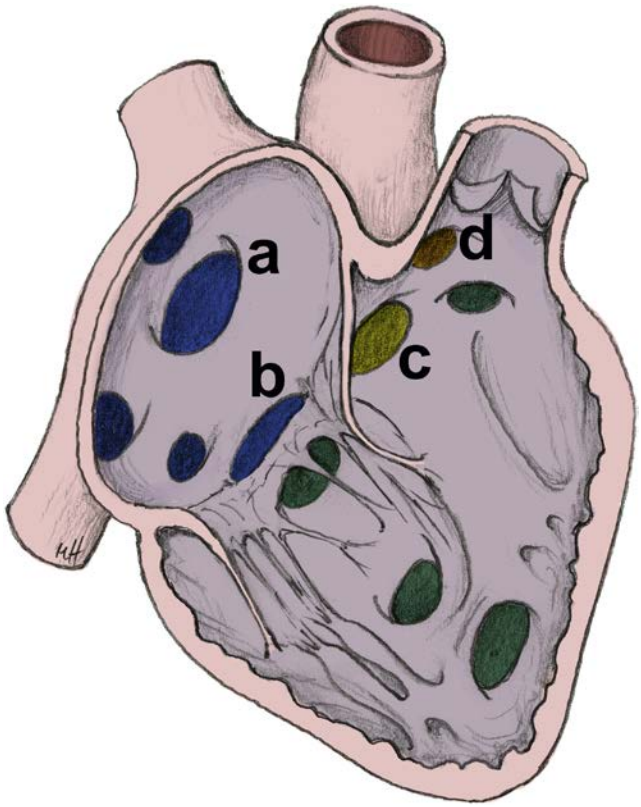

FIG. **9.28** Drawing showing the common locations of atrial septal defects (ASDs) and ventricular septal defects (VSDs). Defects located in the region of the oval fossa are called ostium secundum ASDs or oval fossa defects *(a)*. Other possible locations of interatrial communications include ostium primum *(b)*, sinus venosus, and coronary sinus defects. The most common interventricular communications in horses are the perimembranous (also called membranous or paramembranous) VSDs *(c)*, located in the membranous area of the ventricular septum, adjacent to the aortic root and the tricuspid valve. Less commonly, VSDs can be located in the subpulmonic region adjacent to the pulmonic and aortic valves (*d*, termed subpulmonic, subarterial, supracristal, or doubly committed VSDs) or in the inlet, apical, and outlet portions of the septum (muscular VSDs). (Drawing: Matthias Haab, Equine Department, Vetsuisse Faculty, University of Zurich, Switzerland.)

Pathogenesis of Congenital Heart Disease

The underlying genetic or other etiologic factors responsible for cardiac malformations in horses have not been studied. Potential but unproven causes include drugs, viral infection, environmental toxins, and nutritional disorders. Breed predispositions have been suspected for ventricular septal defects in Arabian horses, Welsh Mountain ponies, and Standardbreds.[190,405,563] Cardiac morphogenesis is complicated, but it is helpful to understand elementary aspects of cardiac development, especially as these pertain to CHD.[802,815-819] Among the fundamentals are septation of the atria, the anatomic components forming the ventricular septum, separation of the great vessels, and the normal fetal circulation.

The right and left atria are separated by incorporation of the right horn of the sinus venosus and through development and fusion of two prominent membranes, septum primum, and septum secundum. The endocardial cushions close the gap between the atrial and ventricular septa. These tissues also contribute to the atrioventricular septum, the septal segment spanning the point of mitral valve septal insertion on the left to the tricuspid valve insertion on the right. The foramen ovale, a normal atrial structure, is located approximately in the middle of the atrial septum, continues almost directly from the entry of the caudal vena cava, and creates a passageway for blood to flow from right to left atrium in the normal fetus.[820] The equine foramen ovale resembles a fenestrated finger cot and can be observed echocardiographically as a mobile septal membrane even in healthy full-term foals. This interatrial path may persist in foals with pulmonary hypertension and elevated right atrial pressures. Failure of normal development can lead to an atrial septal defect (ASD), which is typically designated by the location of the defective membrane (Fig. 9.28).

The ventricular septum is a complicated partition that includes a small membranous portion located adjacent to the aortic root and the tricuspid valve, an inlet septum immediately below the septal tricuspid leaflet, an apically located muscular or trabecular septum, and a dorsal outflow segment that separates the subaortic and the subpulmonic infundibulum (see Fig. 9.28). The ventral atrial septum connects to the dorsal ventricular septum by growth and differentiation of endocardial cushions. These swellings also form major parts of the atrioventricular valves. Insufficient development of any of these embryonic components can lead to a ventricular septal defect (VSD), the most common cardiac malformation in horses. Defective differentiation of the endocardial cushions causes various combinations of an ostium primum (ventral) ASD, an inlet VSD, malformation of the atrioventricular valves, or common atrium with a single atrioventricular valve (see Fig. 9.32B later in this chapter).

During cardiac morphogenesis, the aorta and pulmonary artery begin as a single vessel in the conus arteriosus. This common trunk, or truncus arteriosus, is eventually partitioned by migration of the conus and development of the conotruncal and spiral septa. Twisting of the spiral septum produces appropriate alignment (concordance) of the great vessels with their respective ventricular chambers. The descending aorta and pulmonary artery are connected by the ductus arteriosus Botalli, which carries fetal blood from the pulmonary artery to the descending aorta. Maldevelopment of conotruncal or spiral septal tissues leads to complicated congenital heart defects that can occasionally be seen in the horse, including persistent truncus arteriosus,[181,785,792,821,822] double-outlet right ventricle,[769,803,804] transposition of the great vessels,[173,182,805,806] and aorticopulmonary septal defect.[810] Persistence of the right aortic arch[807-809] and persistent patency of the ductus arteriosus (PDA)[408,731,768,774,809] are both rare in horses.

There are two fetal circulations, one serving the fetus and the other communicating with the placenta.[816] However, unlike the sequentially arranged systemic and pulmonary circulations in the fully developed postpartum organism, the fetal circulations are not completely separate. Functionally there are two right-to-left shunts: one across the foramen ovale and the other across the ductus arteriosus. The fetal lungs are collapsed, pulmonary vascular resistance is high, and pulmonary blood flow is minimal. Desaturated blood returning from the fetal tissues is collected in the cardinal venous system and enters the sinus venosus and right atrium. This blood is largely earmarked for the right ventricle and pulmonary artery. Most pulmonary arterial flow is diverted through the ductus arteriosus to the descending aorta, umbilical arteries, and placenta, where it is oxygenated. Well-saturated blood returning across the umbilical veins is delivered by the caudal vena cava to the right atrium where it preferentially crosses the foramen ovale to enter the left atrium, left ventricle, and ascending aorta, from where it is delivered to the fetal tissues. Note that well-oxygenated blood from the ascending aorta is delivered to the heart (through the coronary arteries) and the brain (through the brachiocephalic trunk), whereas the tissues in the caudal parts of the body receive a mixture of oxygenated blood from the ascending aorta and desaturated blood entering the descending aorta through the ductus arteriosus. These patterns change dramatically with foaling. As the lungs expand, pulmonary vascular resistance falls and pulmonary blood flow increases. The resultant increase in left atrial pressure functionally closes the foramen ovale within the first 24 to 48 hours of life.[820] Similarly, inhibition of local prostaglandins leads to functional closure of the ductus arteriosus within 72 hours after birth in most full-term foals.[408] Persistence of the right-to-left shunts, especially at the level of the foramen ovale, can occur in premature foals or those suffering from severe pulmonary disease with associated pulmonary hypertension. In these cases, shunting across the foramen ovale represents an additional mechanism for arterial desaturation and tissue hypoxia.

Clinical Pathophysiology of Shunts

Fundamental to understanding of cardiac malformations is an appreciation of shunt physiology and the responses of the heart and circulation to a shunt.[59,816,817] Shunting can be defined as an abnormal deviation of blood flow between systemic (left) and pulmonary (right) circulations. Shunting can be left-to-right, right-to-left, and bidirectional. Systemic to pulmonary (left-to-right) shunting is the expected consequence of an ASD, VSD, and PDA as long as systemic pressures and resistances exceed those on the right side and there is no stenosis limiting PA flow. Even in cases of abnormal ventricular-arterial development, as with persistent truncus arteriosus, double-outlet right ventricle, or univentricular heart, the clinical findings of a left-to-right shunt may predominate unless there is obstruction to blood flow or elevated pulmonary vascular resistance.

The actual shunt volume carried to the lungs depends on the caliber (or "restrictive" nature) of the lesion orifice and the relative vascular resistances between systemic and pulmonary circulations. Shunting may not be significant for some weeks after foaling because pulmonary vascular resistance is relatively high, and systemic arterial and left ventricular pressures are relatively low. Eventually left-to-right shunts cause an increase in pulmonary arterial flow and augment pulmonary venous return. Small shunts are easily handled at the expense of mild left-sided dilation and hypertrophy. When the pulmonary-to-systemic flow ratio (Qp:Qs) exceeds about 1.8:1, the shunt is usually considered clinically relevant, and the consequences are obvious volume overload of the LA and LV. The greater the shunt volume, the higher is the potential for left-sided or biventricular CHF from ventricular dysfunction. Pulmonary hypertension can occur in the setting of left-to-right shunting from combinations of increased PA flow, remodeling of the small pulmonary arteries, and left ventricular failure. Thus consequences of significant left-to-right shunting may include any of the following: exercise intolerance, tachypnea, pulmonary edema, respiratory distress, pulmonary hypertension, AF, pleural effusion, jugular venous distention, or ventral edema. The foal may be smaller than expected and may have a history of antibiotic therapy for presumed bouts of "pneumonia."

Right-to-left shunting produces a different clinical presentation. When a shunt is complicated by a right-sided obstruction downstream from the defect, right-to-left shunting will develop once right-sided pressures exceed those on the left. This can occur in a foal with tricuspid valve atresia and ASD or with pulmonary valve atresia and VSD. Conversely, elevated right-sided resistance can develop more chronically from pulmonary vascular disease or vascular remodeling. For example, a large left-to-right shunt can induce medial hypertrophy and intimal thickening of small pulmonary arteries that elevate pulmonary vascular resistance.[645] Though very uncommon, the resultant pulmonary hypertension may become severe and reverse the shunt to right to left (Eisenmenger's physiology). In these cases the left heart chambers are small, and the right ventricle is hypertrophied to generate systemic BP. The entrance of desaturated blood into the left side of the circulation causes arterial hypoxemia with potential consequences of tissue hypoxia, cyanosis, exercise intolerance, mild to moderate polycythemia, hyperviscosity of blood, and stunting of growth. CHF is rare, but sudden death can occur, presumably from arrhythmia. The degrees of hypoxemia and cyanosis in a right-to-left shunt depend on overall pulmonary blood flow and the degree of blood mixing between the circulations. Thus if pulmonary flow is markedly diminished, as with tricuspid atresia, severe cyanosis is likely. However, the impact of right-to-left shunting can be mitigated by overall increases in pulmonary blood flow as with truncus arteriosus or double-outlet right ventricle without pulmonary obstruction. These lesions cause less hypoxemia because the volume of oxygenated blood

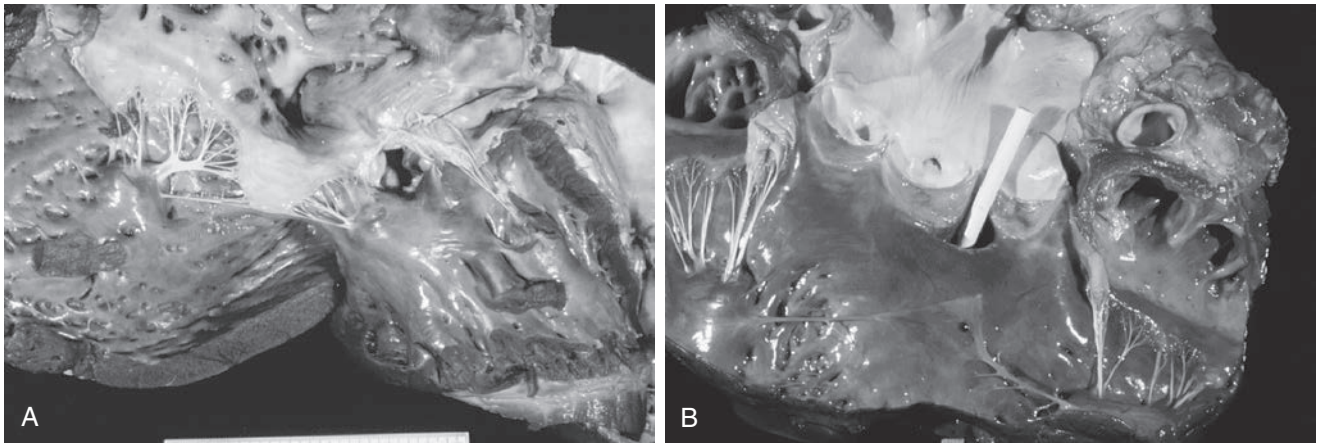

FIG. **9.29** Pathologic evaluation of ventricular septal defects (VSDs). A, Opened right ventricle (RV) from a mare demonstrating a perimembranous septal defect opening just beneath the septal leaflet of the tricuspid valve. Aortic valve cusps are visible through the defect. Congestive heart failure (CHF) occurred late in life, after the development of atrial fibrillation (AF). B, A large VSD in a horse. A probe runs through the defect. The dorsal location immediately beneath the right and the noncoronary cusps of the aortic valve are notable. Ostia of both coronary arteries are also evident.

reaching the left ventricle is increased. The location or "commitment" of a VSD relative to the subaortic or subpulmonic region also influences clinical signs because oxygenated blood from the LV can actually stream preferentially through a VSD into the aorta. In these situations, cyanosis related to any mixing of blood in the RV may be negligible and the clinical condition predominated by left-sided or biventricular CHF. If the increased pulmonary flow is sufficient to minimize arterial hypoxemia but not create heart failure, survival even beyond 5 years of age is possible.

Ventricular Septal Defects

Ventricular septal defect (VSD) is the most important CHD of horses.* A genetic basis is likely in the Arabian breed[190,563] and in Welsh Mountain ponies.[405] In the authors' experience, VSD is also encountered regularly in Standardbred horses[563] and in Quarter Horses. The VSD often accompanies more complicated heart malformations.†

The location of a VSD depends on the embryogenesis of the lesion and influences the designation and even the clinical manifestations of the defect. The nomenclature of VSDs is confusing but can be remembered by considering the main components of the normal ventricular septum (Figs. 9.28, 9.29, and 9.30). In most cases, a VSD is located dorsally ("high") on the ventricular septum, below the right and noncoronary cusp of the aortic valve on the left side, cranial to the septal tricuspid leaflet on the right, and encompassing or contiguous with the fibrous part of the ventricular septum.[563,782] Such defects are generally referred to as "perimembranous," "membranous," or perhaps more correctly, "paramembranous." Most of these holes are also "subcristal" because the VSD is located caudoventral to the supraventricular crest, separating the right ventricular inlet from the outlet. However, a very large paramembranous defect also can extend under the tricuspid valve toward the inlet septum or advance across the supraventricular crest toward the outlet septum. The (conotruncal) septal defects associated with tetralogy of Fallot (see Fig. 9.34 later) and with pulmonary atresia are usually very large and fall into the latter appellation. Sometimes the aortic root is displaced ventrocranially and straddles (or "overrides") the defect, creating a "malalignment" VSD. This is characteristic of the tetralogy of Fallot but also can be seen with large, isolated paramembranous defects. A less common location for a VSD is immediately ventral to the septal tricuspid valve within the muscular septum. Such "inlet" VSDs are typical of a complete endocardial cushion defect and commonly related to a septum primum ASD, common atrioventricular valve leaflet, or persistent atrioventricular canal, which creates a gap between all four cardiac chambers (see Fig. 9.32B later).[773,829,830] A subaortic VSD that communicates with the outlet portion of the ventricular septum directly below the pulmonic valve is variably referred to as a "subpulmonic," "subarterial," "supracristal," or "doubly committed" VSD. This lesion also places the aortic valve at risk for prolapse. Finally, apical muscular (trabecular) defects or multiple VSDs are rare but have been observed in horses. Some of these are small, whereas others have been enormous.

Many VSDs close spontaneously in people. This has also been observed in horses, but whether or not this is common in this species is unknown.[826] However, the flow across a VSD can be diminished by imposition of a cardiac valve. For example, the rim or even a major portion of a VSD may be occluded by fibrotic tissue that ensnares the septal tricuspid leaflet, rendering the defect functionally smaller and possibly creating a hyperechoic aneurysm on the right septal surface. Large defects associated with malalignment of the ascending aorta to the upper border of the remaining septum are often associated with prolapse of the right or noncoronary cusp of the aortic valve (or of the aortic root) into the defect. Aortic prolapse can effectively close even a large VSD, but at the risk of permitting chronic aortic valve insufficiency over time (see Fig. 9.30B).[563]

FIG. **9.30** Echocardiograms demonstrating ventricular septal defects (VSDs). A, This subaortic VSD is not evident from the long-axis image *(left panel)* but is visible in the short-axis tomogram *(arrows).* This Quarter Horse gelding also had pulmonic stenosis. The elevated right ventricular (RV) pressures have led to significant RV enlargement with bulging of the septum toward the left ventricle (LV). B, Malalignment and a perimembranous septal defect associated with prolapse of an aortic valve leaflet across the defect *(arrow)* (*RVW,* right ventricular wall). C, Continuous-wave Doppler study recorded from a foal with a small, restrictive VSD. The maximal velocity of nearly 6 m/sec *(arrow)* predicts a pressure difference of up to 144 mm Hg between left and right ventricles.

The pathophysiology of the uncomplicated VSD is that of a left-to-right shunt as described previously (Fig. 9.31). Much of the shunt volume pumped by the left ventricle is ejected immediately into the pulmonary artery. As pulmonary flow increases, there is increased venous return to the left atrium and left ventricle, causing left atrial enlargement and left ventricular dilation and hypertrophy that can be recognized by echocardiography. Thus the left (not the right) ventricle performs most of the extra volume work. This is made more severe if there is aortic valve prolapse with aortic regurgitation or if mitral regurgitation develops owing to left ventricular enlargement. If the shunt is large and pulmonary arteriolar resistance does not increase significantly, left ventricular failure can develop. This is most likely to occur early in life, as the high fetal pulmonary vascular resistance declines, but late cases of CHF (with AF) also have been observed. The degree of RV hypertrophy and enlargement varies, depending on the location and size of the septal defect and pulmonary vascular resistance. Large nonrestrictive defects create a functional common chamber, allowing ventricular pressures to equilibrate and leading to marked RV hypertrophy as well as pulmonary hypertension.

The clinical features of VSD are variable.[59,190,563,775,782,827] Clinical signs may be absent and the defect identified as an incidental finding. A mature horse may be presented for poor performance or with AF. Foals may be symptomatic for pulmonary edema or biventricular heart failure. Commonly, a murmur is detected incidentally during the physical examination for another problem or during a prepurchase examination (see Fig. 9.7B and Tables 9.1 and 9.4). As most defects communicate near the tricuspid valve, the most consistent physical examination finding is a harsh holosystolic or pansystolic murmur that is loudest just below the tricuspid valve region and above the right sternal border. A slightly less intense ejection murmur due to increased flow across the RV outlet is usually evident over the left base (see Fig. 9.31). The second heart sound may be split more widely than normal owing to disparate ventricular ejection times; the pulmonic component of S_2 will be tympanic if there is pulmonary hypertension. In contrast, the murmur of a subpulmonic (subarterial or supracristal) VSD is loudest over the left cranial base as the high-velocity flow enters the main PA. When a VSD is associated with a complex cardiac malformation, the murmur is likely to be loud over each side of the thorax. The severity of the defect cannot be judged based on murmur intensity. In some cases a small defect may be quite loud, whereas a large, less restrictive defect may cause a murmur related entirely to the increased flow (relative pulmonic stenosis). A holodiastolic murmur of

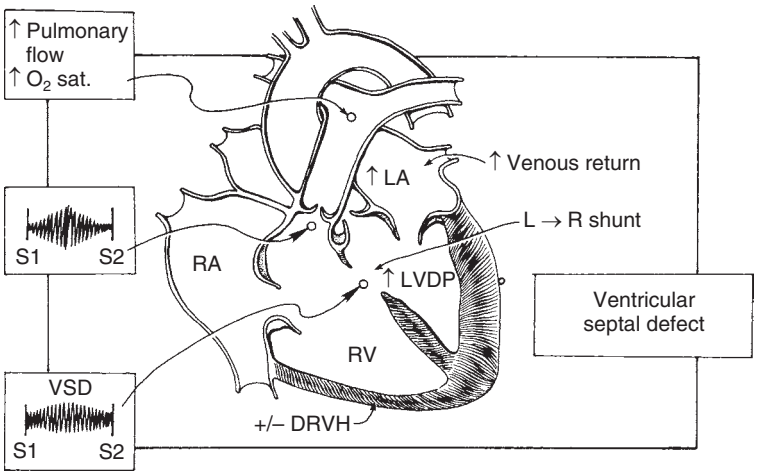

FIG. **9.31** Pathophysiology of ventricular septal defects (VSDs). aortic regurgitation indicates prolapse of an aortic cusp and increases the likelihood that the lesion is relatively large. Substantial aortic regurgitation is associated with a hyperdynamic arterial pulse and an increased pulse pressure. If there is significant left ventricular volume overload, the mitral valve may become incompetent, and a holosystolic murmur of mitral regurgitation may be evident over the left apex. The rare trabecular (muscular) VSD may also create a systolic murmur over the left or right apex. The VSD associated with pulmonary atresia or persistent truncus arteriosus may not create a substantial murmur, but the increased flow through the dilated single vessel usually generates a loud ejection murmur over each side of the chest. If significant cardiomegaly develops, atrial and ventricular premature complexes, or even AF, may be recognized.

Diagnostic studies are needed to confirm the lesion and determine the severity. The performance history is a useful overall indicator of impact, and the horse with an excellent work history is unlikely to have a large defect. The ECG is unreliable for diagnosing cardiomegaly in horses but is indicated in the setting of an arrhythmia. Thoracic radiography can be useful in foals to demonstrate cardiomegaly (see Fig. 9.19A), the pulmonary circulation, the lungs, and the pleural space. 2D echocardiography and color Doppler imaging establish the diagnosis, and spectral Doppler examinations are useful for assessing the hemodynamic burden of the defect.[344,552,563,590,819] Complex congenital disease must be excluded.

2D echocardiography successfully delineates the VSD in almost every case provided sufficient imaging planes are obtained (see Figs. 9.25 and 9.30). It is important to collect long-axis images of the left ventricular outflow tract and aortic valve, as well as short-axis images at the level of the left ventricular outflow tract, at and just ventral to the aortic leaflets. The typical paramembranous defect appears under the aortic valve and adjacent to the septal leaflet of the tricuspid valve. A true defect is characterized by a relatively echogenic tissue interface, whereas an area of false echo dropout tends to be gradual. Most defects can be imaged in orthogonal (long-axis/short-axis) planes. The ostium of the right coronary artery of the horse is relatively large and may be confused with a subpulmonic VSD in short-axis image planes. It also should be noted that a true inlet VSD of an endocardial cushion defect, located immediately ventral to the septal tricuspid valve, might not be easily seen in standard planes. Tipped or oblique views that show both AV valves may be required. Similarly, finding a muscular, apical, or small subpulmonic defect requires more imaging experience and nonstandard imaging planes and is greatly assisted by color Doppler studies.

Attempts should be made to identify the largest diameter of the defect in complementary planes and compare this with the size of the aortic root, as orifice size is an important prognostic factor. Note that the size of the VSD is often underestimated with 2D echocardiography and overestimated with color-flow Doppler echocardiography. Although there are limitations to echocardiographic sizing of the VSD, a defect exceeding 2.5 cm in diameter or a VSD-to–aortic root diameter ratio of greater than 0.4 identifies a large defect with greater likelihood of clinical signs.[563] There is usually some enlargement of the left side of the heart, but cardiac dimensions fall within the normal range if the shunt is small. However, 2D or M-mode evidence of left-sided cardiac dilation, right ventricular enlargement, or marked dilation of the main PA suggests a hemodynamically relevant VSD and one more likely to affect performance or survival. Moderate to severe enlargement of the LA and LV is concerning and increases the risk for AF, PHT, and CHF. Noticeable systolic enlargement of PA indicates pulmonary overcirculation, whereas marked PA enlargement during both systole and diastole suggests PHT.

Identification of shunting across a VSD is confirmed using color Doppler studies. There will typically be a region of flow acceleration proximal to the defect and a high-velocity, turbulent flow entering the right ventricle distal to the defect during systole, with low-velocity, uniform color shunting noted during diastole. Color Doppler imaging is extremely helpful for identifying a very small VSD or one with an atypical location. Aortic regurgitation is identified in some horses, and the regurgitant flow is often directed into the VSD, resulting in high-velocity diastolic shunting. Continuous-wave Doppler is used to estimate the pressure difference between the two

ventricles, as velocity (in meters per second) is proportional to the instantaneous pressure difference across the ventricles (by the modified Bernoulli equation: $\Delta p = 4 \times v_{max}^2$; see Figs. 9.25D and 9.30C). A relatively small VSD is "restrictive" to flow, and the peak shunt velocity will generally exceed 4.5 m/sec, assuming proper alignment to shunt flow.[563] With good alignment, peak velocities greater than 5 m/sec (corresponding to a left-to-right pressure gradient of greater than 100 mm Hg) are expected. Lower shunt velocities (less than 4 m/sec), along with higher pulmonary artery ejection and mitral inflow velocities, indicate a greater shunt volume. In the setting of pulmonary hypertension, pulmonic stenosis, or systemic hypotension, the velocity of left-to-right shunting will also be lower; when pulmonary hypertension is present, a tricuspid regurgitation jet of greater than 3.4 m/sec may be identified.

Potential outcomes of the isolated VSD include the following: (1) tolerance of the lesion; (2) partial or complete closure of a VSD by adherence of the septal tricuspid leaflet, fibrous tissue, right ventricular hypertrophy, or aortic valve prolapse; (3) progressive aortic regurgitation; (4) progressive mitral regurgitation owing to left-sided chamber enlargement; (5) atrial fibrillation; (6) left-sided or biventricular CHF; (7) pulmonary hypertension (with left-to-right shunting); or (8) reversal of the shunt with development of arterial hypoxemia and cyanosis. The last situation is rare and would be caused by either severe pulmonary vascular disease (Eisenmenger's physiology) or fibromuscular obstruction in the right ventricular outlet leading to subpulmonic stenosis.

The horse with a relatively small-diameter paramembranous defect, high-velocity left-to-right shunt, mild cardiomegaly, relatively normal right ventricular cavity, and normal heart rhythm probably has a restrictive VSD that will be well tolerated. Most of these animals can perform sufficiently in the show ring, as a hunter-jumper, or even as an endurance horse or racehorse. Moderate defects are often well tolerated at rest, but performance in high-intensity sports might be affected. Large defects that are associated with echocardiographic evidence of moderate to severe cardiomegaly, right ventricular hypertrophy, aortic root prolapse, aortic malalignment, marked valvular regurgitation (AR, MR, TR), evidence of pulmonary hypertension, atrial fibrillation, or presence of other comorbidities are prone to complications and carry a less favorable prognosis for performance or life regardless of current clinical signs.

According to the 2014 American College of Veterinary Internal Medicine (ACVIM) consensus statement on the management of equine athletes with CV abnormalities,[68] horses with VSDs should be examined annually. Horses with an isolated small (restrictive) VSD and minimal cardiomegaly can be considered safe to compete, whereas horses with larger defects should be evaluated on a case-by-case basis in consultation with a specialist experienced in equine cardiology. Exercise (ECG) testing is recommended in horses with moderate to large VSDs, in prepurchase situations, or when performance is suboptimal. Breeding of affected animals generally should be discouraged, especially in Arabian horses and Section A Welsh Mountain ponies.

Definitive therapy for VSD would involve cardiopulmonary bypass surgery that is impractical in horses. Surgical banding of the PA elevates right ventricular pressures and reduces left-to-right shunting; however, this procedure also limits CO and is not advised. New "hybrid" procedures involving catheter devices delivered by a transventricular approach and guided by echocardiography or angiography are now possible, though perhaps not practical in the majority of affected patients. Medical management of CHF or of arrhythmias associated with CHD can be considered. However, even if the response to treatment is good, the horse should not be used.

Atrial Septal Defects

Atrial septal defects, including endocardial cushion defects, are quite uncommon in foals.* As indicated earlier, an ASD may involve different portions of the atrial septum (see Fig. 9.28) and is more likely to be observed with complex congenital cardiac defects, particularly with tricuspid or pulmonary atresia. An isolated ASD may be clinically irrelevant, with no significant murmur or clinical signs. Moderate to good exercise capacity may be expected because left-to-right shunting decreases as the systemic to pulmonary vascular resistance ratio declines with exercise. In the case of a large ASD, left-to-right shunting leads to right-sided volume overload and pulmonary overcirculation and potentially to pulmonary vascular injury. Atrial fibrillation has been observed in conjunction with ASD. Large defects are visible echocardiographically (Fig. 9.32A), but thinning, billowing, or flailing of the atrial septum in the region of the oval fossa can lead to an incorrect diagnosis of an ASD, particularly in cases with smaller defects and suboptimal image quality.[344,819] Doppler echocardiography and saline contrast studies (by injection of agitated saline into the jugular vein) can confirm the presence and direction of the shunt and estimate its severity. Thereby, it must be considered that physiologic blood flow entering the RA from the caudal vena cava and the LA from the pulmonary veins can easily be mistaken for transseptal flow on color Doppler recordings. Similarly, streaming of vena cava flow in the RA can cause a distinct negative contrast pattern within the RA during saline contrast studies, mimicking left-to-right transseptal flow.[344,831]

Complete endocardial cushion defects are rarely seen but are serious, usually leading to CHF or AF at an early age. Components of this defect typically include a large ASD involving the primum and the atrioventricular septa, a common atrioventricular valve leaflet, and often an inlet VSD (see Figs. 9.28 and 9.32B). The ventricles may be partitioned normally, unequally with one rudimentary ventricular chamber, or not at all, creating a single ventricle. In the most severe cases there is a common atrioventricular canal, a single common atrioventricular valve, and a single ventricle from which both great vessels exit. The clinical signs of a complete endocardial cushion defect are variable. The foal with two ventricles and an unobstructed outlet to the pulmonary arteries will be hemodynamically similar to one with a large VSD. When a common ventricle is present, varying degrees of cyanosis may be observed. A systolic murmur is typical and may reflect flow across the VSD, ventricular outflow, or atrioventricular valve regurgitation. A 2D echocardiogram can reveal the lesions and Doppler echocardiography the intracardiac shunts and AV valvular regurgitation. CHF may supervene, and the prognosis is poor.

Patent Ductus Arteriosus

Patent ductus arteriosus (PDA) is rare as an isolated congenital cardiac defect in foals and is detected most frequently in combination with other, more complex malformations

* References 175, 177, 180, 599, 733, 773, 784, 829, 830.

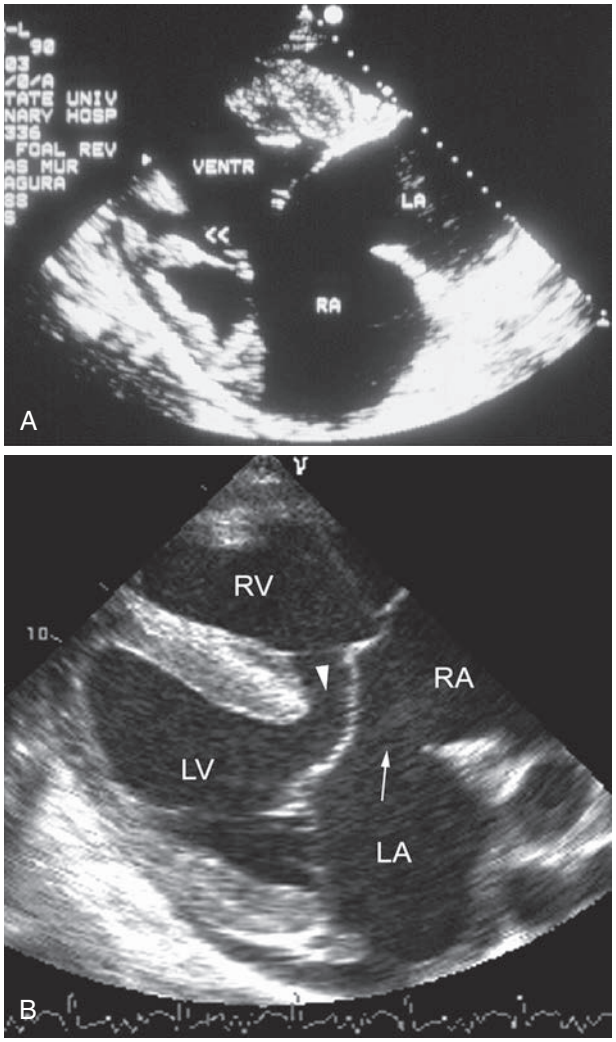

FIG. **9.32** A, Echocardiogram demonstrating a primum atrial septal defect (ASD) in a foal with complex congenital heart disease that included a common *(left)* ventricle, rudimentary *(right)* ventricle, and double-outlet ventricle. The septal defect is evident between the four cardiac chambers. The dorsal secundum septum *(right)* is present, as well as the apical ventricular septum *(left).* B, Long-axis image from a foal with a complete endocardial cushion defect. The primum ASD is evident in the ventral atrial septum *(arrow),* and an inlet ventricular septal defect (VSD) component *(arrowhead)* is observed below the closed common (or straddling) atrioventricular valve. Normal mitral and tricuspid septal leaflets would insert into the septum at slightly different levels (with tricuspid septal leaflet inserting more ventrally than the mitral septal leaflet.)

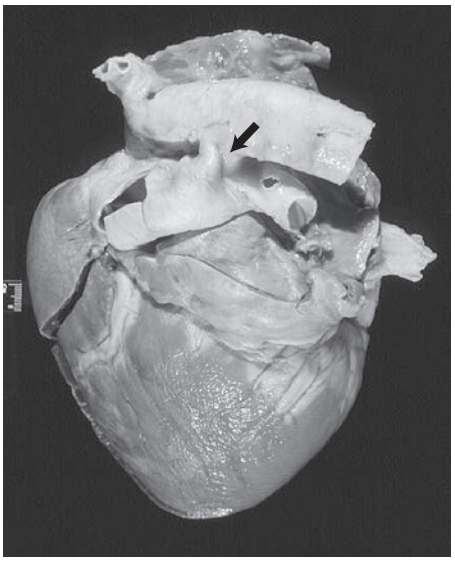

FIG. **9.33** A postmortem demonstration of the ductus arteriosus *(arrow)* between the descending aorta and the pulmonary artery in a foal with complex congenital heart disease.

(Fig. 9.33).* The ductus arteriosus is a fetal vessel, derived from the left sixth aortic arch, that permits shunting from the PA to the descending aorta in the fetus. At birth the ductus arteriosus normally constricts in response to increased local oxygen tension and inhibition of prostaglandins. It is functionally closed 72 hours after birth in the vast majority of foals. If the ductus arteriosus does not close, a left-to-right shunt from the aorta to PA occurs. Although there may be some hereditary predisposition to PDA in other species, this lesion is so rare as an isolated congenital defect that this is not a significant concern. Premature foals, foals with persistent pulmonary hypertension, and foals whose dams have been given prostaglandin inhibitors might be more susceptible to the development of a PDA.

The clinical signs depend on the magnitude of the shunting through the PDA, which is determined by ductal diameter and vascular resistance in the pulmonary circulation. Physical examination findings (with a left-to-right PDA) include a continuous machinery murmur and thrill, usually loudest over the main PA (craniodorsal to the aortic valve area), and bounding arterial pulses. Differential diagnosis includes other systemic-to-pulmonary shunts in association with complex congenital heart disease.

Echocardiography will reveal volume overload of the PA, LA, and LV.[344,819] The severity of these findings depends on the magnitude of the shunt. Direct visualization of the PDA is not always possible by 2D echocardiography because the ductus arteriosus may be obscured by overlying lung. Ductal flow is best identified from the left cranial thorax by Doppler echocardiographic examination of the main PA, which reveals continuous, high-velocity, turbulent flow directed toward the pulmonary valve. Cardiac enlargement and increased pulmonary vascularity may be detected in neonatal foals with a PDA, as well as radiographic evidence of pulmonary edema if the foal has developed CHF. Cardiac catheterization reveals elevated PA and pulmonary capillary wedge pressures and increased PA oxygen saturation. The heart should be evaluated carefully for other congenital cardiac defects before surgical or catheter-based intervention is considered as complex cardiac malformations are likely in a foal with PDA. Late complications of this lesion include rupture of the PA.

Tetralogy of Fallot

The tetralogy of Fallot is one of the more common congenital cardiac anomalies in foals responsible for right-to-left shunting, arterial desaturation, and cyanosis.[171,178,183,190,833-837] The four lesions are (1) large paramembranous-outlet VSD, (2) cranial and rightward (dextro-) positioning of the aorta with overriding of the septal defect, (3) right ventricular outflow

* References 171, 175, 182, 184, 408, 409, 731, 768, 774, 809, 832.

tract obstruction, and (4) right ventricular hypertrophy. Outflow obstruction can be due to subvalvular fibromuscular obstruction, valvular pulmonic stenosis, or hypoplasia of the PA. Ventricular hypertrophy is caused by right ventricular outflow obstruction and the large, unrestrictive, VSD that functionally creates a "common ventricle." Blood leaves the heart along the path of least resistance such that pulmonary flow depends on the severity of right ventricular outflow tract stenosis. As previously discussed, the degree of cyanosis and severity of clinical signs depend on the volume of blood traversing the lungs. In some horses, a PDA is also present (pentalogy of Fallot), and this defect reduces signs by increasing pulmonary flow, left heart filling, and systemic arterial hemoglobin saturation. Tetralogy of Fallot must be distinguished from other causes of cyanotic heart disease, including tricuspid atresia, pulmonary atresia with VSD, transposition of the great vessels, double-outlet right ventricle with pulmonic stenosis, truncus arteriosus, and total anomalous pulmonary venous connection.[816,817]

Affected foals are usually smaller than normal, lethargic, and intolerant of exercise. Cyanosis is most evident after activity and is variably present at rest. Arterial blood gas analysis demonstrates hypoxemia with normal or reduced partial pressure of carbon dioxide (P_{CO_2}). Auscultation is typically characterized by a loud systolic murmur over the pulmonic valve area on the left side caused by (sub-) pulmonic stenosis. The second heart sound is usually unremarkable. Although polycythemia can be significant, it is usually mild, even when arterial oxygen tensions fall to 50 to 70 mm Hg.

Echocardiographic evaluation is diagnostic and reveals a large, unrestrictive VSD, malalignment and overriding of the aortic root, right ventricular outflow tract obstruction, and right ventricular hypertrophy (Fig. 9.34).[344,819] Shunting can be identified by color Doppler or saline contrast echocardiography initiated by injection of agitated saline into the jugular vein. Both studies will demonstrate a right-to-left or bidirectional shunt. Conventional spectral Doppler studies can be used to delineate the shunt (typically bidirectional, low-velocity flow of less than 2 m/sec) and right ventricular outflow obstruction (high-velocity flow exceeding 4 m/sec).

Although it is possible for horses to live for a number of years with tetralogy of Fallot, most affected animals are humanely destroyed due to the poor prognosis for life. Affected horses should not be used or bred if they survive to maturity.

Pulmonary Atresia with Ventricular Septal Defect

Pulmonary atresia with VSD is rare, having been observed most often in Arabian foals (see Fig. 9.34C).[171,172,186,790] This malformation represents the exaggerated form of tetralogy of Fallot, with these findings: (1) the right ventricular outlet does not connect into the pulmonary artery, (2) the right ventricle is hypertrophied, (3) a large malalignment VSD is present (in most cases), and (4) the fetal truncus arteriosus has been partitioned so unequally that the aorta is markedly dilated and the pulmonary trunk atretic or severely hypoplastic. Without careful ultrasound studies (or necropsy dissection) of the pulmonary circulation, the dilated aorta can be mistaken for a persistent truncus arteriosus, hence the moniker "pseudotruncus

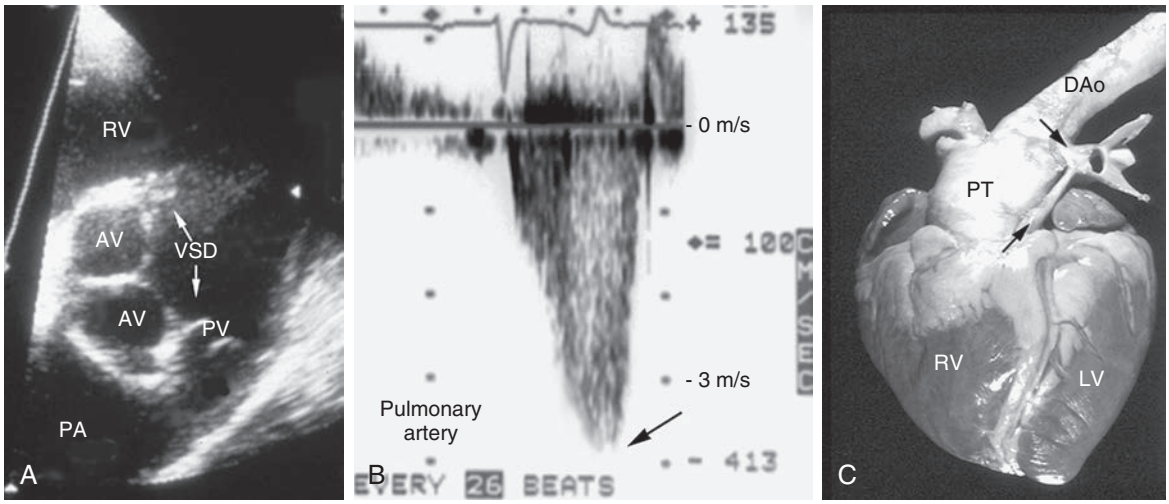

FIG. **9.34** Tetralogy of Fallot. A, Echocardiogram from a filly with tetralogy of Fallot. The image plane shows the right ventricle (RV), right ventricular outlet with stenotic (hypoplastic) pulmonary valves (PV), and poststenotic dilation of the pulmonary artery (PA). There is a very large ventricular septal defect (VSD; *arrows*) connecting the base of the dilated aorta with the right ventricle. Two aortic valve leaflets (AV) are evident in this off-angle plane. B, Continuous-wave Doppler echocardiogram from a horse with tetralogy of Fallot. The Doppler study demonstrates pulmonary stenosis. High-velocity systolic flow is evident, exceeding 4 m/sec. Velocity scale is to the right; ECG at the top. C, Left lateral view of a heart obtained from a foal that died from pulmonary atresia, the "exaggerated" form of tetralogy of Fallot. Because of unequal septation of the truncus arteriosus, a markedly dilated aorta (*PT,* pseudotruncus arteriosus), and a rudimentary, imperforate main pulmonary artery *(lower arrow)* are present. Atresia of the pulmonary valve was evident on opening the heart. Pulmonary artery flow was derived from the ductus arteriosus *(upper arrow),* which serves two underdeveloped pulmonary arteries. *DAo,* Descending aorta; *RV,* right ventricle; *LV,* left ventricle. (From Bonagura JD: Congenital heart disease. In Robinson N, editor: *Current therapy in equine practice,* ed 5, Philadelphia, 2003, WB Saunders.)

arteriosus." Owing to the atretic pulmonary valve, pulmonary blood flow must be derived either from a PDA or the aorta. In the latter instance, the systemic collaterals are usually from bronchial arteries. Pulmonary atresia with an intact ventricular septum has been diagnosed rarely.[791,832]

The diagnosis of pulmonary atresia is usually stimulated by clinical findings of cyanosis, cardiac murmur, and stunting in a foal or weanling. Diagnosis is confirmed by echocardiography.[344,819] Careful imaging can identify the main lesions outlined previously. Of diagnostic importance is the inability to identify the pulmonic valve in the rudimentary right ventricular outflow tract (though a small pouch may be seen). Careful ultrasound examination of the ascending aorta and aortic arch from the right and left sides of the thorax will fail to reveal a normal origin for the pulmonary trunk or an origin of the PA directly from a truncus arteriosus. The bifurcation of the PA may be found from a cranial imaging position, and continuous flow into that vessel documented by Doppler echocardiography suggests that pulmonary blood flow is derived from the ductus arteriosus or a collateral systemic artery.

Truncus Arteriosus Communis (Common Arterial Trunk)

The failure of the fetal truncus arteriosus to partition into the aorta and PA represents a rare anomaly of the equine heart.[181,785,792,821,822,838] In this condition, the fetal truncus never partitions, and both ventricles continue to develop, communicating with the truncus arteriosus across a large malalignment-type VSD. Systemic, coronary, and PA flows each arise from the truncus, which is guarded by a truncal valve (that can be incompetent or stenotic). Pulmonary blood flow originates from one or more pulmonary arteries connected directly to the truncus arteriosus or indirectly from systemic to pulmonary collateral vessels.[802,816,817]

The pathophysiology and clinical findings of this malformation depend largely on the magnitude of pulmonary blood flow. If the PA origins are not stenotic and if pulmonary vascular resistance remains relatively low, the clinical condition resembles a left-to-right shunt, except for right-to-left mixing of blood across the VSD. However, the degree of arterial hypoxemia may not be severe, and cyanosis may not be obvious. Conversely, high pulmonary vascular resistance or obstruction to flow at the truncal origin of the PA is associated with arterial desaturation and findings similar to pulmonary atresia.

Clinical examination usually indicates a systolic cardiac murmur. The mucous membranes may be pink or cyanotic. If there is marked left-to-right shunting, CHF may occur. With careful ultrasound examination, the truncus and origin of the pulmonary arteries may be identified, allowing the condition to be distinguished from pulmonary atresia with VSD.[344,819] Furthermore in some cases an abnormal truncal valve (with four leaflets) may be evident, further supporting the diagnosis. Management is best accomplished by consultation with a cardiac specialist.

Tricuspid Atresia

Another differential diagnosis for cyanotic heart disease is atresia of the tricuspid valve.* This malformation dictates right-to-left shunting of systemic venous blood at the atrial level. The atrial shunt may be across a true ASD or a patent foramen ovale. Because all venous return must mix in the left atrium, this malformation generally causes marked hypoxemia with cyanosis. Affected foals rarely survive to weanling age unless there is also a left-to-right shunting VSD into a functional right ventricular outflow tract that provides good pulmonary flow. Otherwise, pulmonary flow must come from a ductus arteriosus or systemic collaterals (e.g., bronchial arteries). Most foals are stunted, nurse poorly, and exhibit severe exercise intolerance and cyanosis at rest. Arterial oxygen tension can be very low (40–60 mm Hg). Echocardiography reveals a markedly dilated right atrium and coronary sinus, atretic tricuspid valve, and rudimentary right ventricle (larger if there is a functional left-to-right shunting VSD). Atrial shunting that allows systemic venous return to empty into the left atrium must be observed. Abnormal flow patterns can be verified by saline contrast or color Doppler echocardiography. The prognosis is grave.

VALVULAR HEART DISEASE

Healthy cardiac valves maintain normal antegrade flow in the heart and prevent significant regurgitation of blood. Diseased cardiac valves, which can be stenotic or incompetent, limit cardiac output and place an increased workload on the heart. Stenotic valvular lesions in horses are typically congenital in nature and are extremely rare; however, acquired valvular regurgitation (also called valvular insufficiency or valvular incompetency) is common.* The majority of valvular insufficiencies in horses are caused by degenerative valve disease or are related to high-level training.† Infective (bacterial) endocarditis,‡ noninfective valvulitis, and ruptured chordae tendineae[38,212-214,845] are infrequent causes of valvular disease. Box 9.2 summarizes important causes of valvular dysfunction. Degenerative valvular disease and infective endocarditis are the valvular problems most often encountered by the equine practitioner, and are the focus of this section.

The clinical relevance of a valvular lesion depends largely on the severity of regurgitation across the valve. It is clear that many horses adapt to trivial, mild, or even moderate valvular regurgitation with no apparent consequence on performance.* The severity of valvular regurgitation is related to the dynamic cross-sectional area of the regurgitant orifice, the pressure gradient driving blood across the valve, and the time allowed for regurgitation, because not all incompetent valves leak throughout systole or diastole.[74] Regardless of the volume, the movement of blood from a high-pressure to a low-pressure chamber is associated with a high-velocity jet that is proportional to the pressure drop between source and sink. The production of high-velocity jets leads to disturbed flow (with turbulence) and in many cases an audible cardiac murmur, the hallmark clinical feature of valvular heart disease (Fig. 9.35; also see Figs. 9.9 and 9.23D).

Valvular incompetency can be diagnosed by auscultation† or with Doppler echocardiography.‡ Doppler studies are

FIG. **9.35** Phonocardiograms of cardiac murmurs caused by valvular heart disease. A, A holosystolic murmur of mitral regurgitation (MR) in a horse with chronic valvular degeneration. B, A variable, late systolic murmur of MR related to mitral valve prolapse. The murmur has a crescendo and peaks at end systole *(arrow)*. Heart sounds are indicated. The murmur obscures the second sound. C, A holodiastolic, vibratory murmur of aortic regurgitation (AR) with presystolic accentuation. The accentuation probably is related to atrial contraction, altered ventricular volume and pressure, and an incremental increase in regurgitant volume.

highly sensitive for identification of valvular incompetency and represent the gold standard for identification of valvular dysfunction. However, many horses with normal auscultation findings also demonstrate valvular regurgitation by Doppler examination. Most cardiologists consider these "silent" valvular leaks as normal,[71,74] especially when observed on the right side of the heart. Even on the left side silent regurgitation is often observed by color Doppler examination.

Some of these flow signals are brief, representing "backflow" or valve closure signals; these are easily misinterpreted unless carefully timed by spectral Doppler or color M-mode examinations. Certainly some cases of silent regurgitation represent the earliest signs of degenerative valvular disease. But there is no clinical benefit to screening horses by Doppler, nor is the approach practical or even predictive of future outcome. Thus cardiac auscultation remains the most clinically important method for identifying clinically relevant valvular disease. Echocardiography including Doppler studies is used to verify the source of a pathologic murmur, identify underlying structural heart lesions, assess atrial and ventricular function, and quantify the degree of cardiac remodeling that has developed in response to the lesion. It is also emphasized that usually there is no echocardiographic or Doppler correlate to the functional ejection murmur.

Although examiners usually discount "silent" regurgitation, the clinical relevance of *audible* valvular regurgitation also must be placed in context. For example, examination of high-performance athletes will demonstrate murmurs of tricuspid, mitral, or aortic valvular insufficiency in many of these horses.[70,75,208-211,586] These findings are readily verifiable by Doppler imaging. In one study of 2-year-olds,[75] the prevalence of tricuspid and mitral regurgitant murmurs increased significantly over a 9-month training period to an incidence of 25.5% and 21.8%, respectively. Similarly, studies on young Standardbreds and Thoroughbreds in training revealed an increase in the prevalence of valvular regurgitation detected by echocardiography without noticing effects on racing performance.[70,208,211] The causes of these changes and the interpretation of these findings are problematic, especially when referenced to the clinical benchmark of "normal." It is possible that high-level training induces changes in ventricular geometry (i.e., physiologic cardiac hypertrophy, athlete's heart)[208,211,588] or in valvular thickness related to cardiovascular work, elevations of BP during training, or other factors. Nevertheless, whether these murmurs are actually "normal" or not, it is clear that the clinical importance of a regurgitant murmur in a horse must be interpreted with caution and certainly with the perspective of clinical and imaging findings.

The most practical evaluations for assessing the clinical relevance of a heart murmur are the age, work history, physical examination findings, and echocardiography. Other studies such as electrocardiography and exercise testing provide further information by which to judge the importance of a murmur. As a general rule, significant regurgitant murmurs tend to be loud and long. However, the intensity of an insufficiency murmur is related not only to the regurgitant volume but also to the driving pressures of blood and the physical characteristics of the thorax. Therefore although the intensity of a heart murmur can be graded by the examiner (see earlier in this chapter), it is not possible to grade the severity of regurgitation by auscultation alone. Relatively loud murmurs may be associated with regurgitant volumes that are inconsequential to an individual horse, especially when the murmur is high-pitched, vibratory, or musical in quality. Thus although clinically significant valvular heart disease is best identified by auscultation (see Tables 9.1, 9.3, and 9.4), the clinical relevance of a valvular regurgitation must be assessed in other ways.* This approach is emphasized below. A recent consensus statement formulated by a group of experts in the field of equine cardiovascular medicine summarizes the current recommendations for management of equine athletes with valvular heart disease, and the reader is referred to this statement for additional information.[68]

Mitral Regurgitation

Mitral regurgitation (MR) is commonly detected in horses.[68,83,407,843] The etiopathologic basis of mitral valve incompetency may involve any of the following: high-level training, degenerative thickening, prolapse of the valve, ruptured chordae tendineae, bacterial endocarditis, noninfective valvulitis, primary or ischemic myocardial disease leading to papillary muscle dysfunction, severe LV dilation, congenital malformation of the valve, and idiopathic disease (Figs. 9.36, 9.37, and 9.38; also see Box 9.2).† Degenerative, fibrotic thickening of the mitral valve has been observed at necropsy in mature horses and is probably the basis for most cases of mild to moderate MR, including those with "normal" 2D echocardiographic imaging. The basis of mitral valve prolapse is uncertain but could involve connective tissue disease of the leaflets, stretched chordae tendineae, minor chordal ruptures, or injury to a papillary muscle. Ruptured mitral valve chordae

* References 70, 71, 73, 75, 208-211, 390, 391, 406, 560, 586, 602, 849.

FIG. **9.36** A, Postmortem images from a horse with mitral regurgitation (MR) and congestive heart failure (CHF) caused by severe degenerative valvular disease. The left ventricle (LV) is opened and the septal or anterior mitral valve leaflet (AMV) is shown. The free edges of the valve or cusps are slightly thickened for an equine valve. The body of the valve is very irregular and thick, changes most evident when viewed in close-up (see inset at lower left). The cut surface of a papillary muscle (PM) and intact chordal attachments to the valves are evident *(arrows)*. The *arrowheads* point to the LV moderator band or trabeculae septomarginalis, part of electrical conduction system. Myxomatous degeneration of the valve was evident on histopathology. The cause was unknown. B, Chronic suppurative valvulitis caused by chronic endocarditis has led to scarring, thickening, and distortion of the mitral valve. This horse developed severe left-sided CHF. Noninfective valvulitis also is recognized sporadically in horses, particularly in younger animals.

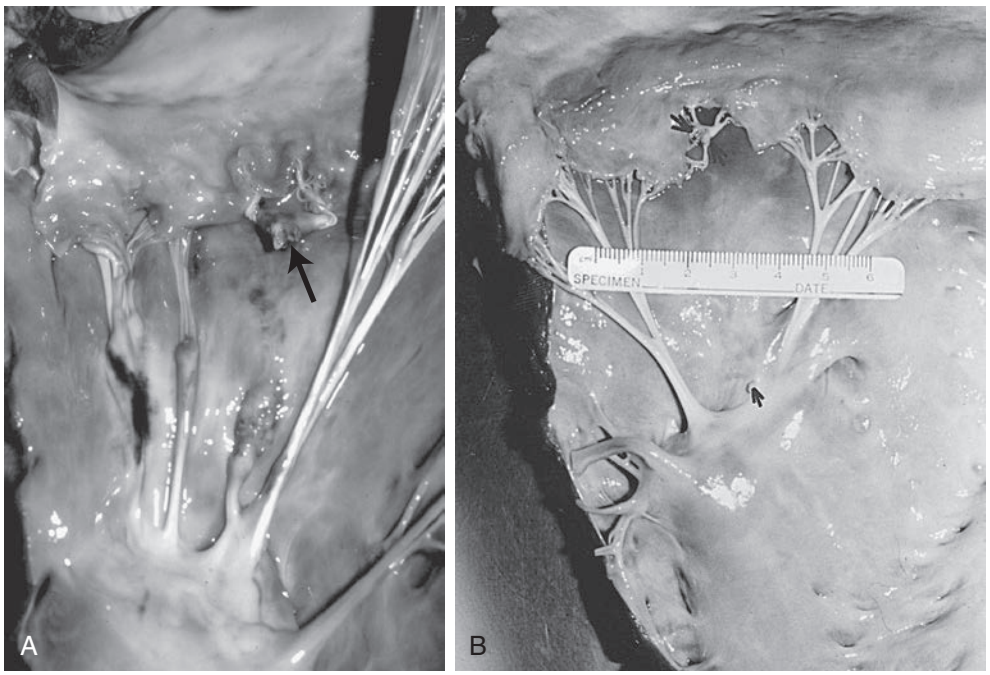

FIG. **9.37** Rupture of the mitral valve chordae tendineae. A, Acute rupture of a chorda tendinea in a horse with lymphocytic plasmacytic valvulitis. The flail mitral cusp actually has twisted because of loss of support. The ventral portion of the tear is obvious adjacent to intact chords. B, Chronic rupture of a chorda tendinea in a horse. The contraction of the scarred segments *(arrow)* is notable.

tendineae with flail mitral leaflet can occur in animals of any age, including foals.[38,212-214,845] Chordal ruptures, which often involve the accessory mitral cusps, may lead to severe MR with fulminant acute CHF. Necropsy findings in these cases often show degenerative thickening of the ruptured strand; rarely endocarditis is involved. Although uncommon, infective endocarditis can lead to ulceration, vegetation, or chordal injury and substantial MR (see later). The authors have observed MR due to severe mitral scarring and thickening in weanlings and young horses. The cause of these lesions is

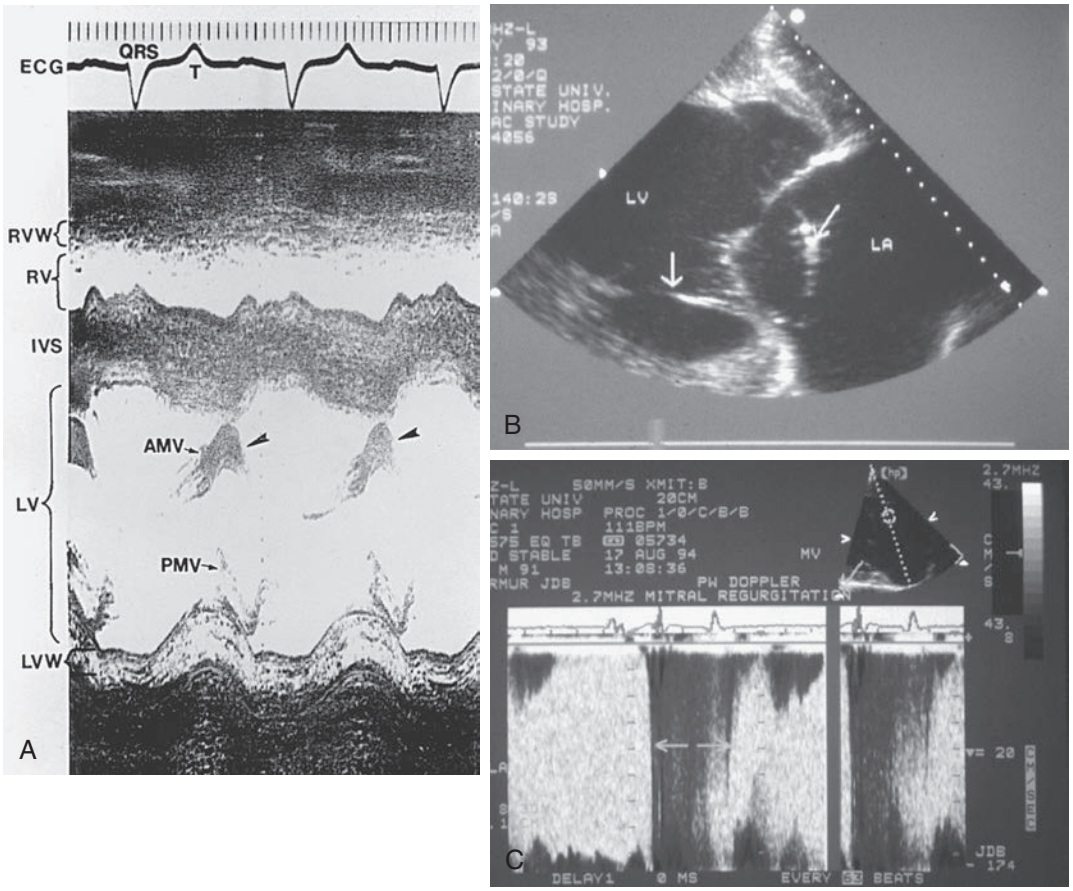

FIG. **9.38** Echocardiograms recorded from horses with mitral regurgitation (MR). A, M-mode study demonstrating significant thickening of the anterior mitral valve (AMV) leaflet *(arrows).* This would be compatible with endocarditis or severe valvulitis (*RVW,* right ventricular wall; *RV,* right ventricle; *IVS,* intraventricular septum; *LV,* left ventricle; *LVW,* left ventricular wall). B, Flail mitral leaflet *(right arrow)* in a horse with multiple chordae ruptures. The prolapsed portion of the mitral valve forms a curved echodense line in the dilated left atrium (LA), whereas the other valve portions are to the left of this echocardiogram. A normal chord is evident *(left arrow).* C, Pulsed-wave Doppler study recorded from the LA demonstrating a turbulent, high-velocity, aliased systolic jet of MR in a Thoroughbred horse. The duration of the event is shown *(arrows).*

unknown, but the nonsuppurative valvulitis identified might be related to an immune-mediated process. Severe aortic insufficiency, nonrestrictive ventricular septal defects, or rarely myocarditis, cardiomyopathy, or myocardial infarction can lead to mitral insufficiency through dilation of the mitral annulus or loss of papillary muscle support.

The clinical presentation of the horse with MR varies. Mitral regurgitation is often an incidental finding detected during a routine examination. In other situations, MR might be identified in a horse with suboptimal performance or overt clinical signs of heart failure. As indicated previously, relatively soft murmurs of MR are common in high-performance horses.[70,75,208-211,586] When MR is only mild to moderate, significant left atrial dilation and LV volume overload are not evident, left atrial pressure (as estimated by pulmonary capillary wedge pressure) increases little compared with healthy controls,[354,355,639] and the horse often performs satisfactorily.[355] Two recent retrospective studies also suggest a good long-term prognosis for cases of mild MR in sport and pleasure horses[583] and in middle-aged to older horses and ponies[407] with left-sided valvular regurgitation. With moderate to severe MR, clinical signs are more likely, including poor performance, exercise-induced pulmonary hemorrhage, or overt CHF. Tolerance of the lesion depends largely on whether the horse is used for vigorous work. Some horses with MR also develop AF, which can further impair cardiac output. When a murmur of MR is identified within the setting of fever, weight loss, polyarthritis, or systemic inflammation, infective endocarditis should be considered. Mitral regurgitation related to chordal rupture is a rare but well-recognized cause of CHF, including peracute disease with fulminating pulmonary edema (see Fig. 9.10). Chronic, hemodynamically relevant MR from any cause can lead to pulmonary hypertension, AF, and biventricular CHF, with clinical signs of right-sided CHF dominating the clinical presentation (see earlier in this chapter).[48,148]

The physical examination of the horse with MR typically reveals a grade 2 to 5/6 holosystolic murmur that is detected most intensely at or dorsal to the palpable left apical impulse and over the mitral valve area (see Figs. 9.7 and 9.35 and Table 9.1). Often the murmur is loud at the aortic valve, probably related to the proximity of the septal mitral leaflet to the aortic valve or to cranial projection of the regurgitant jet. Loud MR murmurs often project quite dorsally and to the right. The typical murmur of MR is long (holosystolic or pansystolic),

extending into the second sound. This timing may cause the listener to misinterpret the third sound as the second, thus preventing a full appreciation of the significance of the murmur. When the third sound is very loud, the clinician should suspect significant volume overload or increased LV diastolic pressure. Because many horses with MR also have concomitant tricuspid regurgitation, echocardiographic examination and Doppler studies may be needed to differentiate bilateral atrioventricular valve insufficiency from isolated MR with radiation to the right. Finally, the murmur of MR can be modified by second-degree AV block, AF, or premature beats.

Two variants of holosystolic MR murmur are the early-to-mid-systolic decrescendo murmur and the mid-to-late systolic crescendo murmur. A decrescendo murmur may be detected with mild MR because coaptation of the leaflets can occur as the ventricular volume decreases during late systole. This type of murmur can be easily confused with a functional ejection murmur, unless the point of maximal murmur intensity is centered near the left apex. Conversely, severe MR with CHF could conceivably cause a decrescendo murmur because atrial and ventricular pressures may equilibrate in late systole. However, this is not a common finding and would be associated with CHF. The other variant of MR, the mid-to-late systolic crescendo murmur (see Fig. 9.35B), presumably is caused by mitral valve prolapse as it starts *after* the left ventricle has begun ejection. Decreasing LV volume predisposes to leaflet prolapse and initiates midsystolic regurgitation that builds through the second heart sound. The resultant murmur can be harsh or musical, and the novice often confuses this flow event with an early diastolic murmur.

Echocardiography including Doppler examinations play a pivotal role in the assessment of the horse with MR* (see Fig. 9.38) and is indicated to examine the anatomy of the valve apparatus (including papillary muscles, chordae tendineae, annulus, and leaflets), estimate the severity of MR, measure the size of the atria, ventricles, and great vessels, and quantify left atrial and ventricular systolic function. The underlying cause of MR may be obvious from the echocardiographic examination. Mild to moderate valvular thickening, although admittedly subjective, is compatible with degeneration or noninfective valvulitis. Prolapse of the mitral valve cusps has been observed in horses with MR, but the limits of "normal" prolapse require further definition. Lesions due to vegetative endocarditis cause the valves to appear irregularly thickened or shortened. In cases of acute endocarditis, there can be evidence of valve thrombus, and a high-frame-rate real-time examination may show oscillation of this tissue. Small, focal lesions are more commonly observed on the atrial surface of the valve that is facing blood flow (see Fig. 9.45B later in this chapter). In chronic endocarditis, the valve may be more echodense or even appear calcified. Chordal rupture is recognized by observing chaotic flutter of a mitral structure (a flail leaflet), prolapse of a large portion of the valve into the atrium, or the contracted chordal remnant flipping into the atrium during systole (see Fig. 9.38B). High-frequency systolic vibrations of the mitral valve may be seen on the M-mode study in horses with a musical murmur of MR. Pulsed- or continuous-wave or color Doppler studies can identify the mitral regurgitant jet (see Fig. 9.38C). The Doppler examination should be performed from both the right- and left-sided thoracic windows. High-velocity or turbulent jets may be difficult to find without a complete and thorough examination of the mitral valve that involves multiple image planes. When color-flow Doppler demonstrates both a wide origin of the regurgitant jet and a pattern of diffuse distribution of turbulence deep into the left atrium, the likelihood of hemodynamically relevant MR is greater. However, receiving chamber (i.e., left atrial) color coding in MR should not be overemphasized because red blood cell entrainment and "spray effects" can result in overestimation of MR severity, whereas wall-hugging jets underestimate severity of MR. Therefore quantitation of cardiac size is instrumental in assessing MR severity. With severe MR and LV volume overload there will be rounding of the LV apex and increased end-diastolic LV dimension. Global LV function may appear normal to exuberant (hyperdynamic) because ventricular preload is increased and afterload decreased in severe MR. However, when MR is both severe and chronic, or if the underlying basis for MR is cardiomyopathy, the ventricular systolic function is normal to decreased. The left atrium often assumes a more circular, almost turgid, appearance when MR is hemodynamically important, and the 2D echocardiographic measure of maximum internal LA dimensions measured from a right-parasternal long-axis view at end-systole often exceed 13.5 cm (for the widest LA diameter parallel to the mitral valve annulus) and 105 cm^2 (for maximum LA area), respectively, in large-breed 500-kg horses.[355,576,689] With acute or chronic MR, the lobar and main PA may be dilated as a consequence of pulmonary hypertension, presumably related to increased LA pressure, interstitial lung edema, vascular remodeling, or other factors.

The prognosis for horses with MR is variable and, as discussed earlier, is related to clinical findings, work history, exercise testing, and results of echocardiographic studies.[68] In one study, MR was the most common valvular disease associated with AF, clinically important ventricular arrhythmias, and CHF.[83] Abnormalities observed during echocardiography, including lesions of the mitral valve leaflets, the degree of LA and LV volume overload, global LV function, and Doppler findings, should be considered when formulating the prognosis. Certainly, when MR is associated with CHF, AF, endocarditis, chordal rupture, marked cardiomegaly, severe valvular thickening, dilated cardiomyopathy, or pulmonary hypertension, the prognosis for life and performance is poor.[148] In the absence of right-sided heart catheterization, increased TR velocity and PA dilation are used as surrogates for the identification of PHT. The detection of PA dilation indicates significant pulmonary hypertension and the low but concrete possibility of PA rupture associated with exercise. Fortunately, the vast majority of horses with MR appear to perform very well, indicating that MR in most cases is not severe enough to be clinically important.[74,355,583] Whether progressive exercise intolerance will develop in a particular case depends on the horse's use and on the progression of the underlying lesion. Generally, when MR is caused by valve degeneration and the heart size is normal, the progression is gradual, the prognosis for life is favorable, and performance is maintained.[74,390,407,583,862] When MR is detected in an untrained colt or filly, the prognosis is less encouraging. The presence of even mild to moderate cardiac dilation in a case of MR recommends a more guarded prognosis, though this assessment is best made by serial examinations. In any case, LA dilation increases the risk for AF. The clinical relevance of trivial to mild MR in the high-performance horse or racehorse is uncertain. In some animals, treadmill exercise is normal whereas

FIG. **9.39** Postmortem lesions of aortic regurgitation (AR; see also Fig. 9.43B). A, A segment of the left ventricular (LV) outflow tract and the ascending aorta. Linear bands are evident on the two valves shown, and a large jet lesion also is visible below the valves between the *arrows*. The lesion is typical in aged horses. B, The aortic valve *(arrow)* viewed from the ascending aorta. Noninfective valvulitis and scarring have caused severe thickening.

others may demonstrate a higher HR for a given level of work than might otherwise be expected. The latter finding may be suggestive of a cardiac limitation to performance.

Regardless of cause or the severity of the condition, the horse diagnosed with MR merits follow-up examinations at least yearly, if not more often, to evaluate progression of the hemodynamic burden and to detect the development of CHF, pulmonary hypertension, or cardiac arrhythmias such as atrial fibrillation (see later discussion).[68] HR and heart rhythm should be monitored on a regular basis with moderate to severe MR. Exercise testing including stress ECG to assess HR response to exercise and occurrence of exercise-induce arrhythmias should be performed (1) in all horses with moderate to severe MR; (2) if AF becomes established (see later discussion); or (3) if MR progresses more rapidly than expected, in the absence of signs of CHF.[68] Treatment of MR involves management of complications of advance disease such as heart failure, endocarditis, or arrhythmias. Limited data have been published about the use of ACE inhibitors in horses (see Therapy for Congestive Heart Failure), and no consensus exists among experts regarding their use in MR in the absence of CHF.[68] These topics are covered elsewhere in this chapter.

Aortic Regurgitation

Aortic regurgitation (AR) is a common valvular insufficiency in horses.[68,83,407] Degeneration of the aortic valve is by far the most common reason for AR.* The degenerative nodular lesions and fibrous bands responsible for AR in older horses have been well described[5] (Fig. 9.39A). Prolapse of the aortic valve is a common echocardiographic finding and probably represents another manifestation of connective tissue degeneration affecting the valve.[194,577] Small fenestrations of the valve also have been identified at necropsy but have uncertain clinical relevance. Other potential causes of AR in horses include infective endocarditis,† congenital valvular disease,[179,189,794] VSD (see earlier in this chapter), noninfective valvulitis, leaflet tearing, and ruptured aortic sinus aneurysm.[34,262-264,777,864-867]

In most cases, AR is an incidental finding encountered during a routine physical, prepurchase, or insurance examination. Most horses with this murmur are older than 10 years of age, and the murmur is especially common in aged horses, a testament to the degenerative nature of the lesion. Careful auscultation in a quiet area may identify a very soft diastolic murmur in a younger horse. Silent AR may also be considered physiologic or trivial, and it is not uncommon to identify a trivial jet of AR by Doppler studies in horses with no identifiable diastolic murmur.[71] Poor performance is an infrequent presenting complaint in horses with AR, and most will continue at their prior performance level, provided that no other clinical or cardiac abnormalities are present. Intermittent fever, weight loss, or lameness should prompt consideration of endocarditis. CHF is infrequently observed in conjunction with isolated AR but may develop in the horses when AR occurs in combination with MR or AF.

Clinically important AR is identified by cardiac auscultation, which reveals a holodiastolic murmur, with the point of maximal intensity over the aortic valve area, and strong radiation to the right and toward the left cardiac apex in many instances (see Table 9.1). The murmur may vary greatly in intensity and character.[18,72,868] The quality is typically harsh and decrescendo with a blowing nature (see Fig. 9.9C), but there may be presystolic accentuation (see Fig. 9.35C). The character can be vibratory, musical, cooing, buzzing, or "dive-bomber" in quality. A precordial thrill is palpable over the aortic valve area when the murmur is loud. A variant of the typical AR murmur is that associated with rupture of an aortic sinus into the right atrium, ventricular septum, or pulmonary artery. An aortic-cardiac fistula leads to a holodiastolic or continuous murmur that is louder over the right side of the thorax.[262-264] However, in the majority of horses with an aortic-cardiac fistula, a continuous machinery-type murmur is detected. A systolic ejection murmur is often present in addition to the typical diastolic murmur of AR, particularly when the regurgitant volume is large, and is explained by ejection of a large stroke volume across the aortic valve. It should be emphasized that there is no evidence for anatomic stenosis due to degenerative aortic valve disease.

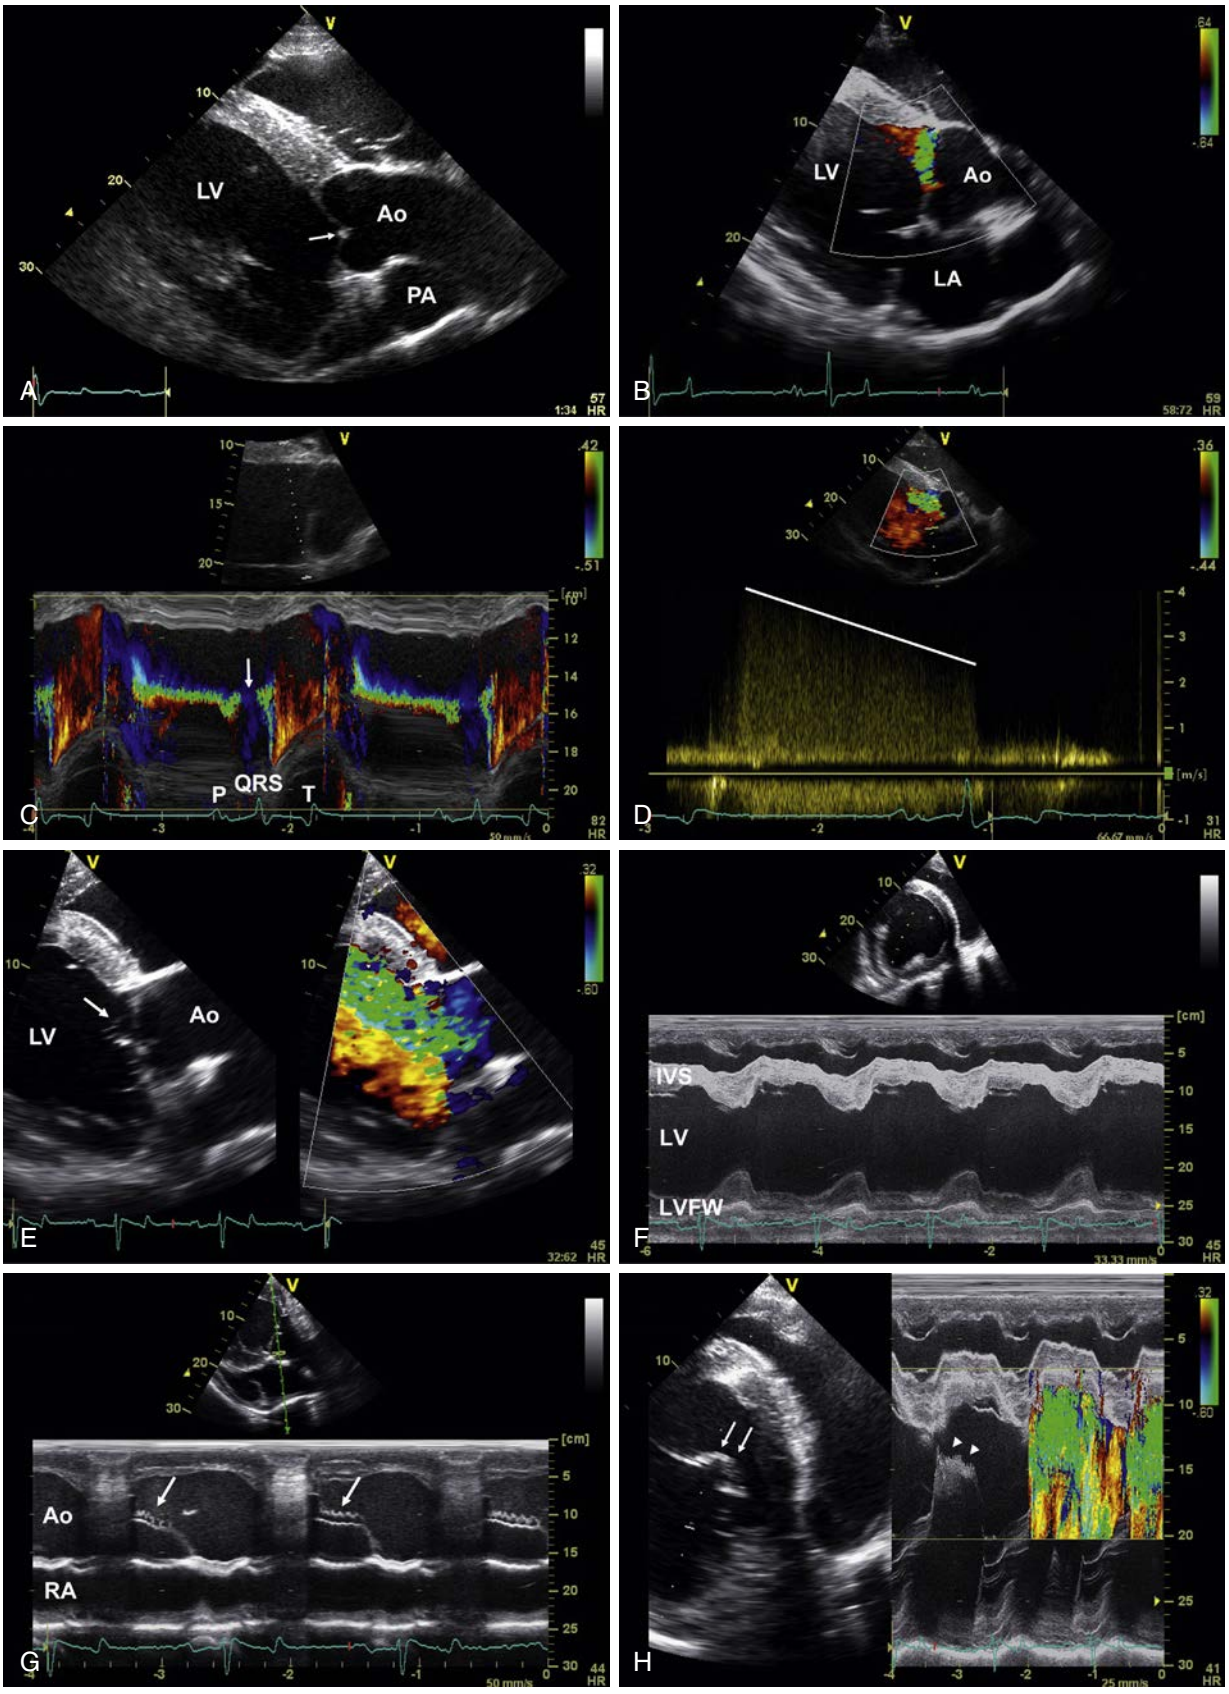
† References 194, 195, 205, 554, 852, 853, 855.

The quality of the arterial pulses is a good indicator of the severity of the isolated AR.[406, 554] Bounding, hyperkinetic arterial pulses, usually corresponding to increased pulse pressures (greater than 60 mm Hg), indicate moderate to severe AR and significant (but compensated) LV volume overload.[406] If the myocardium is failing, the arterial pulses will become weak, the pulse pressure will decrease, and tachycardia will develop.

A complete echocardiographic examination including Doppler echocardiography is useful for further evaluation of horses with AR, particularly when a louder (i.e., grade 3–6/6) murmur is identified, the arterial pulse is abnormal, or cardiac-related clinical signs are suspected.* The most common abnormality observed by 2D echocardiography is mild valvular thickening in association with prolapse of one or more aortic leaflets (Fig. 9.40). Fibrous bandlike lesions appearing as an echoic line parallel to the free edge of the left coronary leaflet or, less often, nodular thickening or a generalized increase in echogenicity of the leaflet's free edge are detected.[68,554] These findings are compatible with degenerative valvular disease. Care should be taken not to overdiagnose the presence of aortic valve prolapse, because prolapse can easily be mimicked by ultrasound probe malignment.[577] High-frequency fluttering or vibration of the aortic valve leaflets or aortic walls may be seen, most commonly in horses with musical or vibratory murmurs. The 2D echocardiographic examination also assists with the differential diagnosis. In cases of endocarditis, the leaflets may appear thickened, irregular, and more highly echogenic. The valve may appear to oscillate if there is fresh thrombus within the vegetation. Other rare 2D echocardiographic findings related to AR include fenestrations of the aortic valve leaflets, flail aortic leaflet, aortic sinus aneurysm, and aortic root prolapse into a VSD. Dilation of the aortic root (exceeding 10 cm) may be observed in some horses with AR. A recent study described echocardiographic assessment of the rate of diastolic decrease in aortic diameter, which is associated with the rate of diastolic runoff of blood from the aorta and may serve as an indicator of AR severity.[602]

Left ventricular volume overload that develops with AR can be detected on 2D and M-mode echocardiography and is characterized by increased end-diastolic LV dimensions, decreased relative wall thickness, and increased stroke volume.[554,576,602,849] An exaggerated or swinging septal motion on 2D or M-mode examination indicates a hyperkinetic LV and represents another subjective observation of compensated volume overload (see Fig. 9.40). Left-ventricular shortening fraction and ejection fraction might be high-normal or increased.[554,576,602,849] If myocardial failure develops, septal motion will diminish, shortening fraction and ejection fraction will decrease, and the end-systolic LV dimensions will increase. Inspection of the mitral valve often reveals high-frequency diastolic vibrations of the septal (anterior) leaflet related to an eccentric high-velocity AR jet directed across the LV outflow tract to the left and caudally. Similar vibrations may also be detected on the interventricular septum when the regurgitant jet is oriented in a right or cranial direction. Increased mitral valve E-point to septal separation (EPSS) can indicate that the regurgitant jet is impinging on the valve or herald LV dilation and failure. In the latter case, other markers of severe insufficiency will be evident, including ventricular dilation, rounding of the LV apex, and a wide origin jet of AR on Doppler studies. Premature (presystolic) mitral closure is an uncommon but ominous finding of severe AR with elevated ventricular end-diastolic pressure.



The flow disturbance of AR is confirmed by Doppler studies. The color Doppler examination shows one or more central or eccentric diastolic jets of AR. The timing of the flow disturbance can be verified by spectral Doppler or color-M-mode studies. Assessing the severity of AR by Doppler studies is ripe with pitfalls, and the examiner should use multiple 2DE, M-mode, and Doppler findings to assess severity. Importantly, a wide jet area in the LV outflow tract does not always indicate severe AR. The finding of a small, central perivalvular jet, with a small cross-sectional area, suggests trivial AR. Often these leaks are confined to mid-to-late diastole. Conversely, a strong spectral signal, holdodiastolic timing, and wide-origin color Doppler signal suggests more significant regurgitation. Examination of the short-axis jet area in cross-sectional studies of the aortic root is especially instructive because a wide ventricular spray is often associated with a small origin jet: this suggests mild AR. The CW Doppler spectrum can be assessed for a short pressure half-time (steep AR slope), which indicates LV diastolic pressure is rapidly increasing and that AR is severe. However, the examiner must be certain the ultrasound beam has remained in good and consistent alignment with the regurgitant jet before this assessment can be made.

The clinical relevance and prognosis of AR is most accurately based on the performance history, physical examination, and echocardiogram. As most cases of AR are associated with a slow degeneration of the aortic valve leaflets, and this occurs in older horses without other cardiac problems, the prognosis for life and performance is usually good. Such animals typically have minimal echocardiographic abnormalities or only mild echocardiographic signs of volume overload that are unchanged at follow-up examinations. Epidemiologic studies suggest that in general AR is mild in most cases and, when taking age into account, is not an independent predictor of mortality.[407] However, when AR is moderate to severe or first recognized in a younger horse (less than 10 years of age), the risks for reduced performance life and longevity are higher.[68] The detection of hyperkinetic arterial pulses or a pulse pressure of greater than 60 mm Hg suggests that progression of AR is likely.[68,406] The findings of flail aortic valve leaflet, endocarditis, moderate to severe LV volume overload, or myocardial failure indicate a poor prognosis for life and performance. Concurrent MR and LA enlargement should be anticipated in horses with severe volume overload and increase the risk of atrial fibrillation, pulmonary hypertension, and CHF.

Ventricular dilation can predispose to ventricular arrhythmias. Sudden cardiac death associated with fatal ventricular arrhythmias has been observed in horses with moderate to severe AR and can occur in isolation, without a history of poor performance or CHF.[68] Therefore an exercising ECG and exercise test should be obtained when moderate to severe AR and volume overload are present or when performance issues are evident, to determine whether the horse remains safe to ride.[68] Electrocardiographic evaluation should be focused on identifying exercise-induced premature ventricular complexes and appropriateness of the exercising HR. A Holter ECG can be considered as a potential test to further identify and quantitate ventricular ectopy at rest.[68]

Follow-up examinations including echocardiography and ECG exercise test are indicated for the horse with moderate to severe AR. Affected horses should be reexamined twice yearly and at least annually thereafter if progression has been

minimal. Longer follow-up intervals are appropriate for horses with mild AR after the first reevaluation.[68] If AF develops in a horse with mild to moderate AR, a reexamination is indicated at that time, including an ECG exercise test. HR and heart rhythm should be monitored on a regular basis in cases of moderate to severe AR; an increased resting HR or an irregularly irregular rhythm suggesting atrial fibrillation or frequent ventricular arrhythmias indicates progression of disease.[68] The detection of exercise-induced ventricular arrhythmias is considered an important negative prognostic indicator; these horses are considered less safe to ride or drive than their age-matched peers.[68] Generally, horses with severe AR should not be ridden or driven by a child, be used as a lesson horse, or participate in a high-risk sport owing to a risk for sudden cardiac death.[68] Limited data have been published about the use of ACE inhibitors in horses (see Therapy for Congestive Heart Failure) and no consensus exists among experts regarding their use in AR in the absence of CHF.[68] These topics are covered elsewhere in this chapter.

Tricuspid Regurgitation

Tricuspid regurgitation (TR) may be the most frequently detected flow disturbance and murmur in the horse.* The prevalence and color Doppler severity of TR increases with age, training, and subtle physiologic increases in RV dimensions, and murmurs consistent with TR are common in horses of racing age.[70,75,208,209] However, the anatomic correlate to this incompetency is uncertain, and there is little information confirming the etiopathogenesis of this condition aside from speculation that it might be related to recurrent physiologic pulmonary hypertension of high-intensity exercise. Tricuspid valve incompetency can further result from any of the following causes: degenerative thickening, prolapse, noninfective tricuspid valvulitis, bacterial endocarditis, ruptured chordae tendineae, pulmonary hypertension (caused by left-sided failure or severe respiratory disease), myocardial disease with secondary cardiomegaly, chronic tachyarrhythmia, and congenital malformation of the valve. Degenerative, fibrotic thickening of the tricuspid valve in mature horses may lead to mild to moderate TR. Endocarditis of the tricuspid valve is in many cases associated with septic thrombophlebitis secondary to jugular venipunctures or catheterization. Compared with the mitral condition, ruptured tricuspid valve chordae tendineae are uncommon and better tolerated unless associated with endocarditis. Pulmonary hypertension, cardiomyopathy, and myocarditis can lead to secondary dilation of the tricuspid annulus or alteration of papillary muscle support, permitting valvular insufficiency. Tricuspid malformation does occur but seems more commonly associated with stenosis or atresia of the valve (see earlier in this chapter).†

Auscultation of the horse with TR typically reveals a grade 2/6 to 5/6 holosystolic murmur with the point of maximal intensity over the right hemithorax at the tricuspid valve area (see Table 9.1). The murmur can be holosystolic, decrescendo, or mid to late systolic. Although the timing and intensity may at times remind the examiner of a functional murmur, the location of greatest murmur intensity argues against that possibility. The murmur usually radiates dorsally and if loud to the extreme left cranioventral thorax. The intensity of the TR murmur in many cases does correlate well to the regurgitant volume, but loudness also depends on PA and RV systolic pressures. A soft, grade 2 to 3/6 systolic murmur of TR is most often an incidental finding detected during a routine examination. The majority of horses with a soft TR murmur perform well; therefore the clinician should first exclude other likely reasons for poor performance before incriminating the tricuspid valve. The murmur is usually more problematic when it is loud. In general, a grade 4 or louder murmur is anticipated

FIG. **9.40** Aortic regurgitation. A, Right-parasternal long-axis view obtained from a 15-year-old Thoroughbred gelding with aortic regurgitation. Nodular thickening of the aortic valve cusps is evident *(arrow).* B, Color Doppler echocardiogram in a right-parasternal long-axis view obtained from a 15-year-old Warmblood mare with aortic regurgitation. The diastolic regurgitant jet is visible as an area of turbulent flow that appears to be directed toward the interventricular septum. Based on receiving chamber analysis, the severity of the regurgitation would be graded as mild. C, Color M-mode echocardiogram in a right-parasternal long-axis view obtained from a horse with aortic regurgitation. The cursor line is placed immediately below the aortic valve *(top).* An ECG is recorded simultaneously for timing. This imaging mode is particularly useful for timing of flow events and identifying brief regurgitant signals or normal valve closure noise. In this case an aortic regurgitant jet is visible as a turbulent flow pattern, starting at the beginning of diastole (i.e., after the T wave) and ending at the onset of systole (i.e., immediately after the QRS complex). Notice the absence of turbulent flow during the PQ-interval *(arrow).* This can be explained by a change in left ventricular pressure occurring after atrial contraction or a reorientation of the regurgitant jet relative to the cursor owing to translational movement of the heart. D, Continuous-wave Doppler recording of a diastolic aortic regurgitant jet from a right-parasternal long-axis view. The absolute velocities are not accurate in this recording because of lack of adequate alignment with blood flow. However, this recording can be used for timing of flow events (an ECG is recorded simultaneously for timing). Furthermore, the change in jet velocity (which can be expressed as "pressure half-time") reflects the rate of decline in pressure gradient between the aorta and the left ventricle and may be useful to assess the severity of regurgitation as long as ventricular relaxation is normal; a relatively flat or gradual slope of the velocity envelope *(white line)* indicates mild aortic regurgitation (AR), a steep slope indicates severe AR. E–H, Echocardiogram of a 21-year-old Hanoverian Warmblood gelding with severe aortic regurgitation and left ventricular volume overload. E, B-mode *(left)* and color Doppler *(right)* echocardiogram of the left ventricular outflow tract in a right-parasternal long-axis view. The aortic valve cusps are irregularly thickened, and aortic valve prolapse is evident during diastole *(arrow).* A large regurgitant jet is visible in the left ventricular outflow tract during diastole *(right panel).* F, M-mode echocardiogram of the left ventricle (LV) in a right-parasternal short-axis view demonstrating LV enlargement and hyperdynamic motion of the interventricular septum (IVS). The LV fractional shortening was 46%. G, M-mode echocardiogram of the aortic valve in a left-parasternal long-axis view. Notice the high-frequency vibrations of the aortic cusps during diastole *(arrows)* caused by the regurgitant blood flow. H, Two-dimensional *(left),* M-mode *(middle),* and color M-mode *(right)* echocardiogram of the mitral valve in a right-parasternal short-axis view. Notice the prolapse *(arrows)* and the high-frequency vibrations *(arrowheads)* of the septal leaflet of the mitral valve, caused by rapid, turbulent regurgitant flow in the left ventricular outflow tract during diastole. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *LVFW,* left ventricular free wall; *PA,* pulmonary artery; *RA,* right atrium. Reproduced with permission of John Wiley & Sons, Ltd.)

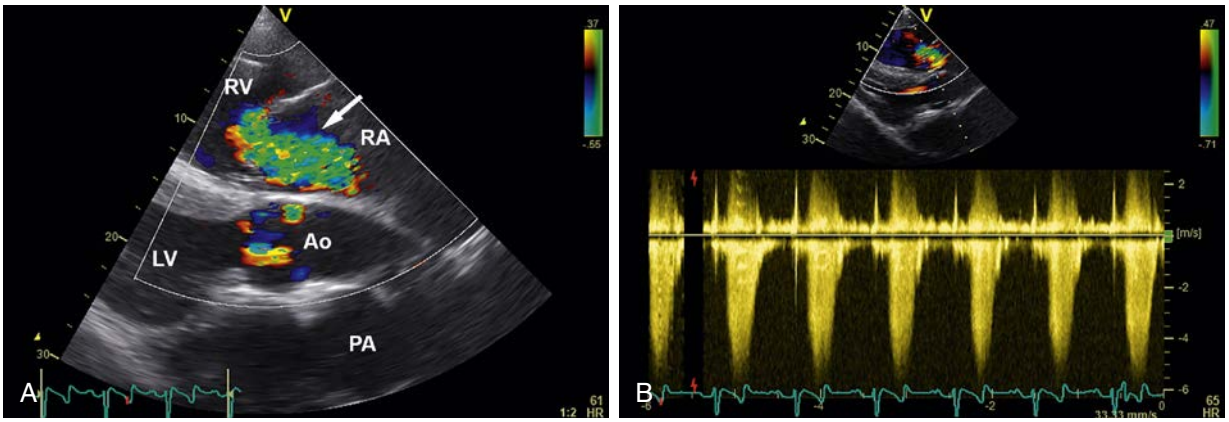

FIG. **9.41** Tricuspid regurgitation (TR) and pulmonary hypertension (PHT) in a 6-year-old Friesian mare with severe mitral regurgitation and congestive heart failure. A, Two-dimensional (2D) color flow Doppler echocardiogram demonstrating marked tricuspid regurgitation *(arrow)*. The right atrium (RA), the right ventricle (RV), and the pulmonary artery (PA) appear enlarged compared with the left ventricle (LV) and the aorta (Ao). B, Continuous-wave Doppler recording of the TR jet. The maximum jet velocity is 4.8 m/sec, corresponding to an RV-to-RA pressure gradient of 92 mm Hg (modified Bernoulli equation: $dp = 4 \times v_{max}^2$). In the absence of RV outflow tract obstruction, the high-velocity TR jet indicates severe pulmonary hypertension. TR jets associated with normal RV pressures are typically less than 3.2 m/sec. An ECG is recorded simultaneously for timing.

when there is moderate to severe TR or when TR is related to pulmonary hypertension. Atrial fibrillation or atrial premature beats are present in some horses with TR, particularly when the right atrium is dilated or the regurgitant jet is large. If chronic, hemodynamically significant TR has developed, peak work effort will suffer and even right-sided CHF may develop. The latter is very uncommon unless the TR is severe, related to pulmonary hypertension or infective endocarditis, or complicated by AF. Prominent jugular pulses (giant c-v waves; see Fig. 9.4) are typical of horses with TR associated with CHF.

Echocardiographic examination is mainly indicated in horses with a grade 4 to 6/6 right-sided systolic murmur compatible with TR in the setting of poor performance, concurrent thrombophlebitis, or fever of unknown origin.[68] However, an echocardiogram may also be performed in horses with softer murmurs in the setting of a prepurchase examination or if the cause or clinical relevance of the murmur is unclear. The tricuspid valve is typically examined from the right side of the thorax, because the tricuspid valve and RV inlet are closer to the right thoracic wall (Fig. 9.41). However, an extreme left cranial transducer location with caudal angulation can also be successful for examining the tricuspid valve. Because there are a number of potential reasons for tricuspid incompetency, careful attention must be directed to the valve and its support apparatus, the size of the PA, and the left side of the heart. In the vast majority of cases, with benign or training-related TR, a clear-cut lesion of the tricuspid valve leaflet is not evident, and the RA and RV are normal in size. With clinically significant TR, there might be structural or motion abnormalities of the TV originating from valve thickening, prolapse, vegetations, chordal rupture, regurgitation secondary to RV dilation, and pulmonary hypertension. As with mitral regurgitation, moderate to severe TR leads to RA and RV volume overload; however, it is more difficult to quantify these chamber volumes owing to their complex geometry.[70,344,573]

Doppler studies can identify the tricuspid regurgitant jet. In trivial or "silent" TR, this jet is typically very narrow at the origin and directed toward the aorta. However, when the jet is wide at its origin, occupies a larger area in the RA, or projects centrally or laterally into the right atrium, cardiomegaly is more likely to be present, and the heart should be examined carefully. The RV (and PA) systolic pressure can be estimated by faithfully recording the peak jet velocity. This requires the examiner to align the CW Doppler cursor parallel to regurgitant flow and may demand a ventral or dorsal placement of the transducer with steep beam angulation. When the jet velocity is less than 2.5 m/sec, pulmonary hypertension is not present. Jets exceeding 3.2 to 3.4 m/sec are indicative of pulmonary hypertension (provided that there is no right ventricular outflow obstruction or VSD; see Fig. 9.41B). The identification of pulmonary hypertension should prompt careful examination of the left side of the heart, because the main cardiac lesion may be centered over the mitral valve, aortic valve, or LV cavity and the right-sided heart changes simply a secondary consequence. If left-sided heart disease can be excluded as a cause for pulmonary hypertension, severe pulmonary disease must be considered, and appropriate diagnostics should be performed.

The prognosis for horses with TR is generally very favorable. A soft murmur of TR in a trained athlete is disregarded as clinically irrelevant; however, defining such a disturbance as purely "functional" would be imprecise. The presence of TR is more likely to cause concern if right-sided cardiomegaly, severe MR, pulmonary hypertension, or AF is evident. Visualization of a vegetation or chordal rupture or clinical signs of CHF would indicate a poor prognosis for performance and a guarded to poor prognosis for life. The width of the regurgitant jet at its origin, recent performance history, and results of exercise testing are useful in developing a prognosis for life and future work. When TR is judged to be moderate or severe, annual reexaminations are indicated to follow the progression of the lesion and to detect cardiomegaly or cardiac arrhythmias if they develop.[68]

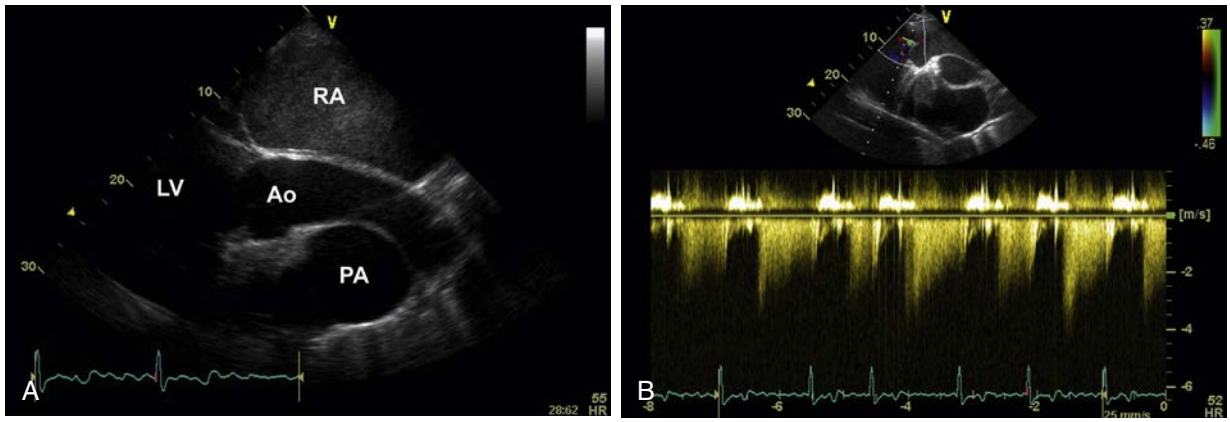

FIG. **9.42** Pulmonic insufficiency and pulmonary hypertension. A, Right-parasternal view of the left ventricular outflow tract obtained from an 11-year-old Paint gelding with severe mitral regurgitation, atrial fibrillation, and congestive heart failure. Enlargement of the right atrium (RA) and severe pulmonary artery (PA) dilation are evident, consistent with pulmonary hypertension. Notice also the marked spontaneous echo contrast (SEC) in the right atrium. B, Continuous-wave Doppler recording of pulmonic insufficiency in a left-parasternal long-axis view of the right ventricular outflow tract, showing diastolic regurgitant flow. The varying peak velocities can be explained by differences in cycle lengths (due to atrial fibrillation), motion of the heart (and the regurgitant jet) relative to the cursor line, and possibly respiratory variations. The highest maximum early-diastolic velocity in this spectral Doppler recording was 3.5 m/sec, corresponding to a transvalvular pressure gradient of 49 mm Hg (modified Bernoulli equation: $dp = 4 \times v_{max}^2$). Assuming a right atrial pressure of 5 mm Hg, the estimated mean pulmonary artery pressure (MPAP) would be at least 54 mm Hg, indicating marked pulmonary hypertension. *Ao,* Aorta; *LV,* left ventricle.

Pulmonic Regurgitation

Trivial and clinically silent, physiologic pulmonic regurgitation (PR) can often be detected by Doppler studies; however, this is a normal finding.[71,209,280,281,391,560] Clinically relevant PR is rare and occurs most frequently with pulmonary hypertension associated with left-sided heart failure or severe respiratory disease. Infective endocarditis, congenital abnormalities of the valve leaflets (bicuspid or quadricuspid valve), and rupture of the pulmonic valve are rare causes of pulmonic insufficiency.[200,730] Murmurs of PR are usually undetectable unless the regurgitant volume is large or is driven by pulmonary hypertension; however, the regurgitant flow can be easily identified using pulsed-wave and color-flow Doppler echocardiography (Fig. 9.42). Dilation of the PA may be detected echocardiographically when pulmonic insufficiency is caused by pulmonary hypertension (see Fig. 9.42A).

When severe pulmonic regurgitation does develop, it is generally a consequence of left-sided heart failure with pulmonary hypertension and accompanied by clinical signs of biventricular failure. Signs of right-sided CHF typically stem from the combination of pulmonary hypertension, pulmonic regurgitation, RV volume overload, and TR. If a murmur of pulmonic regurgitation is detected, it is usually holodiastolic and a decrescendo murmur, with the point of maximal intensity at the pulmonic valve area, radiating toward the right cardiac apex (see Table 9.1). The prognosis for life and performance is usually poor in these cases.

Infective Endocarditis

Infective (bacterial) endocarditis is caused by invasion of the heart valves or endocardium by bacteria. Endocarditis is not common in horses but occurs sporadically in most populations.* Horses of any age may be affected, although the pathogenesis may differ in younger animals or in those that are immunosuppressed. In two reports, the mean age of affected horses was 2.1 and 4.8 years, respectively.[205,855] Numerous bacteria have been associated with bacterial endocarditis. The offending microorganism likely depends on the environment, portal of entry (e.g., respiratory tract, gastrointestinal tract, skin, oral cavity, joint, surgical wound, or intravenous catheter), and the effects of prior antimicrobial therapy that may select for resistant strains. *Streptococcus* spp., *Actinobacillus equuli,* and *Pasteurella* spp. have been isolated most frequently, but *Pseudomonas* spp., *Escherichia coli, Corynebacterium* spp., *Bacillus* spp., *Rhodococcus equi, Erysipelothrix rhusiopathiae,* meningococci, *Staphylococcus* spp., *Candida parapsilosis,* and other organisms (including aspergillosis) have also been reported, with no organism appearing more prevalent than the others.[872]

The pathogenesis involves bacterial invasion from the bloodstream and colonization of the heart valve or endocardial surfaces. Bacteremia is a prerequisite for development of this condition. Direct invasion of a previously normal valve by virulent bacteria, or in the context of overwhelming sepsis, represents the most likely pathogenic mechanism involved in foals with infective endocarditis. Disruption of the endocardial surface by jet lesions associated with congenital intracardiac shunts may also predispose to endocarditis, although this mechanism is not well established in horses. Preexisting valvular heart disease with endocardial changes or high-velocity jets may represent risk factors for bacterial colonization in older horses, but again this is completely unproven.

The most common sites of infective endocarditis are the aortic and mitral valves, although endocarditis lesions have been reported on all cardiac valves. Mural and chordal endocarditis lesions have also been reported but occur much less frequently. The combination of bacterial injury, exposure of

* References 31, 191, 193-206, 824, 852-860, 870, 871.

valve collagen, thrombosis, and host leukocyte response contributes to development of the vegetation (Fig. 9.43), which consists microscopically of bacteria, platelets, fibrin, leukocytes, and varying degrees of granulation or fibrosis. Bacteria may not be evident at necropsy, especially if antimicrobial therapy has sterilized the vegetation.

The pathophysiology of endocarditis in horses is probably similar to that in other species. A host response, as well as the primary cardiac lesions, contributes to the morbidity of this disease. Cardiac manifestations include valvular injury leading to regurgitation, chordal rupture, or rarely to stenosis; secondary cardiomegaly; myocarditis from extension of the infection or through coronary embolization; myocardial infarction if emboli are shed to the coronary arteries; arrhythmias from cardiomegaly, myocarditis, or infarction; and myocardial depression from bacteremia. Recurrent or chronic bacteremia, and hence fever, is characteristic of endocarditis. Metastatic infection, distant thrombosis and infarction, and immune-mediated host responses can occur. Distant infection or immune complex disease can lead to multisystemic clinical signs, including polyarthritis, osteomyelitis, vasculitis, or nephritis. Right-sided thrombi can lead to pulmonary thrombi and/or abscessation of the lungs (see Fig. 9.43).[193, 200]

Clinical features of endocarditis are variable.[205, 855] Affected horses usually have a history of intermittent fever, weight loss, depression, anorexia, lethargy, and often intermittent lameness (Fig. 9.44). Synovial distention may be noted. A predisposing condition or a concurrent infection may be evident, including jugular vein thrombophlebitis, strangles, septic joint, or an abscess. In most horses there is no history of previous illness and no evidence of concurrent infection. The physical examination often reveals fever, and some horses may be tachypneic. The fever is often intermittent. Murmurs of mitral or aortic valvular insufficiency are most commonly detected; those of TR are less common. Systolic murmurs caused by valve destruction must be differentiated from the physiologic flow murmurs that are heard so often in febrile horses. Murmurs of valvular stenosis may also be detected with bacterial endocarditis but occur rarely.[200] Some horses with bacterial endocarditis have no auscultable murmur initially. The quality or intensity of the murmur may change over a number of days. Atrial fibrillation, atrial or ventricular premature depolarizations, and ventricular tachycardia have been observed with endocarditis.[199]

Laboratory studies obtained from horses with infective endocarditis may reveal anemia (related to chronic inflammatory disease), hyperproteinemia (hyperglobulinemia with

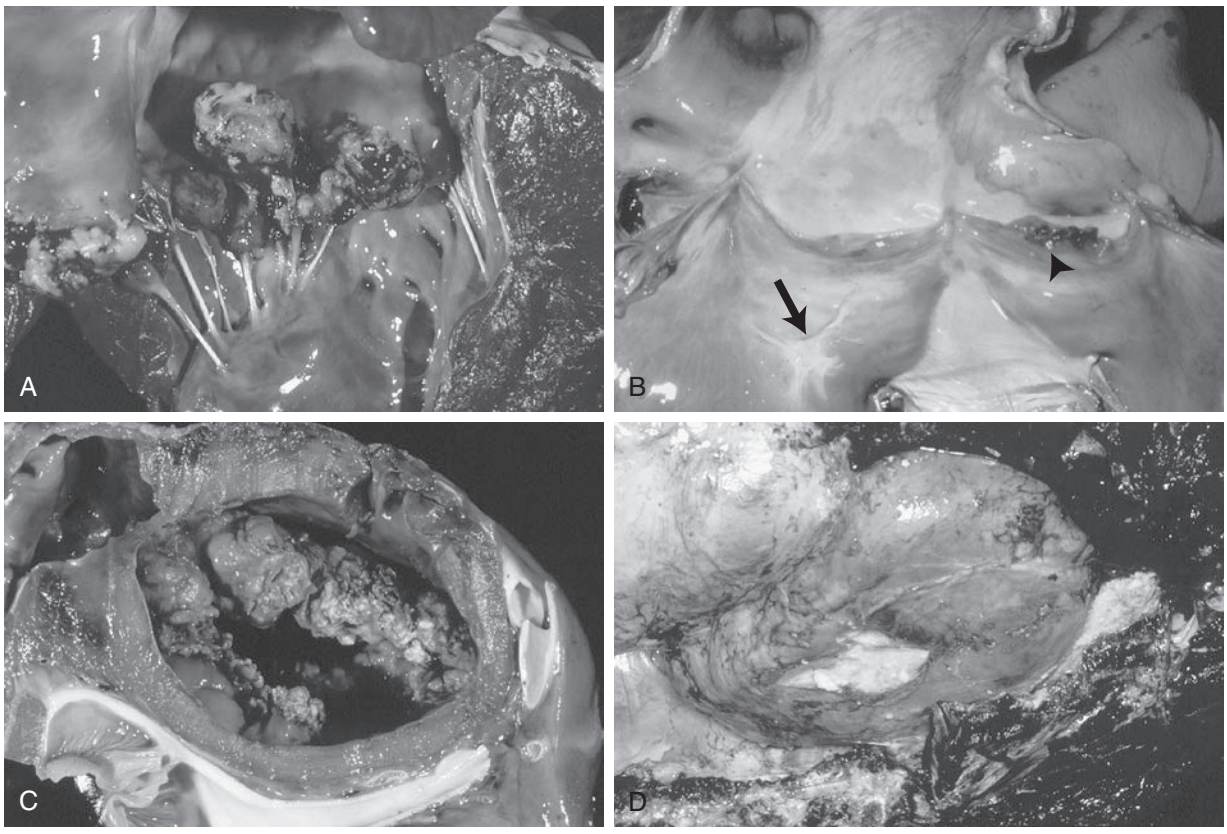

FIG. **9.43** Bacterial endocarditis: postmortem lesions. A, Severe mitral valve endocarditis in a yearling. B, Focal aortic valve endocarditis is evident in this view of the left ventricular (LV) outlet and the ascending aorta. The septal mitral leaflet is at the lower right, and a jet lesion *(arrow)* is visible in the LV outflow tract. Above the mitral leaflet, in the center of the left coronary cusp, is a raised, irregular vegetation *(arrowhead)* that caused aortic regurgitation (AR). C, Tricuspid valve vegetation in a weanling. Although less common than mitral or aortic vegetations, right-sided endocarditis is a definite risk in horses, particularly in animals subjected to repeated jugular venous catheterization. D, A lung abscess in a horse after pulmonary valve endocarditis. The center of the abscess is incised and reveals caseous exudate. Systemic embolization and metastatic infection are recognized complications of valvular infections.

hypoalbuminemia), elevated plasma fibrinogen concentrations, and leukocytosis with a mature neutrophilia.[205,855] Multiple blood cultures should be performed when bacterial endocarditis is suspected. The result of blood cultures may be negative, however, particularly after antimicrobial therapy. A positive blood culture may be more likely if multiple samples are drawn at different times of the day during or near febrile episodes. Antibiotic removal system media might also be of value when culturing blood from horses that have received antibiotics recently, and it can be helpful to consult with a clinical microbiologist regarding optimal broth media used for blood culturing.

FIG. **9.44** Weight loss, loss of condition, and ventral edema in this weanling with endocarditis and right-sided congestive heart failure (CHF; see also Fig. 9.43C).

Diagnosis of infective endocarditis may be definitive in the setting of a compatible clinical history with positive blood cultures or clear echocardiographic demonstration of a vegetation. In the absence of these, the relative likelihood of endocarditis is based on combinations of clinical findings and laboratory tests. Major and minor diagnostic criteria (Duke criteria) have been used for assessment of human patients,[873] and these principles are probably applicable to horses. Endocarditis should be considered in any horse that presents with a fever of unknown origin and one or more of the aforementioned clinical signs, particularly in association with synovial distention and lameness. Endocarditis becomes more likely when the cause of fever cannot be isolated to another body system and concurrent cardiac disease is identified. The diagnosis is confirmed with positive blood cultures in the setting of compatible clinical findings or by echocardiographic detection of vegetative lesions on the valve leaflets or endocardial surface (Fig. 9.45).

Vegetative lesions usually appear echocardiographically as thickened, echogenic to hyperechoic masses with irregular or "shaggy" edges. The valve leaflet often demonstrates diffuse thickening as well. Discrete lesions are generally on the valve surface facing the normal path of blood flow. The typical endocarditis lesion adheres to the valvular endocardium (and therefore moves with the valve). When a fresh thrombus is attached to the vegetation, an oscillatory appearance may be evident with high-frame-rate, real-time imaging. Chronic lesions may contract, calcify, or develop a smooth contour. Rupture of the chordae tendineae or avulsion of a valve leaflet may also be detected echocardiographically, and this complication is not uncommon in mitral or tricuspid valve endocarditis. Pulsed-wave and color-flow Doppler echocardiography can be used to confirm that the valve is incompetent or (rarely) stenotic. Valvular regurgitation often progresses because of continued

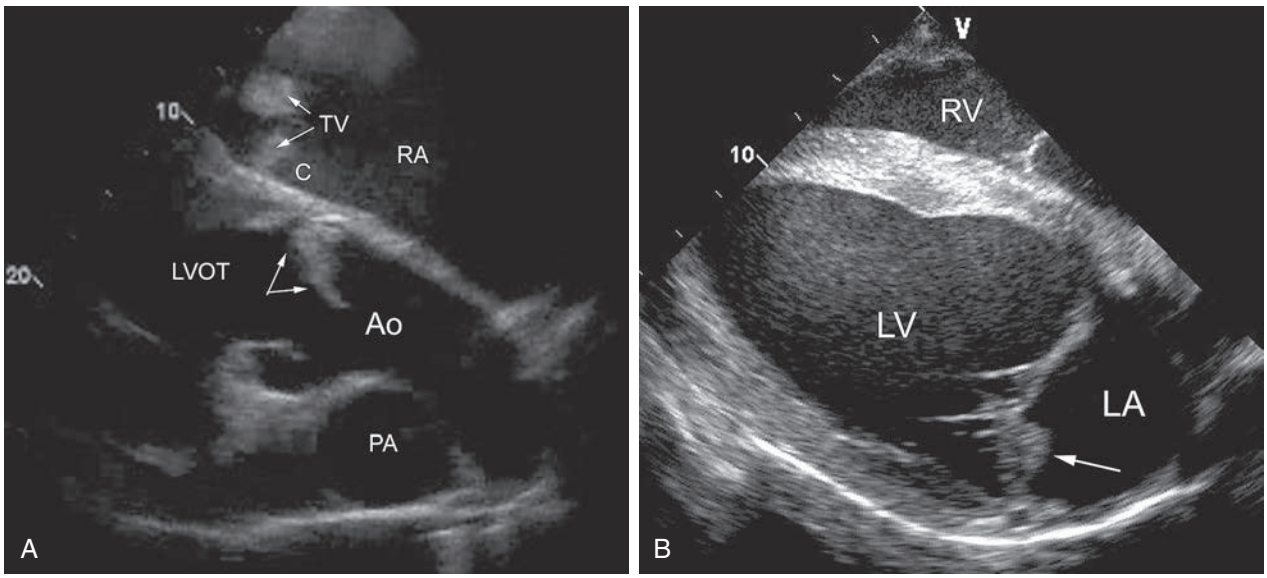

FIG. **9.45** A, Right parasternal long-axis two-dimensional (2D) image from a horse with infective endocarditis affecting multiple valves. Marked thickening of the tricuspid valve (TV) is evident, with spontaneous contrast (C) surrounding the valve. The right leaflet of the aortic valve is markedly thickened *(arrows)* between the left ventricular outflow tract (LVOT) and ascending aorta *(Ao).* Pulmonary artery (PA) and right atrium (RA) are seen in the far and near fields. B, Focal vegetation *(arrow)* is observed on a closed mitral valve in a long-axis image from the right thorax (*RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle).

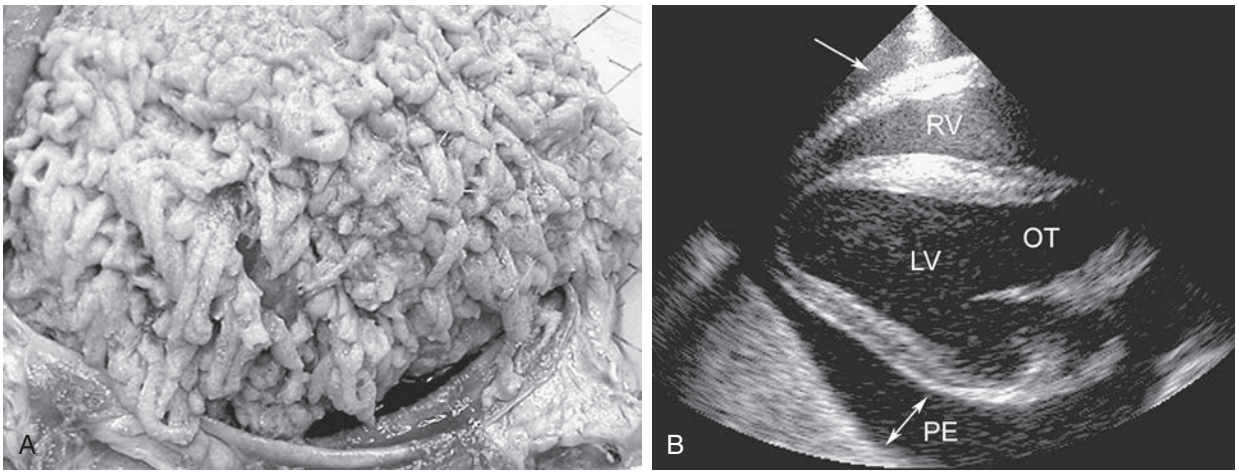

FIG. **9.46** A, Proliferative epicardial reaction in a horse with idiopathic, fibrinopurulent pericarditis. The heart is covered by a layer of organizing fibrin and inflammatory debris creating a shaggy appearance typical of inflammatory pericarditis. B, Two-dimensional (2D) long-axis echocardiogram from another horse demonstrating a moderate pericardial effusion. The effusion (PE) appears more prominent behind the left ventricle (LV) but is also evident *(arrow)* cranial to the right ventricle (RV). *OT,* Left ventricular outflow tract.

damage to the valve leaflets associated with ongoing bacterial infection or subsequent to fibrosis or calcification associated with a bacteriologic cure.

Early diagnosis and aggressive, prolonged treatment are important for successful treatment of infective endocarditis. Treatment should consist of adequate doses of bactericidal antibiotics, ideally based on culture and sensitivity patterns of blood culture isolates. Initial therapy should be broad spectrum, until the results of the blood culture are known or when a positive blood culture cannot be obtained. Intravenous therapy is preferred in the initial stages of treatment. Drugs that penetrate fibrin well, particularly potassium penicillin (22,000–44,000 IU/kg, IV every 6 hours), are reasonable initial choices because bacteria may be sequestered in fibrin and may be unavailable to leukocytes. To extend the antimicrobial spectrum, penicillin is usually combined with gentamicin sulfate (9 mg/kg, IV every 24 hours) or amikacin sulfate (20 mg/kg, IV every 24 hours for adults; 25 mg/kg, IV every 24 hours for foals). Erythromycin estolate (25 mg/kg, PO every 6–8 hours) combined with rifampin (5–10 mg/kg, PO every 12 hours) may be useful in some cases. Nonsteroidal antiinflammatory drugs (flunixin meglumine 1.1 mg/kg, IV q 12 h) may be beneficial to reduce systemic and local inflammatory reactions. Aspirin (10–20 mg/kg, PO every 24–48 hours) and heparin (sodium heparin: 40 IU/kg, SC every 8–12 hours; dalteparin 50–100 IU/kg, SC every 24 hours; or enoxaparin 40–80 IU/kg [0.4–0.8 mg/kg], SC every 24 hours) are used by some clinicians to prevent platelet adhesion, diminish growth of the vegetation, and reduce the risk of thrombotic complications, although the benefits of antithrombotic therapy are uncertain.

With effective antimicrobial therapy, the fever should resolve within 5 to 7 days. Response to treatment should be assessed by repeated examinations, including clinical assessment, laboratory analyses, and serial echocardiograms. Therapy should extend to at least 4 to 8 weeks or until body temperature, plasma fibrinogen concentration, and leukocyte counts have been normal for at least 2 weeks. The duration and type of long-term therapy depend on various factors, and the bacterial isolate, clinical response, cost, and potential toxicosis of the antimicrobial therapy must all be weighed in these decisions.

The expectation for long-term survival is poor in most cases of infective endocarditis causing severe valvular injury. Even in the absence of significant valvular regurgitation, there may be difficulty in achieving a bacteriologic cure, or valvular damage may progress as the vegetation heals and scars the valve. Although some horses have been treated successfully for endocarditis,[31,197,199,205] overall there is a low likelihood of long-term survival with continued use of the horse as a performance animal or in breeding. The absence of an obvious echocardiographic lesion or signs of systemic inflammatory response creates a more favorable situation, provided that a bacteriologic cure can be obtained. Progressive cardiomegaly, CHF, rupture of the PA, development of AF, thromboembolic complications, and sudden death have been reported in horses affected with endocarditis. Accordingly, periodic follow-up examination, including echocardiograms, should be performed in successfully treated cases.

PERICARDIAL DISEASE

Pericardial diseases occur uncommonly and are usually associated with pericardial effusion and fibrinous pericarditis (Fig. 9.46).* Approximately one third of the cases can be attributed to bacterial infection,[872] and an infectious etiology should be assumed until proven otherwise. *Actinobacillus* spp. have most frequently been reported with pericarditis,[872] but *Streptococcus* spp., *Escherichia coli, Enterococcus* spp., *Pseudomonas aeruginosa, Pasteurella* spp., *Corynebacterium pseudotuberculosis, Mycoplasma,* and other microorganisms, including fungal agents, have also been isolated.[126,133-135,739,872,880,881] Outbreaks of pericarditis with largely sterile inflammatory effusates have been described as part of the mare reproductive

* References 67, 119-121, 125-128, 131-137, 140, 191, 738-742, 796, 870, 872, 874-883.

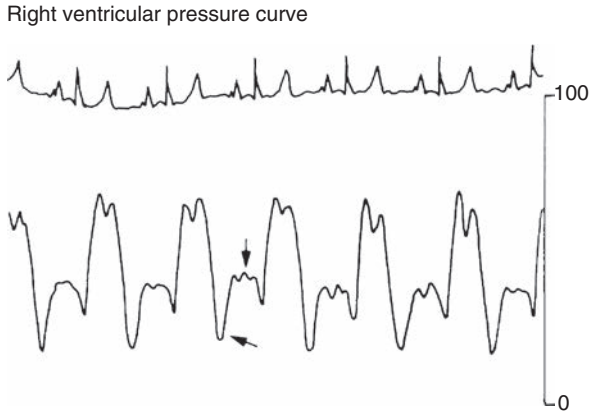

FIG. **9.47** Pressure tracing demonstrating elevated right ventricular (RV) end-diastolic pressure in a horse with constrictive pericarditis and heart failure. A quick rise occurs from the nadir of pressure *(lower arrow)* to a plateau *(upper arrow),* which is typical of constrictive disease and ventricular filling that is limited to early diastole.

loss syndrome, first recognized in Kentucky and subsequently also in other areas.[134,136,884-886] Exposure to eastern tent caterpillars was identified as the greatest risk factor in these outbreaks, and *Actinobacillus* spp. were the principal isolates obtained from necropsy and clinical cases.[134,885] It was proposed that caterpillar-related toxins or hairs of the caterpillars breached the gastrointestinal mucosal integrity and led to secondary opportunistic invasion of commensal bacteria of the mucosal surfaces that appeared to be pericardiotrophic in horses.[885] In many cases, idiopathic pericarditis might in fact be viral in origin, either directly or through immune-mediated mechanisms.[872] Equine influenza, equine viral arteritis, and equine herpes virus infections have been associated with pericarditis, and horses with pericarditis sometimes have a recent or current history of respiratory disease; nonetheless, evidence for a viral etiology is scarce.[872] External thoracic trauma or penetration by a gastric foreign body may lead to bacterial inoculation of the pericardial space.[741,874,877] The pathogenesis of noninfective pericarditis is unknown but might be immune mediated in some situations.[133] Finally, cardiac or pericardial neoplasia can cause pericardial effusion, with mesothelioma and lymphosarcoma being the most common neoplasms affecting the pericardium in horses. Pericardial hernias have also been seen but are rare.

The pathophysiology of pericardial disease in most cases is ascribed to impaired cardiac filling resulting from either external compression (cardiac tamponade) or pericardial constriction.[117] There is typically marked elevation in the venous, atrial, and ventricular end-diastolic pressures (Fig. 9.47). Occasionally a mass lesion compresses the heart or obstructs venous drainage or ventricular outflow and mimics findings of pericardial disease. Other clinical signs may be referable to the underlying cause as with infection or neoplasia.

The *clinical syndrome* of pericardial effusion with tamponade is characterized by reduced cardiac filling despite increases in ventricular filling pressures. The history usually includes systemic signs of illness, such as fever, lethargy, depression, anorexia, tachypnea, ventral edema, colic, and weight loss. A recent history of an upper or lower respiratory tract infection is not uncommon. Physical examination abnormalities include various combinations of tachycardia, fever, pericardial friction rub, muffled heart sounds, tachypnea, pleural effusion, jugular and generalized venous distention, ventral edema, thready pulses, and ascites. In acute cases, clinical signs of depression and weakness may predominate, whereas in chronic cases signs of right-sided CHF are evident. Arterial BP may be decreased in cardiac tamponade, and a pronounced inspiratory fall in BP (pulsus paradoxicus) may be identified by palpation of the pulse or through careful measurement of arterial BP. In chronic disease, BP is normal, owing to fluid retention, elevated venous pressures, vasoconstriction, and tachycardia.

Laboratory studies are contributory to the diagnosis. Clinical laboratory abnormalities are not specific, but the most frequently detected abnormalities include anemia, hyperproteinemia, hyperfibrinogenemia, and a neutrophilic leukocytosis. Other hematologic abnormalities may be observed related to inflammation, CHF, or organ hypoperfusion. Thoracic radiographs usually reveal a globoid cardiac silhouette or pleural effusion and may reveal interstitial pulmonary infiltrates and enlarged pulmonary vessels. The ECG usually demonstrates decreased amplitude of the QRS complexes. If the effusion is large and the heart is swinging, electrical alternans may be observed. Pericarditis may elevate the ST segment in multiple leads, but this change may occur simply as a result of tachycardia. Sinus tachycardia is typical, but ventricular or atrial premature complexes may be detected.

The echocardiographic examination is diagnostic, demonstrating an anechoic or hypoechoic fluid space between the pericardium and epicardial surface of the heart (see Fig. 9.46B) while excluding an extracardiac mass lesion, which can mimic pericardial disease.[140] Fibrin tags frequently are evident on the parietal and visceral pericardial surfaces. Findings of protracted diastolic collapse of the right ventricle or systolic collapse of the right atrium are compatible with a clinical diagnosis of cardiac tamponade. Inflammatory processes may eventually lead to adhesions between the parietal and visceral pericardial layers, causing constrictive pericarditis with minimal or no obvious effusion. Associated pleural effusion is a common ultrasound finding. Echocardiographic diagnosis of constrictive disease without effusion is more challenging but typically reveals thickened pericardium, atrial dilation, systemic venous dilation, exuberant movement of the ventricular septum, and exaggerated inspiratory filling of the heart as documented by pulsed-wave Doppler studies.[121,125] In some cases right-sided heart catheterization is needed to establish the diagnosis. Typical findings are increased central venous pressure, elevated RV diastolic pressure, and possibly a diastolic dip and plateau appearance to the RV waveform (see Fig. 9.47).[125]

Cytologic evaluation of the pericardial effusion is essential to distinguish septic, aseptic, or neoplastic pericardial effusion. Fluid can be obtained in the course of needle pericardiocentesis or during the placement of an indwelling tube for pericardial lavage and drainage. Bacterial culture and sensitivity of the aspirated fluid should be performed so that antimicrobial therapy can be guided in cases of septic pericarditis.

The treatment of pericardial diseases varies, depending on the cause and clinical situation. Even when signs of right-sided CHF dominate the clinical picture, the use of furosemide is generally contraindicated, because aggressive diuresis results in lowered filling pressures, reduced ventricular filling, decreased cardiac output, and possibly syncope. Instead, pericardiocentesis or catheter drainage should be considered as

first-line therapeutic procedure in all cases of pericardial effusion with cardiac tamponade. Because the development of cardiac tamponade depends not only on the volume of pericardial fluid but also on the rate at which it accumulates, the clinician's urgency should be guided by BP, clinical signs, magnitude of pleural effusion, and echocardiographic evidence of cardiac tamponade. Tamponade is an indication for immediate drainage of the pericardial sac. Echocardiography can be used to localize a site for pericardiocentesis and choose an appropriate length of needle, catheter, or drainage tube. Pericardiocentesis should be performed after locally anesthetizing the intercostal muscles and pleura. Electrocardiographic monitoring should be performed continuously during the procedure to monitor for cardiac puncture or in case ventricular arrhythmias develop. Pericardiocentesis is usually performed within the left fifth intercostal space, above the level of the lateral thoracic vein, although it can also be performed at the right hemithorax. Drainage is achieved using a large-bore catheter, teat cannula, or chest tube; the latter is recommended for repeated drainage and lavage of the pericardial sac and is most successful for aggressive management of septic or idiopathic fibrinous pericarditis. After insertion of an indwelling catheter, local therapy is administered that includes pericardial lavage and direct instillation of antimicrobials and possibly anticoagulants such as heparin. Combined with systemic antimicrobials this therapy has been effective in the treatment of septic pericarditis.[133,738] Pericardial lavage should be continued for several days, until there is little accumulation of pericardial fluid (less than 1 L over 12 hours), clinical signs have improved, and the cytologic character of the fluid becomes less inflammatory. Initially, broad-spectrum antibiotics should be used and the antibiotic regimen should then be adapted according to the results of bacterial cultures and antibiotic sensitivity patterns. Nonsteroidal antiinflammatory drugs are indicated to fight inflammation and to reduce the risk of constrictive pericarditis. If the cytologic analysis and culture are negative for bacteria, antiinflammatory doses of dexamethasone may be used for treatment of idiopathic, nonseptic, effusive pericarditis.[126,133] Exudative pericarditis may not respond in all cases to conservative treatment or even to drainage. Surgery is a rarely used option for treatment of pericardial disease but would be most appropriate for constrictive or constrictive-effusive pericarditis.[125] Presumably introduction of minimally invasive thoracoscopic surgical techniques to management of pericardial diseases in horses might prove useful.

The prognosis for survival and maintenance of performance in horses affected by pericardial disease is guarded. The prognosis for cardiac or pericardial neoplasia is quite poor. Caution also must be expressed regarding inflammatory pericarditis because the condition may become chronic, but very good results have been obtained in some reports.[133] The potential of eventual constrictive or fibrotic pericardial disease is also greatest with inflammatory pericardial conditions so that early success may be tempered by later complications of the disease.[126] The best prognosis of horses with fibrinous pericarditis is when treatment includes repeated drainage and lavage. Treated horses should be followed and reevaluated by echocardiography.

MYOCARDIAL DISEASE

Myocardial diseases are probably underrecognized in clinical practice although a variety of reports have been published regarding these disorders.* There is certainly a potential for myocardial injury or inflammation related to drugs and toxins (e.g., ionophore antibiotics, poisonous plants, cantharidin, snake venom), ischemia, hypoxia, infective agents (bacterial, viral, parasitic, fungal), heavy metals, trauma, metabolic disease, or nutritional deficiencies (e.g., vitamin E, selenium). Myocardial injury also can derive from extension of a preexisting infection (pericarditis, pericardial abscess, or endocarditis) or related to sepsis.[652] Infiltrative cardiomyopathies can occur consequent to neoplasia (lymphoma, melanoma, lipoma, hemangioma/hemangiosarcoma, mesothelioma, pulmonary carcinoma)[138,139,166,843,848,907-911] or the very rare amyloidosis[735] (Fig. 9.48; see also Box 9.2). Left ventricular hypertrophy and dysfunction may also develop secondary to systemic hypertension associated with chronic pain, laminitis, chronic kidney disease, or potentially metabolic syndrome.[143,903] Three cases of suspected arrhythmogenic right ventricular cardiomyopathy have recently been described as a cause of episodic collapse and cardiac death.[668,899] Dilated cardiomyopathy (DCM) phenotype has been recognized in the horse, but the underlying cause is generally unknown and the condition is usually considered to be idiopathic. Relentless junctional or ventricular tachycardia developing at a high rate (greater than 100–120 beats/min) and persisting over days can cause tachycardia-induced cardiomyopathy that resembles DCM and is characterized by chamber dilation and systolic dysfunction; control of HR and heart rhythm may lead immediately to more normal LV function, and the cardiomyopathy may resolve following conversion to sinus rhythm.[153]

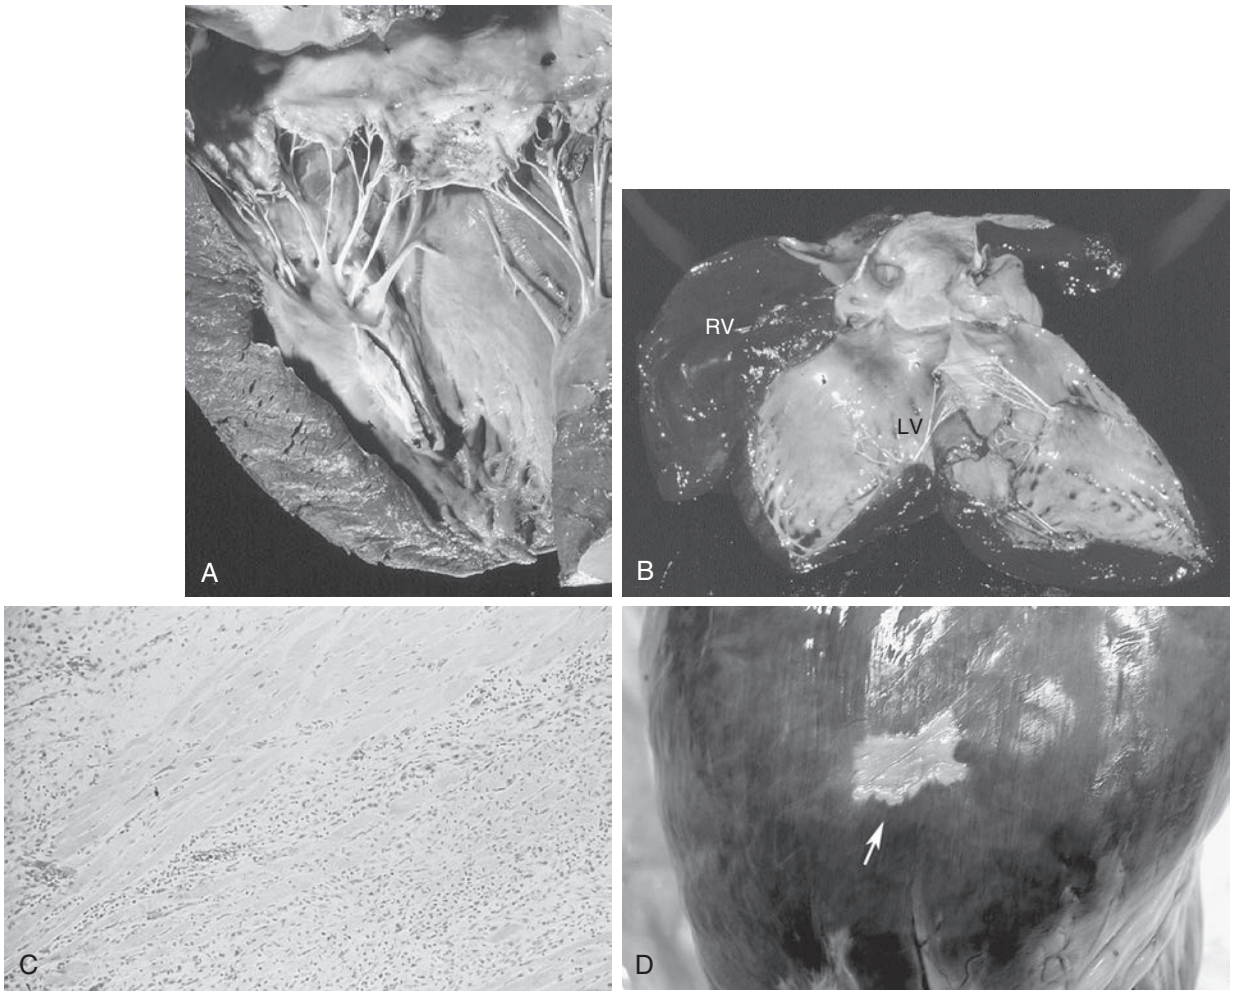
Clinical Features of Myocardial Diseases

The general manifestations of myocardial disease, regardless of the underlying injury, can be attributed to the following pathophysiologic processes: (1) reduced myocardial contractility and ventricular ejection fraction; (2) diastolic dysfunction with impaired ventricular filling; (3) mitral or tricuspid valve incompetency caused by cardiac dilation or papillary muscle dysfunction; or (4) the development of arrhythmias. The overall cardiac disability engendered by myocardial disease varies greatly. Some horses have no detectable clinical signs; others demonstrate exercise intolerance, life-threatening arrhythmias, low-output CHF, or sudden death.

Persistent ventricular premature depolarizations or ventricular tachycardia can be observed in horses with myocardial disease.[162,164,651,900,912] Atrial premature depolarizations, atrial tachycardia, and AF are more often primary electrical disturbances; however, these arrhythmias also can develop in horses with cardiomyopathies. Although it is tempting to diagnose "myocardial disease" in the setting of any cardiac rhythm disturbance, it should be appreciated that many rhythm abnormalities are "functional," without a gross anatomic substrate. This point is especially germane to horses suffering from electrolyte or other metabolic imbalances, high sympathetic tone, sepsis or toxemia, hypoxemia, or ischemia. In horses examined for sudden death at a racetrack, gross or microscopic myocardial lesions were relatively uncommon findings compared with pulmonary lesions.[103,106]

The onset of clinical signs may lag behind the initial myocardial insult, especially in cases of myocarditis or chronic myocardial injury. For example, a horse that has apparently

* References 28, 29, 66, 97, 138, 145, 149, 150, 154, 155, 160-162, 164, 166, 191, 485, 575, 651, 658, 660, 661, 734, 735, 777, 870, 882, 887-906.



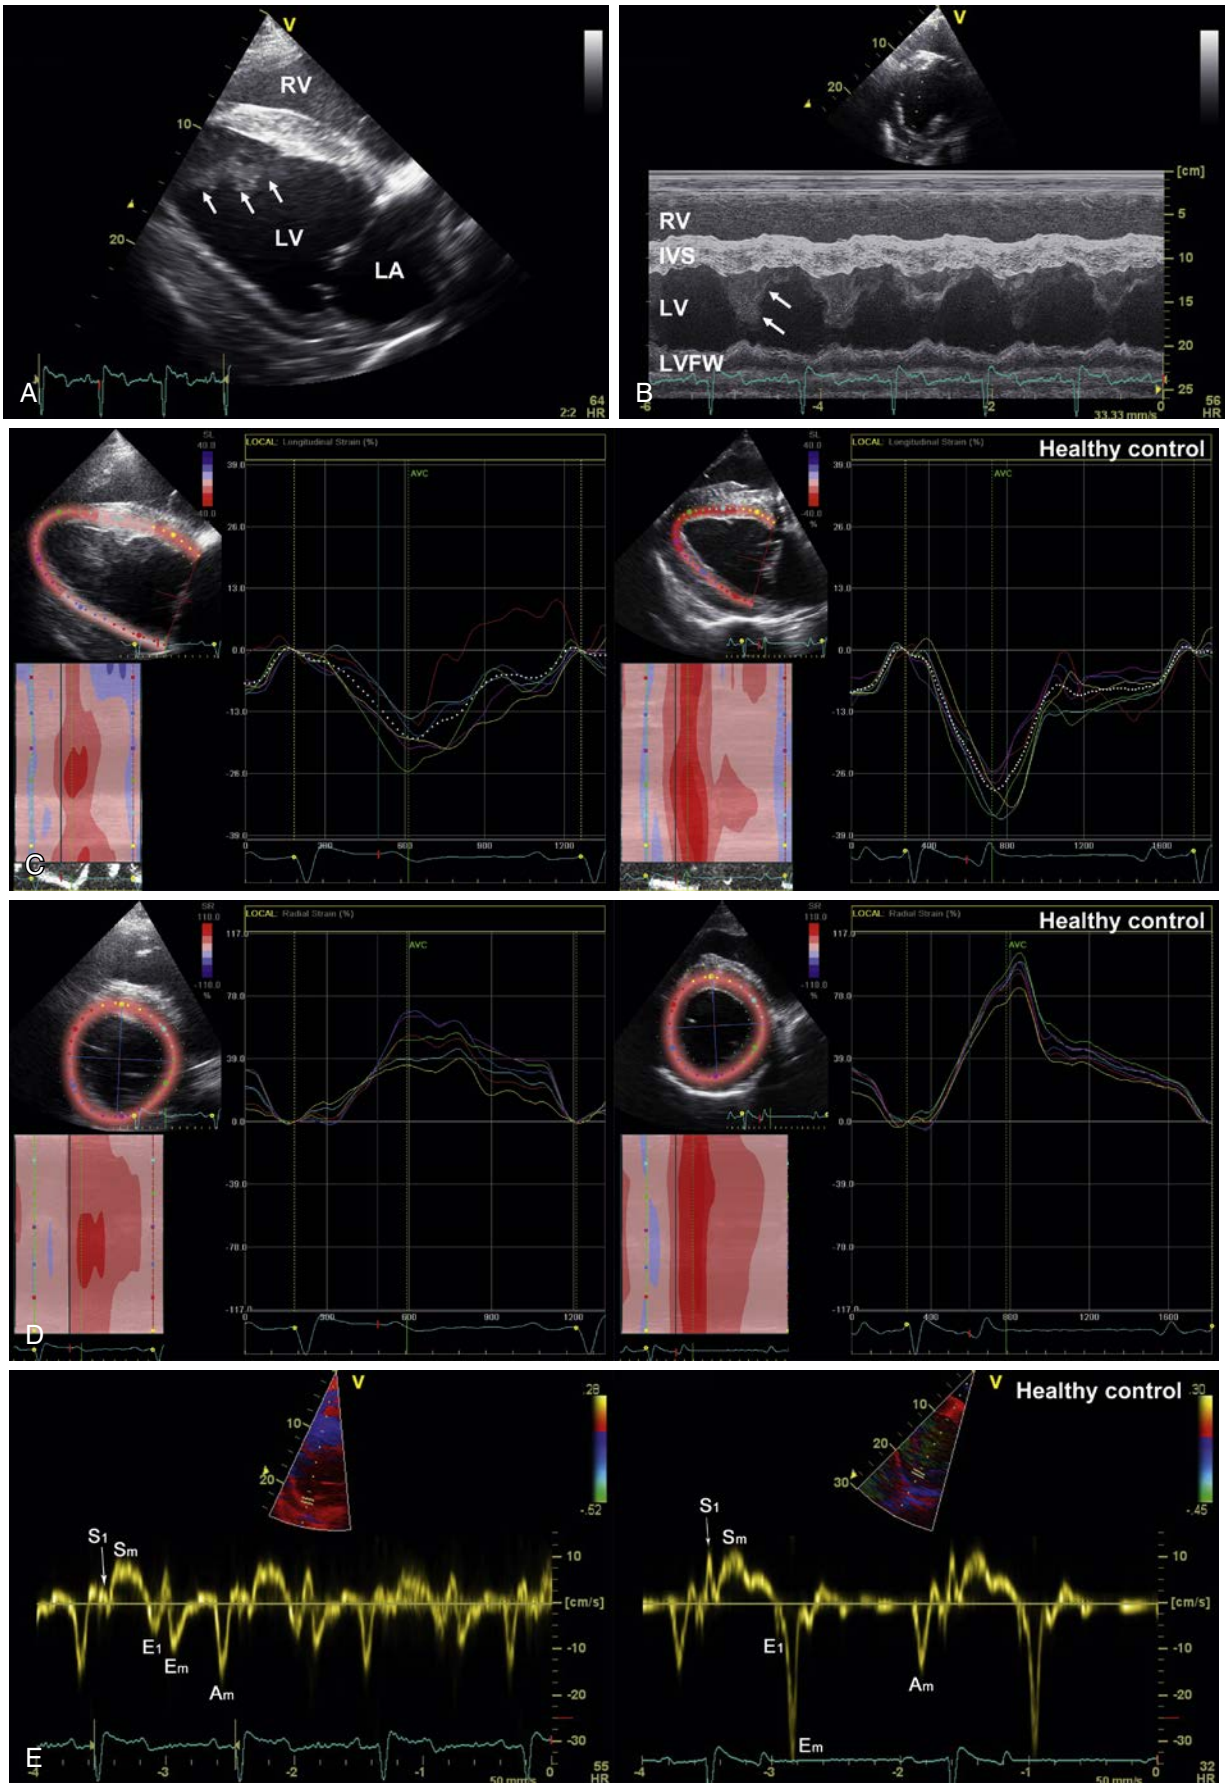


FIG. **9.48** Myocardial diseases. A, An opened left ventricle (LV) revealing a (incised) large, oval area of subendocardial and myocardial fibrosis in a mare. No causative agent was found. B, Significant LV dilation and subendocardial fibrosis in a horse with idiopathic dilated cardiomyopathy. The white discoloration of the LV and left atrium (LA) may result from chronic distention or represent fibrosis after another injury. The opened right ventricle (RV) (to the left) is dilated but is not discolored. C, Myocardial lymphoma. A substantial myocardial infiltration is evident in this photomicrograph. D, Close-up of a left ventricular subepicardial myocardial infarct *(arrow)* of undetermined cause.

recovered from an illness may develop problems once rigorous training is begun. The trainer may complain that the horse is unable to achieve faster speeds or may stop or suddenly slow during hard training. The affected horse may take a long time to "cool out" after a workout. In more severe cases, marked exercise intolerance, weakness, ataxia, or even collapse may occur. Respiratory distress, pulmonary edema, cyanotic mucous membranes, prolonged capillary refill time, and a rapid thready pulse may be detected after exercise. In case of severe myocardial injury, signs such as fever, persistent tachycardia, arrhythmia, murmur, pulmonary or ventral edema, or respiratory distress may be observed. Sudden death may occur without premonitory signs.

Results of the clinical examination in horses with myocardial disease are inconsistent. Resting physical examination findings can be normal or signs of heart disease may be evident. These can include persistent tachycardia, tachypnea, frequent premature beats, sustained arrhythmias, systolic murmurs of AV valvular insufficiency, or CHF. A postexercise examination often detects an abnormally rapid HR, which remains persistently high after exercise is discontinued (note that exercise testing should not be performed in horses with persistent resting tachycardia or tachyarrhythmia that may be attributed to myocardial disease).

An ECG may demonstrate sinus tachycardia or atrial or ventricular arrhythmias. An exercise ECG, in addition to potential exercise-induced arrhythmias, typically records an inappropriately high HR for the level of work undertaken.

Resting echocardiography usually reveals a low normal or unambiguously reduced ventricular systolic function, as demonstrated by low LV shortening fraction or ejection fraction. Novel echocardiographic methods such as tissue Doppler imaging (TDI) or 2D speckle tracking might be more sensitive to detect LV systolic dysfunction compared with conventional 2DE or M-mode echocardiography[161,164] and could be particularly useful to detect subtle myocardial disease in horses (Fig. 9.49). Furthermore, Doppler interrogation of transmitral blood flow (E and A wave) and LV wall motion analysis using TDI (E_m and A_m wave, isovolumic relaxation time) can reveal significant LV diastolic dysfunction in the presence of normal

or impaired systolic function,[164] strongly suggesting myocardial disease (see Fig. 9.49). Depending on the type of myocardial disease, the (relative) LV wall thickness can be increased (i.e., infiltrative or hypertensive cardiomyopathy) or decreased (i.e., dilated or tachycardia-induced cardiomyopathy; see Fig. 9.23). Postexercise echocardiography may demonstrate a paradoxic reduction of LV shortening fraction or regional dysfunction characterized by LV wall motion abnormalities.[167,168] Marked increases in left ventricular or left atrial spontaneous contrast may be observed with very poor myocardial function, although this is not a specific finding (see Fig. 9.49). Abnormal areas of myocardial echogenicity have been observed, but myocardial tissue characterization by echocardiography is not well established in horses, and grayscale also depends on technical factors.

Clinical laboratory tests may be useful in the identification of myocardial damage but may not necessarily distinguish myocarditis from myocardial cell injury induced by a toxin or by ischemia. Elevated plasma or serum creatine kinase activity (CK), myocardial fractions of creatine kinase (CK-MB), or lactate dehydrogenase (LDH_{1-2}) suggest myocardial injury.[352] A more specific marker of myocardial is elevation of plasma cardiac troponin I (cTnI) or troponin T (cTnT).* Although normal values or mild elevations do not exclude cardiomyopathy or myocardial infiltration, markedly elevated values (i.e., cTnI greater than 1 ng/mL) point to recent cardiac muscle damage. Persistently elevated plasma cTnI concentrations indicate ongoing damage, because plasma half-life of cTnI is short.[680]

Diagnosis of myocardial disease requires clinical suspicion and integration of findings from clinical and laboratory examinations. Because of the extreme variability of findings, the presumptive diagnosis of myocardial disease can be made only after reviewing the history, physical examination, echocardiogram, ECG, and clinical laboratory tests. Definitive diagnosis of myocarditis requires transvenous endomyocardial biopsy,[913] but this test is currently limited to research purposes and may not identify piecemeal inflammation, degeneration, infiltration, or necrosis.

Treatment of horses affected by myocardial disease is primarily supportive. Prognosis depends on the cause and severity of myocardial injury and the hemodynamic consequences of myocardial disease. All horses should be rested, preferably in a stall, until myocardial function, ECG, and plasma troponin concentrations return to normal or at least remain stable for several weeks. A minimum rest of 1 month (and usually more) should be instituted before a horse is returned to work. Supplementation with vitamin E and selenium may be beneficial, particularly in cases with suspected nutritional deficiencies. Antiarrhythmic therapy is administered when indicated for potentially life-threatening arrhythmias (see later in this chapter). Theoretically, an ACE inhibitor will reduce myocardial remodeling and unload the ventricle, assuming the drug can be sufficiently absorbed and biotransformed to an active state; however, efficacy of this treatment is currently unknown. When CHF has developed, diuretics, peripheral vasodilators, and positive inotropic agents may be prescribed as previously discussed in the section on CHF. Digitalization should be undertaken with caution in horses with ventricular extrasystoles, as the arrhythmia may be aggravated and it is not indicated in ionophore toxicosis (see later). For a suspected bacterial etiology, antibiotic treatment is indicated. If noninfective myocarditis is believed to be the cause of the arrhythmia or clinical signs, corticosteroid therapy may be indicated, although its value is unsubstantiated. When the principal manifestation of myocardial disease is electrical (arrhythmias with otherwise normal myocardial function), the prognosis is fair to good for resolution of the arrhythmias. Horses with decreased myocardial function by echocardiography or those with CHF must be given a guarded prognosis for life and a poor prognosis for

FIG. **9.49** Nutritional myocardial damage. Echocardiographic examination in a 22-year-old Arabian mare suffering from nutritional masseter myopathy with concurrent myocardial damage (cardiac troponin I concentration 11.6 ng/mL; normal <0.06 ng/mL). This case study demonstrates the clinical use of novel echocardiographic indices for the assessment of systolic and diastolic LV function in horses with myocardial disease. A, B-mode recording of the left ventricle in right-parasternal long-axis 4-chamber view. Left atrial (LA), left ventricular (LV), and right ventricular (RV) dimensions appear normal. There is marked spontaneous echo contrast in the LV *(arrows).* This can be found in healthy horses but may become more distinct with low-output states, bradycardia, and possibly systemic inflammation. B, M-mode recording of the LV in a right-parasternal short-axis view. Notice the flat motion of the interventricular septum (IVS) and the LV free wall (LVFW), suggesting poor LV systolic function (LV fractional shortening 22%; normal 30%–45%). Marked spontaneous echo contrast is evident *(arrows).* C, Two-dimensional speckle tracking (2DST) analyses of an LV long-axis recording. Trace screens of the 2DST software are shown, displaying the following information: *top left,* 2D image with the segmented ROI and parametric color coding at the time of aortic valve closure. *Bottom left,* M-mode with parametric color coding. *Right,* Trace display for longitudinal segmental strain (i.e., relative myocardial deformation). The horizontal axis represents the time in msec, the vertical axis represents radial strain in %. The colors of the trace correspond to the colors of the segmented ROI. An ECG is superimposed for timing. The start and the end of the cycle (R waves) are marked on the ECG with yellow dots. Time of aortic valve closure (AVC) is indicated by a green vertical line, dividing the cycle in its systolic and diastolic component. The dotted line indicates the instantaneous average over all segments at the respective time of the cardiac cycle (global strain). Note that peak longitudinal strain in this case *(left)* is reduced compared with the healthy control *(right),* indicating depressed LV systolic function. D, 2DST analyses of an LV short-axis recording. Trace screens of the 2DST software are shown, displaying longitudinal segmental strain (for further explanations see C). Note that peak radial strain *(left)* in this case is reduced compared with the healthy control *(right),* indicating depressed LV systolic function. E, Pulsed-wave tissue Doppler (PW TDI) analysis of the LV free wall recorded at the level of the chordae tendineae in a right-parasternal short-axis view. The horizontal scales of the spectral tracings indicate the time in seconds, the vertical scales indicate the velocity in cm/sec. The E_m/A_m inversion *(left)* indicates diastolic dysfunction and impaired ventricular relaxation. Notice the normal E_m/A_m ratio in the healthy control *(right)* for comparison. S_i, Peak radial wall motion velocity during isovolumic contraction; S_m, peak radial wall motion velocity during ejection; E_i, peak radial wall motion velocity during isovolumic relaxation; E_m, peak radial wall motion velocity during early diastole; A_m, peak radial wall motion velocity during late diastole. (From Schwarzwald CC: Ultrasonography of the heart. In: Kidd JA, Lu KG, Frazer ML, et al.: *Atlas of equine ultrasonography,* Wiley, Oxford, UK, 2014. Reproduced with permission of John Wiley & Sons, Ltd.)

future performance. It is notable, however, that some horses with LV hypertrophy and dysfunction and some with acute onset of CHF have recovered completely and returned to their prior performance level. Such horses most likely suffered from acute myocarditis that resolved spontaneously or following antiinflammatory therapy. Other horses may achieve a less spectacular recovery but still serve successfully as breeding animals.

Myocarditis

Myocardial inflammation, or myocarditis, is difficult to diagnose. The diagnosis is often entertained in horses with cardiac arrhythmias, concentric LV hypertrophy (supposedly acute myocarditis with cell infiltration and myocardial edema) or severe LV dilation (supposedly chronic or later stages), and abnormal myocardial function, particularly when cardiac signs occur after another illness and are associated with elevated cardiac isoenzymes or plasma cTnI or cTnT concentrations. Often the prior disorder is a viral, influenza-type condition or an infection caused by *Streptococcus* spp., but parasitic migration, fungal infections, or toxic insults can also result in inflammatory myocardial lesions that may not obviously be associated with preceding clinical disease.* It is logical that immune-mediated myocarditis is operative in many of these cases, but definitive cause-and-effect proof is lacking. Myocarditis may also follow pericarditis or infective endocarditis. Hematogenous spread to the heart may be another mechanism for myocarditis. The signs, prognosis, and treatment of myocarditis are similar to that described in the preceding section.

Toxic Injury of the Myocardium

A number of chemicals and plant toxins are potentially injurious to the myocardium. Ionophore antibiotics are among the most notorious causes of myocardial necrosis in horses.[154-163,656,901,902,915] Toxic myocardial injury also can occur following ingestion of glycoside-containing yew plants (*Taxus* spp.), oleander *(Nerium oleander),* foxglove (*Digitalis* spp.), and summer pheasant's eye *(Adonis aestivalis)*[897,898,912,916-920] or from eating feed contaminated by *Epicauta* species (blister beetles), which contain the toxic element cantharidin.[889,891,921-928] Atypical myopathy (AM) and seasonal pasture myopathy (SPM) that are caused by ingestion of hypoglycin A–containing seeds of maple trees (*Acer* spp.)[575,674-676,929-938] and marshmallow *(Malva parviflora)* toxicosis,[904] through different mechanisms, can cause severe generalized myopathy with myocardial involvement/damage. Myocardial necrosis has also been observed in association with clostridial infection and following endotoxemia, particularly with salmonellosis and torsion of the large colon. Venom of rattlesnakes (*Crotalus* spp.) and of other members of the family of vipers *(Viperidae)* has been associated with cardiac injury and arrhythmias.[659,900,939]

Ionophore Toxicity

Horses are uniquely sensitive to ionophore antibiotics, which are used as a coccidiostat in poultry production and as a growth promoter in cattle. Monensin toxicosis (acute oral LD_{50} 2–3 mg/kg) has occurred most frequently,[154-160,163,901,940] but salinomycin (acute oral LD_{50} 0.6 mg/kg)[915,941,942] and lasalocid (acute oral LD_{50} 21.5 mg/kg)[161,162,943] also have caused myocardial injury and death in horses.[928,944-946] Ionophores react with polar cations to form lipid-soluble complexes, leading to cation transport across myocardial cell membranes. Various ionophores demonstrate particular affinities for different cations, though lasalocid may complex with a variety of ions. Exposure of horses to the ionophore antibiotics usually stems from accidental contamination of equine feedstuffs at the mill or through accidental delivery of poultry or cattle feed to horses. In most outbreaks, a recently acquired ration was fed.

Clinical signs of horses with ionophore toxicity vary with the specific type, quantity, and concentration of ionophore ingested and the preexisting health and body condition of the exposed horses. A wide range of clinical signs has been observed in exposed horses ranging from none to clinical signs involving almost all body systems.[156,157,160,162,163,915] Weakness, lethargy, depression, anorexia, ataxia, colic, diarrhea, profuse sweating, and recumbency have been seen. The cardiac findings are similar to those previously described for myocardial diseases. If sudden death occurs, it is usually within 12 to 36 hours of ingestion of the contaminated feed. A single dose may lead to peracute death from cardiac arrhythmias before the development of myocardial necrosis and associated with only mild signs of colic or neurologic deficits.[901]

Sublethal toxicosis may be well tolerated by some but not all horses, and plasma cTnI concentrations, echocardiography, and exercise testing may help to identify horses affected more severely.[160-163,656] Polyuria and hematuria are other signs that have been reported in ponies following ionophore exposure.

A diagnosis of ionophore toxicity is based on the detection of the ionophore in the feed or stomach contents of exposed horses. Various clinicopathologic abnormalities are observed with monensin toxicity, including decreased serum calcium, potassium, magnesium, and phosphorus and increases in serum urea, creatinine, unconjugated bilirubin, aspartate aminotransferase, and muscle enzymes. Elevated concentrations of plasma cardiac troponin (cTnI, cTnT) and isoenzyme patterns of CK and LDH have indicated cardiac, skeletal, and RBC damage. Elevated packed cell volume and total solids have been associated with dehydration. Echocardiographic evaluation of affected horses has revealed marked decreases in shortening fraction with segmental wall motion abnormalities that range from mild to severe.[161]

Prognostically, horses that exhibit decreased shortening fraction and dyskinesis shortly after exposure to monensin generally are unlikely to survive. Horses with mild decreases in shortening fraction survive and may be useful breeding animals, but most do not return to previous performance levels. Horses with normal echocardiograms typically survive and may return to work at their previous level. The magnitude of increase in plasma cTnI or cTnT concentrations and rate of decrease over time likely has some prognostic implications; however, even in surviving animals concentrations can remain increased for several months, likely because of ongoing release from damaged myocytes.[162] Postmortem findings range from no visible lesions to myocardial pallor and signs of CHF. Severe myocardial necrosis and fibrosis has been observed in horses with decreased shortening fraction or ventricular dyskinesis on echocardiography.

Treatment for affected horses is largely symptomatic (see earlier), unless very recent exposure is known. Vitamin E has been suggested to have a protective effect in other species

* References 149, 658, 870, 900, 902, 905, 914.

and may be beneficial in affected horses. Digoxin and calcium channel blockers are contraindicated in acutely affected horses. If ingestion of the contaminated feedstuff is recent, treatment with activated charcoal or mineral oil is indicated to reduce absorption of the ionophore. Intravenous fluid and electrolyte replacement therapy may be indicated, as well as antiarrhythmic drugs, for any life-threatening arrhythmias. Stall rest in a quiet environment for up to 8 weeks after exposure is most important, because echocardiograms recorded after trivial exercise or excitement can reveal residual disease characterized by marked decreases in fractional shortening and myocardial dyskinesis.

Dilated Cardiomyopathy

Idiopathic dilated cardiomyopathy is a disorder of the myocardium characterized by global reduction of LV systolic function that cannot be explained by valvular, vascular, coronary, or congenital heart disease. The inciting cause of dilated cardiomyopathy is generally undetermined, although myocarditis or prior toxic injury is often suspected. Relentless junctional or ventricular tachycardia also can lead to a DCM state that is reversible with control of the tachyarrhythmia (see earlier discussion).[153] The clinical signs of cardiomyopathy are similar to those described earlier for other myocardial diseases. Echocardiography is diagnostic, revealing cardiomegaly with biatrial and biventricular dilation and depressed shortening fraction (see Fig. 9.23B). Symptomatic therapy with digoxin and diuretics may temporarily stabilize CHF and lead to transient improvement, but most horses deteriorate in the 3 to 12 months after diagnosis and are humanely destroyed. Neither the history nor the postmortem examination reveals the cause, and generally only diffuse or multifocal myocardial degeneration, necrosis, and fibrosis are observed.

A form of dilated cardiomyopathy also can be caused by vitamin E and selenium deficiency and is observed primarily in fast-growing foals from mares with a marginal or deficient selenium status raised in selenium-deficient areas.[178] Affected foals are usually younger than 6 months of age and present with an acute onset of weakness, recumbency, respiratory distress, pulmonary edema, tachycardia, murmurs, and arrhythmias. The prognosis for foals affected with the myocardial manifestations of white muscle disease is poor, and most die within 24 to 48 hours after the onset of clinical signs. Laboratory abnormalities in affected foals include marked elevations of CK (including the MB fraction in foals with myocardial involvement), aspartate aminotransferase (AST), and LDH, as well as hyperkalemia, hyponatremia, and hypochloremia. Myoglobinuria may occur. Echocardiography demonstrates the severity of myocardial involvement. Whole blood selenium, RBC glutathione peroxidase, and vitamin E concentrations may be helpful in the diagnosis; however, tissue samples provide a more accurate indication of selenium stores. Treatment with vitamin E and selenium might be successful, but typically the myocardial necrosis is extensive and incompatible with life. Postmortem findings reveal pale streaking of the myocardium with intramuscular edema, myodegeneration, myocardial necrosis, and fibrosis or calcification.[165] Prevention of white muscle disease is important in selenium-deficient areas. Supplementation of pregnant mares should occur during gestation based on individual blood and tissue selenium concentrations and should be continued during lactation, because more selenium is passed to the foal through the milk than across the placenta.

VASCULAR DISEASES

Acquired disorders of blood vessels include a variety of conditions that vary in etiology and range from subclinical to devastating.* Jugular vein thrombosis or thrombophlebitis is probably the most common vascular problem encountered in clinical practice (Fig. 9.50).[456,458,957-962] Catheter fragmentation and embolization are observed periodically and have been amenable to surgical and percutaneous catheter retrieval.[963-967] Venous aneurysms, vascular and lymphatic malformations, and angiomatous lesions are rare.[952,968-974]

Rupture of the aorta or pulmonary artery is usually a life-threatening event or leads to severe sequelae.[768] Aortic aneurysms, rupture of aortic sinus aneurysm into the ventricular septum or right heart chambers (Figs. 9.51 and 9.52), aortic rupture into the pericardium, and acquired aortic-pulmonary fistula have been reported.[34,63,92,261-266,866,975-977] Rupture of the PA is a potential consequence of long-standing pulmonary hypertension and left-sided heart failure. Periparturient rupture of the middle uterine artery[260,978-982] and rupture of the internal carotid artery, external carotid artery, or maxillary artery with guttural pouch mycosis[983-985] are well recognized and may lead to fatal events. Arteriovenous communications occur rarely and may develop after rupture of smaller arteries or subsequent to growth of vascular tumors. Degenerative lesions (see Fig. 9.52A) including calcification may be observed in the great or peripheral arteries.[947,978,986,987] Degenerative and calcific lesions affecting the bifurcation of the right and left pulmonary arteries also have been reported,[988,989] although the clinical importance of these is not well defined. Arteriosclerosis and arterial thrombosis may be caused by parasite migration in the mesenteric arteries[990] and possibly at the terminal aortic quadrifurcation (Figs. 9.53 and 9.54). Aortic inflammation of unknown cause has been observed.[784,991] Pulmonary vascular disease and pulmonary structural remodeling due to pressure loading (e.g., left-sided heart failure) or increased pulmonary flow (e.g., left-to-right shunting through a VSD) can result in pulmonary hypertension with resulting right heart failure or cor pulmonale (see earlier discussion). Tumors of the great arteries and veins are rare,[952] but neoplasms can compress or invade arteries and veins, including the PA and vena cavae.

The ultrasonographic observation of spontaneous echo contrast within blood vessels and cardiac chambers has been suggested to indicate CV or rheologic disease,[992,993] as well as a normal phenomenon caused by rouleaux formation or platelet aggregates. This observation is common during ultrasound examinations, and contrast may be observed in a variety of vessels, as well as in the heart (see Figs. 9.42, 9.49, and 9.50). Pronounced spontaneous echo contrast is especially likely when there is actual obstruction to blood flow in vessels or when there are low flow rates due to bradycardia, arrhythmia, or myocardial failure. Contrast is often prominent in valvular endocarditis. Lesions, thrombosis, or even venipuncture of the jugular vein can lead to spontaneous echo contrast in systemic veins and in blood flow entering the right side of the heart, often becoming become more obvious if venous return suddenly increases. The identification of spontaneous contrast is also dependent on the operator with respect to transducer, gain, and grayscale contrast settings. The clinical significance

*References 34, 63, 64, 85, 91, 92, 96, 100, 145-147, 260-262, 264, 267-273, 364, 450, 451, 456, 458, 549, 768, 771, 864, 866, 867, 947-956.

of isolated intravascular contrast cannot be stated with certainty, and it has been observed in healthy horses as well as those with CV disease.

Serious vascular disease often can be suspected from the clinical examination, although it may not be obvious until a catastrophic vessel rupture or fatal hemorrhage occurs. In general, significant arterial disease reduces perfusion to the affected vascular bed, impairing tissue metabolism and function. If severe or complete, ischemia may lead to tissue necrosis (infarction) and even perforation of a hollow organ. There may be a bruit—auscultatory evidence of vascular narrowing or rupture—over the affected artery or obvious hemorrhage if a superficial the vessel has ruptured. Ultrasound and Doppler examination can demonstrate serious arterial disease provided there is an acoustic window for examination. Rarely angiography or nuclear scintigraphy is required to demonstrate arterial thrombosis or disruption. In major venous disease, the typical sign is swelling of soft tissues drained by the affected vessel. Palpable evidence of local inflammation and thrombosis may be found in superficial venous disease. Right-sided endocarditis, embolic pneumonia, and pulmonary embolism are potential consequences of systemic venous disease.

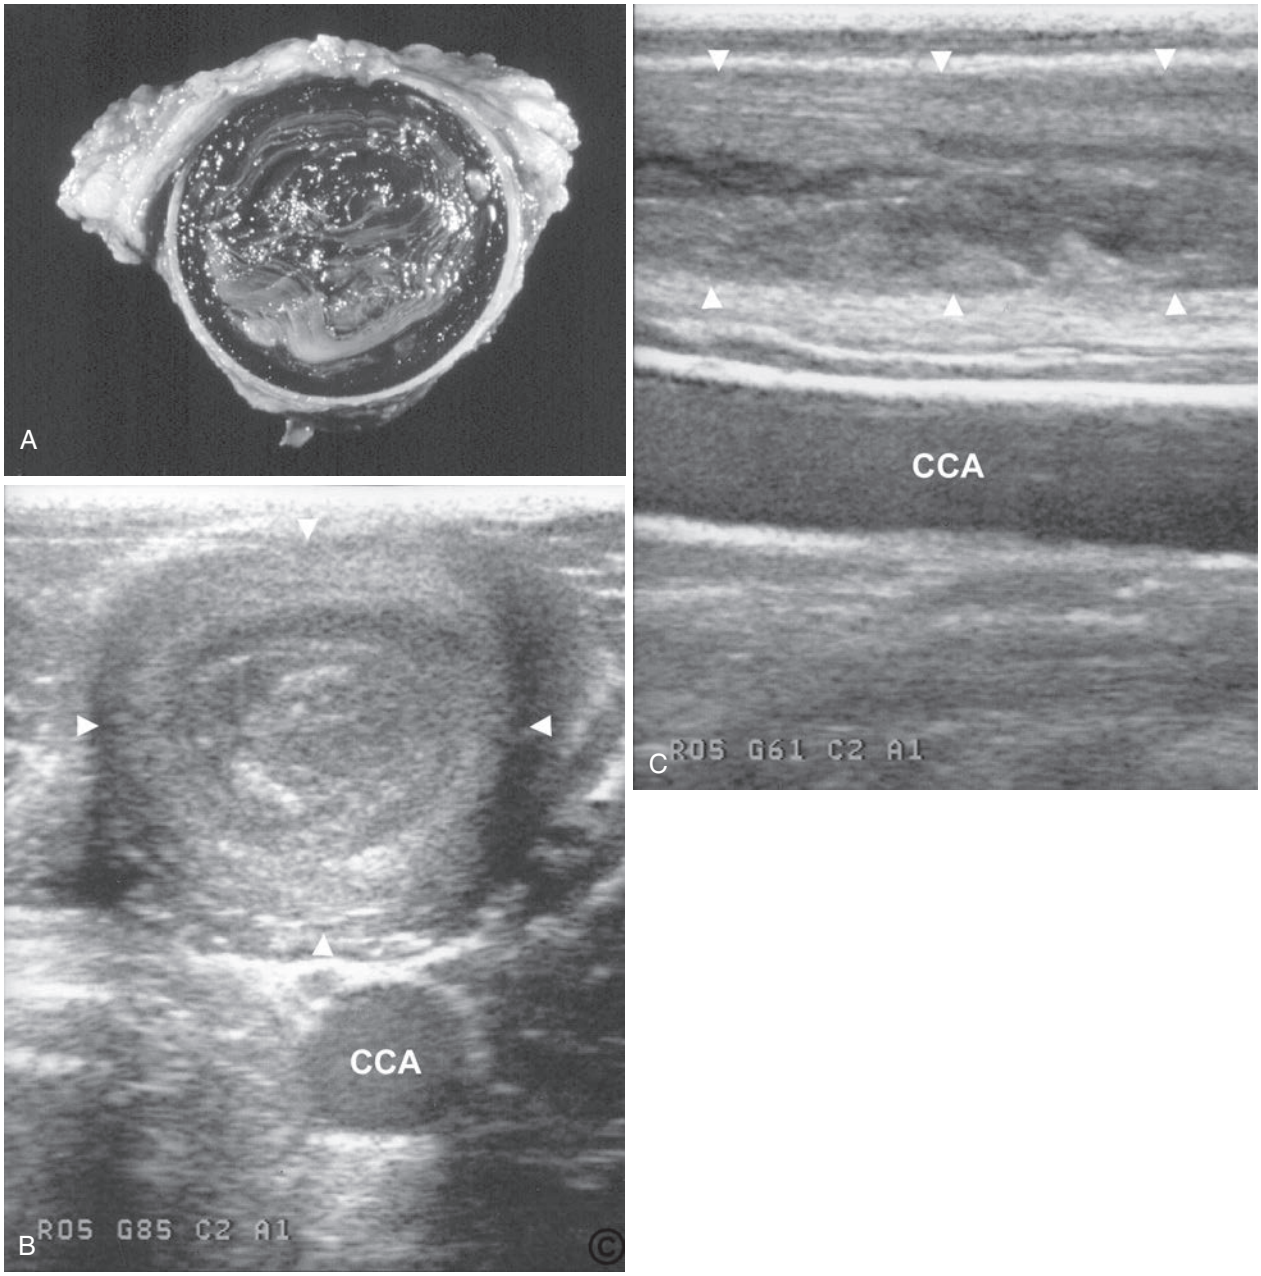

FIG. **9.50** A, Postmortem specimen of a thrombosed jugular vein in cross section. B and C, Ultrasonographic images obtained form a horse with jugular vein thrombosis in a cross-sectional (B) and a longitudinal (C) plane. The images show a mixed echogenic thrombus within the jugular vein *(arrowheads).* The common carotid artery (CCA) is displayed adjacent to the jugular vein. Residual blood flow through the affected area can be evaluated using duplex Doppler ultrasonography or newer vascular imaging technologies that directly visualize blood reflectors (e.g., red blood cells [RBCs]) in a grayscale display.

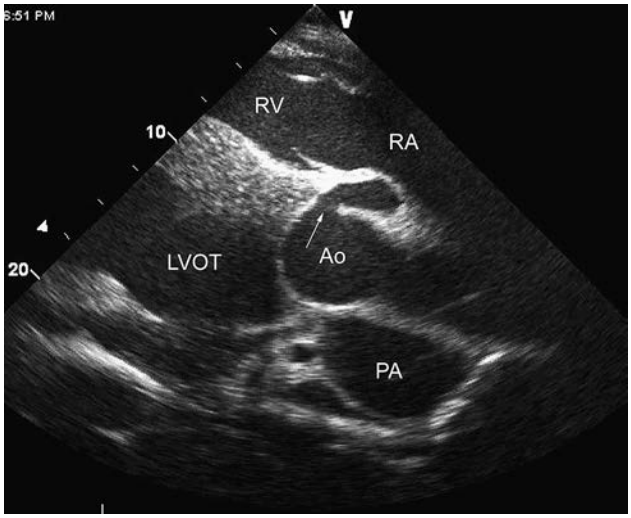

FIG. **9.51** Aortic to cardiac fistula. Off-angle long-axis image of the proximal aorta (Ao) shows the origin *(arrow)* of a ruptured sinus of Valsalva aneurysm. This channel communicated with the right atrium (RA) in another plane. The right ventricle (RV) and pulmonary artery (PA) are slightly dilated because of left-to-right shunting.

Thrombophlebitis

Thrombus formation results from an interplay of multiple factors, including vessel injury or intrinsic vessel wall lesions, blood hypercoagulability, and low-flow states or venous stasis (Virchow's triad).[957] Thrombophlebitis, the inflammation and thrombosis of a vein, in horses is most commonly caused by intravenous catheterization or injection (see Fig. 9.50),[456,458,957-962,994,995] suggesting that local trauma seems to be the most important factor.[959] The jugular veins are most often affected, but cephalic, lateral thoracic, and saphenous veins are sometimes also used for permanent venous access and therefore can be affected as well. The degree of vessel injury and therefore the risk of thrombophlebitis depends on a variety of factors, including technique of catheter placement, stability of the catheter, catheter hygiene and maintenance, training of personnel, and dwell time of the catheter.[457,959,967,996] Catheter material, length, and diameter likely determine the risk of thrombosis or thrombophlebitis. Longer catheters made of materials that are less stiff or rigid are preferable over short, rigid catheters. Polyurethane over-the-wire catheters are thought to carry the least risk of thrombosis and are commonly used for long-term indwelling venous catheterization in horses and foals. Polyurethane over-the-needle catheters are thought to

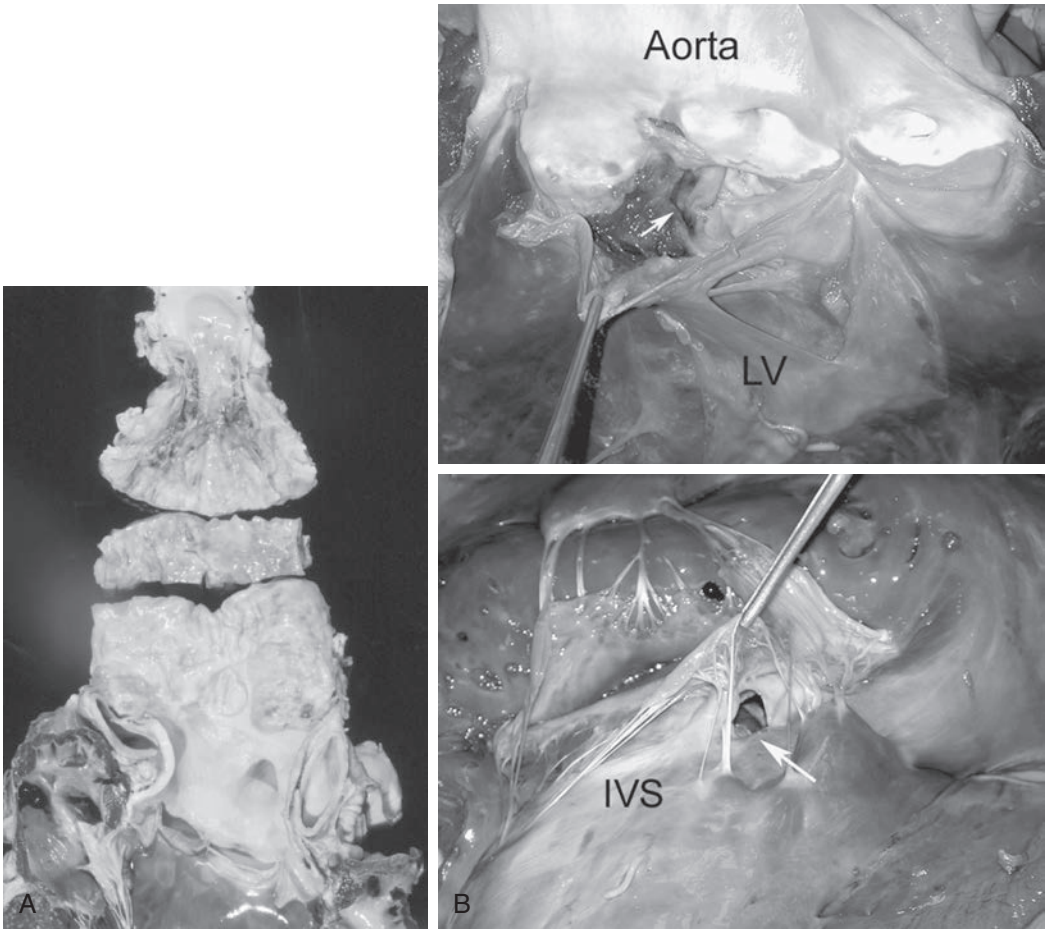

FIG. **9.52** Aortic disease. A, Severe atheromatous change with secondary *Streptococcus* spp. infection of the proximal aorta. The intimal and subintimal change begins just distal to the coronary ostia. Representative sections of the ascending aorta are shown. *Strongylus vulgaris* was not found. The most distal segment was necrotic and severely narrowed flow across the region. B, Dissecting lesion communicating the root of the aorta *(top panel, arrow)* to the right side of the heart across the intraventricular septum (IVS). The distorted tricuspid valve is retracted to demonstrate the lesion on the right *(arrow)*.

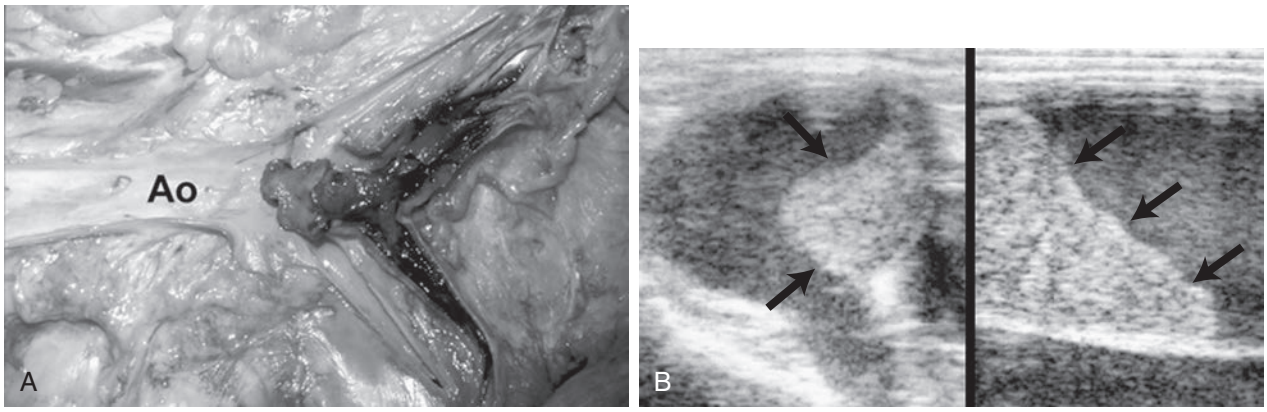

FIG. **9.53** Aortoiliac thrombosis. A, Postmortem image showing the thrombus in the terminal aorta (Ao) and the iliac arteries. B, Images obtained by rectal ultrasonographic examination in cross-sectional *(left)* and longitudinal *(right)* direction. The thrombus is evident as a hyperechoic mass within the vessel *(arrow)*.

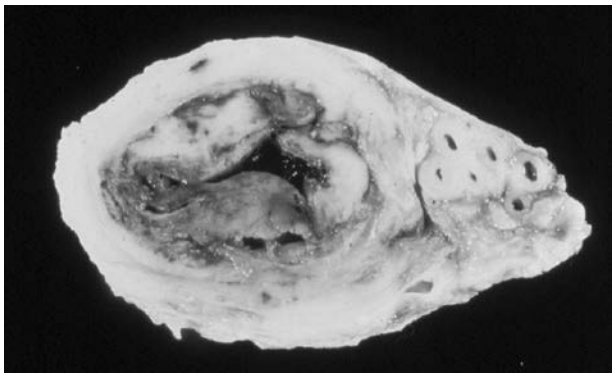

FIG. **9.54** Verminous arteritis and thrombosis in the cranial mesenteric artery caused by *Strongylus vulgaris*.

have a slightly higher risk, and polytetrafluoroethylene (PTFE, Teflon) catheters likely carry the greatest risk of thrombosis.[967,997-999] Some catheters are coated with antibacterial substances to inhibit bacterial growth, but proof of efficacy to prevent catheter-related infection is lacking in horses. The source (i.e., commercially versus locally produced), pH, and osmolality of intravenously administered fluids and the method and rate of IV fluid administration (determining the amount of turbulent blood flow and irritation to the vascular endothelium at the catheter tip) further influence the risk for venous thrombosis or thrombophlebitis.[456,457,967,998,1000] The pharmaceuticals most frequently associated with the development of thrombophlebitis include glyceryl guaiacolate, thiopental, calcium gluconate, oxytetracycline, and phenylbutazone.[957]

Patient factors, including presence of fever, large intestinal disease, hypoproteinemia, salmonellosis, endotoxemia, and other diseases characterized by a hypercoagulable state, are significantly associated with development of catheter-related thrombophlebitis in horses.[457,958,959,967,998,1001] Critically ill patients often stand with their head and neck in a low position, promoting increased turbulence and stagnation of blood flow, which further increases the risk of jugular thrombosis.[998]

Thrombophlebitis can be nonseptic or septic. Migration of skin organisms into the cutaneous catheter tract; direct contamination of catheter or catheter hub by contact with hands, contaminated fluids, or devices or when getting disconnected (e.g., when the horse is moving or rolling in the stall); hematogenous infection from another infectious focus; or contamination of the infusate can result in septic inflammation and thrombosis.[996]

Clinical signs of phlebitis are straightforward, including swelling over the affected vein and pain on palpation of the involved tissues. There is frequently a cellulitis associated with the catheter entrance site causing swelling, pain, and exudation. Note that phlebitis is not always associated with venous thrombosis. Conversely, venous thrombosis can occur without obvious signs of inflammation. Smaller mural thrombi may not cause any obvious clinical signs as long as residual (or collateral) blood flow is sufficient to allow adequate venous drainage. One study showed that approximately 30% of sick horses with long-term indwelling catheters may develop subclinical catheter-related disease.[1001] Partial or complete venous occlusion through a larger thrombus results in distention of the veins and possibly subcutaneous edema adjacent to the affected area. Unilateral complete jugular occlusion is usually well tolerated, but bilateral jugular vein thrombosis can lead to marked head edema and possibly result in poor performance. Marked swelling, heat, and pain on palpation, combined with fever, hyperfibrinogenemia, increased concentrations of serum amyloid A, or a neutrophilic leukocytosis, indicates infection of the thrombus.

The diagnosis and assessment of phlebitis, thrombosis, or thrombophlebitis is based on the detection of the previously described clinical signs and examination by duplex Doppler ultrasonography (see Figs. 9.50B and 9.50C).[458,591,1001] In case of thrombosis, imaging of the affected vein reveals filling of the lumen with an anechoic, hypoechoic, hyperechoic (if gas filled), or mixed echogenic material that partially or completely occludes the vessel. Ultrasonographic evaluation may also reveal thickening of the vessel wall (phlebitis), perivascular swelling, tracts extending from the vein to the subcutaneous tissues or skin, or subcutaneous abscesses. Septate appearance or cavitation in the center of a thrombus is suggestive of infection and represents a target for aspiration and bacterial culture. Anaerobic bacterial infections often result in gas production, creating multiple hyperechoic areas and

an acoustic shadow. Stagnant or turbulent flow may be manifested by increased spontaneous venous contrast. Flow across the affected zone may be evaluated by contrast venography using agitated saline as a contrast agent, with pulsed-wave or color-coded Doppler studies, or with newer vascular imaging technologies that directly visualize blood reflectors (such as red blood cells) in a grayscale or color-coded display. Venous drainage proximal and distal to the area of thrombosis also should be assessed as collateral circulation may still enter the vein distally. A careful evaluation of the communicating large veins and of the heart and lungs should be performed in horses with infective thrombophlebitis, particularly if clinical signs of systemic disease develop. Bacterial endocarditis may develop secondary to embolization of infective thrombus or bacteremia (see earlier discussion). Rarely, embolization of septic thrombi may also lead to pulmonary thromboembolism, pleuropneumonia, and other conditions associated with metastasis of septic thrombi.[961,962]

Early detection and management of phlebitis, thrombosis, or thrombophlebitis are crucial and significantly influence severity and outcome. Therefore at least twice daily careful monitoring of catheter and catheter site is mandatory for all indwelling catheters. Catheter caps and fluid lines should be changed regularly to minimize the risk of bacterial contamination. If a catheter is still in place when a thrombosis or thrombophlebitis is discovered, the catheter should be carefully withdrawn and the tip cultured. If possible, the opposite jugular vein should be preserved to avoid the risk of bilateral thrombophlebitis, and alternative options for fluid and drug administration should be sought.

Local therapy including hot compresses and topical ichthammol (ammonium bituminosulfonate), nonsteroidal antiinflammatory drugs (diclophenac sodium), heparinoids (chondroitin polysulfate), or dimethyl sulfoxide (DMSO) may be helpful in the treatment of thrombophlebitis. Heparin therapy (unfractionated heparin, 40–100 IU/kg of body weight, SC, q 6 h; dalteparin, 50–100 IU/kg of body weight, SC, q 24 h) may be beneficial to decrease progressive thrombosis, particularly if the thrombotic lesion is associated with a generalized coagulopathy.[982,1002,1003] Furthermore, early regional thrombolytic therapy may be used in an attempt to resolve jugular vein thrombosis and to achieve recanalization.[957,1004-1006] However, clear evidence of the efficacy of antithrombotic and thrombolytic treatment is lacking. Infections with multiple organisms should be anticipated in cases of infective thrombophlebitis, and high doses of broad-spectrum antimicrobials should be administered until culture and sensitivity results of the aspirate are obtained. Metronidazole (15 mg/kg PO every 6 hours or 25 mg/kg PO q 12 h) should be considered if anaerobic infection is suspected. Flunixin meglumine (1 mg/kg every 12 hours) may be added to reduce inflammation. If antimicrobial therapy is unsuccessful, surgical resection of the affected tissue or drainage of abscesses may be indicated.

Recanalization of an affected vein often occurs and can be documented by Doppler or contrast ultrasound studies demonstrating blood flow between the vessel wall and the thrombus. Recovery often requires 4 to 8 weeks or longer. Occasionally, loculation may be detected within the ends of the thrombus. Such loculation may result in persistent fibrous webs within the vein that restrict venous return. Venous stricture also may occur due to long-standing thrombophlebitis. Complete fibrous occlusion of the jugular vein may impede venous return from the head such that if adequate collateral circulation does not develop, impaired venous drainage of the head and neck may limit performance or reduce the chance of returning to the previous level of activity in high-level athletes.[961] Bilateral occlusion of the jugular veins with insufficient collateral vascularization may cause swelling of the head and cervical region, leading to dysphagia and airway obstruction that might be performance limiting or even life threatening.[1007,1008]

When jugular vein thrombophlebitis is refractive to medical treatment or causing severe performance-limiting or even life-threatening clinical signs, surgical techniques including phlebotomy, thrombectomy with Fogarty's catheter, or venous grafts may be performed to restore blood flow.[994,995,1009] Alternatively, an expert in interventional radiology or medicine can be consulted regarding other options, such as intravascular stenting.

Prophylaxis for venous thrombosis or thrombophlebitis includes minimizing all of the aforementioned risk factors. Administration of a nonsteroidal antiinflammatory drug while the catheter is in place has been shown to reduce the risk of catheter-related complications.[1001] Antithrombotic prophylaxis is commonly performed using anticoagulants or antiplatelet drugs, but clear evidence of its efficacy is currently lacking.

Aortoiliac Thrombosis

Aortoiliac thrombosis is an uncommon, but potentially serious, disorder. The gross appearance, histologic features, and clinical findings of this vaso-occlusive disorder have been reviewed extensively in the literature.[89,267-272,450-455,950,955,1010-1017] The terminal aorta and the iliac arteries, including their proximal branches, are the focus of involvement in this disease (see Fig. 9.53A). Vessels become partially to completely occluded by multifocal ingrowths of fibrous tissue, laminated thrombi, or fibrous plaques.[267] Histologic lesions include organized, fibrous connective tissue, hemosiderin-laden macrophages, irregular vascular channels, and disruption of the intima and internal elastic lamina. The lesions are generally devoid of fat. Arteriosclerotic and atherosclerotic aortic lesions have also been observed at other sites as well (see Fig. 9.52A). Suggested etiologies of these arterial disorders include *Strongylus vulgaris* infection, systemic infections, embolization, and vasculitis. There is no convincing evidence that aortoiliac thrombosis is consistently caused by *Strongylus* infection, and some have refuted this contention.[269,271]

Although aortoiliac thrombosis is uncommon, it can be associated with severe performance problems. The typical features include exercise-associated, typically (but not uniformly) unilateral, hindlimb lameness, ataxia, or collapse.[267,269,271,272] Aortoiliac thrombosis has also been diagnosed as a cause of breeding failure in stallions.[271,272,955] Physical examination of an affected horse at rest may reveal weak metatarsal arterial pulses or delayed saphenous refill in the affected limb. The temperature of the limb in the resting animal is usually normal, unless complete arterial occlusion has occurred, in which case the limb is cold and painful and may become edematous. Exercise in affected animals results in an exercise-associated gait abnormality (lameness, ataxia, or weakness) with a decreased or absent metatarsal and digital pulse and delayed or absent saphenous refill. This intermittent claudication may cause the horse to become very uncomfortable and reluctant to bear weight on the affected limb. Marked hyperpnea, other signs of distress, and profuse, generalized sweating

are often present with trembling of the affected limb. A rectal examination may reveal fremitus, a weak or absent pulse, or aneurysmal dilation of the affected artery or arteries. These abnormalities may be more evident after exercise and may help to confirm the diagnosis.

The diagnosis can be confirmed by ultrasonographic evaluation of the terminal aorta and iliac arteries (see Fig. 9.53B) with a high-frequency (5–10 MHz) rectal transducer[268,270,451,1016] or by nuclear techniques.[1011,1018] Doppler studies may indicate abnormal blood flow in the femoral arteries.[1019] Essential abnormalities include a hypoechoic to echogenic mass protruding into the arterial lumen. An estimation of the degree of obstruction can be made based on the percentage of the artery occluded. Many cases are longstanding, and hyperechoic areas, even tissues sufficiently echodense to cast acoustic shadows, may be imaged within the aortic or iliac thrombus. These findings suggest mature scar tissue and calcification.

The prognosis for this disorder is guarded. No controlled studies have evaluated therapy for this condition. A case survey[1010] suggests no treatment consistently improves outcome, but there is potential benefit of surgical or catheter-based thrombectomy or anticoagulation. Early diagnosis likely is essential if therapy is to be beneficial. Treatment is aimed at improving collateral circulation and preventing additional thrombus formation. Various medical treatments have been reported including intravenous sodium gluconate, larvicidal dewormings, phenylbutazone, low-molecular-weight dextran, anticoagulants,[455] and a controlled exercise program. There are no reports of successful thrombolytic therapy at this time. Ultrasound-guided balloon thrombectomy has been described and is probably most useful in cases of active thrombosis where the obstruction can be partially relieved.[950,1012,1013,1017,1020] In one study, 65% of the horses regained athletic activity, and 53% of the operated horses performed at their previous level after surgical thrombectomy.[1020] Postoperative complications included severe myopathy (24% of cases), acute thromboembolism on the contralateral limb, wound healing problems, and reocclusion.

Parasitic Vascular Lesions

The migrating larval forms, particularly L4, of *S. vulgaris* are known causes of arterial disease, particularly involving the aorta and the cranial mesenteric artery and its branches (see Fig. 9.54). Lesions have been described as far forward as the bulbous aorta and the aortic sinuses in infected horses. Rounded fibrous plaques and mural thrombi have been reported in the thoracic and cranial abdominal aorta in 9.4% of horses examined immediately after death.[145] These investigators reported a statistical association between the occurrence of proximal aortic *S. vulgaris* lesions and the presence of focal ischemic lesions in the myocardium. They hypothesized that these lesions were consequent to microembolism from parasitic lesions. With the advent of ivermectin and other new anthelmintics, and aggressive deworming programs currently recommended by practicing veterinarians, heavy *S. vulgaris* larval migration damage occurs much less frequently. However, migration of *S. vulgaris* L4 larvae must be considered in horses with poor deworming histories, high potential of exposure, high fecal egg counts, and palpable abnormalities on rectal examination, or when fremitus or aneurysmal dilation of the aorta is found, particularly in the region of the cranial mesenteric artery or iliac system. An ultrasonographic evaluation of the cranial mesenteric artery is possible and can be used to confirm the diagnosis of thrombosis in these vessels.[954,1010,1021] Treatment should consist of larvicidal deworming, combined with a rigorous individual and environmental parasite control program.

Arteriovenous Fistulas

Arteriovenous fistulas occur uncommonly and are most often detected with large vascular tumors (hemangiomas, hemangiosarcomas) or as a rare congenital defect or posttraumatic sequelae.[953,956,969,972] Classic features include a continuous thrill and murmur over the affected area, localized edema, slowing of the HR after occlusion of the shunt, and signs of increased CO if the shunt flow is great. Clinically important fistulas are more likely to develop where large arteries and veins run in parallel, as with the jugular vein and carotid artery. A diagnosis can be made with Doppler ultrasound, including pulsed-wave and color-flow Doppler to demonstrate continuous and pulsatile flow from the artery, through the associated communication, into the distended veins. A complete cardiovascular examination should be performed because a large arteriovenous communication could lead to cardiac failure. Treatment depends on the underlying cause, and an experienced surgeon should be consulted. No treatment may be indicated with small, uncomplicated arteriovenous communications. Large vascular neoplasms are usually inoperable at the time when they are diagnosed or complicated by the possibility of metastasis.

Vascular Rupture

Rupture of the aorta or its branches or of the PA are reported sporadically and often are catastrophic events, with diagnoses made at the necropsy floor. Ruptures of the extrapericardial aorta or other blood vessels leading to fatal hemorrhage or a systemic to pulmonary shunt have been reported.*

Rupture of the middle uterine artery can cause severe periparturient hemorrhage into the broad ligament (hematoma formation) or into the abdomen (acute hemoabdomen). It is more common in older, multiparous mares and is characterized by postpartum colic, tachycardia, anemia, and often sudden death.[260,978-982] Mycotic disease within the guttural pouch is a well-recognized cause of arteritis and rupture of the affected arteries.[983-985] Uterine artery rupture and arterial rupture secondary to guttural pouch mycosis are covered in Chapters 19 and 9, respectively.

Aortocardiac and Aortopulmonary Fistula

Rupture of the aortic root has been commonly reported in older horses, usually older breeding stallions, but it may also occur in older mares or in younger horses.[63,92,262-264,864,866,975] Rupture typically involves the right aortic sinus of Valsalva (see Figs. 9.51 and 9.52B). The aortic root can rupture into the right atrium, right ventricle, interventricular septum, or pericardial space. Dystrophic changes in the media of the aorta, degenerative changes associated with chronic aortic insufficiency, and the hypertension associated with breeding all have been implicated as potential causes of aortic root rupture.[92,263,864,1023] Aneurysms of the right sinus of Valsalva have also been reported and are related to congenital or acquired defects in the media of the aorta near the right coronary sinus.[34,262,864-867,1024]

* References 85, 91, 93, 94, 96, 98-103, 106, 1022.

Rupture of the more distal aorta into the pulmonary artery also can occur.[34] Aortopulmonary fistulation has been mostly reported in Friesian horses.[261,265,266,976,977] The rupture is usually located close to the arterial ligament and concurrent with a circumferential cuff of perivascular hemorrhage.[265] Recent histologic studies suggest a connective tissue disorder affecting elastin or collagen in the aortic media as a potential underlying cause of aortic rupture in Friesian horses.[266,976]

Not all aortic ruptures are immediately fatal. Many horses present with acute onset of poor performance, exercise intolerance, sustained tachycardia, and pain that is often perceived as colic. When aortic rupture or rupture of a sinus of Valsalva aneurysm communicates with the right atrium, right ventricle, or pulmonary artery, right-sided heart failure can occur. Cardiac arrhythmias (usually ventricular tachycardia) may also develop, especially if dissection progresses into the interventricular septum.[263]A continuous machinery murmur loudest on the right side of the thorax with bounding arterial pulses is characteristic of a horse with an aortocardiac fistula.[68,263,264] Friesian horses with aortopulmonary fistulation present with bounding arterial pulses, tachycardia, and a grade 1 to 3/6 holosystolic and early to middiastolic murmur loudest dorsal to the aortic valve; ventricular arrhythmias are rare.[68,265,1025]

Antemortem diagnosis of an aortic sinus of Valsalva aneurysm or aortocardiac fistula is possible by echocardiography and Doppler interrogation (see Fig. 9.51). Because of the more distal location of aortopulmonary fistulas in Friesian horses, echocardiographic imaging is more challenging and requires nonstandard, tilted imaging planes obtained from the left third or fourth intercostal space in order to visualize the aortic rupture and fistula; in addition, right heart and pulmonary artery dilation, tricuspid regurgitation, and pleural and pericardial effusion can be found.[265,1025,1026] Transesophageal ultrasound may allow for better visualization of the aortopulmonary region and for diagnosing aortic rupture in Friesian horses, but the lack of appropriate equipment usually precludes this option in horses.[1026] If echocardiography does not allow definitive diagnosis of an aortopulmonary fistula, cardiac catheterisation may serve to document increased right heart and PA pressures with increased oxygen partial pressures and saturation in the distal pulmonary artery indicating left-to-right shunting of blood.[1025]

Aside from breeding, horses with diagnosed aortic aneurysms should not be used for athletic endeavor, because rupture of the aneurysm could occur at any time. The prognosis for life in horses with aortic rupture is generally guarded to poor, depending on the site and size of the communication. Some horses survive and others may require supportive treatment for CHF. Fatal ventricular arrhythmias can develop any time and lead to sudden cardiac death. Therefore horses with aortocardiac or aortopulmonary fistulas are not considered safe to use.[68]

Pulmonary Artery Rupture

Pulmonary artery rupture is most often caused by chronic pulmonary hypertension and PA dilation.[148,768] This is most commonly detected in conjunction with severe MR and pulmonary hypertension. The potential for PA rupture should be considered whenever a large dilated main PA or left and right PA is detected echocardiographically. Affected horses should be considered unsafe for riding or driving and should not be used, except for breeding, due to the possibility of sudden death. Focal medial calcification of the PA is not uncommon at necropsy[947,989] but is of uncertain clinical significance.

CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are disturbances in HR, rhythm, or conduction and can be classified based on atrial and ventricular rate, anatomic origin of the impulse, method of impulse formation, and conduction sequence. Arrhythmias can develop as isolated electrical disorders or secondary to other etiologic factors, including (1) structural heart disease; (2) metabolic and endocrine disorders; (3) systemic inflammation; (4) hypotension, hemorrhage, anemia, and ischemia; (5) autonomic influences; (6) toxicosis/envenomations; and (7) drugs.[68] A wide variety of cardiac arrhythmias have been recognized.[54,60,736,1027,1028] Of principal concern to the clinician are the hemodynamic consequences of arrhythmias (reduced pressure, flow, perfusion) and the potential for further electrical instability (myocardial fibrillation, sudden death).

The electrophysiologic basis of cardiac arrhythmias will not be discussed here, and the interested reader is referred elsewhere for descriptions of abnormal automaticity, reentry, and triggered activity (early and late afterdepolarizations) as mechanisms of arrhythmogenesis.[57,112,113,117] Cardiac arrhythmias are classified based on the anatomic origin of the manifest ECG mechanism (Box 9.12). The reader should be aware that some arrhythmias, especially those originating in the AV junction, may mimic either atrial rhythm disturbances or "high" ventricular rhythms. For purpose of discussion we have elected to distinguish "atrial" from "junctional"; however, "supraventricular" may also be applied to these rhythm disturbances.

The clinical evaluation of the horse with an arrhythmia is reviewed in Box 9.13. Routine electrocardiography, clinical chemistry, hematology, echocardiography, exercising electrocardiography, and continuous 24-hour electrocardiographic (Holter) monitoring can all play a role in the complete evaluation of a horse suspected of having intermittent cardiac arrhythmias.[68] These points are discussed further later in the chapter. A recent consensus statement formulated by a group of experts in the field of equine cardiovascular medicine summarizes the current recommendations for management of equine athletes with cardiac arrhythmias, and the reader is referred to this statement for additional information.[68]

Sinus Rhythms

A number of physiologic sinus rhythms are recognized. These can be explained by the impact of autonomic nervous system traffic on the SA node (Fig. 9.55). Normal horses at rest demonstrate vagal-mediated sinus bradycardia, sinus arrhythmia, sinus block, and sinus arrest; however, fear or a sudden stimulus may provoke sympathetically driven sinus tachycardia. Exercise leads to pronounced sinus tachycardia, with HRs often exceeding 200 beats/min.[53,54] Atrioventricular (AV) conduction, as a general rule, tends to follow sinus activity. During sinus tachycardia, the PR interval shortens, whereas during periods of progressive sinus node slowing the PR interval generally prolongs. Mobitz type I second-degree AV block (Wenckebach periodicity) often follows a progressive prolongation of the PR interval. Sinus rate and AV conduction usually change in parallel; however, some horses appear to control BP during high sinus tachycardia by blocking impulses in the AV node (see Fig. 9.6). Second-degree AV block is more likely in a standing horse, in a horse that has suddenly stopped submaximal exercise, or after a brief surge of sinus tachycardia in an anxious animal.

Sinus rate and rhythm should be carefully monitored in the critically ill or anesthetized horse because HR is a major

BOX 9.12 Cardiac Rhythms in the Horse

PHYSIOLOGIC RHYTHMS

Sinus Rhythms[a]

Normal sinus rhythm
Sinus arrhythmia
Sinoatrial block/arrest
Sinus bradycardia
Sinus tachycardia

Conduction Disturbances[a]

Atrioventricular block (AV block)
- First-degree (long PQ or PR interval)
- Second-degree (P wave not followed by a QRS complex; commonly Mobitz type I, Wenckebach)

PATHOLOGIC RHYTHMS

Atrial Rhythm Disturbances

Atrial escape complexes[b]
Atrial premature complexes[a]
Atrial tachycardia, nonsustained and sustained
Reentrant supraventricular tachycardia
Atrial flutter, atrial fibrillation[a]

Junctional Rhythm Disturbances

Junctional escape complexes[b]
Junctional escape rhythm[b] (idionodal rhythm)
Junctional premature complexes[a]
Junctional ("nodal") tachycardia
Reentrant supraventricular tachycardia

Ventricular Rhythm Disturbances

Ventricular escape complexes[b]
Ventricular escape rhythm[b] (idioventricular rhythm)
Ventricular premature complexes[a]
Accelerated idioventricular rhythm (idioventricular tachycardia, slow ventricular tachycardia)*
Ventricular tachycardia
Ventricular flutter
Ventricular fibrillation

Conduction Disturbances

Sinoatrial block (high grade or persistent)
Atrial standstill (sinoventricular rhythm caused by hyperkalemia)
Atrioventricular block (AV block)
- Second degree (high grade or persistent)
- Third degree (complete, with AV dissociation)

Ventricular conduction disturbances
Ventricular preexcitation

[a]Most common rhythms and arrhythmias.
[b]Escape complexes develop secondary to another rhythm disturbance.

BOX 9.13 Evaluation of the Horse with a Cardiac Arrhythmia

General medical history, past illnesses, past and current medications
Work history and exercise tolerance
General physical examination
Physical examination: evidence of congestive heart failure
- Subcutaneous edema
- Jugular venous distention and pulsations
- Pulmonary edema
- Pleural and peritoneal effusion
- Weight loss, poor condition

Auscultation of the heart
- Assessment of heart sounds (rhythm, third heart sound)
- Assessment of heart murmurs

Resting electrocardiogram
- Heart rate and cardiac rhythm
- Analysis of P-QRS-T waveforms

Exercise (or treadmill) electrocardiogram
Clinical laboratory studies
- Complete blood count (rule out anemia, infection)
- Blood culture (in cases of suspected endocarditis)
- Serum electrolytes (particularly potassium and possibly magnesium)
- Serum biochemical tests (especially renal function)
- Skeletal muscle enzymes (cardiac isoenzymes)
- Serum troponin concentration
- Red blood cell potassium
- Fractional excretion of potassium

Echocardiogram/Doppler echocardiogram
- Examine for cardiomegaly or reduced myocardial function
- Identify predisposing cardiac lesions and abnormal flow

Serum/plasma concentrations of cardioactive drugs
- Serum digoxin concentration
- Plasma quinidine concentration

Response to medications

determinant of CO and arterial BP (Fig. 9.4B). Sedative drugs and anesthetics can cause sinus bradycardia or sinus arrest. Anesthetic drugs, hypoxia, traction on an abdominal viscus, ocular manipulation, hypothermia, increased intracranial pressure, and hypertension can depress sinus node function. Concurrent depression of the sinus node with stimulation of latent pacemakers in the coronary sinus or AV junction can lead to ectopic rhythms in the anesthetized horse. Conversely, an increasing sinus rate may indicate inadequate depth of anesthesia, pain, hypotension, hypovolemia, hypercarbia and hypoxemia, anemia, endotoxemia or sepsis, pyrexia, systemic inflammatory response syndrome (SIRS), anaphylaxis, or excessive catecholamine administration. Specific therapy for sinus tachycardia is rarely required because it represents a physiologic response to stress. However, when sinus tachycardia is identified, the cause must be sought and treated as appropriate.

Sinus bradycardia is generally a benign rhythm in standing horses; however, when encountered during sedation or anesthesia this rhythm can lead to hypotension. Treatment of symptomatic sinus bradycardia can include the infusion of catecholamines (dobutamine, dopamine, epinephrine) or the administration of anticholinergic drugs (atropine, glycopyrrolate). Dopamine or dobutamine can be infused to increase HR, contractility, and arterial BP; however, reflex AV block may develop in some horses.[237,246,278,327] Excessive administration of catecholamines causes sinus tachycardia and ectopic beats. Anticholinergic drugs may not be effective in the setting of anesthetic-induced depression of SA function, particularly if vagal efferent traffic is low. Gastrointestinal complications including ileus and colic may develop after anticholinergic drug therapy; thus it should not be chosen for trivial rate problems.

Atrial Arrhythmias

Rhythms originating in the atria are common. These disturbances often develop as "functional" disorders with

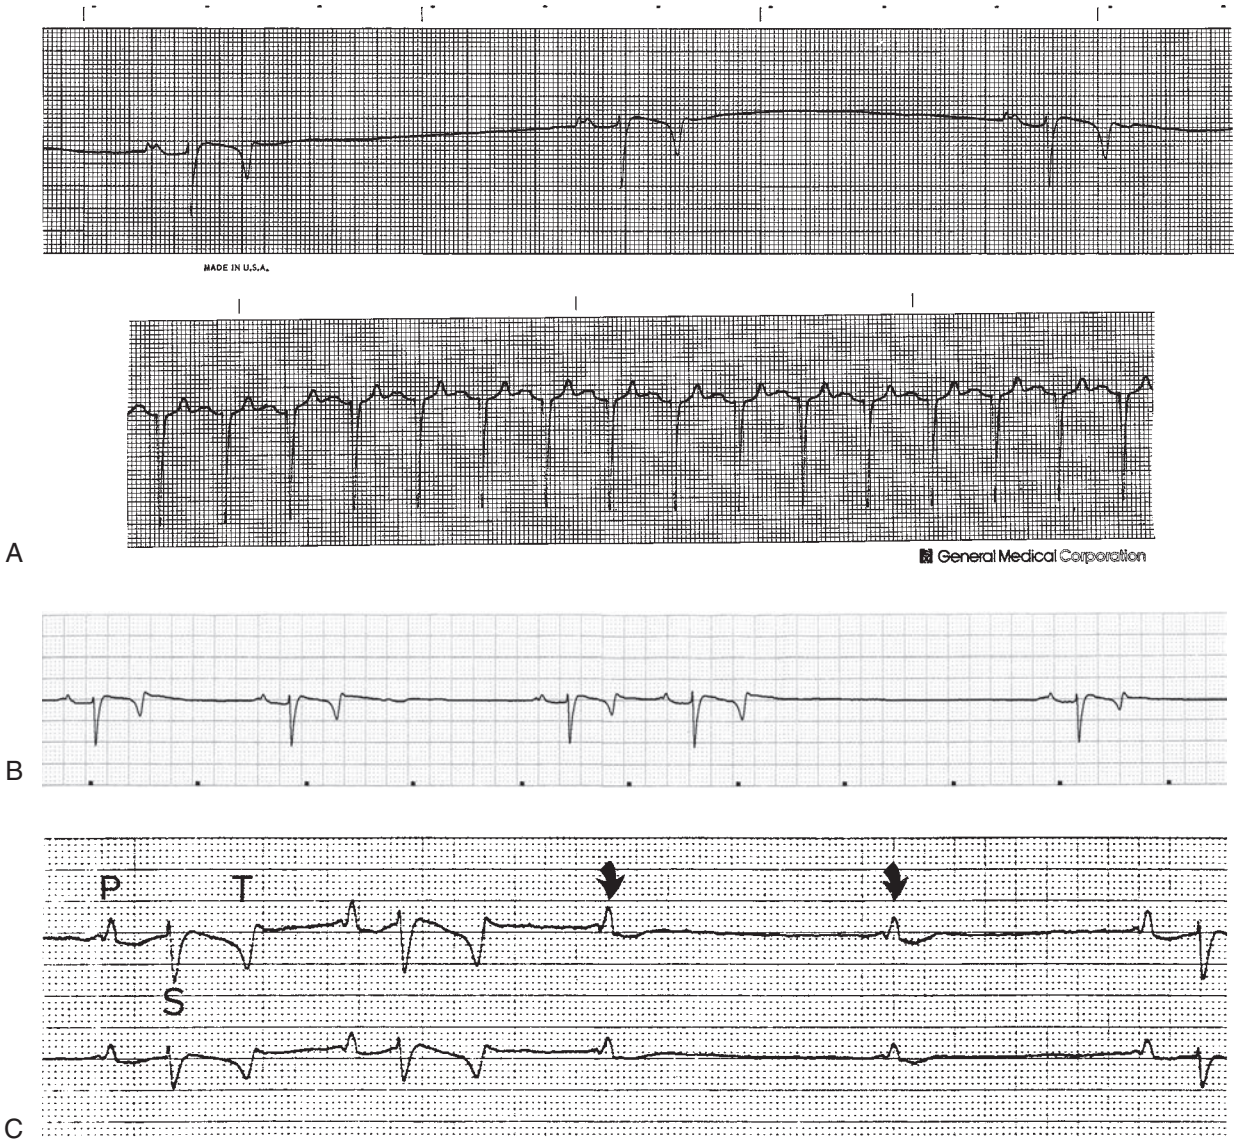

FIG. **9.55** Sinus rhythms. A, Sinus bradycardia *(top)* and tachycardia *(bottom)*. Base-apex lead recorded at 25 mm/sec. B, Sinus arrhythmia with sinus arrest/sinus block recorded at 25 mm/sec paper speed. C, Sinus arrhythmia with second-degree atrioventricular block *(arrows)*. An ambulatory electrocardiogram (ECG) is shown; transthoracic leads recorded at 25 mm/sec. Whereas two consecutively blocked P waves are considered normal on a 24-hour ECG, these phenomena are observed infrequently (in approximately 1% of normal horses).

no overt structural cardiac lesion. Autonomic imbalance (including high sympathetic activity or high vagal tone), hypokalemia, drugs (e.g., catecholamines, anesthetics), infections, fever, anemia, hypoxia, and colic can be associated with atrial premature complexes. Atrial rhythm disturbances are also very common in the setting of structural lesions of the heart valves, myocardium, and pericardium. Cardiac conditions known to predispose to atrial arrhythmias include mitral or tricuspid insufficiency, endocarditis, myocarditis, cardiac (atrial) enlargement, myocardial fibrosis, and myocardial ischemia. Atrial premature complexes can precipitate sustained atrial arrhythmias, including atrial tachycardia, atrial flutter, and atrial fibrillation. The large size of the equine atria and the frequent presence of microscopic atrial fibrotic lesions likely predispose the horse to these sustained arrhythmias. The high resting vagal tone present in most horses serves to shorten the duration of the action potential of atrial myocytes and also facilitates development of sustained atrial tachyarrhythmias, which probably depend on reentry.

Atrial arrhythmias are the most common abnormal rhythms detected in horses (Figs. 9.56 and 9.57).[60,77-84,479,538,1029] Atrial premature complexes are the least complex of these rhythm disturbances; these can be clinically irrelevant or associated with exercise intolerance or other signs of cardiac disease. In contrast, atrial tachycardia, atrial flutter, and AF are more likely to become clinically important. The overall importance of atrial premature complexes is often difficult to ascertain. Interpretation of routine ECG rhythm strips recorded from over 950 horses indicated that atrial arrhythmias, overall, were present in less than 3% of the horses studied (personal communication, JD Bonagura). However, when clinically normal

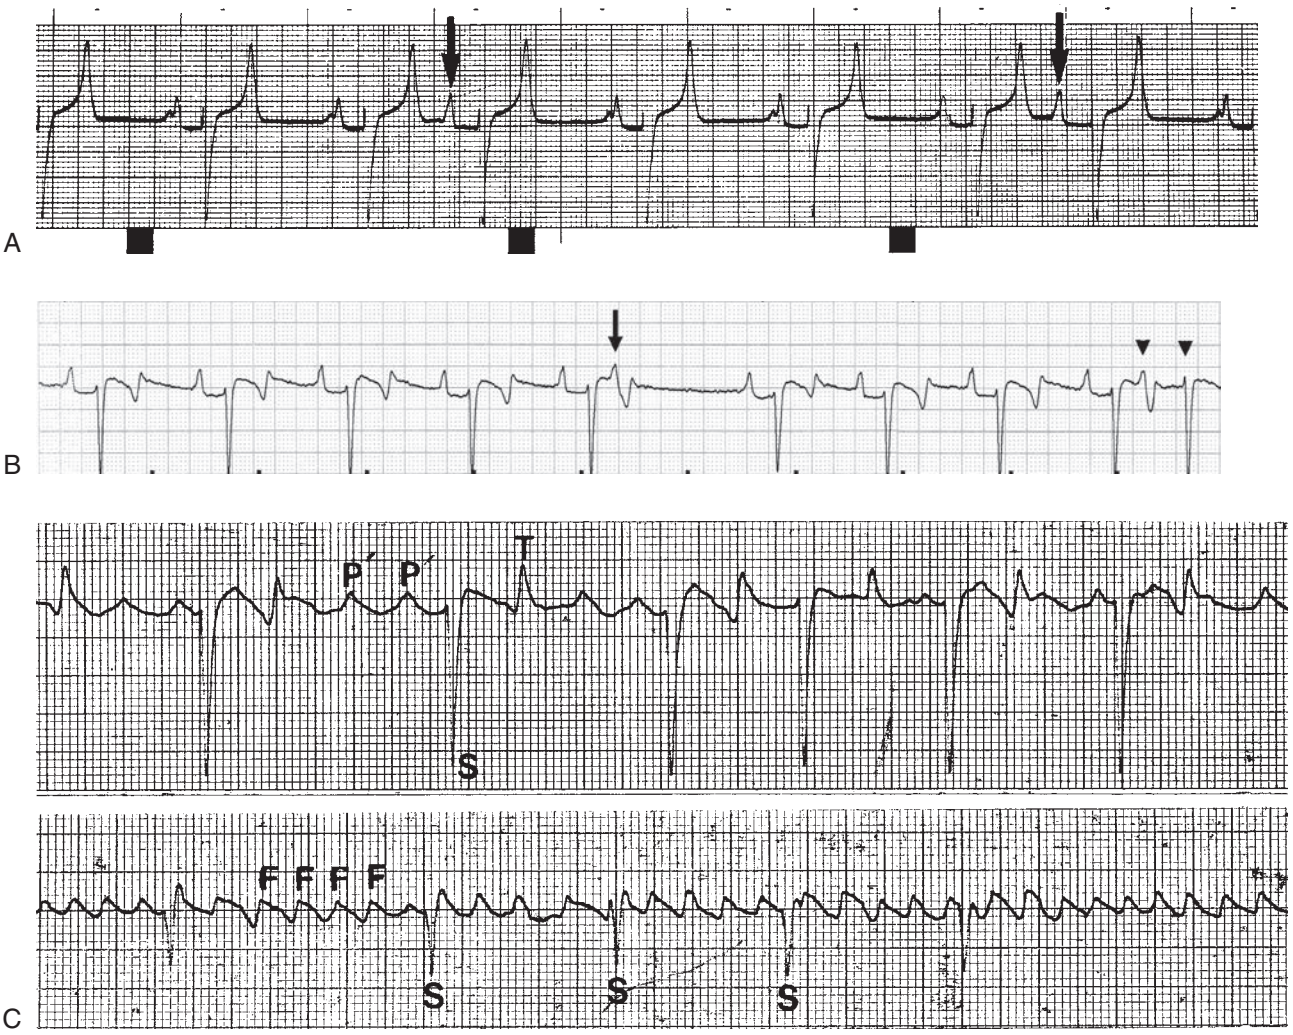

FIG. **9.56** Electrocardiograms (ECGs) with atrial rhythm disturbances (recorded at 25 mm/sec). A, Premature atrial complexes *(arrows).* The premature P waves of different morphology, the slightly prolonged P-R interval indicating atrioventricular nodal refractoriness, and the normal-appearing QRS complex indicating a supraventricular origin are notable. A slight conduction aberrancy is evidence in the second premature QRS complex (see also Fig. 9.15). B, Premature atrial complexes occurring during the QT interval of the preceding complexes. The first premature complex is nonconducted *(arrow),* the second premature complex is conducted with first-degree AV block *(arrowheads).* C, Sustained atrial tachyarrhythmias. The top picture shows atrial tachycardia with rapid, regular P waves (P′) and a variable ventricular rate response to conducted P waves. The base-apex lead recorded at 25 mm/sec. The lower trace shows atrial flutter (F) with variable ventricular response (S). Lead 3 recorded at 25 mm/sec.

horses were examined by Holter monitor, atrial premature complexes were recorded in 28% of the horses (personal communication, VB Reef). The prevalence of atrial arrhythmias during and after exercise has been reported as 29% to 89% and 46% to 62%, respectively,[77-79] with the reservation that it may be difficult to differentiate between supraventricular and ventricular premature beats on exercise ECGs. Thus it appears that the incidence of atrial arrhythmias depends not only on the population examined but also on the methods used for identification. These rhythm disturbances should be assessed in light of other clinical findings.

Atrial Premature Complexes

Atrial premature complexes (APCs) are detected by auscultation and are documented by an ECG. Auscultation usually reveals a regular sinus rhythm that is interrupted by an obviously premature beat or—in case of a blocked APC—by an abnormal pause (see Fig. 9.56A and B). Premature atrial complexes may be fully interpolated (there is continuation of the regular sinus rhythm after the premature atrial contraction), or there may be a pause, if the sinus node is reset or the premature complex is not conducted. The ECG is characterized by a premature (usually narrow) QRS complex, which is preceded by an abnormal, premature P wave (P′ wave) that is often buried within the preceding T wave (see Fig. 9.56B). If the impulse arrives in the AV node before complete repolarization, the PR interval is longer than normal (physiologic first-degree AV block; see Fig. 9.56A). If the ectopic P′ wave is not conducted (physiologic second-degree AV block) a pause will be evident in the ventricular rhythm (see Fig. 9.56). Premature

FIG. **9.57** Atrial arrhythmias. A and B, Successful conversion of atrial fibrillation (AF) using a combination of digoxin and quinidine (see text for details). A, Incomplete conversion of AF to atrial tachycardia with rapid, regular atrial activity *(arrows).* B, Conversion to normal sinus rhythm during combination therapy. Notice the high amplitude of the second part of the P wave, indicating possible atrial enlargement. C, Quinidine toxicosis can be manifested as abnormalities on the electrocardiogram (ECG). In this horse, AF (*top;* base-apex lead recorded at 25 mm/sec) was not converted. The lower recording shows persistent AF with a rapid atrioventricular conduction response, electrical alternans, and widening of the QRS complex (lead 2 recorded at 25 mm/sec; *right panel,* at 50 mm/sec). The rapid rate response is related to the vagolytic effect of quinidine. The electrical alternans is common with regular supraventricular tachycardias with rapid ventricular response rates; this finding indicates varying conduction into the ventricle. The widened QRS is a sign of quinidine toxicosis. An idiosyncratic reaction leading to polymorphous ventricular tachycardia (VT) also has been recognized (see Figs. 9.58 and 9.61). D, Hemodynamic consequences of increasing ventricular response rate in AF. The short QRS-QRS intervals do not generate effective arterial pulsations recorded in the arterial blood pressure (ABP) tracing, which is related to inadequate ventricular filling time during short cycles. Pulse deficits are detectable by physical examination. E, Atrial fibrillation with occasional QRS-T complexes of different morphology (base-apex lead recorded at 25 mm/sec). Note that the large and slightly wider QRS complexes always occur when a short cycle follows a long cycle. These QRS complexes are most likely caused by aberrant ventricular conduction, and this phenomenon is called *Ashman's phenomenon* (or phase 3 aberrancy). F, Atrial fibrillation in a 14-year-old Appaloosa with dilated cardiomyopathy and heart failure (base-apex lead recorded at 25 mm/sec). The heart rate is 132 beats/min. Three ventricular ectopic beats are evident, characterized by different QRS-T morphology.

atrial impulses can also be conducted aberrantly through the ventricle as a result of incomplete repolarization or persistent refractoriness of ventricular conducting tissues; this causes the QRS-T complex to be wider than normal or atypical in configuration. Care must be taken not to overdiagnose atrial premature complexes. Sinus arrhythmia and sinus bradycardia often lead to variations in the P-P intervals, and there is often a "wandering atrial pacemaker" that gradually alters the P wave morphology. Exercise or excitement will abolish such physiologic rhythms.

A continuous 24-hour ECG and an exercising ECG are recommended to assess frequent APCs. Atrial premature complexes are not considered a safety issue. Horses with occasional APCs that are overdriven during exercise and those with occasional APCs during exercise are considered as safe to use as their age-matched peers.[68] The greatest concern about APCs relates to their potential to incite atrial flutter and AF. Atrial premature complexes, as a general rule, are more likely to be clinically relevant in the following circumstances: when they (1) are frequent at rest, (2) are associated with runs of atrial tachycardia, (3) are related to poor performance (if other causes are excluded), (4) precipitate paroxysmal atrial flutter or fibrillation, or (5) develop in conjunction with structural cardiac disease. Documentation of atrial arrhythmias *during* exercise may be critical for determining whether paroxysmal atrial tachycardia, flutter, or fibrillation is likely to be the cause of poor performance.[474] Clinical judgment must be used, however, because supraventricular premature complexes are likely to occur in the immediate postexercise period, probably associated with autonomic imbalance.[77-79,479] If these postexercise arrhythmias are not associated with clinical signs and are not detected during exercise, they are unlikely to be clinically relevant.

Isolated atrial premature complexes generally are not treated. The hemodynamic consequences of these rhythm disturbances are minor, unless sustained abnormal activity develops. Consideration of antiarrhythmic therapy might be appropriate if frequent atrial extrasystoles are documented to precipitate AF or if they occur after conversion of AF to sinus rhythm and pose the horse at a risk of recurrent AF (see later discussion). Unfortunately, neither quinidine nor procainamide is practical for chronic use. Oral administration of sotalol has recently been advocated for chronic antiarrhythmic treatment to reduce the number of APCs, particularly in horses after conversion of AF to sinus rhythm in order to prevent recurrent AF (see Table 9.7).[1030] However, the effectiveness of sotalol and of other antiarrhythmics has not been formally established for this indication. Maintenance of normal serum potassium and magnesium may be important in suppressing atrial ectopic activity. In cases of suspected myocarditis, antiinflammatory doses of dexamethasone might be considered as empiric therapy with consideration of adverse effects of such treatment.

Atrial Tachycardia

Atrial tachycardia can be defined as a series of ectopic atrial premature complexes. Atrial tachycardia may be sustained or nonsustained (paroxysmal) and is generally precipitated by a single atrial premature complex. The atrial rate is rapid and regular; however, because ectopic P′ waves can be blocked physiologically in the AV node, an irregular ventricular rate response often results (see Fig. 9.56C). Atrial rates of 120 to 250 beats/min are typical in horses with sustained atrial tachycardia. At lower atrial rates, 2:1 AV conduction may yield a regular, relentless HR. At the higher atrial rates, the rhythm may be indistinguishable from atrial flutter. Differentiation of atrial tachycardia from flutter is not critical because both arrhythmias carry the same clinical significance and are treated identically. Sustained atrial tachycardia is most often recognized during treatment of horses with quinidine sulfate. Before conversion of AF to sinus rhythm, atrial tachycardia may be observed (see Fig. 9.57A); thus in this setting rhythm indicates a partial therapeutic effect of quinidine on the atrial myocardium. When this atrial tachycardia occurs as an isolated finding, structural or underlying myocardial disease should be suspected and the horse should be considered predisposed to the development or recurrence of AF. Treatment is the same as that described for AF. If the ventricular response rate is especially rapid (greater than 120 per minute) consideration can be given to administration of either digoxin to block AV nodal conduction or possibly to diltiazem if digoxin is ineffective (see Table 9.7). Arterial BP should be monitored carefully if diltiazem is administered.[1031-1033]

Atrial Flutter

Atrial flutter is even less common than atrial tachycardia and represents a form of atrial circuit movement or macroreentry.

The clinical circumstances and assessment of this rhythm disturbance are identical to those of atrial tachycardia. The ECG in atrial flutter is characterized by a very rapid, abnormal, but regular atrial activity that is usually manifested as a "saw-toothed" ECG baseline. The atrial frequency often ranges between 170 and 275 per minute.[68] The RR intervals are usually irregular due to variable AV conduction, and there are fewer QRS and T complexes than flutter waves (see Fig. 9.56C). The ventricular rate depends on the refractory period of the AV node and on the rate and the strength of the atrial stimulus. Treatment of atrial flutter is similar to that for horses with AF.[1034]

Atrial Fibrillation

Atrial fibrillation (AF) is the most common atrial arrhythmia associated with poor performance and exercise intolerance in horses. There is a large body of literature describing different aspects of this important arrhythmia in horses.* Atrial fibrillation is most common in adult horses[82-84,88,1051] and has been reported infrequently in foals,[199,524,733,1065] weanlings, yearlings, or ponies. Several reports indicate a higher incidence in Standardbreds, draft horses, and Warmblood horses compared with the general hospital population,[84,729] and in some Standardbred racehorses it has been identified as a heritable lesion.[1052]

Cardiac output at rest is normal in most horses with AF[621,1045,1066]; however, maximal CO during exercise is limited because the atrial contribution to filling is most important at higher HRs. As expected, exercise intolerance is most common in high-performance horses (e.g., racehorses, advanced combined training horses, polo ponies, eventers, and some Grand Prix jumpers) and less common in show hunters and in pleasure, dressage, and endurance horses. The high LA pressures present in heavily exercising horses[284,637] is further exacerbated by the loss of active atrial transport function[357] and may contribute to exercise intolerance or other associated signs. Exercise-induced pulmonary hemorrhage, respiratory distress, CHF, ataxia, collapse, and myopathy have all been reported with AF; conversely, the arrhythmia is often detected as an incidental finding in horses with no overt clinical signs.[84]

Atrial fibrillation can be acute or chronic, and it can be paroxysmal, persistent, or permanent. Paroxysmal AF is often associated with a single episode of poor performance, with the horse often decelerating suddenly during a race. The arrhythmia usually disappears spontaneously within 24 to 48 hours. Persistent or permanent AF may be less common than paroxysmal AF but is easier to diagnose because the arrhythmia is sustained. Persistent AF is terminating only after treatment, whereas permanent AF is sustained and resistant to therapy. Many horses with paroxysmal and some with sustained AF have no evidence of significant underlying cardiac disease when undergoing physical examination and echocardiography. In these cases, a diagnosis of "lone AF" is often made, implying that AF is the only abnormality present and the etiology of the arrhythmia is purely functional. However, the fact that AF appears to be "lone" in these cases may simply reflect our inability to identify the underlying pathology leading to arrhythmia. Intrinsic factors that are thought to contribute to the risk of developing AF in the horse in general include the (physiologically) large atrial mass and the high resting vagal tone that both can favor development of reentry arrhythmias. Vagosympathetic imbalances during exercise and transient potassium depletion, particularly in horses treated with furosemide or bicarbonate solutions, may further increase the risk of AF. Moreover, ultrastructural and functional myocardial pathology (e.g., focal myocarditis, fibrosis, channelopathies), which cannot be detected using routine diagnostic tests, may be present to promote the substrate that facilitates onset and perpetuation of AF.[1050,1067] Some, often older horses with AF present with underlying structural heart disease that is evident on physical and echocardiographic examination. Left atrial enlargement, most commonly caused by moderate to severe MR, is considered the most important predisposing factor for AF, but RA enlargement or other atrial pathology can contribute in some horses as well.[83,729] Atrial premature complexes likely act as triggers for AF if an adequate substrate for reentry arrhythmias is present.[1050,1067,1068] Finally, once the arrhythmia is established, AF itself can induce atrial electrical, structural, and functional remodeling that may be responsible for the self-perpetuating, progressive, and recurrent nature of AF.[289,290,1050,1062,1067] The duration of AF should be determined when possible because it likely determines the degree of AF-induced atrial remodeling and affects the prognosis for successful conversion and the likelihood of recurrence.[729] Remodeling changes are more likely to be reversible if AF is treated promptly. Recurrent episodes of AF are not uncommon and are more likely in the presence of remodeling and concurrent structural or functional cardiac disease.[291,729,1062]

Horses with AF generally have a normal resting HR, though the rate tends to decrease (and stroke volume tends to increase) following successful conversion of AF to normal sinus rhythm.[621,1048,1066] The presence of resting tachycardia in a horse with AF should give the clinician pause to consider intercurrent cardiac lesions (including marked structural disease or the rare case of an accessory AV conduction pathway[1069]) or a disorder that increases sympathetic tone such as pain, anemia, fever, or infection. A number of factors interact in the prognosis of a horse with AF. Of these, the presence of CHF represents the overall worst prognostic indicator and is invariably associated with resting tachycardia. Severe structural heart disease, recurrent bouts of AF, long-standing AF, and failure to convert with therapeutic serum concentrations of quinidine represent negative prognostic factors inasmuch as affected horses can be more difficult to convert to sinus rhythm or more likely to revert back to AF even when therapy is successful.[291,729,1049,1062]

Diagnostic Workup of Atrial Fibrillation. The diagnosis of AF is initiated by recognition of an irregularly irregular heart rhythm, variable intensity heart sounds, and an absent fourth heart sound during cardiac auscultation. Arterial pulses vary in intensity, and pulse deficits may be present, especially when the ventricular rate is high (see Fig. 9.57D). The ECG is characterized by an absence of P waves; instead, fibrillation or "f" waves are seen in the baseline (see Figs. 9.26, 9.57C, and 9.59). These "f" waves may be coarse (large) or fine (small). The number of atrial impulses per minute cannot be easily counted but usually ranges between 275 and 500 per minute (when analyzed on intracardiac electrograms).[68,572,1062,1063] The QRS-T complexes are normal in morphology and duration, but ventricular rate response is irregularly irregular (chaotic). Infrequently, periodicity leading to a patterned AV conduction sequence may be observed,[219,403] which must be distinguished from second-degree AV block. Although AF often sounds

* References 2, 33, 39, 84, 218, 219, 221, 229, 289-291, 357, 401-403, 472, 572, 621, 647, 721, 729, 1035-1064.

more regular at higher HRs (e.g., immediately after exercise), the rhythm remains irregular and careful auscultation will reveal this. Occasional QRS-T complexes of different morphology may be found, representing aberrant ventricular conduction (e.g., a wide QRS complex following a short RR interval that is preceded by a long RR interval, also called Ashman's phenomenon) or concurrent ventricular premature beats (see Fig. 9.57E and F).

As for all atrial tachyarrhythmias, the ultimate ventricular rate response (and examination HR) depends on the refractory period of the AV node and the frequency and strength of the atrial stimuli.[403] In the otherwise healthy horse in AF, vagal tone will be high and sympathetic tone low when standing; consequently, the ventricular rate will be close to normal or only slightly increased. If sympathetic activity is increased for any reason, or if vagal activity is blocked (as occurs with quinidine sulfate therapy), the ventricular rate response will increase as the AV nodal refractory period shortens. This explains the clinician's simple, but very useful, dependence on measuring pretreatment resting HR in horses with AF.[84,729] Because the horse with structural heart disease will be more likely to require sympathetic support to maintain CO and arterial BP, persistent resting tachycardia, higher than 60 to 70 beats/min, indicates underlying cardiac disease and is associated with a poorer prognosis. Horses with AF also should be examined critically for relevant murmurs that might indicate the presence of valvular regurgitation, atrial enlargement, and remodeling, creating a substrate for AF.

Laboratory studies in horses with AF, including plasma cardiac troponin concentrations, are usually normal. Infrequently, a horse is found to have low serum potassium, urinary fractional excretion of potassium, or RBC potassium. Chest x-rays are usually normal unless there is concurrent pulmonary disease, and this study is not a high-yield procedure in horses without compatible signs of lung disease or structural heart disease.

A complete echocardiogram including Doppler studies should be performed to identify underlying structural heart disease. The echocardiogram is often normal, unless there is concurrent valvular, congenital, or ventricular myocardial disease. Horses in AF often demonstrate a mildly dilated left atrium, even in the absence of significant MR or other structural disease. Significant LA enlargement is usually associated with moderate to severe MR and reduces the likelihood of successful cardioversion and increases the risk for recurrence. Assessment of LV function might be hampered during AF because of ventricular dyssynchrony, tachycardia-induced LV dysfunction and preload, and HR dependence of many of the echocardiographic indices used to assess LV function.[68,344] It is not uncommon for an otherwise normal horse in AF to demonstrate a slightly reduced LV shortening fraction (usually in the 24%–32% range), which returns to normal once the horse has been converted to sinus rhythm.[1070,1071] This decrease in fractional shortening is probably multifactorial in origin and probably related in part to decreased preload from loss of the atrial contribution to ventricular filling and irregular cardiac cycle. Evidence of persistent left ventricular dysfunction, even after the AF has been successfully corrected, might indicate underlying myocardial disease in the horse with AF; these horses often fail to return to their previous level of performance. Echocardiographic evidence of severe volume overload or PHT suggests a grave prognosis.

Although uncommon, horses may collapse after sudden onset of AF during exercise, most likely because of the sudden decrease in CO following the abrupt loss of atrial booster pump function. Recently it was shown that the prevalence of QRS broadening and R-on-T phenomenon is high in horses with AF even at lower levels of exercise. These events are considered risk factors for the development of ventricular arrhythmias and might also explain some of the episodes of weakness and the rare case of collapse or sudden death that have been reported in horses with AF.[472] Atrial fibrillation associated with exercise-induced ventricular arrhythmia resulting in sudden cardiac death has been documented by ECG in at least one horse.[54] An exercise test including an exercise ECG should therefore be performed when a horse is used for any type of performance activity and cardioversion is not an option or could not be attained. The clinician should turn his or her attention to the HR response and maximum HR achieved during exercise and to the occurrence of concurrent ventricular arrhythmias.[472] Horses in AF usually have a slightly higher HR during exercise compared with horses in sinus rhythm. However, the average maximal HR during exercise at an intensity that is at or slightly exceeding the horse's normal activities should not be greater than 220 beats/min. Markedly higher maximal HRs might suggest an increased risk of collapse. Furthermore, ventricular ectopy during exercise or during sympathetic nervous system stimulation indicates a possible risk for sudden cardiac death, particularly when short RR intervals or R-on-T phenomena are observed. Note that conventional HR monitors (as opposed to telemetric ECG devices) may not be able to track HRs above 200 to 220 beats/min and cannot detect arrhythmias and differentiate among different types of arrhythmias (i.e., atrial vs. ventricular). They are therefore not considered suitable for diagnostic workup of horses in AF.

Treatment of Atrial Fibrillation. Cardioversion is generally not performed for the first 24 to 48 hours of a documented, recent onset of AF because spontaneous cardioversion might occur. The most common treatment for AF involves conversion to normal sinus rhythm, unless there is concurrent CHF or the horse is aged and therapy is deemed of little benefit. As a general principle, when AF occurs in the setting of CHF, the treatments should be aimed at controlling CHF and resting HR with furosemide, digoxin, and possibly an ACE inhibitor, as opposed to conversion back to sinus rhythm.

The level of intended activity influences clinical decision making, as sustained AF is likely to limit rigorous athletic work and occasionally also impairs performance at mid to low levels of activity. Other horses with persistent AF are able to perform successfully when used for less intense work. In any case, treatment of AF is recommended for all horses that are still in use for any type of athletic activity when the average maximal HR during sustained maximal exercise exceeds 220 beats/min or when concurrent ventricular arrhythmias are observed (see earlier discussion).[54,68,472] If treatment is not an option in such cases, they should be retired due to safety concerns.[68]

Treatment of AF should only be performed in a controlled setting with continuous (ECG) monitoring, regardless of the treatment method.[68] Conversion of AF to sinus rhythm usually is accomplished using the type I_A sodium channel blocker quinidine* or through electrical cardioversion, generally delivered by intracardiac catheters (transvenous electrical cardioversion [TVEC]).[655,1038,1062,1084-1094] There have been no

* References 58, 401, 729, 752, 1027, 1031, 1034, 1041, 1049, 1070, 1072-1083.

prospective, randomized studies comparing the two methods, and both quinidine and electrical cardioversion are generally safe and effective treatments. Indications for quinidine treatment include lone AF, AF with mild LA enlargement, and comorbidities in which general anesthesia or TVEC is not an option. TVEC can be used to treat lone AF, AF with mild LA enlargement, and horses either intolerant of or unresponsive to quinidine treatment or horses in which quinidine is contraindicated.[68]

Quinidine conversion to sinus rhythm represents the standard therapy for most equine practices and has been used for the longest period of time. Hence, quinidine sulfate is the standard drug against which other drug treatments should be compared, though this agent is becoming more difficult to obtain in some countries. Quinidine cardioversion of AF is successful in many horses, and a number of different treatment plans can be followed (Box 9.14; also see Table 9.7). Based on studies of Reef and colleagues an excellent prognosis for quinidine conversion (greater than 95% conversion rate) may be given for horses with HRs of less than or equal to 60 beats/min, murmurs less than or equal to grade 3/6, and AF of less than 4 months' duration.[729,1070] Recurrences affect approximately 25% of these horses. In a study of transvenous electrical cardioversion, the results were also very positive, with a greater than 98% conversion rate (71 of 72 episodes in 63 horses).[1089] Overall, success rates of 65% to 90% have been reported for both treatment modalities.[68] Young racehorses with lone AF probably have a better prognosis for successful cardioversion, independent of treatment modality. Horses with longer duration of AF, a shorter fibrillation cycle length, or significant structural cardiac disease may be more difficult to convert to sinus rhythm using quinidine or electrical cardioversion and are more likely to have a higher recurrence rate independent of the treatment modality.[729,1062] In one recent study, a recurrence rate of 36%

BOX 9.14 Quinidine Treatment of Atrial Fibrillation (AF)

PREPARATION BEFORE TREATMENT

- Intravenous catheter for rapid venous access in case of an emergency
- Nasogastric tube/transnasal feeding tube for quinidine administration
- (Telemetric) ECG for continuous monitoring of heart rate, rhythm, and conduction times
- Ensure adequate hydration and correct electrolyte and acid-base disturbances
- Prepare emergency drugs and protocols

HORSE WITHOUT HEART FAILURE

Quinidine sulfate PO (by nasogastric tube or feeding tube):

- 22 mg/kg q 2 h until (1) conversion to sinus rhythm, (2) adverse or toxic effects occur, or (3) a total of 4 (to 6) doses have been administered
- If possible, plasma quinidine concentration should be measured if (1) conversion has not occurred 1 hour after the fourth dose, or (2) the patient exhibits adverse or toxic effects
- Therapeutic concentration: 2–5 μg/mL, toxic concentration: >5 μg/mL
- Treatment intervals should be increased to every 6 hours if (1) plasma quinidine concentration is >4 μg/mL or (2) after the fourth dose if concentrations cannot be measured
- Treatment every 6 hours can be continued, until (1) conversion to sinus rhythm, (2) adverse or toxic effects occur, (3) a total cumulative dose of 180 mg/kg is reached
- If conversion to sinus rhythm has not occurred after 24 hours, digoxin at 0.0055–0.011 mg/kg PO q 12 h may be added for 24–48 hours

Quinidine gluconate IV:

- As an alternative to oral treatment if the arrhythmia is recent (<2 weeks) or occurred during anesthesia
- 1–2.2 mg/kg IV as a slow bolus every 10 min or 0.1–0.22 mg/kg/min CRI; to effect
- Total doses exceeding 12 mg/kg are usually not recommended; higher doses (up to 24 mg/kg) may be necessary for conversion but can result in severe adverse effects (hypotension, proarrhythmic effects including ventricular tachycardia and torsades de pointes)

HORSE WITH HEART FAILURE

- Cardioversion using quinidine is usually not attempted; goals of treatment are stabilization of congestive heart failure and ventricular rate control; treat with digoxin to control heart rate and improve myocardial function, furosemide to control edema, and possibly an ACE inhibitor

MONITORING

- Monitor for response to treatment and adverse/toxic effects
- Ensure adequate fluid intake during prolonged quinidine treatment
- Monitor serum electrolytes and BUN/creatinine during prolonged treatment

MANAGEMENT OF QUINIDINE-INDUCED ADVERSE AND TOXIC EFFECTS

- Accelerated ventricular response rate—may occur within therapeutic range:
  - If rate is <100 beats/min and horse is hemodynamically stable, continue treatment with close monitoring
  - If rate is persistently >100 beats/min, administer digoxin (0.0022 mg/kg IV, may repeat dose once)
  - If rate is sustained in excess of 150 beats/min or severe systemic hypotension develops, administer digoxin and $NaHCO_3$ (1 mEq/kg IV)
  - Other options for rate control include diltiazem (see Table 9.7) or alpha-2 agonists; administer to effect, monitor ECG and direct blood pressures
- Prolongation of QRS (>25%)—indication of toxicity, discontinue quinidine
- Severe hypotension—administer phenylephrine (0.1–0.2 μg/kg/min to effect, up to 0.01 mg/kg total dose)
- Ventricular arrhythmia (ventricular tachycardia, torsades de pointes)—discontinue quinidine, administer lidocaine (0.25–0.5 mg/kg slow IV, repeat in 5–10 min, up to 1.5 mg/kg total dose) and $MgSO_4$ (2–6 mg/kg/min IV to effect, up to a total dose of 55 [up to 100] mg/kg)

after first AF episode and an overall recurrence rate of 43% were reported.[291] Long-term recurrence rates after TVEC and quinidine cardioversion are believed to be similar.[68]

Quinidine is typically administered by nasogastric tube or feeding tube because of its irritating effects on the mucous membranes. Intravenous quinidine gluconate can be successful in conversion of horses with AF of recent onset or when nasogastric delivery is not feasible,[1075,1079,1082] but failure to respond does not predict the response to oral treatment (see Box 9.14). Many successful approaches have been used to convert AF in horses, and the clinician should appreciate that the mean quinidine elimination half-life after an oral dose is about 6.7 hours.[327,1082] One treatment approach for AF involves administration of a loading dose of 22 mg/kg quinidine sulfate by nasogastric tube every 2 hours for two to four doses, followed by every-6-hour dosing until the horse converts or develops initial signs of toxicosis. Aggressive q 2 h dosing exceeding 88 to 132 mg/kg is especially likely to induce adverse effects.[1070] Therapeutic serum quinidine concentrations for conversion from AF to sinus rhythm are 2 to 5 μg/mL (6.2–15.4 μmol/L) and should be measured if a horse fails to convert following an appropriate dosing regimen. If conversion to sinus rhythm has not occurred after 24 hours of therapy, digoxin at 0.0055 to 0.011 mg/kg orally twice a day may be added to the treatment regimen for 24 to 48 hours. As in other species, there is a digoxin-quinidine interaction that can effectively double the serum concentration of digoxin.[752] Thus combination therapy beyond 24 hours should be continued only with monitoring of the serum digoxin concentrations (see Table 9.7) and consideration of using the lower end of the digoxin dosage range. Even horses that do not convert on the "standard" administration regimen may convert after the combined use of quinidine with digoxin. The value of using such a treatment plan every 6 hours is that steady-state levels are reached, there is sufficient time to attain myocardial concentrations, and quinidine toxicity is less frequent compared with the every-2-hour regimen. When prolonged treatment over more than 12 to 24 hours is necessary, adequate hydration and electrolyte balance (particularly potassium and magnesium) must be ensured by oral or intravenous administration of crystalloid solutions, because most horses undergoing oral quinidine treatment will become depressed and inappetent, will show reduced water intake, and may develop mild diarrhea.

Careful clinical and continuous electrocardiographic monitoring should be performed on horses with AF during conversion to sinus rhythm. The QRS duration should be monitored and compared with the pretreatment QRS duration before each additional treatment is administered. Prolongation of the QRS duration to greater than 25% of the pretreatment value is an indication of quinidine toxicity and should prompt discontinuation of therapy. The simplest ECG change is an acceleration of AV nodal conduction related to the vagolytic effect of quinidine (see Fig. 9.57C). Rapid supraventricular tachycardias with ventricular rate responses of up to 300 beats/min have been seen in several horses receiving quinidine sulfate. These horses have been treated with intravenous digoxin at 0.002 mg/kg to slow the ventricular response rate, intravenous replacement fluids to improve perfusion, intravenous sodium bicarbonate at 1 mEq/kg to reverse the sodium channel–blocking effects of quinidine (probably by a combined effect of increasing extracellular sodium concentration and alkalinization, leading to increased protein binding of quinidine and decreased extracellular concentrations of ionized calcium), and if needed, a phenylephrine drip to restore BP if there is critical hypotension (see Table 9.7 and Box 9.14). Ventricular arrhythmias (torsades de pointes, multiform VT, and ventricular premature complexes) have also been detected with quinidine toxicosis (Fig. 9.58) and in the rare case may lead to sudden cardiac death during treatment. Intravenous sodium bicarbonate is also indicated in these horses, whereas intravenous magnesium sulfate (up to 25 g in a 450- to 500-kg horse) is the treatment of choice for quinidine-induced ventricular arrhythmias (see Table 9.7). Lidocaine may also be used if needed, starting with an intravenous bolus of 0.5 to 1.5 mg/kg, slowly IV. Conversely, administration of digoxin is contraindicated in horses with ventricular arrhythmias induced by quinidine.

Clinical markers of quinidine toxicosis include ataxia, colic, and nasal edema causing upper respiratory tract stridor. Most toxic reactions to quinidine sulfate are associated with higher serum concentrations of the drug (greater than 5 μg/mL) and can be avoided with careful clinical and electrocardiographic monitoring. Some of the adverse effects of quinidine administration, particularly polymorphic ventricular tachycardia (see Fig. 9.58), are likely an idiosyncratic reaction. These adverse effects should prompt discontinuation of therapy or altering treatment intervals. Depression and paraphimosis occur in most horses treated with quinidine but disappear with the discontinuation of the drug. Diarrhea often develops with the administration of higher doses of quinidine, but this sign also disappears with discontinuation of the drug. Convulsions, hypotension due to vasodilation, CHF, laminitis, urticaria, and sudden death have rarely been reported associated with quinidine sulfate administration. A ventricular rate response in excess of 100 beats/min is an adverse reaction that may be more common in nervous horses, horses that show an excessive ventricular response during exercise, or those prone to the vagolytic effects of quinidine. These horses may benefit from administration of digoxin to blunt the ventricular rate response, particularly if there are no other signs of quinidine toxicosis (that would indicate an excessive serum concentration). If an increased ventricular response rate is anticipated, one may even consider pretreatment with digoxin before initiation of quinidine therapy. Alternatively, alpha-2 agonists (e.g., detomidine)[1063] or diltiazem[259,1031-1033] could be used for ventricular rate control during quinidine treatment, provided that blood pressures can be closely monitored (see Table 9.7). The clinical experience with the use of diltiazem is limited, and doses should be carefully titrated to effect.

Other drugs have been studied for treatment of AF in horses. These might be considered mainly for cases of resistant or recurrent AF or in situations where quinidine or electrocardioversion are unavailable. Procainamide may potentially be effective and could be used at a dose of 1 mg/kg/min IV (up to a maximum of 20 mg/kg) when AF occurs during anesthesia.[327,1095] Based on recent discoveries in dogs, the use of lidocaine could also be attempted to treat acute vagally associated AF that might develop during anesthesia.[1096,1097] However, efficacy of lidocaine for conversion of AF is unknown, and it is certainly not considered the drug of choice for routine treatment of AF in horses. Amiodarone administered as a constant rate infusion has been used for treating experimentally induced and natural AF in horses, but treatment may last up to 54 hours and is expensive, and success rates are considerably lower than those reported for quinidine and TVEC.[1098-1101] Therefore amiodarone cannot be recommended as a first-line therapy at this time. Pharmacokinetics of flecainide, a class IC

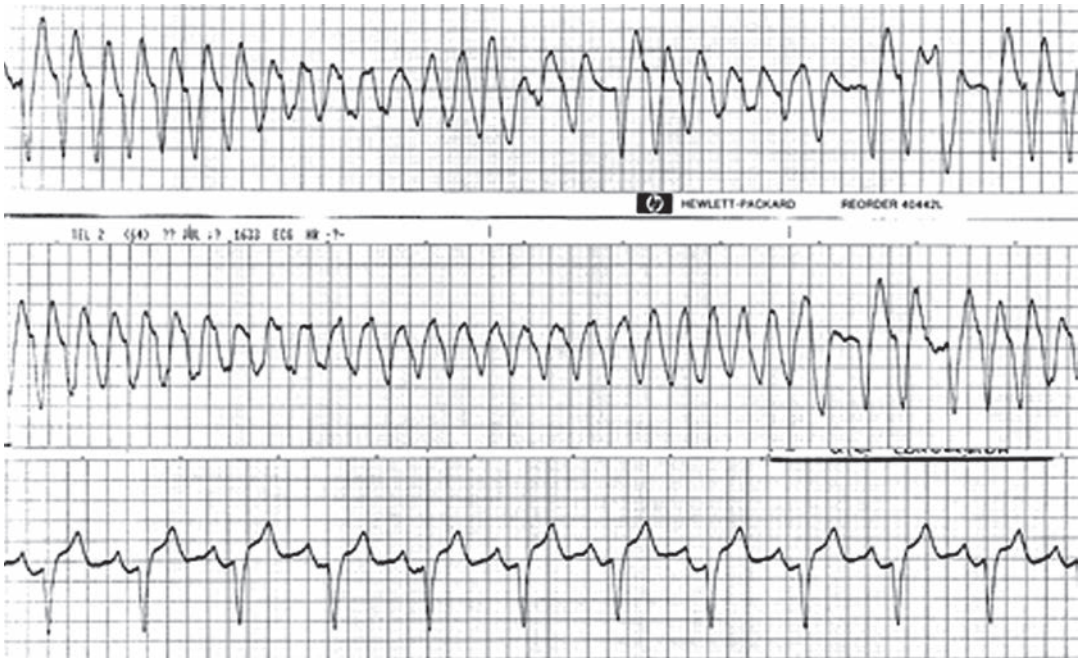

FIG. **9.58** Polymorphic ventricular tachycardia (VT) after administration of quinidine sulfate for attempted conversion of atrial fibrillation (AF). In this case normal sinus rhythm was established *(lower tracing)* after treatment with lidocaine, bicarbonate (to reverse sodium channel–blocking effects of quinidine), and phenylephrine (administered to maintain arterial blood pressure [ABP]).

antiarrhythmic drug, have been studied in horses, and it has been administered for treatment of experimentally induced and naturally occurring AF and atrial tachycardia.[1102-1109] Early studies suggested that flecainide might be a safe and effective alternative to quinidine for treatment of AF. However, intravenous administration of flecainide was not found to be effective to treat chronic naturally occurring AF,[1102,1109] and in an experimental model it failed to show protective properties against immediate reinduction of AF after conversion.[1104] Furthermore, flecainide administration caused widening of the QRS complex and was associated with potentially dangerous arrhythmias and sudden death.[1103,1109] Therefore the use of flecainide is currently not recommended in horses. Intravenous propafenone also has been suggested for conversion of chronic AF[1110,1111] but has recently been shown to be ineffective at a dose of 2 mg/kg IV in horses with naturally occurring and pacing-induced AF, respectively. Therefore the current knowledge does not support the use of this class Ic antiarrhythmic drug for treatment of AF. Potentially, combination therapy using a variety of antiarrhythmic drugs at lower doses might prove useful for treatment of AF in the future. Furthermore, novel ion channel targets and new atrial-selective antiarrhythmic agents are currently under investigation for treatment of AF in horses and other species.[1112,1113] However, more fundamental research has to be conducted before any of the newer strategies can be investigated in clinical studies.

Transvenous electrical cardioversion of AF to sinus rhythm has been used at a number of referral centers as either the primary method of treatment or for management of horses who respond adversely or inadequately to quinidine therapy. As stated, TVEC is a very effective therapy, but it requires special equipment and well-trained, experienced personnel. The procedure involves percutaneous placement of two specialized electrode catheters transvenously with one catheter tip located within the left PA and the other within the right atrial cavity. Catheter placement is done in the standing position under sedation and local anesthesia. The catheters are guided by pressure monitoring through the catheter lumen, 2D echocardiographic imaging, and interrogation of the intracardiac electrogram recorded through the catheter electrodes (Fig. 9.59). Radiography is used to verify the placement of the catheters either before or preferably after induction of general anesthesia. General anesthesia is required because electrical cardioversion is very painful and the shock results in a sudden jolt of the body and limbs. Electrical cardioversion involves a timed shock delivery on the R wave. Proper synchronization of the shock is crucial to avoid shocking on the T wave, which represents the vulnerable period and is susceptible for inducing fatal ventricular arrhythmias. A more detailed description of the specific procedure used for TVEC is beyond the scope of this textbook, and the reader is referred to the respective literature.[655,1038,1062,1084-1094]

The complications associated with electrocardioversion appear to be quite low but are finite related to general anesthesia or electrical shock.[1088,1091,1093] A case of transient complete AV block has been reported,[1092] and depending on catheter position (i.e., placement of the RA catheter close to the AV node) this complication might not be uncommon. Furthermore, fatal arrhythmias can be induced by unsynchronized shock delivery.[1114] The immediate recurrence of AF (IRAF) within the first 24 hours after cardioversion, although infrequent, is more likely than with quinidine cardioversion.[68] Pretreatment with antiarrhythmic drugs before TVEC or administration of an antiarrhythmic drug during and after anesthesia might minimize the likelihood of IRAF.[1038,1090] Amiodarone and sotalol have been used for this purpose (see Table 9.7).

Follow-up Care after Conversion of Atrial Fibrillation. After spontaneous cardioversion, an evaluation is still indicated, including measurement of serum K^+ and Mg^{++}

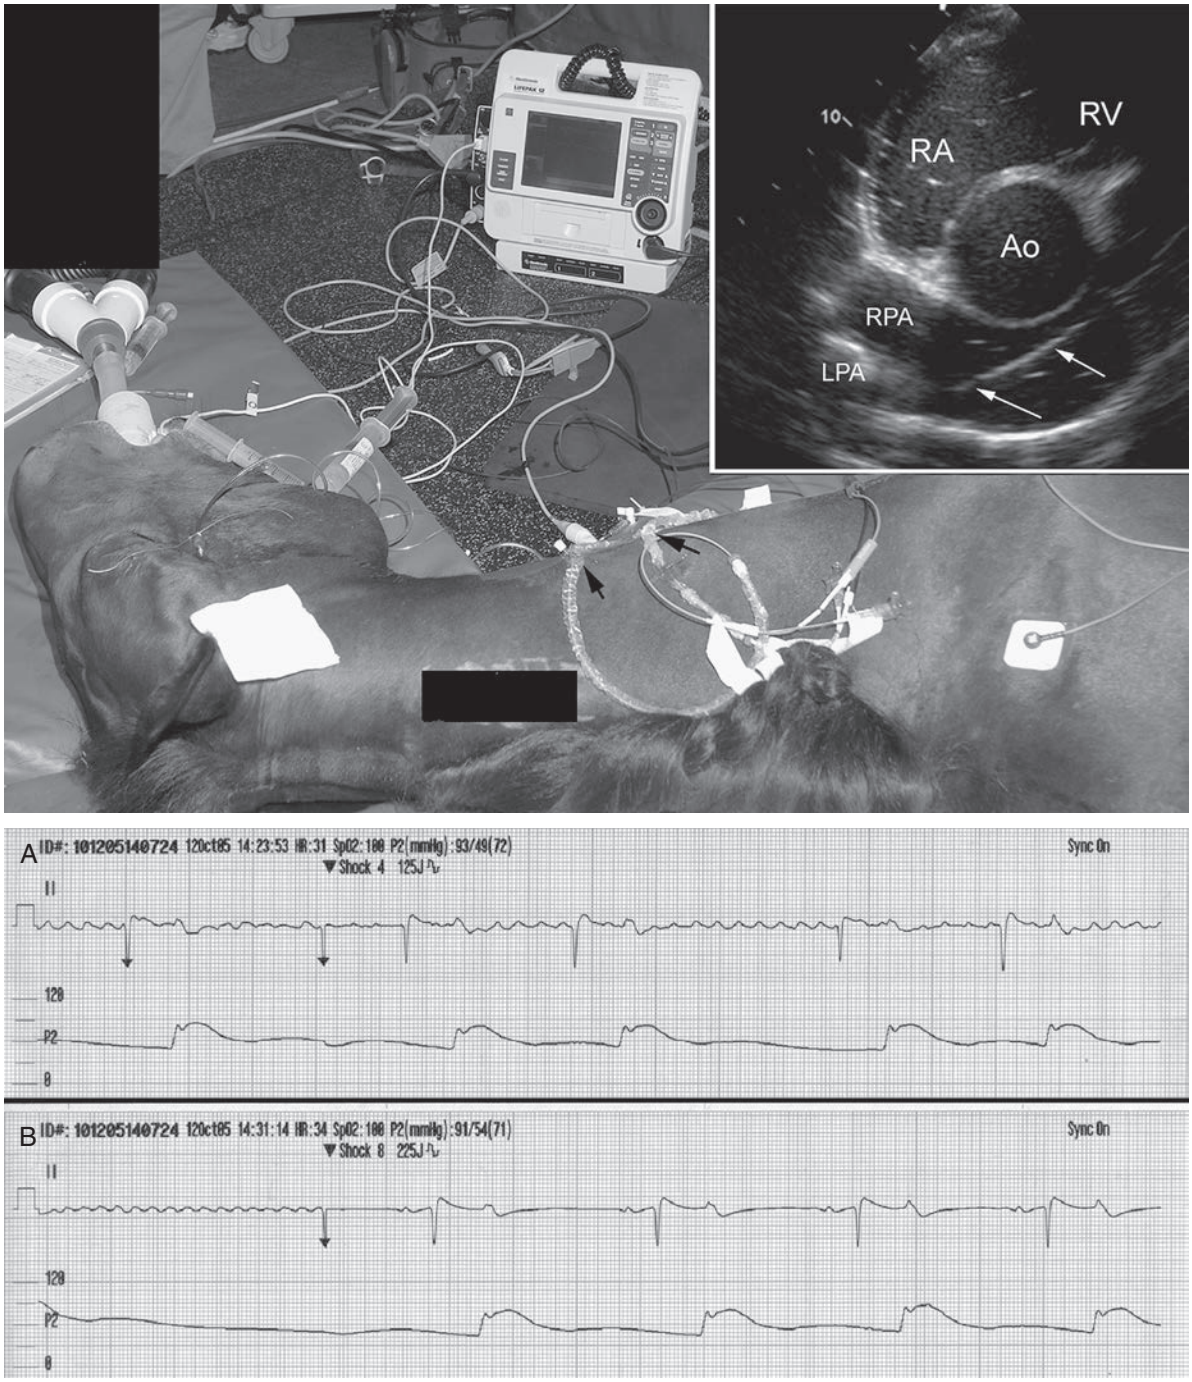

FIG. **9.59** A, Electrocardioversion procedure in a Thoroughbred horse. The horse is under general anesthesia. Two specialized electrode catheters *(arrows)* were previously placed percutaneosly under local anesthesia into the right atrium (RA) and left pulmonary artery under guidance from two-dimensional (2D) echocardiography and intravascular pressure monitoring. The biphasic cardioverter (*top,* center of image) is connected to the catheters and is used to deliver the synchronized cardioversion shock, as well as monitor electrocardiogram (ECG) rhythm, invasive blood pressure (BP), and pulse oximetry. *Inset:* 2D image showing short-axis image at base of heart. The catheter inserted into the left pulmonary artery (LPA) is indicated *(arrows)* (*RA,* right atrium; *RV,* right ventricle; *Ao,* aorta; *RPA,* right pulmonary artery). B, Transvenous electrical cardioversion for treatment of atrial fibrillation (AF) in an 2-year-old Standardbred racehorse under general anesthesia. A surface ECG (25 mm/sec) and an arterial blood pressure (ABP) tracing are displayed. The QRS complexes are automatically detected by the defibrillator unit and marked by small triangles. Biphasic electrical shocks *(larger triangles on top)* are applied at increasing energy levels. Delivery of the shocks is synchronized to the QRS complex to avoid the vulnerable period (T wave) and prevent induction of ventricular arrhythmias. *(A)* Unsuccessful attempt at an energy level of 125 J. *(B)* Successful cardioversion at an energy level of 225 J. Immediately after the shock, the baseline flattens and normal sinus rhythm resumes. No further treatment is required at this point. From Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: *Equine anesthesia: monitoring and emergency therapy,* ed 2, St. Louis, 2009, WB Saunders.

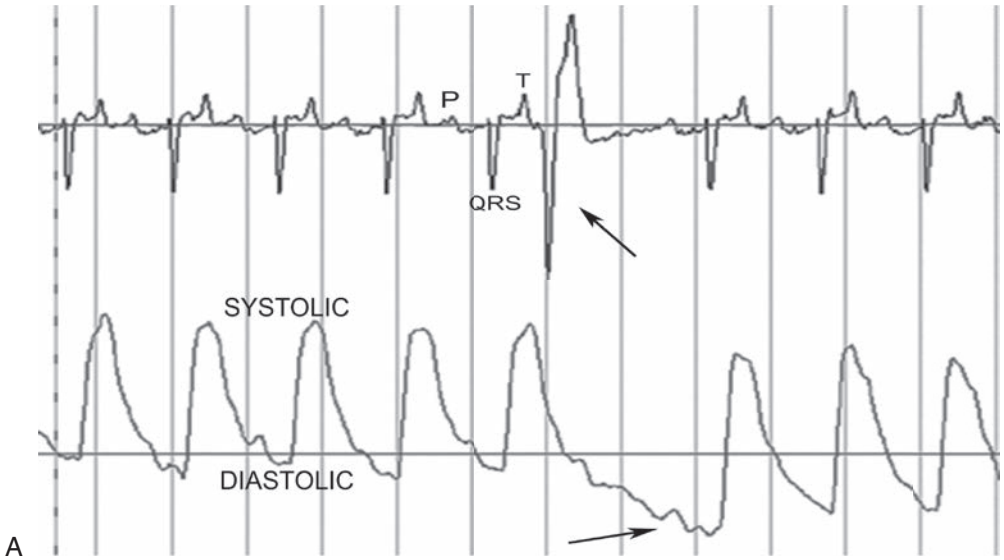
concentrations, fractional excretion of K^+ (in racehorses), echocardiography, continuous 24-hour ECG, and optimally an exercising ECG test to identify atrial triggers or other arrhythmias. These tests are also appropriate in a horse with normal sinus rhythm if paroxysmal AF is suspected from the clinical history.[68]

A continuous 24-hour ECG to detect recurrent atrial arrhythmias is recommended after successful conversion of AF to sinus rhythm. However, the optimal timing of this examination, the influence of premature atrial complexes on long-term prognosis, and the best approach to management of recurrent atrial ectopy are unknown.[68] A complete echocardiogram after cardioversion can evaluate LV and LA mechanical function and reassess heart size and valvular function. Left ventricular function should return to normal within 3 days.[1048] Recovery of LA contractile function can occur within a few days or might take several weeks when AF has been long-lasting.[287,289,1038] Persistent LA contractile dysfunction can be caused by AF-induced atrial remodeling or underlying primary cardiomyopathy and might portend an increased risk of recurrent AF.[291,1038]

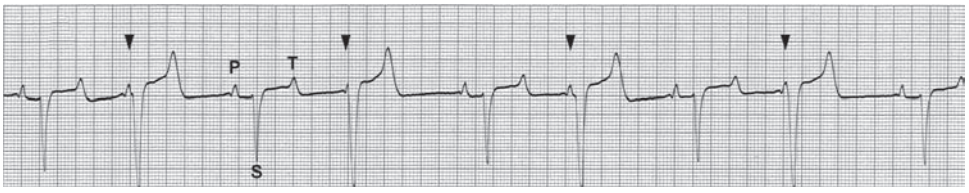
Oral sotalol at an initial dose of 1 mg/kg PO and a maintenance dose of 2 to 3 mg/kg PO q 12 h (see Table 9.7)[1030] is currently used by some clinicians, including the author, in an attempt to suppress atrial ectopy after cardioversion and reduce the risk of recurrent AF. Sotalol is usually weaned before reinitiation of normal training, and only rarely chronic long-term treatment is elected. Although sotalol seems to be well tolerated, its efficacy is currently not well studied. Other antiarrhythmic drugs that, based on human studies or experimental animal models, might potentially be effective against atrial arrhythmias include propafenone,[1110,1111] amiodarone,[1100,1101] and phenytoin.[1115] However, efficacy and safety of these treatments are currently unknown and further studies are needed.[68] Drugs known to predispose to ectopic impulse formation should be avoided, including furosemide, supplements containing sodium bicarbonate, and thyroid hormones. Potassium chloride supplementation is indicated in most horses administered furosemide before racing or in those with low fractional urinary excretion of potassium.[68]

Horses can usually be returned to training within 1 week after conversion with paroxysmal AF or short-duration lone AF, if follow-up examinations after cardioversion are normal. However, horses with long-standing AF or with persistent sinus tachycardia, recurrent atrial premature complexes, or persistent LA dysfunction observed after successful conversion of AF to NSR should be given 4 to 6 weeks to recover.[68] Ideally, rest is enforced until atrial electrical and contractile function has normalized or is nearly normal.



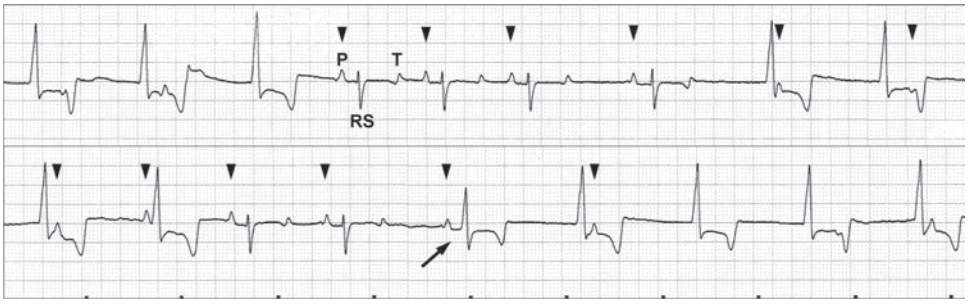
Conversion of horses with AF generally results in a return to their previous performance level.[84,729] Horses with repeated episodes of AF are often converted numerous times with quinidine sulfate or electrocardioversion. Most horses that experience a recurrence of AF do so within 1 year of initial conversion,[291,1038,1070] but much longer intervals have occurred between episodes of AF in some horses. If the duration of sinus rhythm becomes shorter, repeated treatments may no longer be practical and a career change may be indicated. Some horses eventually become refractory to drug or electrical cardioversion, probably due to progressive atrial fibrosis or underlying myocardial disease. However, in the absence of significant, detectable cardiac disease, horses with persistent or permanent AF may still be used at lower levels of exercise (as long as the expected level of performance can be achieved and the results of exercise testing do not suggest an increased risk of collapse or sudden death; see earlier discussion). Alternatively, they can be kept as breeding animals or pasture horses. Importantly, horses with persistent AF should only be ridden or driven by an informed adult and limited to an exercise level considered relatively safe based on an exercising ECG (see previous discussion). The use of an HR monitor might be helpful to track HR during exercise and modify the rigor of the work performed.[68]

Junctional and Ventricular Arrhythmias



Cardiac arrhythmias that originate within the AV conducting tissues, the ventricular specialized conducting tissues, or ventricular myocardium are classified as "junctional" (AV node and parts of the bundle of His) or ventricular in origin. Unlike sinus or atrial arrhythmias, these arrhythmias are not preceded by a conducted P wave. When sustained, junctional and ventricular rhythms often lead to dissociation between the sinoatrial activity (P wave) and that of the ventricle (QRS-T complex), resulting in AV dissociation.[57,60,502] In these cases, an independent atrial rhythm is superimposed on the ectopic rhythm (Fig. 9.60C and D). Note that AV dissociation in these cases develops because the premature AV junctional or ventricular depolarization causes interference to the conduction of normal SA impulses. It is important to realize that escape rhythms (see later discussion) also cause AV dissociation through a different mechanism. Hence, "AV dissociation" is a purely descriptive term of an ECG finding and neither characterizes the type and pathophysiologic mechanism of the arrhythmia nor determines the therapeutic approach.

With sustained junctional or ventricular tachycardias, P waves may be identified that are not conducted and therefore not consistently associated with a QRS complex (see Fig. 9.60). Some of these P waves may be buried in the ectopic QRS-T complexes (especially at higher rates of ventricular activation), making their identification difficult. The use of ECG calipers helps determine the P-P interval and can greatly facilitate the identification of P waves. Occasionally, atrial impulses may be normally conducted, leading to capture beats or fusion beats. *Capture beats* are characterized by a normal P-QRS-T configuration, resulting from normal ventricular activation occurring before the ectopic focus discharges (see Fig. 9.60D). *Fusion beats* are seen when both the conducted impulse and an ectopic impulse cause simultaneous ventricular activation. The QRS-T morphology of a fusion beat represents the summation of a normal and an ectopic beat (see Fig. 9.60C).



It may be difficult to distinguish between junctional and ventricular arrhythmias and to determine the exact location of the abnormal impulse formation. The differentiation of junctional and ventricular rhythms can sometimes be made by inspection of the QRS complex. Junctional impulses are more likely to result in a narrow, relatively normal-appearing QRS complex with normal initial activation and electrical axis, because they originate above the ventricular myocardium. Complexes of ventricular origin, by contrast, are conducted abnormally and more slowly, resulting in a widened QRS, an abnormal QRS orientation, and abnormal T waves. However, junctional tachycardias also may be conducted aberrantly, resulting in a bizarre and wide QRS complex. When sustained, both types of rhythms cause AV dissociation with an independent atrial rhythm superimposed on the ectopic ventricular rhythm. Advanced echocardiographic methods that identify the sequence of ventricular

FIG. **9.60** Ventricular arrhythmias. A, The ectopic complex *(arrow)* is premature and abnormal in morphology. A compensatory pause follows the extrasystole because the next sinus P wave is blocked in the atrioventricular node. The effect of the premature complex on arterial blood pressure (ABP) in the lower tracing *(arrow)* is noticeable. B, Base-apex lead electrocardiogram (ECG) recorded from a 15-year-old Arab mare with ventricular bigeminy. Normal sinus beats alternate with slightly larger and wider ventricular ectopic beats. SA node discharge is not affected by the ectopic beats, as indicated by the presence of nonconducted P waves immediately before the ectopic beats *(arrowheads)* (paper speed 25 mm/sec). C, Base-apex lead ECG recorded from an 18-year-old Arab mare recovering from acute diarrhea and endotoxemia. The ECG shows an intermittent accelerated idioventricular rhythm at a rate of 50 beats/min. P wave intervals are indicated *(arrowheads).* The recording demonstrates that the ectopic focus is suppressed at higher rates of SA node discharge. The ventricular rhythm only becomes manifest when the sinoatrial (SA) rate drops below the rate of the ventricular pacemaker. SA node discharge is not affected by the ectopic rhythm, resulting in AV dissociation. A fusion beat is present *(arrow),* resulting from summation of a conducted sinus impulse with an ectopic ventricular beat (paper speed 25 mm/sec, voltage calibration 0.5 cm/mV). D, Base-apex lead ECG recorded from a 3-year-old Clydesdale gelding. The top recording shows a regular tachycardia at a rate of 120 beats/min. The appearance of the QRS-T complexes does not allow conclusive distinction between a supraventricular rhythm with rapid ventricular response and a ventricular rhythm. However, as the rate slows down *(bottom strip),* AV dissociation because of a ventricular tachycardia (VT) becomes apparent. P waves *(arrowheads)* and a capture beat *(arrow)* are indicated (paper speed 25 mm/sec, voltage calibration 0.25 cm/mV). E, Base-apex ECG recorded from a 5-year-old Clydesdale stallion with acute myocardial necrosis of unknown cause. The serum cardiac troponin I concentrations were severely elevated (404 ng/mL; normal <0.15 ng/mL). The ECG shows multiform VT at a rate of 120 beats/min (paper speed 25 mm/sec, voltage calibration 0.5 cm/mV). (B to E, From Schwarzwald CC, Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: *Equine anesthesia: monitoring and emergency therapy,* ed 2, St. Louis, 2009, WB Saunders.)

activation and allow detection of ventricular dyssynchrony and advanced electrophysiologic studies may be of value in distinguishing ventricular origin complexes from those starting above the ventricle and using the normal conduction system, but these methods are not established in horses.

Junctional Arrhythmias

Junctional complexes that arise early relative to the normal cardiac cycle are designated as *premature junctional complexes.* These complexes may occur as single or repetitive events and can resemble ectopic rhythms that might originate in the atria but without being related to a P wave. Repetitive ectopic complexes that occur in short bursts or runs are termed *nonsustained* or *paroxysmal junctional tachycardias. Sustained junctional tachycardias* may also occur and can lead to cardiomyopathy and CHF, which are reversible with control of the tachyarrhythmia (see earlier discussion).

The clinical relevance of an occasional junctional premature complex is difficult to ascertain. Persistent or repetitive junctional rhythms are indicative of heart disease, systemic disease, or a drug-induced abnormality of cardiac rhythm. The best management choice, besides treatment of the underlying disorder, is uncertain inasmuch as some junctional rhythms behave more like atrial tachyarrhythmias, whereas others cause AV dissociation and appear to act like ventricular ectopic impulses. Because the mechanism responsible for junctional tachycardias can be either abnormal automaticity or reentry (circuit) movement using the AV node, empiric therapy is usually required to control sustained arrhythmias. If there is obvious AV dissociation, lidocaine, procainamide, quinidine, or sotalol would seem reasonable choices (see Table 9.7). If the mechanism is uncertain but is clearly supraventricular, intravenous digoxin or intravenous diltiazem may either silence the rhythm or slow the rate.

Escape Rhythms

The normal heart contains potential cardiac pacemakers within the AV junctional and ventricular specialized tissues that are usually overdrive suppressed by the sinus node, which discharges at a faster rate than these subsidiary pacemakers. The automaticity of the subsidiary pacemakers may become manifest during periods of sinus bradycardia or AV block, creating *escape complexes* or *escape rhythms* (see Fig. 9.62B later). Escape rhythms are characterized by slow ventricular rates, often in the realm of 15 to 25 beats/min. Specific antiarrhythmic drug suppression of escape rhythms is generally not necessary and is contraindicated because these rhythms serve as rescue mechanisms for the heart. Instead management of escape rhythms should be aimed at resolving the underlying cause of sinus bradycardia or AV block.

Accelerated Idioventricular (Idionodal) Rhythms

Occasionally, the subsidiary nodal or ventricular pacemakers may be enhanced and discharge at a rate that is equal to or slightly above the sinoatrial rate (usually between 60 and 80 beats/min). The resulting rhythm is commonly referred to as *accelerated idioventricular (idionodal) rhythm* or *slow ventricular tachycardia* (see Fig. 9.60C). Conditions that favor the development of these rhythms include gastrointestinal disease (possibly due to a combination of endotoxemia, autonomic imbalance, acid-base disturbances, and electrolyte abnormalities)[504] and administration of anesthetics or catecholamines. When the independent atrial and ventricular pacemaker foci discharge at similar rates, the P waves may appear to "march in and out" of the QRS complex. This phenomenon is called *isorhythmic AV dissociation* and is occasionally observed in adult horses during inhalation anesthesia. Accelerated idioventricular rhythms are often quite regular and may be misdiagnosed as sinus tachycardia on auscultation or palpation of peripheral pulses. Persistent, unexplained mild to moderate tachycardia should therefore prompt an electrocardiographic examination to ascertain a correct rhythm diagnosis. However, accelerated idioventricular rhythms generally are of little clinical (electrophysiologic and hemodynamic) relevance and resolve spontaneously with appropriate treatment of potential underlying conditions and reduction of anesthetic dosages. Electrolyte supplementation (potassium, magnesium) and correction of fluid deficits and acid-base disturbances may be beneficial. Lidocaine (see Table 9.7) is sometimes administered as an intraoperative adjunct to general anesthesia, or it is used as an analgesic, antiinflammatory, and prokinetic drug in

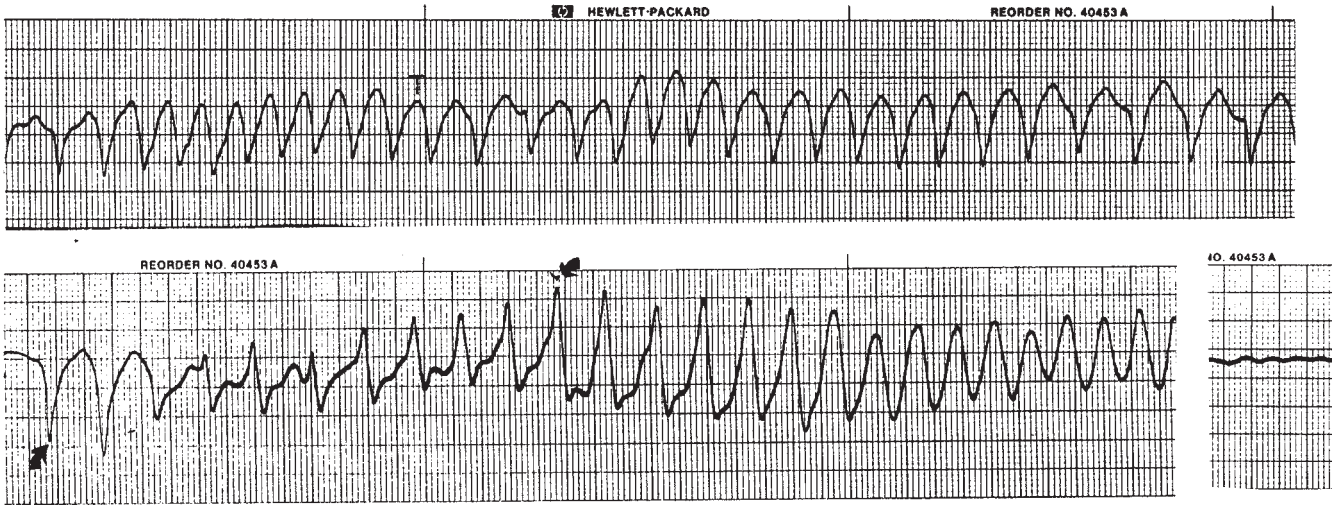

FIG. **9.61** Sustained, rapid ventricular tachycardia (VT) *(top)* of varying rate that develops into a polymorphic ventricular rhythm with varying morphology complexes (torsades de pointes). The horse died of cardiac arrest *(lower right panel).* The arrows indicate QRS complexes of varying polarity (25 mm/sec).

the management of postoperative ileus. In these situations, its antiarrhythmic effects may provide some additional preventive or therapeutic benefits.

In some cases, accelerated idioventricular (idionodal) rhythms can be sustained in an otherwise healthy horse. If the abnormal rhythm is overdriven by exercise, affected horses can be used with caution by an informed adult. However, because of concerns about underlying myocardial or electrical disease and potentially increased risks of exercise-associated collapse and sudden cardiac death, these horses should not be used by a child or as a lesson horse.[68]

Ventricular Arrhythmias

Ventricular arrhythmias (VAs) are less common than atrial arrhythmias but are more likely to be associated with underlying structural cardiac disease, lesions of the myocardium, or a multisystemic disorder, including infections.* VAs may be observed with severe toxemia or sepsis or primary gastrointestinal disorders including proximal enteritis and large bowel disorders. Altered potassium, magnesium, and calcium concentrations can affect myocardial electrophysiology,[1125] and electrolyte and acid-base disorders can induce ventricular ectopy. Other potential causes of VAs include metabolic disorders, ischemia, hypoxia, drugs, toxins, and systemic inflammation. Primary heart diseases, including severe valvular regurgitation, cardiomyopathy, myocarditis, endocarditis, and pericarditis, can induce VAs. This said, VAs are also frequently encountered in apparently healthy athletic horses at rest and during and after exercise.[77-79,82,475,478,479]

Ventricular ectopic rhythms are classified as indicated in Box 9.12. The approach to the horse with VAs should emphasize ruling out the noncardiac causes, correcting them (if possible), and then following if necessary with a complete CV examination, including electrocardiography, echocardiography, and clinical laboratory studies.[68] Plasma troponin concentrations should be measured to identify myocardial injury, although it may be problematic to separate primary from secondary causes of cardiac troponin elevations. An echocardiogram is specifically recommended for horses with ventricular tachycardia or complex VA, when VA is recurrent or persistent, or when VA is associated with poor performance, collapse, a clinically relevant cardiac murmur, or a marked increase in cardiac troponin concentration.[68] Further workup of a horse with VA should include an exercising ECG, unless underlying systemic or myocardial disease, VT, or complex VA is present.[68]

As opposed to atrial arrhythmias, safety of the horse and the rider or driver is more of a concern with VAs, and defining the safety risks is paramount in cases of ventricular ectopy.[68] The complexity of a ventricular arrhythmia (see later discussion) likely relates to the risk of hemodynamic compromise, electrical deterioration, and sudden cardiac death. Although risk stratification for VA is imperfect, recommendations should be biased toward safety as opposed to maintaining athletic activity.[68] A history of collapse, presence of important structural heart disease (and cardiomegaly), or detection of systemic hypotension during a documented run of ventricular tachycardia raises great concern in a horse with VA. In the absence of clinical signs or of serious structural heart disease, the risk of ventricular ectopy is usually defined by electrocardiographic characteristics (see later discussion), accepting the limitations of this analysis.[68]

Ventricular Premature Complexes

Ventricular premature complexes (VPCs) are characterized by premature, widened complexes, often followed by a compensatory pause. The pause occurs because the next sinus impulse is blocked by the refractory AV conduction system. If the sinus rate is slow or the ventricular premature complex is closely coupled to the preceding normal sinus beat, it may be interpolated between two normal beats. Ventricular ectopic impulses are characterized by QRS and T waves that are wide and often bizarre in appearance (Fig. 9.61; see also Fig. 9.60). The premature QRS bears no relationship to any preceding P waves, although the induction of ventricular ectopics may be dependent on underlying cardiac cycle length or HR. The morphology of the VPCs may be uniform (monomorphic) or

*References 57, 77-79, 80, 81, 82, 83, 97, 149, 150, 153, 161, 227, 263, 383, 400, 472, 475, 478, 479, 485, 502, 524, 575, 651, 653, 654, 662, 665, 667, 736, 864, 907, 917, 1028, 1029, 1103, 1116-1124.

multiform (polymorphic) as shown in Fig. 9.60E. The relationship of a ventricular extrasystole to the preceding sinus QRS-T is expressed by the "coupling interval" between them. Often the coupling interval is fixed, although it may vary minimally[1120] or markedly. A very short coupling interval may place the ectopic QRS on the preceding T wave, a phenomenon called "R-on-T" and related to increased ventricular vulnerability for fibrillation. Horses with repetitive ectopic activity with short coupling intervals are therefore considered at a higher risk of collapse or sudden cardiac death.[68]

Ventricular premature complexes are generally considered abnormal, except for possibly those occurring immediately after exercise (see Exercise Testing earlier in this chapter).* However, ventricular ectopy was identified in 14% of clinically normal horses during routine 24-hour continuous electrocardiographic monitoring.[400] The distributional pattern of ventricular ectopic beats may include haphazard distribution of single complexes, bigeminy (VPCs following normal beats in an alternating pattern), couplets (pairs of VPCs), triplets, or runs (four or more) of ventricular ectopic beats. Runs of accelerated idioventricular rhythm (see earlier discussion), usually developing at relatively slow HRs, are not uncommon. Runs of ventricular ectopic beats at a rapid rate—ventricular tachycardia—are more likely to be hemodynamically and electrically unstable, particularly when they develop at rates higher than 100 beats/min (see later discussion).

When premature beats are identified by auscultation, an ECG should be obtained, and a workup similar to that outlined in Box 9.4 should be undertaken. Occasional premature ventricular complexes, as with occasional supraventricular premature complexes, may be clinically irrelevant and do not require treatment. Occasional monomorphic VPCs overdriven with exercise or only detected in the immediate postexercise period are not usually a cause of poor performance, but the importance of these arrhythmias and the risk of sudden cardiac death requires further investigation.[68] VPCs occurring during exercise are more concerning, although their relationship with poor performance is also uncertain and requires further investigation. Generally, horses with occasional VPCs at rest or during exercise can be used with caution by an informed adult. However, because of concerns about underlying myocardial or electrical disease and increased risks of exercise-associated collapse and sudden cardiac death, these horses should not be used by a child or as a lesson horse.[68]

Rest is highly recommended for horses with frequent ventricular premature complexes. In the majority of horses with premature ventricular complexes occurring in the absence of significant structural heart disease, the arrhythmia seems to resolve spontaneously after 4 to 8 weeks of rest. The horse may then be able to return successfully to its prior performance level. Antiarrhythmic therapy (see Table 9.7) is usually successful in abolishing ventricular premature complexes, but most return when the antiarrhythmic agent is discontinued, unless the underlying problem has been resolved. Chronic administration is usually not practical. Dexamethasone and other antiinflammatory drugs have been used to treat ventricular arrhythmias, particularly in the presence of myocardial damage as demonstrated by increased plasma troponin concentrations, but their use is controversial and they should certainly not be administered to horses with a recent or current infection.[68]

Ventricular Tachycardia

Ventricular tachycardia (VT) is an ectopic ventricular rhythm characterized by three or more repetitive or linked VPCs either at a regular or irregular ventricular rate (see Figs. 9.60 and 9.61).[68] Ventricular tachycardia is recognized clinically by an increased HR, often exceeding 100 beats/min. Auscultation of VT is often characterized by a regular rhythm, with variable intensity and often booming heart sounds. Lack of discernible rhythm irregularity on auscultation may cause the possible existence of VT to be overlooked. Because of intermittent aortic valve opening, the rhythm can also sound irregular on auscultation, and an intermittent pulse deficit could be present. Arterial pulses are typically weak or variable in intensity. Multiform VT is characterized by an irregular rhythm (see Fig. 9.60E). With multiform ventricular tachycardia, heart sounds are more likely to vary in intensity, and arterial pulses are likely to be abnormal. Jugular pulsations may be detected due to AV dissociation. Syncope is associated with higher rates of ventricular tachycardia (180 beats/min or higher). Respiratory distress and pulmonary edema may develop from impaired ventricular function. Protracted junctional or ventricular tachycardias (greater than 120 beats/min) may lead to CHF due to reversible myocardial failure (tachycardia-induced cardiomyopathy).[149] Torsades de pointes represents a specific form of polymorphic ventricular tachycardia, characterized by progressive changes in QRS direction leading to a steady undulation in the QRS axis (see Fig. 9.61). Ventricular tachycardias can progress to ventricular flutter and ventricular fibrillation, characterized by chaotic ventricular activation patterns leading to uncoordinated undulations of the electrical baseline. These rhythms often represent terminal rhythms and usually result in cardiac arrest (see Fig. 9.61).

Ventricular tachycardia may be life threatening, and in general, the following are features of complex or potentially "malignant" ventricular arrhythmias: severe hemodynamic compromise (systemic hypotension, poor pulse quality, prolonged capillary refill time, weakness, collapse), sustained VT, rapid ventricular rate (greater than 120 beats/min), short coupling intervals (particularly with R-on-T complexes), and multiform or polymorphic QRS morphology (including torsades de pointes).[68] Immediate treatment of CV collapse may be required.[1027] Intravenous therapies for VT include lidocaine, procainamide, quinidine, magnesium salts, and amiodarone (see Table 9.7). Administration of antiarrhythmic drugs can be associated with adverse effects, including proarrhythmia, seizures, and sudden death. Lidocaine, if administered too fast or at doses exceeding the recommended therapeutic doses, causes central nervous system excitation, but boluses and infusions can be well tolerated in horses, and the drug causes minimal hemodynamic or electrophysiologic alterations at therapeutic, nontoxic doses.* Quinidine may be used for treatment of ventricular arrhythmias but is a myocardial depressant and vagolytic drug.[55,153,327,328,1082] Procainamide[55,327,328,1095] has been studied to a limited degree but is generally well tolerated when given in graded doses. It has similar electrophysiologic effects to quinidine but seems less vagolytic and possibly has fewer gastrointestinal side effects. Cumulative doses of up to 10 mg/kg are generally well tolerated; additional dosing should be guided by ECG, QRS duration, and arterial BP. Magnesium sulfate is an alternative antiarrhythmic that can be effective in both normomagnesemic

* References 55, 327, 328, 797, 798, 1126, 1127.

and hypomagnesemic horses and is generally well tolerated at therapeutic doses.[55,1128] Amiodarone has been evaluated in a small number of horses[1100,1101,1124] and can be considered as a second-line drug for serious, drug-resistant VT. Other antiarrhythmics, including propafenone,[1111] or phenytoin[916,1129-1131] may be tried in refractory ventricular arrhythmias. The use of steroids in horses with ventricular tachycardia is empiric and controversial but may be indicated if there is evidence of acute myocardial damage in the absence of a recent or current infection (see earlier discussion).[68]

A substantial number of horses suffering from VT can be successfully returned to performance after treatment with antiarrhythmics and rest, as long as there is not significant and untreatable structural heart disease evident. A period of rest (4–8 weeks) followed by echocardiographic and electrocardiographic reevaluation (including a 24-hour Holter ECG) once sinus rhythm is restored is indicated for horses with sustained VT.[68] An exercising ECG should be performed before the horse may be returned to normal work, if the preceding echocardiogram and the 24-hour Holter ECG are normal; another exercising ECG should be performed once the horse has returned to full work.[68] Horses diagnosed with a single episode of sustained monomorphic VT generally have a favorable prognosis, although recurrent VT is possible.[68] The safety of horses with a history of symptomatic or complex VA remains uncertain, and these horses should only be used by an informed adult. Strenuous athletic work is not recommended for horses that showed VA in the setting of moderate or severe structural heart disease, including myocardial fibrosis or scar and moderate to severe AR. These horses should only be ridden or driven by an informed adult because of the risk of possible recurrence of VT. These horses are not safe for use by a child or as a lesson horse. For horses with a history of VT that remain in work follow-up 24-hour and exercising ECGs should be performed at least annually.[68]

Conduction Disturbances

Once a cardiac electrical impulse is formed, it is conducted rapidly throughout the heart. The sequence of cardiac electric activation is usually dictated by the specialized conducting tissues in the atria, the AV node, the bundle of His, the bundle branches, and the Purkinje fiber system (see Fig. 9.3). This conduction system permits orderly activation of atrial and ventricular muscle and facilitates effective mechanical activity of the heart.[57,110,112-115,220] A variety of conduction disorders are recognized, including SA nodal exit block, atrial standstill (usually resulting from hyperkalemia), AV block, bundle branch block, and ill-defined ventricular conduction disturbances (Figs. 9.62 and 9.63).*

Rarely, accelerated conduction occurs in the heart, which involves a pathway around the normally slow-conducting AV node and results in early excitation of the ventricles.[1069,1147] These syndromes are termed *preexcitation* and have various associated labels related to similar human disorders (e.g., Wolff-Parkinson-White). A shortened P-R interval is typically found.

Atrioventricular Conduction Block

Delays in AV conduction are the most common conduction blocks. These delays are classified as first-, second-, and third-degree (or complete) block. *First-degree AV block* occurs when the PR (or PQ) interval exceeds a certain value (approximately 400–450 msec in large-breed horses and 250–350 msec in small breeds and ponies; see Fig. 9.16) while the atrial impulse still transmits through the AV conduction system and activates the ventricle, causing a QRS complex. Some P waves are not conducted to the ventricles during *second-degree AV block,* which results in occasional P waves not followed by a QRS-T complex (see Fig. 9.62A).* Second-degree AV block following progressive prolongation of the PQ interval is classified as *Mobitz type I (Wenckebach)* block. Conversely, the AV block is termed *Mobitz type II* if the PQ interval is constant. Occurrence of two or more consecutive second-degree AV blocks in the presence of a normal or slow sinoatrial rate is termed *high-grade (advanced) AV block.*[68, 1151] *Third-degree* or *complete AV block* is characterized by an absence of atrial to ventricular conduction. P waves are not followed by or related to QRS complexes, and to prevent ventricular asystole a junctional or ventricular escape rhythm must develop below the level of the AV block (see Fig. 9.62B).[1092,1138,1141]

First- and second-degree AV blocks are considered normal variations. These rhythms are most often associated with high vagal tone and may be seen with sinus bradycardia or sinus arrhythmia. Auscultation is characterized by an irregular rhythm with a repetitive pattern. In some horses, fourth (atrial) heart sounds that are not followed by first and second heart sounds are audible within the pauses, allowing a definitive diagnosis without ECG.[3,68,72,381,383,384,388] Second-degree AV block can usually be abolished with exercise, stress, or vagolytic drugs such as atropine or glycopyrrolate (though exercise is preferred and drugs are rarely needed).[1132,1152] Note that the AV blocks are likely to resume quickly after exercise.

High-grade (advanced) and third-degree AV blocks are considered abnormal, and high-grade AV block may progress into complete AV block over time. They are indicative of organic heart disease, severe drug toxicity, or abnormally high vagal activity. An exercising ECG should be performed if possible to evaluate the degree of contribution of high vagal tone. A continuous 24-hour Holter ECG with simultaneous video recording should be obtained when there is a history of collapse.[68] Horses with high-grade AV block that disappears with exercise should only be used by an informed adult, and the HR and heart rhythm should be frequently monitored. Horses with high-grade AVB that persists during exercise or after atropine administration should be rested and reevaluated; they are considered less safe to use than their age-matched peers. Horses with symptomatic bradyarrhythmias generally have a poor prognosis and are not safe to use.[68]

Sudden development of high-grade or complete AV block may require the administration of atropine or a catecholamine or temporary transvenous pacing. Chronic third-degree AV block requires treatment with a permanent pacemaker. Pacemakers have been successfully placed epicardially and transvenously in several horses and in a number of Miniature Donkeys with possible congenital complete AV block (Fig. 9.64; see also Fig. 9.62C).[198,1134,1153-1156]

Intraventricular Conduction Blocks

Intraventricular conduction blocks, such as bundle branch block, are less common and more difficult to diagnose. Widening of the QRS complex and axis deviation are typical

FIG. **9.62** Conduction disturbances. A, Second-degree atrioventricular block. Nonconducted P waves and varying P-R intervals are evident (base-apex lead recorded at 25 mm/sec). B, The tracings are from a horse with third-degree atrioventricular block. The upper strip demonstrates multiple blocked P waves. The lower tracing shows nonconducted P waves and ventricular escape complexes (base-apex lead recorded at 25 mm/sec). C, Permanent transvenous ventricular pacing in a Miniature Donkey with a complete atrioventricular block. A pacemaker spike *(arrow)* precedes each paced ventricular complex.

features (see Fig. 9.63B).[1133,1136] As opposed to ventricular premature beats, the aberrantly conducted QRS complex is preceded by a P wave. These abnormalities may also be found after atrial premature complexes, from overdosage with quinidine sulfate, from severe hyperkalemia, or secondary to supraventricular tachycardias with rapid ventricular response.

A recent study indicated a high prevalence of QRS broadening in horses with AF during exercise and suggested that QRS broadening may originate from ventricular ectopic foci or from aberrant intraventricular conduction due, for example, to bundle branch block.[472] In fact, intraventricular conduction blocks leading to aberrant ventricular conduction might explain the high number of complexes currently classified as VPCs recorded on exercise ECGs,[54,77-80,82,90,479] because differentiation between ventricular ectopic beats and aberrantly conducted beats originating from the sinus node is very difficult and often impossible at high HRs, when distinct P waves are not present and motion artifacts hamper interpretation of the ECG.

Preexcitation

Ventricular preexcitation, or accelerated AV conduction, in humans and in dogs is often due to an anomalous conducting pathway around the AV node, which serves as a path for reentrant supraventricular tachycardias. These rhythm

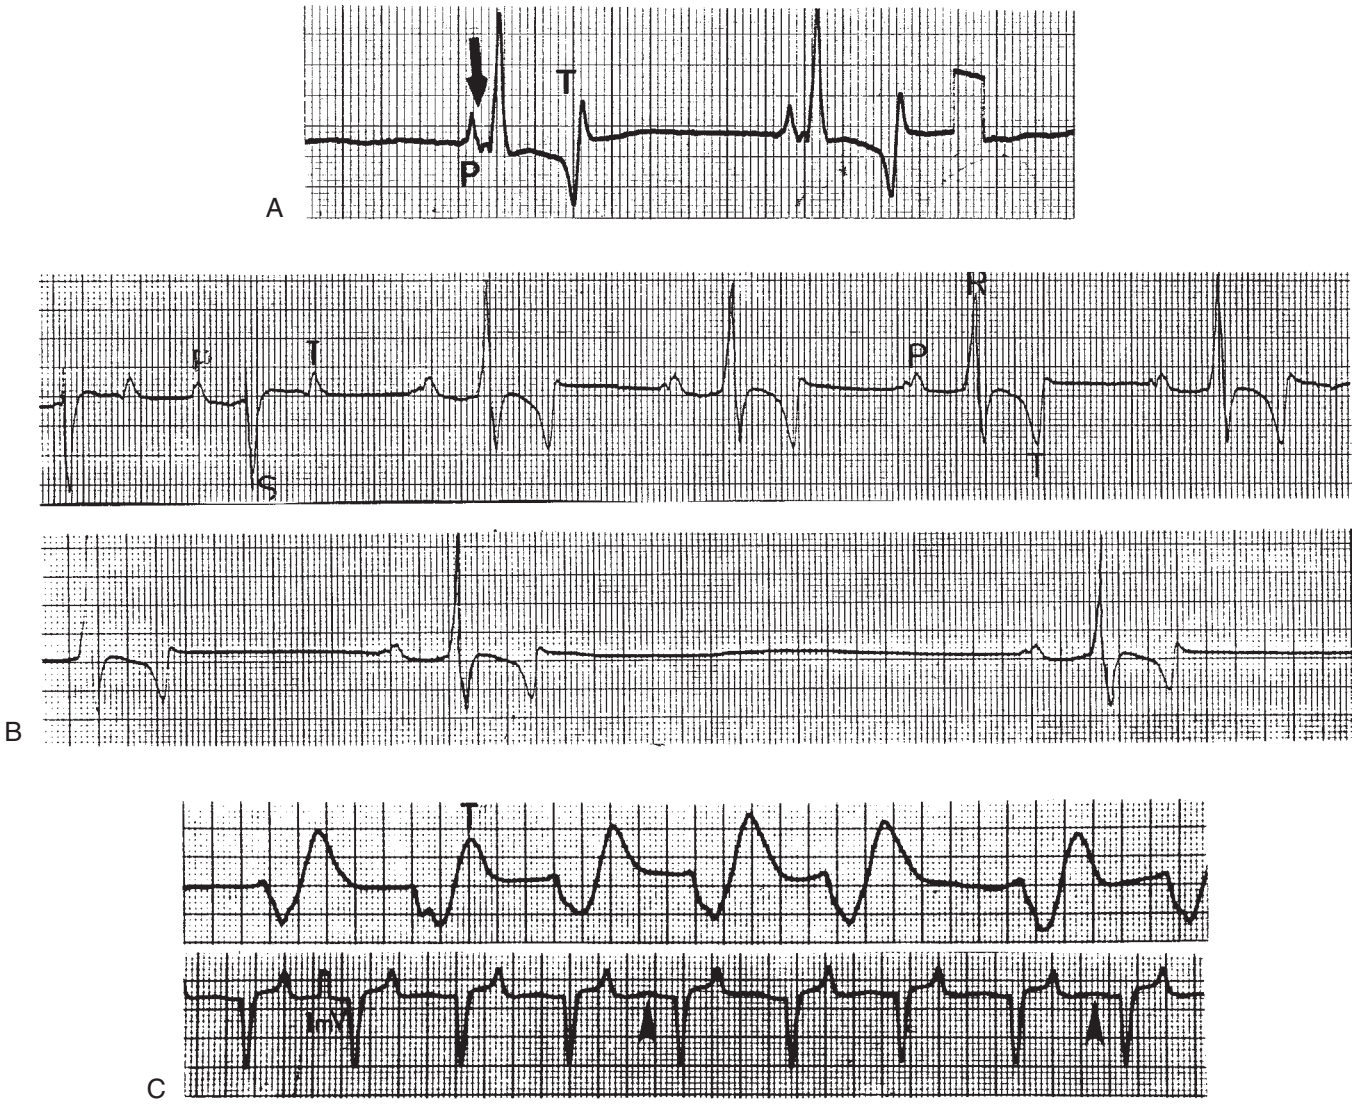

FIG. **9.63** Conduction disturbances. A, Ventricular preexcitation. The short P-R interval *(arrow)* and small deflection in the PR segment (delta wave) indicate an accessory pathway around the atrioventricular node with premature activation of a portion of the ventricle (delta wave and initial portion of the QRS). The large QRS and secondary T wave changes can be explained by the loss of normal cancellation of ventricular electrical forces. B, A sinus arrhythmia and intraventricular conduction disturbance. The sudden change and widening of the ventricular conduction pattern are notable, despite the consistent P-R interval and probably represent a bundle branch block, although this diagnosis is difficult to make in horses (base-apex lead recorded at 25 mm/sec). C, Hyperkalemia in a foal with a ruptured bladder. The top strip demonstrates atrial standstill (no P waves), significant widening of the QRS complexes, and large T waves with a shortened ST segment. The lower tracing shows the effects after initial medical therapy for hyperkalemia, which included treatment with saline and sodium bicarbonate. The normalization of the QRS complexes and the appearance of low-amplitude P waves *(arrows)* are notable. (Tracing courtesy of Ron Hilwig, DVM, PhD.)

disturbances may cause hypotension and syncope. Whether preexcitation syndromes are important in horses has yet to be determined. Nevertheless, ECG traces occasionally show evidence of ventricular preexcitation and are characterized by a P-QRS-T relationship but with an extremely short PR interval, early excitation of the ventricle characterized by a slurring of the initial QRS complex (a delta wave), and an overall widening of the QRS complex (see Fig. 9.63A).[1069,1147,1157]

Hyperkalemia

Hyperkalemia can cause significant depression of atrial, AV, and ventricular conduction and can shorten ventricular repolarization. Serum potassium is most likely to be markedly elevated in foals with ruptured bladder or ureter and uroperitoneum, following renal failure oliguria, during shock, with severe metabolic acidosis, or after excessive intravenous potassium replacement.[226,1143-1146] Hyperkalemia also occurs in Quarter Horses with hyperkalemic periodic paralysis.[1158,1159]

FIG. **9.64** A lateral radiograph of a permanent transvenous pacing system in a Miniature Donkey. The pacemaker is evident at the upper left of the radiograph. The thin transvenous pacing wire extends from the device through the jugular vein and vena cava and into the right ventricular (RV) apex.

Alterations in the ECG are usually evident at serum potassium concentrations greater than 6 mEq/L, with severe changes evident when serum concentrations are between 8 and 10 mEq/L. Broadening and flattening of the P wave are the most consistently observed change. Prolongation of the PQ interval and bradycardia develop, excitability decreases, and atrial standstill (sinoventricular rhythm) characterized by complete absence of P waves may be observed. Either inversion or enlargement (tenting) of the T waves is also likely. Marked widening of the QRS complex may be noted as near-lethal concentrations of potassium are approached (see Fig. 9.63C). Ventricular asystole or fibrillation can develop. The QT interval is not a reliable indicator of induced hyperkalemia, and other electrolyte and acid-base alterations, including serum calcium and sodium concentrations, influence the effect of hyperkalemia on the heart.

Therapy for hyperkalemia includes correction of the underlying problem; infusion of isotonic crystalloid solutions, dextrose, and insulin; and possibly administration of β_2 agonists, calcium salts, and sodium bicarbonate. Lactated Ringer's solution (LRS; 10–40 mL/kg/hr IV) can be used in patients with hyperkalemia. The small amount of potassium contained in LRS is generally not considered problematic, as the beneficial effects of volume replacement and treatment of metabolic acidosis largely outweigh the potential negative effects of additional potassium supply. Alternatively, NaCl or NaCl/dextrose solutions may be used, but maintenance solutions should not be used because of their relatively high potassium content. Dextrose (or glucose) can be administered as a bolus of 0.25 to 0.5 g/kg IV over 15 minutes. The administration of regular insulin (0.1 IU/kg) in conjunction with dextrose infusion (0.5–1 g/kg IV over 15 minutes) should be considered in cases of severe hyperkalemia and is considered most effective. β_2-Adrenoceptor agonists (e.g., clenbuterol, albuterol/salbutamol) administered intravenously or by inhalation might augment the effects of intravenous insulin and glucose by promoting potassium movement into cells,[1160,1161] but this has not been investigated in horses. Sodium bicarbonate may be used in cases of severe metabolic acidosis (provided that ventilation is adequate) at a dose of 1 to 2 mEq/kg IV over 15 minutes or depending on the base excess obtained by blood gas analyses (mEq Na bicarbonate = 0.3 [−0.5] × BE × kg of body weight). However, in the absence of severe acidosis, the use of sodium bicarbonate is not recommended because of the associated risks of sodium and fluid overload[1160,1161] and its effect to lower ionized calcium concentrations that might further destabilize the rhythm. In cases of severe arrhythmias with QRS broadening, 0.2 to 0.4 mL/kg calcium gluconate 23% can be administered over a 10-minute period to effect to stabilize the resting cardiac membrane potential.

CHAPTER 10

Disorders of the Musculoskeletal System

Stephanie J. Valberg

MUSCLE FORM AND FUNCTION

Skeletal muscle is the most plastic tissue in the body, constantly remodeling in response to exercise, diet, and the hormonal milieu. The primary components of muscle are water (80%), protein (10%–15%), and glycogen (1%–2%), with the proteins largely comprising contractile proteins. The type of contractile protein, more specifically the isoforms of myosin heavy chains, determines the speed with which the fiber contracts and the muscle fiber type. The speed of contraction varies from slowest to fastest through type 1, type 2a, and type 2x fibers.

Most equine locomotor muscles are comprised of a mosaic of type 1 and type 2 muscle fibers, but the exact composition depends on the muscle's function and use. For example, digital flexor muscles that support the fetlock joint consist of 50% type 1 and 50% type 2a muscle fibers, whereas proximal locomotor muscles that power the hind end consist of less than 25% type 1 and 75% or more type 2a and type 2x fibers in proportions that vary among individuals, breeds, and state of training (Fig. 10.1).[1] The contractile fiber types have distinctive metabolic properties that also vary with the state of training. Type 1 fibers generally have lower glycogen and glycolytic capacity and higher lipid and oxidative capacity than type 2 fibers. Type 2a fibers have intermediate properties whereas type 2x fibers have higher glycogen, higher glycolytic, and lower lipid and oxidative capacity than type 1 and 2a fibers.

A motor unit consists of a subset of myofibers supplied by the branches of one nerve. Tonic motor neurons with a slow discharge rate supply type 1 fibers and fast discharging phasic motor neurons supplying type 2a and 2x fibers. At slow exercise intensities, type 1 and a small number of type 2a muscle fibers are activated, and as the speed or duration of exercise increases, more muscle fibers will be recruited in the order type 1 to type 2a to type 2x.

Peripheral neuropathies usually affect both fast- and slow-twitch motor units, causing weakness and muscle atrophy. Specific myopathies often affect one particular fiber type and a specific cellular pathway within that myofiber. The disruption in that cellular pathway often produces typical clinical signs for that disease. Wherever possible the goal of internists and researchers is to define the pathway that is dysfunctional in order to provide the most accurate diagnosis and targeted treatments.

Diagnostic Approach

History and physical examination remain the cornerstones of the diagnostic approach. Goals are to (1) determine whether the clinical signs represent a primary or secondary muscle disorder; (2) assess the contributions of fasciculations, weakness, atrophy, muscle pain, or exercise intolerance to the primary presenting complaint; (3) generate a logical list of differential diagnoses; and (4) select the most appropriate diagnostic tests to further characterize and identify the cause of the muscle disorder. The requisite systematic approach begins with the history, is followed by inspection and palpation of every possible aspect of the musculature, and includes assessment of movement using both neurologic and lameness examinations.

History

A thorough history is particularly important with myopathies because many disorders are intermittent in nature and are not necessarily apparent on initial physical examination. In addition, many myopathies are triggered by certain environmental stimuli, and identifying those stimuli can help both to diagnose the disorder and to formulate a management plan to prevent further episodes in the future. In particular, it is important to determine from the history whether clinical signs are associated with exercise. Horses, unlike many other animals, are athletes, and forced exercise is routine. Riders readily note subtle clinical signs of pain, weakness, or exercise intolerance under saddle, and careful note of the rider's complaints aids in the identification of specific exertional myopathies. Temperament, diet, supplements, current medications, exercise regimens, level of performance, changes in exercise tolerance, vaccinations, other animals affected, and any relationships among those animals are documented. Details of the onset, progression of clinical signs, frequency, severity, and duration are recorded. Every effort is made to characterize possible eliciting factors such as recent alterations in diet, tack, exercise schedule, level of fitness, type and duration of exercise, or behavior. The environment, pasture access and quality, size of turnout facilities, footing, and general horsemanship are noted.

Inspection

Before beginning the physical examination, it is important to assess muscle mass, symmetry, stance, and behavior. Inspection is best done at a distance with the horse quietly standing

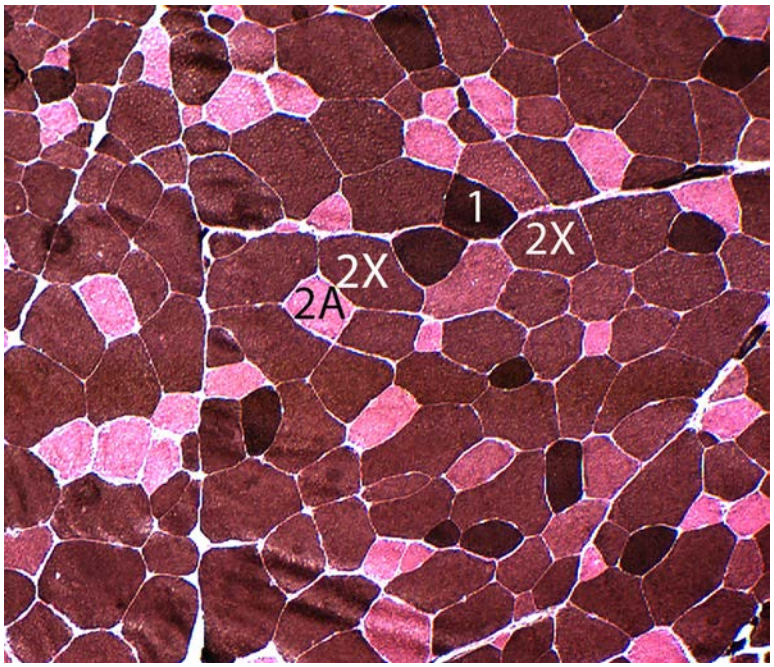

FIG. **10.1** Cross section of equine gluteus medius muscle stained with myosin ATPase (pH 4.6) showing a normal mosaic pattern of type 1 (slow-twitch), type 2A (fast-twitch oxidative), and type 2X (fast-twitch glycolytic) fibers. (20×)

square. If signs of anxiety are present the horse may need to be reevaluated in calm surroundings. The horse is viewed from all sides, comparing left to right, and the tail is moved to assess adductor muscles. Each athletic discipline results in hypertrophy of specific muscle groups. The veterinarian performing the examination should be familiar with the ideal muscle mass present in a horse of that discipline and fitness and should compare the patient at that level of training with the ideal to determine regions of underdevelopment (Fig. 10.2). Notes are made regarding tropic changes, atrophy, alterations in symmetry of particular muscle groups, and any observed spontaneous muscle activity.

Physical Examination

Following a standard general physical examination, each muscle should be palpated, beginning with the temporal and masseter muscles and working caudally to the tail. Where possible, left and right sides are palpated simultaneously and compared. Impressions of muscle tone, consistency, swelling, atrophy, and heat are compared between left and right sides and documented. Sensitivity to superficial followed by deep palpation of each muscle group is noted. The temperament of the horse and level of comfort with the examiner needs to be considered when interpreting results of palpation. Some animals are tense and demonstrate apparent evidence of myalgia when palpation is first performed or when performed by certain individuals. However, given time and patience or another examiner, some horses will relax and muscles or muscle groups that at first appeared to be very sensitive or hypertonic may in reality be normal. Palpation is repeated to ensure the response is consistent. A blunt instrument such as a needle cap or a pen can be run over the lumbar and gluteal muscles to ensure that the horse shows extension (swayback) followed by flexion (hogback) of the spine and sacroiliac joints. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles or pain associated with the thoracolumbar spine or sacroiliac joints.

In animals with spontaneous muscle activity, muscle groups should also be percussed with a percussion hammer. The triceps, pectoral, and semitendinosus muscles are easily accessed for percussion. A positive percussion sign occurs when the muscle holds a contracture for several seconds, creating a dimpled appearance below the contracted muscle (percussion myotonia). This occurs as the result of abnormal mechanical irritability and sustained contraction of the percussed fibers.

Locomotor and Neurologic Examination

A locomotor examination is performed to characterize the impact of a primary neuromuscular disorder on gait and determine whether muscle pain is a secondary consequence of orthopedic lameness. Horses are observed for evidence of lameness, pain, asymmetry, decreased range of joint motion, stiffness, or muscle cramping at a walk and trot and flexion tests performed where appropriate. If necessary to elicit the abnormality noted by the owner, the horse can be observed under saddle. For neurologic assessment horses are observed at a walk on a straight line, serpentines, and spiraled circles, as well as when backing. A tail pull examination while the horse is standing still and walking is used to assess stability and hindlimb weakness. Any atrophy, spasticity, weakness, or ataxia should trigger a full neurologic examination to determine whether clinical signs are associated with the central nervous system, peripheral nerves, or muscle. Severe weakness can be difficult to differentiate from ataxia. In such cases, horses are observed for other signs of muscle/peripheral nerve weakness such as muscle fasciculations, knuckling at the walk, frequent recumbency with difficulty rising, and shifting of weight because of an inability to fix the stifles.

FIG. **10.2** Rear view of two age-matched Quarter Horses. The horse on the right demonstrates normal hindquarter muscle development. The horse on the left has a generalized decrease in muscle mass particularly affecting the biceps femoris and semitendinosus muscles. The horse on the left was diagnosed with myotonia dystrophica by electromyography.

Classification of Muscle Disorders

Findings from the muscle evaluation should be analyzed to determine the following: (1) whether the complaint is a primary or secondary muscle disorder; (2) whether the complaint is focal or generalized; (3) whether it is exercise associated or not exercise associated; (4) if rhabdomyolysis is present; and (5) if clinical signs are primarily associated with pain, atrophy, weakness, abnormal electrical conductivity, or exercise intolerance. A classification scheme for muscle disorders with differential diagnoses is provided in Box 10.1. The first principal divisions are based on the presence of an exertional or nonexertional disorder and whether the condition is characterized by rhabdomyolysis, atrophy, or muscle fasciculations.

Pathophysiology of Rhabdomyolysis

A variety of extrinsic (trauma, toxins, nutritional deficiency) and intrinsic (errors of metabolism, excitation-contraction coupling) insults can cause rhabdomyolysis; however, they often share a final common pathway that leads to cell death—aberrant calcium cycling.[2] If the energy pathways that generate adenosine triphosphate for the calcium pump are impaired, if the calcium pump or channels are not functioning properly, or if the cell membrane is damaged, excessive calcium accumulates in the sarcoplasm. Mitochondria sequester excessive calcium but quickly become overloaded, disrupting oxidative metabolism, generating oxygen free radicals, activating proteases and phospholipases, and generating inflammatory cytokines, all of which combine to disrupt cellular architecture and function within the damaged segment of the myofiber (Fig. 10.3). Fortunately, muscle is a highly plastic tissue and capable of complete repair as long as the basal lamina of the cell is left intact and damaged

BOX 10.1 Exertional Myopathy

1. Rhabdomyolysis
   a. Extrinsic (sporadic) tying-up
      - Dietary imbalances, vitamins, minerals, electrolytes
      - Exercise in excess of training
      - Exhaustion syndrome
   b. Intrinsic (chronic) tying-up
      - Recurrent exertional rhabdomyolysis
      - Malignant hyperthermia
      - Type 1 polysaccharide storage myopathy
      - Type 2 polysaccharide storage myopathy
      - Idiopathic chronic exertional rhabdomyolysis
2. Normal creatine kinase
   a. Focal muscle strain
   b. Type 2 polysaccharide storage myopathy
   c. Vitamin E–deficient myopathy
   d. Mitochondrial myopathy

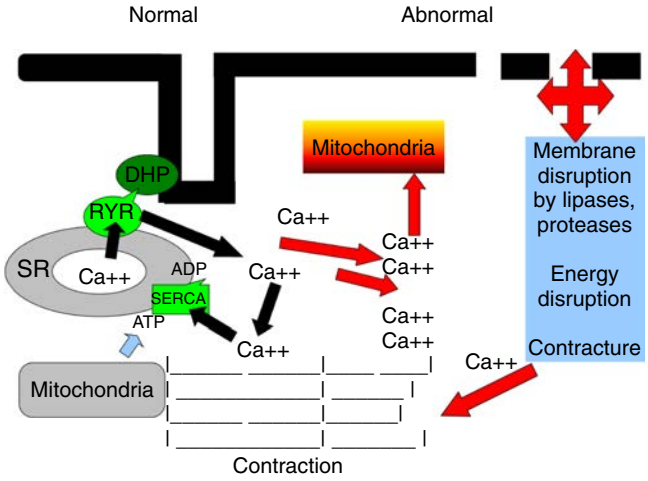

FIG. **10.3** (A) The normal course of excitation-contraction coupling where depolarization of the cell membrane activates the dihydropyridine receptor (DHPR), which triggers release of calcium ions from the terminal cisternae into the sarcoplasm by opening the ryanodine receptor (RYR) in the terminal cisternae of the SR membrane is depicted on the left. This raises myoplasmic calcium concentrations and causes contraction of the myofilaments. Calcium, is actively resequestered in the SR through the calcium pump (SERCA), which utilizes ATP and causes relaxation of the contraction. Excessive release of calcium via the RYR1 can raise myoplasmic calcium, resulting in uptake by mitochondria. Past a threshold, excessive calcium release can alter energy metabolism and cause muscle contracture without relaxation and activation of lipases and proteases, which destroy muscle cell membranes.

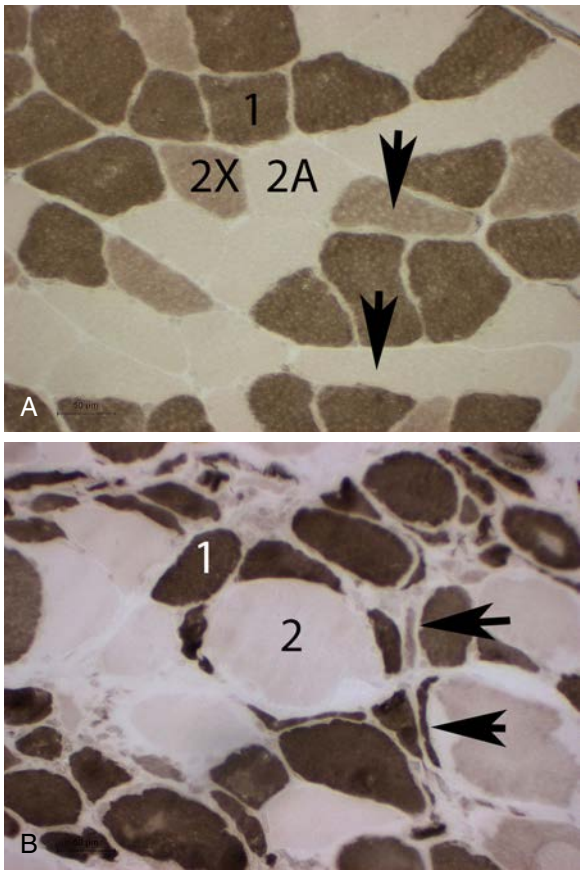

FIG. **10.4** (A) Cross section of equine gluteus medius muscle stained with myosin ATPase (pH 4.6) showing myogenic atrophy in which type 2A or type 2B fibers are smaller in cross-sectional area than type 1 muscle fibers and have lost their normal rounded shape and have an anguloid appearance *(arrow)*. (40×) (B) Cross section of equine sacrocaudalis dorsalis medialis muscle stained with myosin ATPase (pH 4.6) showing neurogenic atrophy defined by the presence of angular atrophy of both type 1 and type 2 muscle fibers *(arrows)*. (40×)

segments can locate their corresponding end. Both ends of the damaged muscle fiber segment are sealed off within hours of damage, and macrophage infiltration and phagocytosis of necrotic debris begin within 16 to 48 hours of the muscle injury. Progenitor cells called *satellite cells* migrate along the remaining basal lamina and form regenerative myotubes within 3 to 4 days of injury, connecting damaged ends, and mature muscle fibers are observed within a month of the original damage.

Pathophysiology of Atrophy

Atrophy can be the result of overt muscle cell damage or activation of ubiquitin-proteasome or autophagy-lysosome machinery within a muscle cell, so-called myogenic atrophy. Atrophy can also be due to damage to the motor nerve supplying that muscle, so-called neurogenic atrophy. Myogenic atrophy usually produces anguloid atrophy of fast-twitch muscle fibers (Fig. 10.4A) whereas neurogenic atrophy usually involves both type 1 and type 2 muscle fibers and is characterized by small angular atrophied fibers (Fig. 10.4B).

Pathophysiology of Fasciculations

Muscle fasciculations can be due to abnormal recruitment of motor nerves causing cramping and fasciculations. This occurs with nerve root irritation, electrolyte abnormalities, weakness, fatigue, anxiety, cold, and many other causes. Less often, fasciculations can be due to ion channel defects within the sarcolemma that cause abnormal propagation of muscle cell depolarization.

Diagnostic Tools

Muscle disorders characterized by rhabdomyolysis disrupt cellular homeostasis to the point that the muscle cell membrane (sarcolemma) ruptures, resulting in leakage of cytoplasmic contents from the muscle cell into the bloodstream and urine. The activity of muscle enzymes within the serum and the presence of myoglobin in urine are used as diagnostic indicators of rhabdomyolysis.

Serum Creatine Kinase and Aspartate Transaminase Activities

Serum activities of the skeletal muscle enzymes creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) are commonly used to detect rhabdomyolysis.[3] Optimal information can be obtained by not only assessing the activity of the enzymes in serum but also by evaluating the respective activities of the enzymes relative to the onset of muscle disease. Note that it is the activity of the enzyme in serum expressed in units per liter (U/L) that is assessed rather than the concentration of proteins.

Serum CK is both sensitive and specific for skeletal and cardiac muscle damage. Serum CK activity increases within

hours of a muscle insult, peaks within 4 to 6 hours after injury, and usually declines to the normal range within 48 hours of an insult (longer if activities were greater than 100,000 U/L). Persistently elevated CK activity indicates ongoing muscle degeneration. Normal ranges vary among laboratories but are generally less than 430 U/L. Elevations from several thousand to hundreds of thousands of U/L occur with moderate to severe rhabdomyolysis. Minor elevations in CK activity can occur with training, transport, and strenuous exercise likely due to increased sarcolemmal permeability rather than muscle cell damage. Endurance rides or the cross-country phase of a 3-day event can result in CK activity greater than 1000 U/L but usually less than 4000 U/L with CK rapidly returning to baseline.[4] CK activity can increase by in general less than 3000 U/L as a result of prolonged recumbency without an underlying myopathy.

Serum AST activity is not specific for skeletal and cardiac muscle damage because it is also present in liver, red blood cells, and other tissues. Elevated AST can result from hemolysis, muscle, liver, or other organ damage, and measures of hemolysis and liver necrosis, as well as CK activity, are used to assess the significance of elevated serum AST. One of the main utilities of assessing AST in muscle disease is that it persists in serum following muscle damage longer than CK and is therefore a good means to assess the chronicity of muscle cell necrosis. AST activity rises more slowly following damage to muscle cell membranes than CK, often peaking 24 hours after the insult, and the half-life of AST is much longer than that of CK. By comparing serial activities of CK and AST the progression and chronicity of muscle degeneration can be assessed. Concurrent elevations in CK and AST reflect relatively recent or active degeneration. If AST activity is elevated accompanied by decreasing or normal CK, activite muscle degeneration is not ongoing.

Elevations in serum LDH activity are not specific to skeletal muscle and can occur with rhabdomyolysis, myocardial necrosis, and/or hepatic necrosis. Because it is not specific for skeletal muscle and because it has a half-life intermediate to CK and AST, it is not used as often as CK and AST for monitoring muscle damage.

Serum CK Exercise Response Test

If serum CK and AST activities are normal at rest but exertional rhabdomyolysis (ER) is suspected based on history, an exercise response test can be a useful adjunct to diagnose an underlying predisposition to ER.[5] The goal of an exercise challenge test is to provoke subclinical rather than clinical ER. Quantifying the extent of subclinical rhabdomyolysis during mild exercise assists in determining the intensity and rapidity with which to put a horse back into training. Blood samples are taken before exercise and about 4 to 6 hours after exercise to evaluate peak changes in serum CK. Serum CK activity measured immediately after exercise will not reflect the amount of damage occurring during the exercise test. Small fluctuations in serum CK activity may occur with exercise due to enhanced muscle membrane permeability, particularly if exercise is prolonged or strenuous and the horse is untrained. A submaximal exercise test provides more consistent evidence of subclinical rhabdomyolysis than maximal exercise tests.[6,7] With unfit horses alternating 2-minute intervals of walking and trotting for a maximum of 15 minutes is often sufficient to induce abnormal elevations in serum CK activity in horses susceptible to chronic ER. In fit horses 3 minutes of walking followed by 12 minutes of trotting should not normally induce elevations in serum CK. If signs of stiffness develop during the test, exercise should be concluded. A normal response would be less than a threefold increase from basal CK; however, most healthy horses show no change in CK activity with this exercise test.

Electrolytes

In horses with muscle fasciculations or moderate to severe rhabdomyolysis serum sodium, potassium, calcium, chloride, and phosphorus concentrations and potentially measures of blood pH are essential parts of the diagnostic profile. Hypocalcemia and hypophosphatemia, especially in alkalotic horses, can contribute to marked muscle fasciculations or synchronous diaphragmatic flutter. With severe rhabdomyolysis, damage to muscle cell membranes results in movement of electrolytes and water from areas of high concentration to lower concentration. Following damage to muscle cell membranes as occurs with rhabdomyolysis, plasma concentration of extracellular electrolytes (sodium, chloride, and calcium) may be lower than normal as ions move out of blood and into muscle. Conversely, plasma concentrations of electrolytes that are typically higher intracellularly (e.g., potassium and phosphorus) may be increased.[8]

Renal Parameter

In horses with myoglobinuria and marked elevations in serum CK and AST, blood urea nitrogen (BUN) and creatinine should be monitored because myoglobinuria is associated with renal tubular necrosis and renal failure.

Urinalysis

Urinalysis can be the fastest means to detect severe rhabdomyolysis and myoglobinuria. Myoglobinuria can be detected by visual inspection of urine color and a positive urine Hemastix test in the absence of hemolysis or hematuria. Urine pH can be a valuable first screen for hypoglycin A myopathy as equine urine is normally alkaline but is acidic with this condition. Urine can be screened for organic acids to diagnose hypoglycin A myopathy.[9]

Selenium and Vitamin E

Selenium should be assessed in foals with severe rhabdomyolysis and α-tocopherol assessed in horses with generalized muscle atrophy. Selenium concentrations are best measured in whole blood (anticoagulated with ethylenediaminetetraacetic acid, [EDTA]) because selenium is incorporated into red blood cell glutathione peroxidase. Serum or plasma for assessment of α-tocopherol concentrations should be chilled as soon as possible after obtaining a sample and protected from light by wrapping in aluminum foil. If analysis is delayed, serum/plasma samples should be stored frozen (−21°F [−70°C]) because α-tocopherol deteriorates rapidly.

Genetic Testing

Genetic testing of hair roots or EDTA blood is currently available for definitive diagnosis of muscle disorders, including hyperkalemic periodic paralysis (HYPP), glycogen branching enzyme deficiency (GBED), malignant hyperthermia (MH), and type 1 polysaccharide storage myopathy (PSSM1). The decision to perform testing should be based on the prevalence

of the mutation within a breed and whether clinical signs fit with the genetic disease. Type 1 PSSM, for example, has such a low prevalence in Thoroughbred horses that genetic testing for PSSM1 is unlikely to yield valuable information.[10] In contrast, PSSM1 is present in over 50% of Percherons, and therefore the significance of a positive PSSM1 test result must be correlated with clinical signs of a myopathy.[10] It is important to note that commercially available genetic tests determine if one specific mutation previously associated with the disease is present in the sample submitted. Commercial tests do not detect any other alterations in DNA sequence within that disease gene, and such a question would require sequencing of the gene of interest.

Muscle Biopsy

Muscle histopathology can reveal the underlying basis for disorders characterized by weakness, atrophy, rhabdomyolysis, and exercise intolerance. The underlying basis for myopathies primarily characterized by muscle fasciculations is often not apparent in muscle biopsies unless there are underlying dystrophic changes. It is imperative that the most appropriate muscle is selected for biopsy based on the differential diagnoses; that an adequate amount of muscle is obtained; that the specimen is handled appropriately; that the proper fixation is used; and that the most appropriate tinctorial, histochemical, and immunohistochemical stains are used to obtain a diagnosis.

In general, open biopsies of the semimembranosus muscle (Fig. 10.5A) or percutaneous 6-mm needle biopsies of the middle gluteal muscle (Fig. 10.5B) are optimal for exertional myopathies. For Quarter Horses with suspected immune-mediated myositis, a gluteal or lumbar muscle biopsy obtained temporal to the onset of atrophy is best whereas for focal atrophy a sample of that specific muscle group is indicated.[11] Equine motor neuron disease or vitamin E–deficient myopathy is optimally diagnosed through biopsy of the sacrocaudalis dorsalis medialis muscle.[12,13] Samples of the diaphragm or deep postural muscles are most likely to reveal excessive lipid storage in hypoglycin A myopathy.[14] Deep pelvic muscles such as the iliopsoas should be obtained postmortem when examining a horse with recumbency from severe rhabdomyolysis.

A limited amount of information restricted to cellular infiltrates and fiber sizes is obtained from standard hematoxylin and eosin stains of formalin fixed paraffin embedded skeletal muscle. Fresh samples frozen in a particular fashion in isopentane suspended in liquid nitrogen can be stained with a battery of tinctorial and histochemical stains to fully characterize a neuromuscular disorder. Such stains will highlight muscle fiber sizes, shapes, fiber type distribution, mitochondrial distribution, polysaccharide and lipid staining pattern, vacuolar content, neuromuscular junctions, nerve branches, connective tissue, and blood vessels.[15] In addition, frozen samples can be used for immunohistochemistry and biochemical analysis of substrate concentrations and enzyme activities, as well as DNA isolation. Fresh samples can be shipped in a watertight hard container on ice packs to specialized laboratories. Samples for electron microscopy (EM) require appropriate fixation in glutaraldehyde. Ideally, thin sections of muscle for EM should be clamped in vivo to maintain fibers at a resting length before they are excised. However, if pathology other than the alignment of thick and thin myofilaments is to be investigated, small muscle pieces can be excised and placed directly in appropriate EM fixative.

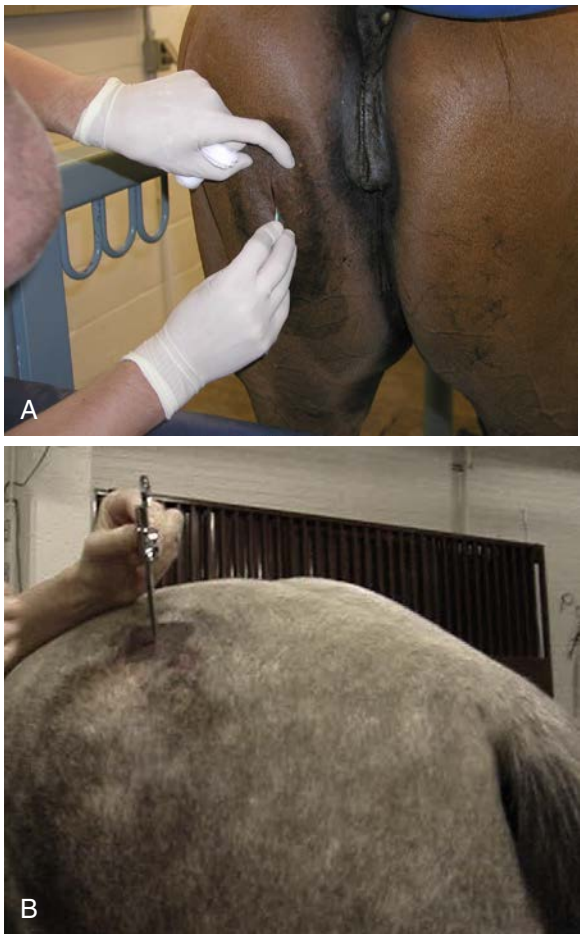

FIG. **10.5** (A) Site of the open surgical biopsy of the semimembranosus muscle. (B) Site of the percutaneous needle biopsy of the middle gluteal muscle.

Electromyography

Fine-needle electromyography (EMG) is very useful for differentiating myogenic and neurogenic atrophy and identifying electrical disturbances of sarcolemmal sodium and chloride channels.[16,17] EMG in horses is usually done under sedation to avoid painful reactions to insertion of the fine EMG needles. EMG of normal skeletal muscle shows temporary insertional activity—a brief burst of electrical activity—when the needle is inserted in muscle and then quiescence. If motor units are recruited (motor unit action potentials) in the muscle examined or the needle is very close to a motor end plate (miniature end plate potentials), normal regular wave patterns are briefly observed. Horses with denervation of motor units have abnormal spontaneous electrical activity in the form of fibrillation potentials and positive sharp waves. Horses with abnormalities in the electrical conduction system of muscle demonstrate forms of complex repetitive discharges or myotonic discharges in numerous muscles. A more detailed EMG analysis evaluates amplitude, duration, phase, and number of phases of motor unit action potentials to identify myopathic features, as well as neuropathic features.[16] Myopathic changes include a decrease in duration and amplitude of motor unit action potentials.

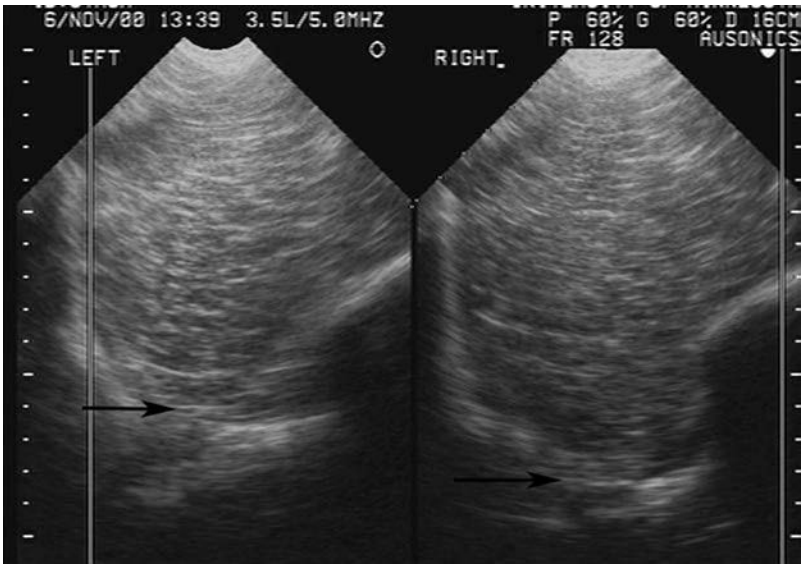

FIG. **10.6** Ultrasonographic appearance of a horse with an acute onset of a stiff short-strided gait on the right hind gait. The depth of the semimembranosus on the right side is much greater than at the corresponding site on the left side *(arrow),* indicating swelling of the right semimembranosus muscles. There is no evidence of tearing or hemorrhage in the muscle.

Imaging

Ultrasonography. Diagnostic ultrasonography can be of value to map the extent of muscle trauma, atrophy, and fibrosis. The typical striated echogenic pattern of skeletal muscle varies among muscle groups, and ultrasonographic evaluation requires that comparisons are made between similar sites in contralateral muscles in both transverse and longitudinal views. It is important that the horse is standing squarely and bearing weight evenly as these can alter the ultrasonographic image. Muscle fiber disruption with an acute injury appears as relatively hypoechoic areas and loss of the normal muscle fiber striation. The jagged edge of the margin of the torn muscle may be increased in echogenicity. Minor trauma may only be apparent as an increase in the depth of the muscle relative to the muscle on the other side (Fig. 10.6). Relatively hyperechoic regions can represent fibrous scarring, whereas hyperechoic regions causing shadowing artifacts can reflect mineralization.[18]

Nuclear Scintigraphy. Nuclear scintigraphy is useful for identification of forms of muscle damage that may not be apparent on physical examination because of depth or location and to assess horses with persistent gait abnormalities and poor performance. Technetium-99m methylene diphosphonate (MDP) is taken up in damaged muscle fibers in the horse and is best seen in the bone phase images (i.e., 3 hours after injection).[19] The mechanism of MDP binding is unknown, but the exposure of calcium binding sites on protein macromolecules in the damaged muscle may be responsible.

EXERTIONAL MYOPATHIES

There are numerous reasons for horses to develop muscle pain with exercise. In many cases mild to moderate muscle soreness can be secondary to extrinsic factors such as orthopedic disease, trauma, ill-fitting saddles, and suboptimal training. A detailed history, physical examination, and lameness examination will often identify the underlying primary disorder and, on correction, exertional muscle pain resolves. When muscle pain and cramping with exercise are associated with elevations in serum CK and AST activity, the muscle disorder is classified as exertional rhabdomyolysis (ER). Overt ER can arise as a sporadic event due to extrinsic factors such as exercise in excess of training, exercise during illness, or nutritional imbalances. ER can also occur as a chronic disease due to intrinsic abnormalities in muscle function.

Exertional myopathies can present with exercise intolerance or exercise-induced pain and poor performance without elevations in serum CK and AST activities or very infrequent elevations. These myopathies are more difficult to accurately diagnose than ER. Evaluation of these cases requires that other orthopedic, respiratory, cardiovascular, and behavioral causes of decreased performance be critically assessed relative to histopathologic abnormalities in muscle biopsies.

The critical steps necessary to diagnose the basis for exertional myopathies include a detailed history, thorough lameness evaluation, measurement of serum CK and AST activities, genetic testing, and muscle biopsy. An exercise challenge test and 4-hour postexercise serum CK activity can be of value in diagnosing ER if not immediately apparent on first evaluation. These procedures are described in detail previously in this chapter.

Sporadic Exertional Rhabdomyolysis

Sporadic forms of ER develop because of an extrinsic event or recurring extrinsic events that induce muscle damage with exercise. Causes of sporadic ER include focal or generalized trauma to muscle, dietary imbalances that affect muscle function, and exercise performed beyond any training adaptation or to the point of exhaustion.

Signalment, History, and Diagnosis

Horses with sporadic ER may be of any age, breed, or sex; may be involved in a wide variety of athletic disciplines; and may have a history of adequate performance before onset of ER.[20]

A diagnosis is made on the basis of history, clinical signs, and elevations of serum muscle enzymes. A reasonable period of rest, a balanced diet, and a gradual introduction of a training program matched with performance will result in resolution of clinical signs and a successful return to performance. If over time ER recurs despite reasonable management, a diagnosis of chronic ER becomes more likely, warranting further diagnostic testing.

Focal or Generalized Trauma

Horses that strain a particular muscle may be very reluctant to move and show signs resembling more generalized ER. This is particularly true when lumbar, gluteal, psoas, adductor, semimembranosus, or semitendinosus muscles are acutely involved.[18] Further, horses that struggle when cast, are caught in a fence, or are thrashed by another horse may have acute signs of rhabdomyolysis caused by severe exertion or trauma. A diagnosis of focal trauma is established by history, physical examination, and serum muscle enzymes. Rectal examination of deep pelvic muscles and ultrasonography may help to localize the extent of muscle damage for focal lesions. On occasion scintigraphy may help to identify specific muscle involvement.[21]

Overexertion

A training imbalance as a cause of ER is usually suspected based on a history of an increase in work intensity without a foundation of consistent training for this level of exercise. Signs of muscle stiffness and gait changes range from mild to severe, and severity is reflected by the magnitude of elevations of serum CK activity. Overexertion is a well-described cause of ER in polo horses with 81% of cases of ER attributed to overexertion and 30% of cases occurring after a day of rest.[22] The incidence of ER is as high as 9% in U.S. polo horses, with most of these horses only having one episode of ER early in the polo season.[22]

Pathologic changes are often not evident in light microscopic evaluation of muscle biopsies from individuals performing unaccustomed exercise, but electron microscopy shows significant disruption of the alignment of muscle contractile proteins within muscle fibers. In more severe cases overt segmental damage to myofibers may be apparent in muscle biopsy. Repetitive overuse of muscles, such as occurs with overtraining, may result in exercise intolerance and is associated with pathologic changes such as increased muscle fiber size variation and centrally displaced myonuclei in muscle biopsies.[23]

Exhaustion

Exhaustion occurs most commonly in endurance horses or racehorses exercising in hot, humid weather. Signs of heat exhaustion include weakness, ataxia, rapid breathing, muscle fasciculations, sweating, and in severe cases collapse. The body temperature may be elevated to 105° to 108°F. Muscles are frequently not firm on palpation, although serum CK activity can be markedly elevated and myoglobinuria may be noted.[24,25]

Dietary Imbalances

Diets with a high nonstructural carbohydrate (NSC) content and low forage content,[26,27] deficient in electrolytes, or inadequate in selenium and vitamin E may exacerbate episodes of ER.

Electrolyte Imbalances

It is important to ensure that horses receive sodium chloride in the diet, especially horses that compete in hot, humid weather. Between 30 and 50 g per day of sodium chloride combined with 15 to 25 g of light salt containing potassium chloride are recommended for horses exercising in hot, humid conditions and sweating extensively. In addition, the entire diet should be adequately balanced with calcium and phosphorus (ratio of 2:1 Ca:P is ideal). Assessing total body electrolyte balance is difficult to accurately perform. One suggested means is to measure urinary fractional excretion of electrolytes[28]; however, marked variation can occur in electrolyte excretion depending on the diet, exercise, and sampling technique, as well as between and within individuals from day to day.[29] Furthermore, the high calcium crystal concentration of alkaline equine urine requires acidification to accurately assess calcium and magnesium content.

Vitamin E and Selenium Concentrations

Whole blood selenium concentrations measured in EDTA or heparin tubes are of value in assessing selenium status in animals housed in areas where soil and therefore diet is deficient in selenium. In cases where selenium has been administered before blood collection, glutathione peroxidase activity can be used to assess potential selenium deficiency. Vitamin E concentration should be measured in serum samples kept chilled and protected from light; however, variability in serum levels can be quite large, and repeat sampling is recommended if marginal levels are identified in the first sample tested. Horses with ER are infrequently deficient in selenium and vitamin E, and alone it may not be responsible for ER[30]; however, anecdotal reports suggest that in some cases supplementation may help to further prevent episodes of ER.

Treatment of Acute Rhabdomyolysis

Hand walking horses with acute rhabdomyolysis is contraindicated as it exacerbates muscle damage. If ER occurs at a distance from home, a trailer should be brought to the horse and a tranquilizer administered to assist the horse in moving to the trailer and loading. During a competition, the horse is treated for rhabdomyolysis on site, and transport home over a long distance should be delayed for at least 24 to 48 hours.

The objectives of treatment are to relieve anxiety and muscle pain, as well as to correct fluid and acid-base deficits.[31] Acepromazine (0.04–0.07 mg/kg), an α-adrenergic antagonist, is helpful in relieving anxiety and may increase muscle blood flow. Dehydrated horses may become hypotensive and recumbent if given acepromazine. Alternatively, xylazine (0.4–0.8 mg/kg) may provide short-term relief from anxiety. In horses in more pain, detomidine (0.02–0.04 μg/kg) combined with butorphanol (0.01–0.04 mg/kg) provides excellent sedation and analgesia. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ketoprofen (2.2 mg/kg), phenylbutazone (2.2–4.4 mg/kg), or flunixin meglumine (1.1 mg/kg) provide additional pain relief. Analgesic treatment is continued to effect, but most horses are relatively pain free within 18 to 24 hours. For horses with extreme pain and distress a constant rate infusion of detomidine (0.22 μg/kg intravenously followed by 0.1 μg/kg/min IV) or lidocaine (1.3 mg/kg intravenously followed by 0.05 mg/kg/min intravenously) or butorphanol (13 μg/kg/hr) can make the difference between adequate time for recovery and euthanasia.

Intravenous (IV) or intragastric dimethyl sulfoxide (as a less than 20% solution) can be used as an antioxidant, antiinflammatory, and osmotic diuretic in severely affected horses.

Some veterinarians administer corticosteroids in the acute stage. If the horse is recumbent methylprednisolone succinate (2–4 mg/kg intravenously) can be given once. Muscle relaxants such as methocarbamol (5–22 mg/kg, slow IV administration) seem to produce variable results possibly depending on the dosage used. Dantrolene sodium (Dantrium) (2–4 mg/kg orally) is administered to decrease release of calcium from the sarcoplasmic reticulum and further aggravation of muscle contractures and necrosis. This can be repeated in 4 to 6 hours. Caution is advised when administering Dantrium to horses with HYPP as it can elevate serum K concentrations and precipitate an episode.

Severe rhabdomyolysis can lead to renal compromise due to ischemia and the combined nephrotoxic effects of myoglobinuria, dehydration, and NSAIDs. The first priority in horses with hemoconcentration, or myoglobinuria, is to reestablish fluid balance and induce diuresis. In mild cases administration of fluids via a nasogastric tube may be adequate, but generally fluids are better given intravenously. Balanced polyionic electrolyte solutions are best. If severe rhabdomyolysis is present, isotonic saline or 2.5% dextrose in 0.45% saline may be necessary because horses often have hyponatremia, hypochloremia, and hyperkalemia.[8] If hypocalcemia is present, supplementing IV fluids with 100 to 200 mL of 24% calcium borogluconate is recommended, but serum calcium should not exceed a low normal range. Affected animals are usually alkalotic, making bicarbonate therapy inappropriate.

The total fluid replacement is based on an estimation of the degree of dehydration and the clinical response: 10 L of fluids may be given rapidly. If the adult horse is 5% dehydrated an additional 15 L may be given over the next 4 hours; if dehydration is severe (20%) an additional 50 L of polyionic fluids may be required at 4 L per hour. Ideally, the need for further IV fluids is guided by reassessment of the packed cell volume, total plasma protein, and serum electrolytes after the initial period of therapy. In severely affected horses, regular monitoring of blood urea nitrogen and/or serum creatinine is advised to assess the extent of renal damage. Diuretics are usually contraindicated unless the horse is in oliguric renal failure.

Good nursing care is important with recumbent animals. This involves deep bedding, prevention or minimization of trauma around the eyes, and appropriate care of decubital sores. Recumbent animals require frequent turning to allow reperfusion of compressed muscle. The use of slings to assist recumbent animals to rise is highly beneficial.

Following treatment of an acute ER episode, after stiffness resolves, rest with regular access to a paddock and weekly monitoring of serum CK activity are recommended. Horses are much more susceptible to a second episode of ER in the 2 weeks following an acute episode, and allowing horses the ability to calmly determine their own exercise through turnout often avoids exacerbating rhabdomyolysis. If that is not feasible, hand walking needs to be performed with caution and limited to no more than a few minutes initially. While the horse is rested, the diet can be assessed to ensure that the ration is fed in an amount recommended by the manufacturer for the corresponding level of exercise. This will ensure that the proper balance of vitamins and minerals is provided. If excessive calories are provided when fed according to the manufacturer's recommendations, the diet should be switched to a less calorie-dense vitamin/mineral-balanced diet. A salt block or 30 to 50 g (1–3 tablespoons) of salt per day will provide the necessary additional sodium chloride, with the amount fed depending on the heat, humidity, and intensity of exercise. Once serum CK returns to normal, training can be resumed gradually. A regular exercise schedule, beginning with 20 minutes or less of exercise per day, is gradually increased to eventually match the expected amount of daily exercise to the underlying state of conditioning.

Chronic Exertional Myopathies

Several inherent disorders of equine skeletal muscle can cause repeated episodes of ER or exertional myopathy: recurrent exertional rhabdomyolysis, malignant hyperthermia, type 1 polysaccharide storage myopathy, type 2 polysaccharide storage myopathy, idiopathic chronic exertional rhabdomyolysis, and mitochondrial myopathy. There are likely many other causes yet to be identified. In these forms of chronic exertional myopathies, there are specific environmental stimuli that are necessary to trigger muscle pain in susceptible horses. Horses cannot be cured of their susceptibility to this condition, but if the specific form of exertional myopathy is identified, changes in management may help to minimize episodes of muscle pain.

Recurrent Exertional Rhabdomyolysis

The term *recurrent exertional rhabdomyolysis* (RER) describes a subset of ER that is believed to be due to an abnormality in the regulation of muscle contraction and relaxation.[5,32-34] Research into RER has primarily been performed in Thoroughbreds and, to a lesser extent, Standardbred horses.[32,35-37] Scientific studies of RER have used a small number of horses that share common clinical signs and have abnormal muscle contracture tests.[32,34,38] Broader epidemiologic and genetic studies have assumed that the same pathophysiologic basis for ER exists in the majority of Thoroughbred and Standardbred horses with similar clinical signs. Whether this is true or not will require more research. There are reports of some Arabian and Warmblood horses[39] with ER that may also suffer from RER based on the overlapping histories, clinical signs, muscle biopsy findings, and response to management.

Rhabdomyolysis is triggered suddenly during exercise in RER horses resulting in a sharp increase in serum myoglobin and CK activity.[6] Clinically, the triggering event is often associated with excitement in a horse that already has an underlying nervous temperament.[35,40] Segmental necrosis in single fibers or small clusters of necrotic fibers scattered throughout fascicles may be apparent in fewer than 5% of type 2a and 2x muscle fibers in a gluteus medius muscle biopsy.[36,37] Serum cortisol concentrations are higher in RER horses than normal horses before exercise and increase during an episode of ER.[6] Serum concentrations of epinephrine and norepinephrine are normal before an episode but increase dramatically in horses with marked elevations in serum CK activity.[6]

Exercise. In Standardbreds, ER commonly begins after 15 to 30 minutes of jogging at 5 m/sec, although clinical signs may not be apparent until after exercise.[36] In Thoroughbreds exercising on the treadmill, ER most commonly develops with intervals of walk, trot, and canter and is less common if horses are allowed to gallop.[41,42] At the racetrack, ER occurs commonly when RER horses are held back to a paced gallop.[35] During eventing, RER commonly occurs after the excitement of the steeplechase or early in the cross-country phase when horses are held to a predetermined speed.[43] ER rarely occurs

when horses are allowed to achieve maximal exercise speeds such as racing. A day or more of rest before this type of exercise results in higher postexercise serum CK activity.

Lactic Acid. There is no basis for an association between RER and lactic acidosis. Thoroughbreds and Standardbreds rarely develop ER during near-maximal exercise[42,44] when muscle lactates reach 240 mmol/kg[45] and plasma lactates are as high as 25 mM. Standardbred horses experience ER during jogging when muscle lactate concentrations are less than 24 mmol/kg.[46] Similarly, plasma lactate concentrations in RER Thoroughbred horses are less than 1.5 mM when performing the walk, trot, and canter treadmill exercise that induces high serum CK activity.[41] Thus rhabdomyolysis in RER horses is not due to lactic acidosis.

Intracellular Calcium Regulation. Research suggests that horses with RER may have an inherent abnormality in intramuscular calcium regulation that is intermittently manifested during exercise.[34,47] Myoplasmic calcium concentrations are tightly controlled by channels and pumps in the sarcoplasmic reticulum and usually are unaffected by normal serum calcium concentrations. Basal muscle intracellular calcium concentrations in RER horses are similar to healthy horses based on assays in muscle cell cultures.[47] Higher intracellular calcium concentrations have been measured in horses of unspecified breeds during an episode of ER; however, this also could be secondary to any insult that impairs energy generation or cell membrane integrity.[48] To specifically study shuttling of calcium between the sarcoplasmic reticulum and myoplasm within the muscle cell, technically complex procedures such as muscle contracture testing, calcium imaging in muscle cell cultures, and calcium release by isolated muscle membrane preparations have been evaluated. Results are reported as the threshold at which a significant increase in muscle tension occurs above baseline levels. Caffeine and halothane are most frequently used to trigger the release of calcium from the sarcoplasmic reticulum to the myoplasm via the ryanodine receptor. This test remains an experimental procedure because of the difficulty in obtaining accurate and timely results. Early studies by Hildebrand et al[38] suggested that some but not all horses with ER showed a lower threshold for caffeine- and halothane-induced muscle contractures than healthy horses. Waldron-Mease et al[49] and Beech et al[32] found that caffeine contracture thresholds were lower in semimembranosus muscle from Thoroughbreds and Standardbreds susceptible to RER versus breed-matched controls. Lentz et al[34,50] studied intact external intercostal muscle fibers and found that Thoroughbreds with RER had a lower contracture threshold for triggering agents such as potassium, caffeine, and halothane but not 4 chloro-m-cresol compared with control horses. An abnormality in intracellular calcium regulation was also supported by a muscle cell culture study of RER Thoroughbred horses.[47] Thus all of these studies support an abnormality in intracellular calcium regulation in most of the Thoroughbred or Standardbred horses studied. Isolated sarcoplasmic reticulum membrane studies, however, have not conclusively identified any abnormalities in intracellular calcium regulation, indicating that there are distinct differences between RER and disorders such as malignant hyperthermia.[32,51] Genetic linkage analysis has failed to associate RER with the genes *RYR1* (ryanodine receptor), *SERCA* (SR ATPase), or *DHPR1* (dihydropyridine receptor), all of which are involved in intramuscular calcium regulation. Thus RER could be a novel defect in muscle excitation-contraction coupling, calcium regulation, or contractility whose basis is yet to be defined. Alternatively, the increased sensitivity of RER horses in contracture testing may be a nonspecific indicator of an abnormality in other pathways governing muscle contraction.

Prevalence and Risk Factors. Assuming that the majority of cases of ER at racetracks are due to RER, the prevalence in Thoroughbred racehorses is remarkably similar around the world, with estimates of 4.9% in the United States,[35] 5.4% in Australia,[21] and 6.7% in the United Kingdom.[40,43] The annual incidence of ER in Standardbred racehorses in Sweden is 6.4%.[52] Exercise obviously increases the prevalence of RER in horses, and episodes are observed more frequently once horses achieve a level of fitness.

In Standardbreds and Thoroughbreds, mares more commonly have RER than males; however, no general correlation has been observed between episodes of rhabdomyolysis and stages of the estrous cycle.[53] There is an interaction between age and gender in RER Thoroughbred horses such that the proportion of affected females to males is much higher in young horses compared with older age groups.[35] Swedish Standardbreds with RER, which do not begin racing until 3 years of age, did not show the same age association with RER as Thoroughbreds.[53] Temperament has a strong effect on the expression of RER in both Standardbreds and Thoroughbreds, with nervous horses, particularly fillies, having a higher incidence of rhabdomyolysis than calm horses.[35,43,52] Young fillies are more likely to have a nervous temperament than mares or male horses. Diet also has an impact, with Thoroughbred horses, fed more than 2.5 kg of grain being more likely to show signs of RER.[41] One study also found a higher prevalence of rhabdomyolysis among Thoroughbred horses with lameness.[35] A few days of rest before exercise increases the degree of elevation on serum CK activity with the next exercise session and in practice predisposes horses to an episode of ER.[42]

Although there is a familial tendency for RER, its genetic basis has not yet been defined. A genetic susceptibility appears to exist in Thoroughbred horses, and RER-afflicted Thoroughbreds may pass the trait to their offspring.[54,55] The difficulty in establishing a specific phenotype, the variable penetrance of the disease, and the possible existence of potential modifying genes have made this hard to firmly establish. Of note is the finding that Standardbred trotters with a history of RER have faster racing times from a standstill start than those without a history of RER, suggesting that the trait may have beneficial as well as deleterious effects.[52]

Diagnosis. A presumptive diagnosis of RER is based on clinical signs of muscle pain and the presence of risk factors commonly associated with RER. Serum CK and AST activities serve as the basis for detecting muscle degeneration, and they often show intermittent abnormal elevations that return to normal relatively quickly during the course of training. If CK elevations are mild there are a number of factors to consider. Timing of the sample with regard to the onset of ER and exercise is important. Reliability is improved by obtaining blood samples at a standardized time after exercise, preferably 4 to 6 hours when CK peaks, and consistently with regard to exercise on the preceding day, because serum CK activity is higher on exercise days that are preceded by a day or more of rest.[56] In addition, normal values need to be adjusted for the age and sex of horses. Two-year-old fillies generally have greater fluctuations in serum CK activity during race training than 3-year-old fillies or geldings.[56]

Muscle histopathology is nonspecific in RER horses; either no abnormalities or evidence of centrally located nuclei in mature fibers and potentially waves of myofiber degeneration or regeneration are found.[5] There is a notable absence of abnormal amylase-resistant polysaccharide, although increased subsarcolemmal amylase-sensitive glycogen may be present.[57] The value of a muscle biopsy as a diagnostic tool in horses with suspected RER is largely confined to particularly recurrent unmanageable cases where a need arises to rule in or out other forms of ER.

Management. Prevention of rhabdomyolysis in horses susceptible to RER is complex, and multiple factors need to be changed to decrease episodes. These factors include the environment, the exercise regimen, and diet. Medication may be needed at times to prevent further episodes of muscle damage.

ENVIRONMENT. Because excitement and nervousness often trigger rhabdomyolysis, stressful situations in the environment that can be modified need to be identified. This may involve a change to a smaller barn with fewer horses and fewer handlers, compatible companions, and a more consistent daily routine. Many stressed RER-susceptible horses respond to a regular routine including feeding before other horses and training before other horses, especially if the horse becomes impatient while waiting. Other horses respond to being housed in a quiet area of the barn next to calm companionable horses. The use of hot walkers, exercise machines, and swimming pools should be evaluated on an individual basis, as some horses develop rhabdomyolysis when using this type of equipment. Horses that develop rhabdomyolysis at specific events, such as horse shows, may need to be reconditioned to decrease the stress level associated with such events or tranquilized as part of the accommodation process. Providing daily turnout with other horses seems to be very beneficial for RER horses and may decrease anxiety and thereby the likelihood of rhabdomyolysis.

EXERCISE. Although for sporadic forms of ER a period of rest is recommended until serum CK normalizes, it is not recommended for horses with RER.[18] Daily exercise is important in preventing episodes of rhabdomyolysis, and when serum CK is less than about 3000 U/L horses should be returned to regular daily exercise. Horses with more severe episodes of rhabdomyolysis may require additional time off in a paddock before gradually resuming exercise. Once back in training, some form of daily exercise is recommended. Avoiding fighting to hold racehorses to slower speeds during galloping may decrease rhabdomyolysis in RER-susceptible Thoroughbreds. Interval training and reduction of jog miles to no more than 15 minutes per session will benefit Standardbreds. For horses under saddle, a relaxed warm-up with intermittent periods of long low stretching may be of benefit, and continued breaks to stretch between episodes of collection are recommended. Event horses may require training that incorporates calm exposure to speeds achieved during the steeplechase or cross-country phase especially when used in an interval training program.

DIET. A nutritionally balanced diet with appropriate caloric intake and adequate vitamin and mineral intake are the core elements of managing RER. For RER Thoroughbreds and Standardbreds in training, the challenge is usually supplying enough calories in a highly palatable form to meet their daily energy demands. This is in part because they often require greater than 30 MCal of digestible energy (DE) a day (5 kg sweet feed, 1.5% of body weight in hay) and because of their nervous temperament they may be more discriminating in their eating habits or prone to gastric ulcers. Of the total daily calories required by RER horses, research suggests that less than 20% DE should be supplied by nonstructural carbohydrates (NSC = starch and sugar), and at least 20% of DE should be supplied by fat.[41,42]

SELECTION OF FORAGE. Thoroughbred horses do not appear to show the same significant increase in serum insulin concentrations in response to consuming hay with an NSC of 17% as seen in Quarter Horses (Borgia L, 2010, PhD thesis, University of Minnesota). This fact combined with the high caloric requirements of racehorses may mean that it is not as important to select hay with very low NSC content in RER Thoroughbreds as it is in PSSM horses. Anecdotally some trainers find that horses with RER have more frequent episodes on alfalfa hay. The nervous disposition of some RER horses may predispose them to gastric ulcers, and thus frequent provision of hay with a moderate NSC and mixed alfalfa content may be indicated.

LOW-STARCH, HIGH-FAT CONCENTRATES. When RER Thoroughbreds are fed a moderate caloric intake (24 MCal/day) in the form of high-starch concentrates (2.5 kg of corn/oats/wheat middlings/molasses), they show very little elevation in serum CK activity with exercise.[41] Most Thoroughbred racehorses, however, are fed at least 5 kg of high-starch concentrate per day at 30 MCal or more per horse per day, and at this level of feeding, postexercise serum CK activity rises significantly.[35] The discovery that substitution of fat for starch in a high-calorie ration significantly reduces muscle damage in exercising RER horses was a major advance in nutritional management of RER.[42] Practically, however, it was difficult to achieve the desired caloric intake of racehorses because the maximum amount of fat that finicky Thoroughbreds will happily consume is often limited to 600 mL for vegetable oil or 5 lb/day of balanced rice bran. Management of RER horses was significantly improved when a palatable means to provide the amount of fat required by fit finicky RER Thoroughbreds was developed. A controlled trial using a specialized feed developed for RER (Re-Leve 13% fat by weight and 9% NSC) determined that NSC should be no greater than 20% of daily DE, and 20% to 25% of daily DE should be provided by fat for optimal management of RER horses fed 30 MCal or more per day.[42] No beneficial effect on serum CK activity occurred when sodium bicarbonate (4.2% of the pellet) was added to a high-starch pellet feed.[42] The amount of fat in the diet of an RER horse depends on its caloric requirements. If an affected horse being fed hay at 1.5% to 2% of body weight and 2.5 kg of grain daily requires additional caloric intake to maintain body weight, additional calories should be supplied by adding a source of fat to the diet.

The benefit of a fat-supplemented diet does not appear to be a change in muscle metabolism. Preexercise and postexercise muscle glycogen and lactate concentrations are the same in RER horses fed a low-starch, high-fat diet compared to a high-starch diet.[44] Low-starch, high-fat diets in RER horses may decrease muscle damage by assuaging anxiety and excitability, which are tightly linked to developing rhabdomyolysis in susceptible horses. High-fat, low-starch diets fed to fit RER horses produce lower glucose, insulin, and cortisol responses and lead to a calmer demeanor and lower preexercise heart rates. Neurohormonal changes may develop in response to high serum glucose, insulin, and cortisol concentrations, resulting in an anxious demeanor.[58] Although a calm

demeanor is desired during training, some racehorse trainers feeding low-starch, high-fat feeds prefer to supplement with a titrated amount of high-starch grain 3 days before a race to potentially increase liver glycogen and increase a horse's energy during the race.

Studies in RER horses show that significant reductions or normalization of postexercise serum CK activity occurs within a week of commencing a low-starch, fat-supplemented diet.[42] Days off training in a stall are discouraged because postexercise CK activity is higher following 2 days of rest compared to values taken when performing consecutive days of the same amount of submaximal exercise.[42,59]

SUPPLEMENTS. Horses require daily dietary supplementation with sodium and chloride either in the form of loose salt (30–50 g/day) or a salt block. Additional electrolyte supplementation is indicated in hot, humid conditions. A myriad of supplements are sold that are purported to decrease lactic acid buildup in skeletal muscle of RER horses. These include sodium bicarbonate, B vitamins, branched chain amino acids, and dimethylglycine. Given that lactic acidosis is no longer implicated as a cause for rhabdomyolysis, it is difficult to find a rationale for their use.

MEDICATIONS. Low doses of tranquilizers, such as acepromazine, before exercise have been used in RER horses prone to excitement.[60] A dose of 7 mg intravenously 20 minutes before exercise is reported to make horses more relaxed and manageable. Reserpine and fluphenazine, which have a longer duration of effect, have also been used for this purpose. Horses given fluphenazine may occasionally exhibit extrapyramidal adverse effects with prolonged bizarre behavior. Use of tranquilizers may only be necessary when horses are in their initial phase of training and accommodation to a new environment. Horses obviously cannot compete on these medications, and withdrawal times must be observed.

Dantrolene sodium (Dantrium) acts to decrease release of calcium from the ryanodine receptor in skeletal muscle and is used to treat malignant hyperthermia. Studies of intact equine intercostal muscle from ER horses show that Dantrium lowers already elevated myoplasmic calcium concentrations.[48] Controlled and field studies have also shown that oral Dantrium can significantly decrease signs of rhabdomyolysis in RER horses.[59,61] One study indicated that horses need to be fasted to achieve measurable blood levels of Dantrium,[59] but more recent controlled trials suggest that absorption of Dantrium is superior in fed versus fasted horses.[62] Administration of 4 mg/kg of Dantrium PO 1 hour before exercise to RER-susceptible horses fed high-grain diets resulted in significantly lower serum CK activity 4 hours after exercise compared with placebo.[59] A dose of 800 mg of Dantrium was given to Thoroughbred horses in the United Kingdom 1 hour before exercise and resulted in significantly lower postexercise CK activity than a placebo.[61]

Phenytoin (1.4–2.7 mg/kg PO b.i.d.) has been reported to be effective in preventing rhabdomyolysis in horses with RER.[33,63] Phenytoin acts on a number of ion channels within muscle and nerves, including sodium and calcium channels. Therapeutic levels vary, so oral doses are adjusted by monitoring serum levels to achieve 8 µg/mL and not to exceed 12 µg/mL.[33,63] Drowsiness and ataxia are evidence that the dose of phenytoin is too high and the dose should be decreased by half. Initial dosages start at 6 to 8 mg/kg orally twice a day for 3 to 5 days. If the horse is still experiencing rhabdomyolysis but is not drowsy, the dose can be increased by 1-mg/kg increments every 3 to 4 days. Phenytoin is a monoaminoxidase activator and can affect plasma concentrations of other medications. Unfortunately, long-term treatment with Dantrium or phenytoin is expensive, and these drugs must be withdrawn before competition.

HORMONE THERAPY. Various hormones, ranging from thyroxine to progesterone and testosterone, have been given to horses with RER. Initial studies linking low T_3 and T_4 concentrations in horses with ER have not been substantiated.[64,65] Some mares appear to exhibit signs of rhabdomyolysis during estrus, and it may well be of benefit in these horses to suppress estrous behavior using progesterone injections. Testosterone and anabolic steroids have been used at racetracks to prevent signs of RER, but their use is no longer permitted.

ADJUNCT THERAPIES. Massage, myofascial release, mesotherapy, stretching, aqua-treadmill therapy, and hot/cold therapy performed by experienced therapists may be of benefit in individual horses.[66] Their use may promote relaxation, promote normal muscle tension, and build muscle strength.

Malignant Hyperthermia

Pathogenesis

Malignant hyperthermia (MH) occurs in Quarter Horses and Paint Horses as a result of an autosomal dominant mutation in exon 46 of the skeletal muscle ryanodine receptor 1 gene *(RYR1)*.[67,68] The mutation lowers the activation and heightens the deactivation threshold of the ryanodine receptor, which intermittently can result in a dramatic efflux of calcium from the sarcoplasmic reticulum, increasing myoplasmic calcium and producing a contracture.[69] Anaerobic glycogen metabolism is activated, lactate is produced, excessive heat is generated, and massive muscle necrosis ensues.

Prevalence and Risk Factors

MH affects less than 1% of Quarter Horses and Paint Horses, particularly affecting halter and pleasure horse lines. Rhabdomyolysis with MH can be induced by exercise or anesthesia and is exacerbated by the presence of the *GYS1* mutation for type 1 PSSM. In many horses, clinical signs are completely unapparent or very intermittent in nature.[68]

Clinical Signs

Clinical signs of hyperthermia (104.9°F [40.5°C]), hypercapnia (P_aCO_2 of 274 mm Hg), and acidosis (pH of 6.72) were reported in an experimental protocol approximately 60 minutes after anesthesia was induced by delivering halothane via a face mask without premedication.[70] Death occurred from cardiopulmonary arrest and was preceded by profound rigor mortis. Hematologic changes present 2 minutes after death included hemoconcentration, hyperkalemia, hypercalcemia, hyperphosphatemia, hyperglycemia, and elevated creatinine. Serum CK activity was mildly increased at 843 U/L, and myoglobin was 10 times higher than the reference range in this horse.

Horses with the *RYR1* mutation may intermittently show signs of ER and high body temperatures.[68] Some MH-affected horses have died suddenly after an episode of ER. Horses with the MH mutation may also have the *GYS1* mutation associated with type 1 PSSM.[71] Such horses have more severe episodes of ER, higher serum CK activity after exercise, and a more moderated response to the diet and exercise regimens recommended for type 1 PSSM.[71]

Diagnosis

Genetic testing is recommended in Quarter Horses and Paint Horses with severe ER or ER associated with elevated body temperature. Muscle biopsy is not particularly useful for diagnosing MH. Biopsies may contain mild myopathic changes, including increased variation in fiber sizes, centrally located nuclei, fiber necrosis, glycogen depletion, and ringbinden fibers.

Treatment

Horses with suspected MH should be treated with oral Dantrium (4 mg/kg) 30 to 60 minutes before anesthesia.[70] The exception to this rule may be horses with MH and hyperkalemic periodic paralysis because Dantrium can cause an excessive rise in serum potassium that can trigger an episode of muscle paralysis.[72] There is no cost-effective means to deliver Dantrium to horses intravenously once an episode of MH has begun. The nature of ER with horses positive for MH is so intermittent that it is hard to justify premedication with Dantrium before exercise.

Polysaccharide Storage Myopathy

Polysaccharide storage myopathy (PSSM) was first recognized as a specific myopathy in Quarter Horse–related breeds in 1992,[73] but reports of abnormal polysaccharide inclusions in equine muscle of individual horses date back to 1979.[74] The remarkable feature of the first horses reported to have PSSM was twofold higher muscle glycogen concentrations than normal horses and abnormal granular amylase-resistant inclusions in histologic sections.[73] Similar biopsy findings were reported in Belgian and Percheron draft horses.[74]

Terminology

PSSM has also been referred to as *equine polysaccharide myopathy* (EPSM or EPSSM). [27,75] Considerable controversy existed as to whether these acronyms encompassed one muscle condition.[7,27,76] In 2008 a mutation in the glycogen synthase 1 gene *(GYS1)* was found to be highly associated with the presence of amylase-resistant polysaccharide in skeletal muscle.[77] Genetic testing of hundreds of horses previously diagnosed with PSSM by muscle biopsy revealed that the majority of cases of PSSM characterized by amylase-resistant polysaccharide in skeletal muscle had the *GYS1* genetic mutation. However, some cases previously diagnosed with PSSM by muscle biopsy, particularly those with excessive amylase-sensitive glycogen, did not possess the genetic mutation. This suggested that there are at least two forms of PSSM.[77,78] For clarity, the form of PSSM caused by an H309G *GYS1* mutation is now termed *type 1 (PSSM1)* whereas the form or forms of PSSM not caused by the *GYS1* mutation and whose origins are yet unknown are termed *type 2 (PSSM2)*.[78] PSSM1 is likely to be the same disorder that was called "azoturia" or "Monday morning disease" in work horses in the nineteenth and twentieth centuries.

Type 1 PSSM

Genetics. PSSM1 is caused by an autosomal dominant missense mutation in *GYS1* that results in an arginine substitution for histidine at codon 309 in glycogen synthase.[77] The effect of this amino acid substitution is a higher than normal activity of glycogen synthase both at basal states and when activated by glucose-6-phosphate.

Prevalence. PSSM1 is estimated to have emerged approximately 1600 years ago when the great horse was being developed from European draft and light horse breeds to carry knights with heavy armor into battle.[77] The highest prevalence of PSSM1 appears to occur in draft horses derived from Continental European breeds.[79] In fact, many Continental European drafts are homozygous for the dominant PSSM1 trait (90% prevalence of PSSM in Trekpaards with 40% of tested Belgian Trekpaards homozygous).[79] North American Belgians and Percherons also have a high prevalence of PSSM1 at 36% and 54% of horses affected.[10] In contrast, the prevalence of PSSM is very low in UK-derived breeds such as Shires and Clydesdales, but PSSM1 is present in other UK horse breeds such as Irish Drafts, Cob, and Connemara.[10,79] Horses of more than 20 other breeds may have the *GYS1* mutation responsible for PSSM1.[80-82] Prevalence estimates of PSSM1 in Quarter Horses range from 6% to 10% of the breed and 6% to 8% for American Paint and Appaloosa horses.[83] The highest frequency of PSSM1 occurs in halter Quarter Horses (28% affected) and the lowest frequency in racing Quarter Horses.[83] The *GYS1* mutation has been identified in approximately 72% of Quarter Horses diagnosed with PSSM by muscle biopsy and in 18% of Warmbloods of a variety of types diagnosed with PSSM by muscle biopsy.[84] The prevalence of PSSM1 is very low to nonexistent in light horse breeds such as Arabians, Standardbreds, and Thoroughbreds.[10]

Risk Factors. Some horses with PSSM1 are asymptomatic, whereas other horses routinely show stiffness with exercise. In a family of Warmbloods sired by a stallion with the *GYS1* mutation, the mutation resulted in a sevenfold higher risk of developing ER, with owners reporting that 66% of horses with the *GYS1* mutation had clinical signs of ER.[85] The reason for variability in clinical signs of PSSM1 probably lies in the influence of diet, exercise, other environmental factors, and other genes on the expression of the disease. There is no significant temperament, body type, or gender predilection for PSSM1.[86,87] The most common trigger for clinical signs of PSSM1 is less than 20 minutes of exercise. Clinical signs occur most commonly at a walk and trot, particularly if the horse has been rested for several days before exercise or is unfit.[86] Diets high in NSC also increase the risk of muscle pain and stiffness in PSSM1 horses.[88] About 40% of owners feel there is a seasonal incidence to the development of clinical signs, which some have attributed to quality of grass available at the time.[82] Although exercise is by far the most common trigger for PSSM, Quarter Horse and Paint Horse foals and weanlings may develop rhabdomyolysis in conjunction with a systemic illness.[89]

Diagnosis. Persistent elevations in serum CK and AST activities are common in symptomatic horses with PSSM1 (Fig. 10.7). If horses have normal serum muscle enzymes at rest, an exercise test consisting of a maximum of 15 minutes lunging at a walk and trot may help to determine if subclinical ER is present.[5] Supportive evidence would include a minimum of a threefold elevation in CK activity 4 hours after exercise.

The gold standard for diagnosis of PSSM1 is genetic testing for the *GYS1* mutation performed on whole blood or hair root samples. It is important to note that in draft horses of continental European origin, the very high prevalence of PSSM in essence means that there is a high chance that any clinical sign could be falsely associated with the disease PSSM1.[79,87] Clinical judgment is required to determine whether the clinical signs of the animal could reasonably be associated with a myopathic process. Muscle biopsy provides a means to diagnose PSSM; however, to classify PSSM as type 1 a genetic test is required. The distinctive features of PSSM1 in muscle biopsy

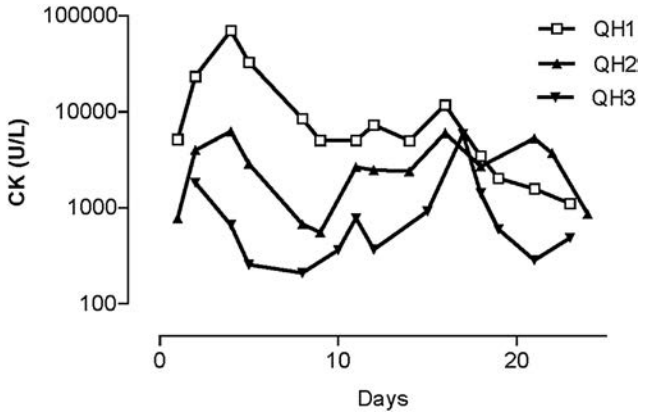

FIG. **10.7** Serum creatine kinase (CK) activity obtained 4 hours after exercise in three Quarter Horses with type 1 polysaccharide storage myopathy (PSSM1) over a 3-week period of training for 20 minutes or less each day. Note that these severely affected PSSM horses have persistent elevations in serum CK activity that do not return to normal reference range.

samples are numerous subsarcolemmal vacuoles and dense, crystalline periodic acid–Schiff (PAS)–positive and amylase-resistant inclusions in fast-twitch fibers (Fig. 10.8). A diagnosis can be made irrespective of diet and proximity of sampling to recent episodes of rhabdomyolysis. A false-negative diagnosis of type 1 PSSM by muscle biopsy may occur if biopsy samples are small or if horses are less than 1 year of age.[90]

Acute Clinical Signs. Horses with the *GYS1* mutation begin to show clinical signs of muscle disease between 1 and 14 years of age, with an average age at onset of signs of 5 years. Acute clinical signs occur when horses are calm and include tucking up of the abdomen, fasciculations in the flank, muscle stiffness, sweating, reluctance to move forward, and overt firm muscle contractures (Fig. 10.9).[86] The hindquarters are frequently most affected, but back, abdominal, and forelimb muscles may also be involved. Signs of pain can last for more than 2 hours, and about 10% of cases become recumbent.[86] Less common signs of PSSM in Quarter Horses include gait abnormalities, mild colic, and muscle wasting. During an acute episode of ER, horses with PSSM1 often have markedly elevated serum CK activity of greater than 35,000 U/L, and myoglobinuria may be present. Severe colic-like pain after exercise and myoglobinuric renal failure are less common presenting complaints.[91,92]

Chronic Clinical Signs

LIGHT BREEDS. Chronic signs of PSSM1 in riding horses include a lack of energy when under saddle, reluctance to move forward, stopping and stretching out as if to urinate, and a sour attitude toward exercise.[39,86] Horses may have a combination of low-grade reluctance to exercise, poor performance, and repeated episodes of ER.[81] PSSM1 may also present in dressage and show jumpers as chronic back pain, failure to round over fences, and fasciculations or pain on palpation of lumbar muscles.[57] The range of severity of clinical signs of PSSM1 can be wide with complete incapacitation in rare cases. Serum CK activities are often elevated in unmanaged horses, even when horses are rested.[92] The median CK and AST activity for all PSSM1 Quarter Horses with muscle biopsies submitted to the University of Minnesota was 2809 and 1792 U/L, respectively.[93]

A small number of Quarter Horses and Paint Horses have both the *GYS1* mutation and the genetic mutation for MH.[71] This results in particularly severe signs of ER and a limited response to diet and exercise changes. During an episode of ER, excessively high body temperatures may develop and sudden death can occur in horses with the *RYR1* mutation. This combination occurs most often in halter and pleasure horses.

DRAFT HORSES AND DRAFT CROSSES. The average age of draft horses diagnosed with PSSM is about 6 years.[87] Many draft horses with PSSM are asymptomatic. Draft horses homozygous for the PSSM mutation have higher serum muscle enzymes than healthy or heterozygous horses.[94] Signs of severe rhabdomyolysis and myoglobinuria may occur in horses fed high-grain diets, exercised irregularly with little turnout, or horses that undergo general anesthesia.[91,95] Rhabdomyolysis can be so severe that it leads to recumbency and death.[91,95] Other signs of PSSM in draft horses include progressive weakness and muscle loss resulting in difficulty rising in horses with normal serum CK activity. Pronounced weakness is more prevalent in horses homozygous for the *GYS1* mutation. Gait abnormalities, such as excessive limb flexion, fasciculations, and trembling, are also reported in draft horses. Although the condition "shivers" was previously attributed to PSSM, studies found no causal association between these two conditions.[87] There is no evidence of impaired myocardial function in horses with PSSM1.[96] In Belgian draft horses mean (± standard deviation [SD]) AST activity was 502 ± 116 U/L for PSSM1 homozygotes, 357 ± 92 U/L for heterozygotes, and 311 ± 64 U/L for controls, with significant differences among groups.[94] The median serum CK and AST activities in draft horses from which biopsies were sent to the University of Minnesota were 459 and 537 U/L, respectively.[93]

Pathophysiology. The *GYS1* mutation causes a gain of function in glycogen synthase both in basal states and when activated by insulin and glucose-6-phosphate, and horses with PSSM1 have on average 1.8-fold higher muscle glycogen concentrations.[77] The abnormal polysaccharide in PSSM1 is less branched than normal glycogen as a result of chronically enhanced glycogen synthase enzyme activity in the presence of elevated glucose-6-phosphate and insulin without the same relative activation of branching enzyme.[97] Foals and yearlings with the *GYS1* mutation rarely have abnormal polysaccharide in skeletal muscle yet they have rhabdomyolysis.[09] Thus abnormal polysaccharide itself is an indicator of PSSM1 but not the direct cause for rhabdomyolysis.

The vast majority of horses that develop rhabdomyolysis with PSSM1 do so with aerobic exercise when blood lactate concentrations are unchanged from preexercise samples at 1.0 mmol/L.[7] Although elevated serum CK activity occurs with near-maximal exercise on occasion, the degree of elevation is often less than with submaximal exercise.[7] A deficit in energy metabolism represented by high myofiber inosine monophosphate (IMP) occurs after light exercise in individual muscle fibers of horses with PSSM1 in association with high serum CK activity. [99]

A high-NSC diet increases the propensity to develop muscle pain with aerobic exercise in PSSM1 horses.[86] A high-NSC versus a low-NSC, high-fat diet results in higher muscle lactate and citrate concentrations, lower glucose-6-phosphate, and similar muscle pyruvate concentrations with aerobic exercise in PSSM1 horses.[98] This suggests that the enhanced glycogen synthase activity in PSSM horses may impair oxidative metabolism of substrates such as pyruvate and fatty acids. Although the exact mechanism for this is not known, it may involve a link between glycogen synthase or glycogen concentrations

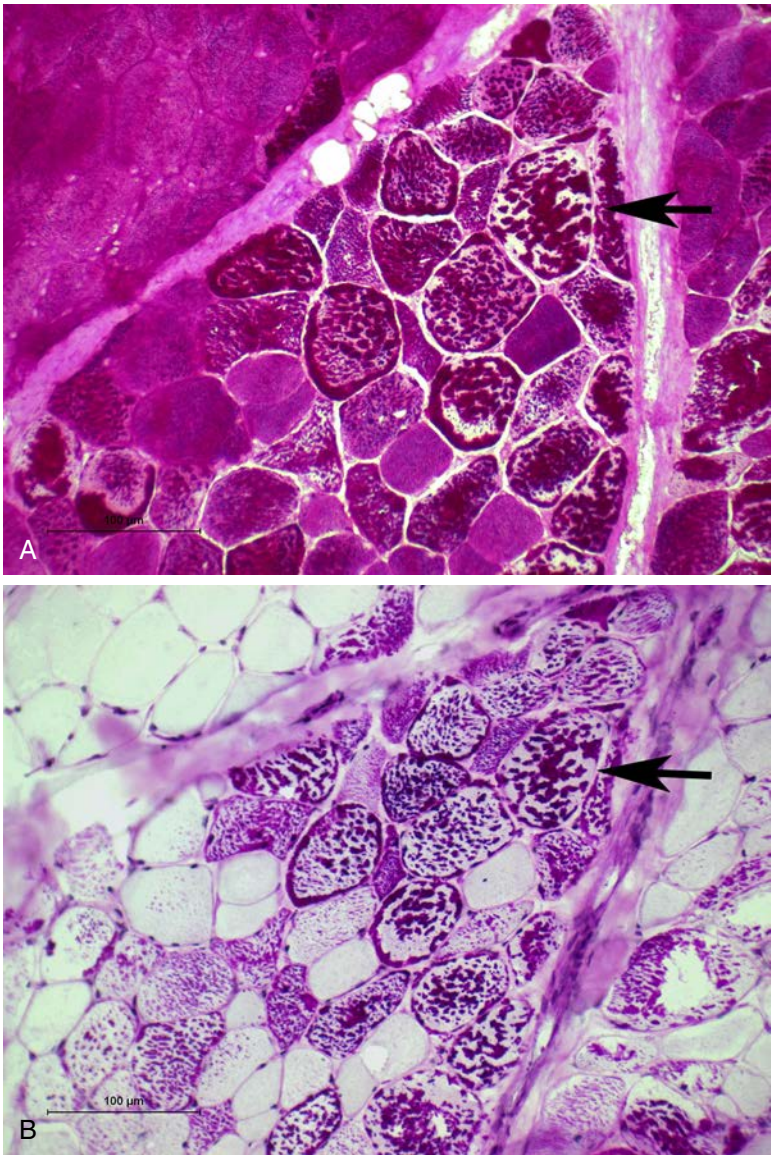

FIG. **10.8** (A) Cross section of semimembranosus muscle showing accumulation of granular periodic acid–Schiff (PAS) inclusions *(arrow)* in a horse with PSSM1. (B) Serial section of the same muscle preincubated in amylase before PAS staining. Note that the abnormal granular material is amylase resistant. (20×)

and metabolic switches and nutrient sensors. One of the key sensors and regulators of substrate flux in skeletal muscles is AMP kinase.[100,101] When energy supply is deemed to be insufficient (↓ [ATP]/[ADP]), activation of AMP kinase leads to the increased transcription of genes involved in oxidative metabolism, stimulation of fatty acid oxidation, and activation of pyruvate dehydrogenase, which increases carbohydrate oxidation.[100-102] Nutrient sensors in the cell could interpret excessive stimulation of glycogen synthesis (arising from the *GYS1* mutation and stimulated by insulin) as an indication not to activate glycogenolysis and lipolysis. PSSM horses fed high-NSC diets may be unable to generate sufficient acetyl CoA from either carbohydrate or fat metabolism to fuel muscle contraction during submaximal exercise. The common occurrence of clinical signs during the first 20 minutes of exercise may be because at this stage of exercise, muscles rely heavily on glycogen/glucose for energy. Low dietary starch and fat supplementation decrease muscle citrate concentrations and increase plasma free fatty acid concentrations, which may facilitate muscle fat metabolism in PSSM1 horses.[98,103]

Type 2 PSSM

Much less is known about type 2 PSSM, because previous controlled research trials on PSSM have largely involved horses with PSSM1 (Valberg, unpublished data). The term *type 2 PSSM* refers to those horses that have altered staining for muscle glycogen that do not possess the *GYS1* mutation.[78] As such it should not be interpreted to necessarily indicate one specific disease. Furthermore, because PSSM2 is not consistently defined by the presence of amylase-resistant polysaccharide but rather includes abnormal appearance of amylase-sensitive glycogen, there is considerable room for overlap of a diagnosis with RER or for false-positive diagnoses in trained animals.[75,76,80]

Much of the current knowledge of managing PSSM2 is based on extrapolation of what works for PSSM1, retrospective

FIG. **10.9** Horse with PSSM1 showing acute clinical signs of rhabdomyolysis that include anxiety, sweating, muscle stiffness, and reluctance to move.

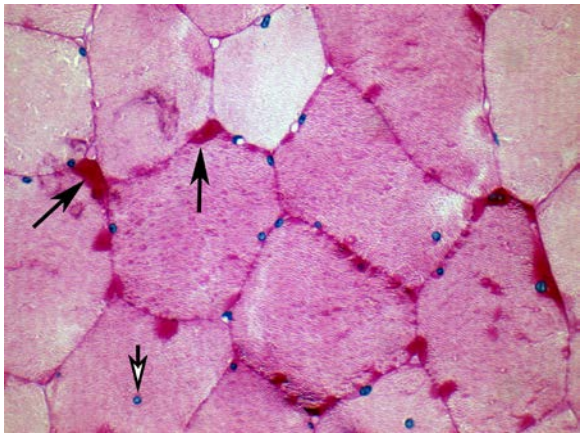

FIG. **10.10** Cross section of semimembranosus muscle (20×) from a horse showing increased accumulation of subsarcolemmal periodic acid–Schiff (PAS) material *(arrows)*. The horse was negative for the *GYS1* mutation, establishing a diagnosis of PSSM2. Note the myopathic finding of centrally displaced myonuclei in some fibers.

evaluation of cases diagnosed with PSSM2 by muscle biopsy,[39] and a few years of prospective clinical data.

Prevalence. Approximately 28% of Quarter Horses with PSSM diagnosed by muscle biopsy do not have the *GYS1* mutation and therefore have PSSM2.[77,93] PSSM2 seems to be common in both high-performance Quarter Horse types such as barrel racing, reining, and cutting horses as well as pleasure and halter horses. In the United Kingdom approximately 35% of PSSM cases diagnosed by muscle biopsy have PSSM2.[80] PSSM2 is also documented in Paint, Appaloosa, and Morgan horses. About 80% of Warmblood horses diagnosed with PSSM by muscle biopsy have PSSM2.[84] Other breeds diagnosed with PSSM2 include Dutch Warmbloods, Swedish Warmbloods, Selle Francais, Hanoverians, Friesians, Westfalians, Canadian Warmbloods, Irish Sport Horses, Gerdlanders, Hussiens, Standardbreds, Thoroughbreds, and Arabians.[77]

Pathogenesis. The cause or causes of PSSM2 are currently unknown. Muscle glycogen concentrations are not as high as those found in horses with PSSM1, and glycogenolytic enzyme defects have not been identified in the few cases where enzymes were measured (Valberg, unpublished data). To date, the only reported abnormality in muscle ultrastructure is an increase in normal β-glycogen particles.[78] It may be that there are a group of conditions currently captured under the term *type 2 PSSM* that have separate etiologies but share common findings of focal glycogen accumulation and poor performance.

Clinical Signs. In adult Quarter Horses, ER is the predominant clinical sign of PSSM2. In Quarter Horses less than 1 year of age an inability to rise or a stiff hindlimb gait is reported with PSSM2.[78] In Warmblood Horses, signs of PSSM2 are usually related to an exertional myopathy with few or rare occasions of a postexercise increase in serum CK activity. Clinical complaints usually relate to poor performance, an undiagnosed lameness, sore muscles, and decreased energy level. Warmbloods with PSSM2 may also have painful firm back and hindquarter muscles, reluctance to collect and engage the hindquarters, poor rounding over fences, poor canter departs, and slow onset of atrophy, particularly if taken out of work. The mean age of onset of clinical signs in Warmbloods is between 8 and 11 years of age, with median CK and AST activities of 323 and 331 U/L, respectively.

Diagnosis. PSSM2 is diagnosed by muscle biopsy where increased or abnormal PAS-positive material that is usually amylase-sensitive is apparent (Fig. 10.10).[78] Determination of what constitutes an abnormal amount of amylase-sensitive glycogen is subjective, the specificity of the diagnosis is low, and false-positive diagnoses occur. Highly trained horses have increased glycogen storages as a normal response to training, and this should be considered when histopathologic interpretations are made. Glycogen is commonly found near capillaries in normal horses, and PAS-positive sarcoplasmic masses can be found in 60% of healthy horses, so the presence of these structures should not be diagnostic criteria for PSSM2.[104] Type of fixation is also a consideration as formalin-fixed sections show a greater deposition of subsarcolemmal glycogen and precipitation of glycogen in one area of a fiber even in healthy horses, and these should not be considered diagnostic criteria for PSSM2.[105] Other histopathologic features that may be present with PSSM2 include centrally located nuclei, subsarcolemmal vacuoles, muscle necrosis, macrophage infiltration of myofibers, regenerative fibers, and anguloid myofiber atrophy.[78] Some laboratories grade polysaccharide accumulation as mild, moderate, and severe where mild accumulation represents a category that has a higher chance of being a false-positive diagnosis. Mild PSSM cases in particular should receive a full physical and lameness examination to ensure that there are no other underlying causes for poor performance.

Management of Type 1 and Type 2 PSSM

Horses diagnosed with PSSM will always have an underlying tendency for muscle soreness. Affected horses should

be managed appropriately to minimize clinical signs. With adherence to both diet and exercise recommendations provided below, at least 70% of horses with PSSM show notable improvement in clinical signs, and many return to acceptable levels of performance.[27,39,86] There is, however, a wide range in the severity of clinical signs, shown by horses with PSSM; those horses with severe or recurrent clinical signs will require more stringent adherence to diet and exercise recommendations in order to regain muscle function.

Rest. PSSM horses that are confined for days to weeks following an episode of rhabdomyolysis often have persistently elevated serum CK activity. In contrast, PSSM horses kept on pasture with little grain supplementation often show few clinical signs of rhabdomyolysis and have normal serum CK activity. After an episode of rhabdomyolysis, horses with PSSM should be confined to a stall for only a brief time (less than 48 hours) followed by turnout in paddocks of gradually increasing size. Providing horses with as much free exercise as possible on pasture appears to be beneficial in the long term. If pasture is lush a grazing muzzle may be needed.[81] Following an acute episode, excitable horses may require tranquilization before turnout to avoid excessive galloping. Hand walking horses for more than 5 to 10 minutes at a time when initially recovering from an episode of PSSM may trigger another episode of rhabdomyolysis.

Exercise. The beneficial response to low-starch, fat-supplemented diets only occurs if it is instituted in conjunction with a regular incremental exercise program.[88] Regular daily exercise in PSSM horses over a 3-week period results in a dramatic decrease in serum CK responses to exercise, whereas stall confinement is associated with elevations in serum CK activity after exercise.[88,98] One common adaptation to daily training is an increase in oxidative capacity in skeletal muscle. The oxidative capacity of skeletal muscle in PSSM Quarter Horses was very low based on markers such as citrate synthase activity and β–fatty acid oxidative marker HAD.[88] The activity of these enzymes, however, was equally low in control Quarter Horses. Whether the beneficial effect of daily exercise on PSSM horses is a result of improved oxidative enzyme capacities or enhanced substrate flux or both has not been elucidated.

EXERCISE REGIMENS. Important principles to follow when starting exercise programs in PSSM horses include the following: (1) provide adequate time for adaptation to a new diet before commencing exercise; (2) recognize that the duration of exercise, not the intensity, is of primary importance; (3) ensure that the program is gradually introduced and consistently performed; and (4) minimize any days without some form of exercise. If horses have experienced a moderate to marked episode of rhabdomyolysis recently, 2 weeks of turnout and diet change are often beneficial before recommencing exercise. Exercise should be very relaxed, and the horse should achieve a long, low frame without collection. For many horses this is most readily done in a round pen or on a lunge-line but can be done under saddle if needed. Successive daily addition of 2-minute intervals of walk and trot beginning with only 4 minutes of exercise and working up to 30 minutes after 3 weeks is often recommended.[18,92] If horses had minor elevations in 4-hour postexercise CK with the 15-minute exercise test, horses may begin at 15 minutes of exercise. Owners often do not recognize that walking the horse for 10 minutes or more initially can trigger muscle soreness in PSSM horses. Advancing the horse too quickly often results in an episode of rhabdomyolysis and repeated frustration for the owner. Work can usually begin under saddle after 3 weeks of ground work and can gradually be increased by adding 2-minute intervals of collection or canter to the initial relaxed warm-up period at a walk and trot. Unless a horse shows an episode of overt rhabdomyolysis during the initial first 4 weeks of exercise, reevaluating serum CK activity is not helpful for the first month. This is because it is very common to have subclinical elevations in CK activity when exercise is reintroduced, and a return to normal levels often requires 4 to 6 weeks of gradual exercise.[92] Keeping horses with PSSM fit seems the best prevention against further episodes of rhabdomyolysis.

Diets for PSSM. The basis for designing PSSM diets is the belief that lowering the daily starch and sugar intake and increasing dietary fat content will decrease the glucose load, increase the availability of nonesterified free fatty acids for muscle metabolism, and lower serum insulin concentrations. It is important to note that the dietary recommendations provided here were tested in horses with PSSM1, and there are no controlled trials to indicate whether these are beneficial for PSSM2 horses. Quarter Horses naturally have very little lipid stored within muscle fibers. The end result would thus be decreased uptake of glucose into muscles cells, less substrate available for—and stimulation of—glycogen synthesis, and normalization of substrate flux. Owners report that this type of diet improves clinical signs of muscle pain, stiffness, and exercise tolerance in draft horses, Warmbloods, Quarter Horses, and other breeds.[27,39,81,86,88] Dietary change appears to have less impact on alleviating gait changes such as shivers.[39]

CALORIC BALANCE. The horse's caloric requirements at an ideal body weight are the most important considerations in designing the diet for PSSM. This is because many horses with PSSM are easy keepers and may be overweight at the time of diagnosis. Adding excessive calories in the form of fat to an obese horse may result in equine metabolic syndrome and is contraindicated. If necessary, caloric intake should be reduced by using a grazing muzzle during turnout, feeding hay with a low NSC content at 1% to 1.5% of body weight, providing a low-calorie ration balancer, and gradually introducing daily exercise. Rather than provide dietary fat to an overweight horse, fasting for 6 hours before exercise can be used to elevate plasma free fatty acids before exercise and alleviate any restrictions in energy metabolism in muscle.

SELECTION OF FORAGE. Quarter Horses develop a significant increase in serum insulin concentrations in response to consuming hay with an NSC of 17%, whereas insulin concentrations are fairly stable when hay with 12% or 4% NSC content is fed.[106] Because insulin stimulates the already overactive enzyme glycogen synthase in the muscle of PSSM1 horses, selecting hay with 12% or less NSC is advisable. The degree to which the NSC content of hay should be restricted below 12% NSC depends on the caloric requirements of the horse. Feeding a low-NSC hay of 4% provides room to add an adequate amount of fat to the diet of easy keepers without exceeding the daily caloric requirement and inducing excessive weight gain. For example, a 500-kg horse on a routine of light exercise generally requires 18 MCal per day of digestible energy (DE). Fed at 2% of body weight, a 12% NSC mixed grass hay almost meets their daily caloric requirement by providing 17.4 MCal per day. Thus with a 12%-NSC hay there is only room for 0.6 MCal of fat per day (72 mL of vegetable oil) to achieve 18 MCal of energy.

In contrast, a 4%-NSC blue grama hay would provide 13.5 MCal per day, which would allow a reasonable addition of 4.5 MCal of fat per day (538 mL of vegetable oil).

SELECTION OF FAT SOURCE. High-fat diets increase plasma free fatty acid concentrations and thus the availability of fats for oxidation in skeletal muscle.[98] The major sources of dietary fat for horses are vegetable-based fat, including vegetable oils and rice bran, or animal-based fat (tallow, lard, fish oil). Vegetable oils are highly unsaturated, very digestible (90%–100%), and very energy dense. Suitable forms include soybean, corn, safflower, canola, flaxseed, linseed, peanut, and coconut. Controlled research studies in exercising PSSM horses have shown a decrease in muscle pain and serum CK in response to the addition of corn oil and also a product containing soy hulls, soybean oil, and rice bran (RE•LEVE®).[86,98] The amount of oil added in these trials constituted at least 13% of daily DE. Some veterinarians have advocated as much as 25% of DE be fed in the form of fat to PSSM horses.[27] As discussed, the principal consideration here should be whether this provides excessive calories and additional weight gain because feeding 13% DE as fat may well be effective in reducing muscle pain.

Limited research has been performed on the form of oil to feed PSSM horses. An odd carbon 7 chain fat (triheptanoin) fed to PSSM horses had a detrimental effect on muscle pain, exercise tolerance, and serum CK activity whereas long-chain fats fed in the form of corn oil or a rice bran/soy oil–supplemented feed had a beneficial effect on lowering serum CK activity.[98] Whether there is any direct beneficial effect on skeletal muscle of providing energy in the form of omega-3 versus omega-6 fatty acids has yet to be determined. Corn oil, sunflower oil, and safflower oil are high in omega-6 and lower in omega-3, whereas soybean and canola oils are moderately high in omega-6 and omega-3. Flax seed, linseed, and fish oils contain more omega-3 than omega-6. It is usually cost-prohibitive to provide sufficient energy to a PSSM horse each day in the form of dense omega-3 fat supplements. Soybean and canola oils provide a relatively affordable alternative with moderately high omega-6 or a mix of these oils and flax or fish oil can be provided. Due to the potential additional oxidant stress of fats, vitamin E (1000–5000 U/day) is recommended for horses receiving oil-supplemented diets.

LOW-STARCH, HIGH-FAT CONCENTRATES. Although oils are energy dense and inexpensive, they have the disadvantages of being messy, unpalatable to some horses, prone to rancidity in warm temperatures, and difficult to feed in large amounts. As such a number of concentrates have been developed that contain fats. The important principle to be met by such feeds is that the starch and sugar components are low enough and fat supplementation high enough to ensure that in the total diet, the calories supplied by NSC comprise no more than 10% to 15% of the daily DE and the calories supplied by fat comprise about 12% to 15% of daily DE. Common fat sources used in such concentrates include, in addition to the oils mentioned above, stabilized rice bran or animal fats. Rice bran and its products are palatable to most horses, have a moderate NSC content (about 25% by weight), contain approximately 20% fat by weight, and are excellent sources of vitamin E and phosphorus. The NSC component of rice bran can vary if the manufacturing process is not careful to exclude the white rice grain. Commercial rice bran products occur as powder or an extruded pellet and are considerably more stable in warm temperatures compared to animal fat and vegetable oils. A number of well-balanced, low-starch, high-fat commercial diets are suitable for horses with PSSM. Some commercial feeds meet the recommended nutritional needs of PSSM horses in one pelleted ration. These feeds typically contain at least 10% to 15% fat by weight and less than 20% NSC by weight. Some feed companies offer similar nutritional content by blending two or more manufactured feeds or by supplementing with oils or rice bran. At present, the NSC content of equine feed products is not consistently listed on the feed tag, and consultation with the feed manufacturer is necessary to obtain this information. Nutritional support is available through most feed manufacturers in designing an appropriate diet. There is a great deal of variation in individual tolerance to dietary starch; however, horses with more severe clinical signs of PSSM appear to require the greatest restriction in starch intake.

EXPECTATIONS. The beneficial effect of low-starch, high-fat diets requires that horses are trained daily to enhance enzymes involved in fat and glucose metabolism. With adherence to both the diet and exercise recommendations 70% to 75% of Quarter Horses and Warmbloods show notable improvement in clinical signs, and many return to acceptable levels of performance.[28,39,81,90] There is, however, a wide range in the severity of clinical signs shown by horses with PSSM; those horses with severe or recurrent clinical signs will require more stringent adherence to diet and exercise recommendations in order to regain muscle function. PSSM horses that also have the mutation for MH do not respond as well to diet and exercise recommendations and may continue to develop ER with the possibility of a fatal episode.[93]

SUPPLEMENTS. There are no specific supplements that have been shown to benefit horses with PSSM. Chromium, which is reported to increase glucose absorption, may be contraindicated in PSSM horses. Carnitine is a dietary supplement that may replenish muscle carnitine stores if depleted and assist in transport of fat into the mitochondria. A deficiency of plasma carnitine has not been identified in PSSM1 horses. Plasma free carnitine concentrations ranged from 10.24 to 27.11 μM in PSSM1-affected horses and from 13.20 to 25.63 μM in normal horses (Valberg, unpublished data). Plasma carnitine does not always reflect muscle carnitine concentrations.

Myofibrillar Myopathy

One recent addition to potential causes of exertional myopathies includes a suspected myofibrillar myopathy (MFM) that was identified in Arabian endurance horses with a history of intermittent elevations in serum CK activity (greater than 10,000 U/L after endurance rides).[107] The Arabian horses did not necessarily show the same degree of clinical signs of reluctance to move, muscle stiffness, and pain that is frequently seen with cases of ER. Muscle biopsies resembled those of PSSM2 with increased aggregates of cytoplasmic glycogen, amylase-resistant polysaccharide in a few myofibers of some horses, and centrally located myonuclei in mature myofibers. Muscle glycogen concentrations in horses with MFM were similar to controls. The distinguishing feature of muscle biopsies in these horses was disrupted myofibrillar alignment and large desmin- and αβ crystallin-positive cytoplasmic aggregates found in horses without a recent episode of ER. The ectopic accumulation of cytoskeletal proteins and Z-disc degeneration identified on electron microscopy had features of a myofibrillar myopathy. Many of these horses were previously diagnosed with type 2 PSSM likely because pools of glycogen forming within disrupted myofibrils appeared to give

the false appearance of a glycogen storage disorder. MFM may represent a specific myopathy formerly grouped under the diagnosis of type 2 PSSM.

Mitochondrial Myopathy

A deficiency of mitochondrial respiratory chain function was identified in a 3-year-old Arabian filly that presented with profound exercise intolerance and normal serum CK activity 4 hours after exercise.[108] Over the course of years the filly developed significant muscle atrophy. During exercise at a trot, the horse would be unable to continue after 7 minutes, becoming stiff and sweating profusely. Venous pH and bicarbonate concentrations dropped abnormally after 6 minutes of trotting, lactic acidosis was present (20 mM), and the horse had dramatically reduced maximum oxygen consumption (maximal VO_2 0.5 mL/kg/sec; normal 2.5 mL/kg/sec). A deficiency of complex I (nicotinamide adenine dinucleotide [NADH]:ubiquinone reductase) in the respiratory chain was identified in muscle samples.

Idiopathic Chronic Exertional Myopathies

Many horses develop chronic ER for which no known cause is apparent. More research needs to be done to further define causes of exertional myopathies in horses.

Fibrotic Myopathy

Fibrotic myopathy affects semimembranosus/semitendinosus muscles and is usually a consequence of trauma to these muscles. Horses have a classic gait abnormality where the anterior phase of the stride ceases abruptly, causing the leg to be pulled back before the foot suddenly slaps the ground rather than continuing its forward motion. In acute cases these muscles may feel warm and painful on deep palpation. Chronically, hardened areas within the muscle may represent fibrosis and ossification.

The extent of tearing can be determined by ultrasonography, providing the muscle is within the depth of penetration of the ultrasound machine. Acute injuries are treated with cold therapy and stretching once the limb is no longer acutely painful. Deep heating ultrasound may be of help in promoting healing. For more subtle strain, intermittent electrical stimulation of focal areas within a muscle may be beneficial. The strength of stimulus necessary to induce contraction can be incrementally assessed and compared between left and right sides. Damaged muscle tends to respond with a greater degree of pain and contraction at lower stimulus strength. Underwater treadmill exercises to strengthen the muscles once healing is apparent on ultrasound can help restore normal limb function. Horses with a fibrotic band within the muscle or ossification of the muscle have a much poorer prognosis. Surgical resection of fibrotic muscle is attempted, but full restoration of function is unlikely to occur.[18]

NONEXERTIONAL MYOPATHIES

Specific causes of nonexertional rhabdomyolysis are listed in Box 10.2.

BOX 10.2 Nonexertional Rhabdomyolysis

1. Metabolic myopathy
   a. Glycogen branching enzyme deficiency in Quarter Horses
   b. Type 1 and type 2 polysaccharide storage myopathy
   c. Malignant hyperthermia
2. Inflammatory myopathies
   a. Immune mediated
      - Infarctive hemorrhagic purpura
      - Immune-mediated myopathy
3. Infectious
   a. Clostridial myositis
   b. *S. equi* myositis
   c. *Anaplasma* myositis
   d. Viral myositis
   e. *Sarcocystis* myositis
4. Nutritional myopathy
   a. Vitamin E and selenium deficiency
5. Toxic myopathy
   a. Ionophore toxicity
   b. Pasture myopathies
      - Hypoglycin A myopathy
      - Rayless goldenrod/white snakeroot
      - *Cassia occidentalis*
6. Traumatic myopathy
   a. Compressive anesthetic myopathy
   b. Trauma

Glycogen Branching Enzyme Deficiency

Pathogenesis

Glycogen branching enzyme deficiency (GBED) occurs in foals of Quarter Horse–related breeds caused by a premature stop codon in exon 1 of the *GBE1* gene.[109] Branching enzyme activity is minimal in skeletal and cardiac muscle as well as liver.

Prevalence

Nine percent of the breed is a carrier of this autosomal recessive mutation, and 3% of abortions are attributed to this disease in Quarter Horses.[110] The prevalence of carriers is particularly high in pleasure horses, with 26% carrying the *GBE1* mutation.[83]

Clinical Signs

Clinical signs of GBED include abortion in second or third trimester, stillbirth, hypothermia at birth, mild flexural deformities, intermittent seizures, skeletal and respiratory muscle weakness, and sudden death (Fig. 10.11).[109-111] Most foals diagnosed with GBED have presented with transient flexural contractures at 1 day of age. Persistent leukopenia, intermittent hypoglycemia, and moderately high serum CK (1000–15,000 U/L), AST, and γ-glutamyltransferase (GGT) activities are usually present in affected foals.

Diagnosis

A diagnosis is best obtained by confirming the presence of the *GBE1* genetic mutation in blood, hair, or tissue samples or by identifying typical PAS-positive inclusions in muscle or cardiac samples.[109-111] Gross postmortem changes are not evident, and routine hematoxylin and eosin stains of tissues may be normal or show basophilic inclusions in skeletal muscle and cardiac tissues. Frozen sections of muscle, heart, and liver show a notable lack of normal PAS staining for glycogen, as well as abnormal PAS-positive globular or crystalline intracellular inclusions (see Fig. 10.11).

FIG. **10.11** Foal with glycogen branching enzyme deficiency (GBED). Foals with GBED are often born with slight forelimb flexural limb deformities and appear mentally less alert and less active than healthy foals. (Photo courtesy Dr. Alicia Foley.)

Treatment

Although foals initially respond to treatment in neonatal intensive care, all foals with GBED have died. Death occurs as sudden collapse, with the longest survivor being 18 weeks of age.

Nutritional Myodegeneration

Nutritional myodegeneration (NMD) (white muscle disease, nutritional muscular dystrophy) is an acute degenerative disease affecting cardiac and skeletal muscle of primarily young foals.

Pathogenesis

NMD is caused by a dietary deficiency of selenium and/or vitamin E (α-tocopherol) in young, rapidly growing foals born to dams that consumed selenium-deficient diets during gestation.[112,113] Selenium and vitamin E appear to be synergistic in preventing NMD; however, selenium deficiency appears to be the most important contributor to oxidant damage of muscle cell membranes. Selenium is a key component of glutathione peroxidase (GSH-Px) that acts to destroy hydrogen peroxide and lipoperoxides that are generated during normal muscle metabolism. Vitamin E acts within the cell membrane as an antioxidant that scavenges free radicals that otherwise might react with unsaturated fatty acids to form lipid hydroperoxides. The precise interrelationships among selenium, vitamin E, other metabolic factors, and triggering mechanisms in NMD are not fully understood because many foals deficient in selenium and/or vitamin E have no evidence of muscle disease. In certain situations, deficiencies of both selenium and vitamin E are necessary for disease to occur. In other animals NMD can occur when a deficiency of only one of the nutrients is present and the other is normal in blood and tissues.

Clinical Signs

Some foals present with a cardiorespiratory syndrome characterized by dyspnea, a rapid irregular heartbeat, profound weakness, recumbency, and sudden death.[8,112] Other foals have primary skeletal muscle involvement with signs of weakness, trembling, stiffness, and inability to stand for more than short periods. Affected muscle groups are firm and painful to palpation. Dysphagia due to necrosis in the tongue may be the only sign in some affected foals and is frequently accompanied by aspiration pneumonia. The tongue, gastrocnemius, semitendinosus, semimembranosus, biceps femoris, lumbar, gluteal, and neck musculature are often affected.

Clinical Pathology

Serum CK and AST activities are usually in the thousands to hundreds of thousands of U/L. Myoglobinuria is common. Hyperkalemia, hyperphosphatemia, hyponatremia, hypochloremia, and hypocalcemia can occur with severe rhabdomyolysis when the normal distinction between extracellular and intracellular compartments is destroyed by massive tissue necrosis.[8] Neutrophilia is common due to the high incidence of aspiration pneumonia.

Diagnosis

Whole blood selenium (normal range 0.07 to greater than 0.1 ppm) or plasma α-tocopherol (normal range 1.1–2 ppm) concentrations below the normal range in conjunction with appropriate clinical signs are considered diagnostic. Selenium-dependent GSH-Px formed in the red cells during erythropoiesis could also provide an index of body selenium status. Adequate GSH-Px activities are greater than 20 to 50 U/mg of hemoglobin per minute in horses. However, GSH-Px reference values are only specific to the laboratory where the analysis is performed and must be validated by comparison with blood selenium concentration. Plasma samples for α-tocopherol analysis need to be put on ice immediately, protected from the light by wrapping in aluminum foil, and stored frozen (−21°F [−70°C]) if analysis is to be delayed. Tissue specimens can be assayed for selenium content. Normal liver concentrations of selenium are 1.05 to 3.5 ppm on a dry matter (DM) basis (fresh liver approximately 30% DM).

Pathology

Skeletal muscle degeneration is characterized by pale streaks of discoloration and a dry appearance of affected muscle, calcification, and intramuscular edema in bilaterally symmetric muscle groups.[112] Affected muscle bundles are often adjacent to apparently normal or minimally affected muscle. Histologically, affected muscle fibers are often hypercontracted and fragmented, with some mineralization of muscle fibers, and in later stages macrophage infiltration is notable.[114]

Treatment and Prognosis

The cardiorespiratory form of NMD carries a poor prognosis. In contrast, the skeletal form of NMD is more amenable to treatment if secondary complications such as pneumonia can be managed. Progressively decreasing CK activity and ability to stand are good prognostic indicators for NMD. The label

dose for selenium is 0.055 to 0.067 mg/kg (2.5–3 mg/45 kg) body weight given intramuscularly. Injections can be irritating so dilution in sterile saline and administration in muscles such as pectorals is recommended. Dosage should not be greatly increased above the label dose to prevent an inadvertent selenium toxicosis. Absorption and distribution of injectable selenium occurs rapidly and may account for the rapid improvement in clinical signs seen in reversible cases. Injectable selenium products contain a minimal amount of α-tocopherol (50 mg/mL [68 IU]), and additional supplementation with water-dispersible RRR-α-tocopherol is recommended (10 IU/kg).

Supportive therapy may include administration of antibiotics to help combat secondary pneumonia and infected decubital lesions that are common in recumbent patients. When dysphagia is present feeding via nasogastric tube, provision of adequate energy intake, and attention to the fluid and electrolyte balance are of critical importance if recovery is to be successful. Hyperkalemia may be life threatening in affected foals. Mineralocorticoids, alkalinizing fluids, and dextrose and insulin may be used to reduce circulating potassium concentrations.[8]

Foals with primary muscular NMD often show improvement after a few days of rest and treatment with selenium. They can often stand and walk within 3 to 5 days.

Prevention and Control

In regions where selenium deficiency exists, diets of pregnant mares need to be supplemented with selenium either in their daily concentrate or through additional oral supplementation to provide 1 mg of selenium per day.[115,116] Only limited selenium may cross the placenta; however, supplementation during lactation increases the levels of selenium in milk and thus provides a potential means of selenium supplementation in foals. In deficient areas, this increased level of selenium in milk may not meet a young animal's nutrient requirements.[117] In such cases injectable selenium products used every 30 to 45 days might be needed in areas where NMD is a particular problem.[118] Periodic blood sampling of foals in high-risk areas is recommended. On the basis of these assessments, adjustments to the rate or extent of selenium supplementation can be made. Access to high-quality green forage should ensure adequate vitamin E intake.

Masseter Muscle Myodegeneration

Pathogenesis

Masseter muscle swelling and degeneration occur in adult horses and can be followed by masseter muscle atrophy and trismus (Fig. 10.12). An inflammatory myopathy such as that seen in dogs with canine masseter muscle myositis has not been identified (Valberg, unpublished data). An association has been made between selenium deficiency and masseter muscle myodegeneration in some cases.[119-121] Histopathologic evidence of bilateral symmetric lesions in masseter muscles, as well as muscles of the hind and thoracic limbs, has been observed in such cases.[120]

Clinical Signs

Unilateral or bilateral swelling of the masseter and temporal muscles is the predominant acute clinical sign accompanied by pain or difficulty opening the jaw. Exophthalmos can be present. If tachycardia and dysrhythmias are present myocardial damage should be suspected. Chronic clinical signs include masseter muscle atrophy, trismus, dysphagia, and weight loss. Horses usually have normal postural and locomotor muscles on clinical examination, although stiffness has been reported. Accompanying clinical pathologic findings include pigmenturia, elevated serum AST and CK activity, and potentially elevated cardiac troponin concentrations. Ultrasonography is useful to determine the extent of masseter muscle swelling or atrophy and to assess myocardial dysfunction.

FIG. **10.12** Pronounced atrophy of the masseter muscle in a Quarter Horse resulting in prominence of the facial crest.

Diagnosis

Elevated serum CK and AST activities accompanied by low whole blood selenium concentrations (less than 1.1–2 ppm) support selenium deficiency as a cause of masseter muscle atrophy.

Treatment

Analgesics, intramuscular selenium (0.055–0.067 mg/kg), oral α-tocopherol (2000–5000 IU/day RRR-α-tocopherol), nutritional and fluid support if needed via stomach tube, and IV fluids are recommended. A fasciotomy to relieve pressure in masseter muscles has been advocated, but results are not reported. Progression to bilateral muscle atrophy can occur, and depending on the severity of myofiber and nerve damage this can resolve after a period of months. Prognosis is guarded, but there are individual reports of successful treatment. Without early treatment, permanent trismus can occur due to muscle atrophy and fibrosis.

Vitamin E–Deficient Myopathy

Pathogenesis

Vitamin E–deficient myopathy may be an entity unto itself or a predecessor to development of equine motor neuron disease (EMND). Clinical signs of EMND occur in the absence of the

hallmark of EMND, neurogenic atrophy in sacrocaudalis dorsalis medialis muscle biopsies.[13] Unlike EMND, horses with a vitamin E–deficient myopathy have characteristic histochemical alterations in mitochondrial distribution that appears to be a reversible manifestation of skeletal muscle mitochondrial oxidative stress.[13]

Clinical Signs

Horses can present with a gradual onset of reduced performance and muscle loss, but usually owners report a sudden onset of muscle weakness. Horses show signs of symmetric generalized muscle atrophy, trembling, muscle fasciculations, inability to fix the stifles with weight shifting, and frequent attempts to lie down (Fig. 10.13A). Differential diagnoses for horses with muscle atrophy are provided in Box 10.3.

Diagnosis

Low muscle α-tocopherol concentrations have been identified in affected horses, and serum α-tocopherol concentrations can be low or within the normal range. The distinction between vitamin E–deficient myopathy and EMND is the presence of myopathic rather than neuropathic features in sacrocaudalis dorsalis muscle biopsies and the remarkable response to treatment with vitamin E.[13,122] The characteristic finding in muscle biopsy is the presence of a "moth-eaten" staining pattern in mitochondrial stains of frozen sections of the sacrocaudalis dorsalis muscle. Mitochondrial stains of muscles such as the gluteus medius are normal.

FIG. **10.13** (A) Belgian Warmblood gelding with generalized symmetric muscle loss, decreased performance, and low serum and muscle vitamin E concentrations. Muscle biopsy of the sacrocaudalis dorsalis muscle revealed numerous moth-eaten mitochondria establishing a diagnosis of vitamin E–deficient myopathy. (B) The same horse after 8 weeks of vitamin E treatment and an exercise program. In addition to weight gain, increased muscle mass in the hindquarters is apparent.

Treatment

Vitamin E–deficient myopathy is highly responsive to treatment with natural liquid RRR-α-tocopherol (5000 IU/day for a 500-kg horse) and a very gradual reintroduction to exercise once strength returns (Fig. 10.13B).[13] Powdered formulations of α-tocopherol acetate are not recommended as an acute treatment because they do not restore serum α-tocopherol concentrations at the same rapid rate as liquid α-tocopherol.

INFLAMMATORY MYOPATHIES

Viral-Associated Myopathies

Infrequently, skeletal muscle degeneration and stiffness occur in association with equine influenza A2 and equine herpesvirus 1 in association with typical clinical signs of viral disease.[123,124]

Sarcocystosis

Pathogenesis

Equine skeletal muscle, especially esophageal muscle, commonly contains a few dormant cysts of the sporozoan parasite *Sarcocystis fayeri,* for which the dog is the definitive host. Cysts usually pose no problem, but when ponies and horses were experimentally infected with large doses of *S. fayer* dysphagia, severe myositis and stiff gait occurred. There are also a few clinical cases of *S. fayeri* myositis reported in horses.[125]

Clinical Signs

Clinical signs include fever, malaise, chronic muscle atrophy, stiffness, weakness, and muscle fasciculations. Clinicopathology is typified by normochromic normocytic anemia and elevations in CK and AST activities.[125,126]

BOX 10.3 Atrophy

1. Myogenic
   a. Disuse
   b. Cachexia
   c. Cushing's disease
   d. Immune-mediated myositis (rapid atrophy)
   e. Vitamin E–deficient myopathy
   f. Type 2 PSSM
   g. Severe rhabdomyolysis
2. Neurogenic atrophy
   a. Focal nerve damage
      - Trauma
      - Tumor
      - Infectious (equine protozoal myelitis)
      - Idiopathic peripheral neuropathy
   b. Generalized nerve damage
      - Equine motor neuron disease

Diagnosis

Diagnosis of sarcocystosis requires history, clinical signs, laboratory and serologic evaluation, and the demonstration of immature cysts in muscle biopsies, ideally in conjunction with inflammatory infiltrates.

Treatment and Control

Successful treatment of sarcocystosis is reported using phenylbutazone, trimethoprim-sulfamethoxazole, and pyrimethamine.[125] Current antiparasitic medications such as diclazuril should also be effective. Control involves preventing gross contamination of equine feeds with carnivore feces.

Bacterial-Associated Myositis

Clostridial Myonecrosis

Clostridial myonecrosis is caused by infection with one of a variety of clostridial bacteria, most commonly *Clostridium perfringens.* Sporadic cases have been attributed to *C. septicum, C. chauvoei, C. novyi,* and other related species. Clostridial organisms are gram-positive, rod-shaped, spore-forming obligate anaerobes with the potential to produce a variety of exotoxins that can cause extensive tissue damage and necrosis with secondary life-threatening toxemia, multiple-organ failure, and death.

Pathogenesis. Clostridia gain access to the body through the alimentary tract and are present in liver and muscle in the dormant spore form.[127] Most reports of clostridial myonecrosis in horses implicate intramuscular injection sites or, less commonly, puncture wounds or other traumatic injuries in creating a suitable environment for the development of clostridial myonecrosis.[128,129] Intramuscular injections of irritating drugs such as NSAIDs, prostaglandins, anthelmintics, and antihistamines are commonly implicated as initiating factors for clostridial myonecrosis in horses. When local tissue is devitalized and the appropriate anaerobic condition is created, spores may vegetate and begin exponential growth, releasing powerful exotoxins that act locally and systemically to create widespread organ dysfunction. The specific toxins vary depending on the clostridial species involved. With *C. perfringens* infection, the most important toxin implicated in clinical disease is alpha toxin, a dermonecrotic toxin with phospholipase C and sphingomyelinase activity. Theta toxin (perfringolysin), kappa toxin (collagenase), and mu toxin (hyaluronidase) may also play important roles in the development of clinical disease. *Clostridium septicum, C. chauvoei, C. sporogenes,* and mixed infections are associated with a high fatality rate, whereas *C. perfringens* type A has a mortality rate of 20% in horses that receive early and aggressive treatment.[129]

Clinical Signs. Horses initially have clinical signs related to their wound or disease that required an intramuscular injection. Depending on the injection site, lameness or a sore neck may be the initial clinical sign. Within 48 hours of the inciting event horses develop swelling and variable crepitus at the wound/injection site accompanied by depression, fever, toxemia, and tachypnea. Clostridial infection can migrate along fascial planes to affect extensive areas of the body with resultant spread of crepitus (Fig. 10.14). Severe toxemia, multiorgan failure, coma, and death can occur within the next 12 to 24 hours in severely affected horses. An intravascular hemolytic crisis may develop late in the disease process in some affected horses. It is unclear whether hemolysis is the result of a bacterial exotoxin or another mechanism.

Diagnosis. Hematology and serum biochemical analyses usually reflect a generalized state of toxemia with hemoconcentration and a stress/toxic leukogram. In severely affected horses with rapid disease progress, there is usually evidence of multiorgan failure and disseminated intravascular coagulation. Moderate increases in the activities of serum CK and serum AST usually occur; however, they often do not reflect the clinical toxicity of clostridial myonecrosis. Characteristic hyperechoic gas accumulation and hypoechoic fluid are usually observed with ultrasonography of the affected site. Fasciotomy or aspiration of the affected area usually reveals the presence of malodorous, serosanguineous fluid with an odor of rancid butter. Aspirates of affected tissues examined via direct smears or fluorescent antibody staining should show characteristic gram-positive, rod-shaped bacteria. Anaerobic bacterial culture of freshly acquired samples may also be of value. At postmortem, swelling, crepitus, and autolysis are rapid, and bloodstained fluid is often observed discharging from body orifices.

Treatment. Wound fenestration and aggressive surgical debridement over the entire affected area are required for successful treatment.[129] Sufficient fenestrations should be made to establish drainage and aeration over the entire affected area. The horse should be frequently reevaluated to assess spread of cellulitis and repeat fenestration procedures may be required. Fenestrations should be made in parallel to muscle fiber bundles to prevent excessive scarring and future impairment of muscle function. Additional treatment includes high doses of IV potassium penicillin (up to 88,000 IU/kg) every 2 to 4 hours until the animal is stable (1–5 days) in combination with oral metronidazole. Aggressive fluid, electrolyte, and cardiovascular support is often required. Severe hypotension, diminished cardiac output, impaired renal function, and high levels of myoglobinemia place the patient at risk for pigment nephropathy and acute renal failure. Extensive skin sloughing over the affected area is common in surviving horses. The prognosis for life in all horses with clostridial myonecrosis is guarded, and the owner should be aware from the start of treatment that extensive skin sloughing can occur and euthanasia could become a consideration at a later stage.

Anaplasma-Associated Rhabdomyolysis

There is a report of a Quarter Horse with clinical signs of stiffness, pyrexia, tachycardia, and marked elevations of serum CK activity in association with *Anaplasma phagocytophilum* infection.[130]

Streptococcus equi Subsp. *equi*–Associated Myopathy

Acute Rhabdomyolysis

Pathogenesis. Quarter Horses generally less than 7 years of age can develop severe, generalized rhabdomyolysis in association with an active *Streptococcus equi* subsp. *equi* infection (referred to as *S. equi* for the remainder of this chapter).[131,132] Two etiologies have been proposed: (1) a toxic shock–like reaction arising from profound nonspecific T-cell stimulation by streptococcal superantigens with the release of high levels of inflammatory cytokines and (2) bacteremia with local multiplication and production of exotoxins or proteases within skeletal muscle. *S. equi* virulence factors that may account for muscle necrosis include an unidentified cytotoxic protein, several proteases, streptokinase, and streptolysin S.[133] Although *S. equi* has not been cultured in skeletal muscle from horses

FIG. **10.14** *Clostridium perfringens* myositis in the cervical muscles following an intramuscular injection. The low head posture was due to pain and depression. (A) Malodorous fluid exudes from multiple fenestrations made over areas of crepitus. (B) Granulation tissue and minor sloughing of skin is apparent at wound edges. (C) Subsequent massive sloughing of skin. (D) Healing wound after many months of treatment.

with rhabdomyolysis, *S. equi* bacteria have been identified in affected muscle using immunofluorescent stains for both Lancefield group C carbohydrate and *S. equi* M protein.[131] There is currently no evidence that the *S. equi* involved is an atypical genetic strain of *S. equi*.[134]

Clinical Signs. Affected horses have evidence of enlarged submandibular lymph nodes and/or guttural pouch empyema. Horses develop a stiff gait that progresses rapidly to markedly firm, swollen, painful epaxial and gluteal muscles. The majority of reported cases become recumbent, are unable to rise, and develop unrelenting pain necessitating euthanasia within 24 to 48 hours of hospitalization.

Diagnosis. Hematologic abnormalities include mature neutrophilia, hyperfibrinogenemia, normal albumin, and marked increases in serum CK (115,000–587,000 U/L) and AST activities (600–14,500 U/L). Titers to the M protein of *S. equi* are low in affected horses, unless horses have been recently vaccinated for strangles. Titers to another protein called *myosin binding protein* have been high in a small number of horses that were tested.[131] Endoscopy of the guttural pouches reveals pools of pus that are positive in culture and polymerase chain reaction (PCR) for *S. equi*.

At postmortem examination, large pale areas of necrotic muscle are evident in hindlimb and lumbar muscles. The histopathologic lesions are characterized by severe acute myonecrosis with a degree of macrophage infiltration. Sublumbar muscles often show the most severe and chronic necrosis as indicated by greater macrophage infiltration of myofibers.

Treatment. A high mortality rate has been reported in horses receiving IV penicillin therapy once clinical signs of strangles and myopathy were well established. It is possible that early recognition of the signs of muscle stiffness in horses with *S. equi* infections and prompt aggressive treatment may be required for a successful outcome. Although streptococcal species are exquisitely susceptible to β-lactam antibiotics, a mortality rate of 85% has been reported in human group A streptococcal myositis despite penicillin treatment.[135] An antimicrobial that inhibits protein synthesis, such as rifampin, combined with IV penicillin, might enhance survival rates in horses with *S. equi* rhabdomyolysis. In addition, flushing infected guttural pouches and draining abscessed lymph nodes will diminish the bacterial load. NSAIDs and possibly high doses of short-acting corticosteroids may assist in diminishing the inflammatory response. Control of unrelenting pain is a major challenge in horses with severe rhabdomyolysis. Constant rate infusion of lidocaine, detomidine, or ketamine may provide better anxiety and pain relief than periodic injections of tranquilizers. Horses should be placed in a deeply bedded stall and moved from side to side every 4 hours if they are unable to rise. Some horses may benefit from a sling if they will bear weight on their hindlimbs when assisted to stand.

FIG. **10.15** Infarctive hemorrhagic purpura resulting in firm painful swelling within the muscles of the antebrachium on the right forelimb. (Photo courtesy Dr. Raphaela Texeira.)

FIG. **10.16** Extensive infarction of the large colon in a horse with infarctive hemorrhagic purpura.

Immune-Mediated Myopathies

Infarctive Purpura Hemorrhagica

Pathogenesis. Infarctive purpura hemorrhagica (IPH) is a severe form of purpura with a high fatality rate. Infarctions initially occur in skeletal muscles that are compressed during recumbency and progress to involve multiple organs, including the gastrointestinal tract and the mucous membranes.[136] In one study prevalence of IPH was 3 of 53 cases of purpura.[137] Exposure to *S. equi* within 3 weeks of presentation, vaccination for *S. equi,* or a concurrent *Salmonella infantum* infection are reported inciting causes. IPH resembles Henoch-Schönlein purpura in humans, which is characterized by infarctive vasculitis of the skin, kidneys, and gastrointestinal tract resulting from immunoglobulin A (IgA) immune complex deposition. Immune complexes present in the sera of horses with IPH appear to be composed primarily of IgM or IgA and streptococcal M protein.[138] Deposition of complement near immune complexes in vessel walls may result in cell membrane destruction, cell death, and vascular occlusion.

Clinical Signs. The primary presenting complaint is often painful lameness with limb swelling, muscle stiffness, and/or colic (Fig. 10.15). Careful physical examination reveals classic signs of IPH such as petechiae, oral infarctions resembling ulcers, and well-demarcated moderate limb edema. Horses with IPH will have focal firm intramuscular swellings in abdominal, pectoral, adductor, and tarsocrural muscles. Horses with evidence of colic may have markedly decreased borborygmi and hemorrhagic gastric reflux.

Diagnosis. Hematologic abnormalities include a leukocytosis characterized by neutrophilia with a left shift and toxic change, hyperproteinemia, hypoalbuminemia, and marked elevations in CK (47,000–280,000 U/L) and AST (960–7000 U/L) activities.[132,139] Serum titers for enzyme-linked immunosorbent assay (ELISA) M protein are usually markedly elevated.[139] Peritoneal fluid obtained by abdominocentesis may be normal or may have an increased total protein and nucleated and red blood cell counts if gastrointestinal infarction is present. Ultrasonographic examination of swollen muscle reveals focal hypoechoic lesions within muscle tissue. Biopsies of abnormal muscle show diffuse acute coagulative necrosis, whereas samples from palpably normal muscle tissue show no pathologic abnormalities.

Postmortem findings of horses with IPH include infarction of the skeletal musculature, skin, gastrointestinal tract, pancreas, and lungs and *S. equi* abscessation of a lymph node (Fig. 10.16). Definitive histopathologic findings include leukocytoclastic vasculitis and acute coagulative necrosis resembling infarction in numerous tissues.[139]

Treatment. Early recognition of signs and aggressive antibiotic and corticosteroid treatment are essential to combat the high fatality rate with IHP. Treatment of Henoch-Schönlein purpura in humans, including cases with intestinal infarctions, involves high-dose IV pulse therapy with methylprednisolone followed by oral corticosteroids plus immunosuppressive agents such as cyclophosphamide and azathioprine. One horse with IPH was successfully treated with penicillin, NSAIDs, and 3 weeks of dexamethasone (0.1–0.07 mg/kg) followed by a 10-week tapering course of oral prednisolone (2 mg/kg initially).[139]

Immune-Mediated Myositis in Quarter Horse–Related Breeds

Pathogenesis. Malaise, rapid onset of severe atrophy particularly affecting epaxial and gluteal muscles, and high serum CK and AST activities occur in equine immune-mediated myositis (IMM) as a result of lymphocytic destruction of myofibers by CD4+ and to a lesser extent CD8+ cells.[11] For yet unknown reasons a loss of self-tolerance to antigens expressed by muscle cells may occur after rhabdomyolysis, infection with *S. equi,* or vaccination. Myoblasts and myotubes do not normally express detectable human leukocyte antigen (HLA) class II molecules and therefore do not display potentially immunogenic peptides to cells of the immune system. Loss of self-tolerance could occur with IMM as a result of activation of otherwise inactivated autoreactive T cells by either (1) shared epitopes with an infectious agent causing antigenic mimicry; (2) microbial superantigens produced by infectious agents; (3) high concentrations of local cytokines such as interleukin-2 (IL2) or IL4; or (4) expression of an abnormal protein on sarcolemmal membranes. There is strong evidence of a genetic susceptibility to IMM in the Quarter Horse breed.[11]

History and Clinical Signs. Generalized IMM usually affects horses of Quarter Horse–related breeds that are either younger than 8 years of age or older than 16 years of age without gender predilection.[11] A history of exposure to a

FIG. **10.17** Pronounced atrophy of the gluteal muscles of a young Paint Horse with immune-mediated myositis. Atrophy is more severe on the right side, which creates shadowing over the area where a biopsy was previously obtained. (Photo courtesy Dr. Carrie Finno.)

triggering factor exists in approximately one third of cases; the known triggering factor is usually exposure to *S. equi,* another respiratory pathogen, or possibly vaccination. The most prominent clinical sign is dramatic muscle atrophy, particularly of the epaxial and gluteal muscles, accompanied by stiffness and general malaise (Fig. 10.17). Muscle atrophy is usually rapid and may progress to involve 40% of the horse's muscle mass within a week. Horses can develop generalized weakness leading to frequent periods of recumbency. Muscle atrophy often persists for months before a gradual increase in muscle mass occurs.

Diagnosis. Hematologic abnormalities apart from elevations in CK and AST activities are uncommon with IMM unless there is a concurrent infectious process. During the acute phase of muscle atrophy serum CK and AST activities are moderately to markedly elevated, but during the later phase of chronic atrophy serum CK and AST activities can be normal. The most useful diagnostic test during the acute phase of the disease is a muscle biopsy of the epaxial and/or gluteal muscles.[11] Several formalin-fixed Trucut samples from the epaxial or gluteal muscles are often sufficient to establish a clinical diagnosis. Histologic abnormalities include infiltration of the myofibers by lymphocytes, lymphocytic vasculitis, anguloid atrophy of the myofibers, fiber necrosis, and multinucleated giant cells. Biopsies taken several weeks after the onset of atrophy may reveal only nonspecific findings of myogenic atrophy without evidence of the hallmark feature of lymphocytic infiltrates. Biopsies of the semitendinosus or semimembranosus muscles may not be helpful in establishing a diagnosis because they are often normal or have evidence of atrophy and mild inflammatory cell infiltration.

Treatment and Prevention. Appropriate antimicrobials should be selected if there is evidence of concurrent infection. Corticosteroids are the mainstay of treatment, and, unlike immune-mediated disorders in humans and dogs, antiinflammatory rather than immunosuppressive doses are effective. Recommended dosages are dexamethasone (0.05 mg/kg intravenously) for 3 days, followed by prednisolone (1 mg/kg PO) for 7 to 10 days tapered by 100 mg per week over 1 month.[11] Prevention is challenging because only a small proportion of affected horses have a history of a triggering factor. Suggested strategies include preventing exposure to respiratory infections where possible; spacing out vaccines to prevent a surge of inflammatory cytokines; avoiding immune stimulants; and monitoring horses closely to institute treatment early if atrophy recurs. Malaise often resolves rapidly following treatment with corticosteroids and muscle atrophy quickly ceases. Serum CK activity often returns to normal after 7 to 10 days of corticosteroid treatment. Recovery of the muscle mass is more gradual and usually takes 2 to 3 months, and some focal residual muscle atrophy can remain.[11] Horses that are not treated with corticosteroids may develop extensive muscle atrophy, but in many cases muscle mass will gradually recover. Atrophy recurs in approximately 40% of susceptible horses, and these horses may require repeated bouts of corticosteroid treatment.

Systemic Calcinosis

Pathogenesis. Systemic calcinosis occurs in humans, particularly those on dialysis because of renal failure. In human medicine a product of Ca multipled by P of greater than 65 to 70 is used as an indicator of a potential risk of dystrophic calcification.[142] A Ca × P product greater than 66 was present in horses that developed systemic dystrophic calcification. The reason for the elevated Ca × P in horses with systemic calcinosis is not known, but there is a strong suspicion that a predisposing inflammatory process could be a trigger. Hyperphosphatemia can induce dystrophic calcification through (1) passive calcium phosphate deposition from phosphate supersaturation in the blood; (2) an active process promoting the conversion of smooth muscle cells to osteogenic cell types; (3) directly increasing parathyroid hormone secretion and transcription; or (4) interference with renal production of 1,25-(OH)2D levels, which has been associated with increased coronary artery calcification in humans.[143]

A novel fatal syndrome of systemic dystrophic calcification called *systemic calcinosis* or *calciphylaxis* occurs in horses that share a similar initial presentation to generalized IMM that is followed by diverse organ failure.[140,141] Systemic calcification appears to be triggered when the serum calcium concentration multiplied by serum phosphorus concentration exceeds 65.

Clinical Signs. All horses reported with systemic calcinosis have been of Quarter Horse–related breeds and under 9 years of age.[140,141] Initial clinical signs include a mild fever, malaise, stiffness, and loss of muscle mass, particularly over the lumbar and gluteal area (Fig. 10.18). Many horses have evidence of cough, tachypnea, and mild ventral edema. As the disease progresses progressive weakness, inability to remain standing, respiratory distress, laminitis, or gastrointestinal inflammation may become evident. Whether these signs are a direct result of systemic dystrophic calcification or an underlying precipitating inflammatory disorder is unclear.

Diagnosis. A wide range of hematologic abnormalities may be observed depending on the underlying disease process that precedes dystrophic calcification. The most consistent alterations in the hemogram are hyperfibrinogenemia and mild leukocytosis.

FIG. **10.18** Severe muscle wasting of the topline and hindquarter muscles in a horse with systemic calcinosis.

In the biochemistry profile the product of calcium multiplied by phosphorus is greater than 65, and serum CK activities are at least threefold higher than the normal range.[140]

Systemic calcinosis should be suspected if a horse presents with muscle atrophy, malaise, respiratory distress, or renal insufficiency with evidence of hyperfibrinogenemia and an elevated Ca × P product. The histopathologic findings in muscle biopsies resemble those of IMM; however, multinucleated giant cells are consistently present, and dystrophic calcification of muscle fibers is also evident.[140] At postmortem, dystrophic calcification is also evident in one or all of the following tissues in addition to skeletal muscle, the alveoli in pulmonary tissue, cardiac myofibers, renal tubules, and tunica intima of blood vessels.[140] In one case, dramatic lesions of arterial medial calcification of the aorta and coronary and pulmonary arteries were reported.[141]

Treatment and Prognosis. This condition is often associated with a fatal outcome. Horses are usually euthanized because of progressive weakness, inability to remain standing, respiratory distress, laminitis, or other underlying disease. Treatment is largely directed toward the underlying inflammatory condition. In human medicine, corticosteroid treatment has been implicated as a triggering mechanism for systemic calcinosis. In horses, however, the clinical signs that precede systemic calcinosis so closely resemble IMM, a corticosteroid-responsive disease, that corticosteroid treatment is often instituted when signs of rapid muscle atrophy develop.

Idiopathic Immune-Mediated/Inflammatory Myopathies

Individual cases of myositis occur outside the Quarter Horse breed that likely have an inflammatory or immune-mediated basis. Focal atrophy of neck muscles was reported in a 16-year-old pony with normal serum CK and AST activities and interstitial aggregates of lymphocytes, plasma cells, histiocytes, and eosinophils.[144] Muscle mass returned to normal following treatment with dexamethasone. Within the Neuromuscular Diagnostic Laboratory database at Michigan State University a small number of horses of breeds other than Quarter Horses have also been diagnosed with a suspected inflammatory or immune-mediated myositis. These included an Anglo-Arabian, a mixed breed pony, a Percheron, a Warmblood, and two Thoroughbreds. The common clinical presentation was muscle atrophy, and the suspicion of an inflammatory/immune process was based on the presence of lymphocytic infiltrates in muscle biopsy specimens.

TOXIC CAUSES OF RHABDOMYOLYSIS

Chemical

Horses can periodically gain access to ionophores when equine grains are mixed in a feedmill that did not properly clean machinery after producing cattle feeds containing ionophores. The primary clinical signs of ionophore toxicity depend on the type of ionophore but usually suggest cardiomyopathy or neurologic disease rather than overt rhabdomyolysis. Experimental studies have indicated that LD_{50} values for monensin are 2 to 3 mg/kg body weight for horses versus 21 to 36 mg/kg for cattle.

Several miniature horses being fed a complete feed containing tetrachlorovinphos, an oral fly control agent, were reported to develop chronic myonecrosis involving masseter, tongue, neck, respiratory, and postural muscles and occasionally cardiac muscle.[145] Affected horses showed signs of lethargy, dysphagia, fasciculations, tachypnea, and tachycardia. Muscle tissue showed evidence of chronic myonecrosis and lipid accumulation. Myonecrosis was attributed to acetylcholine accumulation at muscarinic and nicotinic sites producing oxidant stress. Low selenium concentrations may contribute to the toxicosis.

Blister beetle toxicosis can cause elevations in serum CK in some horses.[146]

Plants

Cassia obtusifolia (sicklepod) is prevalent in the southeastern United States, and ingestion of seeds can cause degenerative myopathy and cardiomyopathy with evidence of myofiber atrophy, segmental necrosis, and mitochondrial disruption.[147] Tremetone-containing plants can cause a fatal cardiomyopathy and severe skeletal muscle degeneration in horses when ingested at 0.5% to 2% of body weight.[148,149] Both white snakeroot *(Eupatorium rugosum),* which grows in shaded areas of the eastern and central United States, and rayless goldenrod *(Isocoma wrightii),* which is common in the Southwest on open pastures, contain tremetone. Tremetone remains active in hay and in the stalks of the dead plants on pasture, so both the fresh and the dried forms of the plants should be kept from horses.[150] Microsomal activation of the toxin in the liver may be necessary for toxic effects.[148]

Hypoglycin a Myopathy

Pathogenesis. Seeds or young shoots of *Acer* species trees such as the box elder *(Acer negundo)* and the European sycamore maple *(Acer pseudoplatanus)* contain highly variable amounts of the toxic nonproteogenic amino acid hypoglycin A (Fig. 10.19).[151,152] Hypoglycin A is metabolized in the liver to methylenecyclopropylacetic acid (MCPA), and MCPA CoA irreversibly binds to multiple acyl CoA dehydrogenases, enzymes that are essential for metabolism of short- and medium-chain fatty acids and branched chain amino acids.[9,153] Accumulation of fat esters damages muscle cell membranes, and an energy deficiency arises from an inability to metabolize fat.

Prevalence. Cases of hypoglycin A myopathy have been reported in northern and central Europe, the United Kingdom, New Zealand, and central and northeastern North America.

FIG. **10.19** (A) Seeds from box elder trees. (B) Sycamore maple seed. When either seeds are ingested by horses they can cause hypoglycin A myopathy.

The distribution of cases overlaps with the distribution of sycamore maple trees (UK and Europe) or box elder trees (North America).[14,154-157] Before identification of the toxin, hypoglycin A myopathy was termed *atypical myopathy* or *seasonal pasture myopathy* because it occurred in pastured horses in the fall and less often the spring and often preceded by wet, windy weather. Affected horses are usually young or new to affected pastures and kept on wooded pastures for more than 12 hours a day without additional feed provided.[158,159] Selenium deficiency appears to enhance toxic effects.[160]

Clinical Signs. Clinical signs develop acutely within 3 to 5 days of exposure to toxic doses and include muscular weakness, sweating, fasciculations, stiffness, tachycardia, tachypnea, recumbency, and, when urine is observed, myoglobinuria. A rapid rise in respiratory rate is usually followed by collapse and death from respiratory or cardiac failure. Pasture-mates can be subclinically affected.

Diagnosis. A high index of suspicion of hypoglycin A myopathy occurs in horses with rhabdomyolysis and an acidic urine pH. The most notable change in serum biochemistry is a marked increase in serum CK and AST activity, which is often accompanied by hyperglycemia, lactic acidemia, and in some cases elevated serum troponin I concentrations.[161] A definitive diagnosis can be made by identifying a specific pattern of accumulation of serum acylcarnitines and urine organic acids and glycine conjugates typical of a deficiency in multiple acyl CoA dehydrogenases, as well as isolation of the conjugated toxic metabolite methylenecyclopropyl acetic acid (MCPA) or hypoglycin A in blood or urine.[9,151,153,154] Postmortem findings include extensive necrosis in deep postural and respiratory muscles and the myocardium in 50% or more of cases. Frozen sections of myocardium, intercostal, diaphragm, or deep postural muscles show marked intracellular lipid accumulation in oxidative fibers (oil red O stain).[14,156]

Treatment and Prognosis. The mortality rate for horses with overt clinical signs is high at 75%; however, early recognition may improve the prognosis.[159] Early aggressive fluid therapy with antioxidant and antiinflammatory treatment, including dimethylsulfoxide (DMSO), vitamin E, vitamin C, and NSAIDs, is indicated.[14] Cograzing horses with elevated serum CK activity and no clinical signs may be successfully treated if removed from the source of seeds immediately.

Although many older horses are asymptomatic on pastures with *Acer* species trees, young horses or new horses should not be pastured with box elder or European sycamore maple trees in the fall or early spring. Provision of additional feed or reducing grazing time during these seasons may also decrease the incidence of hypoglycin A myopathy.

POSTANESTHETIC MYOPATHY

Postanesthetic myopathies occur in several forms: focal myopathy-neuropathy, generalized postoperative rhabdomyolysis, and fulminant malignant hyperthermia.

Focal Myopathy

Pathogenesis

Focal myopathy and potentially neuropathy occurs in muscles that are in contact with a hard surface during anesthesia or in muscles that have positional occlusion of arterial blood supply. If mean arterial pressure is allowed to fall below 70 mm Hg for several hours during inhalation anesthesia the incidence of postanesthetic myopathy increases substantially.[162,163] Muscles with dense fascia are most susceptible to necrosis as arterial blood flow and oxygen supply decrease further with the increased pressure within a compartmentalized swollen muscle. Commonly affected muscles include triceps, deltoid, masseter, hindlimb extensors, or, if the horse has been in dorsal recumbency, the hindlimb adductor and gluteal muscles.[164-166] Injury can also occur to nerves in the compressed swollen muscles, resulting in temporary radial, peroneal, or femoral nerve paralysis.

Clinical Signs

Clinical signs become apparent on recovery or 30 to 60 minutes after recovery from anesthesia. Affected muscles are swollen, hot, and painful on deep palpation, and the horse is often reluctant to bear weight on the affected limb. Weakness of affected muscles is common, particularly with peripheral nerve involvement. In some horses this condition may limit the animal's ability to stand for some time following anesthesia. The loss of muscle strength, particularly when involving adductor muscles, can contribute to orthopedic injury during repeated attempts to rise. Many horses with mild to moderate muscle injury recover over a period of hours to days even if untreated.[164]

Diagnosis

Diagnosis is based on a history of anesthesia or prolonged recumbency, clinical signs, and marked elevations in serum CK activity (thousands to tens of thousands of IU/L) within 4 to 6 hours after anesthesia.

Treatment

Antiinflammatory drugs, dimethylsulfoxide, and dantrolene sodium 2 to 4 mg/kg PO often are sufficient in mild

to moderate cases.[59] Significant muscle atrophy may develop over the ensuing 3 to 4 weeks but usually will resolve within 2 to 3 months unless substantial nerve damage has occurred. Treatment of more severe cases is outlined previously in this chapter (see section on treatment of acute rhabdomyolysis).

Prevention

Correct positioning and judicious use of padding and water- or air-filled mattresses can reduce dependent muscle pressure up to 50%, thereby aiding in the reduction of this disorder. In addition, by elevating the upper limb during anesthesia, the pressure on the lower limbs is significantly reduced. Pulling the lower forelimb forward also markedly reduces pressure in the dependent triceps muscle. When the horse is in dorsal recumbency, padding under the shoulders and hips is absolutely imperative.

Maintaining anesthesia at the lightest plane possible for a specific surgical procedure is beneficial in prophylaxis. Similarly, if possible, maintaining systemic mean arterial blood pressure above 80 to 85 mm Hg during anesthesia is advisable. The use of ionotropic agents such as dobutamine during anesthesia has been useful in reducing the occurrence of anesthetic myopathies. Administration of dantrolene sodium (2 to 4 mg/kg PO) 1 hour before induction of anesthesia may result in a reduction in the incidence of this myopathy; however, decreased cardiac output can occur in conjunction with higher Dantrium doses.[72]

Generalized Postanesthetic Myopathy

Pathogenesis

The development of generalized rhabdomyolysis and weakness in horses can occur during recovery from anesthesia or hours after recovery. In some cases, systemic hypotension and hypoxemia may create local ischemic lesions, with the pathologic changes becoming more generalized as a result of the stress of anesthesia and the sensitivity of muscle cells to anesthetic agents or muscle relaxants.[162,164] In other cases, an underlying myopathy such as hyperkalemic periodic paralysis, recurrent exertional rhabdomyolysis, or PSSM may increase the risk of a generalized postanesthetic myopathy.[34,38,95,167]

Clinical Signs

Anxiety, hyperthermia, tachycardia, tachypnea, profuse sweating, and myoglobinuria with firm painful swelling of multiple muscle groups is an occasional serious complication of anesthesia.[165,166] Horses may not be able to rise and may struggle violently, resulting in prolonged, traumatic recoveries.

Diagnosis

Diagnosis is based on clinical signs and assessment of serum CK activity taken at least 4 hours after anesthesia to allow levels to peak.

Treatment

Aims of therapy include pain relief, correction of fluid and electrolyte deficits, prevention of ongoing necrosis, and nursing care as outlined previously in this chapter (see section on treatment of acute rhabdomyolysis).

Prevention

The principles described for localized myoneuropathies apply to the prevention of generalized anesthetic-related myopathies. Horses with HYPP should be premedicated with acetazolamide. Dantrolene sodium at 2 to 4 mg/kg PO 1 to 2 hours before anesthesia may be beneficial in reducing the incidence of postanesthetic myopathies in problematic horses; however, 6 mg/kg has caused decreased cardiac output and hypotension, as well as elevated serum potassium, which would be detrimental to horses with HYPP.[72,168]

Malignant Hyperthermia

Pathogenesis

Fulminant cases of malignant hyperthermia (MH) are documented in horses of many breeds. In Quarter Horses a mutation in the ryanodine receptor 1 *(RYR1)* gene, the same gene involved in MH of swine, has been linked to fulminant anesthetic reactions caused by excessive calcium release from the sarcoplasmic reticulum.[67-72] In other breeds, a specific cause of MH reactions has not been identified. Excessive myoplasmic calcium concentrations result in muscle contractures, anaerobic metabolism of glycogen, hyperthermia, lactic acidosis, and hypercapnia.

Clinical Signs

Marked muscle rigidity, hyperthermia, hyperkalemia, hypercapnia, and metabolic and respiratory acidosis develop during anesthesia.[38,70,169,170] Horses usually die within a matter of hours. In some cases, shock and pigmenturia may lead to renal failure.

Treatment and Prevention

Genetic screening for MH in Quarter Horses and Paints may be warranted before elective procedures, although the prevalence of the MH mutation is less than 1% in these breeds. If hyperthermia and contracture develop during anesthesia, anesthesia should be immediately discontinued. Attempts to cool the animal with alcohol or cold-water baths are indicated. IV administration of sodium bicarbonate at dosages calculated from acid-base measurements is most appropriate. If not possible, a dosage of 1 to 2 mEq/kg slowly is recommended. Administration of a large amount of soluble, lyophilized dantrolene sodium for IV administration may alleviate clinical signs in these horses. However, availability and expense of the agent in this form highly restrict its use. A dosage rate of 1 mg/kg intravenously may be appropriate, although more controlled studies are required.[164]

MYOTONIC DISORDERS

Differential diagnoses for muscle fasciculations in horses are listed in Box 10.4.

Myotonia

Pathogenesis

Myotonic muscle disorders are a heterogeneous group of acquired or congenital diseases that share the feature of delayed relaxation of muscle after mechanical stimulation or voluntary contraction caused by abnormal muscle membrane excitability. Congenital or inherited causes include defects in the skeletal muscle chloride channel (myotonia congenita) or sodium channel (hyperkalemic periodic paralysis). Acquired causes include infestation with the spinous ear tick *Otobius megnini.* The cause of many cases of myotonia in horses, especially dystrophic forms, remains unknown.

BOX 10.4 Muscle Fasciculations

1. Pain, anxiety
2. Weakness
   a. Botulism
   b. Vitamin E–deficient myopathy
   c. Equine motor neuron disease
3. Increased motor neuron firing
   a. Electrolyte abnormalities
   b. Focal nerve irritation
   c. *Otobius megnini* ear tick infestation
   d. Stiff horse syndrome
   e. Shivers
   f. Neuromyotonia
4. Abnormal sarcolemmal conductivity
   a. Hyperkalemic periodic paralysis
   b. Myotonia congenita
   c. Myotonia dystrophica

FIG. **10.20** Middle gluteal muscle hypertrophy and superficial gluteal muscle atrophy in a horse with myotonia dystrophica.

Clinical Signs

Myotonia Congenita. Myotonia congenita is usually detected in the first year of life.[171-174] Affected foals have conspicuously well-developed musculature with mild to moderate pelvic limb stiffness that is most pronounced when exercise begins and diminishing as exercise continues. Bilateral bulging (dimpling) of the thigh and rump muscles is often obvious, and percussion dimpling occurs with tactile stimulation over the muscle. Percussed muscles can remain contracted for up to a minute or more with subsequent slow relaxation.[174,175] Progression of clinical signs does not usually occur beyond 6 to 12 months of age.[175] An autosomal recessive mutation of the *CLCN1* gene was identified in one New Forest Pony with myotonia congenita.[176]

Myotonia Dystrophica. Myotonia dystrophica resembles myotonia congenita in early phases; however, weanlings have progressive multifocal muscle atrophy, hypertrophy, and persistent stiffness that worsen with exercise (Fig. 10.20). It has been described in a variety of breeds, including Quarter Horses, Appaloosa, and Italian-bred foals.[175,177,178] In some foals retinal dysplasia, lenticular opacities, and gonadal hypoplasia have been documented.[178] The basis for myotonia dystrophica is unknown.

FIG. **10.21** Severe muscle cramping *(arrow)* associated with ear ticks that is so painful to horses it results in colic-like signs and recumbency.

Diagnosis

A tentative diagnosis of myotonia can be made on the basis of age, clinical signs of stiff gait, muscle bulging, and myotonic dimpling following percussion. Definitive diagnosis requires electromyographic (EMG) examination. Affected muscles manifest pathognomonic high-frequency repetitive discharges that wax and wane, creating the sound of "dive bombers" resulting from abnormal repetitive firing of affected muscle fibers.[49] Muscle biopsies from foals with myotonia congenita can have normal histopathology or may demonstrate extremely variable muscle fiber diameters up to twice those of normal age-matched controls.[174] Type 1 fiber hypertrophy or hypotrophy is reported. Muscle pathology is more dramatic in myotonia dystrophica, including ringed fibers, centrally displaced myonuclei, sarcoplasmic masses, and an increase in endomysial and perimysial connective tissue.[175,177-179] Fiber type grouping and atrophy of both type 1 and type 2 muscle fibers are present.

Treatment and Prognosis

There is no efficacious treatment for myotonia in horses. Prognosis appears to be variable and dependent on the severity of clinical signs. Mildly affected animals with myotonia congenita can show improvement in clinical signs with increasing age. The reason(s) for regression of signs is unknown. Other more severely affected horses, particularly those with myotonia dystrophica, have progression of signs, including atrophy and fibrosis or pseudohypertrophy to the point at which the animal is no longer able to move without great difficulty. Euthanasia of such animals is often warranted. Conclusive evidence regarding the genetic basis of myotonia dystrophia is lacking.

Ear-Tick Associated Myotonia

Otobius megnini is commonly found in the southwestern United States. Intermittent painful nonexertional muscle contraction and mild to moderate rhabdomyolysis occur in some horses in conjunction with *O. megnini* infestations.[180] Intermittent contraction of pectoral, triceps, abdominal, or semitendinosus/semimembranosus muscles, lasting from minutes to a few hours, can be so painful that it results in recumbency often resembling colic (Fig. 10.21). Contraction with myotonic dimpling of a muscle can be induced by tactile stimulation of the muscle with a percussion hammer. Horses may fall over with pain when stimulated. Between muscle cramps horses appear

to be normal. Horses have elevated serum CK activities ranging from 4000 to 170,000 IU/L. Numerous ear ticks are present in the external ear canal of affected horses. Without treatment for ear ticks, the spasms continue; however, local treatment of the ear ticks using pyrethrins and piperonal butoxide results in recovery within 12 to 36 hours. Acepromazine may be helpful to relieve painful cramping.

HYPERKALEMIC PERIODIC PARALYSIS

Sharon J. Spier

Pathogenesis

Hyperkalemic periodic paralysis (HYPP) is an autosomal codominant form of myotonia in Quarter Horses, American Paint Horses, and Appaloosas that are descendants of the popular Quarter Horse stallion Impressive. HYPP is due to a mutation in the gene encoding the voltage-dependent skeletal muscle sodium channel.[181-185] Horses with HYPP have resting sarcolemmal membrane potentials that are closer to firing. When muscle cells begin to depolarize during an episode of HYPP, a subpopulation of sodium channels fail to inactivate, producing an excessive inward flux of sodium and outward flux of potassium resulting in persistent depolarization of muscle cells, general muscle fasciculations, and weakness.

Prevalence

Approximately 1.5% of the Quarter Horse breed and 4.5% of the Paint Horse breed are affected.[83] Notably, however, 58% of halter horses of these breeds have the HYPP mutation likely because the disorder is linked to large muscle mass and success in the halter horse industry.[83] Horses homozygous for the HYPP mutation can no longer be registered with the American Quarter Horse Association.

Clinical Signs

Clinical signs are intermittent and highly variable in nature beginning by 2 to 3 years of age.[182,183] Some heterozygous horses are completely asymptomatic, whereas other heterozygous horses have daily muscle fasciculations and weakness. Episodes often begin with a brief period of facial myotonia and potentially prolapse of the third eyelid. Sweating and muscle fasciculations progress to involve the flanks, neck, and shoulders. Attempts to move the horse can exacerbate muscle tremors. Overt myotonic cramping of muscle groups can occur in some horses (Fig. 10.22). Heart and respiratory rates can be elevated. During mild attacks horses remain standing, but episodes can evolve within a few minutes to encompass severe weakness, swaying, staggering, dog sitting, and recumbency. Paralysis of upper respiratory muscles during episodes can result in respiratory distress and sudden death if a tracheostomy is not performed. Horses remain conscious even when recumbent and often have an anxious alert eye responding to noise and painful stimuli. Episodes usually last from 15 to 60 minutes. After the episode subsides, horses regain their feet and appear normal with no apparent or minimal gait abnormalities.

Foals homozygous for the HYPP mutation can present with dysphagia, respiratory stridor, and periodic obstruction of the upper respiratory tract (Fig. 10.23). Endoscopic findings include pharyngeal collapse and edema, laryngopalatal dislocation, and laryngeal paralysis.[186]

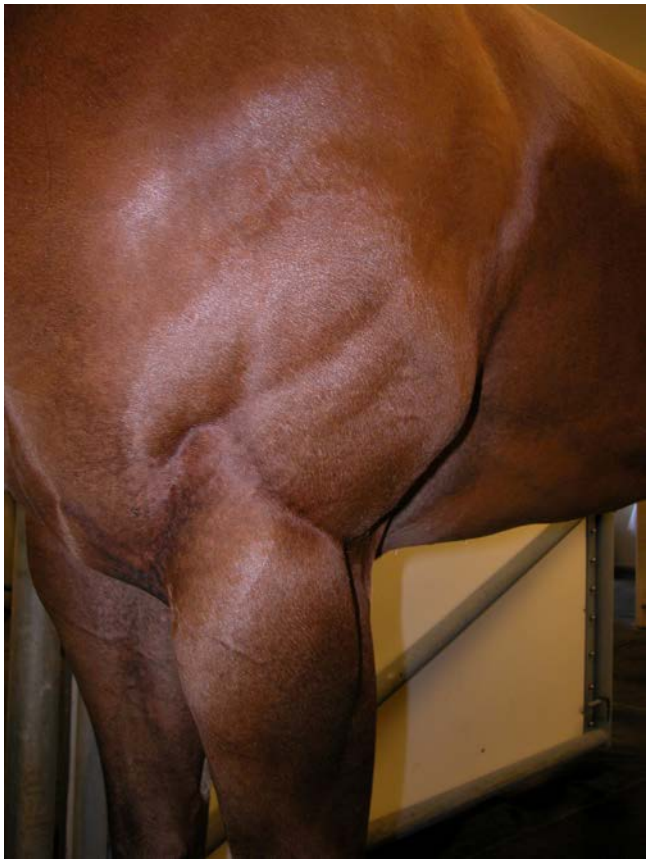

FIG. **10.22** Heavily muscled phenotype and myotonic cramping in a Quarter Horse suffering from HYPP. (Photo courtesy Dr. Monica Aleman.)

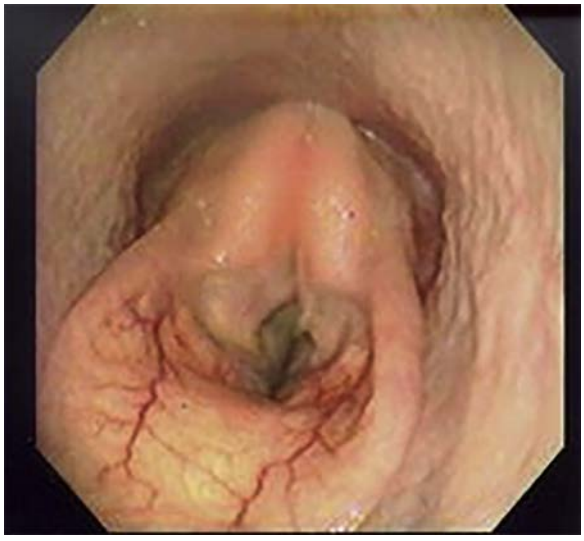

FIG. **10.23** Hypertrophy and closure of the vocal folds in a foal homozygous for HYPP that resulted in severe dyspnea.

Risk Factors

The factor that precipitates an episode of HYPP in genetically susceptible horses is often not obvious. Diets high in potassium (greater than 1.1%), such as those containing alfalfa hay, molasses, electrolyte supplements, and kelp-based supplements, can precipitate an episode.[187,188] Other potential

triggering factors include sudden dietary changes, fasting, anesthesia or heavy sedation, trailer rides, stress, cold, pregnancy, and concurrent disease. HYPP is not triggered by exercise.

Clinical Pathology

In most cases, hyperkalemia (6–9 mEq/L), hemoconcentration, and mild hyponatremia occur during periods of muscle fasciculations with normal acid-base balance.[183] Serum potassium concentration returns to normal following the abatement of clinical signs. Some affected horses may have normal serum potassium concentrations during minor episodes of muscle fasciculations.[182] Serum CK activity shows no change or only mild increases during episodic fasciculations and weakness.

Diagnosis

A definitive diagnosis of HYPP is made through genetic testing for the F1416L mutation in the *SCN4A* gene encoding the alpha subunit of the sodium channel.[184] Submission of mane or tail hair with roots should be made to a licensed laboratory such as the Veterinary Genetics Laboratory at the University of California, Davis, www.vgl.ucdavis.edu. Electromyographic examination of affected horses has also been used for diagnostic purposes. Affected horses have abnormal fibrillation potentials, complex repetitive discharges, occasional myotonic potentials, and trains of doublets even between episodes of HYPP.[183,189]

Treatment

Many horses experience spontaneous recovery from episodes of paralysis and appear normal by the time a veterinarian arrives. If horses are just beginning to exhibit clinical signs, owners may be advised to provide mild exercise or to feed grain or corn syrup before the veterinarian's arrival. Grain and high-fructose corn syrup (e.g., Karo syrup) lower serum potassium by stimulating insulin-mediated movement of potassium across cell membranes. Other options for treatment during an acute episode of hyperkalemia include epinephrine (3 mL of 1:1000/500 kg administered intramuscularly), acetazolamide (3 mg/kg PO every 8–12 hours), or calcium gluconate (0.2–0.4 mL/kg of a 23% IV solution, diluted in 1 L of 5% dextrose). An increase in extracellular calcium concentration raises the muscle membrane threshold potential, which decreases membrane hyperexcitability. Other options include IV dextrose (6 mL/kg of a 5% solution) alone or combined with sodium bicarbonate (1–2 mEq/kg) to enhance intracellular movement of potassium. With severe respiratory obstruction, a tracheostomy may be necessary.

Control

Ideally, horses with recurrent episodes of HYPP should be fed a balanced diet containing between 0.6% and 1.1% total potassium by weight and meals containing less than 33 g of potassium.[187,188,190] The principal source of potassium in the equine diet is forage. In general, early cuts of alfalfa, orchard grass, and brome hay have higher potassium concentrations, and later cuts of timothy or Bermuda grass hay have lower potassium concentrations, but this is not always the case. Horses having frequent episodes should have forages analyzed for potassium concentrations.[190] Pasture works well for horses with HYPP because the high water content of pasture grass makes it unlikely that horses will consume large amounts of potassium in a short period of time. Feeds containing soybean meal, sugar molasses, or beet molasses can have higher potassium concentrations. Oats, corn, wheat, barley, and beet pulp should be fed in small meals several times a day. Horses will adapt to diets higher in potassium over a period of 2 weeks and will experience fewer fluctuations in serum potassium with subsequent decreased frequency of clinical signs.[188] Regular exercise and/or frequent access to a large paddock or yard are also beneficial. Supplementation with salt and balanced vitamins and minerals is indicated to meet nutritional requirements. Commercially available complete feeds with a guaranteed K^+ content may be more convenient for some HYPP horses, especially for owners with few horses.

For horses with recurrent episodes of muscle fasciculations even with dietary modification, acetazolamide (2–3 mg/kg orally, every 8–12 hours) or hydrochlorothiazide (0.5–1 mg/kg orally, every 12 hours) may be indicated. Although these agents exert their effects through different mechanisms they both increase renal potassium excretion. Acetazolamide also stabilizes blood glucose and potassium by stimulating insulin secretion. Breed registries and other associations may have restrictions on the use of these drugs during competitions as diuretics may mask prohibited substances.

Prognosis

HYPP is usually a manageable disorder, although recurrent bouts may occur and severe episodes can be fatal. As this is a dominant trait, breeding an affected horse to a normal horse results in a 50% chance of producing a foal with HYPP. All affected horses share the same mutation regardless of whether or not owners have witnessed symptoms in their horses.[191] Owners of affected horses should advise veterinarians of HYPP status before anesthesia or procedures requiring heavy sedation, as these circumstances could precipitate an episode of paralysis.[192]

ELECTROLYTE IMBALANCES

Muscle Cramping

Severe electrolyte imbalances cause muscle cramping. Muscle cramps are a painful condition that arises from hyperactivity of motor units caused by repetitive firing of the peripheral and/or central nervous system. The origin of the cramp in most cases is believed to be the intramuscular portion of the motor nerve terminals.[193,194] Most muscle cramps are also accompanied by fasciculations in the same muscle. Muscle cramps can be induced by forceful contraction of a shortened muscle, by changes in the electrolyte composition of extracellular fluid, and by ear tick infestations in horses.[180,193] In contrast, muscle contractures are painful muscle spasms that represent a state of muscle contracture unaccompanied by depolarization of the muscle membrane.[192] Muscle contractures occur with MH and some forms of exertional myopathies and are invariably accompanied by markedly increased serum CK activity.

Hypocalcemic Tetany

Pathogenesis. Hypocalcemia is a rare occurrence in horses and is usually associated with parturition, heavily lactating mares, transportation, prolonged endurance rides, or grazing lush pastures.[195] Idiopathic fatal hypocalcemia has also been reported in foals.[196]

Clinical Signs. Clinical signs are similar to those seen with tetanus and include a stiff, stilted gait, muscle fasciculations (especially temporal, masseter, and triceps muscles),

trismus, dysphagia, salivation, anxiety, profuse sweating, tachycardia, elevated body temperature, cardiac arrhythmias, synchronous diaphragmatic flutter, convulsions, coma, and death.[195] Subclinical evidence of abnormal neuromuscular conductivity has been documented by EMG in horses with experimentally induced hypocalcemia.[197] In lactating mares this disorder can be progressive over a 24- to 48-hour period and potentially fatal. Clinical signs are related to the magnitude of decline in serum calcium concentration. Increased excitability is usually the only sign when values are below normal but above 8 mg/dL total calcium. Values of 5 to 8 mg/dL usually produce tetanic spasms and incoordination. Concentrations below 5 mg/dL usually result in recumbency and stupor.

Diagnosis. Diagnosis is usually based on clinical signs, a history of lactation, previous prolonged exercise, or transport. Along with hypocalcemia, metabolic alkalosis, hypomagnesemia/hypermagnesemia, and hyperphosphatemia/hypophosphatemia are frequently present. These alterations may need correction before tetanus and fasciculation abate.

Treatment. IV administration of calcium solutions such as 20% calcium borogluconate or those recommended for the treatment of parturient paresis in cattle is required. These preparations should be administered slowly in conjunction with close monitoring of the cardiovascular response. Dilution at the rate of 250 to 500 mL/500 kg diluted 1:4 with saline or dextrose before infusion decreases the chance of cardiotoxicity. Normally there is a positive inotropic effect in response to calcium administration; however, alterations in rate or rhythm provide evidence to suspend the infusion. If no response to an initial infusion occurs, a second dose may be given 15 to 30 minutes later. Most cases respond to this form of therapy, although in some cases in which signs persist, repeated treatments may be necessary.

Synchronous Diaphragmatic Flutter

Pathogenesis. Synchronous diaphragmatic flutter (SDF), or "thumps," arises when fluid and electrolyte imbalances disrupt the membrane potential of the phrenic nerve. The phrenic nerve begins to discharge in concert with atrial depolarization with subsequent contraction of the diaphragm.[198] The most consistent metabolic derangement reported in horses with SDF is low serum ionized calcium concentrations usually associated with hypochloremic metabolic alkalosis.[198,199] Metabolic alkalosis may alter the ratio of free to bound calcium (increasing calcium binding to protein and decreasing ionized calcium), which possibly induces SDF.

Risk Factors. Inciting causes include hypocalcemia arising from lactation, transport, prolonged endurance exercise, primary hypoparathyroidism, digestive disturbances, administration of furosemide, and possibly other medications.[198-200] Ingestion of blister beetles (cantharidin toxicosis) can also cause hypocalcemia and SDF.[146]

Clinical Signs. A thumping or twitch in the flank region (unilateral or bilateral) is seen when the diaphragm contracts synchronously with the heart. In severe cases this twitch may produce an audible thumping sound. Signs of dehydration and volume depletion can be present depending on the etiology of the calcium imbalance. SDF is a component of the exhausted horse syndrome in endurance horses and often accompanies signs of dehydration, inappropriate sweating responses, persistently elevated body temperature, depression, anorexia, and aperistalsis.[25] In some horses SDF may be a chronic, recurring problem, particularly if they have received prolonged administration of high-calcium supplements.[199]

Treatment. In most cases SDF is a transient event, usually abating when the underlying cause resolves, either spontaneously or in response to treatment.[199] Most horses undergo rapid remission of signs when given calcium solutions intravenously as described earlier for treatment of hypocalcemic tetany. Although hypomagnesemia is often present with SDF, horses do not respond to magnesium supplementation unless calcium is administered concurrently. Response to therapy is also reflected by improved mental status, return of appetite, and gut motility.[198]

Control. Electrolyte supplementation and some dietary manipulations may help reduce the incidence of SDF in some endurance horses suffering recurrent bouts. Provision of chloride, potassium, and sodium during prolonged exercise may help reduce fluid losses and the metabolic alkalosis that commonly accompanies this form of exercise and frequently occurs in association with SDF. Metabolic alkalosis decreases the amount of free calcium available. Supplementation of calcium and magnesium during endurance rides has been suggested to be helpful in horses prone to SDF.

Alternative approaches involve reduction of dietary calcium in horses prone to SDF for a few days before an endurance ride. It is postulated that this reduction in dietary calcium stimulates the endocrine homeostatic mechanisms and increases osteoclastic activity. In the short term the horse depends less on dietary calcium and is able to mobilize substantial amounts of calcium in response to the demands imposed by exercise; calcium losses in sweat are overcome by the release of calcium from endogenous storage pools (bone).[199] Horses routinely fed alfalfa hay, which has a relatively high calcium concentration, may be more prone to development of SDF. Limitation of this feedstuff may be indicated in chronically affected horses.

CONFLICT OF INTEREST STATEMENT

CHAPTER 11

Disorders of the Neurologic System

Monica Aleman, Yvette S. Nout-Lomas, and Stephen M. Reed*

NEUROLOGIC EXAMINATION

Assessment of the central nervous system (CNS) in horses may seem a difficult task; however, with careful examination using a craniocaudal approach, assessment is not difficult. A craniocaudal approach is the most logical and efficient. The goal of the examination is to determine the neuroanatomic localization of the lesion or lesions and should be completed as part of the physical examination. Subtle neurologic deficits may be hidden by musculoskeletal disease or missed because of lack of knowledge or understanding of these disorders. To accomplish a complete and accurate neurologic examination, the veterinarian must feel comfortable with the format chosen for evaluating the nervous system and must have knowledge of which musculoskeletal disorders commonly are associated with neurologic disease. Problems such as osteochondrosis of the stifle, hock, and shoulder joints often occur concurrently in horses with cervical vertebral stenotic myelopathy.

Examples of typical histories in horses presented for neurologic examination, especially for signs of spinal ataxia, include previous medial patellar desmotomy, bilateral bog spavin in early life, osteochondrosis of the distal tibia or femur, and contracted tendons. All of these problems associated with developmental orthopedic diseases are examples of conditions that may occur simultaneously. Bilateral bog spavin often is associated with osteochondrosis of the distal tibia or other sites in the tibiotarsal joint. Patellar desmotomy to correct upward fixation of the patella may be necessary because of a conformational problem of the stifle joint or as a result of abnormal joint proprioception or quadriceps weakness after neurologic disease. The foregoing problem is more commonly associated with neurologic disease than many veterinarians realize, and the gait deficits caused by these lamenesses often mimic neurologic disease. Horses with bilateral osteochondritis dissecans (OCD) lesions of the stifle joints will often "bunny-hop" while running, which may be interpreted as a sign of neurologic disease rather than as a result of an underlying musculoskeletal disease.

The goals of a neurologic examination are to establish whether a neurologic problem is present and to determine the anatomic localization of the problem. Being able to account for all clinical signs with a single lesion is ideal; however, if this is not possible, one should consider the possibility of multifocal disease or multiple diseases. In addition to anatomic localization of a lesion, it is important to record the findings of the examination as a baseline for comparison of future evaluations. After anatomic localization, one must decide what additional testing is necessary to determine the underlying cause of the clinical signs. Ancillary imaging, cerebrospinal fluid (CSF) analysis, and electrodiagnostic testing may be useful in locating and determining the cause of the lesions.

The neurologic examination should be considered part of the physical examination. The author prefers to begin the examination at the head and proceed caudally to the tail. The examiner should proceed in a consistent fashion and should record findings in an orderly manner to avoid any part of the examination being omitted. Fig. 11.1 shows a sample format. One may use the craniocaudal approach for all animals, whether ambulatory or recumbent.

The equine neurologic examination procedure has been described in detail elsewhere.[1-4] The author follows the format developed by Mayhew,[4] which divides the examination into five categories: (1) the head and mental status, (2) gait and posture, (3) neck and forelimbs, (4) trunk and hindlimbs, and (5) tail and anus. The functional divisions of the nervous system include the sensory, integration, and motor systems.

Before starting the examination, the age, gender, breed, and use of the horse should be determined, although these are not essential. The owner should be questioned about any unusual behavior the horse has exhibited and the date of onset of the behavior. Age is helpful because problems such as cervical vertebral stenotic myelopathy and cerebellar abiotrophy begin at a young age, usually less than 1 year. These problems occur more often in certain breeds. For example, cervical vertebral stenotic myelopathy is most common in Thoroughbreds, and cerebellar abiotrophy most often is observed in Arabians.

Examination

The evaluation of the head should include observation of the horse at rest and during motion; palpation, postural reactions, cranial nerve function, and cervicofacial reflexes; and evaluation of sensation. At the start of the examination the horse should be observed for alertness, mentation, attitude, and behavior (remembering that the animal's environment may influence its degree of excitement). Evaluation of the head

*The editors and authors acknowledge and appreciate the contributions of Frank M. Andrews, Veronique A. Lacombe, Bonnie R. Rush, Barbara A. Byrne, Caroline N. Hahn, Martin Furr, W. David Wilson, Nicola Pusterla, William J. Saville, Joseph Bertone, Maureen T. Long, Cartla S. Sommerdahl, Peter R. Morresey, Ramiro E. Toribio, Robert H. Mealey, and Eduard Jose-Cunillerasas previous contributors to this chapter. Some of their original work has been incorporated into this edition.

includes observation of the behavior and mental status of the horse. This portion of the examination can be completed by careful observation even before handling the horse. A close and careful examination is necessary to evaluate the head and neck posture and coordination and to identify abnormalities of the cranial nerves. Initial consideration includes the environmental awareness of the horse. A normal horse appears bright and alert and responds appropriately to external stimuli. While the horse is being caught, the examiner can look for unusual behaviors such as yawning, abnormal or aimless wandering, seizures, or circling or head tilt and can begin to assess the vision and hearing of the horse. This is also a good time to observe how the horse is standing and whether it has the limbs positioned appropriately under its body. The veterinarian should note any

behavioral abnormalities, such as head pressing (a clear sign of cerebral disease) and aggressiveness (noted in animals that are not feeling well, as well as animals with CNS disease). If the examiner suspects rabies, precautions should be taken to avoid unnecessary and potentially dangerous exposure.

Lesions of the reticular activating system or the cerebral hemispheres could result in coma or obtundation of consciousness. Horses demonstrating compulsive walking may have a diffuse cerebral disease, whereas a horse walking in large circles may have an asymmetric forebrain lesion. Horses that have a serious systemic illness also may appear depressed or stuporous. The level of consciousness is recorded as *alert, depressed, stuporous,* or *comatose.* An animal that is depressed may react to its environment in an inappropriate or unresponsive fashion. Stuporous horses may appear to be asleep unless stimulated with pain, light, or noise and often demonstrate impaired reactivity. Comatose animals are completely unresponsive and cannot be aroused.

Head posture and coordination are controlled by the cerebellar and vestibular regions of the brain and brainstem in response to sensory input from receptors in the head, neck, limbs, and trunk. Examining the head and neck posture with the horse at rest, while eating, and while moving is helpful. In horses with normal head carriage, the head should be held straight and upright when viewed from the front. Careful examination of the vestibular region is important because many horses develop a head tilt resulting from head trauma, temporohyoid osteoarthropathy (THO), or guttural pouch disease. A head tilt is characterized by the poll deviated about the muzzle and must be distinguished from abnormal or unusual turning of the head or lateral deviation of the head as may occur with damage to the forebrain or injury to the cervical vertebrae. Additional signs that may accompany vestibular disease or injury include nystagmus, ipsilateral weakness, and facial nerve paralysis.

Postural abnormalities of the head and neck sometimes can be difficult to distinguish from head tilt. Horses with torticollis of the head and neck may have a congenital abnormality of the vertebrae or may have injured the muscles of the neck region. Damage to the dorsal gray columns can result in abnormal head and neck posture (acquired scoliosis) that has been described as a result of parasitic migration such as *Paralaphostrongylus tenuis.*[5] Careful examination, including palpation, should help identify fractures of the cervical vertebrae or painful muscles caused by trauma or an injection reaction. Neck pain may manifest as a reluctance to move the head and neck through a full range of motion. In the absence of pain or mechanical limitations to movement, normal horses should be able to turn their head to retrieve feed offered at the lateral thorax on each side, elevated to a level above the withers, or lowered to a point between the front legs just beneath the pectoral muscles. In some horses, radiographs of the cervical vertebrae may be useful to confirm a fracture or osteomyelitis. Blindness sometimes can lead to an abnormal head or neck posture.

The cerebellum helps regulate rate and range of motion. With damage to this area a horse often shows fine resting tremors of the head that worsen with intentional movements. One may normally observe this tremorous movement of the head and neck in the newborn or young foal, but it is not normal in older foals and adult horses. In young Arabians and a few other breeds, a condition of cerebellar abiotrophy has been reported. Horses with this condition show a hypermetric gait, failure to blink when exposed to bright light, and absence of a menace response.

After evaluating the alertness, mental attitude, head and neck posture, and coordination of the horse, the examiner should examine the face and cranial nerves closely. Systematic examination of the first to twelfth cranial nerves helps to ensure that a subtle lesion along the brainstem is less likely to be missed, although in fact the examiner assesses many of the cranial nerves simultaneously on approach to the horse. The examiner evaluates facial symmetry, facial sensation (including sensation inside the nares), head posture, eyes, nose, mouth, jaw tone, pharynx, and larynx. To determine whether an animal can detect scent is usually not as important, but determining whether it can see, hear, breathe, and swallow is critical.

Examination of the eyes should include evaluation of the blink or menace response, the ability of the horse to negotiate in a strange environment, pupillary light response, and in some cases a funduscopic examination. Excellent descriptions of the equine neuroophthalmic examination are available elsewhere.[6,7] If a horse has a lesion of the eye or optic nerve, the lesion will result in complete or partial ipsilateral blindness. To develop contralateral blindness, the horse would have to have a lesion in the optic tract or the lateral geniculate nucleus. Pupil size and symmetry are under control of the autonomic nervous system and are affected by environmental light and level of fear or excitement. To test the pupillary response, one should direct a light in each eye and note the constriction of the pupil. Identifying a consensual response in the horse is often difficult when one works alone. A swinging light test has been described. In the performance of this test, the light is shone alternately into each eye, and the more powerful direct pupillary light response is observed. A unilateral lesion affecting the afferent tracts in the eye, optic nerve, optic chiasm, or optic tract to the level of the midbrain will result in ipsilateral dilation when the light reaches the affected eye. Moving the light from side to side takes advantage of the ipsilateral light response being stronger than the consensual response. The examiner can perform this procedure alone. These reflexes are in the brainstem and are not affected by lesions in the visual cortex.

One possible cause of asymmetric pupils in a horse is Horner syndrome. Horner syndrome is the collection of clinical signs associated with dysfunction of the sympathetic nerve supply to the head and neck. The sympathetic nerve supply to the head includes upper motor neurons in the caudal hypothalamus, parts of the midbrain and pons, and parts of the medulla oblongata. Axons from these centers descend in the cervical spinal cord to the preganglionic neurons in the cranial thoracic spinal cord. From here, preganglionic axons leave the cord and join the paravertebral sympathetic trunk, where they ascend up the neck to synapse in the cranial cervical ganglion in the guttural pouch. This syndrome includes ptosis of the upper eyelid, miosis of the pupil, and protrusion of the third eyelid (nictitating membrane). In addition, the horse has unilateral facial sweating, increased facial temperature, and hyperemia of the nasal and conjunctival membranes. These signs should alert the examiner to the possibility of a previous perivascular injection, guttural pouch disease, or damage to the sympathetic nerves in the vagosympathetic trunk, which courses from the cranial thoracic spinal cord through the thoracic inlet and upward to the orbit. Loss of sympathetic innervation to the head results in the triad of clinical signs described, with the most prominent initial sign being increased sweating caused by disruption of sympathetic fibers to the blood vessels and sweat glands of the head and neck. This results in cutaneous vasodilation with subsequent more local circulating adrenaline.

Loss of symmetric positioning of the eyes or the presence of abnormal deviation (i.e., strabismus) occurs when a horse has injured the third (oculomotor), fourth (trochlear), or sixth (abducens) cranial nerve or the connections between the eighth (vestibulocochlear) cranial nerve and these nuclei in the brainstem along the medial longitudinal fasciculus. Deviations of the eyes may occur with head trauma or midbrain lesions or can be normal variations in newborn foals. When the head is elevated dorsally, the eyes should move ventrally to maintain a normal horizontal gaze. When the head is moved from side to side, the eyes should move slowly opposite to the direction of the head movement, move quickly in the direction of the head movement; this is referred to as *normal vestibular nystagmus.* Spontaneous or positional nystagmus is always abnormal.

The nuclei along the fifth (trigeminal) cranial nerve are among the largest nuclei along the brainstem of the horse. The fifth cranial nerve contains motor and sensory branches that supply innervation to the muscles of mastication and sensation to the skin and mucous membranes of the head. Injury to this nerve leads to dropped jaw and ipsilateral loss of, or decreased sensation to, the side of the face and the inside of the nares.

Damage to the seventh (facial) and eighth cranial nerves is common in horses. Injury to the seventh cranial nerve results in unilateral facial paralysis. This nerve contains branches that supply the ears, eyelids, and nares; therefore injury to this nerve may affect all or only part of these structures. The most easily recognized sign is deviation of the nares toward the unaffected side coupled with drooping of the eyelid and ear on the affected side. Because this nerve also innervates the salivary and lacrimal glands, loss of or damage to this nerve may cause dry eye and decreased salivation.

Eighth cranial nerve deficits are easy to recognize, because unilateral injury to this nerve results in a head tilt toward the affected side. The eighth cranial nerve is important to hearing and control of balance. Projections from this nerve pass to the medulla and cerebellum. A horse that has damage to this nerve often appears disoriented and has a head tilt toward the side of the lesion along with abnormal position of the limbs and body and horizontal nystagmus. If the lesion involves the peripheral portion of the vestibular system, the fast phase of the nystagmus is directed away from the side of the lesion. If the lesion involves the central portion of the vestibular system, the nystagmus may appear vertical, rotary, or horizontal and may not always appear the same, depending on head position.

Horses that have peripheral damage to the vestibular system usually compensate for the deficits in a short time by use of visual and proprioceptive input. Therefore avoiding the use of a blindfold in cases of suspected vestibular disease is judicious. Using a blindfold hampers the ability of the horse to compensate, and the horse may become dangerous. However, blindfolding a horse with a suspected vestibular disease but no longer showing an obvious head tilt may be helpful to localize the lesion.

Within the medial compartment of the guttural pouch, along the caudodorsal and lateral walls, are the ninth (glossopharyngeal) cranial nerve and a branch of the vagus nerve. When a horse develops guttural pouch disease, these nerves may be damaged, resulting in loss of innervation to the pharyngeal muscles. The clinical signs include dysphagia on the same side as the damaged nerve. If the disease is severe enough to involve the internal carotid nerve, which contains postganglionic sympathetic fibers to the structures of the head and eye, Horner syndrome results. As mentioned, the signs include ptosis of the upper eyelid, enophthalmos resulting in prolapse of the third eyelid, miosis of the pupil, and sweating along the side of the face.

Other diseases one should consider when Horner syndrome is evident during a neurologic examination include injury or infarction to the cranial thoracic spinal cord, avulsion of the brachial plexus, a hematoma, or tumor invading the sympathetic trunk in the region of the caudal, cervical, or cranial thoracic sympathetic trunk. Mycosis of the guttural pouch can cause damage to the internal carotid nerve or the cranial cervical ganglion along the caudodorsal wall of the guttural pouch. Finally, an injury to or neoplasia of the structures within or just behind the orbit also may cause Horner syndrome. Focal sweating in a horse indicates involvement of the peripheral preganglionic or postganglionic sympathetic neurons. Identification of this problem also can aid in the anatomic localization of a neurologic lesion.

Intact innervation to the larynx and pharynx is important, especially if the horse is to be used as an athlete. The easiest means to evaluate this region is by endoscopic examination of the pharyngeal and laryngeal regions. One can perform throat latch palpation and a laryngeal adductory slap test. Endoscopic examination is helpful and important to a complete evaluation. The innervation of the pharynx and larynx is via the ninth, tenth (vagus), and eleventh (accessory) cranial nerves and the connections of these nerves in the caudal medulla oblongata.

The twelfth cranial nerve, the hypoglossal nerve, has cell bodies in the hypoglossal nucleus of the caudal medulla oblongata and provides motor innervations to the muscle of the tongue. Normal horses provide a strong resistance to withdrawing the tongue from the mouth; horses with unilateral cranial nerve XII dysfunction have unilateral atrophy with weak retraction. Bilateral dysfunction interferes with prehension and swallowing, the tongue often protrudes from the mouth, and the horse has difficulty or is unable to withdraw the tongue. Severe cerebral lesions may also interfere with tongue retraction because of interference with voluntary control pathways.

After careful examination of the mental status and behavior of the horse and of the head, neck, and cranial nerves, the examiner should look for asymmetry of the muscles of the trunk, pelvic region, tail, and anus. Identification of focal sweating, focal muscle atrophy, or increased or decreased pain responses is helpful in localizing signs. In addition, the horse has two cervical reflexes. The cervicofacial reflexes result in a local twitch and drawing back of the lips (smile reflex) when one pricks the skin along the side of the neck down to the region of the second cervical vertebra. Below the region of the second cervical vertebra one should observe a local response.[8]

To evaluate the tail and anus, the tail carriage is first observed at rest and with the horse in motion. The normal tail carriage is straight down but with free movement in all directions. Some normal horses allow the tail to be lifted, giving little resistance, whereas other horses strongly resist and clamp the tail. The usual response to anal stimulation is to clamp the tail and squat down, although with prolonged stimulation the horse may relax and eventually raise its tail.

Before evaluation of gait, evaluation of postural reactions and possibly evaluation of spinal reflexes should take place. Spinal reflexes can be evaluated in foals or small horses, as well as in recumbent horses. Evaluation of spinal reflexes can be very helpful in lesion localization, although interpretation of responses is sometimes difficult in adult recumbent horses.[9] The author nearly always places the feet and limbs in an unusual position to observe the response of the horse; however, because postural reactions are sometimes difficult to interpret in horses, it is essential to use gait evaluation to help localize a lesion. Additional tests to assess proprioceptive function include a standing sway test in which one applies pressure to the shoulder. The horse initially should press into the examiner and then lean away, and finally it should step away with the offside limb. Also, the examiner might lift one thoracic limb and force the horse to hop on the opposite limb in a modified postural reaction test. The important centers for posture and coordination in the brainstem and spinal cord are

located in the regions of the sixth cervical to second thoracic (T2) and fourth lumbar to second sacral (S2) vertebrae in the spinal cord, along with coordination centers in the brainstem. Horses that demonstrate a wide base stance at rest often have a lesion of the cerebellum or vestibular system or may have conscious proprioceptive abnormalities.

Evaluation of Gait

Foals are ambulatory within hours after birth, making it possible to evaluate gait at a young age; however, newborns may appear weak and ataxic. Gait abnormalities that are observed commonly in horses with neurologic disease include ataxia, dysmetria, and weakness or paresis. Evaluation of gait is critical because subtle neurologic gait deficits often go unrecognized or sometimes may incorrectly be considered insignificant.

The horse should be observed at a walk and trot in a straight line and while turning. At a walk the examiner can walk alongside, in step with first the pelvic limbs and then the thoracic limbs. This allows the examiner to more easily determine the stride length and foot placement. A weak limb often has a low arc and longer stride length. In some horses, observing the horse negotiate over small obstacles such as a curb is helpful. It can also be helpful to evaluate the horse on different surfaces (hard ground vs. arena) at different gaits. Blindfolding the horse can also be helpful during a neurologic evaluation. Observing a horse during the backing process is important. When a normal horse is backing, it should lift each leg and place it in a coordinated and appropriate location. Horses with neurologic abnormalities often place the limbs in wide-based positions or lean back and are reluctant or refuse to move. The horse also may step on the feet of a pelvic limb with the front feet. The horse should be observed closely while being turned in a tight circle to identify abnormal wide outward excursions of the pelvic limb (circumduction). When possible, the examiner should observe the horse turned free and walking up and down an incline. Elevation of the head and walking on a slope may exaggerate a subtle deficit and make it more noticeable. These procedures provide a degree of "challenge" to the horse and may help to demonstrate if the horse is showing persistent irregular movements with its limbs. In some circumstances horses may need to be evaluated under saddle or in tack. Although observing the horse running free in a paddock or round pen and while being ridden can sometimes be helpful, this is not always possible. One must consider safety for the horse and rider, as well as certain legal ramifications, before asking a person to ride a horse during the examination.

The examiner should pay attention to which limbs show abnormal posture or abnormal movements and must be able to determine whether the horse has a painful or mechanical musculoskeletal problem or a neurologic gait deficit. Horses with a musculoskeletal problem have been described as having a regularly irregular gait, whereas a horse with neurologic gait deficits shows less consistency placing its limbs (an irregularly irregular gait). Differentiating between subtle lameness and subtle neurologic disease can be very difficult. One should reexamine horses with an obscure or unusual gait that might be the result of lameness after the use of local anesthetics (to block selected peripheral nerves) or intraarticular medications. The use of nonsteroidal antiinflammatory drugs (NSAIDs) for a period of 1 to 2 days or longer also may alleviate pain and help one distinguish between lameness and a neurologic gait deficit.

Following a neurologic examination, the examiner must identify the presence of weakness, ataxia, and dysmetria in each limb. One can evaluate the strength and ability of the horse to correct body positions by performing the sway test at a walk, in addition to the standing sway test. One applies lateral pressure at the shoulder, hip, and tail while the horse is walking. One should apply pressure several times while the horse is walking to catch the limb in various stages of weight bearing. The examiner should observe the movements of each limb carefully to determine whether a deficit is present and should assign a grade to the deficit. The author uses a system modified from the grades described by de Lahunta and colleagues[1] and Mayhew.[4] The severity is graded between 0 and 5. Grade 0 means no gait deficits. A grade 1 deficit requires careful observation to be certain the gait abnormality is caused by a neurologic dysfunction. Grade 2 deficits are mild to moderate but obvious to most observers as soon as the horse begins to move. Grade 3 deficits are obvious and are exaggerated during the negotiation of a slope or with head elevation. Grade 4 gait deficits may cause a horse to fall or nearly fall. When attempting to walk, an animal with these severe deficits often displays abnormal positioning while standing in its stall. Grade 5 horses are recumbent. However, clinicians should be cautious making decisions about horses based on this subjective assessment of gait, especially when signs are subtle. A recent investigation showed only poor to fair agreement between skilled and experienced observers of gait abnormalities in horses using this scale.[10]

Weakness or paresis is a deficiency of voluntary movement as a result of loss of muscle power because of either damage to upper motor neurons, lower motor neurons, or the muscle. It can be described as knuckling, stumbling, or buckling and sometimes can be characterized by toe-dragging while walking. Weakness may be associated with an upper motor neuron or lower motor neuron lesion. In the case of a lower motor neuron or peripheral nerve injury or illness, the horse shows muscle atrophy and sensory loss. A spastic movement of the limbs often accompanies the weakness that results from loss of upper motor neurons. Ataxia is typified by abnormal foot placement and wide swaying of the foot and limb, especially while turning. Ataxia appears as a lack of coordination of motor movements. It can arise from damage to the vestibular, cerebellar, or sensory portions of the nervous system. Ataxia in horses is most often a result of loss of sensory input through injury, damage, or disease in the spinal cord blocking normal input to the cerebellum. Cerebellar ataxia is seen most often in young horses, typically Arabians with a condition known as *cerebellar abiotrophy*. Vestibular ataxia is often accompanied by a head tilt and other cranial nerve deficits.

Horses may also demonstrate dysmetria, which is characterized as exaggerated hypermetric or hypometric movements of the limbs. Horses with hypometric gaits often appear to have a straight leg or "tin soldier" way of moving (sometimes referred to as *spasticity*). A spastic gait is the result of increased muscle tone and is generally associated with upper motor neuron disease resulting from reduced inhibition of extensor motor neurons.

The gait abnormalities, along with the findings from other parts of the neurologic examination, allow the examiner to

determine the neuroanatomic site of the disease. The severity of the clinical signs also helps one evaluate the extent or severity of the condition.

One must realize that many horses that have minimal (grade 1 or mild grade 2) deficits often can race or perform other athletic activities.[11] The examining veterinarian has the responsibility of separating a neurologic from a musculoskeletal gait deficit and helping the owner determine the usefulness of the horse. For example, a horse with gait deficits up to grade 3 may be useful as a broodmare or breeding stallion if the condition is not considered genetic and if the horse is handled by careful, knowledgeable persons who understand the risks and have the facilities to accommodate a horse in need of special management. Stallions with this degree of impairment may require assistance when mounting and dismounting mares. If the breed association allows artificial insemination, the stallion may be easier to manage.

Localization of the Lesion

At the conclusion of the examination, the veterinarian needs to determine whether a neurologic abnormality exists and where it is located. If the horse shows no evidence of abnormal behavior, seizures, or abnormal mental status and shows no cranial nerve deficits, the lesion is most likely caudal to the foramen magnum. The most difficult lesions to localize are in the brainstem, unless the signs include cranial nerve deficits or depression. Horses with brainstem lesions often show signs of weakness and ataxia similar to horses with a lesion in the cervical spinal cord. Two of the most common brainstem lesions in horses involve the seventh and eighth cranial nerves. Vestibular disease or injury may be a sequela of head trauma or an inner ear infection. Facial nerve paralysis may result from trauma to the nerve root origin in the brainstem or where the nerves course along the neck and face to the ears, eyelids, and nares. Specific cranial nerve involvement, such as head tilt, facial nerve paralysis, or loss of facial sensation, can result from trauma, guttural pouch infection, THO, or equine protozoal myeloencephalitis. In addition, cranial nerve deficits may occur with polyneuritis equi and equine motor neuron disease. Cerebellar lesions are characterized by a failure to blink to bright light, lack of a menace response, and a head tremor that worsens with intentional movements. The most common form of cerebellar disease in horses is abiotrophy, which occurs most frequently in Arabian horses.

Cervical spinal cord disease includes gait and proprioceptive deficits in all four limbs with no signs of brain, brainstem, or cranial nerve deficits. One should note that horses with cervical vertebral stenotic myelopathy might have mild pelvic limb deficits with minimal or barely detectable signs in the thoracic limbs. Horses with signs of neurologic gait deficits confined to the pelvic limbs have a neuroanatomic localization caudal to T2. When examining a horse with a lesion caudal to T2, carefully checking the tail and anus for involvement of the peripheral nerves or spinal cord segments in this region is important.

Horses that have peripheral nerve injury (Table 11.1), equine motor neuron disease, or polyneuritis equi show evidence of weakness, muscle atrophy, and in some cases selected areas of sensory loss. Primary muscle diseases such as exertional rhabdomyolysis, myotonia (congenita or dystrophica), and hyperkalemic periodic paralysis are covered elsewhere in this book (see Chapter 10). These conditions sometimes can mimic a neurologic problem.

Description of Normal and Abnormal Gaits

A walk is a natural four-beat gait in the horse. At this gait the normal horse has three feet on the ground at all times. Therefore the walk is a stable gait. The trot is a two-beat symmetric gait in which the diagonal limbs are in contact with the ground at the same time. If one examines the horse on hard pavement, the trot is the most helpful gait to distinguish lameness from a neurologic gait deficit. The pace is a two-beat symmetric gait in which the legs on the same side of the body strike the ground simultaneously, resulting in significant truncal sway. In horses that have neurologic disease, identifying ataxia with truncal sway, which is often accompanied by pacing, is common. In horses with subtle ataxia, one observes pacing when horses walk with the head held in an extended position. Whenever one observes a horse pacing, the pacing may indicate an underlying neurologic disorder; however, many normal horses will also pace when their head is elevated.

The gallop is a high-speed four-beat gait that often seems to be easier to perform than walking in a tight circle or moving at a slow trot. Therefore some horses with a neurologic gait deficit may perform better at high speed. As the horse accelerates or slows down, one may detect abnormalities, and one must observe the horse carefully at this time when an ataxic horse is most unsafe.

Abnormal gaits associated with stringhalt, upward fixation of the patella, and fibrotic myopathy deserve careful attention. Horses that show these gait abnormalities have a mechanical lameness, although the exact cause is unknown and may sometimes be associated with underlying neurologic disease. Stringhalt often begins as an abrupt onset of excessive flexion of one or both rear limbs. In some horses the condition may worsen and result in frequent episodes of the foot hitting the abdomen. The condition has been reported for a long time and in some areas of the world may occur as an outbreak. The clinical syndrome is similar to the movement of a horse with a tibial neurectomy with unopposed flexion of the hock and extension of the digit. In the case of Australian stringhalt, the forelimbs and neck muscles may be involved. Stringhalt deserves mention in this chapter because when the examiner observes this gait, the examiner should be certain no other signs of neurologic gait deficits exist. The primary condition usually can be corrected by a tenectomy of the lateral digital extensor tendon, including a portion of the muscle belly. The underlying cause of the disease may be a sensory neuropathy, a myopathy, or primary spinal cord disease. The defect likely affects the neuromuscular spindle, as well as the efferent and afferent pathways controlling muscle tone. Fibrotic myopathy results from scar tissue formation after injury to the semitendinosus and semimembranosus muscles. One may confuse the characteristic foot placement coupled with the abrupt rearward movement of the affected limb with a spastic gait caused by spinal cord injury or disease. With careful examination, a horse suffering from fibrotic myopathy likely will not go undiagnosed. Upward fixation of the patella in horses with neurologic disease may result from weakness in the quadriceps muscle group. This weakness is thought to occur because of a lack of use of these muscles or may be caused

TABLE **11.1 Localization of Peripheral Nerve Injuries in Horses**

Nerve	Clinical Signs	Common Causes of Injury
Suprascapular	Injury is termed *sweeney.* Eventual atrophy of supraspinatus and infraspinatus muscles. Lateral subluxation (popping) of the shoulder on weight bearing. This may be caused by lack of lateral collateral support (suprascapular muscles) or by additional involvement of the pectoral nerve, subscapular nerve, caudal cervical nerve roots, or other muscular and tendinous supporting structures of the shoulder.	Collision of shoulder with objects.
Radial	Unable to bear weight on affected limb because of a lack of elbow extension. The shoulder is rested in an extended position, and the limb rests with the dorsum of the pastern on the ground. The limb may be moved forward by the action of the pectoral girdle muscles while the horse walks.	Often damaged in conjunction with humeral fracture; occasionally observed after recovery from general anesthesia.
Brachial plexus	Signs of radial nerve paralysis often predominate. Evidence of suprascapular involvement not uncommon. Involvement of other nerves and nerve roots may be confirmed with EMG. Possible long-term atrophy of triceps. May have diffuse hypalgesia of lower limb.	Compression of the brachial plexus and radial nerve roots between the scapula and the ribs.
Musculocutaneous	Paralysis not common. Gait not markedly altered. Elbow may be overextended. Hypalgesia of medial forearm. Ultimately biceps and brachial muscles atrophy.	Uncommon.
Median and ulnar	Stiff, goose-stepping gait with hyperextension of the carpal, fetlock, and pastern joints.	Uncommon.
Femoral	Unable to support weight as a result of lack of stifle extension. At a walk, the limb is advanced only with difficulty, and the stride is markedly shortened. The limb buckles due to stifle, hock, and fetlock flexion if the horse attempts to bear weight. Quadriceps muscle will atrophy after 10–14 days. Patellar reflex is absent.	External blow to the limb; occasionally observed after recovery from general anesthesia.
Sciatic	Poor limb flexion with stifle and hock extended and fetlock flexed when the horse is not bearing weight. Weight can be supported if the foot is extended; otherwise weight is supported on the dorsal surface of the foot. Limb hypalgesia from stifle downward with the exception of the medial surface between stifle and hock.	Variety of injuries may be causal. Occasionally occurs secondary to intramuscular injections, especially in foals; occasionally observed after recovery from general anesthesia.
Tibial	Hypermetric or stringhalt-like gait with flexion of the hock (dropped hock) at rest. Hypalgesia of areas of caudal limb distal to the hock including most of the caudal and medial coronary band area.	Uncommon.
Peroneal	Frequently a component of sciatic nerve injury. Inability to flex the hock and extend the digits. Acutely there is hyperextension of the hock and hyperflexion of the fetlock and interphalangeal joints causing the horse to drag the fetlock along the ground. Short protraction phase to the stride. If the foot is placed in a normal position, the limb may bear weight. Hypalgesia of the craniolateral portion of the limb from the level of the hock to the fetlock.	Accessible to injury as it passes across the lateral surface of the tibia. Injury seen in horses after recovery from general anesthesia or secondary to a kick or blow to the lateral side of the pelvic limb.

by abnormal transmission of proprioceptive information to and from the muscles and joint capsule because of damage to the spinal cord.

Horses with profound ataxia may pace when they walk, which often is accompanied by circumduction of the outside rear limb while turning. These signs suggest general proprioceptive deficits. If the horse has these deficits while walking, the examiner should observe the horse walking with its head elevated and on a slope (these maneuvers often exaggerate a subtle problem). If the horse shows signs only in the trunk and pelvic limbs, the neuroanatomic localization of the lesion is between T2 and S2 or involves the nerves and muscles of the pelvic limbs. However, horses with cervical spinal cord lesions often demonstrate signs in the pelvic limbs that are one grade worse than those observed in the thoracic limbs. Therefore a mild cervical spinal cord or brainstem lesion could show minimal or no thoracic limb signs with grade 1 or subtle signs in the pelvic limbs.

Palpating the horse over its back, rump, and muscles of the rear limbs while being careful to detect any muscle atrophy is helpful.

The author routinely stimulates the horse over the side of its body and observes for any twitching of the cutaneous trunci muscles. Such twitching usually is accompanied by a cerebral response and requires a fairly severe lesion to detect areas of analgesia.

A sway reaction performed while the horse is standing and walking is also necessary to assess the pelvic limb strength and proprioceptive functions. In addition, one may evaluate strength by slow but deliberate and forceful pressure along the back and sacral muscles. A normal horse should reflexively arch its back upward, whereas a horse with rear limb weakness may be unable to withstand this pressure, and its rear limbs may even buckle.

To complete the neurologic examination, one must examine the tail and anus to determine whether damage has occurred to the sacrococcygeal nerve and muscle segments. A normal perineal reflex results in contraction of the anus and clamping of the tail in response to light stimulation of the skin in this region. Cauda equina neuritis or polyneuritis equi, trauma, and iatrogenic injury resulting from an alcohol tail block are some disorders that may affect this area.

The evaluation of the major peripheral nerves in the horse is also an important part of the neurologic examination (see Table 11.1). The important points to remember are that damage to a peripheral nerve can result in sensory and motor deficits in the area supplied by the nerve and that focal muscle atrophy follows within a short time after damage to one of these nerves. The examiner is referred to other portions of this book for a more detailed anatomic description of these nerves in the horse; however, a dropped elbow joint with radial nerve paralysis, inability to fix the stifle with femoral nerve paralysis, and atrophy of the supraspinatus and infraspinatus muscles (sweeney) with damage to the suprascapular nerve are classic examples of what to expect with peripheral nerve injuries.

CONCLUSION

For a horse to be a good athlete, it must gather information from muscles, tendons, and nerves; process this information in the brain, brainstem, and spinal cord; and relay this information to the musculoskeletal system. The horse must accomplish all of this in a short time to perform complex maneuvers at a high rate of speed. When performing in a setting involving many other horses or when a rider or driver is involved, the horse needs to be able to control these movements in a coordinated fashion to protect itself, other horses, and especially those persons handling, riding, or driving the horse.

Beyond this, veterinarians must recognize which musculoskeletal and neurologic conditions occur together to assist prospective buyers with horse-purchasing decisions. Recognizing and understanding these things helps the veterinarian determine whether a particular horse with subtle neurologic gait deficits caused by trauma, infection, or compression may still be a safe and useful athlete.

CEREBROSPINAL FLUID EVALUATION

Yvette S. Nout-Lomas

Cerebrospinal fluid evaluation has diagnostic importance regarding neurologic disease in horses. Collection and analysis of CSF is indicated to make or confirm a diagnosis of neurologic disease, but this is not without limitations. CSF values may be normal in an animal with severe neurologic deficits because the lesion is extradural, collection occurred early or late in the course of disease, collection occurred too far from the lesion, or the ventral roots and peripheral nerve have been affected by the disease. Even with its limitations, CSF provides valuable information about the CNS. However, one must emphasize that CSF evaluation is another piece of the diagnostic puzzle and together with the history, physical examination, neurologic examination, and other ancillary procedures may help in the diagnosis and prognosis of neurologic disease in horses.

Formation, Flow, and Function of Cerebrospinal Fluid

CSF is produced as an ultrafiltrate of plasma and is actively secreted by ependymal cells of the ventricles and choroid plexus. The CSF is located in the ventricles of the brain and subarachnoid space of the spinal canal (Fig. 11.2) and bathes the CNS. CSF flows from the ventricular system up and over the cerebral hemispheres and through the subarachnoid space surrounding the spinal cord. Pulsation of blood in the choroid plexuses forces the CSF in a caudal direction. The rate of CSF production is constant, varies among species, and is independent of vascular hydrostatic pressure. The rate of CSF production for horses has not been determined but in humans is estimated to be approximately 0.34 mL/min.[12] Hypertonic solutions such as mannitol, when added to blood, decrease CSF production and decrease CSF pressure and edema.[1]

Collections of arachnoid villi (arachnoid granulations) are located in the venous sinus or the cerebral vein and absorb CSF. CSF absorption is related directly to the pressure gradient between the CSF and venous sinus. When CSF pressure exceeds venous pressure, these villi act as one-way ball valves, forcing CSF flow to the venous sinus.

CSF functions to protect the brain from trauma and to maintain a consistent extracellular environment for the CNS.

Collection of Cerebrospinal Fluid

Techniques for collecting CSF in horses have been described in detail elsewhere.[1,3,4,13] CSF may be collected from the lumbosacral site in a standing sedated horse. Alternatively, it can be collected from the atlantooccipital site of an anesthetized horse. In foals and recumbent adult horses, one can collect CSF from the atlantooccipital site while the animal is recumbent, restrained, and heavily sedated. The lumbosacral collection of CSF is traditionally performed based on anatomic landmarks, but one can also perform the procedure using ultrasound guidance.[14] Similarly, atlantooccipital collection of CSF is typically performed in the recumbent horse using anatomic landmarks. Two techniques have been described for upper cervical puncture in the standing sedated horse using ultrasound guidance.[15,16] Pease and colleagues[16] describe fluid collection between C1 and C2 using a lateral approach in the standing sedated horse under ultrasound guidance, and Depecker and colleagues[15] describe fluid collection from the spinal cistern at the atlantooccipital site using parasagittal ultrasound guidance. If the lesion is localized to an area above the foramen magnum (at least cranial to the second cervical vertebra), CSF collected from the atlantooccipital site may be more diagnostic. If the lesion is localized to an area below the

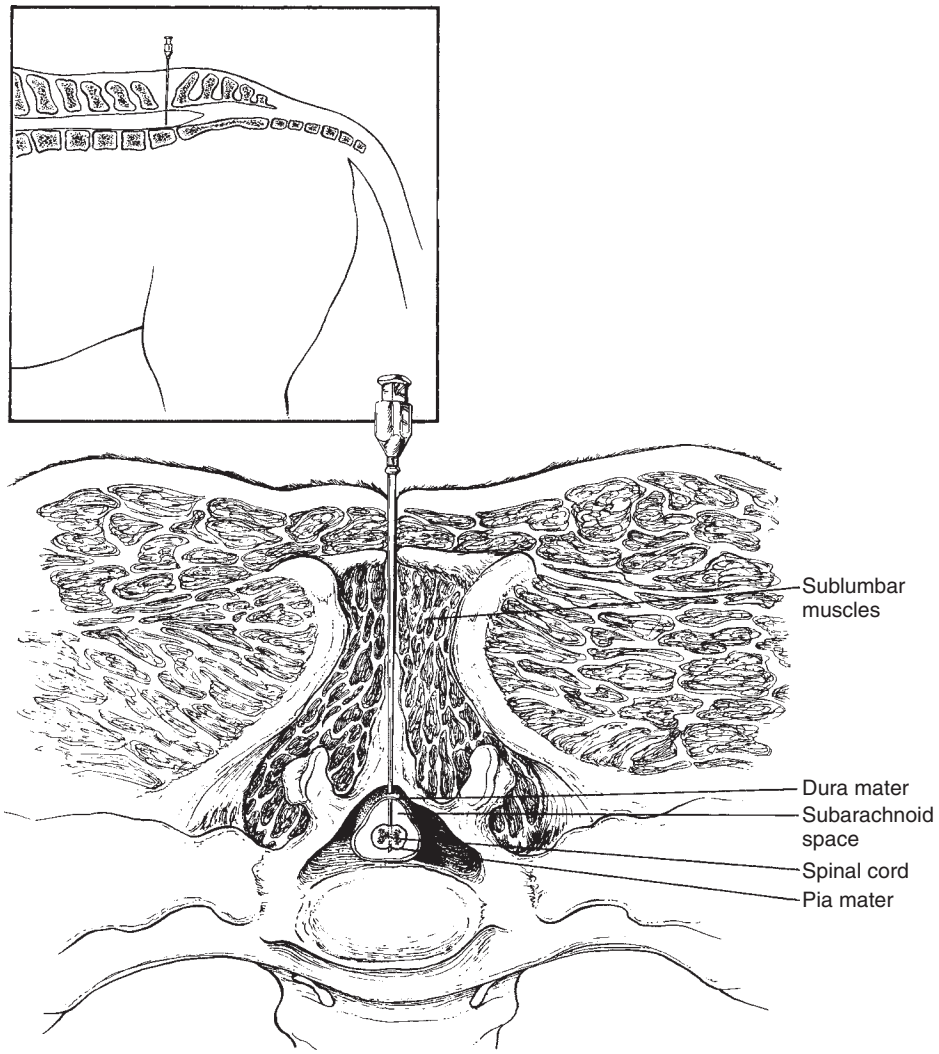

FIG. **11.2** Lumbosacral spinal fluid collection from a horse showing the various tissue layers that the spinal needle must pass through to obtain a sample. The spinal fluid is collected ventral to the spinal cord in the subarachnoid space. *Inset,* Lateral view of spinal needle placement in the lumbosacral space for collection of cerebrospinal fluid (CSF). (From deLahunta A, Glass EN: *Veterinary neuroanatomy and clinical neurology,* ed 3, St. Louis, 2009, WB Saunders.)

foramen magnum (caudal to the second cervical vertebra), CSF collected from the lumbosacral site will be more diagnostic. These differences result from the craniocaudal circulation of CSF. Collecting CSF from both sites at the same time and comparing the findings may be helpful in cases in which neuroanatomic localization of the lesion is difficult.[4]

Examination of Cerebrospinal Fluid

Reference values for CSF in foals, horses, and other equids have been reported,[3,17-23] but each laboratory should determine its own reference ranges. CSF determinations that are helpful in evaluating horses with neurologic diseases include pressure, appearance, cellular content, protein concentration (total protein, albumin, immunoglobulin G [IgG]), enzyme activity (creatine kinase [CK], aspartate aminotransferase [AST], lactate dehydrogenase), and lactic acid concentration.

Pressure

One can measure opening CSF pressure before withdrawal of CSF by attaching a manometer tube with a three-way stopcock to a properly placed spinal needle, allowing the CSF to rise within it.[21] Because the cranial and vertebral cavities are enclosed in a rigid bony compartment, changes in blood pressure or volume can cause a concomitant increase in CSF pressure. Thus increased CSF pressure may occur from venous compression or jugular occlusion. Venous compression causes increased blood volume in the cranial cavity and compression of the CSF space, leading to increased CSF pressure. One can use jugular occlusion clinically to increase CSF pressure and facilitate collection of CSF fluid. The jugular compression maneuver, or Queckenstedt's phenomenon, can help one diagnose compressive lesions, neoplastic lesions, or an abscess along the spinal cord. With compression and obliteration of the subarachnoid space by a compressive lesion in the cervical or thoracic spinal cord, jugular vein compression does not cause a CSF pressure increase in the lumbosacral site.[1]

Increased CSF pressure may occur after injury, after systemic changes in blood pressure, and in the presence of an intracranial space-occupying mass such as a tumor, abscess, hemorrhage, or edema. One must provide an adequate airway

after injury and during surgery to prevent hypoxia-mediated cytotoxic cerebral edema and vasogenic cerebral edema. Cytotoxic edema is caused by inadequate cerebral oxygenation and leads to neuronal, glial, and endothelial cell swelling. Such reactions are especially important during long surgical procedures or recumbency in which respiratory hypoxia and poor alveolar ventilation (hypercapnia) may occur. Hypercapnia increases cerebral blood flow in the cranial cavity, and CSF pressure and may worsen existing cerebral edema.

Increased CSF volume may occur in hydrocephalus, which is defined as an increased volume of CSF and can be classified as *compensatory* or *obstructive*. Compensatory hydrocephalus is an accumulation of CSF in areas in which brain tissue has been destroyed and may occur from brain injury or inflammation. Hydranencephaly is destruction of brain tissue from a viral or other infectious agent and results in severe accumulation of CSF. CSF pressure in compensatory hydrocephalus usually does not increase.

Obstructive hydrocephalus is an accumulation of CSF in the ventricles from an obstruction to CSF outflow or absorption. Cerebral aqueduct malformation may lead to obstruction of ventricular CSF outflow. Inflammatory lesions, especially of the arachnoid villi, result in decreased absorption of CSF and increased CSF pressure. The white matter is affected more severely than the gray matter in obstructive hydrocephalus, but the cerebral cortex usually is spared. CSF pressure in obstructive hydrocephalus usually increases. The presence of an abnormally high opening pressure that drops by 25% to 50% after removing 1 to 2 mL of fluid suggests a space-occupying intracranial mass or spinal cord compression cranial to the site of collection. The removal of more fluid would risk causing tentorial herniation.[21]

Appearance

One can evaluate the appearance of CSF immediately after collection. Normal CSF is clear and colorless and does not clot, and newsprint is visible through it. CSF may be red tinged from blood contamination after a traumatic tap or from preexisting trauma to the CNS. In the case of a traumatic tap, the CSF usually will clear if allowed to flow for several seconds (about 0.5–1.0 mL). With preexisting trauma and secondary hemorrhage, the supernatant of CSF after centrifugation is xanthochromic.

Other causes of CSF xanthochromia include increased protein concentration (150 mg/dL) and direct bilirubin leakage from serum in horses with high serum bilirubin concentration. In addition, indirect bilirubin may leak across a damaged blood-brain barrier. Clots in the CSF are abnormal and may be caused by increased amounts of fibrinogen resulting from inflammation.

Turbid CSF may indicate an increased number of white blood cells (greater than 200/μL), an increased number of red blood cells (RBCs) (greater than 400/μL), epidural fat, bacteria, fungal elements, or amebic organisms. Cytologic evaluation and cultures can help differentiate causes of turbidity.

Cytologic Evaluation

One can use a standard hemocytometer to obtain a complete blood count (CBC). In addition, a sedimentation chamber requiring 0.5 to 1.0 mL of CSF is a rapid method for cytologic evaluation. One must perform cell counts and cytologic evaluation within 30 minutes to avoid degeneration. If cell counts or cytologic evaluation cannot be performed immediately, one can mix a portion of the sample with an equal volume of 50% ethanol to preserve cellular characteristics.[21] CSF from normal horses and foals usually contains fewer than 7 white blood cells per microliter.[3] Most studies show no differences in white blood cell counts in normal CSF samples obtained from the atlantooccipital space compared with samples obtained from the lumbosacral space.

Small mononuclear cells (70%–90%) and large mononuclear cells (10%–30%) predominate in equine CSF. Rarely, one may see neutrophils in horse CSF. Increased CSF large mononuclear phagocytes are visible in diseases of axonal degeneration.[18] One may see increased CSF neutrophil numbers in encephalomyelitis, bacterial meningitis, parasitism, and diseases with extensive inflammation. Occasionally, in severe inflammatory diseases of the neurologic system or parasitism, eosinophils may be visible.[18,24] In some cases, cytologic evaluation of CSF may reveal specific agents causing neurologic disease such as fungal organisms, bacteria, or tumor cells. Although CSF cytologic examination may support a diagnosis of neurologic disease, it may not yield a specific causative diagnosis. Analysis of cytokine gene expression in the nucleated cells of equine CSF suggests that there are distinct gene signatures expressed by nucleated cells in the CSF of horses without neurologic signs versus horses with inflammatory or traumatic neurologic disorders.[25]

Protein Concentration and Composition

Normal total protein values range from 20 to 124 mg/dL, depending on the measuring method used (Table 11.2). Total protein concentration is higher in lumbosacral CSF compared with atlantooccipital CSF.[26] A difference of 25 mg/dL of protein between the atlantooccipital and lumbosacral spaces may suggest a lesion closer to the space with greater spinal fluid protein.[22] Proteins in the CSF are derived from the peripheral blood and include albumin, IgG, and possibly other globulins. Increased CSF albumin and IgG concentrations may occur with damage to the blood-brain barrier or increased intrathecal production of IgG. One can determine CSF albumin and IgG concentrations by electrophoresis and radial immunodiffusion, respectively, and can compare these with serum concentrations. One can calculate the albumin quotient (AQ) ([Albc]/[Albs] × 100) and IgG index ([IgGc]/[IgGs] × [Albs]/[Albc]) to determine blood-brain barrier permeability and intrathecal IgG production. Increased intrathecal IgG production (increased IgG index) may occur in inflammatory spinal cord disease such as equine protozoal myeloencephalitis (EPM), equine neuroborreliosis, bacterial meningitis, some tumors, and equine motor neuron disease. Determining blood-brain barrier integrity is also important in planning therapy. If the blood-brain barrier is damaged, pharmacologic agents such as penicillin that do not normally penetrate the blood-brain barrier will penetrate a disrupted blood-brain barrier and attain bactericidal CSF concentration.

Enzyme Determination

CSF enzyme activity may be increased in neurologic disease. CK and AST activity may be increased in diseases with myelin degeneration and neuronal cell damage such as EPM, polyneuritis equi, equine degenerative myelopathy, and equine motor neuron disease. Increased CK activity also may occur in conditions that alter blood-brain barrier permeability, such as equine herpesvirus–1. In diseases in which the blood-brain barrier is damaged, serum CK can leak into the CSF and increase CSF CK activity. This increased CK activity is not associated with damaged myelin.

TABLE **11.2 Cerebrospinal Fluid Values from Atlantooccipital and Lumbosacral Spaces of Normal Healthy Adult Horses**

	Atlantooccipital Space (Mean ± SD [Range])	Lumbosacral Space (Mean ± SD [Range])
Red blood cell (RBC) count (per μL)	51.0 ± 160 (0–558)	36.8 ± 59.7 (0–167)
White blood cell count (per μL)	0.33 ± 0.49 (0–1)	0.83 ± 1.11 (0–3)
Total protein (mg/dL)[a]	87.0 ± 17.0 (53 ± 11.6) (59–118) (35–74)	93.0 ± 16.0 (58.0 ± 11.0) (65–124) (39–78)
Albumin (mg/dL)	35.8 ± 9.7 (24–51)	37.8 ± 11.2 (24–56)
Albumin quotient (AQ)	1.4 ± 0.4 (1.0–2.0)	1.5 ± 0.4 (1.0–2.0)
Immunoglobulin G (IgG) (mg/dL)	5.6 ± 1.4 (3–8)	6.0 ± 2.1 (3–10)
IgG index	0.19 ± 0.046 (0.12–0.27)	0.19 ± 0.5 (0.12–0.26)
Creatine kinase (CK) (IU/L)	0–8	0–8
Lactate dehydrogenase (IU/L)	0–8	0–8
Aspartate aminotransferase (AST) (IU/L)	4–16	0–16
Glucose (mg/dL)	35%–70% of blood glucose	
Lactate (mg/dL)	1.92 ± 0.12	2.30 ± 0.21
Sodium (mEq/L)	140–150	140–150
Potassium (mEq/L)	2.5–3.5	2.5–3.5

[a]Total protein concentration next to the mean ± SD in parentheses is the value expected using a total protein standard.

Increased CK activity also may suggest other diseases of the CNS. In one study, CK activity (greater than 1 IU/L) most often was associated with EPM in horses and may be helpful in differentiating compressive spinal cord disease from EPM. Furthermore, persistently increased CSF CK activity may be associated with a poor prognosis in horses with EPM.[27] Lactate dehydrogenase activity may be increased in spinal lymphosarcoma.

Lactic Acid Concentration

CSF lactic acid concentration may be an indicator of neurologic disease (see Table 11.2). CSF lactic acid concentration increases in eastern equine encephalomyelitis (4.10 ± 0.6 mg/dL), head trauma (5.40 ± 0.9 mg/dL), and brain abscess (4.53 mg/dL). Lactic acid concentration may be the only CSF parameter increased in horses with brain abscess.[28]

Caffeine

CSF concentrations of caffeine and its metabolites were evaluated using a novel microdialysis system that allowed simultaneous monitoring of locomotor activity and collection of CSF and blood samples for pharmacokinetic analysis.[29] Investigators found that 3 mg/kg caffeine increased spontaneous locomotor activity, which was correlated to increased blood and CSF caffeine concentrations.

Summary

Normal CSF findings do not always rule out the presence of neurologic disease. CSF values may be normal with lesions outside the CNS that are not bathed in the CSF, such as extradural, ventral root, and peripheral nerve lesions. Normal CSF values also may occur early or late in the disease process and in CSF samples obtained from a site distant from the lesion. Acute neurologic disease, especially if multifocal, may not have sufficient time to cause significant damage to the blood-brain barrier and alter CSF constituents, whereas in chronic CNS disease the blood-brain barrier may be repaired and functional but with nervous tissue replaced by fibrous tissue. Fibrosis of nervous tissue may result in significant neurologic gait deficits and normal CSF constituents. CSF taken away from the site of the lesion shows normal findings despite significant neurologic gait deficits. For example, CSF in a horse with a cervical spinal cord abscess may show a suppurative inflammation in the lumbosacral CSF and a normal atlantooccipital CSF. This discrepancy is caused by the caudad flow of CSF.

CSF may be helpful in supporting the diagnosis of neurologic disease in horses and is part of the diagnostic workup. Because CSF evaluation is an ancillary diagnostic test, one should use it with, and not as a substitute for, a thorough history, physical examination, neurologic examination, and other diagnostic tests.

NEUROELECTRODIAGNOSTICS

M. Aleman

Neuroelectrodiagnostic testing is a useful modality that comprises various diagnostic modalities to evaluate brain, brainstem, nerve, neuromuscular, and muscle electrical activity, among others. Neuroelectrodiagnostics should be used as an extension of the neurologic examination that might aid in further localization of lesions in certain challenging cases. Depending on the specific diagnostic aid, horses might require sedation (i.e., electromyography, electroretinography, brainstem auditory evoked potential, otoacoustic emissions, visual evoked potentials, electroencephalography) or general anesthesia (i.e., nerve conduction studies, repetitive nerve stimulation).[30]

Electromyography

Electromyography (EMG) refers to the study of the electrical activity of the muscle.[31-34] The distribution of EMG abnormalities can assist in the localization of lesions to spinal cord segments, nerves, and/or muscles.[31-34] Quantitative EMG can further assist in the determination of disorders as myopathic,

TABLE **11.3** **Muscles, Nerves, and Nerve Roots Evaluated during Routine Electromyographic Examination of Horses**

Muscles	Peripheral Nerve	Spinal Nerve Root
REAR LIMB		
Long digital extensor	Peroneal nerve	L6–S1
Gastrocnemius	Tibial nerve	S1–S2
Deep digital flexor	Tibial nerve	S1–S2
Semimembranosus	Ischiatic nerve	L5–S2
Vastus lateralis	Femoral nerve	L3–L5
Biceps femoris	Caudal gluteal, ischiatic, and peroneal nerves	L6–S2
Middle gluteal	Cranial and caudal gluteal nerves	L5–S2
PARAVERTEBRAL		
Paravertebral muscles (segmentally)	Dorsal branches of ventral spinal nerves (L6–C1)	L6–C1
THORACIC LIMB		
Subclavius	Pectoral nerve	C6–C7, T1
Supraspinatus	Suprascapular nerve	C6–C8
Infraspinatus		
Deltoideus	Axillary nerve	C6–C8
Biceps brachii	Musculocutaneous nerve	C6–C8
Triceps	Radial nerve	C7–T1
Extensor carpi radials	Radial nerve	C7–T1
Superficial digital flexor	Ulnar nerve	C8–T2
Deep digital flexor	Ulnar and median nerve	C7–T1, T2

neurogenic, or both.[31-35] EMG might not provide a definitive diagnosis but will aid to support or refute a suspected clinical diagnosis and further our understanding of disease processes. EMG can be performed in the unsedated horse; however, for safety reasons and duration of the study, sedation is recommended. Sedation can be achieved with xylazine hydrochloride at 0.2 to 0.5 mg/kg IV or detomidine hydrochloride at 0.005 to 0.01 mg/kg IV.[30] Examination of the awake horse aids in evaluating motor unit action potentials (MUAPs).[30] The waveforms of EMG are derived from the action potentials of the muscle fibers that are firing singly or in groups near the electrode.[32]

In the needle EMG examination, one should thrust the exploring electrode briskly into the muscle and hold it until the animal completely relaxes. To enable relaxation, pressure can be applied to the animal to bear weight on the opposite limb. Once relaxation has occurred, resting activity or any postinsertional activity of the muscle can be evaluated. EMG records insertional and spontaneous activities (normal and pathologic). Evaluation of multiple areas (at least four to six) and depth within skeletal muscles under study should be performed. Table 11.3 provides examples of muscles, nerves, and spinal cord segments that can be tested. A thorough and systematic evaluation must be performed to avoid missing a lesion.

Normal Electromyographic Potentials

Motor Unit Action Potentials. MUAPs result from voluntary or reflex muscle contractions observed after insertion of the needle electrode. They represent the sum of a number of muscle fiber potentials. MUAPs are characterized by its appearance, duration, amplitude, number of turns, number of phases, area, and rise time.[32] MUAPs normally have a triphasic configuration but could be monophasic, biphasic, or polyphasic (Fig. 11.3).[32] A few polyphasic potentials (greater than four phases) might occur in normal muscle but usually do not exceed 5% to 15% of the population of MUAPs observed.[31-33] MUAPs have an amplitude ranging from 500 to 3000 μV and a duration ranging from 1 to 15 ms. Examination of the conscious horse enhances the evaluation of the amplitude and number of phases of MUAPs in the muscle. MUAPs can be observed when the horse bears weight on or retracts a limb, resulting in contraction of that explored muscle. As muscle contraction becomes more intense, more motor units are recruited and the greater frequency of MUAPs is observed.

Resting Activity. Resting activity (electrical silence appears as a flat line) is observed in relaxed muscle.[31-33] When the needle comes to rest near a nerve twig or end plate, the needle might irritate small intramuscular nerve terminals. However, end plate noise and end plate spikes might be observed. End plate noise produces a rippling of the baseline and a low-pitched continuous noise (Fig. 11.4).[31,33] End plate spikes, on the other hand, are high-amplitude intermittent spikes and make a popping sound. End plate noise and spikes can occur alone or together. The origin of end plate noise is due to extracellularly recorded miniature end plate potentials,[31,33] whereas end plate spikes are due to single muscle fiber contractions after needle electrode irritation of the nerve terminals.[31,33] In human beings, these potentials are associated with dull pain; repositioning the needle often eliminates their activity.

Insertional Activity. Insertional activity is that EMG activity caused by mechanical stimulation of muscle fibers on needle insertion and usually does not go beyond 1 to 2 seconds after insertion. Spontaneous activity might be found at the end plate

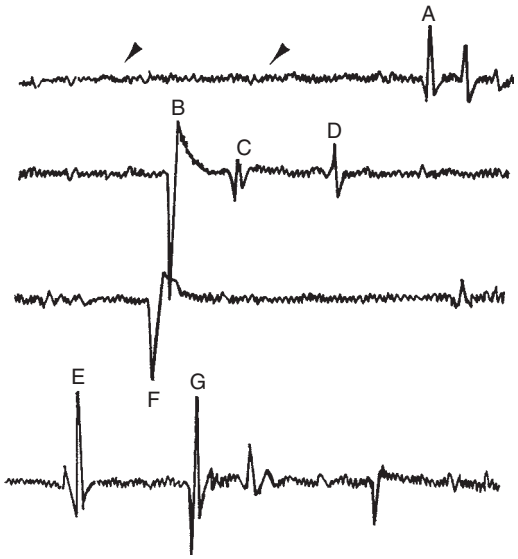

FIG. **11.3** Electromyograph of the middle gluteal muscle showing normal resting activity *(arrowheads),* fasciculation potentials ***(A, E, G),*** fibrillation potentials ***(C),*** positive sharp waves ***(B, F),*** and a small motor and action potential ***(D).***

or motor unit region.[31-33] Alterations of insertional activity include absent, decreased, increased, or prolonged activities.[31-33] Insertional activity consists of short bursts of high-amplitude, moderate- to high-frequency (less than 200 Hz) electrical activity during and shortly after the insertion or movement of the exploring electrode in the muscle (Fig. 11.5). Prolonged ongoing electrical activity after cessation of needle insertion is considered abnormal.

Prolonged Insertional Activity. Prolonged electric activity continuing 1 to 10 ms after needle insertion and placement in the muscle is considered abnormal and caused by hyperirritability and instability of the muscle fiber membrane.[31-34] Increased or prolonged insertional activity usually precedes the onset of other denervation potentials (fibrillation potentials and positive sharp waves) and might suggest early denervation atrophy.[31-34] However, prolonged insertional activity can also be observed in myotonic disorders and myositis.[31-34]

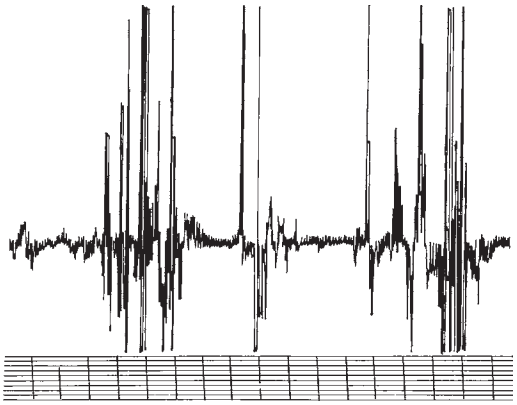

FIG. **11.5** Normal insertional activity in the infraspinatus muscle. Gain: 0.500 mV/division; time: 10 ms/division.

Decreased Insertional Activity. Decreased insertional activity (decreased amplitude, duration, or both) is associated with a decreased number of functioning muscle fibers and can be seen with neuropathies and myopathies. Infiltration of connective tissue and fat in the muscle leads to a decreased number of muscle fibers, which decreases insertional activity. Complete fibrosis of the muscle results in loss of insertional activity. Insertional activity also might be absent when muscle fibers are functionally inexcitable, as occurs during attacks of familial periodic paralysis,[31-34] or if a faulty needle electrode is used.

Abnormal Electromyographic Potentials

Spontaneous activity in a relaxed muscle after cessation of needle movement is considered abnormal. Abnormal spontaneous activities include fibrillation potentials, positive sharp waves, complex repetitive discharges, myotonic discharges, pseudomyotonic discharges, and neuromyotonic discharges.[31-34] In acute neuropathic disorders, EMG abnormalities might not be evident immediately.[31-34] It might take about 2 weeks to detect EMG alterations.[31-34]

Polyphasic Motor Unit Action Potentials. Polyphasic MUAPs (myopathic potentials) have increased frequency (greater than four phases) and decreased amplitude and duration (Fig. 11.6) observed during submaximal muscle contraction and that result from an increased number of action potentials for a given strength of contraction. Myopathic potentials result from a diffuse loss of muscle fibers and indicate the need for extra motor units to perform the work normally done by fewer motor units.[31-33] Myopathic potentials are polyphasic and most often occur in primary myopathies such as myotonia-like syndromes, periodic paralysis, myositis, botulism, and myasthenia gravis–like syndromes. These potentials also have been reported in steroid-induced myopathies, pars intermedia pituitary dysfunction, and membrane defect myopathies.[36] MUAPs of neurogenic origin can have a decreased frequency and longer duration than myopathic potentials and might occur during minimal and maximal muscle contraction (see Fig. 11.6). Thus one observes fewer MUAPs of increased amplitude than expected for the strength of contraction, which is more noticeable during maximal contraction and produces a sputtering or motorboat sound. Abnormal MUAPs of neurogenic origin can be caused by a decreased

EMG FINDINGS

	Lesion / EMG steps	Normal	Neurogenic lesion		Myogenic lesion		
			Lower motor	Upper motor	Myopathy	Myotonia	Polymyositis
1	Insertional activity	Normal	Increased	Normal	Normal	Myotonic discharge	Increased
2	Spontaneous activity		Fibrillation Positive wave				Fibrillation Positive wave
3	Motor unit potential	0.5-3.0 mV 5-10 ms	Large unit Limited recruitment	Normal	Small unit Early recruitment	Myotonic discharge	Small unit Early recruitment
4	Interference pattern	Full	Reduced Fast firing rate	Reduced Slow firing rate	Full Low amplitude	Full Low amplitude	Full Low amplitude

FIG. **11.6** Differential electromyographic findings in neurogenic and myogenic conditions. (Modified from Kimura J: *Electrodiagnosis in diseases of nerve and muscle: principles and practice*, Philadelphia, 1984, FA Davis.)

number of functioning axons firing during maximal muscle contraction. These potentials are most often present in primary neuropathies in which collateral reinnervation has occurred.[31-33]

Fibrillation Potentials. These spontaneous discharges (see Fig. 11.3) sound like frying eggs, crinkling cellophane, or frying bacon and have an initial positive deflection of 100 to 300 μV in amplitude and 2 to 4 ms in duration.[31-33] They are diphasic or triphasic in waveform. Fibrillation potentials strongly suggest denervation but have been observed in polymyositis, muscular dystrophy, and botulism.[37] Fibrillation potentials could result from spontaneous discharges from acetylcholine-hypersensitive denervated muscle fibers or muscle inflammation and focal muscle degeneration.[31-33] A few fibrillation potentials have been observed in normal healthy muscle, but they are usually not reproducible in other areas of the muscle.

The onset of fibrillation potentials after denervation depends on the size of the animal. The larger the animal, the later the onset of fibrillation potentials; they have been reported between days 5 and 16 after denervation in dogs and human beings.[31-33,37,38] The authors have observed fibrillation potentials 7 to 10 days after nerve injury in horses. Fibrillation potentials often occurred along with positive sharp waves; they increase and then decrease in amplitude as the muscle atrophies, with activity ceasing on complete muscle atrophy. Fibrillation potentials occurring alone denote a more severe disease process than the presence of positive sharp wave potentials alone. Fibrillation potentials are helpful in evaluating the length of time muscle denervation has been present and are important in diagnosing denervation before clinical muscle atrophy. Fibrillation potentials can be used to monitor progression of disease over time. In addition, a decrease in fibrillation

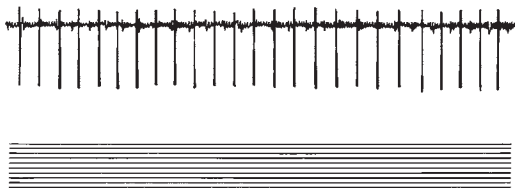

FIG. **11.7** Electromyograph showing trains of positive sharp waves. Gain: 500 V/stair step.

potentials followed by the recording of MUAPs might indicate reinnervation and might suggest a favorable prognosis.[31-33]

Positive Sharp Waves. Positive sharp waves are potentials in which the primary deflection is downward, followed by a lower amplitude, longer duration negative deflection (see Fig. 11.3). This waveform has been described as resembling a sawtooth.[31-33] Positive sharp waves occur with muscle denervation and muscular diseases such as myositis, exertional rhabdomyolysis (tying-up syndrome), and spinal shock. Positive sharp waves might occur in denervated muscle after chronic exertional rhabdomyolysis, myotonia, EPM, laryngeal hemiplegia, suprascapular nerve injury (sweeney), and compressive myelopathies.[39-42] Positive sharp waves often precede or appear along with fibrillation potentials in denervated muscle. These potentials can be observed singly or in trains (Fig. 11.7) and sound like a machine gun.[31-33]

Fasciculation Potentials. Fasciculation potentials are spontaneous discharges from a group of muscle fibers representing the whole or part of a motor unit (see Fig. 11.3).[32] Fasciculation potentials occur in diseases of anterior horn cells and irritative-type lesions of root or peripheral nerve, such as radiculopathies and nerve entrapments in human beings.[31-33]

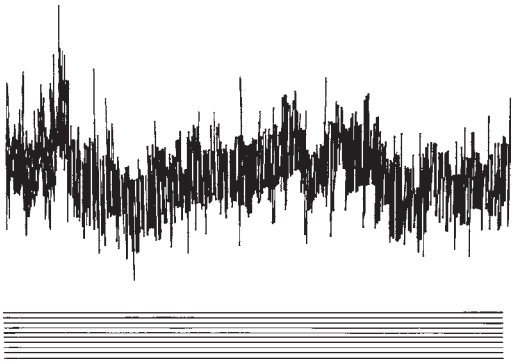

FIG. **11.8** Electromyograph showing waxing and waning myotonic potentials. Gain: 500 V/stair step.

Fasciculation potentials in the presence of fibrillation potentials or positive sharp waves might indicate lower motor neuron disease[43] and might occur in suprascapular nerve entrapment (sweeney) in horses.

Complex Repetitive Discharges and Myotonic Potentials. These potentials are repetitive MUAPs induced by insertion of the needle electrode or percussion of muscle.[31-33] Bizarre high-frequency potentials tend to be shorter in duration and end abruptly compared with myotonic discharges. Bizarre high-frequency potentials sound like a machine gun. However, myotonic potentials wax and wane in amplitude, last 4 to 5 seconds, and sound like a dive-bomber, hence the nickname dive-bomber potential (Fig. 11.8).[31-33] Myotonic and bizarre high-frequency potentials are associated with hyperexcitability of the muscle cell membrane.[31-33] Bizarre high-frequency potentials might occur in diseases of the lower motor unit such as muscular dystrophy, steroid-induced myopathy, polymyositis, chronic denervation, and hyperkalemic periodic paralysis.[31-33,44,45] Myotonic potentials occur in myotonia congenita and myotonia dystrophica and might occur in hyperkalemic periodic paralysis in human beings, which reflects abnormal muscle chloride or potassium conductance.[31-33] Complex repetitive discharges are seen in horses with hyperkalemic periodic paralysis.[45]

Nerve Conduction Studies

Nerve conduction velocity (NCV) studies assess the motor and sensory evoked responses to stimulation of nerves.[33] The evaluation of nerve conduction velocities requires knowledge of the topographic anatomy of nerves and muscles. In horses, this diagnostic modality could be technically challenging, is time consuming, and requires general anesthesia because electrical stimulation is applied.[30] NCV studies aid in the localization of nerve, neuromuscular junction, and muscle disease. Furthermore, it aids in the distinction between axonal degeneration and demyelination.[33] Nerve conduction velocity studies of the maxillary, facial, radial, median, ulnar, lateral and medial palmar and plantar, sural, superficial, and deep peroneal nerves have been reported in horses and ponies.[46-56]

Stimulation of a specific motor nerve consists of inserting a needle near the nerve that records a compound motor action potential from an innervated muscle (Figs. 11.9 and 11.10). The examiner might see or palpate the contraction of appropriate muscles on stimulation. The unaffected limb can be used as a control. In horses, radial nerve recordings can be obtained from the *extensor carpi radialis* and *abductor digitorum longus* muscles (Fig. 11.10) and for the median nerve from the humeral and radial heads of the deep digital flexor muscle[50,51] (Fig. 11.9). Facial nerve recordings can be obtained from the *levator nasolabialis* muscle by stimulating the buccal branch of the facial nerve just ventral to the facial crest.[47] Sensory nerve action potentials (SNAPs) can also be evaluated in the anesthetized horse.

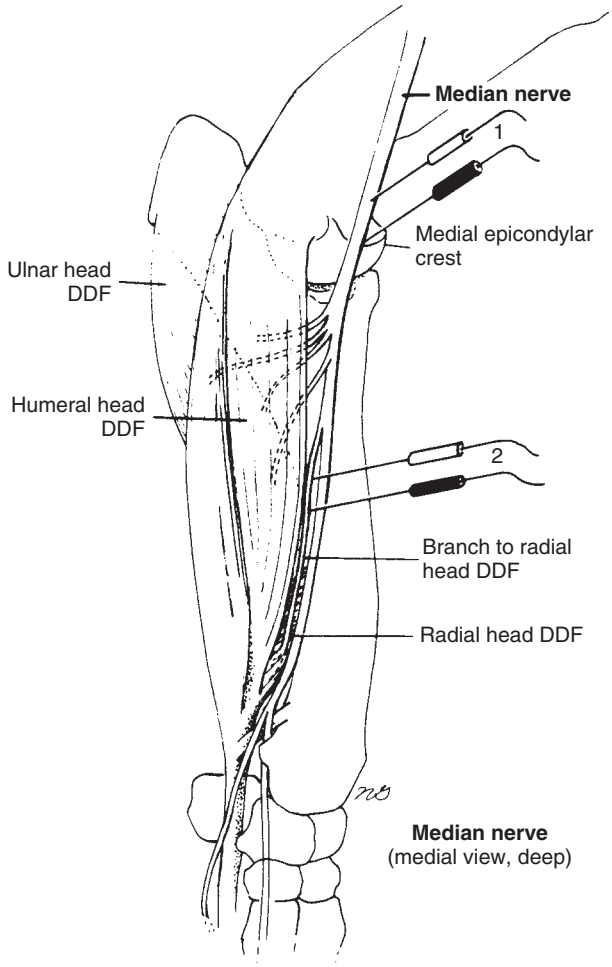

FIG. **11.9** Illustration of anatomy and electrode placement used in median nerve conduction velocities. *DDF,* Deep digital flexor. (From Henry RW, Diesem CD, Wiechers MD: Evaluation of equine radial and median nerve conduction velocities, *Am J Vet Res.* 40:1406-1410, 1979.)

Diseases Affecting the Motor Unit and Nerves

Focal and Multifocal Myelopathies

Compressive cervical myelopathies, cervical stenotic myelopathy, and EPM are common causes of neurologic disease in the horse. These conditions can affect sensory and motor pathways. Physical examination might reveal muscle atrophy and sweating over affected muscles. Needle EMG of the cervical axial musculature in horses with truncal, thoracic, and pelvic limb ataxia might reveal increased insertional activity, fibrillation potentials, and positive sharp waves supporting the conclusion that there is a lesion of the ventral horn cells or ventral roots. Abnormal postinsertional activity at the level of the

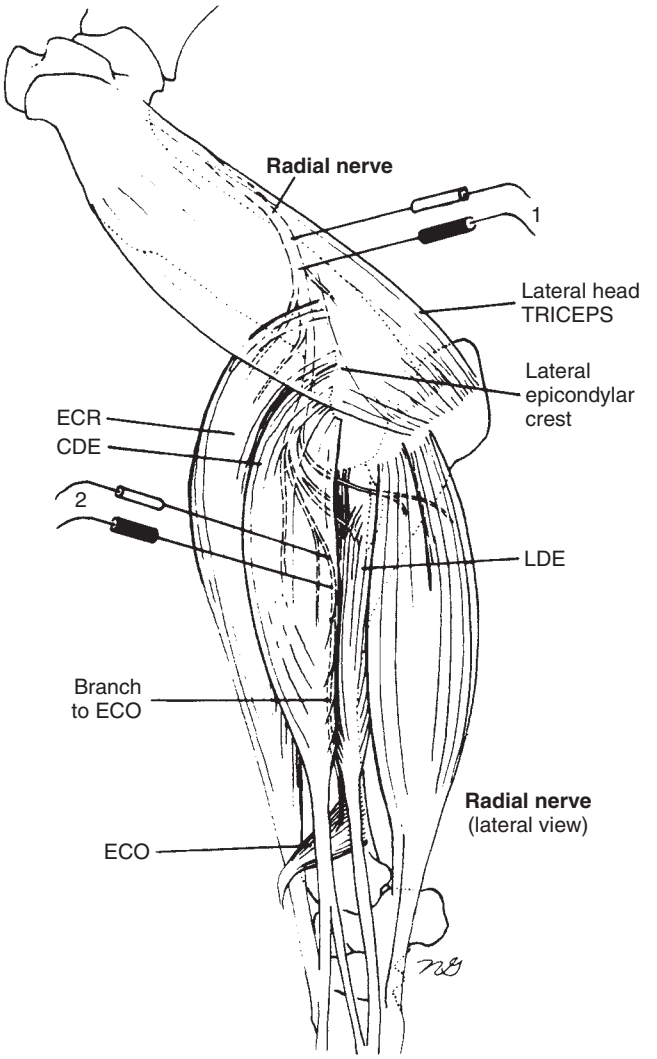

FIG. **11.10** Illustration of anatomy and electrode placement used in radial nerve conduction velocities. *ECR,* Extensor carpi radialis; *CDE,* common digital extensor; *LDE,* long digital extensor; *ECO,* extensor carpi obliquus. FIG. **11.11** Horse with gluteal muscle atrophy due to EPM showing distribution of abnormal electromyographic potentials.

spinal cord compression might allow the clinician to focus the radiographic examination.

In cases of EPM, needle EMG might reveal fibrillation potentials, positive sharp waves, and abnormal insertional activity in affected limb muscles in horses presented for obscure lameness. One also can examine horses with muscle asymmetry (Fig. 11.11) via needle EMG to determine the extent of muscle involvement. Serial needle EMG examination also might be helpful in monitoring the response to treatment and prognosis. For more in-depth information on electrodiagnostics in the horse, the reader is referred to multiple publications by Wijnberg.[34]

Radial and Suprascapular Nerve Injury

Damage to nerves leads to muscle atrophy of the innervated muscle. Damage to the radial and suprascapular nerves can occur with trauma to the cranial aspect of the shoulder. Needle EMG and nerve conduction studies are helpful in evaluating the extent of damage to these and other nerves and might be able to differentiate lost or reduced limb function caused by nerve damage from painful conditions. Muscle groups that have atrophied because of disuse (disuse atrophy) caused by a painful condition show no postinsertional activity on needle EMG examination.

Positive sharp waves and fibrillation potentials in the *triceps brachii* and *extensor carpi radialis* muscles might suggest radial nerve injury. Positive sharp waves and fibrillation potentials in the *supraspinatus* and *infraspinatus* muscles suggest injury to those muscles or suprascapular nerve injury (Fig. 11.12). Postinsertional activity in these muscle groups and the lateral head of the triceps suggests damage to the brachial plexus (Fig. 11.13). Thus needle EMG might be helpful in differentiating suprascapular nerve injury from brachial plexus injury. Visible evidence of muscle atrophy might not be present until several days to weeks after injury. To confirm a radial nerve injury, nerve conduction velocity studies are recommended (Fig. 11.14). Nerve conduction velocity less than 60 m/sec or significantly less than the opposite limb supports radial nerve dysfunction. In addition to reduced nerve conduction velocity, alterations in amplitude and duration of the action potential support abnormalities. Needle EMG and nerve conduction studies might be helpful in determining success of nerve decompression surgery and evaluating whether permanent nerve damage has occurred and the extent of return of nerve function.

Laryngeal Hemiplegia

Laryngeal hemiplegia has been described extensively in the literature as denervation of the intrinsic laryngeal musculature, specifically the recurrent laryngeal nerve.[57] Recognizing

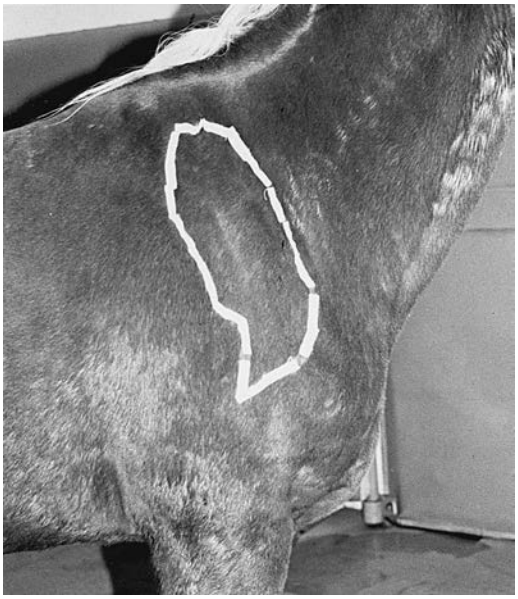

FIG. **11.12** Horse with suprascapular nerve injury with characteristic electromyographic distribution of fibrillation potentials and positive sharp waves in supraspinatus and infraspinatus muscles.

FIG. **11.13** Horse with brachial plexus injury showing characteristic distribution of electromyographic charges, including fibrillations and positive sharp waves. The involvement of the supraspinatus, infraspinatus, triceps brachii, extensor carpi radialis, and pectoral muscles is notable.

the disorder before the onset of clinical signs could be challenging. However, fibrillation potentials and positive sharp waves in the dorsal cricoarytenoid muscle on needle EMG examination might appear before clinical signs.[58] Thus needle EMG might be useful in the early detection of laryngeal hemiplegia in horses. Spontaneous EMG activity, including fibrillation potentials, positive sharp waves, or bizarre high-frequency discharges, have been reported in the dorsal cricoarytenoid muscle of horses affected with laryngeal hemiplegia. Fibrillation potentials and positive sharp waves are the most common abnormalities observed in horses with laryngeal hemiplegia. Decreased insertional activity and bizarre high-frequency discharges were reported at a lesser frequency.[58]

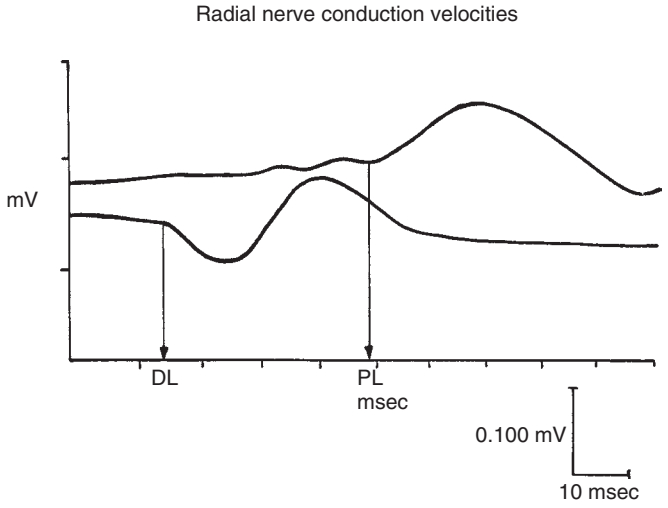

FIG. **11.14** Evoked muscle action potential from the extensor carpi radialis muscle showing decreased amplitude and decreased nerve conduction velocity, suggesting radial nerve injury. *DL,* Distal latency; *PL,* proximal latency.

Brainstem Auditory Evoked Response

Brainstem auditory evoked response (BAER) testing evaluates the integrity of the auditory pathway from its peripheral part (cochlear nerve) to the brainstem.[59] It is useful in the detection of unilateral and bilateral deafness, as well as differentiation between conductive and sensorineural hearing loss. Reference values for BAERs in adult horses and ponies[60-73] and neonatal foals are available in the literature.[61,72] Headphones or earphones are used to transmit sound through the external ear canal to the middle ear to the inner ear to evoke a response. The BAERs are evoked potentials, or waves, arising within the first 10 ms after delivery of an acoustic stimulus (clicks; Fig. 11.15). In human beings, BAERs are recognized as consisting of from five to seven waves, generally designated I through VII. Of these, waves I through V are the most common. In dogs, cats, and horses waves I to V are easily identified if normal (Fig. 11.16).[60] In human beings and animals, a correspondence exists between these waves and certain anatomic generator sites.[59,60] Wave I corresponds to cochlear nerve, II to cochlear nucleus, III to olivary nucleus, IV to lateral lemniscus, and V to caudal colliculus. Two derivations (vertex to mastoid and vertex to C2), depending on recording electrode placement, have been used in the horse to better identify the waves.

BAERs vary with age, gender, breed, head size, and temperature in other species. No differences in BAER latencies are apparent between neonatal foals and adult horses.[60,61] However, older horses might suffer from partial hearing loss as they age. Auditory brainstem response (ABR) testing is a method of assessing not only auditory function but also a variety of neurologic disorders involving the brainstem. ABR testing is unaffected by the state of arousal of the test subject, and responses are not degraded by sedation or general anesthesia.[61] Examination can be done in the awake horse, with or without mild sedation, or anesthetized. If a conscious awake horse is tested, one stimulates each ear and records the resultant waveforms independently. If the patient is anesthetized, one examines the uppermost ear first, turns the horse, and examines the lower ear.

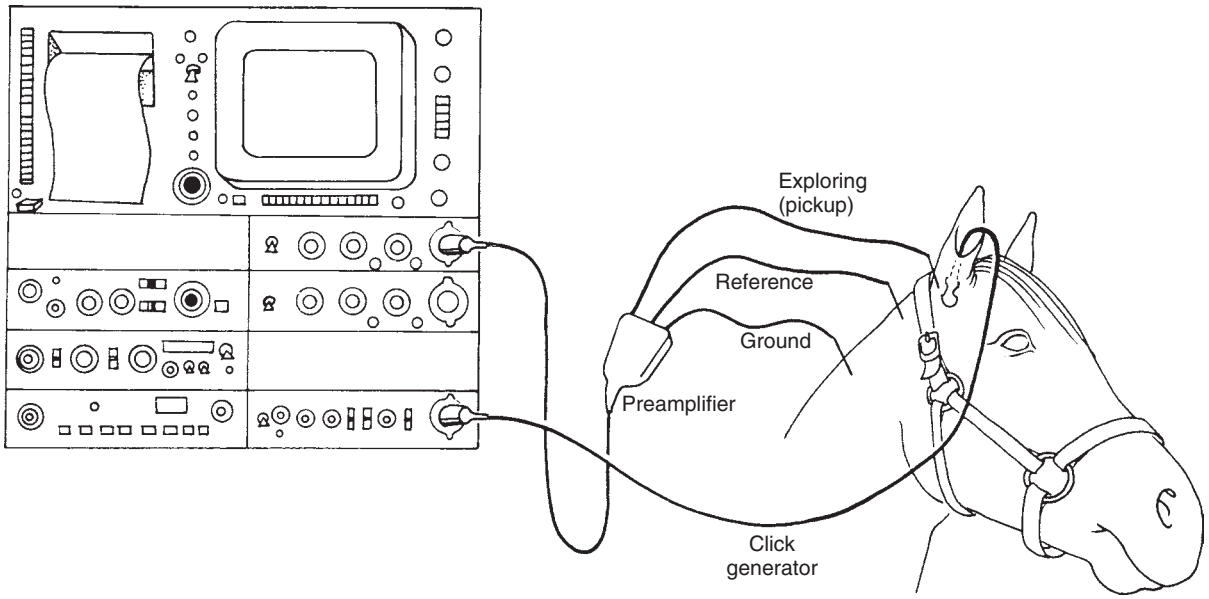

FIG. **11.15** System used for auditory brainstem response (ABR) testing in the horse. (From Rolf SL, Reed SM, Melnick W, et al.: Auditory brainstem response testing in anesthetized horses, *Am J Vet Res.* 48:910-914, 1987.)

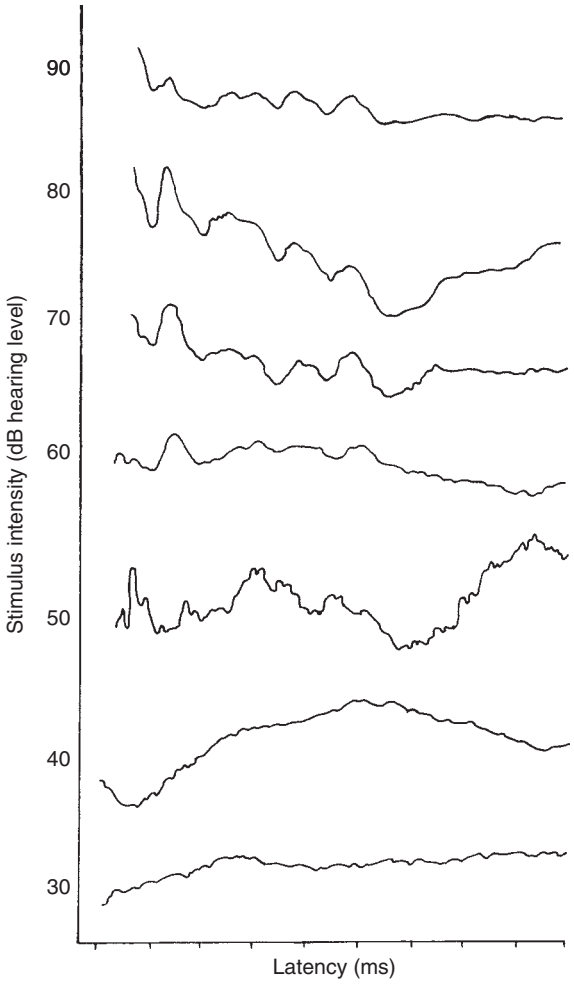

FIG. **11.16** Mean latency waves at 136 dB, sound pressure level (SPL) through 87 dB SPL. Five waves are present, except at 40 of 80 dB SPL. (From Rolf SL, Reed SM, Melnick W, et al.: Auditory brainstem response testing in anesthetized horses, *Am J Vet Res.* 48:910-914, 1987.)

The most common causes of BAER abnormalities in adult horses include temporohyoid osteoarthropathy, congenital sensorineural deafness in Paint Horses, multifocal brain disease, and otitis media/interna. BAER can be used in horses with vestibular disease (Fig. 11.17) to investigate if hearing is also affected as is the case in horses with temporohyoid osteoarthropathy. BAER testing might be helpful in the diagnosis and prognosis of traumatic, infectious, or inflammatory brainstem lesions such as vascular infarcts or anomalies, ischemic fibrocartilaginous emboli, basisphenoid bone fracture, and protozoal encephalomyelitis. Reported causes of hearing loss in neonatal foals include congenital sensorineural hearing loss, congenital anomalies (skull deformation), sepsis, neonatal encephalopathy, neonatal isoerythrolysis, and prematurity.[61,72]

Electroencephalography

Electroencephalography (EEG) is the graphic representation of the difference in voltage in microvolts between two different locations within the cerebral cortex plotted over time. EEG recordings represent spontaneous electrical activity primarily synaptic, excitatory postsynaptic potentials, and inhibitory postsynaptic potentials from cortical neurons. Pyramidal cells are the most important neuronal source for the EEG. It is estimated that a minimum of 108 neurons or an area of 6 cm^2 is required to produce a detectable change in voltage. Thalamic oscillations are transmitted to the cortex via projection neurons and are thought to be responsible for the slow waves and spindles associated with slow wave sleep (SWS). This electrical activity might be modified by deeper structures such as the brainstem, reticular activating system, and thalamus. EEG is a valuable tool for the investigation of brain disease, particularly seizures and sleep disorders, localization of abnormal activity, and extent (focal or diffuse). EEG has been used extensively in other species and more limited in horses.[74-88] In horses, EEG has been used to study sleep, seizures, nociception, effects of drugs on cerebral activity, and euthanasia.[74-88]

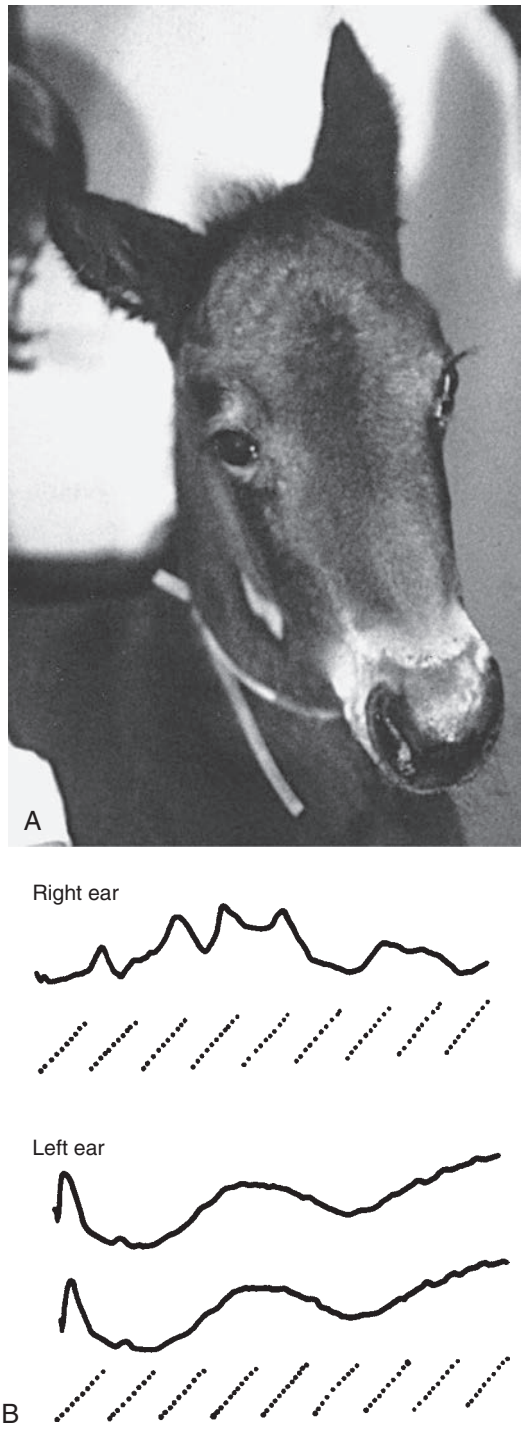

FIG. **11.17** A, Photograph of foal with a right head tilt and drooping of the right ear. B, Auditory brainstem response (ABR) (see Fig. 11.18) shows a hearing loss in the left ear, the presumed cause of the head tilt. The right ear was normal.

Two EEG montages have been described: bipolar and referential. Electrode placement could be rostral to caudal or transverse in a bipolar montage (Fig. 11.18). EEG recordings are evaluated for symmetry, waveform, morphology, frequency, and amplitude. There is a wide range of frequencies but confined to a relatively low range (0.5–50 Hz) with most below 30 Hz. Amplitude varies from a few to several hundred microvolts but usually remaining below 100 μV. Waveform nomenclature

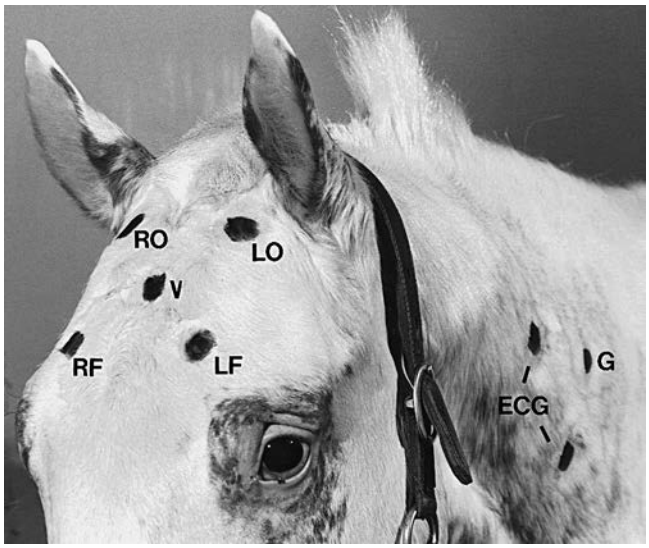

FIG. **11.18** Photograph of horse illustrating bipolar montage for electroencephalography (EEG). *RO,* Right occipital; *LO,* left occipital; *RF,* right frontal; *LF,* left frontal; *V,* vertex; *G,* ground; *ECG,* electrocardiogram position.

is as follows: delta 0 to 3 Hz, theta 4 to 7 Hz, alpha 8 to 12 Hz, beta 13 to 29 Hz, gamma ≥30 Hz.

Whenever possible EEG should be done in the nonanesthetized horse because the effects of drugs on EEG recordings such as suppression of EEG activity, transient paroxysmal discharges, and the lack of observation of all states of vigilance. The major disadvantage of performing EEGs in the sedated horse is movement artifacts. However, interpretable recordings are possible. Further, the states of vigilance can be evaluated. States of vigilance in the horse as determined through EEG consist of wakefulness, drowsiness, slow wave sleep, and rapid eye movement (REM) sleep.[86]

Transcranial magnetic stimulation testing: Although not entirely new to equine neurology, transcranial magnetic stimulation testing has not be used a lot in evaluation of neurological disease in horses. In human medicine, evoked potentials are widely used to quantify the function of both descending and ascending spinal cord tracts. The descending tracts, which carry motor information from the brain to spinal cord neurons, can be evaluated using transcranial magnetic motor evoked potentials (TMMEPs). These evoked potentials are non-painful and produced by electromagnetic stimulation of the brain in the conscious human or animal with simultaneous electrical recordings made from needle electrodes in relevant muscle groups.[265]

MAGNETIC RESONANCE IMAGING

Katherine S. Garrett

Although magnetic resonance imaging (MRI) has been used for diagnosis of neurologic disease in human beings for decades, it has only come into clinical use for horses within the past 15 years.[89-102] Imaging of the brain and spinal cord is essentially impossible without MRI or computed tomography (CT), so this represents an exciting new imaging modality to aid in the diagnosis of neurologic disease in horses.

Principles

Magnetic field strength is measured in Tesla (T). The strength of the magnetic field varies among types of magnets but is typically between 0.25 T and 1.5 T for most magnets currently in routine equine clinical use, although 3.0-T magnets will likely become more widely available in the near future.

Most MRI applications use hydrogen nuclei (protons) as the molecule of interest, but other nuclei can be used. Application of the strong magnetic field causes the magnetic moments of the protons within tissues to orient themselves parallel to the main magnetic field. A radiofrequency pulse at a specific frequency is then applied, which causes a change in the cumulative magnetic moment of the protons and synchronizes the phase of the protons' precessions (rotation about an axis). After the radiofrequency pulse is discontinued, the protons will return to the resting state governed by the main magnetic field alone, and the precessional phase synchrony will degrade. Different tissues return to the resting state at different times and in different ways. In a basic sense, the time for the magnetic moment of a tissue to return to the direction of the main magnetic field is a description of the T1 time of the tissue, and the time for the phase coherence to degrade is a description of the T2 time of the tissue. These are inherent properties, and the differences between tissues form the basis of MRI.

Different pulse sequences produce different types of contrast, based on each tissue's hydrogen content and its response. Proton density sequences have contrast determined by the proton content of each tissue. Cortical bone, tendons, ligaments, and air have low proton density, so they appear hypointense (dark) on all sequences, as well as on proton density–weighted sequences. T1-weighted sequences have contrast dominated by the T1 relaxation times of the tissues. Fat is hyperintense (bright) and fluid is hypointense. T2-weighted sequences have contrast dominated by the T2 relaxation time of the tissues. Fat is hypointense and fluid is hyperintense. Fluid attenuation inversion recovery (FLAIR) sequences have the signal from CSF specifically nulled using an inversion pulse. This allows abnormal fluid within the brain or spinal cord parenchyma to be more apparent. Intravenous contrast can also be used in MRI. Gadolinium compounds are typically used, which allow assessment of abnormal patterns of blood flow or delineation of anatomic structures, similar to the use of contrast in CT imaging.

Two major families of pulse sequences exist. Spin echo sequences use multiple radiofrequency pulses to generate a signal. Turbo or fast spin echo sequences are a subset of spin echo sequences that are faster than traditional spin echo sequences. Image contrast can be altered slightly; for example, fat on T2-weighted turbo spin echo sequences is hyperintense instead of hypointense. Gradient echo sequences use a changing magnetic field gradient to generate a signal. Gradient echo sequences can be acquired more quickly than spin echo sequences but are more susceptible to magnetic field inhomogeneities.

For each series of slices, the operator must choose the orientation of the slices, as well as the type of pulse sequence used. A typical MRI examination will consist of many series, each with a different combination of orientation and pulse sequence. Unlike CT imaging, the orientation of the images obtained during each pulse sequence can be selected by the operator. These are typically 1- to 5-mm-thick slices. A complete examination produces hundreds of individual images to be reviewed, and it usually takes between 1 and 2 hours to complete the acquisition of images. Some series are acquired in a way that permits reconstruction in multiple planes or in three dimensions.

Equipment

The main magnetic field can be generated in a variety of ways. Permanent magnets are used in lower field systems (less than 0.4 T). These magnetic fields are generated by using ferromagnetic materials of the same type as in everyday magnets. Stronger magnetic fields are produced using superconducting electromagnets. These magnets use liquid helium to cool the electromagnetic coils and reduce the resistance, allowing much stronger magnetic fields to be generated. Liquid helium is expensive and requires periodic replenishment, but it is necessary to efficiently generate the stronger magnetic fields in clinical use. Regardless of the type of magnet, the room must be shielded to prevent any external radiofrequency pulses (e.g., radio signals, cellular phone transmission) from entering the room and introducing artifacts.

Two types of MRI systems are used for horses. One type consists of systems designed for use in human beings. These tend to be high field magnets with strengths ≥1.0 T of closed bore construction and require the horse to be under general anesthesia. The horse is positioned either in lateral or dorsal recumbency on a nonferromagnetic padded table with the body part of interest positioned into the bore. Foals can be imaged using the human patient table in any recumbency.

The other group consists of magnets that have been specifically designed for veterinary use. These magnets are generally low field magnets with a strength in the 0.25-T range. Many have an open bore design and can be positioned about a body part; some require general anesthesia and some only sedation. The images produced with these weaker magnets require longer scan times to obtain and are of lower resolution. Motion artifact in studies obtained on standing horses can significantly reduce image quality.

Examinations are limited to regions that can fit into the bore of the magnet to be positioned at or near the isocenter (center of the magnetic field). Depending on the type of magnet, this requires that either the horse be pushed into the center of the magnet bore or that the magnet be positioned around the region of interest. These limits will vary among magnets based on their construction.

Safety

Most safety hazards associated with MRI are related to the introduction of ferromagnetic objects into a strong magnetic field, as opposed to the existence of the magnetic field itself. No known adverse effects have been reported for MRI at field strengths currently used in equine clinical imaging. Any object that is magnetic (scissors, oxygen tanks, scalpel blades) will be attracted to the magnet; thus all the equipment in the room must be nonmagnetic or MRI compatible, including the anesthesia equipment. The strength of the magnetic field increases exponentially as the distance to the magnet decreases. In practical terms, this means that the pull of the magnet on any ferromagnetic object becomes quickly stronger as the object approaches the magnet (to prevent injury this is especially important to bear in mind when considering stronger magnets).

The strong magnetic field can also affect internal implants and is especially dangerous for people with cardiac pacemakers, who should not enter an MRI room under any circumstances because of the potential for serious cardiac arrhythmias resulting from the effect of the magnetic field on the pacemaker. Metal shards in the cornea can also be affected by the magnet and can move within the cornea, causing ocular damage. The changing of the magnetic gradients can be quite loud. Any personnel who remain in the scan room during the examination should wear protective equipment to prevent hearing damage.

Patient Preparation

Horseshoes should be removed before the examination to eliminate the risk of potential magnetic attraction. Appropriate preparations should be carried out for images requiring general anesthesia. After induction to anesthesia but before entering the scan room, any metal objects (e.g., halters) should be removed from the horse. A specialized, nonferromagnetic table must be used to support the horse during the examination. After the horse is positioned in the bore of the magnet, it must remain completely motionless during image acquisition to prevent blurring of the image. Because MRI examinations typically take between 1 and 2 hours, urinary catheterization or some other means of urine collection is recommended to protect the equipment from contamination with fluid. Because an MRI examination can be lengthy, it is extremely important that the primary region of interest be localized as specifically as possible. MRI has proven particularly useful in areas that are not amenable to examination using other diagnostic imaging modalities.

Use of Magnetic Resonance Imaging in Equine Neurologic Disease

In adult horses, examination is limited to the brain and cranial cervical spine because of limitations of current magnet design. However, the trunk of foals up to approximately 500 lb may fit inside the bore of some magnets, enabling imaging of any part of the spinal column. Few reports exist of clinical use of MRI in neurologic disease.[89-102] Some examples of neurologic disease include nigropallidal encephalomalacia, head trauma, brain abscess, pituitary mass, cholesterol granuloma, congenital hydrocephalus, trigeminal neuritis, stylohyoid bone fracture, EPM, and cervical vertebral compressive myelopathy.[89-91,93,95,97,98,101,102] Diagnoses of equine protozoal myelitis, neoplasia, inflammatory disease, encephalomyelitis, meningitis, otitis media, hydrocephalus, and ischemic injury have been made at the author's clinic. In addition, substantial information has been gained regarding the extent of damage after traumatic injury. Although this clinic's experience with MRI of the nervous system is limited, the possibilities of this technique are exciting.

Pituitary Adenoma

A 13-year-old Thoroughbred mare had decreased mentation, poor appetite, weight loss, and absence of normal estrous cycles. The decreased mentation had progressed to prolonged periods of somnolence, slow circling behavior, and an apparent decrease in vision. The mare had decreased menace and pupillary light responses and demonstrated slight weakness on a tail pull test. An anatomic diagnosis of a CNS lesion rostral to the foramen magnum was made. Endogenous adrenocorticotropic hormone, triiodothyronine (T_3), and thyroxine (T_4) levels were normal. An MRI examination was undertaken in an attempt to find the cause of the neurologic signs and to further investigate a possible pituitary lesion.

A mass was found on the median plane ventral to the diencephalon, with the ventral aspect of the mass within the sella turcica (Fig. 11.19). A portion of the pituitary distinct from the mass can be identified in part of the sella turcica. The mass compresses the thalamus, hypothalamus, and optic chiasm. Portions of the mass appear hemorrhagic, and regions of the thalamus and hypothalamus surrounding the mass are edematous.

This horse was treated with pergolide and cyproheptadine in an attempt to ameliorate the signs of pituitary pars intermedia dysfunction, and improvement was seen for a brief period of time. Its condition then deteriorated after 6 weeks with progressive anorexia, weight loss, and depression despite aggressive supportive care. The mare was euthanized, and necropsy results showed a large pituitary mass with histologic features consistent with a pituitary macroadenoma of the pars intermedia.

Equine Protozoal Myeloencephalitis

An 18-year-old Thoroughbred gelding became ataxic 9 months before presentation. Two months before presentation, the horse started to exhibit weight loss, dysphagia, and facial muscle wasting. The animal had been treated for equine protozoal myelitis twice before presentation and exhibited grade 3/4 ataxia in all limbs. In addition, the horse had atrophy of the left facial muscles, as well as the

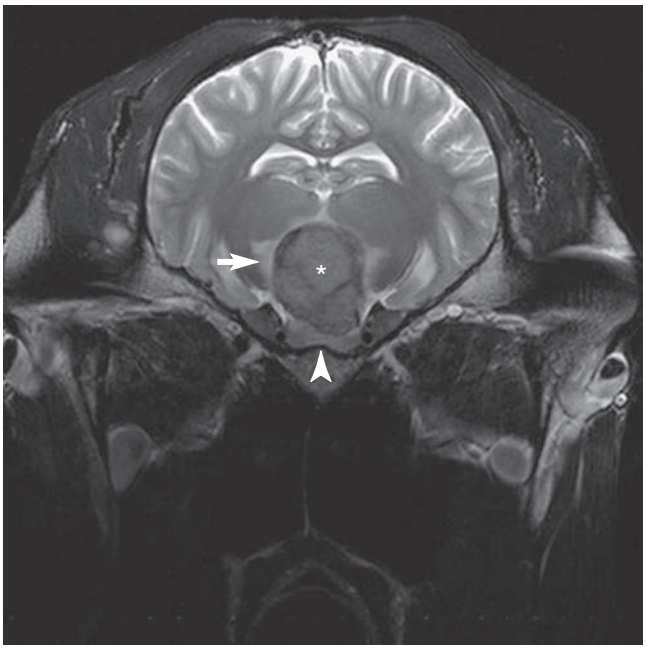

FIG. **11.19** Transverse T2-weighted fast spin echo image of the brain at the level of the sella turcica. The *asterisk* indicates a large mass of heterogeneous signal intensity displacing the diencephalon laterally. The *arrowhead* indicates normal pituitary tissue compressed by the mass. The *arrow* indicates high T2 signal (edema) within the diencephalon adjacent to the mass.

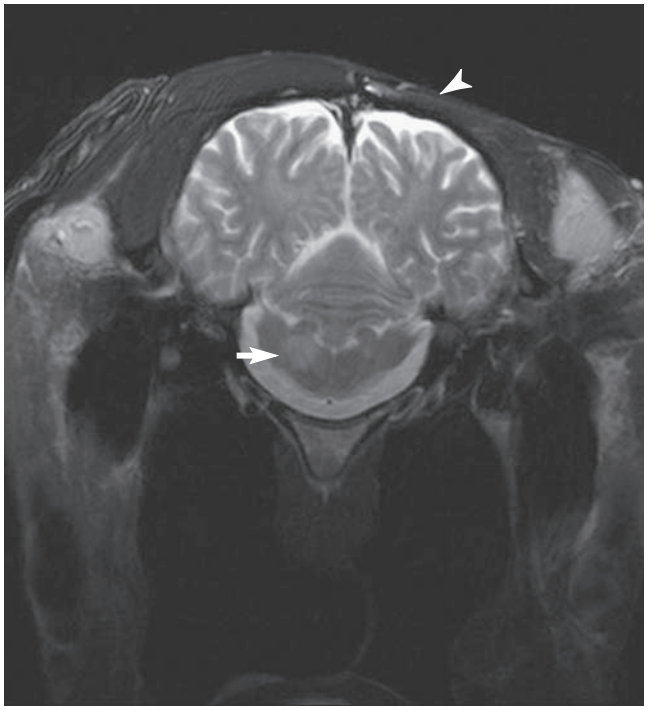

FIG. **11.20** Transverse T2-weighted fast spin echo image of the brain at the level of the pons. The arrow indicates an area of T2 hyperintensity in the region of the nuclei of the seventh and eighth cranial nerves. The arrowhead indicates temporalis muscle atrophy.

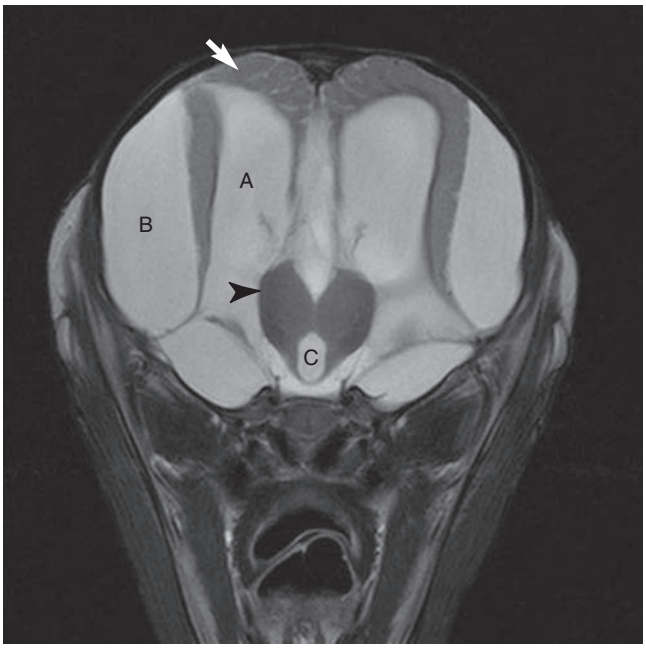

FIG. **11.21** Transverse T2-weighted turbo spin echo image of the brain at the level of the thalamus. The lateral ***(A)*** and third ***(C)*** ventricles are massively dilated with cerebrospinal fluid (CSF) present outside of the brain ***(B)***. The *arrow* indicates the cerebral cortex, and the arrowhead indicates the thalamus.

left temporalis and masseter muscles, muzzle deviation to the right side, and difficulty moving food to the pharynx with normal tongue tone, prehension, and ability to swallow. These neurologic signs suggested multifocal disease with involvement of cranial nerves V, VII, IX, and X, as well as the cervical spinal cord and brainstem. Equine protozoal myelitis Western blot was weakly positive on the CSF and positive on serum.

MRI findings consistent with inflammation and edema were seen throughout the right side of the medulla and caudal pons in areas including the nuclei of cranial nerves V, VII, VIII, and XII (Fig. 11.20). These findings are consistent with those seen in a previously reported case of EPM.[95]

Nitazoxanide, vitamin E, and flunixin meglumine were administered. Supportive care, including intravenous fluid therapy and enteral feeding via nasogastric tube, was also performed. The horse became progressively more depressed and developed pleuropneumonia 1 week after admission, likely secondary to aspiration because of dysphagia. The next day, the horse became acutely more ataxic, was unable to rise, and died. On postmortem examination, neuronal degeneration, inflammation, and protozoal organisms consistent with *Sarcocystis neurona* were identified in the nuclei and nerves of cranial nerves V, VII, and VIII.

Hydrocephalus

A 1-month-old Quarter Horse filly was noticed by the owners to have a dome-shaped head, blindness, and obtundation. A congenital brain lesion was suspected.

MRI images showed severe communicating hydrocephalus with a specific location of obstruction not identified (Fig. 11.21). The ventricles were enlarged and filled with CSF. The parenchyma of the cerebral hemispheres was thinned, and the cerebellum was compressed and herniated through the foramen magnum. A meningocele and an open fontanelle were noted at the junction of the left and right frontal and parietal bones.

Treatment was not pursued, although the possibility of placement of a ventriculoperitoneal shunt was discussed with the owners. The foal remained alive and was weaned successfully.

Spinal Cord Compression

A 4-month-old Thoroughbred colt had a 2-day history of pyrexia and "knuckling over" of the left hind fetlock. Ultrasound examination of the lumbar, sacral, and gluteal regions showed an abscess within the musculature. The extent of the abscess could not be determined but was suspected to involve the pelvis, so MRI examination was undertaken.

Severe compression and inflammation of the spinal cord in the sacral region was seen on MRI (Fig. 11.22). The left side of the sacrum had heterogeneous signal intensity suggestive of osteomyelitis.

The foal was treated with antiinflammatory and antimicrobial medication and establishment of drainage of the intramuscular portion of the abscess. The foal's condition improved, and it was discharged on long-term antimicrobial therapy. During follow-up MRI examination 2 months later, the compression of the spinal cord had been relieved, and the intramuscular abscess had decreased in size. The heterogeneous signal intensity within the sacrum had improved but not resolved completely.

Conclusion

Although MRI of equine neurologic disease remains in its infancy, veterinarians are increasingly able to use this

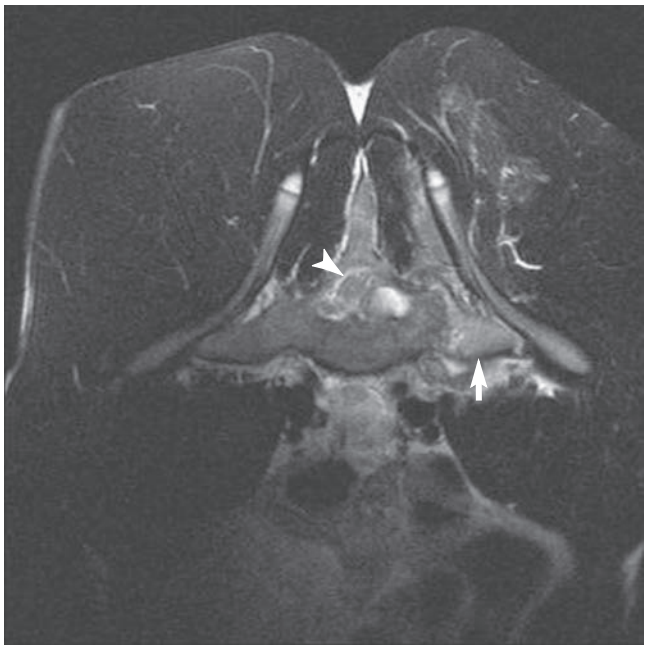

FIG. **11.22** Transverse T2-weighted turbo spin echo image of the spinal canal at the level of the sacroiliac joint. The *arrowhead* indicates the laterally compressed spinal cord, and the *arrow* indicates a region of edema and proteinaceous fluid accumulation within and around the sacrum (osteomyelitis).

technology to make more specific and timely diagnoses. As the knowledge base regarding MRI progresses, practitioners will be able to advance their care and treatment of equine patients to new levels.

SEIZURES AND SLEEP DISORDERS

Seizures

Monica Aleman

Terminology

Seizures (from the Latin *sacire,* "to take possession of") have been referred as fits, attacks, strokes, convulsions, or epilepsy and were first described around 500 to 700 B.C. Seizures are a common problem in both human and veterinary medicine but are less common in horses compared with other species. Seizures are clinical manifestations of rapid excessive and/or hypersynchronous abnormal neuronal activity from the cerebral cortex that result in involuntary alterations of motor activity, consciousness, autonomic functions, or sensation.[103-105] Seizures can occur as single or recurrent events. Recurrent seizures are termed *epilepsy.* There has been a great deal of confusion about the definition and classification of *seizures* and *epilepsy,* terms that have been used mistakenly as the same. The International League Against Epilepsy (ILAE) has defined *epileptic seizure* as "a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain" and *epilepsy* as "a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, congnitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one epileptic seizure." *Status epilepticus* (SE) is defined as "a condition resulting either from the failure of the mechanisms responsible for seizure termination or from the initiation of mechanisms, which lead to abnormally prolonged seizures (after time point t1). It is a condition [that] can have long-term consequences (after time point t2), including neuronal death, neuronal injury, and alteration of neuronal networks, depending on the type and duration of seizures." In the case of tonic-clonic convulsions, the time points are 5 minutes for t1 and 30 minutes for t2. Emergency treatment of SE in human medicine is instituted if epileptic seizure is greater than 5 minutes.

Epileptic seizure has a specific neural origin and can occur as a single event or be recurrent. Epileptic seizures can be further classified as primary (i.e., idiopathic), secondary (as the result of structural cerebral abnormalities), or reactive (reaction of the healthy brain to transient systemic insult). Epilepsy specifically refers to reoccurring epileptic seizures from a chronic brain disorder, which may be genetic (primary) or acquired (secondary). Epilepsy has been rarely documented in horses, except for juvenile idiopathic epilepsy in Arabian foals.[75] Finally, convulsions refer to seizures accompanied by tonic-clonic muscle activity and loss of consciousness. Classification of epilepsy has been done by the ILAE in human medicine. Previously, epilepsy was classified as idiopathic (primary) and symptomatic or cryptogenic (secondary). Idiopathic epilepsies included disorders with suspected genetic etiology with no brain abnormalities. Symptomatic epilepsies have a known cause that involves brain pathology, whereas cryptogenic epilepsies were those with unknown etiology. Classification of epilepsy has evolved to genetic, structural, and unknown. In small animal medicine, the International Veterinary Epilepsy Task Force reported a consensus on epilepsy definition, classification, and terminology.[103,105]

Similar to standardized classifications described in small animals and humans, seizures in horses can be classified as being partial (simple and complex), generalized (primary or secondary), or status epilepticus.[106,107] Seizures that involve a discrete area of the cerebral cortex are classified as simple partial seizures when consciousness is not impaired and complex partial seizures when consciousness is impaired. Partial seizures result in localized clinical signs, such as facial or limb twitching, compulsive running in a circle, or self-mutilation. A partial seizure might be observed following a procedure such as collection of CSF, cervical myelography, anesthesia, or cranial trauma that might spread throughout the cerebral cortex and produce a secondary generalized seizure. A generalized seizure involves the entire cerebral cortex and results in generalized tonic-clonic muscle activity over the whole body, with loss of consciousness. Seizures generalized from the onset are defined as primary generalized seizures. Secondary generalized seizures could originate from both types of partial seizures. The most common types of seizures observed in an equine referral center were partial seizures (simple or complex, 30%) and secondary generalized seizures (30%).[106] This is in agreement with data in dogs, for which partial seizures with or without secondary generalization appear to be the most common types of seizures observed. Complex partial seizures are commonly observed in neonatal foals and are referred as "chewing-gum fits," jaw chomping, and lip smacking.[4]

Etiology/Pathogenesis

Etiologies of seizures in horses include intracranial and extracranial diseases (for which the healthy brain is reactive to an insult) (Tables 11.4 and 11.5). The most common causes of seizures in foals under 2 weeks of age are neonatal maladjustment syndrome (both hypoxic-ischemic and nonhypoxic encephalopathy), trauma, and bacterial meningitis.[108-111] The most common causes of seizures in foals less than 1 year of age are shown in Table 11.4. The most common causes of seizures in adult horses older than 1 year of age are brain trauma, hepatoencephalopathy, and toxicity.[105] Masses such as melanoma, pituitary adenoma, cholesteatoma, and rarely glioma can cause seizures in mature to older horses.

Irrespective of the etiology, the pathogenesis of epileptic seizure is caused by an abnormal hypersynchronous electrical activity of neurons, caused by an imbalance between excitation and inhibition in the brain.[104,112-116] If the balance shifts toward excessive excitation (theory of excitatory postsynaptic potentials), a prolonged depolarization of neuronal aggregate will occur, a phenomenon known as "paroxysmal depolarization shift," which might generate an epileptic seizure. Several mechanisms are thought to cause paroxysmal depolarization shifts and include increased excitatory neural transmitters (e.g., glutamate), decreased inhibitory neural transmitters (e.g., γ-aminobutyric acid), alteration in neural transmitter receptor sites, or a derangement in the internal cellular metabolism of the neuron. Notably, much research has focused on glutamate, the principal excitatory neurotransmitter in the brain, and its receptor complex, the *N*-methyl-D-aspartate (NMDA) receptor. Glutamate binds to NMDA receptors, which open sodium and calcium channels, leading to entry of these ions in the neuron and to postsynaptic depolarizations.[112-116] In addition, NMDA receptors have been implicated in the pathogenesis of seizures in infants and foals because if exacerbated (e.g., during perinatal asphyxia), intracellular calcium overload causes neuronal necrosis by activation of lytic enzyme systems and nitric oxide synthase with generation of free radicals.[113,114] Conditions leading to the summation of excitatory postsynaptic potentials include excessive excitations and also loss of inhibitions without normal regulatory feedbacks. In response to the sudden depolarization shift of a neuronal aggregate, local surround inhibitory zones are established to try to prevent the spread of the epileptogenic activity. γ-Aminobutyric acid (GABA) is the major inhibitory neurotransmitter of the CNS. GABAergic inhibition can be presynaptic (release of GABA from the GABAergic nerve terminal into presynaptic nerve terminals causing a reduction of neural transmitter release) or postsynaptic (caused by the interaction of GABA with specific postsynaptic receptors).[115] In GABA-system dysfunction, an abnormal neuronal hypersynchronous activity will spread, resulting in depolarization of more neurons.[115] Once a "critical mass" of neurons has fired, uncontrolled spread of electric activity may occur over the cerebral cortex, which may precipitate an epileptic seizure. Thus these seizures can be blocked by use of agents that potentiate inhibitory neural transmitters, such as phenobarbital. In brief, seizures may develop because of a summation of synchronous excitatory postsynaptic potentials in large groups of neurons that may be precipitated by an increase in excitatory neurons, a decrease in inhibitory neurons, a decrease in inhibitory neurotransmitters, or any combination of these mechanisms.

Alterations in the neuronal cell microenvironment might also lead to seizure generation. Systemic and local neuronal electrolyte abnormalities might disturb excitatory neuron homeostasis and lead to spontaneous and excessive action potentials.[115] Intracellular potassium released during neuronal activity may reach sufficient concentration to move the resting membrane potential toward the threshold and

generate a seizure focus. Spontaneous action potentials generated by alteration in intracellular potassium concentration may spread to other parts of the cerebral cortex, causing a generalized seizure. Alterations in one intracellular neuronal electrolyte may alter the homeostasis of other intracellular electrolytes. Increased intracellular potassium concentration and decreased intracellular calcium, magnesium, and chloride concentrations are observed during interictal epileptogenesis and the transition from interictal to ictal activities.

Alterations in sodium conductance have also been implicated in the onset of seizures. Rapid influxes of sodium into the neuron may lead to hyperexcitability of the neuron and rapid firing. Phenytoin, a hydantoin derivative, blocks these rapid influxes of sodium into neurons and suppresses repetitive firing by hyperexcitable neurons.[116] Thus a complex interaction may occur between these electrolytes and the internal cell homeostasis that precipitates seizure formation.

Clinical Signs and Diagnosis

Seizure activity is manifested clinically in a variety of ways depending on the area and the extent of the cerebral cortex involved. In partial seizures, asymmetric twitching of a limb, facial twitching, excessive chewing, compulsive behavior, or self-mutilation might occur. A localized seizure might develop into a generalized seizure. Three distinct clinical periods might be observed in a generalized seizure. Just before the seizure (aura), horses might exhibit signs of anxiety and uneasiness. During the seizure (ictus), horses might become recumbent, unconscious, and have symmetric clonic muscle contractions (contractions and relaxations of muscles occurring in rapid succession), followed by symmetric tonic muscle contractions (continuous unremitting muscle contractions).[4,75,106,107] Horses also might show deviation of eyeballs, dilated pupils, ptyalism, trismus or jaw clamping, opisthotonos, lordosis or kyphosis, violent paddling movements of the limbs, uncontrolled urination and defecation, and excessive sweating. After the seizure (postictus), horses might appear obtunded, disoriented, and blind for a few minutes, hours, or days.[4,75,106,107]

Diagnosis of seizure is based on history, clinical signs, and ancillary diagnostic tests to determine an underlying cause, whenever possible (see Tables 11.4 and 11.5). Diagnosing seizures in horses can be challenging. Because many horses are unobserved for long periods of the day, the presence of a seizure might be suspected after recognition of unexplained trauma to the head or limbs and disruption of the stall or outside paddock. At other times, the caretaker might identify a change in attitude or behavior of the horse such as restlessness or a "far-off" appearance, which might be a prodromal sign (aura) of an impending seizure. Careful and thorough questioning of the caretaker should be performed to determine the duration and frequency of the episodes, date(s), the time of day, the relationship to feeding, any event(s) associated with the episode (e.g., injection in the carotid and traumatic event), any unusual environmental circumstances (stimuli such as thunderstorms, fireworks, changes in housing), recent trauma, febrile episodes, exposure to drugs or toxins, recent behavioral changes, and the seizure history of the dam, sire, and other siblings. The veterinarian should always consider rabies in the list of differential diagnoses, even if the horse has been vaccinated and especially in endemic areas.

A complete physical examination should be performed to rule out noncerebral clinical conditions that might mimic seizures, including painful conditions (acute severe pain, tremors and fasciculations, episodes of hyperkalemic periodic

paralysis, sleep disorders). In these conditions, horses do not lose consciousness but remain bright and alert. Horses with HYPP might show prolapse of the nictitating membranes of the eye and muscle fasciculations but remain anxious, alert, and have normal pain perception. Cardiac disorders might precipitate syncopal episodes, which could be confused with seizures. Auscultation of the heart might help identify the presence of murmurs, and electrocardiography may help determine the presence of arrhythmias.

A complete blood cell count (CBC) and serum biochemistry analysis should elucidate the presence of systemic extracranial disease, which may predispose to seizures. CBC and fibrinogen may suggest inflammation (leukocytosis and hyperfibrinogenemia) or viral infection. A complete serum biochemistry profile should be performed to rule out metabolic abnormalities that might trigger seizures. Hypoglycemia could be a cause of seizures in both adults and foals. An arterial blood gas evaluation is indicated to rule out hypoxia. Liver function tests, liver biopsy, and determination of serum ammonia concentration should be performed if hepatic encephalopathy is suspected.

CSF evaluation might be helpful in approaching a diagnosis but commonly does not provide a definitive diagnosis. A normal cytology and biochemistry profile does not rule out disease. The site of choice is the atlantooccipital cistern, but this may be contraindicated if the horse is showing signs of increased CSF pressure (such as mydriasis or papilledema) or if general anesthesia is not appropriate. Alternatively, CSF fluid collection from the lumbosacral space could be performed, providing that it can be safely done in the standing and sedated animal. Interpretation of equine CSF abnormalities is described previously in this chapter.

EEG, the graphic recording of the rhythmic bioelectrical activity arising predominantly from the cerebral cortex, is the most important clinical test in humans suffering from epilepsy. Similarly, this diagnostic test has been useful in horses with seizures.[80,85-88,117] Paroxysmal activity includes spikes, sharp waves, spike-and-wave discharges, and other transient events.[80,85-88,117] Focal, multifocal, or generalized epileptiform activity can be recorded on EEGs of epileptic patients, depending on the localization of the discharges and the extent of the cerebral cortex involved.[80,85-88,117] The lack of recording of epileptical activity does not rule out seizures.[88] The proximity of a seizure to the EEG examination might influence the amount of epileptiform activity present in the EEG. Therefore consideration of performing more than one EEG examination is recommended.[80,85-88,117] Horses suffering from extracranial diseases might also have an abnormal EEG recording such as during metabolic diseases.[80,85-88,117]

The best imaging modality specifically for the brain is MRI. Other modalities might aid in identifying abnormalities of the skull, including trauma that might be associated with or causing seizures. Those modalities include skull radiographs and CT.

Treatment

The goals of treatment are to stop ongoing seizures, address underlying diseases, and prevent future seizure activity.

Initial Therapy: Controlling Seizures. Prompt control of seizures is a priority as prolonged or recurring seizures might result in neuronal injury, self-trauma, and trauma to caregivers. Short- and long-term anticonvulsants have been used in horses.[75,118-121] Short-term treatment implies controlling seizures at the time they are occurring. Long-term therapy should be considered if recurrent seizures occur. However, long-term therapy can be expensive, and expectations must be discussed with the owner because antiseizure medication is not a curative measurement and the horse might still have seizures while on medication. For short-term management, drugs such as benzodiazepines (diazepam, midazolam) or intravenous barbiturates (phenobarbital) can be used.[114]

Benzodiazepines hyperpolarize neuronal cells by binding to GABA receptors, resulting in change of the chloride conductance pathways and making cells resistant to depolarization. The overall result is a decrease in the electrical activity of the seizure focus and an increase in the seizure threshold.[114] Although quite effective, the half-life of diazepam is short, 10 to 15 minutes, making repeated doses sometimes necessary. Caution is warranted as prolonged usage might cause respiratory depression/arrest and drug accumulation in foals as its clearance is slower in this age group.[120] In patients that do not respond to the initial bolus doses of diazepam, a constant-rate infusion of diazepam can be implemented at an initial rate of 0.1 mg/kg/hr.[75,122] Midazolam is a potent short-acting benzodiazepine that can be used in foals at 0.05 to 0.1 mg/kg intravenously or intramuscularly or as a continuous-rate infusion.[122]

Intravenous phenobarbital rapidly (within 20 minutes) provides a high serum concentration and will reduce cerebral metabolic rate. The mechanisms of action of phenobarbital include (1) facilitation of inhibitory neurotransmission via GABA receptors; (2) inhibition of postsynaptic potentials produced by glutamate; and (3) inhibition of voltage-gated calcium channels at excitatory nerve terminals. Caution must be practiced in neonatal foals, and lower loading dosages compared with adult horses can be used such as 3 to 6 mg/kg IV diluted in saline and infused over 30 minutes (unpublished data, Aleman). Start with the lowest dosage and increase if needed. Older foals and adults can be loaded with 6 mg/kg IV diluted in saline (500 mL) and given over 30 minutes. Maintenance dosage is 3 to 4 mg/kg PO q 12 h. If necessary, higher dosages or frequency of administration can be used (q 8 h instead of q 12 h). Other authors have reported higher loading dosages for foals of 20 m/kg IV followed by maintenance dosages of 9 mg/kg IV q 8 h.[118] In adult horses, a parenteral loading dosage of 12 mg/kg IV followed by 6 mg/kg IV (20-minute infusion) q 12 h has been recommended.[119] The therapeutic dosage for horses is unknown. Maintenance therapy is administered by the oral route at dosages of 3 to 6 mg/kg.

Sodium pentobarbital could be used for the short-term management (1–3 days) of seizures in neonatal foals because of its anesthetic effects. Although this anesthetic agent has little use in the management of seizures in adult horses, general anesthesia with continuous infusion of pentobarbital (for up to 24 hours) might be required for horses suffering from status epilepticus, which might not be controlled effectively with regular anticonvulsant therapy. Other agents such as propofol and ketamine might be considered for the management of status epilepticus.[123]

Primidone and phenytoin might be considered as an alternative therapy if previous drugs are ineffective. Primidone is metabolized to phenobarbital (main active metabolite) and to a smaller extent to phenylethylmalonamide (a metabolite that might potentiate the anticonvulsant effects of phenobarbital). Primidone has been reported anecdotally for treating foals with seizures.[124] Phenytoin inactivates voltage-dependent neuronal sodium channels, preventing depolarization of the

presynaptic neuronal membrane at the excitatory nerve terminal, and thus reducing release of glutamate. Adverse effects of phenytoin include prolonged depression in foals, as well as mild atrioventricular block and decrease in blood pressure in adults.[114]

Drugs such as acetylpromazine, xylazine, and ketamine should be used with caution for emergency seizure management if emergency antiseizure medication is not available. There have been reports of acetylpromazine lowering seizure threshold; however, the editor has used acepromazine safely in the past in small and large animals with seizure disorders without triggering seizures. Ketamine might exacerbate seizures because it increases cerebral blood flow, oxygen consumption, and intracranial pressure. However, ketamine also antagonizes NMDA receptors and thus appears helpful in a rodent model of status epilepticus, as well as in some neonatal foals with seizures, although further studies are required.[122]

Maintenance Therapy: Preventing Seizures. The goal of long-term anticonvulsant therapy is to reduce the frequency, duration, and severity of seizures with no or minimal adverse effects associated with such therapy. Therefore the initiation of long-acting anticonvulsant therapy depends on consideration of the underlying cause, frequency, and severity of the episodes. Client factors such as owner preference and compliance and the long-term expense of medication should also be considered. The owners should be aware that therapy for the control of seizures, particularly in adult horses, might continue for months or years. In addition, the initiation of treatment does not guarantee elimination of seizures. It is paramount to recommend against riding a horse with seizures or on antiseizure medication.

With identified intracranial diseases, the therapy should be initiated at the onset of seizures. When no etiology has been determined, the decision to place the horse on long-term maintenance therapy is based on recognition of either a cluster of seizures (greater than 3–4 times per year or 2 seizures per month) or severe generalized seizures that result in injury to the horse and danger to those in the environment regardless of frequency. Foals with idiopathic epilepsy that have several seizures over 1 to 3 days also might require long-term (months) anticonvulsant therapy.[105,108]

One should select a single anticonvulsant medication for maintenance; the choices include phenobarbital, bromide, phenytoin, and primidone. Phenobarbital is the drug of choice for long-term maintenance in horses. Phenobarbital is well absorbed following oral administration and is metabolized in the liver. It induces hepatic cytochrome P450 enzyme complex with resultant increase in its own rate of metabolism, often resulting in the need to adjust the dose over time.[125] Therapy must be tailored to fit the individual needs, using the lowest concentration effective at controlling seizures, in conjunction with monitoring of serum drug concentration. Once the seizure activity is under control, phenobarbital monitoring approximately every 60 days is usually adequate. Although phenobarbital is well tolerated in horses, potential adverse effects include excessive sedation, respiratory depression, bradycardia, hypotension, and hypothermia in neonatal foals. Veterinarians should avoid using other drugs with known interactions, such as ivermectin, a GABA agonist. Tetracyclines and chloramphenicol inhibit hepatic microsomal enzymes, thereby prolonging the effects of phenobarbital. If the adverse effects are unacceptable and seizures are not controlled with one anticonvulsant therapy, one could consider reducing the dose by 20% or to nontoxic level and beginning a second anticonvulsant therapy, such as potassium bromide.[124]

Bromide (sodium or potassium) appears to compete with chloride to hyperpolarize neuronal membranes, as well as enhancing GABA-activated chloride conductance. Because the elimination half-life of this drug in horses is 3 to 5 days, it often takes a few weeks to reach a steady-state level in horses. Because of the long elimination half-life, potassium bromide should not be used alone to treat ongoing seizures but in combination with phenobarbital, with an initial dose of 25 to 40 mg/kg/day PO.[126,127] When used as monotherapy, a loading dose of 120 mg/kg daily for 5 days followed by a daily oral dose of 40 mg/kg achieved a serum level of 1 mg/mL. The therapeutic level for horses is not known. Adverse effects appear to be rare in horses.

Newer antiepileptic drugs have been introduced in veterinary medicine, with improved therapeutic indices (i.e., effective dose compared with toxic dose) with a reduction of the sedative and organ-toxic adverse reactions. These drugs include felbamate, gabapentin, clorozepate, toparimate, levetiracetam, and zonisamide and can be used as monotherapy or in combination.[128,129] Gabapentin, a structural analog of GABA, has been used as adjunctive therapy in humans and dogs for the treatment of partial seizures refractory to phenobarbital and bromide therapy. Gabapentin[128] at 5 to 10 mg/kg orally 2 to 3 times a day has been used anecdotally to aid in seizure management. However, the clinical efficacy of gabapentin and other new anticonvulsant drugs is currently unknown in horses. Based on pharmacokinetic studies on levetiracetam in horses using 20 mg/kg IV or 30 mg/kg intragastric immediate and extended release, an intravenous or oral dosage of 32 mg/kg q 12 h was proposed.[129] Bioavailability in this study was determined to be excellent, and the mean terminal half-life was 6 to 7 hours.[129]

It is difficult to provide recommendation for when to terminate anticonvulsant therapy. If no adverse effects are seen, the dose should not be altered for most horses until the patient has been seizure free for at least 6 months in the author's opinion (Aleman). If one needs to discontinue anticonvulsant therapy, this should be done slowly because sudden withdrawal of drugs might precipitate seizures. In neonates, the dose can be decreased by one-fourth to one-half each day for a minimum of 3 days and then discontinued. In an adult that has been on long-term anticonvulsant maintenance therapy, a longer weaning period is suggested. Anecdotal reports of decreasing dosages by 20% every other day for 1 week before stopping the anticonvulsant have been proposed. The editor prefers a more gradual decrease of the dosage by 20% every 2 to 4 weeks. Serial EEGs might provide valuable information on the progression or resolution of the disease in horses and might help the clinician in determining whether continued maintenance anticonvulsant therapy is necessary.

Sleep

Monica Aleman

Sleep in the horse is essential for its overall health.[130] Lack of sleep and sleep disorders can compromise the horse's health, performance, and quality of life. Limited information and lack

of understanding of normal sleep in the horse can result in erroneous interpretation of normal and abnormal sleep, inaccurate diagnosis of presumed sleep disorders, and management failure. Studies of sleep in the horse have mainly relied on behavioral observations, which is the first essential step in the evaluation of sleep. In addition to observation, the use of simultaneous EEG has redefined sleep medicine in humans through the determination of EEG characteristics of sleep and its various stages. This is important because the definition of various sleep disorders in people depends on identifying alterations in the sequence, duration, and pattern of stages of sleep. Sleep staging is based on specific features recorded in the EEG, electrooculogram (EOG), EMG, electrocardiogram (ECG), and respiratory patterns. Collectively, these studies and their interpretation are known as polysomnography. Polysomnography is emerging in veterinary medicine.

Horses sleep an average of 3 to 4 hours per day with multiple phases of rest and sleep (polyphasic sleepers) throughout a 24-hour period.[130] Most of their sleep occurs at night. Approximately 6 phases of rest and sleep during nighttime have been seen in horses based on observational studies. Duration of lateral recumbency during nighttime has been reported to be 2% to 9% and 5% to 15% in wild and stabled horses, respectively. In the wild, horses take turns for rest and sleep, where a few horses remain on alert while others rest or sleep. Horses on alert stand on higher areas where visualization of possible predators is better. Foals and especially neonatal foals sleep more time per day than adults. Their periods of rest and sleep are more in number and frequency and of longer duration than those of adults. The need for rest and sleep in the foal declines as the foal matures. From observational studies in wild horses and horses housed in pastures, it has been noted that a shift in the amount of sleep substantially declines in foals by 3 months of age. Differences in breed and gender have been reported, with draft breeds resting more than light breeds and fillies resting more than colts. There are many factors that can influence sleep in horses such as the environment, safety, companions, hierarchy, physiologic state and age, exercise, diet, and disease (see causes of sleep deprivation). Naturally, horses are herd animals, and through domestication we have altered sleep in horses.

Stages of Sleep

Sleep staging in horses is not nearly as sophisticated as it is in humans because of the unease of performing EEG in the natural setting.[86] However, the recent introduction of telemetric EEG units in veterinary medicine has opened a major opportunity to study sleep in the horse. Challenges presented in performing EEG include distance of recording, maintaining EEG electrodes, and movement artifacts. In horses, four states of vigilance can be determined through observation and simultaneous video and EEG recording. The electrophysiologic evaluation includes EEG, EMG, EOG, ECG, and respiratory monitoring for the definition of the stages of sleep. The stages include wakefulness, drowsiness, slow wave sleep, and REM sleep.

In wakefulness, the horse is bright and alert, standing with all limbs unless moving. Movement artifacts (eyes, ears, jaw, head) and EMG activity are common. Heart and respiratory rates are within reference values. Horses can adopt a stance characterized by weight bearing of both thoracic limbs and one pelvic limb with the other pelvic limb primed (ready to kick predators?) during drowsiness. Occasional vertex sharp waves (V waves) and transient benign variants that may appear epileptiform have been observed in healthy horses. These transient discharges are similar to those observed in healthy humans during this stage of sleep. These benign variants have been observed in sleep-deprived horses. During slow wave sleep, horses can sleep standing with the head held low or in sternal recumbency if safe and comfortable. Many horses in this stage display a second atrioventricular block (not present during other states of vigilance).

REM sleep is similar among species in which low voltage and mixed frequencies with episodic fast eye movements and loss of EMG activity are noted. Horses appear to devote about 15% of their total sleep time to this state. Horses can have REM sleep while in sternal recumbency while supporting their head on the ground or on an object, or more commonly in lateral recumbency if safe and comfortable. During REM sleep there is loss of muscle tone. In addition to rapid eye movements, twitching, blinking, flaring nostrils, and even limb stretching might be observed. These movements have been wrongly interpreted as seizures. Brief standing REM sleep has been documented, but the accompanying loss of muscle tone precludes extended periods because of resulting collapse. Lack of REM sleep can result in sleep deprivation.

Sleep Deprivation

Sleep deprivation is the result of lack of adequate sleep.[130,131] What is considered adequate or enough sleep in the horse? This should be considered on an individual basis, and variations among healthy individuals can be expected. Sleep deprivation can be manifested in the horse as excessive daytime sleepiness and collapsing episodes. Horses commonly present with abrasions in their dorsal carpi and fetlocks that suggest collapsing episodes. Sleep deprivation must be considered as a possible cause of collapse, but other causes of collapse must be ruled out. Complete history, presence of concurrent medical problems, and information about the environment where the horse sleeps are essential in the investigation of alterations of sleep. Horses could be subjected to a variety of factors that can interfere with normal sleep. These factors are listed in Table 11.6.

OTHER SLEEP DISORDERS

Sleep disorders in horses are poorly understood. A few disorders have been reported or suspected in equine medicine. These include hypersomnia, narcolepsy with cataplexy, altered arousal, and REM disorders. Before considering a sleep disorder, first rule out sleep deprivation.[132,133] Hypersomnia means excessive sleepiness. However, these horses appear to have "apparently normal" cycles of sleep but may lack periods of REM sleep despite being observed lying down for considerable time. A common complaint in these horses besides excessive sleep is decreased performance. This disorder might be secondary to other diseases such as endocrinopathies (suspected hypothalamic dysfunction, pituitary pars intermedia dysfunction),[134] neurologic disease (encephalitis, brain trauma, EPM, West Nile virus observed by author), and others yet to be identified. Specific mechanism of disease is unknown.

TABLE **11.6 Causes of Sleep Deprivation**

Environmental	Nonneurologic Medical Problems	Neurologic Problems

Wild horses
• Predators
• Rank in the herd
  • Dominant horses (on constant alert)
  • Bottom of herd (constant harassment by others)
  • Establishing ranking order in the pack
• Constant search for food
• Extreme temperatures, natural disasters (e.g., fire)
• Physiologic state
  • Pregnant mares not lying down enough
  • Lactating mares on constant alert to protect their foal
• Domesticated horses
• Housing (indoors: stall vs. outdoors: pasture)
• Predators in the area
• Rank in the herd
• Lack of companion(s)
• Bedding (lack of or uncomfortable)
• Traveling and shows
• Quarantine areas
• Hospitalization (more common in intensive care units)
	Pain (specially chronic)
	• Orthopedic, musculoskeletal disease
	• Gastrointestinal (e.g., enteroliths)
	• Pleuropneumonia
		Inability or unsafe to lie down
		Recumbency
		Neuropathic pain

A history of collapse or presence of abrasions or fibrosis in the dorsal carpi and fetlocks should alert the clinician of a possible sleep disorder. Other causes of collapse must be ruled out (cardiovascular, respiratory, neurologic conditions, electrolyte derangements). Video surveillance for 24 hours for a minimum of 7 days will provide useful information about the sleep behavior of the affected horse. Ideally, this video should be recorded in the environment where the horse usually sleeps. Hospital video monitoring is useful but can greatly alter sleep patterns (stress, noise, unfamiliar territory). However, it is recommended. A questionnaire with specific questions regarding the environment, presence of wildlife, companions, diet, traveling, shows, medical or painful conditions, and medication should be included. Ask if other horses suffer from similar problems. Before considering a sleep disorder, rule out sleep deprivation as the cause of abnormal sleep behavior because this might be corrected if the primary cause is corrected. Without simultaneous video and electrodiagnostic testing, it is not possible to determine whether all stages of sleep occur or if paroxysmal activity may be occurring.

Narcolepsy

Narcolepsy is a nonprogressive sleep disorder of the central nervous system characterized by excessive daytime sleepiness with manifestations of REM sleep. These manifestations also include uncontrolled episodes of loss of muscle tone (cataplexy), although narcolepsy might also occur without cataplexy.[132]

Narcolepsy has been recognized in humans and suspected in a variety of domestic animals, affecting 0.02% of adults worldwide and over 17 breeds of dogs.[132,133,135] Although its prevalence is not known in horses, narcolepsy appears to be rare and is breed specific. Both familial and sporadic cases of narcolepsy have been presumed observed in horses.[136-140] The disease has been reported in Suffolk and Shetland foals (the fainting disease),[137] Welsh ponies, Miniature Horses, Thoroughbreds, Quarter Horses, Morgans, Appaloosas, Standardbreds, and Lippizaners.[136-140] A familial occurrence is thought to exist in affected Suffolk and Shetland pony foals, American Miniature Horses, and Lippizaners. In general, narcolepsy is identified in two distinct groups: in foals (for which the onset occurs within a few months of life) and in adult horses.

A condition of excessive daytime sleepiness with episodes of collapse or near-collapse is described in horses that have been deprived of REM sleep or not enough slow wave sleep for a period of time.[130,131] This might be the result of medical conditions inhibiting recumbency (pain, altered neurologic status), housing and environmental factors (weather, wildlife), or social and behavioral factors. This apparently excessive sleepiness has been commonly confused as narcolepsy, but this clinical manifestation in many instances is due to lack of adequate sleep as defined for the particular individual. However, this lack of sleep can have serious consequences in the overall health and performance of the horse. Therefore every effort to determine and address the primary cause must be made.[130]

Pathophysiology. Four components of narcolepsy are apparent in human beings: excessive daytime sleepiness associated with short periods of REM sleep, cataplexy, hypnagogic hallucinations, and sleep paralysis.[133] Cataplexy or sudden collapse with complete inhibition of skeletal muscle tone occurs in horses with narcolepsy.[137-140] Respiratory and cardiac muscles are spared.

With narcolepsy and cataplexy, a biochemical abnormality of the brainstem or sleep-wake center might be present. In people, evidence suggests that narcolepsy with cataplexy is related to an underlying deficiency in the hypothalamic orexin/hypocretin system.[132,133,135] Although their physiologic roles are not fully understood, hypocretins are hypothalamic-specific neuropeptides, which are involved in various functions such as sleep, feeding, energy homeostasis, and neuroendocrine and autonomic nerve functions. A mutation in the hypocretin receptor 2 gene has been identified in Dobermans and Labrador Retrievers, with secondary impairment in postsynaptic hypocretin neurotransmission. In acquired canine narcolepsy, the concentration of hypocretin-1 in the brain and CSF was undetectably low, suggesting a loss of production of hypocretin peptides, similar to the pathophysiologic mechanisms reported in humans.[132,133] Although the role of hypocretins in equine narcolepsy is unknown, horses with pituitary pars intermedia dysfunction and narcolepsy-like episodes had low concentration of hypocretin-1 in the CSF.[134]

Clinical Signs. Cataplectic episodes are triggered by strong emotions (usually positive), such as laughing or anger in humans and excitement associated with play or the presentation of food in dogs. In horses, the initiation of eating or drinking, petting or stroking of the head and neck, hosing with cold water after exercise, and leading out of a stall might precipitate a cataplectic episode. The episodes have also been reported during riding. Adult horses might drop their heads, buckle at the knees, and stumble. If forced to walk, the horse might appear ataxic. Pony breeds are more likely to become recumbent. Affected horses are neurologically normal between attacks.

Diagnosis. Diagnosis of narcolepsy is based on history, clinical signs, pharmacologic testing (not always reliable), and the absence of other diseases. Careful questioning of the caretaker should be performed to determine any event(s) associated with the episode, and video documentation of the episode(s) is optimal. Physical examination may reveal the presence of superficial trauma, particularly over the dorsal aspect of the fetlocks and carpi in most, but not all, cases. A CBC and serum biochemical profile are normal in affected horses and may help to exclude underlying systemic and metabolic abnormalities. CSF cytology is usually normal, and EEG might reveal REM sleep during an episode.

A presumed provocative test with variable results to diagnose narcolepsy or cataplexy in horses is the use of physostigmine salicylate. Physostigmine is an anticholinesterase drug given at 0.05 to 0.1 mg/kg slowly intravenously that might precipitate a cataplectic attack within 3 to 10 minutes after administration in affected horses. This compound crosses the blood-brain barrier. Careful monitoring of the horse after physostigmine administration is necessary because of untoward effects such as colic and cholinergic stimulation. In addition, lack of positive response to physostigmine does not rule out a diagnosis of narcolepsy because individual response to the drug is quite variable and some affected horses failed to respond to this provocative testing.

Atropine sulfate, a muscarinic blocker, given at 0.04 to 0.08 mg/kg intravenously, reduces the severity of cataplectic attacks minutes after administration and can prevent their reoccurrence for 12 to 30 hours following administration. Response to atropine sulfate supports a possible cholinergic mechanism for causing cataplexy. One must monitor horses given atropine sulfate for ileus and colic.

Differential Diagnosis. Cataplexy, which is commonly seen with narcolepsy, is the best diagnostic marker of this disease and should be distinguished from other causes of episodic weakness or collapse. Ruling out collapse secondary to prolonged sleep deprivation is important as it might be common in horses. This disorder might be caused by chronic pain, environmental factors, or social/behavioral factors. In these cases, administrating NSAIDs to animals with chronic pain and/or providing the horse with a comfortable environment (to encourage the horse to lie down) might resolve the clinical signs.[130] Acute collapse without premonitory signs is characteristic of cardiovascular collapse or syncope, and unlike narcolepsy is not preceded by gradual lowering of the head and drowsiness. Atrial fibrillation, ruptured chordae tendinae, myocardial infarction, myocardial fibrosis, aortic endocarditis, and pericarditis have been associated with syncope in horses. Cerebral hypoxia might occur in these conditions and might lead to coma, with or without signs of cardiac failure. One should differentiate seizures from narcolepsy/cataplexy, botulism, myasthenia-like syndrome, hypocalcemia, and hyperkalemic periodic paralysis, among others.

Treatment and Prognosis. In general, drugs that stimulate monoamine systems (e.g., dopamine) in the brain are effective suppressors of narcolepsy, whereas drugs that stimulate cholinergic activity in the brain exacerbate narcolepsy. Imipramine, a tricyclic antidepressant drug, has been recommended to control narcolepsy and cataplexy.[138] The drug blocks the uptake of serotonin and norepinephrine and decreases REM sleep. Oral administration (250–750 mg) produces inconsistent results.[138] Potentially serious adverse effects including muscle fasciculations, tachycardia, hyperresponsiveness to sound, and hemolysis may be seen in horses receiving intravenous dosages of imipramine that exceed 2 mg/kg.[138] Adverse effects are not seen when the drug is administered orally, but that is likely because of very poor bioavailability. The disorder might persist for life.

CENTRAL NERVOUS SYSTEM TRAUMA

Yvette S. Nout-Lomas

Trauma to the CNS is the most common cause of neurologic disease in horses, accounting for 22% to 24% of neurologic disorders.[141,142] Both of these studies reported trauma to the spinal cord to be more prevalent than brain injury. Traumatic brain injury (TBI) was reported in 23% to 44% of cases, and spinal cord injury (SCI) was reported in 56% to 77% of cases. A more recent investigation into exercise-associated sudden deaths in previously apparently healthy Thoroughbred racehorses from six racing jurisdictions around the world showed that 13% (18 of 143) of deaths were attributed to CNS trauma.[143] Of these, 60% (11 of 18) had SCI associated with cervical vertebral fracture, 17% (3 of 18) had CNS hemorrhage, 11% (2 of 18) had TBI associated with skull fracture, 6% (1 of 18) had CNS injury associated with both skull and cervical vertebral fractures, and 6% (1 of 18) of cases had SCI associated with cervical vertebral instability.

Although mechanisms of CNS cell damage, to a certain degree, are similar after TBI and SCI, a few different processes exist with regard to cause and pathophysiology. Clinical syndromes as a result of traumatic injury to the CNS can vary tremendously, but the most common are coma, vestibular disease, tetraparesis, paraparesis, tetraplegia, and cauda equina syndrome. Treatment regimens for CNS injury are aimed toward reducing inflammation and swelling, halting secondary injury mechanisms, and promoting regeneration and recovery of function. Prognosis depends primarily on severity of primary injury and on the extent and neuroanatomic location of CNS damage.

Traumatic Brain Injury

Pathophysiology

Head trauma is typically caused by incidents such as collision with an immovable object such as a fencepost or another horse, falling down, flipping over backward, being kicked by another horse, and, although rare, impact by a projectile (e.g., gunshot). A retrospective study involving 34 horses with TBI showed that the most common cause (44%) of injury was rearing and falling backward, resulting in poll injury.[144] Another type of head injury that may lead to CNS damage is fracture of the petrous temporal bone associated with THO.[145]

Although traumatic injury to the head is reported to be common in horses, subsequent TBI occurs only in 25% to 50% of cases.[146,147] The remaining horses typically present for fractures of the orbit, periorbital rim, and zygomatic, mandibular, or maxillary bones. TBI may occur with or without fracture of the calvarium; however, some of the most severe injuries to the brain occur when the injury is contained within the closed calvarium (i.e., no skull fractures).[148] Within the closed calvarium, the sum of the intracranial volumes of the brain, blood, and CSF are constant; volume or pressure changes within one of these compartments will affect volume (anatomy) or pressure of the other compartments.

Consequences of impact sustained to the poll in horses that flip over backward include fracture of the bones on the side and base of the calvarium such as the petrous temporal, squamous temporal, and parietal bones. However, more commonly these bones remain intact, and more serious injury occurs to the basilar bones as a result of strong traction forces from the rectus capitis ventralis muscles (Fig. 11.23).[149,150] In addition, adjacent large vessels are lacerated, and hemorrhage into the retropharyngeal spaces or guttural pouches can occur. In severe cases, transverse fracture of the basilar bones at the level of the basioccipital-basisphenoidal suture can occur. Young horses may be more susceptible to this type of injury because the joint between the basilar bones fuses by 5 years of age.[150] In most cases the fracture site is stable, and minimal displacement occurs. The cerebellum is seldom severely damaged after poll impact,[145] but the cerebral parenchyma is more commonly injured after being subjected to rapid acceleration-deceleration forces. Moreover, optic nerves and other attachments may be torn from the cerebral hemispheres.[151] Impact to the dorsal surface of the head may result in damage to the frontal or parietal bones, with subsequent cerebral cortical injury or, more commonly, damage to the cervical vertebrae with subsequent SCI. In addition, cranial nerve XII may be injured as it exits the hypoglossal foramen. Furthermore, occipital cortical injury may occur and, as described for poll impact injuries, with frontal injuries the optic nerves may be stretched.

Pneumocephalus was diagnosed by radiographs or CT in horses after trauma to the head with suspected or confirmed fractures to the sinuses[152] and after sinus surgery.[153] *Pneumocephalus,* also known as intracerebral airocele or pneumatocele, is defined as the presence of gas within any intracranial compartment (intraventricular, intraparenchymal, subarachnoid, subdural, and epidural). In the six horses described in these reports, there were no neurologic sequelae noticed that could be attributable specifically to the pneumocephalus. However, in humans clinical signs include headache, nausea and vomiting, seizures, dizziness, and depressed neurologic status. Although pneumocephalus can be an incidental finding, it is a possible life-threatening complication that can occur after head trauma in horses.

After trauma, the most severe damage generally takes place at the place of impact (coup), opposite to the side of impact (contrecoup), or in both locations. Additionally, the brain is subjected to other forces after trauma, such as rotational and shock wave forces. TBI is a result of both direct, immediate mechanical disruption of brain tissue (primary injury) and indirect, delayed (secondary) injury mechanisms. The primary damage is a result of the biomechanical effects of the injury and is characterized by immediate and often irreversible damage to neuronal cell bodies, dendritic arborizations, axons, glial cells, and brain vasculature. This initial brain injury may be focal, multifocal, or diffuse. Secondary injury is a complex cascade of molecular, cellular, and biochemical events that can occur for days to months after the initial insult, resulting in delayed tissue damage. In addition, systemic alterations further contribute to the tissue damage. Hypoxia, ischemia, brain swelling, alterations in intracranial pressure, hydrocephalus, infection, breakdown of blood-brain barrier, impaired energy metabolism, altered ionic homeostasis, changes in gene expression, inflammation, and activation and release of autodestructive molecules occur and exacerbate the initial injury. Recently the pathology of TBI after blunt nonmissile and penetrating missile head injuries in veterinary species was reviewed.[154]

Principles of raised intracranial pressure are described in the Monro-Kellie doctrine, which states that once the fontanelles and sutures of the skull are closed, the brain is enclosed in a nonexpandable case of bone, the brain parenchyma is nearly incompressible, the blood volume in the cranial cavity is therefore nearly constant, and a continuous outflow of venous blood from the cranial cavity is required to make room for continuous incoming arterial blood.[155] Blood flow to the brain is controlled by changes in diameter of resistance blood vessels, and cerebral blood flow is controlled by autoregulation whereby the perfusion pressure is maintained within a range of approximately 50 to 150 mm Hg. Beyond these limits, cerebral blood flow decreases at pressures below the lower limit and increases at pressures above the higher limit. Cerebral perfusion pressure (mean arterial blood pressure minus intracranial pressure) is the stimulus to which the autoregulatory response of the vasculature occurs. Cerebral autoregulation is altered unpredictably after TBI, and it appears that the minimum acceptable cerebral perfusion pressure is higher than normal after trauma. Increased intracranial pressure leads to a decreased cerebral perfusion pressure and subsequently

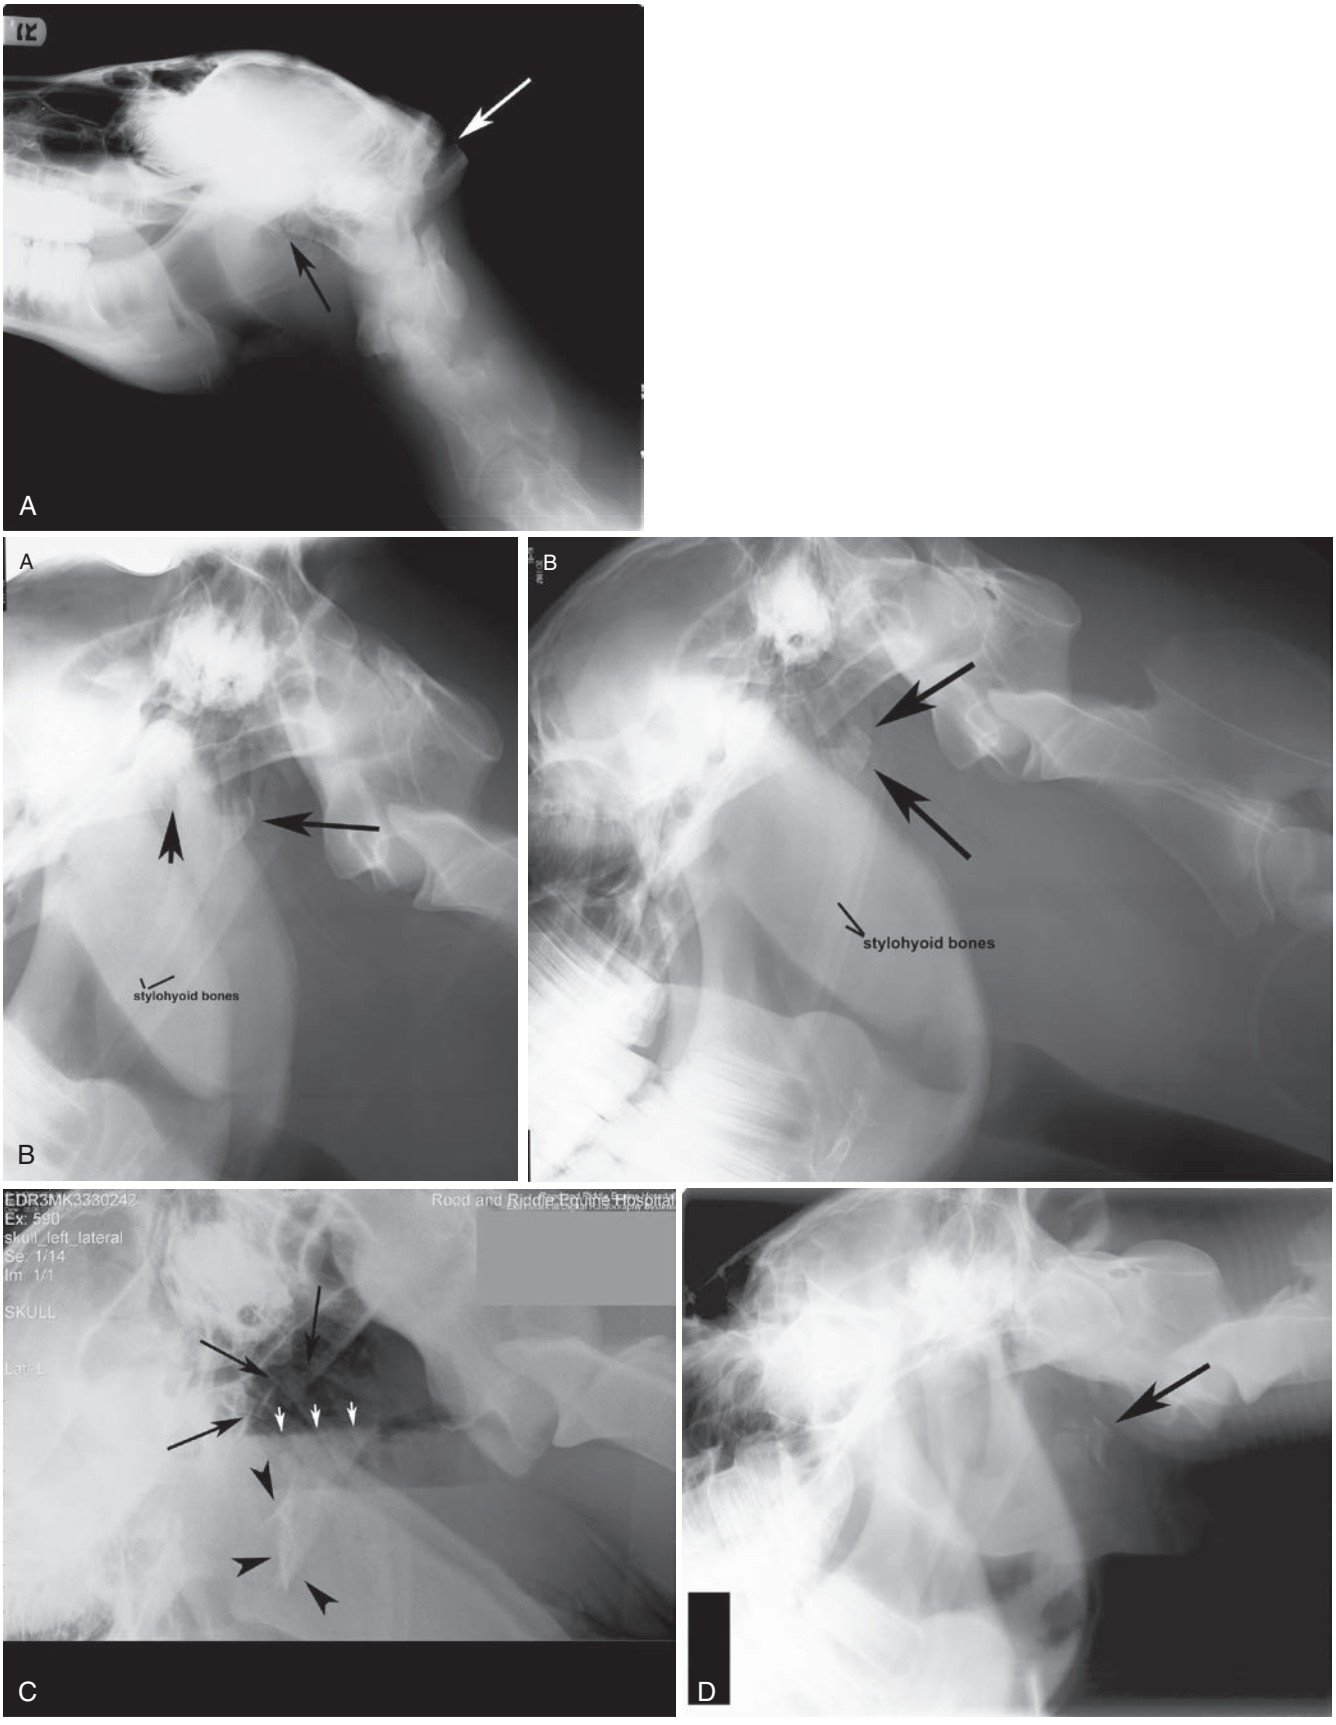

FIG. **11.23** A, Radiograph from a 3-year-old Thoroughbred colt that flipped while playing on the end of the lead shank. The horse hit its head on a small board along the side of the walkway and was unconscious for 3 to 5 minutes. The horse had blood coming from the nostrils, paralysis of the right eyelid, a corneal ulcer on the right eye, and weakness in all four limbs. The radiograph shows a fluid line in the guttural pouch *(small white arrows)* and a basisphenoid fracture *(large black arrows)* with a large fragment *(arrowheads)* visible in the guttural pouch area. B, This is a radiograph taken from a horse after head injury and subsequent rupture of the longus capitis muscle and an avulsion fracture from the basisphenoid bone. This is a radiograph image C taken from a horse that flipped while playing on the end of the lead shank. This is a radiograph image D taken from a horse with head injury that resulted in rupture of the longus capitus. The *arrow* is pointed at the avulsed bone located behind the guttural pouch. reduces cerebral blood flow. Reduced cerebral blood flow results in areas of ischemia and subsequent restriction of delivery of substrates such as oxygen and glucose to the brain. Brain swelling after TBI because of edema formation and hematoma formation within the skull are the most common causes of increased intracranial pressure. Vascular damage that occurs after head injury can be epidural (between dura mater and the skull), subdural (between the dura mater and arachnoid mater), subarachnoid (between arachnoid mater and pia mater), superficial (vessels immediately under the pia mater), intraparenchymal, and intraventricular.

The cascade of secondary injury that results in necrotic and apoptotic cell death is described in more detail in the section on pathophysiology of SCI. Uncontrolled glutamate release and failure of energy systems in neuronal and supporting tissues lead to elevated intracellular calcium concentrations and subsequent cell death. Hemorrhage, ischemia, and the primary tissue damage lead to sequestration of vasoactive and inflammatory mediators at the injury site and are thus involved in the secondary injury cascade. Inflammation and endothelial damage cause derangements in normal cerebrovascular reactivity and contribute to a mismatch of oxygen delivery to tissue demand, resulting in local or diffuse ischemia.

A major consequence of ischemia is reduced delivery of oxygen and glucose. Blood flow interruption is responsible for disruption in ion homeostasis (especially calcium, sodium, and potassium) and a switch to anaerobic glycolysis resulting in lactic acid production and acidosis. Cell membrane lipid peroxidation with subsequent prostaglandin and thromboxane synthesis, formation of reactive oxygen species (ROS), nitric oxide, and energy failure also ensue. Because of the high metabolic rate and oxygen demand of the brain, disruption of blood flow rapidly compromises the energy-supplying processes and leads to impaired nerve cell function and even cell death. Impaired mitochondrial function with subsequent energy depletion leads to a loss in maintenance of membrane potentials resulting in depolarization of neurons and glia.[156] Cytotoxic edema develops through the failure of the sodium-potassium ATPase-dependent pump in the presence of hypoxia and the subsequent influx of water that passively follows sodium and chloride. In addition to cytotoxic edema, vasogenic edema develops as a result of disruption of the blood-brain barrier, which includes damage of endothelial cells, degeneration of pericytes, and loss of astrocytes.[157] Extravasation of blood components and water occurs resulting in increased extracellular fluid accumulation. Understanding the complex pathophysiologic events that take place after TBI is important for the development of effective monitoring and treatment strategies.

Neurologic Evaluation

Clinical signs associated with TBI range from inapparent to recumbency with unconsciousness or death (Fig. 11.24). A complete physical examination is very important in head trauma cases, because fractures and other concurrent injuries are not uncommon and require identification and treatment. Physical examination findings as a result of head trauma can include fractures; hemorrhage from the nostrils, mouth, and ears; CSF draining from the ear (Fig. 11.25); respiratory distress; cardiac arrhythmias; and hypotension or hypertension.

Hemorrhage from the nose typically presents as dark-colored (venous) blood and originates from a paranasal sinus, ethmoid turbinates, or nasal cavity. Occasionally, blood is bright red and then usually originates from larger vessels in the guttural pouches. Respiratory distress can occur associated with significant throat swelling after profuse hemorrhage into the guttural pouches. Furthermore, neurogenic pulmonary edema has been reported to occur. Acute elevation of intracranial pressure may result in Cushing's reflex, which is a hypothalamic response to brain ischemia and is characterized by hypertension and secondary baroreceptor-mediated bradycardia. Continued elevation of intracranial pressure and reduction of cerebral blood flow results in increased sympathetic discharge (catecholamines), with subsequent myocardial ischemia and development of cardiac arrhythmias. This is referred to as the *brain-heart syndrome*.

Life-threatening injuries should be attended to first, and then a complete neurologic examination should be performed. Horses may be recumbent, intractable, or both after a traumatic incident; examination and management of these horses can be difficult and dangerous.[9] Signs of focal brain injury are listed in Table 11.7. Sedation may be necessary for examination. Although α_2-agonists may transiently cause hypertension, which may potentiate intracranial hemorrhage, xylazine has been found to cause a minor decrease in cerebrospinal pressure in normal, conscious horses[158] and is considered a safe sedative to use in horses with head trauma if the head is not allowed to drop too low that it could affect physiologic changes in intracranial pressure.

The complete neurologic examination should include an assessment of the horse's mentation, cranial nerve function, posture, and ability to coordinate movements, as well as its ability to regulate rate and range of motion. In addition, reflex and nociceptive testing should be performed to investigate any concurrent SCI. Serial neurologic examinations, particularly during the first hours, are important for diagnostic purposes and to allow prediction of a more accurate prognosis. Furthermore, serial examinations are important to assess response to therapy. Pupil size, symmetry, and response to light should be assessed in all horses and followed carefully, particularly in recumbent horses. A change from bilateral pupillary constriction to bilateral dilation with no response to light is a poor prognostic indicator.

The most common neurologic syndromes after head trauma are a result of hemorrhage into the middle and inner ear cavities. Signs are those of central or peripheral vestibular disease and facial nerve damage and include recumbency, head tilt, neck turn, body lean, and circling, all toward the side of the lesion. The ipsilateral eye may be rotated ventrally and laterally, and there may be horizontal or rotary nystagmus with the fast phase away from the lesion. Facial paralysis on the same side as the lesion is seen with cranial nerve VII damage. Central vestibular disease is suspected when signs of brainstem disease or other cranial nerve deficits are present. Central vestibular lesions can result in a paradoxic vestibular syndrome, in which the lesion is located on the side opposite to that which is expected from the clinical signs. More serious trauma can lead to alterations of mentation, behavior, or both.

The level of consciousness is affected by the degree of damage to the cerebrum and reticular activating system in the brainstem. Immediately after cerebral injury, a period of concussion occurs, with unconsciousness for various periods of time, or even coma. Usually a horse recovers from this in minutes to hours. Comatose horses may have an irregular breathing pattern with periods of either Cheyne-Stokes breathing or hyperventilation. In some horses, seizures can

occur after initial concussion; these are typically generalized seizures. Level of mentation and responsiveness to reflexes should be assessed and recorded. Injury to the occipital cortex can result in impairment of vision and menace response of the eye contralateral to the lesion. Pupillary light reflex, however, should remain intact. Injury to the parietal cortex can result in decreased facial sensation on the contralateral side. Another sign of cerebral damage is dementia, or altered behavior, such as walking in circles (toward the side of the lesion), head pressing, hyperexcitability, or aggression.

Severe rostral brainstem injuries (mesencephalon) can be associated with coma and depression because of damage to the reticular activating system. Strabismus, asymmetric pupil size, and loss of pupillary light response can be present because of damage to cranial nerve III. Apneustic or erratic breathing reflects a poor prognosis, and bilaterally dilated and unresponsive pupils indicate an irreversible brainstem lesion. These lesions can occur immediately after injury, secondary to herniation of components of the cerebrum or cerebellum, or after hemorrhage. Severe brainstem injuries may result in a decorticate posture, characterized by rigid extension of neck, back, and limbs. Injury to caudal parts of the brainstem (pons and medulla) result in dysfunction of multiple cranial nerves in addition to depression and limb ataxia and weakness. To make a distinction between a cranial cervical spinal cord and caudal brainstem lesion, careful assessment of the

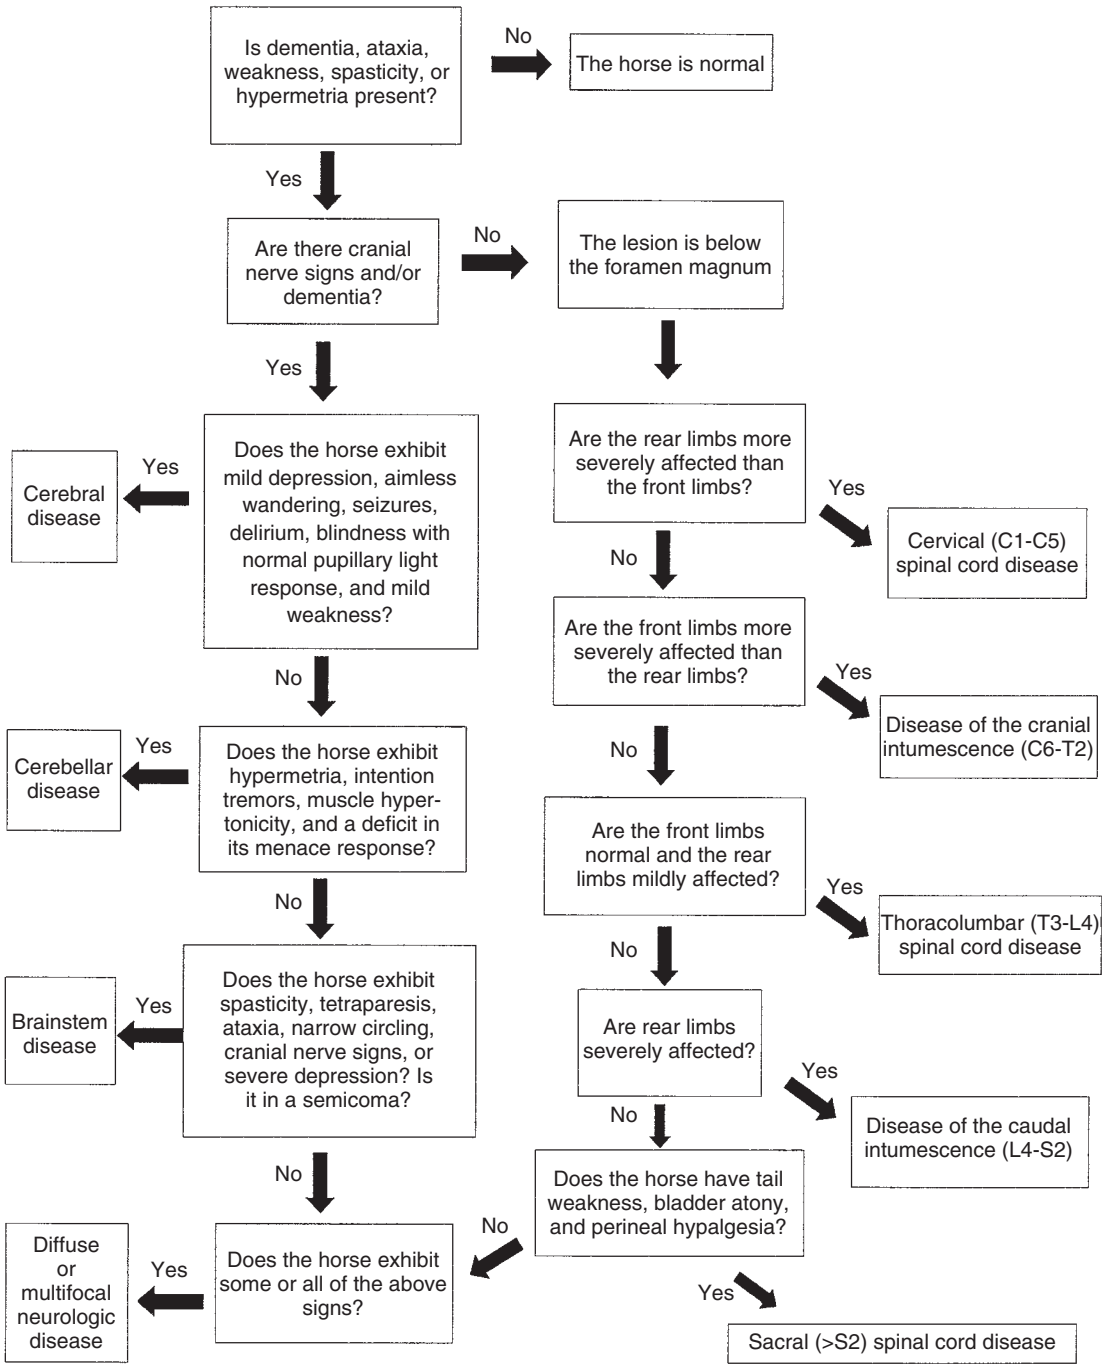

FIG. **11.24** Flow chart for localizing a lesion in the nervous system in a recumbent horse.

horse's mentation and function of cranial nerves X and XII is important.

Signs of cerebellar injury occur infrequently and include intention tremor, broad-based stance, spastic limb movements, and absent menace response with normal vision. If multiple areas of the brain are damaged, this will be reflected in the different clinical signs. Multifocal damage or progression of disease through hemorrhage, secondary injury mechanisms, or both is suggested when clinical signs become more widespread.

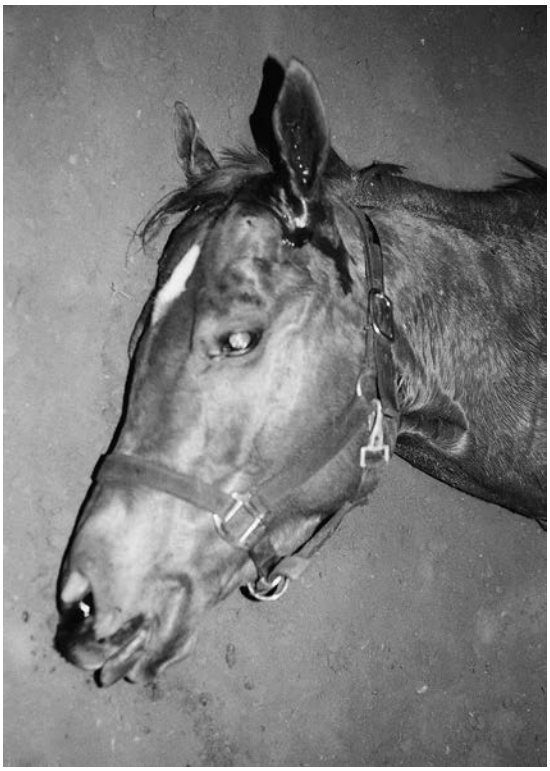

FIG. **11.25** Blood and cerebrospinal fluid (CSF) draining from the ear after a basilar skull fracture.

Diagnostic tools that are helpful in further defining cranial trauma include radiography, CT, MRI, endoscopy, electrodiagnostics, transcranial magnetic stimulation, and CSF analysis. Although radiographs typically are the first-line diagnostic tool to use for determination of the presence and severity of fractures, hemorrhage in cavities, or thickening of stylohyoid bone or bulla (or both), one study showed that only 50% of bony fractures of the calvarium were confirmed radiographically.[144] CT has been shown to be an excellent neurodiagnostic tool in identifying skull fractures, intracranial space-occupying lesions (e.g., neoplasia), and acute hemorrhage and allows one to rule in intracranial disorders.[159] However, this same report showed that CT has limited sensitivity in identifying inflammatory disorders and small parenchymal lesions in the equine brain. Soft tissue changes that can be seen on CT after TBI include change in the size, shape, and position of the ventricles, deviation of the falx cerebri, and focal changes in brain opacity. Enhancement of areas of injury or hemorrhage is sometimes possible with iodinated contrast agents. MRI offers a higher sensitivity for examination of soft tissue structures and has the ability to acquire images in all planes. However, the use of MRI is not yet possible for all equine clinicians. Upper respiratory endoscopy is an important diagnostic procedure for evaluation of cranial nerve function, stylohyoid bones, retropharyngeal area, and appearance of guttural pouches. Transcranial magnetic stimulation and measurement of the magnetic motor-evoked potentials in the thoracic and pelvic limbs has been shown to be helpful to assess the integrity of the descending motor pathways, to confirm or exclude a descending motor tract lesion as the cause of the recumbency.[160] Electroencephalograms are used for assessment of seizure activity, BAER is used for examination of vestibular function, and

TABLE **11.7** **Signs Characteristic of Focal Brain Injury**

Levels	Consciousness	Motor Function	Pupils	Other Sign
Cerebrum	Behavior change, depression, coma	Circling	Normal	Blindness
Cerebellum		Ataxia and hypermetria, intention tremor		Menace response deficit without blindness
Diencephalon (thalamus)	Depression to stupor	Normal to mild tetraparesis, "aversive syndrome"[a]	Bilateral, nonreactive pupils with visual deficit	None
Midbrain	Stupor to coma	Hemiparesis, tetraparesis or tetraplegia	Nonreactive pupils, mydriasis, anisocoria	Ventrolateral strabismus
Pons	Depression	Ataxia and tetraparesis, tetraplegia	Normal	Head tilt, abnormal nystagmus, facial paralysis, medial strabismus
Rostral medulla oblongata (including inner ear)	Depression	Ataxia or hemiparesis to tetraplegia	Normal	Same
Caudal medulla oblongata	Depression	Ataxia, hemiparesis to tetraparesis, abnormal respiratory patterns	Normal	Dysphagia, flaccid tongue

visual function is examined with visual-evoked potential in combination with electroretinography. CSF analysis may not always be indicated after acute trauma, but it may be useful for excluding other diseases. Cisternal CSF collection is contraindicated if increased intracranial pressure is suspected because of the possibility of brain herniation through the foramen magnum. Lumbosacral collection is a safer alternative but can be normal despite a traumatic episode, especially in the acute phase, and because if the sample is not obtained closest to the lesion it may not reflect the changes that have occurred.

In human medicine, development of advanced bedside neuromonitoring devices has been an important focus in neurocritical care. The four most important parameters to be determined are (1) intracranial pressure, (2) cerebral blood flow, (3) information on brain metabolism, and (4) functional outcome. For example, catheters can be placed into the brain tissue to determine glucose, glycerol, and glutamate concentrations, indicators of secondary ischemia, by microdialysis, and probes can be placed to determine brain tissue oxygen tension. Methods to measure and monitor intracranial and cerebral perfusion pressures have been described for use in foals[161] and adult horses[162]; however, these techniques have thus far not been scientifically evaluated in clinical cases. One study demonstrated the use of near-infrared spectroscopy to measure regional cerebral oxygen saturation in horses.[163]

Treatment and Prognosis

Based on the pathophysiology of events that occur after TBI, it is likely that single-drug intervention would not be effective. Treatment of TBI is aimed at optimizing delivery of oxygen and substrates to brain tissue to salvage brain tissue that is undamaged or reversibly damaged. This requires optimizing cerebral blood flow (i.e., optimizing mean arterial blood pressure and hemoglobin concentration; ensuring intracranial pressure is not elevated). Emergency surgical treatment (although not commonly performed) is warranted in open cranial fractures and in the face of deterioration despite medical therapy. In Fig. 11.26 a flow chart is shown that can serve as a guide to the management of cranial trauma in horses.

Methods to reduce intracranial pressure include hyperventilation, CSF drainage, treatment with hyperosmolar agents or barbiturates, head elevation, and decompressive surgery. Hyperventilation reduces the partial pressure of carbon dioxide in blood and subsequently leads to cerebral vasoconstriction. Reduced cerebral blood volume reduces intracranial pressure. However, cerebral vasoconstriction may lead to reduction of cerebral blood flow to ischemic levels. Hyperventilation could be considered in cases of increased intracranial pressure in horses. Proper hyperventilation requires monitoring of arterial blood gases and may require use of neuromuscular blockers if the horse is not comatose and is resisting the ventilator. CSF drainage is commonly used in people to reduce intracranial pressure; however, it is therapeutic only if CSF outflow obstruction is noted. If these methods are ineffective, repeat imaging is pursued to investigate the presence of mass lesions before medical treatments are commenced such as administration of hyperosmolar substances and induction of barbiturate coma. Hyperosmolar treatment is commonly used in horses with neurologic signs attributable to TBI. This is discussed later in this section.

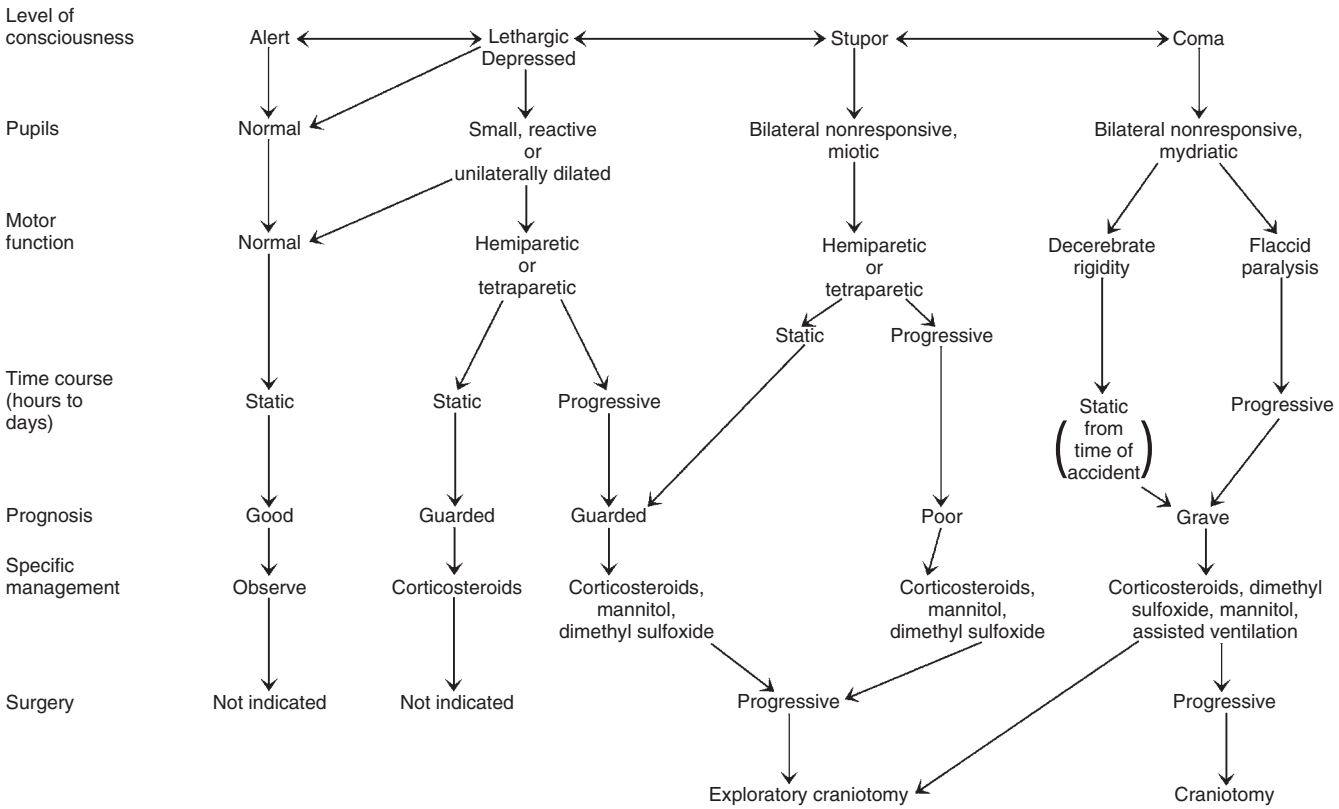

FIG. **11.26** Flow chart for management of cranial trauma. (From Robinson NE, editor: *Current therapy in equine medicine,* ed 6, St. Louis, 2009, WB Saunders; modified from Kirk KW, editor: *Current veterinary therapy VII,* Philadelphia, 1980, WB Saunders.)

Mean arterial blood pressure should be maintained within normal limits. Blood transfusion may be indicated in cases of severe hemorrhage. Crystalloid fluids are recommended as fluid therapy of choice, particularly in light of findings of the serum versus albumin fluid evaluation (SAFE) study[164] that determined no difference in outcomes between administering albumin versus normal saline in the intensive care unit. Furthermore a post hoc follow-up study demonstrated a higher mortality rate in TBI patients that were treated with albumin compared with those treated with saline.[165] There remain questions concerning optimal composition and volume of fluid therapy for TBI. There is a physiologic rationale why excessive fluid administration and positive fluid balance may increase brain swelling and intracranial pressure, and current recommendations include refined usage of intravenous fluids.[166]

It has been well established that maintaining blood glucose concentrations at 80 to 110 mg/dL through intensive insulin therapy reduces morbidity and mortality in human critical care patients.[167] However, neurointensivists have shown that intensive insulin therapy increases markers of cellular distress in the brain and suggest that systemic glucose concentrations of 80 to 110 mg/dL are too low in TBI and may lead to cerebral hypoglycemia. Recommendations now are to maintain blood glucose concentrations at 120 to 140 mg/dL in TBI.

Treatment with antiinflammatories is likely the most commonly used treatment in equine TBI. Indications for use of antiinflammatory treatment are to combat the inflammatory pathways of secondary injury mechanisms (cytokine release, free radicals), improve comfort level, and reduce fever. Fever is extremely common after TBI, and it has been well documented in animal models and in human beings to negatively affect outcome after TBI (e.g., by augmenting secondary injury mechanisms).[168,169] Researchers have proposed that a proactive approach should be taken toward reducing fever. In fact, hypothermia has been shown to be neuroprotective. Hypothermia results in decreased cellular metabolism, and in humans therapeutic hypothermia and targeted temperature management have been proven efficacious as a treatment for TBI in experimental and clinical settings; however, large multicenter trials have so far failed to demonstrate clinical benefits.[170] Therapeutics with antiinflammatory properties that are common to equine practice include corticosteroids, NSAIDs, dimethyl sulfoxide (DMSO), and vitamin E. These drugs are discussed in more detail in the section pertaining to SCI. Corticosteroids are no longer recommended for use in TBI following results of studies showing no benefit of these drugs and results of the CRASH trial that showed increased mortality in adults who received methylprednisolone after TBI.[171]

Controlling seizure activity is very important after TBI, because seizure activity increases cerebral metabolic rate and is detrimental to secondary injury. It is not unusual for horses sustaining cranial trauma to develop seizures. Diazepam, midazolam, phenobarbital, and pentobarbital are drugs that can be used to control seizures. Intractable seizures may necessitate general anesthesia. Agents useful for general anesthesia include guaifenesin, chloral hydrate, barbiturates, and gas anesthesia. Ketamine is not recommended as part of a balanced anesthesia regimen because it increases cerebral blood flow and intracranial pressure.

Barbiturate treatment or coma may decrease cerebral metabolism, thereby providing a protective effect against cerebral ischemia. Barbiturates may also limit lipid peroxidation. However, the actual benefits of barbiturate use on the neurologic outcome remain controversial. The effects of barbiturates on lowering intracranial pressure are enhanced by concurrent hyperventilation. An exact dosage regimen for barbiturate treatment in horses has not been investigated, but 5 to 10 mg/kg IV to effect is reported to be useful. The major adverse effect of barbiturates is hypotension, especially if mannitol and furosemide have been administered, so they must be used with caution and adequate blood pressure monitoring. Barbiturates should be reserved for those cases in which elevated intracranial pressure is refractory to other treatments. Other methods to lower intracranial pressure include elevation of the head by 30 degrees if no cervical fractures are present and decompressive craniectomy.

Hyperosmolar therapy, which includes mannitol or hypertonic saline, is frequently used in human patients to reduce intracranial pressure. Both of these treatments appear effective at reducing intracranial pressure, and there does not appear to be a clinically significant difference between the two with regard to mortality or neurologic outcomes.[172] Hypertonic saline has a number of beneficial effects in TBI. The permeability of the blood-brain barrier to sodium is low. Hypertonic saline produces an osmotic gradient between the intravascular and the interstitial-intracellular compartments, leading to shrinkage of brain tissue and subsequent reduction of intracranial pressure. It augments volume resuscitation and increases circulating blood volume, mean arterial blood pressure, and cerebral perfusion pressure. Other beneficial effects include restoration of neuronal membrane potential, maintenance of blood-brain barrier integrity, and modulation of the inflammatory response by reducing adhesion of leukocytes to endothelium. In horses, hypertonic saline can be administered intravenously to head trauma patients in shock as 5% or 7% sodium chloride (NaCl) solutions (4–6 mL/kg) over 15 minutes. Isotonic fluids can then be used for maintenance if needed. Contraindications to the use of hypertonic saline include dehydration, ongoing intracerebral hemorrhage, hypernatremia, renal failure, hyperkalemic periodic paralysis, and hypothermia. Systemic side effects include coagulopathies, excessive intravascular volume, and electrolyte abnormalities. Monitoring central venous pressure and maintaining it within normal limits (5–7 cm H_2O) is therefore important, as well as monitoring serum sodium and potassium concentrations if hypertonic saline is used frequently. Mannitol induces changes in blood rheology and increases cardiac output, leading to improved cerebral perfusion pressure and cerebral oxygenation. Improved cerebral oxygenation induces cerebral artery vasoconstriction and subsequent reduction in cerebral blood volume and intracranial pressure. Mild dehydration after osmotherapy is desirable and may improve cerebral edema; however, severe dehydration can lead to hyperosmolality and renal failure. In horses, 20% mannitol can be administered at 0.25 to 2.0 mg/kg IV over 20 minutes. Horses receiving osmotic diuretics should be adequately hydrated. The use of osmotic substances is warranted in any horse with worsening mental status, abnormal pupillary size or inequality indicating transtentorial herniation, or development of paresis. Although mannitol administration is very effective in reducing intracranial pressure, several limitations to its use exist. Hyperosmolality can be associated with renal and CNS effects. Furthermore, administration of multiple doses of mannitol may lead to intravascular dehydration, hypotension, and reduction of cerebral blood flow. Furosemide has experimentally been found effective in

decreasing intracranial pressure. Normal hydration status is required before furosemide is administered. Furosemide may also be used concurrently with mannitol to increase the duration of intracranial pressure reduction provided by mannitol and to diminish the potential for rebound intracranial pressure elevation. Antibiotic treatment is usually warranted in cases of head trauma, especially when fractures are involved. The presence of hemorrhage increases the possibility of septic meningitis. Antibiotic choice should be based on culture and sensitivity testing. Good empiric choices for broad-spectrum coverage include trimethoprim-sulfamethoxazole and penicillin in combination with gentamicin. Appropriate monitoring for aminoglycoside toxicity should be undertaken with their use. Owing to disruption of the blood-brain barrier, other antimicrobials probably penetrate into the CNS, and therefore their use may also be efficacious.

Nutritional support plays a role in the outcome after neurologic injury. In human beings, neurologic recovery from head injury occurs faster in patients receiving early adequate nutritional support.[173] If the horse is able to eat and the gastrointestinal tract is functioning normally, water and good-quality hay should be available at all times. Small amounts of grain should be fed three to four times a day to boost caloric intake. The amount of grain fed should be based on the horse's condition and ability to tolerate grain feeding. Horses in which enteral feeding is not possible are candidates for total parenteral nutrition. Thiamine may be of benefit in treating head injuries because thiamine aids in metabolism of lactic acid and is a necessary coenzyme in brain energy pathways.

The prognosis for cranial trauma is dependent on severity of insult and early treatment, and it is gauged by response to treatment. An early prognosis based on initial findings is important to establish for owners and thus can influence clinical decisions. However, in a study performed in human TBI patients, even with sophisticated clinical and radiologic technologies, it was not possible to predict outcome on the first day after the accident with sufficient accuracy to guide early management.[174] In general, recumbency of more than 4 hours' duration and the presence of basilar fractures and severe brainstem injuries carry a grave prognosis.[144] Time, good nursing care, and adequate nutritional support, especially in the recumbent horse, are vital for a positive outcome.

Spinal Cord and Vertebral Injury

Pathophysiology

Trauma to the vertebral column is typically caused by incidents such as collision with an immovable object or falling down. Recently there have been a number of reports on exercise-associated vertebral trauma with or without secondary SCI as a cause of sudden death in Thoroughbred and Quarter Horse racehorses.[143,175,176] Injury to the vertebral column can occur at all sites, but trauma to or fractures of the cervical vertebrae are the most common.[141,142] Foals appear to be more susceptible to vertebral trauma than adults and frequently suffer injury to the cranial cervical (C1–C3) and caudal thoracic (T15–T18) regions.[148] In fact, fracture of the axial dens with atlantoaxial subluxation is most commonly seen in foals less than 6 months of age and involves disruption of the physis of the dens and separation of the odontoid process.[177] Vertebral fracture with subsequent SCI, not as a result of trauma but secondary to osteomyelitis, has been reported in a foal.[178] Predilection sites for vertebral trauma in adult horses are the occipital-atlantoaxial region, the caudal cervical region (C5–T1), and the caudal thoracic region. Reports also exist of injuries at the lumbosacral[143,175,176] and coccygeal[179] regions.

Typically, the more severe the insult is, the more damage occurs to the vertebral column (and the more severe clinical signs are due to soft tissue damage and osseous fragments compressing the spinal cord; Table 11.8). With very severe injury, soft tissue structures supporting the vertebral column may be disrupted, resulting in dislocation of vertebrae. Both subluxation and luxation of vertebrae have been reported in horses.[180] An increased incidence of luxations, subluxations, and epiphyseal separations is seen in young horses, which is likely because cervical vertebral growth plate closure does not occur until 4 to 5 years of age. Compression injuries are

TABLE **11.8 Common Types of Vertebral Trauma**

Level of Injury	Age	Type of Vertebral Trauma	Common Traumatic Injury	Syndrome
Cervical	Foal to yearling	Fracture of dens, luxation C1–C2	Hyperflexion (e.g., somersault)	Tetraparesis, respiratory depression, death
Cervical	Young adult	Epiphyseal fracture	Hyperextension	Tetraparesis to tetraplegia
Cervical	Adult	Compression fracture	Head-on collision	Tetraparesis to tetraplegia
Cranial thoracic	Usually young	Fracture of dorsal spinous process	Flipping over backward	Often none
T2–S1	Any	Transverse fracture of vertebral arch, with dislocation	Somersaulting or falls	Paraparesis
Sacroiliac subluxation	Adult	Subluxation	Falls or slipping on ice	None
Sacral fracture	Any	Compression	Fall over backward or dog sitting when backed	Urinary and fecal incontinence with or without posterior paresis, paralysis of the tail and anus

associated with shortening of the vertebral body and result from a head-on collision with an immovable object.

SCI secondary to trauma is a dynamic process of which the severity is related to the velocity, degree, and duration of the impact. Cord concussion with transient neurologic deficits is a result of local axonal depolarization and transient dysfunction, whereas permanent paralysis is a result of primary tissue injury followed by spreading of secondary damage that expands from the injury epicenter.

Primary injury is the initial mechanical damage to the components of the spinal cord that follows acute insult. Blood vessels are broken, axons are disrupted, and neuron and glial cell membranes are damaged. Ensuing pathophysiologic processes involving ischemia, release of chemicals from injured cells, and electrolyte shifts alter the metabolic milieu at the level of the lesion and trigger a secondary injury cascade that substantially compounds initial mechanical damage. These secondary injury processes do not necessarily coincide with the clinical picture, because pathologic changes may progress in severity for weeks to months, even in the face of clinical improvement.

Secondary injury involves both necrotic and programmed cell death, and although mechanisms involved in this are not fully understood, some aspects of this process are well described. Disruption of cellular and subcellular membranes of glia, neurons, and vascular endothelial cells is believed to be the initiator of this autodestructive cascade of events, and it is likely that multiple mechanisms are involved such as ischemia, inflammation, free radical–induced cell death, excitotoxicity, cytoskeletal degradation, and induction of apoptotic pathways. The consequence of secondary injury is enlargement of the area of cell death. The phase of secondary injury is widely studied because this process progresses from minutes to months after injury and is thus considered to be a target for therapeutic interventions. Minimizing secondary injury through protection of neural elements that initially survived the mechanical injury would increase the quantity of spared tissue and could lead to reduced functional impairment.

Acute injury results in immediate hemorrhage and cell destruction within the central gray matter. Loss of microcirculation and cord swelling within minutes of injury occur mainly because of hemorrhage and development of edema. The initial hemorrhage, edema, and hypoperfusion of the gray matter extend centripetally within minutes to hours of injury and result in central necrosis, white matter edema, and, eventually, demyelination of axons through secondary injury processes. Spinal cord ischemia develops over several hours after injury and is considered one of the most important contributors to secondary injury.[181,182] Mechanical disruption of the microvasculature, vasospasm of intact vessels, and edema together lead to profound local hypoperfusion and ischemia. Cord swelling that exceeds venous blood pressure results in secondary ischemia, and ischemia is further exacerbated by cessation of autoregulation of spinal cord blood flow and systemic hypotension.

During the ischemic hypoxic state, cell metabolism is altered such that a shift occurs from aerobic to anaerobic metabolism, which is a less efficient method of energy production. Anaerobic metabolism results in lactic acid accumulation, causing acidosis in nervous tissue, thus decreasing glucose and oxygen consumption. Furthermore, lactic acid stimulates prostaglandin production, adenosine diphosphate release, platelet aggregation, thromboxane A_2 release, vasospasm, vasoconstriction, and the inhibition of neurotransmitter release. In addition, in hypoxic states, the sodium-potassium ATPase-dependent cell pump is inhibited or damaged, resulting in the cell's inability to maintain its electric polarity. Damage to this pump allows for accumulation of potassium extracellularly and sodium intracellularly, which contributes to the development of edema.[183]

Free radicals can cause progressive oxidation of fatty acids in cellular membranes (lipid peroxidation) through reactions with their unpaired electrons. Furthermore, oxidative stress can disable key mitochondrial respiratory chain enzymes, alter DNA/RNA and their associated proteins, and inhibit sodium-potassium ATPase. These changes can induce metabolic collapse and necrotic or apoptotic cell death and are considered important during the initial period of hypoperfusion (and perhaps even more important during the period of reperfusion). In addition to oxidative stress and membrane damage, nitric oxide production and excitatory amino acid–induced calcium entry are considered important mediators of necrotic and apoptotic cell death.[184] Apoptosis, or programmed cell death, is a slowly spreading form of cell death induced by the injury. It is characterized by apoptotic neurons at the lesion margins and, even later, apoptosis of oligodendrocytes in areas with degenerating axons that were injured at the original lesion site.[184,185] Apoptosis can thus occur at quite remote distances from the point of impact. Oligodendrocytes appear vulnerable to apoptosis, and death of these cells can result in demyelination of otherwise spared axons, thus contributing to the loss of distal neurologic function.

Excitotoxicity refers to the deleterious cellular effects of excess glutamate and aspartate stimulation of ionotropic and metabotropic receptors. Extracellular concentrations of both of these excitatory amino acids are increased after acute SCI, which occurs through release from damaged neurons, decreased uptake by damaged astrocytes, and through depolarization-induced release. Ionotropic receptors include the NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainite receptors through which extracellular calcium and sodium can pass down a massive concentration gradient into the cell or, when activated, can result in release of calcium from intracellular stores. Metabotropic glutamate receptors are coupled to G proteins that act as secondary intracellular messengers to mediate a wide spectrum of cellular functions. Furthermore, elevation of intracellular calcium concentration can occur through direct membrane damage and voltage-gated calcium channels triggered by membrane depolarization. Elevated intracellular calcium concentrations can trigger a multitude of calcium-dependent processes that can lethally alter cellular metabolism, such as activation of lytic enzymes (calpains, phospholipase A_2, proteases, and lipoxygenase), generation of free radicals, impairment of mitochondrial function, spasm of vascular smooth muscle, and binding of phosphates with subsequent depletion of cell energy sources. Sodium dysregulation is thought to be important in the pathophysiology of damage to axonal and glial components in the white matter through similar mechanisms that lead to elevated intracellular calcium concentrations.

Controversy exists surrounding the role of inflammation in acute SCI, mainly because the effects of inflammatory cells can be both cytotoxic and protective. After SCI, the injury site is rapidly infiltrated by blood-borne neutrophils, which can secrete lytic enzymes and cytokines. Later, blood-borne macrophages and monocytes are recruited, as well as locally activated resident microglia, both of which subsequently invade to

phagocytize the injured tissue. These and other reactive cells produce cytokines, such as tumor necrosis factor–α (TNF-α), interleukins (ILs), and interferons, that mediate the inflammatory response and can further damage local tissue and recruit other inflammatory cells. Among the cytokines involved in secondary SCI, TNF-α is perhaps the most extensively studied. It is produced by a range of different cell populations, including neutrophils, macrophages and microglia, astrocytes, and T cells and has been shown to accumulate quickly at the site of SCI. It has been suggested that the early inflammatory phases are deleterious in nature, whereas the later inflammatory events appear to be protective.[182]

Neurologic Evaluation

Clinical signs seen as a result of SCI reflect the extent and location of the injury. Neurologic signs are usually observed immediately after the accident but may occur weeks to months after the initial insult because of delayed damage to the spinal cord caused by instability, arthritis, or bony callus formation at the site of impact. Clinical signs depend on the neuroanatomic location of injury and range between inapparent to severe incapacitating tetraparesis or tetraplegia (see Fig. 11.24). Lesions causing recumbency are mostly found in the caudal cervical or thoracic spinal cord, whereas lesions of nonrecumbent horses are mostly found farther cranial in the cervical spinal cord or in the lumbosacral cord.[142]

Initial evaluation of the patient should be directed toward stabilization and correction of any life-threatening problems such as airway obstruction, hemorrhage, cardiovascular collapse, and pneumothorax. In addition, major long-bone fractures must be identified, because these may be the limiting factor for survival of the horse. All affected horses may be nervous or agitated as a result of pain and the inability to stand. A systematic neurologic evaluation should then be performed to localize the site of injury.[3] In recumbent horses the use of a sling to assist standing may be a valuable diagnostic tool for localizing the site of injury and for assessing progression of disease and prognosis.[9]

In animals, SCI usually occurs as a solitary lesion and the level of the lesion can be diagnosed by neurologic examination.[186] Depression or loss of a segmental spinal reflex implies damage to either the afferent, efferent, or connecting pathways of the reflex arc. However, after acute SCI a phase of spinal shock can occur in which profound depression is noted in segmental spinal reflexes caudal to the level of the lesion, even though reflex arcs are physically intact. Spinal shock occurs in all species; however, it appears to be of much shorter duration in dogs, cats, and rabbits compared with primates.[1,186] Another syndrome that occurs infrequently and is short-lived in the horse is Schiff-Sherrington syndrome, in which extensor hypertonus is present in otherwise normal thoracic limbs in patients with severe cranial thoracic lesions.[1]

Cord injury typically results in damage that is worse in the large myelinated motor and proprioceptive fibers compared with the smaller or nonmyelinated nociceptive fibers. Therefore ataxia and loss of proprioception and motor function will occur before the loss of deep pain. Flaccid paralysis with hyporeflexia or areflexia, muscular hypotonia, and neurogenic muscle atrophy are characteristic of a lower motor neuron lesion. Signs resulting from an upper motor neuron spinal cord lesion include loss of voluntary motor function, whereas muscle tone may be increased and spinal reflexes may be normal to hyperactive.

In horses, lesions in the C1 to T2 region are most common and result in varying degrees of dysfunction ranging from tetraparesis to recumbency. Thoracolumbar SCI can result in paraparesis to recumbency, and horses may dog sit. Sacral cord damage can result in fecal and urinary incontinence, loss of use of tail and anus, muscle atrophy, and mild deficits of pelvic limb function. Sacrococcygeal cord injury can produce hypalgesia; hypotonia and hyporeflexia of the perineum, tail, and anus; or total analgesia and paralysis of those structures. In addition to these clinical signs, loss of sensation can occur distal to the level of SCI. Furthermore, diffuse sweating can be seen as a result of loss of supraspinal input to the preganglionic cell bodies of the sympathetic system in the thoracolumbar intermediate gray matter. Patchy sweating can be seen with damage to specific preganglionic or postganglionic nerve fibers.

Ancillary diagnostics that may aid in diagnosing or localizing SCI include radiography, myelography, CT, MRI, nuclear scintigraphy, CSF analysis, nerve conduction velocities, EMG, and transcranial magnetic stimulation. Radiography may demonstrate fractures, luxations, subluxations, and vertebral compression. As presented previously, CT and radiography are the diagnostic aids of choice to evaluate skeletal injury, whereas MRI is more sensitive for evaluation of soft tissue structures such as the spinal cord and ligaments. With respect to imaging the vertebral column with computed tomography and MRI devices, however, the size of the horse, the size of the equipment aperture, and the cost of the equipment aperture limit its use to investigations of the cervical and cranial thoracic spinal cord. Myelography may be required to confirm spinal cord compression and can be used at the level of the cervical, cranial thoracic, and sacral-coccygeal spinal cord. Nuclear scintigraphy can be useful in diagnosing nondisplaced or occult fractures and soft tissue lesions. Common CSF abnormalities after SCI include xanthochromia and mild to moderate increased total protein concentrations. CSF analysis may be normal, especially in very acute or chronic cases. NCV and EMG studies evaluate the lower motor neuron and aid in lesion localization. Electromyographic changes, however, may not develop until 1 to 4 weeks after nerve damage. Transcranial magnetic stimulation allows detection of functional lesions in descending motor tracts through recording of magnetic motor-evoked potentials. This method has been validated and used to distinguish motor tract disorders from other causes of recumbency in clinical cases.[160]

Treatment and Prognosis

Spinal cord injury is currently incurable, and treatment is limited to minimizing secondary complications and maximizing residual function by rehabilitation. It is the assortment of pathophysiologic processes that occur during the period of secondary injury that are considered the target for pharmaceutical intervention. The first 48 hours after acute SCI are dominated by the vascular and biochemical changes that occur within the spinal cord. Then follows a period characterized by the effects of inflammatory cells that occurs within hours of injury, peaking around 4 days after injury. Last there is a period that starts approximately 1 week after injury and is characterized by axonal regeneration and lesion repair. The goals of treatment are to stop the cascade of cellular events initiated by the traumatic insult, to protect spared neural tissue, and to promote regeneration. Studies of spinal cord repair can be categorized by clinical target and have been reviewed

elsewhere.[183,187] Rescue therapies encompass early interventions that prevent the spread of damage beyond the initial site of injury. Examples include surgical decompression, cooling or hypothermia, and interventions targeting a specific biologic event such as inflammation. Reactivate therapies refer to how spared systems, which are nearly always present in clinical SCI, can be exploited through rehabilitation, pharmacologic or electrical stimulation of spinal networks, or remyelination of denuded axons. Rewiring interventions encompass treatments aimed at regrowth of injured axons or repurposing of spared ones, with strategies aimed at increasing the intrinsic growth capacity of injured neurons or reducing inhibitors of axon growth.

Surgical intervention is warranted when the need exists for stabilization or fracture repair, as well as when a compressive lesion is evident; however, this is uncommonly done in equine medicine.[177] Conservative management is often effective, but there may be advantages of performing stabilization surgery before clinical signs deteriorate.[188] Furthermore, it is possible that future neurologic disease progression occurs as a result of a "domino effect" involving the vertebral bodies cranial and/or caudal to an (incomplete) fused articulation.[189] This process may take months to years to occur. The use of medical treatment to stabilize the patient should always be instituted before surgery is performed.

Acute SCI often results in impaired cardiopulmonary function such as impaired ventilation, bradycardia, and hypotension. This is particularly the case in lesions cranial to C5 (respiratory center affected) and cranial to T2 (origin of sympathetic outflow = thoracolumbar spinal cord). Systemic hypotension may exacerbate spinal cord hypoperfusion and ischemia, and maintaining systemic blood pressure has been shown to improve spinal cord perfusion. Volume resuscitation is clearly indicated in shock and for restitution of tissue perfusion. The current recommendation is to maintain euvolemic normotension; because of sympathetic outflow disruption after cranial SCI, pressor therapy is commonly indicated in the treatment regimen. Maintaining normal mean arterial blood pressure is also important to consider during stabilization of the acutely injured horse, and it is particularly important when horses are placed under general anesthesia for various diagnostic and therapeutic procedures.

Similar to TBI, SCI has a complex multifactorial pathophysiology and likely requires a combinational treatment intervention for successful outcome. Many agents, which could target different aspects of the secondary injury mechanisms, have been investigated for use in SCI and have been reviewed.[187] After the initial trauma of SCI, cell death and tissue loss continue for several weeks, a period during which one could intervene with neuroprotective strategies. Historically, three approaches have been taken to restrict secondary damage: surgical decompression, therapeutic hypothermia, and drugs targeting inflammation or excitotoxicity.[187] Methylprednisolone sodium succinate (MPSS) offers little benefit and might actually have detrimental effects, but although it has been formally denounced as a standard of care for human SCI in most countries, the drug is still used in some clinical practices. In horses, corticosteroids, alone or in combination with other drugs, are likely the most commonly used drugs for acute CNS trauma. Reported dosages of dexamethasone for horses range from 0.1 to 0.25 mg/kg intravenously every 6 to 24 hours for 24 to 48 hours. A favorable response is expected within 4 to 8 hours after administration. Horses on corticosteroid therapy should be monitored closely for the development of laminitis or *Aspergillus* spp. pneumonia. If improvement in clinical signs is observed, the horse may be placed on oral prednisolone therapy (0.5–1.0 mg/kg tapered over 3–5 days) to decrease the chance of laminitis. The neuroprotective effect of corticosteroids is thought primarily to be mediated by free radical scavenging but may include decreased catecholamines and glutamate, as well as decreased apoptosis-related cell death.[190] Other potential beneficial effects of corticosteroids include reduction in the spread of morphologic damage, prevention of the loss of axonal conduction and reflex activity, preservation of vascular membrane integrity, and stabilization of white matter neuronal cell membranes in the presence of central hemorrhagic lesions.[183] Furthermore, their antiinflammatory properties may be useful in reducing edema and fibrin deposition, as well as their ability to reverse sodium and potassium imbalance because of edema and necrosis. Another beneficial effect of corticosteroids is maintenance of normal blood glucose concentrations while maintaining electrolyte balance.[183]

Promising studies that target rescue investigate (1) the macrophage response after SCI; (2) peroxisome proliferator-activated receptors, which are a family of ligand-activated transcription factors that regulate many aspects of neuroinflammation; (3) GM6001, a broad-spectrum matrix metalloprotease inhibitor; and (4) riluzole, a sodium channel blocker and glutamate antagonist. As mentioned for TBI, the use of NSAIDs such as flunixin meglumine and phenylbutazone may decrease the inflammation in horses associated with a traumatic episode. In addition, there is likely a benefit to maintaining a normal rectal temperature. These compounds work by inhibiting cyclooxygenase, which converts arachidonic acid to inflammatory mediators (endoperoxides). In addition, the potential beneficial properties of DMSO, 1 g/kg intravenously as a 10% solution for 3 consecutive days followed by three treatments every other day, likely warrant inclusion of this drug in the treatment of CNS trauma.[147] Reported benefits of DMSO include increased brain and spinal cord blood flow, decreased brain and spinal cord edema, increased vasodilating prostaglandin E_1 (PGE_1), decreased platelet aggregation, decreased prostaglandin E_2 (PGE_2) and prostaglandin F_2 (PGF_2), protection of cell membranes, and trapping of hydroxyl radicals.[183] The exact mechanism of DMSO remains unknown, and this treatment remains controversial because some researchers have found no positive effects on neurologic outcome from the use of DMSO. Although the free radical scavengers vitamin E and selenium have been shown to be beneficial in SCI, these antioxidants do not appear useful in the acute management because of the length of time required to achieve therapeutic concentrations in the CNS.

Similar as is stated for TBI, antibiotics are not always necessary in the treatment of vertebral or spinal cord trauma; however, they are indicated in treating open fractures and secondary complications associated with a recumbent horse, such as pneumonia and decubital sores.

Physical therapy is important in the rehabilitative process in spine-injured horses. The field of equine rehabilitation is growing rapidly, and novel techniques and ideas have recently been reviewed.[191-194] Controlled exercise allows the unaffected parts of the nervous system to compensate for the affected parts by increasing strength and conscious proprioception. Exercise is especially helpful in improving weakness, ataxia, spasticity, and hypermetria. In recumbent horses, massage,

therapeutic ultrasound, and hydrotherapy of affected muscle groups for 10 to 15 minutes at least twice a day are important. These measures help combat necrosis and muscle atrophy of the horse's dependent muscle groups. Passive flexion and extension of all limbs are helpful in maintaining full range of motion in recumbent horses. Furthermore, experimental studies have shown that exercise enhances functional recovery after SCI.[195]

Prognosis is based on response to therapy and is directly related to the time from injury to the institution of treatment. Horses that show rapid neurologic improvement have a fair to good prognosis. Recumbent horses or horses suffering from fractures or luxations have a guarded to poor prognosis. Horses that have lost deep pain sensation have a functional or anatomic spinal cord transection and have a grave prognosis. The longer the time from loss of deep pain to treatment, the poorer the prognosis. Partial or complete recovery of horses with spinal cord trauma may take weeks to months, so time and nursing care are required.

VESTIBULAR DISEASE

Monica Aleman

The vestibular system is a special proprioceptive system responsible for maintenance of balance and reflex orientation to gravitational forces. This system functions to maintain appropriate eye, head, trunk, and limb position during rest and movement.[1,4,196]

Vestibular System

The vestibular pathway, from neural receptor to cerebral cortex and tracts in the spinal cord, is comprised of peripheral and central components.[196] The peripheral part of the vestibular system is housed in the petrous part of the temporal bone. Neuron 1 (first-order neuron) is located in the vestibular ganglion, which receives impulses from five sites: the crista of the ampulla of each of three semicircular canals, and the macula of the utricle and macula of the saccule. The cristae record movement of the head, and the maculae record position of the head. Movement and gravity act on neuroepithelial cells that transform physical forces into electrical impulses. The axon of neuron 1 projects into the vestibular nuclei of the same side. Neuron 2 is located in the vestibular nuclei, which lie near the cochlear nuclei in the medulla oblongata. Some of the axons from these neurons ascend on the same side, and others decussate. Their axons project to one of multiple areas[196]:

1. Cerebral cortex:
   a. Axons of the medial geniculate nucleus (neuron 3) within the medial geniculate body project to the cerebral cortex.
2. Brainstem:
   a. Motor nuclei of cranial nerves III, IV, and VI—influencing eye movement (nystagmus) when the head moves. This normal movement is called physiologic nystagmus or vestibular-ocular nystagmus.
   b. Ascending and descending reticular formation (involved in cardiovascular and vomiting reactions [people] with vestibular disturbances)
3. Cerebellum:
   a. Flocculonodular lobe of cerebellum (when altered: paradoxic vestibular disease)
4. Spinal cord:
   a. Lateral vestibulospinal tract
   b. Medial vestibulospinal tract

A more detailed explanation follows. Axons from the medial vestibular nucleus project through the medial longitudinal fasciculus. Vestibular signals travel through to the contralateral medial geniculate nuclei of the thalamus to the cerebral cortex. In addition to proprioceptive information from other parts of the body, the cerebral cortex facilitates conscious perception of orientation.[1]

The ascending portions of the medial longitudinal fasciculus course to the motor nuclei of the third, fourth, and sixth cranial nerves (oculomotor, trochlear, and abducens).[1,4,196] These fibers coordinate conjugate eye movement with changes in head position. This pathway, along with cerebellar input, controls physiologic (vestibular) nystagmus.[1,196] Nystagmus is characterized by involuntary, conjugate, rhythmic eyeball oscillations with a fast and slow phase. The direction of nystagmus is defined by the direction of the fast phase and is induced by movements of the head. Rapid dorsiflexion of the neck results in vertical nystagmus, whereas side-to-side movement of the head induces horizontal nystagmus. Turning the head to the left results in a horizontal nystagmus with the fast phase to the left. The accompanying slow phase is in a direction opposite to body motion and allows the eyes to fix on a stationary image. The fast phase is initiated when the eyeball reaches the lateral limit of ocular movement and allows the eyeballs to jump forward and focus on a new image.[1] The slow phase is controlled by vestibular input, and the fast phase is a function of the brainstem.[1] Physiologic nystagmus induced by rapid manipulation of the head is called the *oculocephalic reflex*. This reflex occurs independent of vision.[1,196] Descending portions of the medial longitudinal fasciculus travel in the ventral funiculus of the cervical and cranial thoracic spinal cord segments and control the position and activity of the limbs and trunk in coordination with head position.[1,196]

Fibers from the vestibular nuclei that project to the reticular formation provide afferent nerves to the vomit center, which is the pathway for the development of motion sickness. Reticulospinal tracts also aid in the maintenance of extensor tone to support the body against gravity.[1,196]

Vestibular impulses enter the cerebellum via the caudal cerebellar peduncles. Fibers of the vestibulocerebellar tracts terminate primarily in the flocculonodular lobe and fastigial nucleus.[1,196] The cerebellum functions to coordinate protagonistic, antagonistic, and synergistic muscle groups for controlled responses to gravity. The vestibular apparatus provides information to the cerebellum, dictating the relative degree of contraction necessary to maintain equilibrium.[1,196]

The vestibulospinal tract courses in the ipsilateral ventral funiculus and terminates in interneurons of the ventral gray column. Stimulation of the vestibulospinal tract is facilitatory to α- and γ-motor neurons of the ipsilateral extensor muscles, inhibitory to the α-motor neurons of the ipsilateral flexor muscles, and inhibitory to contralateral extensor muscles.[1,196] The net result is ipsilateral extensor tonus and contralateral flexor tonus that act as an adaptive mechanism against gravity by catching the body and preventing a fall in the direction of vestibular stimulation.[196]

The vestibular system is capable only of detecting movement and orientation of the head in relationship to the rest of the body. Afferent pathways from the neck allow the head

to be cognizant of the orientation of the rest of the body.[1,196] Exteroceptor receptors of the skin and proprioceptive receptors in other joints also are integrated in the cerebellum and reticular formation to aid in the maintenance of equilibrium. These signals allow the vestibular system to know if the body remains in an appropriate position with respect to gravity while the head is bent. Visual images can help to maintain balance by visual detection of the upright stance. In addition, slight linear or angular movement of the head shifts the image on the retina, which relays directional information to equilibrium centers. Visual compensation might be capable of maintaining balance in the face of vestibular dysfunction, if the eyes are open and motions are performed slowly.[196]

The seventh cranial nerve (the facial nerve) emerges from the lateral medulla ventral to the vestibulocochlear nerve at the level of the trapezoid body. The two nerves are associated closely with the petrous temporal bone and enter the internal auditory meatus together.[1,196-198] Within the internal auditory meatus, the facial nerve separates from the vestibular nerve and courses through the facial canal of the petrosal bone.[1,196-198] The facial nerve exits the cranium from the stylomastoid foramen located immediately caudal to the external auditory meatus. Because of the proximity of the facial and vestibular nerves, a single disease process commonly affects both nerves simultaneously.[197,199]

Sympathetic innervation to the eye also is associated anatomically with the petrous temporal bone. Damage to this nerve (Horner syndrome), along with vestibular and facial nerve deficits, frequently occurs with petrous temporal bone trauma and otitis media in small animals.[4] The association of Horner syndrome, facial nerve paralysis, and vestibular disease rarely is documented in the horse.[1]

Clinical Signs of Vestibular Dysfunction

Knowledge of the anatomy and function of structures related to the peripheral and central vestibular system aids in neuroanatomic localization of the lesion.[1] Differentiation of central versus peripheral vestibular disease is important for establishing a list of differential diagnoses, initiating therapy, and formulating a prognosis. A thorough physical and neurologic examination is essential. Historical information, including duration of condition, rate of onset, and disease progression, also may aid in differentiation of central from peripheral vestibular disease.

Signs of acute peripheral vestibular system dysfunction include head tilt (Fig. 11.27), nystagmus, falling, circling, reluctance to move, and asymmetric ataxia with preservation of strength. Horses affected with peracute vestibular disease are often violent because of disorientation.[4] Head tilt is a consistent sign of vestibular disease and is characterized by ventral deviation of the poll of the head toward the affected side (Fig. 11.28).[1,4,197,199,200] The horse prefers to lie on the side of the lesion and might lean on the wall toward the affected side when standing. When forced to move, the horse takes short, uncoordinated steps in a circle toward the direction of the lesion. The body may be flexed laterally with a concavity toward the lesion.[198,201] Extensor hypotonia ipsilateral to the lesion and mild hypertonia and hyperreflexia of the extensor muscles of the contralateral side result in asymmetric ataxia.[200] Extensor hypotonia occurs from loss of facilitatory neurons of the vestibulospinal tract to ipsilateral extensor muscles.

FIG. **11.27** Horse with peripheral vestibular disease. Note head tilt and turn to the left; horse is bright and alert.

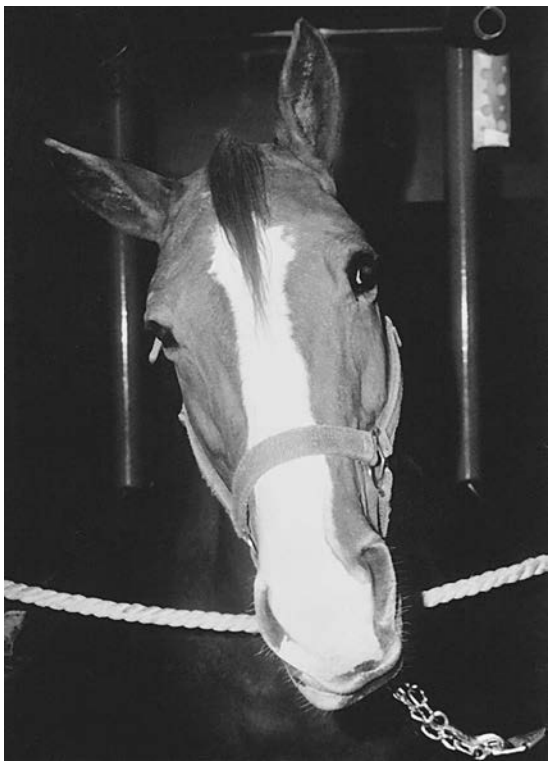

FIG. **11.28** Thoroughbred with right-sided peripheral vestibular disease caused by a temporohyoid osteoarthropathy (THO) and acute fracture. The head tilt, dropped pinna, and eyelid droop occur on the affected side, whereas the muzzle is pulled toward the contralateral side.

Contralateral extensor hypertonia occurs from loss of inhibitory neurons and unopposed extensor tone of the contralateral vestibulospinal tract.[1] Central vestibular disease has similar clinical signs, but proprioceptive deficits are a distinguishing sign from peripheral vestibular disease. Other signs of central vestibular disease include involvement of other cranial nerves, alterations in mentation, cerebellar disease, and dysconjugate and/or positional nystagmus.[1,202] The presence of vertical nystagmus is only observed with central vestibular disease.[1]

Pathologic nystagmus, rhythmic oscillations of the eyes occurring while the head is in a normal position, is involuntary and indicates a lesion in the vestibular system or cerebellum.[202] As in physiologic nystagmus, one can identify a fast and a slow phase. The direction of nystagmus is defined by the direction of the fast phase.[1,198,203] Pathologic nystagmus might be spontaneous, occurring with the head in the resting position, or positional, which is induced by elevation or lateral flexion of the head.[1] Nystagmus usually appears with the onset of other peripheral vestibular signs but might last only 2 to 3 days because of central compensation.[200] Concomitant blinking of the eyelid might hinder detection of nystagmus.[1]

Peripheral vestibular dysfunction might result in horizontal or rotary nystagmus. The fast phase of nystagmus is directed away from the lesion and does not change with changing head position.[1,201] The direction of rotary nystagmus is defined by the direction the limbus moves from the 12 o'clock position during the fast phase.[1] Horizontal, rotary, or vertical nystagmus can result from a central vestibular lesion. In addition, the type of nystagmus observed might change with changing head position in a patient with central vestibular disease.[4,198] In central vestibular disease, the fast phase is away from the lesion except in cerebellar-vestibular disease (paradoxic vestibular disease).[4,204]

In the healthy animal a constant stream of electric stimulation arises in each vestibular end organ and transmits signals that control ocular position via the medial longitudinal fasciculus. These signals normally drive the eyes toward the opposite direction. The eyes are maintained centrally, however, because vestibuloocular pathways are opposed in an equal and opposite manner. Unilateral vestibular disease upsets this balance, resulting in slow deviation of both eyes toward the lesion. Individuals that are blind at birth or have been blind for an extended time might exhibit irregular eyeball oscillation with no slow or fast component.[1] Loss of hearing is a common finding with peripheral vestibular disease because of the proximity of the cochlea to the vestibular receptor organs.[60-62,205]

Signs of vestibular disease along with obtundation and proprioceptive deficits are signs of central vestibular disease (Fig. 11.29).[1] With a central lesion, abnormal proprioception occurs because of damage within the brainstem of the descending upper motor neuron tracts to the limbs.[4] Damage to the spinocerebellar tracts or caudal cerebellar peduncles results in abnormal unconscious proprioception and hypermetria.[4] The nuclei of the trigeminal (fifth cranial nerve) and the abducens nerves (sixth cranial nerve) are in anatomic proximity to the vestibular nuclei and are damaged readily in a common disease process. Trigeminal nerve paralysis creates a loss of sensation to the head and atrophy of the muscles of mastication. Trochlear nerve damage results in medial strabismus.[197]

Destructive space-occupying lesions in the cerebellopontine angle or flocculonodular lobe may result in paradoxic central vestibular disease.[1,4,202] This syndrome is manifested by ataxia, head tilt contralateral to the side, and postural reaction deficits.[1,4,202]

FIG. **11.29** Horse with central vestibular disease. Note mild head tilt and turn to the right; horse is obtunded.

Central or peripheral vestibular disease might produce strabismus. One observes ventrolateral strabismus ipsilateral to the vestibular lesion with elevation of the head and extension of the neck.[1,4,202] One observes mild ventral deviation of the eyes in normal horses when the head is elevated, but the finding is symmetric. Ventrolateral strabismus of vestibular disease is not a sign of a cranial nerve deficit of the extraocular muscles[1] but is a reflection of abnormal upper motor neuron influences on the oculomotor nucleus from the ipsilateral vestibular nucleus via the medial longitudinal fasciculus. If the strabismus is purely vestibular in origin, normal ocular mobility is visible with manipulation of the head.[197]

Signs of vestibular disease might improve rapidly 2 to 3 weeks after onset because of visual and central accommodation.[1,197] Central vestibular lesions are slower to compensate than peripheral vestibular lesions; signs might even progress if the central lesion is an expanding space-occupying mass. Blindfolding a horse with compensated disease results in ataxia and a head tilt (Romberg's test). Blindfolding eliminates visual and limb proprioceptive orientation; the body is forced to rely on the impaired vestibular system for equilibrium.[1,197,199] This test is unreliable for localizing the side of the lesion.[196] Horses might decompensate dramatically when the blindfold is placed over the eyes, resulting in anxiety, disorientation, and falling.[1] One should perform the test with caution on a padded surface with good footing.

Horses affected with bilateral peripheral disease demonstrate no head tilt, circling, or pathologic nystagmus, and one cannot induce physiologic nystagmus by rapid manipulation of the head (the oculocephalic reflex) or by caloric testing. The head might sway with wide excursions from side to side.[203] As with all peripheral vestibular disease, strength is preserved.[1] Clinically, horses affected with bilateral vestibular disease exhibit more symmetric ataxia similar to generalized cerebellar disease.[4]

Facial nerve (seventh cranial nerve) paralysis frequently occurs concurrently with peripheral vestibular disease because of its proximity to the vestibular nerve within the petrous temporal bone. Facial nerve paralysis worsens the long-term prognosis and complicates the management of vestibular disease

patients. The facial nerve innervates the muscles of facial expression, and damage to this nerve results in muzzle deviation away from the affected side, lack of menace and palpebral response, ear droop, decreased nostril flare impeding air flow, and buccal impaction of feed.[197,198] Keratitis and corneal ulceration are common because of the inability to blink and decreased tear production.[62,198] Decreased tear production results from damage to parasympathetic fibers to the lacrimal gland. Preganglionic fibers travel with the facial nerve through the internal auditory meatus and separate in the facial canal proximal to the geniculate nucleus.[198] The fibers split from the facial nerve to join the superior petrosal nerve, which carries fibers to the sphenopalatine ganglion. Postganglionic fibers join the sympathetic fibers to the eye and travel with the vasculature to the lacrimal gland.[1,198] Corneal ulcerations occur in the inferior portion of the cornea and are slow to heal because of ongoing exposure.[62,197] Lack of tear production aids in localization of the lesion, indicating the damage is within the petrous temporal bone, proximal to the geniculate nucleus.[1,62,198] Clinical signs of facial nerve paralysis might not appear for several days after the onset of vestibular disease, because damage to the nerve might result from hematoma, callus, or an extension of inflammation and secondary neuritis.[203] Because of the proximity of the nuclei of the facial and vestibular nerves, extensive lesions of the medulla might involve both nerves. If no improvement of facial nerve deficits occurs within 3 to 4 months after the onset of disease, the prognosis is poor for recovery. If one notes even mild improvement in the first 4 months, facial nerve function might return.[203] Horses might learn to retract the globe, allowing the eyelid and nictitating membrane to slide across the surface of the cornea, distributing lubrication and protecting the eye from trauma.[197] Careful observation is necessary to differentiate this adaptation from improvement of lid function.

Peripheral Vestibular Disease

Acute onset of peripheral vestibular disease and facial nerve paralysis is not a rare occurrence in the horse. Damage to the temporal bone is the most likely anatomic location when these nerves are affected concurrently. THO and traumatic skull fractures are the most common causes of these signs in large animals.[1] THO is the most common cause of peripheral vestibular disease in horses and should be the number one rule out for horses with acute onset of vestibular dysfunction, especially if accompanied by facial nerve palsy.[62,205-207]

Temporohyoid Osteoarthropathy

Temporohyoid osteoarthropathy is one of the most common causes of acute-onset peripheral vestibular disease, facial nerve paralysis, or both in horses.[60,62,205-207] Varying causes for the disorder have been suggested, including extension of inflammation and infection from otitis media-interna[208] or guttural pouch infection, repetitive trauma, and nonseptic osteoarthritis. Much of the older veterinary literature refers to this disorder as *otitis media-interna,* whereas newer references use the designation *THO* because of the uncertaintly concerning underlying cause in most horses. The earlier presumption of underlying otitis media-interna hypothesized that rather than rupturing the tympanic membrane, the inflammatory process might extend ventrally to involve the bones of the tympanic bulla and temporohyoid joint. However, this theory remains speculative, and relatively few horses with THO have evidence of otitis or guttural pouch infection at the time of diagnosis or historically. Some or all cases of THO are quite likely the result of primary degenerative joint disease rather than an extension of a bacterial ear or guttural pouch infection.

Regardless of initial cause, inflammation induces bony proliferation at the articulation of the stylohyoid bone with the petrous temporal bone, resulting in loss of the joint space and fusion of the temporohyoid joint. The hyoid apparatus is attached to the tongue and larynx; fusion of the temporohyoid joint results in impaired flexibility of the unit. A stress fracture of the petrous temporal bone, the stylohyoid bone, or both might result from eating, vocalization, or any activity associated with normal tongue movement.[201,202] Occasionally, fracture and acute onset of severe neurologic signs (collapse and seizure) may be associated with passage of a nasogastric tube or other veterinary procedure.[207] The fracture line may extend into the cranial vault at the level of the internal auditory meatus, resulting in direct neural tissue trauma and hemorrhage into the middle and inner ear.[4,206]

Neurologic signs are rarely apparent during the formation of proliferative osteitis and temporohyoid joint fusion. The onset of neurologic signs corresponds with the occurrence of the stress fracture. Early signs, before fracture, might include headshaking, resistance to the bit, ear rubbing, resentment of manipulation of the head or ears, or pain on pressure at the base of the ear. Occasionally more overt signs of otitis externa or otitis media-interna might be present, including evidence of exudate from the external ear canal. Most horses exhibit acute onset of cranial nerve VII or VIII abnormalities (or both) at the time of fracture. Fractures can tear or stretch the facial or vestibulocochlear nerves as they exit the skull or within the skull, respectively. Some fractures extend into the cranial vault with resultant seizures, bacterial meningitis, or death.[206,207] Vestibular signs can vary between mild head tilt to circling with severe loss of balance and horizontal nystagmus or recumbency. Auditory abnormalities are evident in most affected horses when assessed by brainstem auditory-evoked responses.[60,62,205] If the facial nerve is damaged, ptosis, muzzle deviation away from the side of the lesion, a drooping lower lip and ear on the side of the lesion, and accumulation of feed within the cheek occur. Preganglionic parasympathetic fibers in the facial nerve that innervate the lacrimal gland may also be damaged with resultant keratoconjunctivitis sicca. Many affected horses have corneal ulceration varying from mild to severe. Corneal disease is secondary to decreased tear production and facial nerve dysfunction that diminishes the horse's ability to effectively close the eyelids and spread the tear film across the eye. Rarely, horses may have intermittent acute episodes of vestibular disease with intervening periods of apparent normal neurologic function. Occasionally, the fracture extends to the foramen lacerum, caudal to the petrous temporal bone, where the glossopharyngeal and vagus nerves exit the skull. Trauma to these nerves might result in dysphagia.[197]

A diagnosis of THO may be confirmed by imaging of the stylohyoid bone or petrous temporal bone by endoscopy, radiography, nuclear scintigraphy, CT, or MRI.[207,209] Although most affected horses have acute onset of unilateral neurologic signs, it is not uncommon for imaging to identify bilateral THO and bony proliferation.

CT of the skull followed by endoscopy of the pharynx and guttural pouch are the most sensitive diagnostic tests for THO in horses.[207,209] One should perform this noninvasive procedure on every horse suspected of having proliferative osteitis,

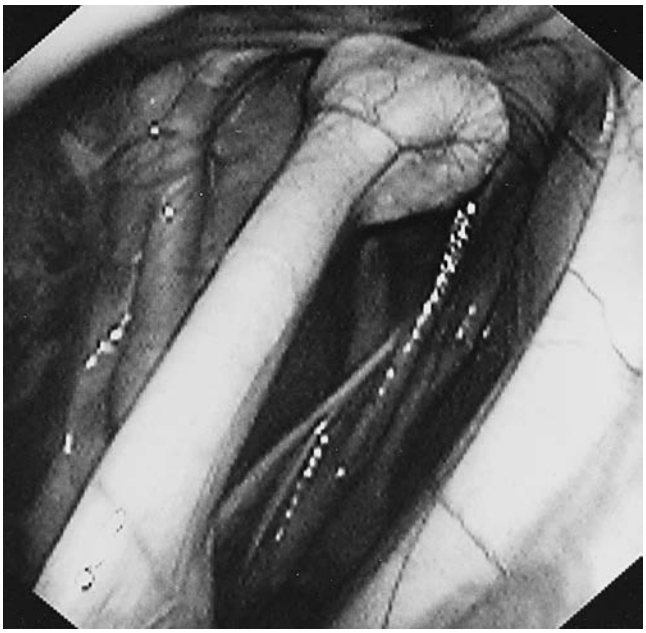

FIG. **11.30** Endoscopic view of the right guttural pouch of a horse with acute onset of right-sided vestibular disease and facial nerve paralysis. Bony proliferation of the proximal stylohyoid bone is consistent with chronic THO.

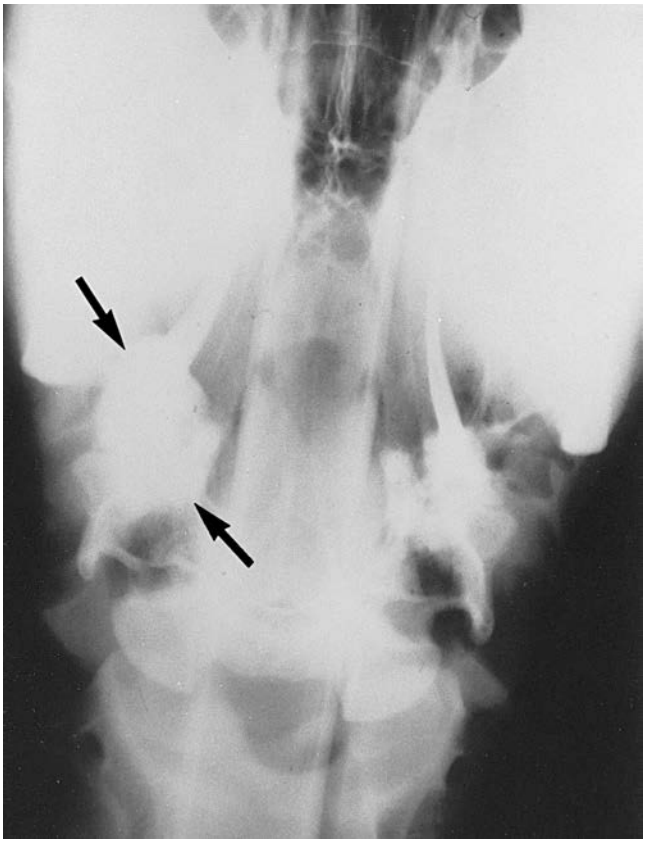

FIG. **11.31** Ventrodorsal skull radiograph demonstrating bony proliferation of the proximal left stylohyoid and petrous temporal bones *(arrows)* associated with THO.

because one often can identify bony proliferation of the proximal stylohyoid bone within the guttural pouch (Fig. 11.30). Many horses also have evidence of hyperemia, bruising, or hematoma formation in the dorsal mucosa of the guttural pouch, near the head of the stylohyoid bone.

Dorsoventral radiographs of the caudal skull should reveal the characteristic periosteal proliferation and sclerosis of the stylohyoid bone and petrous temporal bone (Fig. 11.31). The fracture line is often difficult to identify because of minimal displacement of the fracture fragments. Lateral oblique radiographs obtained at varying angles might aid in localization of a fracture of the basisphenoid, occipital, or petrous temporal bones. Moderate bony proliferation might not occur for several weeks and must be present to diagnose the condition radiographically.[205]

Bone scintigraphy is a noninvasive technique that may allow for an immediate identification of early lesions of the petrous temporal bone. Radiography can identify only structural abnormalities of bone. Bone scintigraphy is capable of detecting dynamic characteristics of bone. Increased metabolic activity and blood supply to the bone, caused by infection or fracture, results in increased uptake of the radiolabeled compound (technetium-99m–labeled phosphate) before radiographic evidence of bony proliferation.[210,211]

When available, CT and MRI are extremely sensitive diagnostic tests for identification of inflammation, bony proliferation, and fracture.[212-214] However, CT and MRI of the skull of horses require general anesthesia. The risks associated with recovery from general anesthesia, when a horse has compromised neurologic function and possible skull fracture, should be considered seriously before recommendation of these procedures.

One might consider analysis of CSF in affected horses. Cytologic evaluation, culture, and sensitivity may help to reveal the presence of secondary bacterial meningitis and can be used to direct the selection of an appropriate antimicrobial treatment plan.[200]

Treatment of horses with acute onset of neurologic dysfunction secondary to THO should focus on four areas:

1. Stabilization of the horse and decreasing inflammation near the fracture site
2. Treatment with broad-spectrum antimicrobials for either extension of a possible otitis interna-media or secondary infection in the hemorrhage that follows the fracture
3. Treatment of exposure keratitis and keratoconjunctivitis sicca
4. Surgical procedures to remove pressure on the temporohyoid articulation to decrease pain and to decrease the likelihood of repeated petrous temporal bone fracture

Medical therapy usually includes antiinflammatory medications as described elsewhere in this text for treatment of acute head trauma. Trimethoprim-sulfonamide antimicrobials for 30 days are often recommended to treat potential bacterial infection. If culture and sensitivity of CSF or other diagnostic sample are available, those results may direct alternative antimicrobial choices. Treatment of corneal ulceration and keratoconjunctivitis sicca is described elsewhere in this text.

Surgical treatment of THO might take the form of either a partial stylohyoid ostectomy or a ceratohyoidectomy.[205-207,215-217] Surgical removal of a 2- to 3-cm segment of the midbody of the stylohyoid bone results in a fibrous nonunion of the stylohyoid bone that should interrupt the transmission of hyoid forces to the temporohyoid joint. Reported

complications include transection of the lingual artery, injury to the hypoglossal or facial nerve, and regrowth of the stylohyoid ostectomy site.[215,216] The goal of ceratohyoidectomy is also to remove mechanical stress on the fused temporohyoid joint, but the surgery is technically easier to accomplish without the risk of many of the more serious complications that may be seen with partial stylohyoidectomy.[216,217]

Diagnosis of THO before the acute onset of neurologic signs is difficult because most horses exhibit few, if any, clinical signs before fracture. Some horses may demonstrate ear rubbing, head tossing or shaking, chomping movements, and sensitivity or pain on palpation at the base of the ear.

Prognosis for life in horses with THO is fair to good if the horse survives the immediate fracture episode.[205,207] However, it might take up to 2 years for maximum neurologic improvement after fracture, and the majority of affected horses have long-term, probably permanent, deficits. Some degree of facial nerve paralysis is common, and persistent or recurrent corneal ulceration may result. However, many horses eventually learn to retract the globe to assist in eyelid closure to spread the tear film across the eye, lessening the severity and frequency of corneal ulceration. Many horses return to some level of athletic function after THO.[207] However, owners of horses with THO should be cautioned regarding the potential for acute onset of severe neurologic signs with no warning as a result of refracture. Therefore affected horses pose a risk to human beings in the environment, and recognition of this risk is important. Surgical treatment may possibly diminish the risk for subsequent fracture[217]; however, currently no long-term follow-up studies of large numbers of affected horses exist to quantify or compare risk with or without surgery.

Head Trauma

Traumatic fractures of the petrous temporal bone result in damage to the vestibular and facial nerves. Profuse aural hemorrhage or loss of CSF from the external ear canal frequently is observed. Bleeding from the nose occurs if the fracture extends to the cribriform plate.[203] Clinical signs usually appear immediately after trauma and include vestibular disease, facial nerve paralysis, recumbency, or coma. Damage to nervous tissue might be caused by hematoma, callus formation, or displacement of fracture fragments resulting in delayed onset of clinical signs. Signs from brainstem contusion or concussion might be more severe than vestibular dysfunction. If blindness is present, the prognosis worsens because of the loss of visual compensation of vestibular disease in the future. If one cannot elicit the oculocephalic reflex (physiologic nystagmus), the examiner should suspect damage to the medial longitudinal fasciculus, indicating extensive brainstem damage; a poor prognosis is indicated.[1] One might recall that bilateral peripheral vestibular disease also results in loss of the oculocephalic reflex; however, this is an unlikely scenario for trauma.

Fractures of the basioccipital and basisphenoid bones occur most frequently in horses that rear over backward and strike the poll of the head. This fracture does not result from referred impact from the poll but is thought to be an avulsion fracture from the pull of the powerful ventral straight muscle of the neck (rectus capitis ventralis) on its insertion on the basioccipital bone.[218] Basioccipital fractures result in neurologic signs associated with damage to the brainstem; signs of vestibular disease are common. Petrous temporal bone fractures are difficult to identify radiographically; tympanosclerosis appears as early as 20 days after trauma and obscures the fracture line.[203] One often can identify basioccipital fractures easily but can confuse them with the suture lines in the base of the skull.[218] Treatment of vestibular signs after head trauma is similar to that of any acute head trauma as described previously in this chapter.

Drug Toxicities

Drug toxicities can result in unilateral or bilateral peripheral vestibular disease and deafness. Degeneration of the hair cells within the peripheral receptor organs of the auditory and vestibular system occurs with prolonged administration of aminoglycoside antibiotics. Severely affected animals also develop neural degeneration. A more common manifestation of aminoglycoside toxicity is renal failure. As renal clearance of the aminoglycoside decreases, the ototoxic effects of the antibiotics are potentiated.[4,199] Clinical signs of vestibular disease appear before deafness. Early vestibular disease may be reversible or centrally compensated, but loss of auditory function is permanent.[1,199] Streptomycin preferentially affects the vestibular system, whereas dihydrostreptomycin, kanamycin, gentamicin, neomycin, and vancomycin are more toxic to the auditory system.[1,202] Vincristine, a vinca alkaloid, can cause bilateral cochlear nerve damage in human beings. Auditory function improves several months after discontinuation of the drug. This antimitotic drug is a common component of multiagent chemotherapy protocols in the treatment of lymphoma in the horse. Vincristine also is used for immunosuppression and stimulation of platelet function in refractory cases of immune-mediated thrombocytopenia. One should carefully monitor auditory function when using this drug.

Sudden loud noises can result in degeneration and necrosis of the sensory hair cells of the inner ear. A lightning strike, although usually fatal, is reported to cause acute onset of unilateral vestibular disease in the horse. Facial nerve paralysis may or may not accompany the vestibular signs. Documentation of histopathologic findings in one case revealed hemorrhage and necrosis of the temporal bone, vestibular nerve, and adjacent tissue. Whether the mechanism of damage is electrocution or noise trauma is unknown.[4]

Central Vestibular Disease

Any inflammatory disease or space-occupying mass of the CNS may damage the vestibular nuclei and related tracts. Clinical signs vary with the type and extent of the disease process. One should suspect a CNS disease if abnormal mentation, seizures, blindness, or multiple cranial nerve abnormalities are seen with general proprioceptive deficits. One should perform an EEG to detect the location and extent of the CNS lesion. The EEG can detect only cerebral damage and cannot identify lesions of the brainstem. Inflammatory, parasitic, and neoplastic diseases have been implicated in central vestibular disease of the horse.

Inflammatory disease affecting the CNS includes bacterial abscess, equine protozoal myelitis, and viral encephalitis. One should perform CSF analysis to identify the inflammatory process. In the case of brain abscessation, a culture of the CSF might identify the causative organism; *Streptococcus equi* subsp. *equi* is a common causative agent.[210,211] EPM is a common neurologic disease in America and should be suspected if multifocal disease is present.[4] For polyneuritis equi to occur with vestibular dysfunction

is common, but the signs of cauda equina neuritis predominate.[1] Rabies might present as an encephalitis or spinal cord disease and should be considered in the differential diagnosis of any horse with neurologic disease. Spinal ataxia is the primary neurologic deficit observed in horses affected with equine herpesvirus (EHV) myelitis, but the presence of concurrent vestibular disease is reported.[219] The major clinical signs observed with a togavirus (eastern, western, and Venezuelan encephalitis) infection are depression and seizure, although cranial nerve deficits are observed.[4,211] Horses with West Nile virus (WNV) infection may display cranial nerve signs, including vestibular disease. Concurrent behavioral and mentation changes, ataxia, fever, and muscle fasciculations are common

Aberrant parasite migration of the CNS in horses results in acute onset of neurologic signs. Clinical signs vary, but progression of clinical signs occurs in most instances. Neurologic signs are generally asymmetric because of the random nature of migration. Neurologic disease secondary to parasite migration is discussed in detail later in this chapter. Fungal granulomata caused by *Aspergillus* spp. and *Cryptococcus neoformans* have been reported as space-occupying masses within the cranium of a horse.[4,220] Cholesteatoma (cholesterol granuloma) could involve the vestibular system by extending from the choroid plexus of the fourth ventricle of the brain.[4] Neoplastic diseases of the CNS are rare in the horse. Any tumor affecting the cerebellomedullary angle could result in vestibular signs.[1] Lymphoma, ependymoma, meningeal melanoma, and melanotic hamartoma have been reported to affect the CNS of the horse.[1,221]

Ancillary Diagnostic Tests

Caloric Testing

The caloric test is a diagnostic aid that might be helpful in differentiating central from peripheral vestibular disease. The test is able to assess each peripheral vestibular sensory organ separately. In the normal animal, irrigation of ice-cold water (12°C) into the external auditory canal for 3 to 5 minutes induces a horizontal nystagmus with the fast phase away from the tested labyrinth.[1,201] The water cools endolymph closest to the tympanic membrane, increasing its density. A density gradient is created within the semicircular canal, and the cooled endolymph sinks, causing displacement of the hair cells. Warm water (45°C) irrigation of the external auditory canal results in horizontal nystagmus with a fast phase toward the tested labyrinth. The warm-water test is less reliable.[199] The test does not induce nystagmus in a nonfunctional labyrinth. Animals may resist the procedure, making the test difficult to interpret, and in some animals, one cannot induce nystagmus. If an asymmetric response is obtained, the depressed reaction indicates the abnormal labyrinth.[1] The test is difficult to perform and not entirely reliable, although it might be a helpful diagnostic aid in the anesthetized or comatose horse.[201]

Brainstem Auditory Evoked Response

The cochlea is damaged by trauma or inflammation of the peripheral vestibular receptor organs, and detection of hearing loss may help to differentiate central from peripheral vestibular disease. Unilateral hearing loss is difficult to assess subjectively in the horse. BAER is a method of objective assessment of auditory function in the horse. This noninvasive, electrodiagnostic test stimulates the auditory system with a series of clicks. Far-field potentials of the brainstem auditory components are recorded via cutaneous electrodes and a signal-averaging system.[60-62,67,71,205] The response is a series of evoked potentials occurring within 10 ms after the stimulus. In the horse the evoked potentials appear on the oscilloscope as a series of five waveforms.[33] Abnormalities of the specific waveforms can identify a lesion of the corresponding neurologic structure. In the horse, functional loss of the cochlea or eighth cranial nerve results in the loss of the entire waveform on the side of injury, and the presence or absence of the waveform can differentiate a central from a peripheral vestibular lesion. General anesthesia is not necessary to perform the test, but sedation is recommended.[60-62,71,205]

DISEASES OF THE CEREBELLUM

Cerebellar abnormalities reported in horses consist primarily of neurodegenerative disorders confined primarily to a small number of breeds, including Arabians and Gotland pony foals. The cerebellum is essential for the coordination of movement. Afferent information arises from the general and special (vestibular) proprioceptive systems and the special somatic (auditory and visual) systems. The cerebellum is responsible for regulation of the rate, range, and strength of movement, as well as integration and coordination for balance and posture. Cerebellar abnormalities in horses are unusual; however, when present, they can have a profound effect on gait and posture.

Structure and Function

Knowledge of the structure and development of the cerebellum is important for understanding cerebellar function in health and disease. The cerebellum is located in the metencephalon dorsal to the pons and is attached to the pons via three cerebellar peduncles (Fig. 11.32). The caudal peduncle is composed primarily of afferent fibers arising from the medulla, the vestibular nuclei via the vestibulocerebellar tracts, and the spinal cord via the spinocerebellar tracts. The middle cerebellar peduncle contains only afferent fibers to the cerebellum that arise from the transverse fibers of the pons. The rostral cerebellar peduncle is the primary connection to the mesencephalon and carries the majority of cerebellar efferent fibers, although a few afferent fibers arise from the spinocerebellar tracts. The cerebellum consists of two hemispheres and a central region known as the *vermis*.[1] The extensive convolutions of the cerebellar cortex are termed *folia*. The cortex covers the surface of the cerebellum. On cut section, the cerebellar medulla is a central region of white matter with multiple projections called *arbor vitae*. These branches extend to the cerebellar cortex and form the white matter portion adjacent to the cerebellar cortex.

The cerebellar medulla has three nuclei: (1) the fastigial, (2) the interpositus, and (3) the lateral nuclei from medial to lateral on each side of the cerebellum. The cerebellum also can be divided into three bilateral longitudinal regions in association with these nuclei.[1,222] The medial zone, containing the vermis and the fastigial nucleus, primarily regulates the tone, posture, and equilibrium of the body in general. The intermediate zones contain the interpositus nucleus and cortex adjacent to the vermis and adjust the orientation of limbs in space, maintaining balance, posture, and muscle tone during

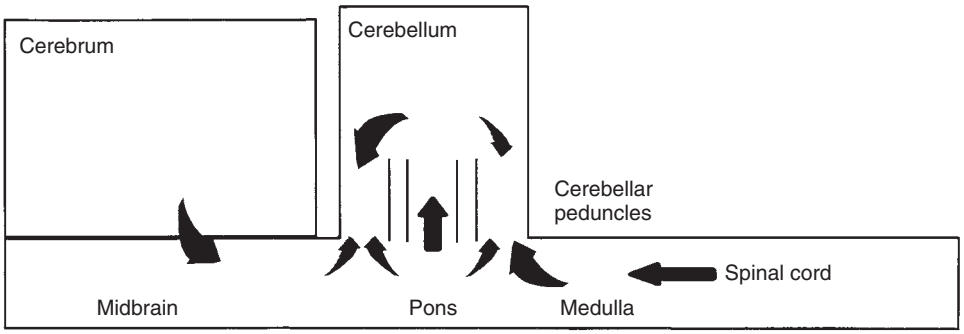

FIG. **11.32** Schematic diagram of cerebellar efferent and afferent information pathways via the cerebellar peduncles. The arrow size reflects the relative contribution of each pathway (see text for details).

complex movements. The lateral zones, consisting of the lateral nuclei and lateral portions of the cerebral hemispheres, have a similar function but do not influence posture or muscle tone directly.[222]

The cerebellum arises from the alar plate region of the metencephalon and originates initially as a proliferation of cells in the rhombic lip that extend dorsally and medially to form the dorsal portion of the metencephalon. Germinal cells proliferating in the rhombic lip eventually migrate into the cerebellum and differentiate to form the specialized neurons of the cerebellar cortex. The cerebellar cortex has three layers: (1) the outer molecular layer, (2) the middle Purkinje layer, and (3) the inner granular layer (Fig. 11.33). The molecular layer is acellular and consists primarily of the dendritic zones of the Purkinje cells and axons of the granular cells.[1] The Purkinje layer is only one cell thick and consists of Purkinje neurons. The granular layer is densely cellular with granular neurons. All layers must be present and aligned in proper orientation for normal function.

Organization of the specialized structure of the cerebellar cortex allows integration and coordination of movement. The cerebellum primarily provides regulation of skeletal movement, allowing coordinated movement; it does not initiate muscular activity. Afferent information regarding movement and balance arising from the mesencephalon, the brainstem, and the spinal cord enters the cerebellum via the cerebellar peduncles, and regulation of movement is coordinated by the inhibitory influence of Purkinje neurons on the cerebellar nuclei. Information enters the cerebellum via the cerebellar peduncles and is carried on two major afferent nerves termed *Mossy fibers* and *climbing fibers*.[1] Mossy fibers originate from the brainstem and spinal cord. Mossy fibers send collateral fibers to synapse with the cerebellar nuclei; they terminate by synapsing with granular neurons in the cerebellar cortex. These fibers are facilitatory at these synapses. The axons that granular neurons send to the molecular layer course transversely through this layer to synapse with the dendritic zone of multiple Purkinje cells and also provide facilitatory influence at these synapses. Climbing fibers originate in the olivary nucleus, which provides most of the extrapyramidal projections to the cerebellum. Similar to mossy fibers, climbing fibers send collaterals to synapse on neurons in the cerebellar nuclei; however, the axon continues through the cerebellar cortex to synapse with the dendritic zone of the Purkinje neurons in the molecular layer. As with mossy fibers, climbing fibers provide a facilitative influence at the synapses.

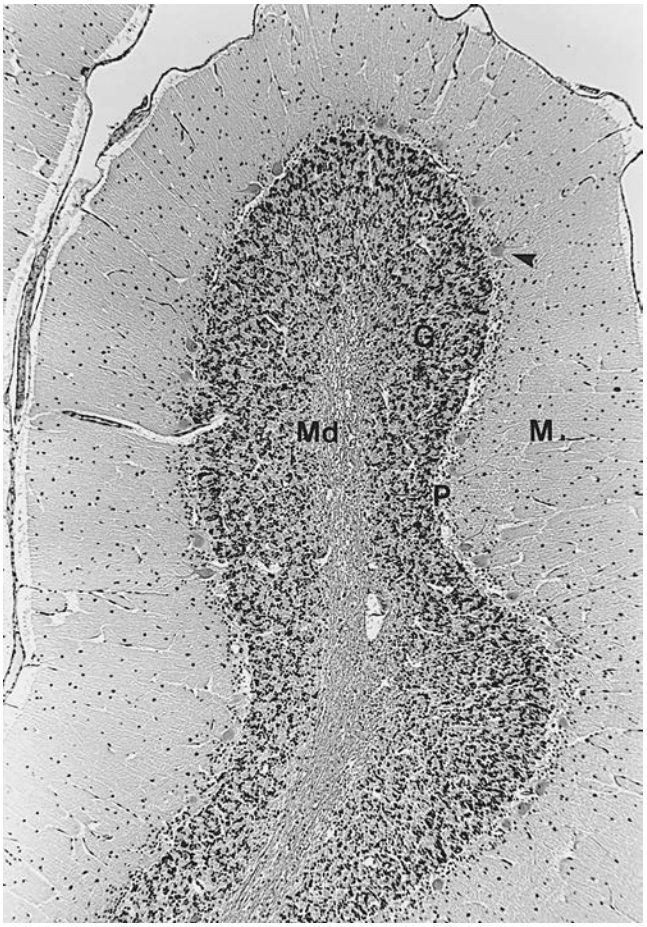

FIG. **11.33** Photomicrograph of a normal cerebellum. *M,* Molecular layer; *P,* Purkinje layer; *G,* granular layer; *Md,* medulla; *arrowhead,* a Purkinje neuron. (Hematoxylin-eosin stain; ×55.) (Courtesy the Washington Animal Disease Diagnostic Laboratory, Pullman, WA.)

Purkinje neurons provide the sole efferent fibers from the cerebellar cortex. The majority of Purkinje cell axons terminate on neurons in the cerebellar nuclei, although direct projections from these neurons to the vestibular nuclei occur via the caudal cerebellar peduncle. Purkinje neurons are inhibitory and use the neurotransmitter GABA.[1] Efferent nerves from the cerebellum are primarily from the cerebellar nuclei that facilitate activity of upper motor neurons originating in the brainstem.

Thus much of the influence of the cerebellum on skeletal muscle activity is to modulate the upper motor neuron. Information regarding movement and balance enters the cerebellar cortex via the cerebellar peduncles. This afferent activity stimulates inhibitory Purkinje neurons by climbing or mossy fibers. Purkinje neurons in turn modulate the activity of the cerebellar nuclei to regulate movement and muscular tone. Purkinje neurons also provide direct inhibitory input to the vestibular nuclei.

Clinical Signs

Clinical signs associated with cerebellar disease generally reflect the loss of coordination. Mentation is normal in horses with cerebellar disease, provided that other regions of the brain are unaffected and metabolic disturbances such as septicemia or endotoxemia are not present. Cerebellar disturbances result in ataxia and inability to regulate the rate, range, and force of movement.[1] *Dysmetria* refers to alterations in the range of gait. *Hypermetria* is an exaggerated range of movement. When moving, the limb has a higher or longer flight compared with normal. Initiation of movement might be jerky and awkward, and the trunk may sway from side to side when the horse moves. Spasticity is caused by hypertonia and results in a jerky stiff gait. Diffuse cerebellar disease results in bilateral signs. In general, unilateral lesions result in signs ipsilateral to the lesion. Intention tremor is another prominent sign of diffuse severe cerebellar disease. Tremor is most obvious as vertical or horizontal head motions and can be observed readily as a horse approaches feed or attempts to nurse. The tremor is present only when a movement is initiated and tends to become more exaggerated as the horse approaches an object.

Cerebellar disease also might cause loss of menace response and vestibular abnormalities. Disruption of the flocculonodular lobe, located in the ventral cerebellum, or the fastigial nucleus might result in vestibular signs characterized by disequilibrium; a variable nystagmus, which may be positional; and positioning difficulties.[1] Unilateral lesions might result in a head and body tilt toward the side of the lesion and nystagmus with the fast phase away from the lesion. Paradoxic vestibular syndrome, characterized by a head tilt away from the lesion and nystagmus with the fast phase toward the lesion, is apparent with unilateral lesions involving the cerebellar peduncle.[1,222]

Diseases of the Cerebellum

Cerebellar Abiotrophy and Degeneration

Cerebellar abiotrophy is the most commonly reported cerebellar disease in horses.[202,223-229] Abiotrophy in the nervous system refers to premature degeneration of neurons caused by some intrinsic abnormality in their structure or metabolism.[230] Cerebellar abiotrophy has been reported in Arabian, Gotland pony, and Oldenburg horse breeds. Degenerative cerebellar lesions have been observed in one Thoroughbred and two Paso Fino newborn foals.[231] The disorder has been commonly reported in Arabian and Arabian-related breeds.[202,223-225,227,229] The disorder is inherited as an autosomal recessive trait and is associated with a single-nucleotide polymorphism (SNP) on equine chromosome 2 (13074277G>A), located in the fourth exon of TOE1 and in proximity to MUTYH on the antisense strand.[232] The incidence in some Arabian horse herds has been reported to be as high as 8%. In one report, colts were affected more frequently than fillies, although subsequent reports have not substantiated this finding.[225] The cerebellar abiotrophy that occurs in Oldenburg horses is progressive and fatal, with atypical histologic lesions compared with the syndrome that occurs in Arabian foals, in which the degeneration is characterized by apoptosis of Purkinje cells.[233] Cerebellar abiotrophy generally affects foals less than 1 year of age and occurs most frequently in 1- to 6-month-old foals. Adult-onset cerebellar abiotrophy has been reported in other species such as the dog and has been observed in two horses.[1] Many foals are born with no abnormalities and later develop disease; however, occasionally they are affected at or shortly after birth.[202,225,228]

Clinical signs associated with cerebellar abiotrophy include intention tremors of the head, ataxia, wide-based stance and gait, dysmetria, and spasticity.[202,223-229] The most frequently reported initial signs noted by owners are an intention tremor of the head, vertical or horizontal, or a hypermetric forelimb gait.[223,228] The neurologic examination reveals no change in mentation. One almost never observes nystagmus, which has been reported in only one case of abiotrophy in a Gotland pony.[226] A menace reflex frequently is absent or diminished.[202,228] One must interpret this finding with caution because normal foals may lack or have a depressed menace reflex until at least 2 weeks of age.[234]

Stance and gait abnormalities seen with cerebellar abiotrophy generally consist of a wide-based stance or gait and ataxia.[202,227,228] The foal may move stiffly and have a high goose-stepping gait. The horse may protract the limb when walking, resulting in slamming of the foot to the ground. Movement may be spastic with circumduction. Walking on an incline, asking the foal to step over obstacles, and blindfolding the foal exacerbate gait abnormalities. Generally, gait abnormalities are symmetric, although in a Welsh Cob and Arabian cross foal the initial signs were characterized by a stiff motion in the left front limb. Signs in this foal progressed to severe ataxia.[224] Foals affected at birth may have difficulty rising.[202,225,226] Segmental reflexes are normal. Some affected animals fall when startled or when raising their heads. Signs are generally progressive for several months after diagnosis. Once the animal has reached maturity, the condition becomes static, although mild improvement has been observed.[229]

Ancillary testing is of limited value in diagnosing cerebellar abiotrophy but can be helpful to rule out other causes of ataxia. The CBC and serum biochemistry profile are normal in affected foals. Usually, there are no abnormalities in CSF and, if present, are not specific. In one study, three of four foals had an elevated CSF CK activity. Values in affected foals ranged from 6.6 to 62 IU/μL (normal range, 0–8 IU/μL).[228] CSF CK elevations generally are associated with neural necrosis or degeneration, although they are not associated specifically with a particular disease.[27,235,236]

In addition, CSF total protein might be elevated. In the study cited previously, three foals had elevated total protein with an average of 226 mg/dL (normal, 0–100 mg/dL) in all foals with cerebellar abiotrophy. As with CK, total protein elevations are not specific for abiotrophy and might occur with disruption of the blood-brain barrier or with CNS inflammation or degeneration. Many foals with cerebellar abiotrophy have normal CSF analysis. EEG abnormalities, including increased synchrony and increased number of abrupt frequency changes, also may be detectable in affected foals.[228] In this study, these abnormalities were not observed in normal foals anesthetized under similar conditions. Skull and cervical radiographs are

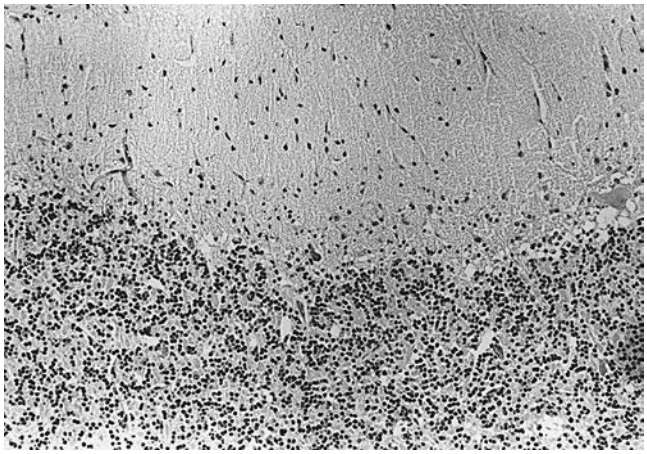

FIG. **11.34** Photomicrograph of the cerebellum from a 9-month-old foal with cerebellar abiotrophy. The decreased number of Purkinje neurons is notable. (Hematoxylin-eosin stain; ×139.) (Courtesy the Washington Animal Disease Diagnostic Laboratory, Pullman, WA.)

unremarkable. However, because mentation is normal in foals with cerebellar abiotrophy, EEG examination is not necessary to make a diagnosis and is primarily useful to exclude seizure disorders as a cause of the tremors observed.

Antemortem diagnosis of cerebellar abiotrophy is based on a typical history and the clinical signs of intention tremor, lack of menace, failure to blink to bright light, and ataxia in Arabian, part-Arabian, or Gotland pony foals. The differential diagnoses for cerebellar abiotrophy include cranial malformations; congenital spinal malformations, including atlantoaxial malformations and stenotic myelopathy; inflammation or infection of the cerebellum; and trauma. One can rule out these conditions based on the neurologic examination, CSF analysis, and radiography. The signs of characteristic ataxia and head tremor without weakness in the appropriate breed are nearly pathognomonic.

Postmortem examination provides a definitive diagnosis of this disorder. Generally, no gross abnormalities are notable; however, careful examination of the cerebellum might reveal an increased lobular pattern with prominent folia. In the Gotland pony, the weight ratio of the cerebellum to the cerebrum is reduced significantly in foals with cerebellar abiotrophy.[226] Normal foals had a 13% ratio, and affected foals had a 10% ratio. In the degenerative cerebellar condition in the Paso Fino and Thoroughbred foals, a decrease in the cerebellar-to-whole brain weight ratio was evident.[231] This ratio in normal foals was 8% and in affected foals was 6%.

Histologic abnormalities are consistent in cases of cerebellar abiotrophy. The most prominent finding is the widespread loss of Purkinje neurons[202,223-229] (Fig. 11.34). Degenerative changes, such as shrunken and angular neurons with hyperchromasia and dispersion of Nissl's substance, are apparent. One may observe occasional "baskets" or clear spaces where the Purkinje neuron is lost. Thinning of the molecular layer occurs with gliosis. The granular layer is also thin with a loss of cellularity. Similar histologic findings were found in Thoroughbred and Paso Fino foals with vacuolation and proliferation of Bergmann's glia in the Purkinje cell layer.[231]

The pathogenesis of cerebellar abiotrophy is unknown. Viral, toxic, and genetic causes have been investigated.[202,223,225,228] To date no evidence has been found to support an infectious cause. No virus has been isolated from the CSF or brain of affected foals, and no viral inclusions have been observed on histologic examination. No toxin has been associated consistently with cerebellar abiotrophy of Arabian foals. Experimental breedings of Arabian horses indicate an autosomal recessive mode of inheritance, but an exact genetic basis for disease has not been determined. A pedigree analysis of Gotland ponies similarly suggests an autosomal recessive mode of inheritance[226]; however, a high degree of inbreeding was noted, making definitive conclusions difficult. Attempts to breed affected individuals in this study were unsuccessful.

No treatment exists for cerebellar abiotrophy. As noted previously, signs may be progressive until the foal reaches maturity. Signs may stabilize or improve slightly with time.

Gomen Disease

Gomen disease is a degenerative cerebellar condition recognized in the northwest part of New Caledonia.[237] Gomen disease is a progressive cerebellar disease that causes mild to severe ataxia. Horses that are indigenous or are introduced to the region may be affected. The disease occurs only in horses that are allowed to roam free, and signs may take 1 to 2 years to develop once a horse is introduced into an endemic area. Horses that are confined generally are unaffected. Clinical signs consist of ataxia, which is most prominent in the pelvic limbs; toe dragging; and a wide-based stance. As the disease progresses, horses might have difficulty rising. The signs are primarily referable to involvement of the cerebellum; however, weakness likely is caused by brainstem or spinal cord involvement. Nystagmus is not observed. Ataxia is progressive over 3 to 4 years until the horse dies or is euthanized.

Mild cerebellar atrophy might be apparent on gross examination of the brain. Histologically, severe depletion of Purkinje neurons is evident throughout the cerebellum.[238] Purkinje neurons might contain lipofuscin pigment and vacuoles. Moderate to severe lipofuscin pigmentation of neuron cell bodies occurs throughout the brain and spinal cord. Although lipofuscin accumulation might be considered a normal variation of aging, the degree of pigment accumulation is far more severe than that in horses of similar age. The pathogenesis of this disease is unknown. Pedigree analysis has not revealed any genetic component for susceptibility to development of disease.[237] A condition of neuronal lipofuscinosis in dogs has some similarities to this disease.[238] The accumulation of lipofuscin pigment and association with free-ranging horses suggest a metabolic disorder, perhaps resulting from toxicity.[237,238]

Developmental Abnormalities

Dandy-Walker syndrome is characterized by a midline defect of the cerebellum and cystic dilation of the fourth ventricle, which separates the cerebral hemispheres.[239] Frequently, all or portions of the cerebellar vermis fail to form, and the corpus callosum may be absent. The condition is rare in horses and has been observed in Thoroughbred and Arabian foals.[240] Foals with this syndrome might be abnormal neurologically from birth, with difficulty rising, seizures, and absence of the suckle reflex.[240] The forehead might be domed excessively. Ataxia, nystagmus, aggression, and difficulty in training might persist as the foal ages.[240] Diagnosis generally is made at postmortem examination; however, one case was diagnosed antemortem using CT.[240]

Several individual cases of equine developmental cerebellar abnormalities have been described. Cerebellar hypoplasia has been described in a Thoroughbred foal that had difficulty rising and developed seizures shortly after birth.[241] Bilateral focal cerebellar cortical hypoplasia has been reported in a 6-year-old Thoroughbred gelding.[242] No gait abnormalities were detected in this horse, although it had fallen over repeatedly before euthanasia. The relationship between falling and the cerebellar abnormality is unclear. Possibly the abnormality in this adult horse resulted from a secondary problem, such as vascular injury, rather than a developmental defect.[233]

A single case of cerebellar dysplasia has been described in a 4-year-old Thoroughbred horse.[243] This horse had a 7-month history of circling and collapsing to the left side. In this case the horse had hyperplasia of the right side of the cerebellum with no associated central white matter. Histologically, the granule layer was thinning, with increased thickness of the molecular layer and cavitation of the white matter.

Additional reported developmental disorders include cerebellar hypoplasia with internal hydrocephalus and cerebellar aplasia with hydranencephaly in two fetuses from Haflinger mares with hydrops allantois.[244] Mild cerebellar degenerative changes consisting of Purkinje neuron granularity have been noted in a Standardbred filly with a chromosomal abnormality.[245] This abnormality was accompanied by mild spongiotic degeneration of the cerebrum. Abnormal neurologic signs in this filly included difficulty standing at birth, mental dullness, and a head tilt. Growth retardation, small inactive ovaries, and a consistently wrinkled muzzle accompanied these signs.

Infectious Conditions

Unlike in many other large animals, no infectious agents have the cerebellum as their primary target; however, a number of agents might affect the cerebellum. Any agent that targets the CNS, especially those that have a multifocal distribution, also may involve the cerebellum. Occasionally, disseminated *Streptococcus equi* subsp. *equi* infection (bastard strangles) may result in a cerebellar abscess.[246] Neurologic abnormalities in one reported case included proprioceptive deficits in the right thoracic limb, nystagmus, and a head tilt. Meningitis contributed to other CNS signs such as depression, blindness, and recumbency. Diagnosis of this condition can be based on a history of previous *S. equi* subsp. *equi* infection, evidence of severe suppurative inflammation in the CSF, and culture of *S. equi* subsp. *equi* from the CSF. Treatment consists of penicillin. The prognosis is guarded; however, successful surgical drainage of a cerebral *S. equi* subsp. *equi* abscess has been reported.[247]

Focal involvement of the cerebellum has been associated with aberrant parasite migration in the horse.[224,248] In a 6-year-old pony, infection with *Halicephalobus gingivalis* resulted in severe ataxia.[248] Histologic study showed lesions scattered throughout the cerebellum, brainstem, thalamus, and pituitary gland, and nematodes were observed throughout the lesions. A second case involving a 1-year-old Thoroughbred colt had a sudden onset of severe ataxia.[224] Multifocal malacia with numerous eosinophils was observed throughout the cerebellar white matter. No nematode was detected, although parasitic involvement was suspected based on the eosinophilic inflammation.

Miscellaneous Conditions

A familial neurologic condition in newborn Thoroughbred foals has been reported.[249] This syndrome affected three of five foals of a Thoroughbred mare. The foals were normal at birth and developed signs of severe incoordination, a wide-based stance, and recumbency at 2 to 5 days of age. The condition appeared more severe when the foals became excited or struggled; consequently, they were treated symptomatically with diazepam. The signs would improve with this treatment and return as the sedation diminished. These foals improved with stall rest over 7 to 10 days. The cause of the clinical signs in these foals is unknown; however, the authors suggested possible viral or toxic causes.

Cerebellar ataxia in two Thoroughbred fillies has been associated with hematoma in the fourth ventricle.[250] These two horses demonstrated fever, dysmetria, spasticity, and weakness. Clinical signs most likely resulted from compression of the adjacent cerebellum. CSF analyses in these cases revealed xanthochromia, elevated RBC and white blood cell counts, and elevated total protein concentrations. The cause of the hematomas was not identified; damage to regional small vessels and a vascular anomaly were suspected.

Chronic methylmercurial poisoning in horses can cause a number of clinical abnormalities, including cerebellar ataxia.[251] Severe poisoning can result in incoordination, dysmetria, and gross head nodding in the experimental setting. Associated clinical signs include lethargy, anorexia, exudative dermatitis, and laminitis. Lesions in the cerebellum consisted of focal atrophy and cellular depletion in the granular layer with little to no involvement of Purkinje cells. Additional abnormalities included neuronal necrosis and gliosis in the cerebrum, lymphocytic perivascular cuffing, and swollen axons in the spinal cord. Preferential accumulation of inorganic mercury in the brain and resulting cell injury most likely led to the neurologic signs observed. Diagnosis of methylmercurial poisoning can be based on clinical signs and measurement of mercury in the liver and kidney.

SHIVERS

Monica Aleman

Shivers is a chronic progressive equine movement disorder of unknown etiology. Affected horses display difficulty walking backward, assume hyperflexed pelvic limb posture, and have tremors during backward movement.[252,253] The condition might progress to involve thoracic limb movement. The condition has been reported in draft breeds, Thoroughbreds, Warmbloods, and others with less frequency such as Connemara, Welsh, Quarter Horses, Standardbreds, Saddlebreds, Tennessee Walking horses, Missouri Fox Trotters, Paint, Morgan, and mixed breeds.[252] Gait patterns of shivering were characterized in one study as (1) hyperextension when backing and lifting the limb, (2) hyperflexion and abduction during backward walking, (3) shivering hyperflexion with abduction during backward walking, and (4) shivering-forward hyperflexion including intermittent hyperflexion and abduction with forward walking.[253] Horses with shivering-hyperflexion, shivering-forward hyperflexion, and stringhalt had a prolonged swing phase duration compared with control horses and others with other types of shivers. Initially forward movements are normal.[253] Other signs might include muscle atrophy, reduced muscle strength, exercise intolerance, facial twitching, elevated tail head, and problems picking up feet for farrier (common complaint).[252] Shivering signs usually begin at less than 5 years of age and progress in the majority of cases (74% reported in one study).[252] Horses with shivers are significantly

taller (mean 173 ± 6.2 cm) with a higher male-to-female reatio (3:1) than a control population.[252]

There are no histologic lesions in the thoracic and pelvic limb skeletal muscle. In a study, eosinophilic segmented axonal spheroid and calretinin-positive axonal spheroids were found to be common lesions in the CNS, particularly in the nucleus cuneatus lateralis.[254] Calretinin-negative, calbindin-positive, and glutamic acid decarboxylase-positive spheroids were found increased 80-fold in Purkinje cell axons within the deep cerebellar nuclei in affected horses.[254] Unusual lamellar structures resembling marked myelin decompaction were observed between myelin sheaths of presumed Purkinje cell axons in the deep cerebellar nuclei of shivers but not control horses.[254] The authors concluded that shivers is characterized by end-terminal neuroaxonal degeneration in the deep cerebellar nuclei, which results in context-specific hypermetria and myoclonus.[254]

CERVICAL VERTEBRAL COMPRESSIVE MYELOPATHY

Yvette S. Nout-Lomas

Cervical vertebral compressive myelopathy (CVCM) is a common cause of ataxia and weakness in horses. It is the most common cause of ataxia in horses in Europe and Australia and is an important differential diagnosis in regions affected by inflammatory diseases such as EPM and WNV. Differentiating CVCM from other conditions that cause ataxia is important for prognostic and therapeutic considerations. The disease is also referred to as cervical vertebral malformation, cervical vertebral stenotic myelopathy, cervical stenotic myelopathy, cervical spondylotic myelopathy, equine sensory ataxia, equine incoordination, spinal ataxia, and wobbler syndrome. Compression of the spinal cord occurs secondary to stenosis, or narrowing, of the vertebral canal anywhere from C1 to T1. Stenosis of the cervical vertebral canal is a result of bone and joint malformations, the pathogenesis of which remains unclear but is likely multifactorial.

CVCM is most frequently seen in young, well-fed, rapidly growing horses. Analysis of over 800 horses with CVCM confirmed what previous studies have shown: males (stallions and geldings) and Thoroughbreds, Tennessee Walking Horses, and Warmbloods have a significantly higher likelihood of having CVCM compared with mares and other breeds. CVCM has been shown to affect 1.3% to 2% of Thoroughbred horses.[255,256] Furthermore, horses that ranged from less than 6 months to less than 7 years of age had significantly higher odds of having CVCM compared with horses 10 years of age or older.[257] Developmental bone disease in younger horses can lead to deformation and malarticulation or malalignment of vertebral bodies (Fig. 11.35A). In older horses, spinal cord compression more commonly occurs secondary to vertebral malformation because of osteoarthritis of caudal cervical articular process joints, although there may be some overlap in this distinction. Male horses and horses of Warmblood or Tennessee Walking Horse breeds may be predisposed to development of CVCM at an older age.[258] Spinal cord compression has traditionally been separated into two categories: (1) dynamic vertebral compressions, whereby the spinal cord compression is intermittent and occurs when the cervical vertebrae are flexed (more cranial vertebral) or extended (more caudal vertebrae), and (2) static compressions, in which spinal cord compression is continuous regardless of cervical position.[259] Both syndromes are likely to occur in individual cases or can occur simultaneously. The clinical significance of distinguishing between the two types of CVCM is unknown, but it is important for imaging studies because significant flexion or extension may be necessary to demonstrate dynamic compressions. Proposed etiologic factors that result in developmental bone disease include high planes of nutrition,

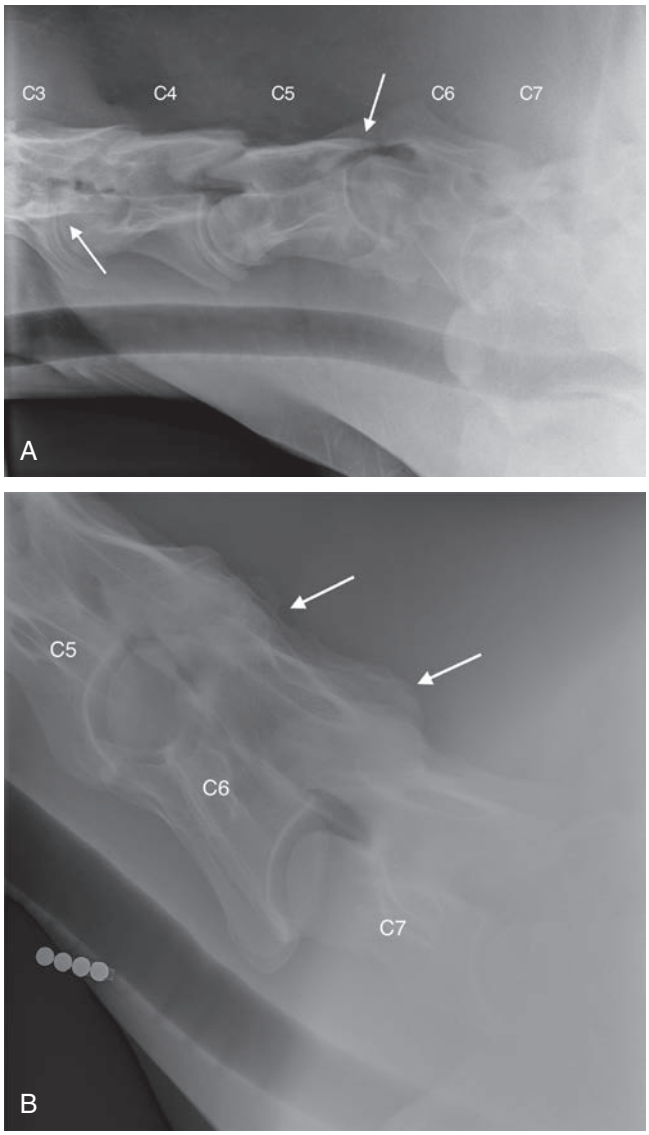

FIG. **11.35** A shows a lateral cervical radiograph taken from an 8-month-old Quarter Horse colt with grade 4 out of 5 ataxia. Cervical vertebrae 3–7 are indicated with evidence of malformation at C3–4 and C5–6 (arrows). Collapsing of the dorsal aspect of the disk space is seen at C3–4 with surrounding bony proliferation. Caudal extension of the dorsal aspect of the vertebral arch of C5 (arrow) and obvious malalignment and stenosis of the vertebral canal at C5–6 are shown. B shows a lateral cervical radiograph taken from a 17-year-old Thoroughbred gelding with a chronic bilateral front limb lameness and a 1-month history of progressive ataxia. Shown are the C5–C7 vertebrae with extensive bony proliferation at the articular processes (arrows) of both C5–C6 and C6–C7.

accelerated growth rates, altered ratios of copper and zinc, and inherited genetic determinants. None of these has so far been shown to be a direct cause of CVCM.

Clinical Signs

Most horses are diagnosed with CVCM when they are between 12 and 23 months of age.[257] Cervical vertebral compressive myelopathy is characterized by symmetric ataxia, upper motor neuron paresis, and dysmetria, which are usually worse in the pelvic limbs than thoracic limbs.[40] Physical examination sometimes reveals palpable cranial cervical vertebral flexion-fixation, and affected horses tend to be large for their age and breed. Male animals appear to be more frequently affected. Often a history of increased clumsiness occurs, and mild to moderately affected horses show symmetric ataxia with circumduction of the pelvic limbs, especially when the animal is made to walk in small circles. Proprioceptive deficits, toe dragging (flexor paresis), and varying degrees of upper motor neuron extensor paresis (assessed by pulling on the horse's tail at a walk) are also present. Thoracic limbs often have a hypometric, stiff (spastic) component to the strides, especially while walking the horse down a slope and with the head elevated. Thoracic limb deficits are usually less severe than pelvic limb deficits because of the more superficial location of pelvic limb spinocerebellar proprioceptive tracts in the spinal cord. Horses with chronic disease tend to show less paresis than those with recent-onset clinical signs.[4] Neck pain or stiffness may be present in some older horses. An accident or injury to the neck is sometimes in the history, and clinical signs may have an abrupt onset or indeed the horse may be tetraplegic, especially if external trauma plays a major role. The ataxia, however, was likely present before the traumatic incident.

Clinical signs of concurrent developmental orthopedic disease of the appendicular skeleton, such as physeal enlargement of the long bones, joint effusion after osteochondrosis, and flexural limb deformities, are often present in young horses with CVCM.[40] It is worth remembering that sometimes horses affected with CVCM may have another concurrent neurologic disease such as equine protozoal encephalomyelitis.

Pathogenesis

Compression of the spinal cord is a result of stenosis, or narrowing, of the vertebral canal anywhere from C1 to T1. Stenosis of the cervical vertebral canal is a result of bone and joint malformations, the pathogenesis of which remains unclear. Currently it is thought that in some horses there is an underlying developmental disorder of bone and cartilage morphogenesis and maturation that leads to cervical vertebral malformations, whereas in other horses malformations are thought to be the result of abnormal biomechanical stresses and forces on the cervical column.[94] Neurologic signs result from progressive spinal cord compression secondary to structural changes to vertebral and surrounding tissues. Pathologic changes of the cervical vertebrae leading to spinal cord compression consist of malformation including angular deformity of the vertebrae, malalignment between adjacent vertebrae, stenosis of the vertebral canal, flare or epiphysitis of the caudal vertebral epiphysis of the vertebral body, extension of the dorsal aspect of the vertebral arch, abnormal ossification of the articular processes, and degenerative joint disease of the articular processes (Fig. 11.35B).[40,260] Recently, detailed MRI and histopathologic analyses have also identified bone cysts within the articular processes of horses with CVCM.[94] The abnormalities found in the necks of horses with CVCM are generalized and not limited to the site(s) of spinal cord compression. Histopathologic examination of the spinal cord reveals wallerian-like degeneration, loss of axons and fibrosis at the sites of spinal cord compression, and axon loss in the ascending and descending white matter tracts within adjacent segments of the spinal cord cranial and caudal to the site of spinal cord compression.[40]

A high dietary energy intake is almost certainly necessary for expression of the disease, and trauma to the neck probably plays a role as young, large, fast-growing animals (often male animals) are most commonly affected. CVCM resulting from developmental bone disease almost certainly has a genetic basis; however, a breeding trial using horses with CVCM that had had corrective surgery resulted in offspring that did not have CVCM but did have a higher frequency of developmental orthopedic diseases than expected.[261]

CVCM in older horses is frequently associated with arthritis of the articular processes of the caudal (C5–T1) cervical vertebrae, and articular process osteophytes are the most commonly seen radiographic lesions.[258] Biomechanical forces are likely to play a part in the onset of the disease. Compression of the spinal cord is due to vertebral malformation at C5, C6, and C7, resulting in cone-shaped caudal cervical vertebrae with a reduction in a cross-sectional area of the vertebral canal and resultant impingement on the spinal cord by proliferating articular and periarticular soft tissues. There may be concurrent formation of epidural and periarticular cysts, which can result in sudden onset of symmetric or asymmetric signs without a contemporaneous episode of external injury. Bleeding into one of these cysts has been observed and adds to the compression. Occasionally these cause acute-onset severe clinical signs that can abate within a few hours only to reappear later.

Diagnosis

Fortuitously, the narrowing of the cervical vertebral canal and associated spinal cord compressive lesions in horses occur most commonly in a dorsoventral orientation, allowing the diagnosis to be made using (lateral) cervical myelography (Fig. 11.36). Good-quality, standing plain lateral radiographs of C1 to T1 vertebrae provide information on anatomy of the vertebral bodies and width of the vertebral canal but do not show the spinal cord. It should be remembered that the lack of dorsoventral radiographic projections effectively makes traditional lateral imaging an incomplete diagnostic series. The assessment of qualitative features of vertebral malformation, including physitis of the caudal vertebral body, caudal extension of the dorsal arch of the vertebral body, intervertebral malalignment, and arthropathy of the articular processes, is useful; however, alone these findings offer poor positive and negative predictive values.

The most important factor in the diagnosis of CVCM in adult horses and foals is the identification of a decrease in the diameter of the vertebral canal, be it within a vertebra or, more commonly, between two vertebrae. Corrected intravertebral and particularly intervertebral sagittal ratios (SRs) from C2 to C7 calculated from lateral standing cervical radiographs can be used to accurately diagnose CVCM in horses.[262,263] The intravertebral and intervertebral sagittal diameter of the vertebral canal is measured at the narrowest

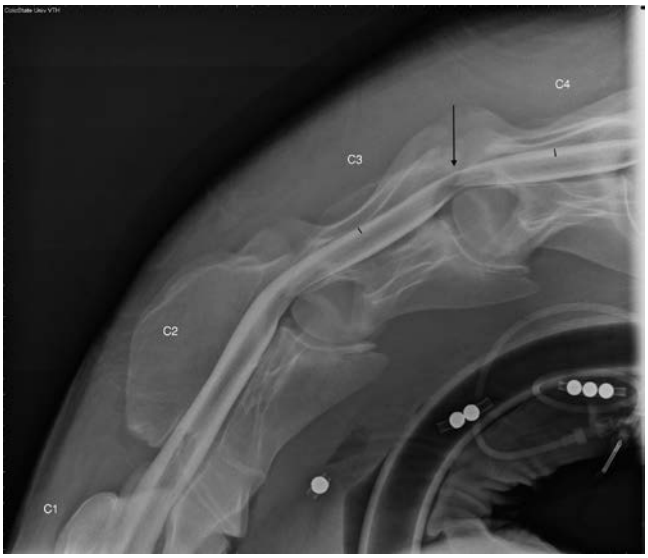

FIG. **11.36** A lateral cervical myelogram showing compression of the cervical cord at C3–C4 (arrow). At C3–C4 there is complete attenuation of the ventral contrast column with significant narrowing (>50%) of the dorsal contrast column.

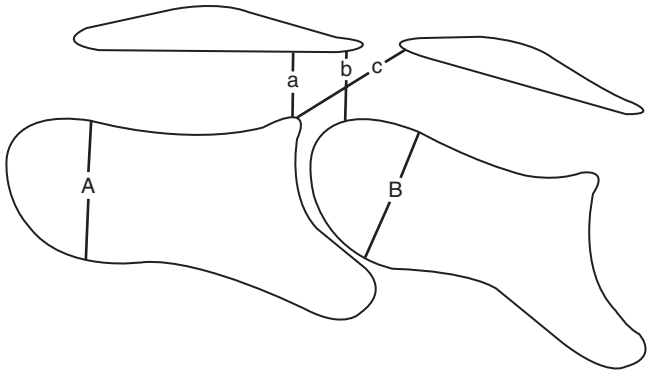

FIG. **11.37** Two cervical vertebra showing sites for measuring the intravertebral and intervertebral sagittal diameter and the width of the vertebral body *(A) (B).* For a particular vertebra, the minimum intravertebral diameter could be anywhere along the vertebral canal *(a),* and the minimum intervertebral sagittal diameter is the smallest of the two measurements *(b)* or *(c)* compared with the diameter of the more caudal vertebral diameter *(B).*

points and corrected for radiographic magnification and size of horse by being expressed as a ratio of the maximal height of the cranial vertebral physis (Fig. 11.37). The minimum intravertebral diameter is measured at the point along the vertebral canal where the diameter is at a minimum, whereas the minimum intervertebral sagittal diameter ratio is made from the caudal aspect of the dorsal lamina of the vertebral arch of the more cranial vertebra to the dorsocranial aspect of the body of the more caudal vertebra, or from the caudal vertebral body of the more cranial vertebra to the cranial dorsal lamina of the vertebral arch of the more caudal vertebra, whichever was smaller. For vertebrae C2–C3 to C5–C6, the minimum diameter is invariably found to be the former measurement (see Fig. 11.37).

Reference figures for intravertebral and intervertebral SR in a limited number of horses are shown in Tables 11.9 and 11.10. A specific site can be considered very likely to be compressed if it is more than 2 standard deviations smaller than the reference values. As a general rule of thumb, horses with signs of cervical spinal cord disease that have SR values at any intervertebral or intravertebral site that are less than 50% of reference values have a greatly increased risk of having cervical vertebral canal stenosis. One must consider, however, that there is poor agreement among observers when performing these measurements, which is likely influenced by experience. This may limit the accuracy of this method and could result in discrepancies of diagnosis.[264]

In older horses with CVCM, spinal cord compression is most often the result of coning of affected caudal cervical vertebrae. The measurements can be difficult to perform on caudal cervical vertebrae, particularly if the radiographs in large horses are underexposed. In addition, these horses have enlarged and remodeled intervertebral joints of the caudal cervical vertebrae. Many horses without neurologic signs have degrees of cervical vertebral osteoarthritis and considerable arthritic enlargement of articular processes that can occur well lateral and dorsal to the vertebral canal with no spinal cord compression.[4] Cervical scintigraphic examinations similarly cannot determine whether active arthritis is actually causing spinal cord compression. Spinal magnetic motor evoked responses[265] may be used more in the future to objectively grade the degree of electric conductivity across a spinal lesion site.

Before deciding on surgical decompression or vertebral fusion, positive contrast myelographic evidence of spinal cord compression is mandatory. It should be remembered, however, that myelography under general anesthesia is not an innocuous procedure in the horse. Adverse reactions have been shown to occur in one third of horses undergoing myelography, with the procedure having a mortality rate of 2%, which is similar to any type of surgery under general anesthesia.[266] Neurologic complications including worsening of neurologic grade and seizures are the most common adverse reaction seen.[266] Myelography has traditionally been considered the gold standard antemortem diagnostic test; however, sagittal diameter ratio analysis may be more sensitive and specific than myelography, at least if the 50% or 2-mm reduction of the dorsal contrast medium myelographic rules are used.[267,268] Myelography can result in acceptable sensitivity and specificity for detecting sites of compression by using a 20% reduction of the total dural diameter on a neutral myelographic view for the midcervical sites, and a 20% reduction of the same measurement at C6–C7 with the neck in either neutral or flexed position.[267] In some horses with CVCM, particularly those with caudal cervical arthropathy, spinal cord compression may occasionally occur in a lateral or transverse plane with no dorsoventral compression. In these cases, more subjective assessments, such as observing a blanching of the contrast column or split dorsal margins, may be the only myelographic abnormalities.

More recently a technique has been described for cervical vertebral canal endoscopy during which a flexible videoendoscope with an external diameter of 4.9 mm is introduced into the subarachnoid space dorsal to the spinal cord.[269] This technique allows for direct visualization of the structures in the vertebral canal and may allow for recognition of more subtle abnormalities in the epidural space. In the future this

TABLE **11.9 Summary Data for Sagittal Diameter Ratio by Vertebral Site in Eighteen Horses without Cervical Vertebral Malformation**

	Intravertebral						Intervertebral				
Site	C2	C3	C4	C5	C6	C7	C2–C3	C3–C4	C4–C5	C5–C6	C6–C7

technique may prove to be reliable for localization of vertebral canal stenosis and diagnosis of CVCM.[270]

Treatment

Stall rest, glucocorticoids, DMSO, and other antiinflammatory drugs may provide transient improvement in clinical signs in horses with CVCM, especially if acute exacerbation of disease secondary to trauma is seen. However, continued compression of the spinal cord is inevitable, and clinical signs will persist. For most horses for which surgical treatment is not an option or with multiple intervertebral site involvement and severe, chronic clinical signs, the prognosis is poor to grave and humane destruction is advised. A recent review of 103 horses with presumptive CVCM showed that 33 were euthanized after diagnosis, and of the remaining horses 30% had at least one racing start. Horses were more likely to race if they had a neurologic grade less than 1 in the thoracic limbs and less than 2 in the pelvic limbs.[11] In a controlled field study, in which growing foals with CVCM were fed a diet restricted in protein and energy (65%–75% of National Research Council recommendations), clinical signs and radiographic lesions resolved in some foals and significantly improved in others.[271] A positive effect of dietary modification and changing the rate of growth is likely to be seen only in young horses less than 1 to 2 years of age.[11]

Young patients with mild clinical signs of short duration and with only one site of cervical spinal cord compression have a good prognosis for return to athletic function with surgery. No controlled trials have been performed; however, it is estimated that more than 60% of such horses return to athletic function.[272-274] Ventral intervertebral fusion using a stainless steel fenestrated basket or threaded cylinder can allow expansion of the vertebral canal, atrophy of articular enlargements, and resolution of some or all the clinical signs in selected cases. This procedure has been most successful in horses with acute clinical signs resulting from spinal cord compression at only one intervertebral site between C2 and C7 and in horses with absolute stenosis and enlarged articular processes of the caudal cervical vertebrae. Horses with persistent neck pain associated with cervical osteoarthritis but no evidence of fractures to the bodies of the vertebrae are also well suited to cervical intervertebral fusion surgery.

EQUINE NEUROAXONAL DYSTROPHY/ EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

Yvette S. Nout-Lomas

Neuroaxonal dystrophies (NADs) are a group of neurodegenerative diseases described in human beings and animals that are characterized by dystrophic alterations of neurons and axons and development of spheroid bodies. In the horse, equine degenerative myeloencephalopathy (EDM) is considered a more severe form of equine neuroaxonal dystrophy (ENAD) where CNS lesions are thought to be on a continuum, with EDM lesions being more widely distributed than those seen in ENAD.[3,275,276] Clinically, ENAD and EDM are indistinguishable, and both have the same basic underlying neuropathologic lesions.[277-279] ENAD/EDM is a noncompressive, diffuse, symmetric, degenerative neurologic disease characterized by symmetric ataxia, weakness, and dysmetria in young horses of many breeds and both genders. Mayhew and colleagues first described the disease in 1976,[280] and it has been subsequently diagnosed in many other breeds of horses. In addition, identical syndromes have been observed in Mongolian wild horses *(Equus przewalskii)*[281] and Grant's zebras.[282] Earlier work suggested that the pathogenesis of the disease involved a familial vitamin E deficiency,[283,284] and a series of recent studies supports the theory that ENAD/EDM is inherited as a complex trait and affects genetically predisposed horses that undergo a period of α-tocopherol deficiency.[279,285] ENAD/EDM was one of the most prevalent causes of spinal cord disease in horses in the United States during an approximate 15-year span after it was first recognized. Although no recent epidemiologic surveys exist, the prevalence of EDM appears to have declined since about 1990.[3] In Europe the disease has been reported only sporadically. However, it should be noted that clinical signs of ENAD/EDM are similar to those seen in CVCM, and the diagnosis can only be made after careful histologic evaluation of the CNS.

Clinical Signs

The onset of clinical signs may be abrupt but is usually insidious, and the age at which signs are noticed varies from less than 1 month to several years, with most horses manifesting

signs within the first year of life. One older study of 128 horses with EDM showed the age of onset ranged between 1 month to 20 years, with 16% of the horses showing signs at older than 28 months of age.[286] A more recent evaluation of a group of 88 horses with neurologic deficits suspected to be secondary to ENAD/EDM showed that 42% of the horses were older than 3 years at the time of examination; however, no specific information on age of onset of clinical signs was provided.[279] There is no sex predilection.

Signs are referable to upper motor neuron and general proprioceptive deficits and include symmetric ataxia, weakness, and dysmetria, most notably hypometria (spasticity), of all four limbs, often worse in the pelvic limbs.[3,287] Signs may begin in the pelvic limbs and progress to the thoracic limbs. Postural placing reactions may show conscious proprioceptive deficits. The gait is characterized by dysmetria and stabbing of the ground with the limbs. Horses may walk with a two-beat lateral gait, referred to as *pacing,* as also sometimes seen in horses with any spinal cord disease.[3] Often, hindlimb interference and dragging or scuffing of the toes are present. When walking backward, the horse may resist or rock back on the pelvic limbs and dog sit. When circling, affected horses often pivot on the inside hindlimb and circumduct the outside limb. Affected horses may have trouble stopping, and it is not unusual for them to fall while running in the pasture or being worked. Cranial nerve involvement, muscle atrophy, or changes in skin sensation or tail tone are absent in ENAD/EDM[280]; however, a recent evaluation of 88 horses with suspected ENAD/EDM found 60% of those horses to have an abnormal mentation ranging from quiet to obtunded, and 38% had a decreased or inconsistent to absent menace without loss of vision.[279] In addition, the presence of a pigment retinopathy in 4 out of 10 related Warmblood horses that had clinical signs of ENAD/EDM was recently demonstrated.[288] Because previous work from this same group had not found evidence of ocular disease in a group of Quarter Horses with ENAD/EDM it is suspected that the development of ocular lesions is associated with genetic differences and/or severity of α-tocopherol deficiency. It should be noted that none of the horses in which ocular lesions were identified had clinical signs of visual deficits; however, given these findings it is highly recommended to perform a careful ophthalmologic examination on cases in which ENAD/EDM is suspected. Lower motor neuron signs such as hyporeflexia over the neck and trunk with diminished to absent cervical, cervicofacial, cutaneous trunci, and laryngeal adductor reflexes may be found, especially in severe and long-standing cases.[283] The disease is considered not or very slowly progressive, and most horses stabilize at around 3 years of age. Horses do not recover from this neurodegenerative condition.

ENAD/EDM should also be included in the differential diagnosis of young horses presenting with different neurologic deficits, because it is possible for ENAD/EDM to occur in conjunction with other developmental brain diseases. For example, a 2009 report described a foal with confirmed ENAD that had clinical signs of cerebellar disease, most noticeably a head tilt and head tremor and pendular nystagmus, in addition to signs consistent with ENAD.[289] A detailed postmortem examination showed a prominent external granular layer of the cerebellum, in addition to the histopathologic features of ENAD. The authors suggested that the cerebellar lesion might have been a type of migration disorder, although this could not be proven to have occurred in conjunction with ENAD. Migration disorders are another complex group of diseases resulting from failure of embryologic neuronal cells to migrate properly to their final location.

Pathology

Gross necropsy findings in EDM are unremarkable. Classic histologic lesions are evident in the brainstem and spinal cord.[40,279,287,290] In ENAD, lesions are restricted to certain nuclei in the brainstem and spinal cord gray matter, whereas in EDM, lesions also occur in white matter tracts of the spinal cord.[3,279,290] Specific brainstem nuclei in which lesions have been found are the lateral and medial cuneate nuclei, gracile nucleus, nucleus of the solitary tract, trigeminal nucleus, vestibular nuclei, olivary nuclei, and reticular formation. Lesions have also been identified in the medial lemniscus of the medulla oblongata and cerebellar vermis. Spinal cord gray matter lesions have been found in the lateral cervical and thoracic nuclei, and lumbosacral and cervical intermediate gray columns.[279,287] Ascending spinal cord white matter tracts involved in horses with EDM are the spinocuneocerebellar tract (unconscious proprioception; thoracic limbs), the spinocerebellar tract (unconscious proprioception; trunk and pelvic limbs), and the dorsal column-medial lemniscal tract (conscious proprioception).[287,290] Lesions in the ventromedial funiculi of the spinal cord containing descending tracts have also been described.[287,291] With chronicity, the dorsal and ventral spinocerebellar tracts and the medial part of the ventral funiculi of the thoracic segments are more severely affected.[40,287] Astrocytosis, astrogliosis, vacuolization, myelin loss, spheroid formation (axonal swelling), and lipofuscin-like pigment accumulation are present in these areas.[287,290] Recently, histopathologic changes characteristic of EMND were identified in horses with clinical signs of ENAD/EDM.[292] EMND is also attributable to α-tocopherol deficiency but is characterized by clinical signs of lower motor neuron disease and seen in older horses. Although clinical signs of EMND and ENAD/EDM are very different, this report shows that there is overlap possible in the histopathologic lesions identified in horses with these diseases.

Pathophysiology

For years it has been proposed that there is a familial tendency to develop EDM and that there was an association between disease development and vitamin E deficiency. Breeds in which a familial tendency to develop EDM has been suggested include the Arabian,[287] Thoroughbred,[283] and wild horses,[281] and breeds in which this has been demonstrated include Morgans,[293] Appaloosas,[278] Standardbreds and Paso Finos,[283] Lusitanos,[276] American Quarter Horses,[285] and Warmbloods.[288] Pedigree analyses support a genetic cause for increased susceptibility to α-tocopherol deficiency with subsequent development of NAD/EDM; however, the mode of inheritance of NAD/EDM has been difficult to ascertain. From previous studies the mode of inheritance was most likely considered to be an autosomal dominant one with variable expression or a polygenic one, based on a breeding trial in Morgan horses and pedigree analysis in Lusitano horses.[276,286] Most recent work indeed suggests the disease is being inherited as a complex trait,[285] whereby effects of more than one gene along with environmental influences determine the

phenotype. Currently, it is hypothesized that the genetic variant of ENAD/EDM is a susceptibility locus, and the amount of α-tocopherol received by a foal during the first year of life may play a role in determining the final phenotype.[285]

In humans a condition referred to as ataxia with vitamin E deficiency occurs that is caused by various mutations in the α-tocopherol transfer protein gene (TTPA). Clinical signs and neuropathologic findings in people are similar to those seen in horses with ENAD/EDM. In a group of 88 American Quarter Horses pedigree analysis demonstrated inheritance as a polygenic trait with high heritability; however, this study excluded TTPA as a candidate gene for ENAD in this group of horses.[285]

Degenerative myelopathy in other species, which bears clinical and histopathologic similarities to EDM, has been linked to vitamin E and copper deficiencies, hereditary factors, and toxic insults.[294] An older study involving 56 affected and 179 control horses identified three risk factors associated with the development of EDM: (1) use of insecticides, (2) exposure to wood preservatives, and (3) spending frequent time on a dirt lot.[295] This same study showed that spending time on green pastures was found to be a protective factor, and a foal was 25 times more likely to develop EDM if its dam had any other foals diagnosed with EDM. More recently an epidemiologic study involving 3 index case horses with ENAD and 145 randomly selected horses from a single farm showed that most affected and unaffected horses had low serum vitamin E concentrations, hepatic vitamin E concentrations were low, and the pastures on the farm were deficient in vitamin E and selenium.[279] Further, serum concentrations of other trace minerals were within normal limits, and environmental samples were negative for insecticides and ionophores. Heavy metal concentrations in samples were within normal limits. Studies over the years support the hypothesis that exposure of genetically predisposed young foals to environmental oxidants and lack of antioxidants, including vitamin E, are important factors in the pathophysiology of ENAD/EDM.

Oxidative stress is caused by the imbalance between production of prooxidants and the antioxidant defenses. ROS (e.g., superoxide anion, hydrogen peroxide, hydroxyl radical) are formed during the reduction of oxygen to water in normal cellular metabolism (Fig. 11.38A). Aerobic cells have antioxidant defense mechanisms that protect them from oxidative stress (Fig. 11.38B). The brain's high consumption of oxygen, high metabolic activity, and high concentration of polyunsaturated fatty acids, which can easily be oxidized to ROS, make the CNS extremely vulnerable to oxidative attack by ROS. Another source of ROS is through the metabolism of excitatory amino acids and neurotransmitters such as glutamate and aspartate. When present in excess, excitatory amino acids can trigger a series of events including an increase in intracellular calcium, which can lead to the production of free radicals and subsequent neuronal damage and death. Other sources of free radicals that arise from brain metabolism include cytochrome P-450 electron transport, monoamine oxidase activity, and endogenous guanidine compounds. Lipid peroxidation of cellular membranes and the direct oxidation of amino acids leading to inactivation of enzymes, receptors, and structural proteins are the main consequences of oxidative injury (Fig. 11.39A). Increased evidence exists for a role of redox signaling by oxygen radicals that targets mitochondrial cytochrome *c* release, DNA repair enzymes, and transcriptional factor nuclear factor–κβ. Neuronal damage occurs once these physiologic systems are disrupted.[296]

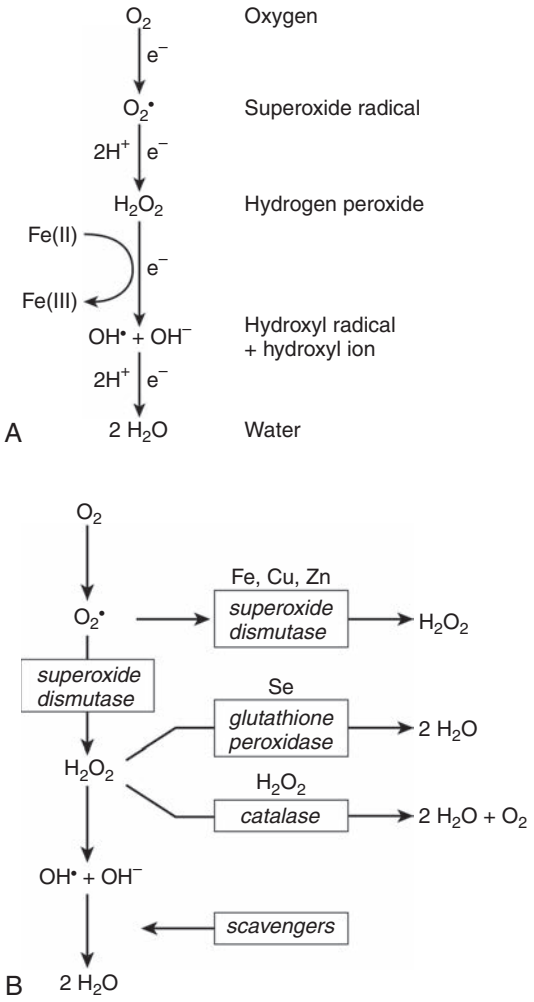

FIG. **11.38** A, Physiologic metabolism of molecular oxygen to water. B, The mechanisms of action of four antioxidant systems. Superoxide dismutase may act as a prooxidant by increasing the formation of hydrogen peroxide and as an antioxidant by decreasing the superoxide radical concentration. Cofactors for superoxide dismutase are iron, zinc, and copper. The cofactor for glutathione peroxidase is selenium.

The main endogenous antioxidants are superoxide dismutase, catalase, glutathione peroxidase (that contains selenium), α-tocopherol (vitamin E), and ascorbic acid (vitamin C) (see Fig. 11.38B and Fig. 11.39B). Another protective mechanism is the existence of iron-binding proteins that keep iron in a less reactive form and prevent iron from catalyzing free radical reactions. Vitamin E reacts directly with OH^- and prevents oxidant injury to polyunsaturated fatty acids and thiol-rich proteins in cellular membranes (see Fig. 11.39B). Insufficient vitamin E may result in oxidative damage and lipid peroxidation of cell membranes and may therefore cause the accumulation of lipopigment. Accumulation of lipofuscin-like pigment is a common feature of experimentally induced vitamin E deficiency in rats and monkeys[297] and in human and equine motor neuron disease.[298] Lipofuscin accumulation in the CNS of ENAD/EDM-affected horses has been reported,[283,290,299] and the amount exceeds the amount found in age-matched controls.[299] Further evidence for oxidative injury within the spinal cord of horses with EDM has been provided by positive immunoreactivity for peroxynitrite (3-NT) and unsaturated

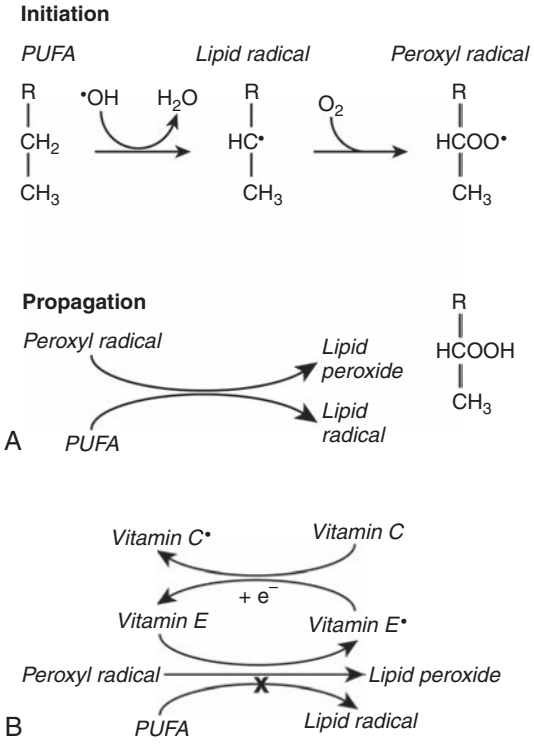

FIG. **11.39** A, Mechanism of peroxidation of polyunsaturated fatty acids in cell membranes. B, Antioxidant mechanisms of α-tocopherol (vitamin E) and ascorbic acid (vitamin C). Polyunsaturated fatty acids are spared from oxidation because vitamin E is oxidized to a free radical instead. This prevents the propagation of lipid peroxidation in cell membranes and is referred to as the *chain-breaking action of vitamin E*. Vitamin C is a reducing agent that donates electrons to free radicals.

aldehyde (4-NHE).[291] These substrates markedly increase in neurons in conditions involving oxidative stress and mediate neuronal apoptosis.

The association between vitamin E deficiency and ENAD/EDM is based on epidemiologic studies, the similarities between ENAD/EDM and vitamin E deficiency in human beings and other animals, the reduced incidence of ENAD/EDM seen after prophylactic treatment with vitamin E, and the response to treatment with vitamin E in affected horses. However, vitamin E deficiency has not been a consistent finding in horses with ENAD/EDM.[300] Two studies have shown a high incidence of ENAD/EDM on farms in which low serum vitamin E concentrations were found, and in both studies affected and unaffected horses were vitamin E deficient.[279,283] Furthermore, vitamin E supplementation decreased the incidence and severity of disease seen in both studies. Another study documented significantly lower vitamin E concentrations and clinical signs compatible with EDM in eight of nine foals sired by an EDM-affected stallion. Age-matched control foals raised in the same environment had normal serum vitamin E concentrations and no signs of EDM. Oral vitamin E absorption tests were performed on both groups, and no significant differences were found between the groups.[284] Thus an inability to absorb vitamin E from the gastrointestinal tract does not appear to be a factor in the low serum vitamin E concentrations in EDM-affected horses.

In horses with EDM evidence has been found for severe axonal transport impairment. Abnormal expression of synaptic proteins and abnormal accumulation of neurofilaments in dystrophic axons has been described in two Arabian horses with EDM.[301] Presynaptic proteins such as synaptophysin, synaptosomal-associated protein 25 kDa (SNAP-25), syntaxin-1, and α-synuclein participate in trafficking, docking, and fusion of the synaptic vesicle to the plasma membrane, facilitating synaptic transmission and exocytosis of neurotransmitter. Findings in this study are similar to what has been reported in dogs with NAD and suggest a loss of synapse and accumulation of synaptic proteins in dystrophic neurons.

Diagnosis

Definitive diagnosis of ENAD/EDM can be made only with histopathologic examination of the spinal cord and brainstem. Antemortem diagnosis is based on clinical signs and ruling out other neurologic diseases (especially CVM and EPM). In ENAD/EDM, CSF analysis and cervical spinal radiographs are usually within normal limits, although increased CSF creatine kinase (CK) levels have been found in horses affected with EDM.[40]

Measuring serum/plasma α-tocopherol concentrations may be unreliable when the animal is examined after the critical deficient period. Moreover, it should be noted that a single serum α-tocopherol sample may not adequately reflect the true vitamin E status of the horse, because up to 12% variation in concentrations can occur normally.[302] However, a low serum/plasma α-tocopherol concentration (less than 1.5 mg/mL) in a horse with clinical signs is supportive of the diagnosis. One can also measure the α-tocopherol concentration in the CSF, which is significantly correlated to the serum[303] and brain tissue concentration.[304] Reference ranges for serum/plasma and CSF α-tocopherol concentrations are available.[305]

Treatment and Prevention

Oral supplementation with vitamin E to genetically susceptible foals in the first year of life may reduce the incidence and severity of disease[279,283,295,299]; however, one of these studies showed that new cases did still occur despite vitamin E supplementation.[279] Typically animals are supplemented at 1000–2000 IU/450 kg/day of vitamin E. There are mixed reports on efficacy of supplementation with vitamin E in affected horses, where some reports suggest improvement of clinical signs after treatment with vitamin E at 6000 IU/day,[306] and others report no effect.[279] Additionally, one study reports improvement of clinical signs after gaining access to fresh grass.[307] The NRC requirements for dietary vitamin E concentrations are 500 to 1000 IU/kg dry weight for a 500-kg horse. Additional supplementation for healthy adult horses appears not necessary.[305] Heat-treated pellets, stored oats, and sun-baked forages have marginal vitamin E concentrations, and horses fed a diet of these or horses kept on dry lots should have frequent access to fresh green forage or vitamin E supplementation to meet their reported needs. Horses with clinical signs of ENAD/EDM may benefit from large doses of vitamin E (6000–10,000 IU/day) for an extended period of time; however, more recent work suggests that this does not lead to resolution of clinical signs.[279] The current recommendation is that a natural RRR-α-tocopherol (nonacetate) form of vitamin E is used to supplement deficient horses with ENAD/EDM because this form is the most biologically available, is the most readily absorbed, and has the most potent antioxidant activity.[305] Vitamin E toxicity associated with supplementation in horses has not been reported, and the risk is considered minimal in horses;

however, adverse effects have been reported with doses greater than 10 times NRC requirements.[305]

Prognosis

Although clinical signs of ENAD/EDM typically appear to stabilize by 2 to 3 years of age, affected horses are neurologically abnormal and often unfit for any performance activity. Generally, horses with ENAD/EDM do not progress to a state of recumbency. Severely affected horses usually have an earlier age of onset and rapid disease progression, whereas mildly affected horses usually have a later age of onset and the disease has a less rapid course.

EQUINE PROTOZOAL MYELOENCEPHALITIS

Yvette S. Nout-Lomas

Equine protozoal myeloencephalitis is a commonly diagnosed condition of the horse, which J. Rooney originally described in 1964 and termed *segmental myelitis.* Later descriptions used the terminology *focal myelitis encephalitis,* recognizing that lesions within the brain occurred.[308] Eventually, an organism that resembled toxoplasma was seen in histologic sections, and in 1976, Dubey first suggested that EPM was caused by a member of the genus *Sarcocystis.*[309] A *Sarcocystis* organism was eventually cultured from the spinal cord of an affected horse and named *Sarcocystis neurona* because it often develops within neurons.[310] Since that time, *S. neurona* or *S. neurona*–like organisms have been cultured from several ataxic horses, as well as numerous other animals including the zebra, domestic cat, Canadian lynx, sea otter, straw-necked ibis, mink, raccoon, and skunk. Another protozoan parasite *(Neospora hughesi)* has also been shown to be a cause of EPM in the horse; however, the majority of cases are because of infection with *S. neurona.*[311-313] The *S. neurona* genome has now been sequenced and annotated, potentially leading to discovery of better diagnostic methods and therapies.[314] Recently a panel of experts has provided a comprehensive review of this disease[315] and up-to-date information on the pathophysiology, diagnosis, and treatment of this clinically important disease in the form of a consensus statement.[313]

Epidemiology

EPM is one of the most commonly diagnosed neurologic diseases of the horse in the Western Hemisphere. Given the complexity of clinical diagnosis, and the difficulty of finding conclusive lesions in the CNS, the true incidence of EPM is difficult to state conclusively. Two older studies reported that 25% of equine neurologic cases were diagnosed with EPM,[40,316] and a national study conducted by the United States Department of Agriculture (USDA/APHIS NAHMS Equine '98 study) in 1998 found an average incidence of 14 + 6 cases per 10,000 horses per year. The overall prevalence was estimated at 0.5% to 1% of the horse population. The lowest incidence was in farm and ranch horses (1 + 1 case/10,000 horses), with 6 + 5 cases/10,000 horses for pleasure horses. A much higher incidence of 51 + 39 and 38 + 16 cases/10,000 horses was seen for competition and racing horses, respectively. An intermediate incidence of 17 + 12 cases was reported for breeding animals. This is similar to the findings of other studies showing racing and showing animals to have a higher risk than breeding and pleasure horses.[317]

Numerous seroprevalence studies have been performed, casting light on the distribution of the infection and life cycle of the organism. Horses in the United States have a variable but generally high seropositive incidence to *S. neurona,* ranging from 15% to 89%, depending on geographic location.[312,313] Seroprevalence increases with increasing age, and an association with temperature whereby the lowest seroprevalence was found in regions with a higher number of days of freezing temperature or during the colder months.[312,315,317,318] Seroprevalence against *N. hughesi* is low and has been reported to vary from less than 3% to 10%.[312,313] A large seroprevalence study recently demonstrated that some horses are seropositive for both *S. neurona* and *N. hughesi.*[312]

All horses are susceptible to the development of EPM, but epidemiologic surveys have suggested that the average age of affected horses is approximately 4 years.[319,320] More than 60% of cases were less than 4 years old, and less than 20% were 8 years or older.[320] Another study found that young horses (1–5 years) and older horses (greater than 13 years) had a higher risk of developing EPM.[317] The age range of reported cases is from 2 months[321] to 24 years.[322] Data from 364 horses with histologically confirmed EPM taken from across the United States and Canada revealed that Thoroughbreds, Standardbreds, and Quarter Horses were most commonly affected, although many other breeds were represented; no gender predilection exists.[320]

Most cases appear to be individual cases, and "outbreaks" of EPM appear to be very rare, although one author has described an epizootic of EPM on a single farm.[323] A report from Ohio, however, did find that previous diagnosis of the disease on the farm increased a horse's risk of subsequently developing EPM (greater than 2.5 times higher).[317] This finding suggests clustering of cases may occur when all the risk factors for EPM are present. Analysis from data collected during the USDA/APHIS NAHMS Equine '98 study[324] and another epidemiologic study[317] demonstrated the following risk factors for EPM:

1. Environmental and management factors that affect exposure to opossums. A higher risk for disease occurs in the fall of the year.
2. Type of housing for horses (decreased risk with pasture housing), stocking density (increased risk with increased numbers of horses), the choice of bedding material (wood products lower odds than straw or corn stalks), or safe storage of concentrate feeds (lower odds at operations that stored feeds in rodent-proof containers).
3. Horses that were used primarily for racing had a greater risk compared with horses used primarily for pleasure. Thoroughbreds, Standardbreds, and Warmblood horses had markedly greater odds of disease compared with Quarter Horses. Young horses had a higher risk of developing EPM than older ones, and recent transportation increased odds of disease.
4. Larger number of resident horses and finding evidence of wildlife on premises increased the risk of EPM. Premises near a marsh/creek/river decreased the risk for EPM.
5. Horses were more than twice as likely to have EPM if they resided in Kentucky, Michigan, Missouri, New Jersey, New York, Ohio, Pennsylvania, and Tennessee.

EPM is a disease of the Western Hemisphere, with cases reported from many states within the United States, as well as Canada, Mexico, Panama, Argentina, and Brazil. Most

horses with a diagnosis of EPM outside this region appear to have spent some time in the endemic area. EPM has been reported in England among horses imported from the eastern United States and in an 8-month-old Arabian horse in South Africa that had been imported from the United States approximately 5 months before the onset of signs.[325] Another report concerned a horse from California that developed clinical signs of EPM after 10 months in Hong Kong.[326] These cases demonstrate the probability of persistent, subclinical, latent infections. However, a few reports exist of neurologic horses with consistent clinical signs, positive immunoblot test results, and no history of travel in the American continent.[327,328] The nature of the infection in these horses is unclear and may be because of cross-reacting antigens.

Immune suppression because of stress or advanced age might predispose a horse to development of EPM. Stressful events such as heavy exercise, transport, injury, surgery, or parturition have all been found to increase the risk of EPM.[317] Racehorses and show horses had a higher risk of developing EPM compared with breeding and pleasure horses. Not surprisingly, horses with EPM that were treated with an anticoccidial drug were 10 times more likely to improve than untreated horses.

Life Cycle

Sarcocystis spp. belongs to the phylum Apicomplexa, which includes several genera of coccidia that use an obligatory predator-prey or scavenger-carrion life cycle.[329] *Sarcocystis* spp. produce sporulated oocysts by sexual reproduction (gametogony) in the gut wall of the appropriate predator or definitive host. Infective sporocysts are introduced into the food and water supply of the prey animal or intermediate host by fecal contamination from the predator. In the *S. neurona* life cycle, the definitive host is the opossum, whereas the intermediate hosts are skunks, raccoons, and armadillos, among others. Once ingested by the intermediate host, sporocysts excyst, releasing four sporozoites that penetrate the gut and enter arterial endothelial cells in various organs. Meronts develop rapidly and eventually rupture the host cell, releasing merozoites into the bloodstream, which usually is followed by a second round of merogony in capillary endothelial cells throughout the body. Second-generation merozoites are released into the bloodstream and usually enter skeletal muscle cells, where they develop into specialized meronts known as *sarcocysts.* Mature sarcocysts contain bradyzoites, which are able to complete the life cycle only when ingested by the appropriate predator or scavenger.

S. neurona may infect a large number of intermediate hosts aberrantly, unlike most *Sarcocystis* spp. Several species of animals and birds have been reported to exhibit signs similar to those in horses with EPM. This feature made the experimental elucidation of the *S. neurona* life cycle quite challenging. At the present time, domestic cats *(Felis domesticus),* nine-banded armadillos *(Dasypus novemcinctus),* striped skunks *(Mephitis mephitis),* raccoons *(Procyon lotor),* and sea otters *(Enhydra lutris nereis)* are considered to be viable intermediate hosts. Feeding studies, as well as epidemiologic and seroprevalence data, have determined this. Initially the domestic cat was thought to be only a laboratory intermediate host; however, several epidemiologic studies have now incriminated domestic cats as natural intermediate hosts.[330] The life cycle of *S. neurona* has been completed in a laboratory setting.[331] The horse has traditionally been considered an aberrant, dead-end host, in that sarcocysts have never been reported. One report, however, describes mature sarcocysts that were well characterized as *S. neurona* and found on the tongue of a horse suffering from EPM.[332] This suggests that horses can be intermediate hosts but requires further confirmation.

Horses are infected with *S. neurona* by ingesting food or water that has been contaminated with feces from an infected opossum. Some evidence suggests that the organism may be transmitted by methods other than direct contact with opossum feces. It has been suggested that birds may mechanically disseminate sporocysts and that secondary transmission via "pass-through" of infective sporocysts in the feces of budgerigars, canaries, mice, and chickens fed opossum feces has occurred. At least some organisms appeared to retain viability and infectivity after transit through the digestive tract.[333] This is most likely to be a laboratory phenomenon; its importance in nature is unknown but likely to be small. Importantly, *S. neurona* is not transmitted horizontally among horses, nor can it be transmitted to horses from nonequine intermediate hosts. Antibodies against *S. neurona* in foals before suckling have been reported,[334,335] but current evidence indicates that transplacental or lactogenic transmission of *S. neurona* is very uncommon or absent.[313,315]

The life cycle of *Neospora hughesi* in horses is understood poorly. The definitive host of *N. caninum* has been demonstrated to be the dog,[336] but whether the dog is the definitive host of *N. hughesi* is not known. Tachyzoites, as well as tissue cysts, have been found in other horse tissues in two of the horses reported to have EPM caused by *Neospora* spp.[337] Vertical transmission of *N. caninum* is very efficient in cattle, and several recent studies indicate that *N. hughesi* can be transmitted transplacentally in horses.[335,338]

Pathogenesis

Despite the often-high rate of exposure to the organism, only a small percentage of horses develop clinical illness. This suggests that immune clearance of the parasite is very effective but that unknown factors must exist in certain cases to allow clinical disease to be expressed. Parasite dose is likely to be a factor, and in fact this has been experimentally demonstrated.[339] Other factors that have been considered to have a role in the induction of EPM include physiologic stress associated with shipping, training, showing, and pregnancy that may make animals more susceptible to EPM.[317] Indeed, one reliable model of inducing EPM incorporates long-range shipping as a stressor, performed immediately before infection.[340] Other attempts to induce EPM using the oral infection route that do not incorporate stressors such as shipping have led to inconsistent and only mild illness.[341] The assumption is that these stressors lead to some degree of immune suppression, which is a commonly implicated factor in protozoan parasite infections. However, treatment of horses with immunosuppressive doses of steroids associated with oral infection with *S. neurona* did not result in significantly worse histopathologic changes in the CNS, although clinical signs were slightly more severe than in non–steroid-treated horses.[341] Additional evidence for the role of physiologic stress is found in the observation that stressed horses develop more severe clinical signs than naturally infected (nonstressed) horses.[342] It thus appears likely

that stress has a role in the development of EPM; however, the interaction is complex and not fully understood at this time. Further, genetic variation has been observed among the strains of *S. neurona* that have been analyzed,[343,344] and although there is evidence that specific parasite genotypes may be particularly virulent in marine mammals,[345] such an association has not been found in isolates from horses clinically affected by EPM. Recent studies have demonstrated differences among isolates in the expression of surface receptors, which may have substantial implications for immunodiagnosis.[346]

After infective sporocysts of *S. neurona* are passed from the definitive host and subsequently ingested by a horse, infection proceeds. Clinical disease results from the inflammation and neuronal necrosis associated with infection of the CNS with live organisms. The mechanisms by which *S. neurona* enters the CNS are unclear but are thought to involve either infection of endothelial cells or leukocytes.[347-350] One hypothesis is that *S. neurona* organisms that have been phagocytosed by leukocytes in the periphery are transported across the blood-brain barrier in the process of normal immune surveillance. Once within the CNS, the organisms proliferate. This "Trojan horse" hypothesis of CNS infection is attractive and has support from experimental work in which clinical disease can be induced by administering horses autologous lymphocytes, which have been infected with *S. neurona*.[348] There does not appear to be "targeting" of the CNS by the organism; rather the organism is not cleared from the CNS tissue while it is cleared elsewhere. Once organisms enter the CNS, it is likely that the immunosuppressive environment of the CNS plays a role by diminishing clearance of the organism in this immune-privileged tissue. The parasite itself may also induce some immunosuppression.

Resistance to *Sarcocystis neurona* is presumed to be the result of the combined effects of humoral and cellular immunity. After infection, a relatively rapid production of antibodies occurs. In horses challenged with live *S. neurona* organisms orally, all horses seroconverted within 32 days,[341] whereas in another study, horses challenged with a larger number of organisms seroconverted by day 13 after infection (if stressed by transport) and by day 30 if unstressed.[340] It has been demonstrated with various apicomplexan parasites that antibody is at least partially protective.

Although the effects of circulating antibody are likely to be very important, cell-mediated immunity is necessary for the elimination of intracellular forms of most organisms. Mouse studies have confirmed the importance of CD8+ T cells in protection against *S. neurona* encephalopathy in that species; it is presumed to be similar in horses. Endothelitis and meningoencephalitis developed in CD8 knockout mice after challenge with *S. neurona,* highlighting the importance of this cell subset in protection against *S. neurona,*[351] at least in the mouse. The CD8+ T cell is one important source of interferon-gamma (IFN-γ), which is critical for protection against *S. neurona*–induced neurologic disease in mice.[315,352] Infection of IFN-γ knockout mice leads to fulminant neurologic disease. These findings support the critical importance of IFN-γ in protection against *S. neurona.* Recent research demonstrated that *S. neurona*–infected horses have altered immune cell subset expression and immune cell function that changes during disease progression. *S. neurona* infection alters the ability of antigen-presenting cells to stimulate CD4+ and CD8+ proliferation, and the data suggest that the process between antigen-presenting cells (monocyte/dendritic cells) and/or T-cell antigen recognition may be impaired in *S. neurona*–infected horses.[350]

Pathology

Confirmation of disease is through demonstration of protozoa in CNS lesions. However, the diagnosis is frequently made presumptively when organisms are not detected if the characteristic inflammatory lesions are found.[313] Gross lesions consist of multifocal areas of hemorrhage in the acute setting and foci of malacia and areas of discoloration ranging from pale to dark tan in the subacute to chronic phase.[315] Lesions are most commonly seen in the spinal cord. The brainstem is more often involved than other parts of the brain, and, in rare cases, lesions are found in both spinal cord and brain. Microscopically, lesions are characterized by focal to diffuse areas of nonsuppurative inflammation and necrosis with perivascular infiltration of mononuclear cells, including lymphocytes, macrophages, and plasma cells. Giant cells, eosinophils, and gitter cells also are present in inflammatory infiltrates. Gray or white matter (or both) is affected. Organisms have been found in neurons, leukocytes, and vascular endothelium, although they tend to develop most often in neurons.

Clinical Signs

The clinical signs associated with *S. neurona* infection vary from acute to chronic with insidious onset or focal or multifocal signs of neurologic disease involving the brain, brainstem, or spinal cord. Clinical signs are variable, which reflects the random distribution of the lesions that may occur within the CNS. Signs of gray matter involvement include focal muscle atrophy and severe muscle weakness, whereas damage to white matter frequently results in ataxia and weakness in limbs caudal to the lesion.

Usually the physical examination is within normal limits, and the horse appears bright and alert, although one may observe focal muscle atrophy. Neurologic examination typically reveals asymmetric ataxia, weakness, and spasticity involving all four limbs. The most common signs of brain/brainstem involvement are obtundation, head tilt, facial nerve paralysis, and difficulty swallowing. Abnormal airway function, unusual lameness, and seizures are also sometimes seen, and visual deficits and behavioral abnormalities have also been reported. A typical history is a slowly progressive ataxia, which may initially have been identified as a musculoskeletal disorder, since early signs may include stumbling and frequent interference between limbs. Commonly horses exhibit a gradual progression in severity and range of clinical signs. Sometimes clinical signs stabilize and then relapse days or weeks later, and sometimes a gradual onset of clinical signs suddenly worsens, resulting in recumbency. Occasional acute and rapidly progressive disease is seen; empirically this presentation seems more commonly associated with brainstem disease, although this has not been formally evaluated.

The presence of ataxia, asymmetry, and atrophy (the "three *A*'s of EPM") suggests multifocal or diffuse disease, which is characteristic of, although not pathognomonic for, EPM. Less commonly observed are diseases of the cerebrum, cerebellum, or brainstem resulting in a variety of cranial nerve deficits including dysphagia, head tilt, tongue or master paralysis, or masseter atrophy. The clinician needs to recognize that all of the clinical signs listed previously may be caused by conditions other than EPM, all of which should be considered in the differential diagnosis.

Diagnosis

An important point to remember is that EPM is an easy diagnosis to make but difficult to substantiate and confirm in a live patient. Experts recommend the following steps to be taken before a diagnosis of EPM is rendered.[313]

1. A thorough neurologic examination must reveal clinical signs arising from disease of the nervous system that are consistent with EPM as described previously.
2. Other conditions that could give rise to the clinical signs observed should be ruled out to the degree possible. This may require radiographs of the cervical spine or head, nuclear scintigraphy, CSF evaluation, or testing for EHV, for example. These tests will be determined based on a careful physical and neurologic examination, as well as a consideration of the horse's history and progression, risk factors, and related information.
3. Immunodiagnostic testing of serum and CSF should be conducted to confirm intrathecal antibody production against *S. neurona* or *N. hughesi.*

At the present time there are several immunodiagnostic tests in use for EPM diagnosis. These tests are all based on detection of antiprotozoal antibodies in serum, CSF, or both. EPM only occurs in a small portion of horses infected with *S. neurona* so serologic testing has minimal diagnostic value unless test results are negative (low positive predictive value, high negative predictive value). A negative serum test usually indicates that the horse has not been infected; however, a recently infected horse may display clinical signs before seroconversion, and retesting in 10 to 14 days is recommended. Detection of antibodies in the CSF alone is not a definitive indicator of EPM because there is passive transfer of antibody across a healthy blood-brain barrier and blood contamination of CSF samples can cause false-positive results.[353,354] Intrathecal antibody production, indicative of active parasite infection in the CNS, can be determined by tests of proportionality that assess whether the amount of pathogen-specific antibody in the CSF is greater than should be present from normal passive transfer across the blood-brain barrier. The Goldman-Witmer coefficient (C-value) and the antigen-specific antibody index (AI) are such tests.[313,354]

The immunodiagnostics that have been developed over the years include a Western blot, a direct agglutination test, an indirect fluorescent antibody test (IFAT), and enzyme-linked immunosorbent assays (ELISAs) based on single or multiple *S. neurona* surface antigens (SnSAGs). The first test developed to aid in the diagnosis of EPM was immunoblot analysis (Western blot) of serum and CSF to provide antemortem information regarding exposure to *S. neurona.*[355] The test uses cultured merozoites to detect antibodies directed against proteins considered unique to *S. neurona.* Antibodies produced to proteins shared with *S. fayeri* or other organisms found in North America can be differentiated with this test. False-positive results are obtained through hemorrhage occurring in the brain or through blood contamination of CSF samples. In an effort to differentiate false-positive CSF antibody tests, a number of techniques have been described, including determination of the albumin quotient (AQ) and the IgG index; however, the sensitivity of these tests appeared to be too low, and their use is no longer recommended as a diagnostic aid for EPM.[356] False-negative results have been rare but may occur. The possible causes of false-negative responses are important to consider so that one does not misdiagnose affected horses. Some horses simply may fail to respond to the *S. neurona*–specific proteins identified by the immunoblot. Horses that initially tested positive have become negative after several weeks of treatment and apparently have recovered. A chronically affected horse may test negative and still be infected, or the horse still may exhibit neurologic signs. Persistent neurologic damage (i.e., scarring) may be present in some cases, resulting in permanent neurologic damage in the absence of active infection. One should retest acute cases that initially test negative in 2 to 3 weeks. However, the incubation period appears to be sufficiently long to allow production of detectable amounts of IgG before the onset of clinical signs in most cases.

A whole organism IFAT was developed and is currently available from the University of California Diagnostic Laboratory.[357] Serum titers of greater than 1:100 and CSF titers of greater than 1:5 are considered positive and diagnostic of active infection. This test is considered to be robust in the presence of blood contamination of the CSF sample. However, the superiority of the IFAT as a diagnostic for EPM is not clearly established and it has been demonstrated that the test was unable to differentiate between *S. neurona* and *S. fayeri* (a nonpathogenic *Sarcocystis*) infection.[358]

Most recently the SnSAG ELISAs, quantitative (end-point titer) tests based on *S. neurona* surface antigens, have been evaluated as a diagnostic tool.[354,359,360] These surface antigen molecules have proven to be good serologic targets in the assays because of their high level of expression in the parasite and their immunogenicity in infected horses. The SnSAG2 ELISA and the SnSAG4/3 ELISA accurately detect antibodies against *S. neurona* in equine serum and CSF samples,[361,362] and although none of the tests described here is considered a gold standard,[313] most recent studies suggest the SAG2, 4/3 ELISA serum:CSF titer ratio, should be utilized for antemortem testing for EPM.[359,360] A study that used 59 sets of samples from 57 horses compared the SnSAG ELISAs to the IFAT and showed that using serum alone was least accurate, and that the overall accuracy was highest for the SnSAG2, 4/3 ELISA with a titer ratio set at 0.97. The sensitivity was 0.88 and the specificity was 1. The IFAT CSF and titer ratio results also showed high accuracy at 0.88 but lower sensitivity at 0.65.[359] Another study confirmed the value of detecting intrathecal antibody production, and the authors showed excellent diagnostic sensitivity and specificity obtained from the SnSAG2, 4/3 serum:CSF titer ratio with sensitivity and specificity of 93.2 and 81.1%, respectively, using a ratio cutoff of ≤100. If a more rigorous cutoff of ≤50 was used sensitivity and specificity were 86.4% and 95.9%, respectively.[313] Two studies have also shown that modest blood contamination of the CSF, up to 10,000 RBCs/L, will have minimal effect on SnSAG2 test results.[353,354]

There is an NhSAG1 ELISA and an IFAT available for immunodiagnostic testing for *Neospora hughesi.* Neither one of these tests has been fully validated for EPM diagnosis because of inadequate number of samples from EPM cases caused by this parasite.[313]

As previously noted, most horses with EPM do not show constitutional signs of illness, such as fever, depression, or anorexia. Changes in the CBC are not recognized, and changes in serum biochemistry analysis are not noted, unless the severity of the neurologic signs is such that the horse falls or is recumbent, or it is dysphagic and cannot drink or eat. In these

horses, secondary changes in the serum biochemistry panel may be seen.

A key part of the diagnosis of EPM is ruling out other conditions that may be present; evaluation of CSF is necessary for this process. Conditions such as intrathecal hemorrhage, neoplasia, meningitis, neuroborreliosis, and verminous encephalitis can be ruled out when evaluating EPM suspects using CSF analysis. CSF analysis should be considered a key part of the full diagnostic evaluation of horses with CNS disease. Most horses with EPM have normal CSF cytology. Early work identified the occasional increase in RBC count; however, in more recent times this finding has been considered to be spurious and a result of unrecognized blood contamination from the collection. The severe and fulminant case may have a mildly increased total protein or white blood cell count, but these situations are rare.

Differential Diagnosis

Given the variety of clinical abnormalities that may be expressed in horses with EPM, the differential diagnosis includes virtually all diseases of the equine CNS. However, the results of a careful history, physical examination, and neuroanatomic localization help to limit the number of rule outs and guide further diagnostic efforts. The most common and likely rule out is probably cervical vertebral compressive myelopathy (CVCM). In contrast to EPM, CVCM usually results in symmetric gait deficits, which are worse in the pelvic limbs and are characterized by spasticity and hypermetria, with good retention of strength and no muscle wasting.

Infectious diseases such as WNV encephalitis, equine encephalitis (eastern equine encephalitis [EEE] and western equine encephalitis [WEE]), and equine herpesvirus–1 (EHV-1) may all cause neurologic disease that could resemble EPM. Horses affected with these conditions are typically systemically ill, demonstrating fevers and alterations in the leukogram. The neurologic deficits of EHV-1 are fairly characteristic in that dysuria is a common component that is not often seen in horses with EPM. CSF cytology is abnormal in most such cases (e.g., WNV, EEE, EHV-1), in contrast to EPM, and a variety of specific diagnostic tests exist for each of these conditions, such as IgM capture ELISA for WNV and PCR testing for EHV-1.

Polyneuritis equi and ENAD/EDM may also be confused with EPM and can have signs of multifocal disease, ataxia, and muscle atrophy. Less common conditions, such as verminous encephalitis, bacterial meningitis, or CNS abscessation, can be seen, but alterations in the leukogram and the CSF are usually present, distinguishing these cases from EPM.

Treatment

The cornerstone of treatment for horses with EPM is antiprotozoal medication. At the present time the Food and Drug Administration (FDA) has approved a number of compounds for the treatment of EPM. The first compounds used for the treatment of EPM were the sulfonamide drugs combined with pyrimethamine to achieve a synergistic effect. Clinical efficacy studies have been performed using sulfadiazine (20 mg/kg) and pyrimethamine (1 mg/kg) orally once per day, marketed and FDA approved as Re-Balance (PRN Pharmacal). Using this dose in well-characterized cases of EPM, the overall success rate (e.g., improvement by one clinical grade) is 60% to 70%.[313,363] The duration of treatment varied between 90 to 270 days, and complications of this drug regimen were reported as anemia (22%), leukopenia (19%), and neutropenia (5%).[363] These signs are usually self-limiting and resolve with cessation of treatment. Folic acid supplementation has been advised by some authors to limit the degree of anemia; however, no support for this practice exists, and research has demonstrated increased toxicity when folic acid supplementation is provided. Hence its use is discouraged. Use of sulfadiazine in breeding animals is controversial, although one study has shown no effect on pregnancy rates or early embryonic death.

The first FDA-approved drug for the treatment of EPM was ponazuril (Marquis, Bayer Animal Health) to be administered as an oral paste. Ponazuril is a member of the benzeneacetonitrile compounds, which have demonstrated broad-spectrum anticoccidial activity in many avian and mammalian species. These drugs are related to the herbicide atrazine and are thought to target the parasite's apicoplast organelle. Ponazuril is well absorbed orally and within 3 days achieves a therapeutic steady-state concentration in the CSF of horses treated with 5-mg/kg body weight.[364] A field efficacy study of 101 horses with well-characterized EPM and treated with ponazuril demonstrated successful treatment in 60% of treated animals, success defined as improvement by at least one neurologic grade. A 90-day relapse rate of 8% after the termination of treatment was found.[365] Animals typically responded within 10 days and often continued to improve even after treatment stopped at 28 days.

Diclazuril is chemically similar to ponazuril and is also a member of the benzeneacetonitrile compounds. Diclazuril is FDA approved as Protazil, antiprotozoal oral pellets to be administered as a top dressing. In one study, treatment of EPM-affected horses with diclazuril resulted in improvement in 58% of the treated animals, when given for 28 days.[363] Because ponazuril and diclazuril are highly selective against apicomplexan parasites, little to no toxicity is to be expected at therapeutic doses.

Regardless of the drug used, the duration of treatment necessary and when to stop treatment are considerations in all EPM cases. Duration of treatment depends on response to antiprotozoal administration, and although the FDA-approved products are labeled for a treatment course of 28 days, the majority of horses with EPM are treated for a longer period of time, generally 6 to 8 weeks or longer if clinical improvement is still apparent.[313] Attempting to treat until the horse is negative on immunodiagnostic testing is currently not recommended.[313] Other treatments that have been investigated or used in the past have been reviewed elsewhere.[315,366]

Administration of nonsteroidal antiinflammatory drugs, corticosteroids, and dimethyl sulfoxide is justified in certain conditions—for example, to prevent worsening of neurologic signs during the early antiprotozoal treatment or in horses that are in danger of falling down or exhibit signs of brain disease. Similarly, vitamin E is sometimes used; however, some information suggests that this may not be efficacious if the horse is not vitamin E deficient.[305] Furthermore, some people include immunomodulators in the treatment of this disease based on the thought that horses with EPM may be immune compromised; however, there are no studies to evaluate efficacy of this practice.[313]

Relapses are a concern and are probably dependent on a number of factors, including the exact drug and dose used and the duration of treatment. Extended dosing may reduce the occurrence of relapse.[363] The relapse rate for horses treated for 28 days with ponazuril was 8%, when examined 90 days after cessation of therapy.[365] Relapse rates for the other drugs are not reported. Relapse implies that the horse responded well to the initial drug treatment; hence horses that relapse can be treated with the same drug that was initially used but for a longer period.

No studies have been conducted to determine the effectiveness of the currently approved antiprotozoal medications against *N. hughesi.* Ponazuril has demonstrated in vitro effectiveness against *N. caninum.*[367,368] Ponazuril (5 mg/kg body weight, once per day for 28 days) was used in three horses with *N. hughesi* EPM. All three horses showed clinical improvement, and one showed complete resolution.[369]

The prognosis for horses diagnosed with EPM appears to be similar regardless of the treatment used, because most reports suggest an approximate improvement rate of 60% to 75% with the standard therapy.

Prevention

The widespread distribution of the parasite and the variety of intermediate hosts make control of EPM complicated. A vaccine was available, but it has been removed from the market because of failure to demonstrate efficacy. Decreasing stress and preventing contamination of feed and water with opossum feces is essential to prevent EPM in the horse. Opossums can produce millions of sporocysts that can be excreted in feces for months. Sporocysts are resistant to environmental influences, and most commonly used disinfectants do not kill *S. neurona* sporocysts.[315] Practical approaches including not feeding off the ground, providing separate sources of fresh water for horses and preventing wildlife access to horse pastures, paddocks, and stalls may also help reduce the incidence of protozoal infections in horses.[313]

Monitoring high-risk age groups such as young and old horses closely for evidence of neurologic disease may help detect EPM early. That EPM may be the cause of the clinical signs when horses are presented for treatment of neurologic disease in the warmer months should raise the index of suspicion. Because many major horse competitions take place in the fall of the year, monitoring of horses before transport and competition may be helpful. Close monitoring of broodmares close to foaling and horses that develop a major illness or injury is important, because it may help early diagnosis of EPM cases.

Intermittent use of coccidiostatic and coccidiocidal drugs is another approach used to prevent EPM. Two studies that evaluated prophylactic use of ponazuril showed that daily or intermittent treatment minimized but did not eliminate infection in horses experimentally infected with *S. neurona.*[370,371] Recently it was shown that the daily administration of a low-dose diclazuril pellet top dressing to healthy foals from a farm with a high exposure rate to *S. neurona* significantly reduced the monthly seroprevalence to *S. neurona* compared with untreated foals.[372,373] This preventive strategy has the potential to be used in high-risk horses in an attempt to reduce the incidence of EPM, although future longitudinal studies will be required before establishing a standard protocol.[313]

EQUINE HERPESVIRUS–1 MYELOENCEPHALOPATHY

EHV-1 is an economically important pathogen of horses and exerts its major effect by inducing abortion storms or sporadic abortions in pregnant mares, early neonatal death in foals, and respiratory disease in young horses.[374-381] Myeloencephalopathy is an uncommon manifestation of EHV-1 infection but can cause devastating losses during outbreaks on individual farms, racetracks, veterinary hospitals, or boarding stables.[382-384] Although EHV-4 rarely causes clinical manifestations of disease in organs other than the respiratory tract, isolated cases of myeloencephalopathy and sporadic abortions have been reported in EHV-4 infections.[374-376,385,386] Clinical signs of neurologic disease reflect a diffuse multifocal myeloencephalopathy after vasculitis, hemorrhage, thrombosis, and ischemic neuronal injury. Sudden onset and early stabilization of signs including ataxia, paresis, and urinary incontinence; involvement of multiple horses on the premises; and a recent history of fever, abortion, or viral respiratory disease in the affected horse or herdmates are typical features, although considerable variation exists between outbreaks concerning epidemiologic and clinical findings.[387] Prevention is difficult because many horses are latently infected with EHV-1, allowing the virus to circulate silently in horse populations, and current vaccines do not confer protection against neurologic manifestations of infection.[381,388] The distribution of lesions that can result after infection with neurotropic EHV-1 results in the need to include many conditions on the differential diagnosis list, including EPM, cervical vertebral instability, cervical stenotic myelopathy, vertebral or CNS trauma, polyneuritis equi, fibrocartilaginous emboli, aberrant parasite migration, degenerative myelopathy, togaviral encephalitis, rabies, botulism, toxins, and other disorders.

Virologic Findings

Of the five distinct herpesviruses that are known to infect horses, three are typical α-herpesviruses with a double-stranded DNA genome and are designated EHV-1 (equine abortion virus, formerly known as *EHV-1, subtype 1*), EHV-4 (equine rhinopneumonitis virus, formerly known as *EHV-1, subtype 2*), and EHV-3 (equine coital exanthema virus), and two are γ-herpesviruses, designated EHV-2 (formerly called *equine cytomegalovirus*) and EHV-5 (which has recently been associated with interstitial pulmonary disease).[375,376,389-391] In addition, three asinine α-herpesviruses (AHV1, AHV2, and AHV3) have been isolated from donkeys. Of these, AHV3 has been shown by many criteria to be related closely to EHV-1. Indeed, EHV-1 and AHV3 are related more closely to each other than either is to EHV-4.[375,391-393] Phylogenetic analysis and epidemiologic evidence suggest that EHV-1 recently has been derived from AHV3 and that donkeys may remain an alternate host for EHV-1, serving as a reservoir to infect horses.[389,391]

EHV-1 and EHV-4 are distinguishable from EHV-2, EHV-3, and EHV-5 by biologic properties and virus neutralization tests (and distinguishable from each other by restriction endonuclease fingerprinting of DNA, DNA sequences, and several immunologic tests based on monoclonal antibodies to each virus).[374-376,389,390,394] EHV-1 and EHV-4 produce eosinophilic intranuclear inclusion bodies in infected cells in vivo and in vitro. Several strains have been identified within EHV-4 and

EHV-1, although the epidemiologic, immunologic, and pathogenic significance of this finding is not known. The 1-p and 1-b subtypes of EHV-1 likely are capable of inducing neurologic disease. Apart from differences in endotheliotropism, genetic and antigenic fingerprinting and experiments in baby mice have not yielded clear markers distinguishing EHV-1 strains that induce neurologic disease or abortion (or both).[389,395-399] However, a recent analysis of EHV-1 isolates from neurologic and nonneurologic disease outbreaks revealed a point mutation within the DNA polymerase gene that was strongly associated with neuropathogenic disease.[400,401] A hamster model has been described showing some potential for discrimination between abortigenic and neuropathogenic EHV-1 strains.[402]

Epidemiology and Immunity

EHV-1 and EHV-4 are enzootic in most horse populations, and the majority of horses show serologic evidence of exposure to these viruses. Most horses become infected via the respiratory tract with EHV-1 or EHV-4 (or both) during the first year of life. After an incubation period of 2 to 10 days, clinical signs of respiratory disease of variable severity develop and resolve within 1 to 2 weeks in uncomplicated cases.[374-376] Resolution of clinical signs is coincident with development of virus-specific neutralizing antibody directed primarily against surface viral glycoproteins. The development of cell-mediated responses is probably critical for recovery.[403] Resistance to reinfection with homologous virus is demonstrable after recovery but generally persists for only 3 to 4 months. Subsequent infections typically induce milder clinical signs or subclinical infection, although virus shedding from the nasopharynx occurs.[374,375] The immune response frequently is not successful in clearing herpesviral infection, and the majority of clinically recovered horses remain latently (asymptomatically) infected with EHV-1 or EHV-4 (or both) for life.[374,375,404,405] EHV-1 has been shown to evade the host immune system in part by downregulating major histocompatibility complex class I expression at the cell surface. This process may be a prerequisite to the establishment of latency.[406]

Recrudescence of latent infection is important in the epidemiology of EHV-1 and EHV-4 and explains why these diseases can occur in closed populations without the introduction of new horses.[374,375,405,407] Signs of EHV-1 infection may occur in the horse in which stress-associated recrudescence of infection has occurred, or the horse may remain asymptomatic but shed infectious virus in nasal secretions to infect other horses. Natural infection with EHV-1 occurs by inhalation or ingestion of aerosolized infective virus or by direct contact with virus shed in the products of abortion or in the nasal and ocular discharges and saliva of horses with overt clinical disease, subclinically infected horses, or shedding carrier horses.[374,375,394] Infectious EHV-1 virus was detected in the feces of experimentally infected foals that developed diarrhea, suggesting that fecal spread is a possibility.[408] Virus may be shed by clinically affected and inapparently infected horses for 3 weeks or more, and EHV-1 may remain infective in the environment for up to 14 days and on horse hair for 35 to 42 days.[375,409,410]

The first definitive association between EHV-1 and myeloencephalopathy was made in 1966 in Norway with the isolation of the virus from the brain and spinal cord of a horse that showed signs of severe neurologic dysfunction.[411] The myeloencephalopathic form of EHV-1 infection now is considered to have a worldwide distribution, having been recognized in Denmark, The Netherlands, Germany, Sweden, Austria, Britain, Ireland, Australia, India, the United States, and Canada.[382,383,387,398,412,413] In view of the ubiquitous occurrence of EHV-1 infection in horse populations, outbreaks of EHV-1 myeloencephalopathy are rare. In many instances, cases of neurologic EHV-1 infection occur in association with outbreaks of abortion or respiratory disease, although some outbreaks occur in the absence of other manifestations of EHV-1 infection and without the introduction of new horses into the group.[394,407,414,415]

The myeloencephalopathic form of EHV-1 infection may occur as sporadic individual cases or, more often, as outbreaks involving multiple individuals over a period of several weeks on one or more premises within a limited geographic region. Secondary or tertiary waves of clinical disease may occur as previously unexposed horses become infected from a common source over a short period.[383,394,416,417] There has been an increased reporting of occurrences of EHV-1 myeloencephalopathy[418] in congregations of horses around the United States. Most of these outbreaks have been associated with a mutant strain of herpesvirus, which appears to replicate rapidly, leading to a very high level of viremia and an apparent increased incidence of neurologic manifestations of this disease.[400,401,419] Morbidity rates ranging from less than 1% to almost 90% of exposed individuals and mortality rates ranging from 0.5% to 40% of in-contact horses have been reported. Neurologic EHV-1 infection can occur at any time of year, but the highest incidence is in the late winter, spring, and early summer, perhaps reflecting the seasonal occurrence of abortigenic EHV-1 infections during the same months.[219]

The neurologic form of EHV-1 infection has been observed in pregnant mares, barren mares, geldings, stallions, and foals, although foals frequently do not show neurologic manifestations of infection during outbreaks that involve severe neurologic disease in adult horses.[382,416] The disease also appears to less commonly affect pony breeds. Pregnant mares and mares nursing foals appear be at increased risk for developing neurologic manifestations of EHV-1 infection, and the stage of gestation may be important in determining the outcome of infection in pregnant mares.[377,382,416,420,421] Mares infected during the first 2 trimesters of gestation appear to be more likely to develop neurologic signs without abortion, whereas mares infected during the last trimester are more likely to abort without showing neurologic signs.[377,394,420,422,423]

All breeds of horses are susceptible to the neurologic form of EHV-1 infection, and other Equidae also may be affected. EHV-1 was the suspected cause of myeloencephalopathy that developed in a zebra 1 week after an in-contact onager *(Equus hemionus onager)* aborted an EHV-1 infected fetus.[424] The authors are unaware of reports of neurologic EHV-1 affecting donkeys and mules, although donkeys and mules have shown seroconversion indicating infection with EHV-1 while in contact with affected horses during outbreaks.[425-427] Indeed, donkeys and mules returning from a show were thought to be responsible for dissemination of EHV-1 and propagation of multiple outbreaks of neurologic EHV-1 infection in Southern California in 1984 (and in several subsequent years), suggesting that a donkey-adapted variant of EHV-1 with an increased neuropathogenicity for horses may have been involved.[427]

A modified live EHV-1 vaccine of monkey cell line origin was associated with neurologic disease in 486 of 60,000 recipients, prompting its withdrawal from the U.S. market

in 1977.[406] No reports of EHV-1 myeloencephalopathy have been associated with use of the modified live vaccine currently approved for use in horses in the United States.

Pathogenicity and Pathogenesis

Natural infection with EHV-1 occurs by inhalation or ingestion, after which the virus attaches to and rapidly replicates in cells of the nasopharyngeal epithelium and associated lymphoreticular tissues, causing necrosis, exudation, and infiltration of phagocytic cells. Bronchial and pulmonary tissues also become infected, particularly in foals, thus predisposing them to secondary bacterial pneumonia.[374,375,394,403,428] Migration of virus-infected phagocytes into the circulation results in viremia associated with mononuclear cells (primarily T lymphocytes) of the buffy coat.[374,375,394,429] The immunologically privileged intracellular location of the virus appears to protect it from inactivation by circulating antibody and permits dissemination to other tissues, including the CNS, even in the presence of high levels of antibody.[430] EHV-1 is capable of spreading directly from one infected cell to contiguous cells without an extracellular phase.[394] Vascular endothelium is the initial site of infection in the CNS and appears to be the predilection site for replication of EHV-1 after transfer of the virus from circulating leukocytes.[377,431,432] Viremia, which may be of prolonged duration, can occur during primary and all successive infections with EHV-1, even when no clinical signs are apparent; thus all EHV-1 infections pose a threat of inducing neurologic disease or abortion.[374,382]

The acute onset of clinical signs of EHV-1 myeloencephalopathy appears to result from vasculitis and thrombosis of arterioles in the brain and especially the spinal cord. This causes functional impairment of blood flow and metabolic exchange and, in severe cases, hypoxic degeneration and necrosis (malacia) with hemorrhage into adjacent neural tissues of the white and, to a lesser extent, gray matter. This proposed pathogenesis, based primarily on interpretation of the prominent vasculitis seen histopathologically in infected horses and the lack of definitive evidence of viral multiplication in neural tissues, contrasts greatly with the well-established pathogenesis of encephalitis caused by herpesviruses in other species.[389] The propensity of certain EHV-1 isolates to induce myeloencephalopathy does not appear to reflect specific neurotropism but rather a significant endotheliotropism. The finding of chorioretinopathy and neural lesions in experimentally infected specific pathogen-free ponies, however, suggests that at least some strains of EHV-1 may exhibit neurotropism.[433] Furthermore, strong evidence indicates that in addition to circulating T lymphocytes, epithelial cells of the respiratory tract, and lymphoid tissues draining the respiratory tract, trigeminal ganglia are important sites for establishing and maintaining the lifelong state of latency that occurs in most, if not all, horses during primary infection with EHV-1 and EHV-4.[388,433-435] The ubiquitous EHV-2 has been proposed to play an important role in promoting reactivation of EHV-1 and EHV-4 from these sites in latently infected horses.[404]

No satisfactory explanation exists as to why some outbreaks of EHV-1 infection are associated with a high incidence of neurologic disease, whereas others are not, or why different horses show different clinical manifestations of EHV-1 infection during outbreaks.[382,383,417,436] A genetic strain of EHV-1 with an adenine-to-guanine mutation at the open reading frame 30, causing a mutation in the DNA polymerase, is associated with replicative aggressiveness and a greater potential for causing neurologic disease.[419] The nature and extent of lesions resulting from EHV-1 infection appear to be influenced by the age, gender, reproductive status (including stage of pregnancy), and immune status of the horse; the magnitude of challenge; strain variations; and perhaps the route of infection.[382,436,437] In one carefully monitored outbreak of EHV-1 infection on a stud farm in England, less than 17% of infected horses developed neurologic manifestations of infection, even though almost 60% of the horses on the farm were confirmed to have been infected.[382] Endothelial cell infection and perivascular cuffing within the CNS appeared to be at least as pronounced in foals that died during this outbreak without showing neurologic signs as in profoundly paretic mares with severe CNS lesions; however, parenchymal neural lesions were minimal in the foals.[382,436] A notable finding during this outbreak was that mares and stallions that developed neurologic signs had considerable antibody responses, whereas the majority of foals did not, despite experiencing a prolonged period of viremia.[382]

The majority of EHV-1 infections that cause neurologic signs probably represent reinfection rather than a new infection.[412,438,439] Infection occurs in horses with significant preexisting serum EHV-1 antibody titers. Affected horses frequently have high titers at the onset of neurologic signs, and those horses that develop the most severe clinical signs are frequently the ones that show the most rapid increase in antibody titer after infection.[77,382,421] In addition, the characteristic vascular lesions in neural tissues of affected horses are typical of type III (Arthus) hypersensitivity reactions, and circulating immune complexes have been demonstrated at the onset of neurologic signs, suggesting that they may result from an immune-complex vasculitis. An immune-mediated mechanism is supported further by the difficulty experienced in isolating the virus from neural tissues of affected horses.[413,414,436] In addition, assessment of risk factors during outbreaks of neurologic EHV-1 infection in Southern California in 1984 revealed that horses vaccinated with killed or modified live EHV-1 vaccine within the previous year were significantly (9–14 times) more likely to develop neurologic manifestations of infection than were nonvaccinated horses.[427]

The finding of circulating antibodies to the myelin protein P2 in the serum of horses that died from EHV-1 myeloencephalopathy (but not in horses that recovered) has led to the suggestion that an alternate immune-mediated mechanism may play a role in the pathogenesis of neurologic EHV-1.[440] The presence of this antibody, however, may represent a response to leakage of the protein after damage induced by another mechanism.

Despite the foregoing observations, evidence for an immune-mediated pathogenesis for EHV-1 myeloencephalopathy is by no means conclusive. In experimental EHV-1 infections in which the onset of neurologic signs 8 to 9 days after infection correlated with a peak in the level of circulating immune complexes, vasculitis was not present in vessels in which endothelial cells did not support viral replication or in organs such as the kidney that one would expect to trap circulating immune complexes.[431] The finding of greatly depressed platelet counts several days before the onset of clinical signs, presumably the result of consumption in thrombi after endothelial damage, suggests that the neuropathologic changes are initiated before circulating immune complexes peak and

that the action of immune complexes may be secondary and localized. Failure to isolate the virus from the CNS may be attributable to high levels of circulating antibody and to the endotheliotropism of the virus.[431]

Clinical Signs

In natural and experimental infections, neurologic signs appear 6 to 10 days after infection by the intranasal route. The onset of neurologic signs may be preceded or accompanied by signs of upper respiratory disease, fever, inappetence, or hindlimb edema within the previous 2 weeks, although in many instances no antecedent signs are notable unless one routinely monitors rectal temperature. However, frequently one finds a herd or stable history of current or recent cases of respiratory tract infection, fever, inappetence, distal limb edema, abortion, neonatal death, foal diarrhea, or neurologic disease, and for one to encounter different signs of EHV-1 infection in different groups of horses on a particular farm is not unusual.[382]

Affected horses are occasionally febrile at the onset of neurologic disease, although most are normothermic and some are hypothermic. Neurologic signs are generally of acute or peracute onset, after which they tend to stabilize rapidly and generally do not progress after the first 1 or 2 days.[219,412,416,420,441] Clinical signs vary depending on the location and severity of lesions, but in most horses, signs reflect predominant involvement of the spinal white matter.[219] Ataxia and paresis of the limbs are the most common signs, with hypotonia of the tail and anus, tail elevation, and urinary incontinence being common but not invariable findings. Clinical signs are usually bilaterally symmetric or only mildly asymmetric, although hemiparesis or sudden onset of unilateral hind- or forelimb lameness progressing to unilateral or more generalized ataxia, paresis, and recumbency have been reported.[219,442-445] Lesions in peripheral nerves and spinal cord were observed in some of these cases.[442] The hindlimbs generally are affected more severely and earlier in the disease course than the forelimbs. In mildly affected horses, transient ataxia and stiffness of the pelvic limbs or dribbling of urine after overflow from a distended atonic bladder may be the only signs noted.[219,420] One may note conscious proprioceptive deficits in these cases as reluctance to move, clumsiness, toe dragging, knuckling, stumbling, pivoting, and circumduction in one or more limbs on circling, with spasticity evident in some cases.[44,52,85] These signs are often subtle and may go unnoticed. More severely affected horses show profound limb weakness and swaying of the hindquarters, and a small proportion show complete paralysis of affected limbs, manifested as paraplegia and sitting like a dog, complete recumbency, or tetraplegia.[219,382,394,446]

Distention of the urinary bladder is common and may cause signs of colic or dribbling of urine, which frequently results in scalding of the perineum, legs, and other areas.[426] Cystitis is a frequent complication, particularly when repeated catheterization is necessary to relieve bladder distention.[441] Affected stallions and geldings may develop penile flaccidity and paraphimosis or repeated erections, whereas mares may develop vulvar flaccidity. In addition, stallions may experience reduced libido and swelling of the testes.[382,436] Scrotal edema may accompany hindlimb edema at the onset of neurologic signs in some cases.[382,416,420,423,436] Sensory deficits are uncommon, but perineal hypalgia or analgesia has been noted, and analgesia of the caudal half of the body was observed in one affected horse.[219,412,420,446] Consistent with predominant involvement of the white matter of the spinal cord, flexor reflexes are normal and perineal reflexes are preserved. In recumbent horses, spinal tendon reflexes can be tested and may be increased. Atrophy is rarely seen, even in the later stages of the disease.[219] Affected horses usually remain alert and have good appetites, even when recumbent, although some show modest depression and inappetence.[416,447] Severe depression, when it occurs, is more often caused by secondary complications than by brain involvement.[447] Unequivocal signs of brain disease are rare, although infarction of the brainstem may cause depressed sensorium, altered behavior, and cranial nerve damage leading to vestibular signs and to lingual, mandibular, and pharyngeal paresis, which may manifest as dysphagia.[422,445,447-449] Strabismus, nystagmus, circling, and head tilt have been observed on occasion.[219,387,422,446]

Affected horses show variable progression of clinical signs. Those horses that are affected mildly frequently stabilize rapidly over a period of hours to a few days as edema and hemorrhage resolve; generally they recover completely over a period of days to several weeks.[382,383,412,416,417] If recumbency occurs, it generally does so during the first 24 hours, with some horses showing such complete motor paralysis that they are unable to lift their heads.[442] Severely affected horses may show progression of signs during the first few days and may die in coma or convulsion or be euthanized because of secondary complications.[382]

Laboratory Findings

CSF analysis typically, although by no means always, reveals xanthochromia, an increased protein concentration (100–500 mg/dL), and increased AQ (ratio of CSF to serum albumin concentration), reflecting vasculitis and protein leakage into CSF. The white blood cell count in CSF is usually normal (0–5 cells/μL) but occasionally is increased. Abnormalities in CSF are not present at the onset of clinical signs in some horses, and changes resolve rather quickly; thus the CSF may be normal within 2 weeks of onset of clinical signs.[219,377,441]

The presence of antibodies to EHV-1 in the CSF of affected horses strongly suggests a diagnosis of EHV-1 myeloencephalopathy, although such antibodies are absent in many cases.[219,377,387,422,450] One should take into account the albumin concentration, IgG concentration, and EHV-1 antibody titer in serum and CSF when interpreting positive antibody titers in CSF.[451] Because the AQ usually is elevated in affected horses and the IgG index is normal, the presence of EHV-1 antibodies in CSF reflects leakage of protein across a damaged blood-brain or blood-CSF barrier after vasculitis rather than intrathecal antibody production.[440,450,451] Antibodies therefore are more likely to be present in the CSF of affected horses with concomitantly high serum titers.[219,377,440,450,451] Blood contamination during collection of CSF and other diseases that cause an increase in the permeability of the blood-brain barrier or bleeding into the subarachnoid space may elevate CSF antibody titers falsely if serum titers are also high. Isolation of EHV-1 from the CSF of affected horses would confirm a diagnosis but is rarely successful.[219,426]

Virus isolation and identification of EHV-1 from nasopharyngeal swabs or buffy coat samples strongly support a diagnosis of EHV-1 myeloencephalopathy in a horse with compatible clinical signs and should be attempted by submission of nasopharyngeal swabs in viral transport medium

and an uncoagulated blood sample (citrated or heparinized). Diagnosis may be achieved more rapidly using real-time PCR for identification of EHV DNA from nasopharyngeal swabs or buffy coat samples. The likelihood of isolating EHV-1 during outbreaks of neurologic disease increases by monitoring in-contact horses and collecting nasal swab and buffy coat samples during the prodromal febrile phase before neurologic signs develop.[416] Even so, interpretation of positive results can be confusing because EHV-1 and EHV-4 have been isolated from the respiratory tract of normal horses.[409] Application of new diagnostic methods such as polymerase chain reaction (PCR), in situ hybridization, antigen-capture ELISA, and dot immunobinding to nasal swabs or scrapings, buffy coat samples, or pathologic specimens have improved the speed and specificity greatly with which one can diagnose EHV-1 infection.[452-460] Many conventional PCR protocols targeting specific genes of EHV-1 have been published in recent years for molecular detection of EHV-1 in nasopharyngeal swabs or buffy coat samples.[405,455-459] Although considerable progress has been made in developing PCR protocols for clinical use, quality control of nucleic acid amplification techniques remains an ongoing challenge because of lack of protocol standardization among laboratories.[461] Furthermore, the majority of PCR assays targeting genomic EHV-1 DNA are unable to differentiate between a lytic and a latent infection. Novel technologies such as real-time PCR that allow quantitation of viral DNA and detection at the level of gene expression likely will feature prominently as molecular diagnostic approaches to EHV-1 infection are refined further in the future.

Serologic testing that demonstrates a fourfold or greater increase in serum antibody titer using serum-neutralizing or complement fixation tests on acute and convalescent samples collected 7 to 21 days apart provides presumptive evidence of infection. Many horses with EHV-1 myeloencephalopathy, however, do not show a fourfold rise in serum-neutralizing titer, and some actually show a decline.[426] This may be explained by the finding that when antibody titers rise, they do so rapidly within 6 to 10 days of infection and already may have peaked by the time neurologic signs appear. Although serologic testing has limitations in confirming a diagnosis of EHV-1 myeloencephalopathy in an individual horse, testing of paired serum samples from in-contact horses is recommended because a significant proportion of affected and unaffected in-contact horses seroconvert, providing indirect evidence that EHV-1 is the causative agent. Interpretation of the results of serologic tests is complicated by the fact that the serum-neutralizing, complement-fixation, and ELISA tests in use at most diagnostic laboratories do not distinguish between antibodies to EHV-1 and EHV-4 because of cross-reaction between these viruses. A specific ELISA test based on the C-terminal portion of glycoprotein G of both viruses has been developed and should prove valuable in the investigation and management of disease outbreaks in the future.[462-464]

Diagnosis

The multifocal distribution of lesions results in variability of clinical presentation, which necessitates inclusion of a number of conditions in the differential diagnosis. These conditions include EPM, cervical stenotic myelopathy, and cervical vertebral instability (wobbler syndrome), cervical vertebral fracture or other CNS trauma, neuritis of the cauda equina, fibrocartilaginous infarction, aberrant parasite migration, degenerative myelopathy, other viral encephalitides (flaviviruses and alphaviruses), rabies, botulism, CNS abscess, and a variety of plant and chemical intoxications.[219,387] Sudden onset and early stabilization of neurologic signs including ataxia, paresis, and urinary incontinence; involvement of multiple horses on the premises; and a recent history of fever (most consistently reported clinical sign before onset of ataxia), abortion, or viral respiratory disease in the affected horse or herdmates are sufficient to make a tentative diagnosis of EHV-1 myeloencephalopathy.[387] Antemortem diagnosis is supported by ruling out other conditions; demonstrating xanthochromia and elevated protein concentration in CSF; identifying EHV-1 in or isolating EHV-1 from the respiratory tract, buffy coat, or CSF; and demonstrating a fourfold increase in antibodies using serum-neutralizing, complement fixation, or ELISA tests performed on acute and convalescent serum samples collected from affected or in-contact horses 7 to 21 days apart.[383,417,465] Antemortem confirmation of a diagnosis of EHV-1 myeloencephalopathy is frequently not possible, however, particularly when an individual horse is affected, because the foregoing tests do not yield consistent results in all cases. Hematologic abnormalities with EHM are inconsistent but may include mild anemia and lymphopenia, followed by increased plasma concentration of fibrinogen.

Treatment and Prognosis

Because EHV-1 is a contagious and potentially devastating infection, horses suspected of being affected should be isolated promptly and strictly until EHV-1 is ruled out by confirmation of an alternate diagnosis.[447] No specific treatment is available; thus management of horses with EHV-1 myeloencephalopathy aims toward supportive nursing and nutritional care and reduction of CNS inflammation.[387] One should encourage horses that are not recumbent to remain standing and should protect them from self-inflicted trauma by the provision of good footing, such as a grass paddock, by placement of food and water in an accessible location at a convenient height above ground level, and by other measures, including the use of padded hoods and elimination of obstacles. Patients that become recumbent should be maintained in a sternal position on a thick cushion of dry absorbent bedding and should be rolled frequently (at least every 2–4 hours) to reduce the risk of myonecrosis and decubital ulcers. Whenever possible, one should lift and support the horse in the standing position using an appropriately fitting sling.[383] Slings are most beneficial for moderately affected horses that are too weak to rise but are able to maintain a standing position with minimal assistance.

Affected horses usually maintain a good appetite, even when recumbent, although hand feeding may be necessary to encourage some horses to eat. Maintenance of hydration is important, and provision of a laxative diet or the administration of laxatives such as bran mashes, mineral oil, or psyllium may be necessary to reduce intestinal impaction. One usually can meet the caloric and water needs of anorectic patients by feeding gruels of alfalfa-based or similar pelleted feeds in water or balanced electrolyte solution via nasogastric tube. If oral intake is insufficient to meet the daily water needs of 60 to 80 mL/kg of body mass per day, one can maintain hydration by intravenous administration of balanced electrolyte solutions.[219] Partial or total parenteral nutrition can also be used to meet the caloric needs of anorectic, recumbent horses.

If affected horses are unable to stand and posture to urinate or if bladder function is impaired significantly, manual evacuation of the bladder by application of pressure per the rectum may be necessary. If these measures are unsuccessful, judicious urinary catheterization is indicated and should be performed aseptically with the collection tubing attached to a sterile closed bag to minimize the risk of inducing urinary tract infection.[387,446,447] Cystitis is, however, a frequent complication, particularly in recumbent horses, and can lead to bladder wall necrosis, bladder rupture, and systemic sepsis. Urine scalding can become a major problem, particularly in mares that dribble urine. Prevention involves regular washing of the perineum, tail, and hind legs with water, application of water-repellent ointments, and braiding or wrapping the tail to simplify cleaning.[387] Administration of enemas or manual emptying of the rectum also may be necessary to promote defecation and improve patient comfort.[387]

Because vasculitis, hemorrhage, and edema are prominent early lesions and may have an immune basis, treatment with corticosteroids early in the disease course is recommended by some clinicians, although no objective data are available to document the efficacy of these or other antiinflammatory drugs.[219,416,447] A short course of treatment with prednisolone acetate (1–2 mg/kg/day) or dexamethasone (0.05–0.25 mg/kg parenterally twice daily) for 2 to 3 days with decreasing doses over another 1 to 3 days may be beneficial.[219,387,446] Flunixin meglumine (1.1 mg/kg body mass every 12 hours) is indicated to treat CNS vasculitis. DMSO at a dose of 0.5 to 1.0 g/kg administered intravenously as a 10% to 20% solution in normal saline or 5% dextrose once daily for up to 3 days commonly is used to treat horses with suspected CNS trauma or inflammatory disease, such as EHV-1.[384,387] Although the efficacy of DMSO for treating herpesvirus myeloencephalopathy has not been evaluated, its reported ability to inhibit platelet aggregation and scavenge free radicals supports its continued use. Because of the high risk of development of cystitis and other secondary bacterial infections, administering broad-spectrum antibiotics such as potentiated sulfonamides (trimethoprim-sulfamethoxazole 30 mg/kg body mass orally every 12 hours) or ceftiofur (2.2 mg/kg body mass intramuscularly or intravenously every 12 hours) is advisable, particularly when corticosteroid treatment is used.[19,383,387] One should base the choice of antibiotics for treating established secondary bacterial infections of the urinary tract, respiratory tract, or other areas on the results of culture and susceptibility testing.

Acyclovir, a synthetic purine nucleoside analog with inhibitory activity against several human herpesviruses, has been shown to exert an inhibitory effect on EHV-1 in vitro.[466] Apparent efficacy of acyclovir was suggested by a successful treatment outcome in occasional outbreak situations.[417,467] Although these anecdotal reports seemed promising, data describing the pharmacokinetics, bioavailability, and safety of acyclovir in horses do not support claims of efficacy, especially after oral administration. Bioavailability of acyclovir after oral administration to horses is extremely low; in contrast, bioavailability of valacyclovir, a prodrug for acyclovir, is much higher.[468,469] Clearly, additional studies are needed to define the appropriate dose for valacyclovir in horses and to document its efficacy for the treatment of EHV-1 myeloencephalopathy. Another nucleoside analog, penciclovir, has been shown to have excellent activity against EHV-1 in tissue culture and in a mouse model of EHV-1 infection.[470]

Affected horses that remain standing have a good prognosis for recovery, and improvement generally is apparent within a few days, although a period of several weeks to more than a year may be required before horses with severe deficits show complete recovery. In these instances, control of urination frequently returns before gait abnormalities resolve completely.[447] Some horses may be left with permanent residual neurologic deficits, including urinary incontinence and ataxia, that may necessitate euthanasia many months beyond onset of neurologic signs.[219,383,425,426] Horses that become recumbent have a greatly increased likelihood of developing complications such as myonecrosis, urinary tract infection, decubital ulcers, respiratory tract infection, gastrointestinal obstruction and ulceration, injuries, and complications of dehydration and malnutrition. Their prognosis for recovery is therefore poor, particularly if they remain recumbent for more than 24 hours and they are unable to stand after being lifted with a sling.[382,383] One should not elect euthanasia prematurely in valuable horses, however, because reports document horses standing again and recovering completely to race successfully after being recumbent for several days to 3 weeks.[416,423,442] Most mildly affected mares return to breeding soundness in the same season, whereas fertility is likely to be compromised in more severely affected mares that experience urinary retention.[382] Recurrence or exacerbation of neurologic signs in horses that have recovered completely has not been documented, even though the majority likely remain latently infected.[219,394,407,447]

Pathologic Findings

When horses with suspected EHV-1 myeloencephalopathy die or are euthanized, one should submit the whole carcass or at least the head, spine, spleen, thyroid, and lung for postmortem examination because lesions frequently are not confined to the CNS of horses with EHV-1 myeloencephalopathy.[471] Gross pathologic lesions in the CNS frequently are not found, but small (2–6 mm) focal areas of hemorrhage distributed randomly throughout the meninges and parenchyma of the brain and spinal cord may be observed. More diffuse dural hemorrhage is notable in some cases and may extend to spinal nerve roots and the cauda equina.[377,421,414] Small plum-colored areas of degeneration and hemorrhage are sometimes grossly visible in fresh tissue at various levels of the spinal cord (white matter), and malacic foci may be visible macroscopically in the gray and white matter in sliced fixed sections of brain.[377,414,421,423,428]

The gross and histologic lesions in the CNS reflect vasculitis, congestion, and secondary ischemic degeneration of nervous tissue. Although vasculitis is a consistent finding, degeneration of nervous tissue is evident chiefly in those horses with clinical signs of severe neurologic disease.[377,421,436] The vasculitis is often severe and has a widespread, random, multifocal distribution, with the most severe lesions usually in the brainstem and spinal cord. In the brain the meningeal and penetrating or radiating vessels in gray matter are the major sites of vascular involvement. Thus foci of axonal swelling and malacia develop in the gray and white matter, particularly adjacent to the meningeal surface and in the deep cortex adjacent to the white matter.[377,421,414] In the spinal cord a similar orientation to meningeal vessels results in degeneration of white matter within ovoid, linear, or wedge-shaped foci, affecting predominantly the lateral and the ventral white columns.[377] In some instances, sheaths

of nerve roots and nerves and capsules of ganglia also are involved.[219,377,421,436] Trigeminal ganglionitis might be present but usually is not manifest clinically.[442]

Ocular lesions, including uveal vasculitis with perivascular mononuclear cell cuffing in the ciliary body and optic nerve or extensive retinal degeneration, have been observed in foals showing signs of bilateral hypopyon and iritis or severe visual impairment and chorioretinopathy without anterior segment involvement during field and experimental EHV-1 infections.[377,382,414,433,436] In some foals, EHV-1 appears to induce ocular and neural damage in the absence of gross signs of neurologic or visual impairment.[433] During paralytic infections, secondary viral replication occurs in blood vessels of the testis and epididymis in addition to CNS and may be responsible for reported signs of scrotal edema and loss of libido in affected stallions.[382,472]

EHV-1 infrequently is isolated from the CNS of affected horses that show typical lesions. Thus one should attempt to isolate the virus from other sites to support the diagnosis. Those sites most likely to yield virus or to contain viral antigen include the turbinates and nasal passages, as well as lymph nodes draining the upper respiratory tract, lung, thyroid, spleen, and endometrium, in addition to the brain.[219,436,473] Immunofluorescent antibody testing of brain and spinal cord sections is considered to be more sensitive than virus isolation, but false-negative results have been observed.[219,413,436] An indirect immunoperoxidase method using orthodox light microscopy was highly sensitive for identifying individual antigen-containing cells in the CNS and other areas of the body, even at sites containing few or no lesions or inclusion bodies and in which virus could not be detected by immunofluorescent antibody testing or virus isolation.[436] Similarly, the PCR technique is more sensitive than virus isolation for detecting viral antigen in nasopharyngeal swabs collected from horses with respiratory tract disease caused by EHV-1 or EHV-4.[455] Both of these techniques—as well as antigen-capture ELISA tests, dot immunobinding, and in situ DNA hybridization, which are sensitive and readily differentiate between EHV-1 and EHV-4—show great promise for routine application to samples collected antemortem or at necropsy from affected horses.[432,436,453,456,460]

Control and Prevention

Control measures during outbreaks of EHV-1 infection aim at reducing spread by infectious aerosols, direct contact, and fomites, as well as at reducing stress-induced recrudescence of latent EHV-1 infection.[374,375,394] If neurologic signs or other clinical signs suggestive of EHV-1 infection occur, one should isolate affected animals promptly and completely in a well-ventilated airspace separate from the remainder of the herd. In-contact horses should be isolated in their current location in small groups for at least 1 month; pregnant mares should be isolated preferably until they foal.[374-376,382,394,416,449] On breeding farms, one should suspend covering.[382] Aborted fetuses and fetal membranes are rich sources of infectious virus; therefore they should be collected and placed in leak-proof containers (e.g., heavy-gauge plastic bags) for submission for diagnostic evaluation or disposal by burning.[374,375] Similarly, bedding and dirt contaminated with fetal fluids should be disposed of or burned, and stalls or other areas occupied by infected horses should be cleaned thoroughly, disinfected with an iodophor or a phenolic product, and left empty for several weeks.[394] Equipment used to handle, groom, feed, water, muck out, or transport affected horses also should be cleaned and disinfected or disposed of properly. Thereafter separate equipment and personnel should be used for affected and unaffected horses, or at least caretakers should handle affected horses last and wear disposable gloves, surgical masks, and protective clothing that can be changed or disinfected between groups.[394] Although control measures are frequently successful in stopping further spread of infection during outbreaks, one should note that transmission of infection before control measures are implemented may result in a secondary wave of disease 1 to 2 weeks later.[382,394,416]

Traffic of horses and human beings on the premises should be minimized, and movement of horses onto and off of the infected premises should be suspended until at least 3 weeks after resolution of acute signs in the last clinical case or until tests show that virus transmission is no longer occurring.[374-376,387,394] Collection of nasal swabs and uncoagulated blood (buffy coat) samples from clinically affected and exposed horses within each group and demonstration of stable or declining antibody titers in serum samples proved to be helpful in determining patterns of exposure and spread and in establishing when virus transmission had ceased in one reported outbreak. Protracted viremia lasting several weeks or months occurs in some horses and extends the period during which movement of horses should be restricted.[382]

If horses must enter the farm, they should be current on EHV-1 vaccination and should be isolated away from the resident population. Although giving booster vaccinations to exposed pregnant mares during outbreaks of abortigenic EHV-1 infection is common practice,[374,375,394] vaccination of exposed horses during outbreaks of EHV-1 myeloencephalopathy has not been investigated and cannot be recommended at this time because of the possibility of an immune-mediated pathogenesis. Administering booster doses of inactivated EHV-1 vaccine to all unexposed horses that have not been vaccinated within the previous month is common practice, however.

Preventive measures should include routine management practices aimed at reducing the chances of introducing and disseminating infection.[376,394,444,474] New arrivals should be isolated for at least 3 weeks before joining the herd, distinct herd groups should be maintained based on the age and use of horses, and care should be taken to minimize or eliminate commingling of resident horses with visiting or transient horses. In particular, pregnant broodmares should be maintained in groups separate from the remaining farm population. In addition, minimizing stress associated with overcrowding and handling procedures is prudent in an attempt to reduce recrudescence of latent EHV-1 infection.[394,407,444,474]

No method is known that reliably prevents the neurologic form of EHV-1 infection. None of the EHV-1 or EHV-4 vaccines currently available carries a claim that they prevent EHV-1 myeloencephalopathy, and the disease has been observed in horses vaccinated regularly at 3- to 5-month intervals with inactivated or modified live vaccines.[219,387,417,426,448] Repetitive administration of currently available EHV-1 and EHV-4 vaccines appears to induce some immunity to respiratory disease and reduce the incidence of abortion but does not block infection and induction of viremia or eliminate the possibility of clinical disease and establishment of the carrier state.[374,375,394,448,474-479] Although the protection induced by inactivated EHV-1 vaccines is incomplete and of short duration, the vaccine reduces virus excretion in horses that do

become infected.[476,479] To maintain appropriate vaccination procedures in an attempt to reduce the incidence of other manifestations of EHV-1 infection and reduce the magnitude of challenge experienced by in-contact horses is logical. This indirectly may help prevent EHV-1 myeloencephalopathy.[219] An attenuated live virus vaccine based on the temperature-sensitive and host range mutant clone 147 of EHV-1 has been evaluated recently. The novelty of this vaccine lies in the fact that a low dose administered intranasally replicated in conventional target species and conferred exceptional efficacy against respiratory disease, virus shedding, viremia, and abortion caused by a severe EHV-1 challenge.[480-482] Intranasal vaccine also claims to protect against less common manifestations of EHV-1 infection such as paresis and jaundice.[381]

POLYNEURITIS EQUI

Polyneuritis equi is an uncommon neurologic disease of all equine species that is characterized by tail and anal sphincter paralysis, often accompanied by cranial and peripheral nerve damage.[4,483-493] Previous reports referred to the disease as *neuritis of the cauda equina* because of the susceptibility of this region, but frequent involvement of the cranial and peripheral nerves led to the term *polyneuritis equi*.[375] Although the disease has been recognized more readily in Europe, where Dexler first reported it in 1897, cases have now been reported in Great Britain, Canada, and the United States.[485,486,488,494] The disease does not appear to have a breed, gender, or age predilection, but the youngest horse affected was 17 months of age.[484,487,488,494,495]

The cause of this disease is unknown. Primary immune reaction and viral inflammatory disease have been suggested, although possibly one may be a consequence of the other.[484] Several infectious agents have been suggested, such as EHV-1, equine adenovirus, and streptococcal and *Campylobacter* spp. bacteria.[491,493,496] The pathologic lesions resemble those of Guillain-Barré syndrome in human beings, and the disease is similar to experimental allergic neuritis in rats.[491] Evidence suggests that the immune system is involved because horses with polyneuritis equi have circulating antibodies to P2 myelin protein, which is present in rats with experimental allergic neuritis.[491,497] Inflammatory lesions contain both T and B lymphocytes, suggesting the possibility of an immune-mediated reaction to myelin.[495,498]

Clinical Signs

Although the disease manifests itself in two forms, signs are generally slow and progressive: (1) the acute or early signs include hyperesthesia of the perineal or head regions (or both), and (2) in the chronic form, horses show paralysis of the tail, anus, rectum, and bladder. Paralysis often is accompanied by fecal and urinary retention, urinary scalding of the pelvic limbs, and penile paralysis in male horses.[4,483-485,488,490,493]

The pelvic limb signs are often symmetric, whereas the signs involving the head and cranial nerves are often asymmetric.[488] Muscle atrophy in the gluteal region is sometimes present along with mild degrees of ataxia.[484,485,487,488,490] Muscle atrophy associated with cranial nerve involvement may occur in the head region. Damage to peripheral motor nerves might result in gait deficits and abnormal use of thoracic or pelvic limbs.[483,493]

Although cranial nerve involvement is reported primarily to affect cranial nerves V, VII, and VIII, any of cranial nerves II, III, IV, VI, IX, X, and XII also may be involved.[4,484,486,487] As a result of damage to the cranial nerves, horses might have trouble with mastication and swallowing.[493] A head tilt, ear droop, lip droop, and ptosis are common signs.[4,493] One report describes a horse with brachial neuritis along with involvement of cranial nerves V, VII, and XII. The horse in that report also exhibited mild ataxia and weakness in all limbs. The horse performed the hopping test poorly on the right thoracic limb, and the horse resented palpation in the right caudal cervical and prescapular region.[484]

Colic caused by fecal retention may be the primary sign when one initially examines horses with polyneuritis equi. Fecal retention leads to an impaction caused by the flaccid anal sphincter, often accompanied by an atonic, distended bladder.[483] If the clinician sees these signs in the acute or hyperesthetic form, they usually progress to hypalgesia or anesthesia. An area of hyperesthesia might surround the area of anesthesia.[4,483,484]

Diagnosis

The definitive diagnostic test is a postmortem examination. Blood work might be normal or reveal a mature neutrophilia with hyperfibrinogenemia, mild to moderate anemia, and an increased total protein—all indications of a chronic inflammatory process.[485,487] Results of CSF are variable and nonspecific, ranging from mild mixed mononuclear to primarily neutrophilic pleocytosis, with normal to increased protein concentrations (70–300 mg/dL). There could be a mixed pleocytosis with predominance of lymphocytes and marked lymphoid reactivity supportive of humoral response to inflammation.[495] Cytologic examination of CSF might be normal in the acute stage of disease.[4,484,485,487,488,492]

Radiography might be helpful to rule out trauma to the tailhead or cranial nerve involvement, such as a fractured petrous temporal or other bones of the skull.[4,484]

Some horses with clinical signs exhibit circulating serum antibodies to P2 myelin.[491,497] However, the presence of this antibody is only weakly supportive of the diagnosis because the same antibody has been detected in horses with EHV-1 and equine adenovirus infections.[440,483,491,496]

Classically, the primary pathologic lesions involve the extradural nerve roots but also might involve the intradural nerve roots.[484,485,487,493] The lesions are granulomatous with various degrees of inflammation and infiltration of lymphocytes, eosinophils, macrophages, giant cells, and plasma cells. This inflammation leads to myelin degeneration, subsequent axonal degeneration, and thickening of the epineurium, endoneurium, and perineurium with proliferation, which causes obliteration of the neural architecture by the fibrous tissue.[483,484,490] The most severe lesions are in the cauda equina, but swelling, edema, and hemorrhage of cranial nerves may occur. The fibrous tissue formation might lead to adhesions between the meninges and the periosteum of the vertebral bodies. Reports describe involvement of the autonomic nervous system, but no changes in clinical signs have been reported (postmortem only).[484,486]

The polyneuritis lesions are similar to those observed with Guillain-Barré syndrome in human beings, experimental allergic neuritis in rats, and coonhound paralysis in dogs.[484,487,492,493] This similarity might indicate a combination of inflammatory and immune-mediated mechanisms in the pathogenesis of polyneuritis equi.

Differential Diagnosis

The most important differential diagnosis is trauma to the sacrococcygeal area of the spinal canal, which can be differentiated by radiography of the area looking for fractures or displacements.[4,484,488] EPM is the second most common disease in the differential diagnosis of polyneuritis equi. The usual signs of EPM include asymmetric multifocal signs of brain and spinal cord injury causing cranial nerve deficits with alterations in mentation, whereas the cranial nerve deficits of polyneuritis equi are peripheral, with no change in mentation or behavior.[313,488]

EHV-1 myeloencephalitis should be another rule out of polyneuritis equi. However, signs of fever in the acute stage of EHV-1 infection does not develop in horses with polyneuritis equi. This condition frequently affects more than one horse on a farm. Herpesvirus has a rapid onset with ataxia as a predominant or common sign, which is usually not the case in horses with polyneuritis equi. Urinary incontinence can commonly develop in horses with EHV-1 infection along with ataxia and pelvic limb neurologic deficits. The ataxia and weakness are usually symmetric and might result in recumbency. Occasionally, affected horses sit like a dog because of profound pelvic limb weakness. Cranial nerve involvement is not common but might occur in between 10% and 15% of affected horses.[375,421,471,499]

One should consider verminous myeloencephalitis as a differential diagnosis for polyneuritis equi. The signs vary and depend on the migratory pathway of the parasite. Diffuse or multifocal brain and spinal cord lesions have been reported. The onset is usually sudden, with rapid deterioration and death. The incidence of this disease is low, perhaps because of more intense parasite control.[248,500,501]

One should consider EMND in the differential diagnosis. Horses with motor neuron disease have symmetric muscle wasting or atrophy and weight loss with significant weakness, sweating, and muscle fasciculations. However, these horses are usually not ataxic, and their unique clinical feature is that they walk better than they stand. This disease is a denervation atrophy of both muscle fiber types (1 and 2) with a predominance of type 1 muscle fibers. The diagnosis is through a spinal accessory nerve biopsy or sacrodorsalis caudalis muscle biopsy.[502] However, any muscle containing both fiber types is useful for diagnosis.

Treatment

The primary therapy is palliative. No treatment for the disease is known. Removing feces from the rectum and evacuating the bladder are usually necessary. If cystitis caused by bladder distention occurs, systemic antibiotics might be indicated. Some attempts have been made at treating the inflammation with corticosteroids, but the effects have been short lived. The prognosis is poor. Some animals might be maintained for a few months.

ACQUIRED EQUINE POLYNEUROPATHY IN SCANDINAVIA

Monica Aleman

Acquired equine polyneuropathy (AEP), also known as Scandinavian knuckling syndrome, is characterized by acute onset of bilateral pelvic limb digital extensor dysfunction and knuckling.[503,504] Ataxia is not a feature of this polyneuropathy. The disease has been described in horses of various breeds during the months from December to April in Sweden, Norway, and Finland. The estimated prevalence of disease on farms in Norway and Sweden is 27% with a case fatality rate of 29%. Duration of clinical signs in survivors varies from 1 to 17 months (median 4.4 months). Survivors can return to full work within 19 months (median 6.6 months). Younger horses have a greater chance of survival than older horses. However, the disease was less prevalent in horses over 12 years old according to an epidemiologic study.[503] The exact etiology of disease is unknown but suspected to be forage-related toxicity. Histologic lesions consist of inflammatory demyelinating polyneuropathy and intracisternal Schwann cell inclusions.[505]

NEUROMUSCULAR DISORDERS

The neuromuscular system is an important part of the nervous system. This system has central and peripheral components. The central components include motor neurons located in the central nervous system (brain [nuclei of cranial nerves III–VII, IX–XII] and spinal cord). Its peripheral part includes all structures located outside the brain and spinal cord. The peripheral nervous system can be classified into two major functional systems: afferent or sensory and efferent or motor systems. The neuromuscular system is composed of motor units. A motor unit consists of a single lower motor neuron, its axon and supportive cells (Schwann cells), neuromuscular junction, and all the muscle fibers innervated by the motor neuron. The neuromuscular junction can be further divided in presynaptic (axonal terminal), synaptic (synaptic space), and postsynaptic (muscle membrane) regions.

A single lower motor neuron innervates muscle fibers contained within one muscle and not of different muscle groups. One muscle fiber is innervated by one motor neuron. Large muscles (postural and locomotion muscles) on which fine movements are not required generally have a few hundred to thousands of muscle fibers per motor unit. Whereas muscles required for more dexterous movement such as those for ocular movement have fewer muscle fibers per motor unit. A single discharge of a motor neuron will result in the contraction of all muscle fibers innervated by its axon. All motor neurons innervating skeletal muscle are exclusively excitatory. However, interneurons located within the spinal cord can have either excitatory or inhibitory effects on the motor neurons.

Neuromuscular disorders are those affecting any component of the neuromuscular system and their supporting cells. Signs of dysfunction can be variable depending on the specific area affected. Lower motor neuron dysfunction results in muscle weakness, paresis to paralysis, decreased muscle tone, decreased to absent reflexes, and neurogenic muscle atrophy. Definition of a few terms will be provided for clarification. Neuronopathy is the abnormality of the neuron cell body, whereas neuropathy is the abnormality of the nerve. A nerve might be motor or sensory or both. Neuropathies can be characterized by degeneration of its axons (axonopathy), demyelination (e.g., Schwannopathy), or both. Junctionopathies are disorders involving any of the presynaptic, synaptic,

and postsynaptic regions of the motor end plate. Examples of neuromuscular disorders are shown in Table 11.11.[30]

Diagnostic Approach

Complete signalment and history are the essential first step in the investigation of any disorder. A history of a few or several horses affected in the same premises should raise suspicion of nutritional, toxic, or infectious causes. A thorough physical and neurologic examination must be performed for the evaluation of patients with suspected neuromuscular dysfunction. Neuroanatomic localization is essential, and disorders that may present with clinical signs similar to those of neuromuscular dysfunction must be ruled out, particularly in the sick neonatal foal on which weakness, inability to rise, apparent decreased muscle tone, among others, might be a common presentation for various disorders. Full blood work (CBC, chemistry panel, blood gases and pH), and urinalysis should be part of a minimum database collection. Neuromuscular disorders on which muscle enzymes may be elevated include ionophores and OP toxicity and those associated with tick infestation. Electrolyte analysis must also include ionized calcium (Ca^{++}) and magnesium (Mg^{++}) because these are physiologically active ions essential for neuromuscular homeostasis and function. Cerebrospinal fluid (CSF) cytology is usually normal in neuromuscular disorders. Toxicologic screening of the diet, water, plants, soil, blood, stomach contents, feces, and body fluids including CSF might add useful information. Consider imaging modalities such as radiographs, ultrasound, scintigraphy, computed tomography, and magnetic resonance if indicated by a problem-oriented diagnostic approach. A full body necropsy and thorough evaluation of the nervous system by a trained neuropathologist are essential. Neuroelectrodiagnostics are essential in the evaluation and diagnosis of neuromuscular dysfunction. Examples of electrodiagnostics include electromyography (EMG), nerve conduction studies (NC), single fiber EMG (SF-EMG), and repetitive nerve stimulation (RNS—more specific for neuromuscular disorders).

Paraneoplastic

VIRAL ENCEPHALITIS

Monica Aleman

A wide variety of viruses can affect the CNS of horses, resulting in encephalitis, meningoencephalitis, encephalomyelitis, or myeloencephalitis. Table 11.12 depicts reported viral diseases that affect the CNS in equids. Viruses can spread to the CNS from distal sites through adjacent tissues, nerves or via blood. To spread from blood, viruses must cross the blood-brain barrier, which can occur via infected leukocytes or by active or passive transport through the vascular wall. Viruses can infect neurons and glial cells (astrocytes, microglia, oligodendrocytes). Lytic infections to neurons are caused by togaviruses, flaviviruses, herpesviruses, and others leading to encephalitis or encephalomyelitis. Lytic infections are characterized by neuronal necrosis, neuronophagia, perivascular inflammation. In contrast to noncytocidal infection of neurons as in the case of rabies virus on which little to no inflammation is observed. EHV-1 can produce infection of the respiratory system; reproductive tract; fetus or embryo causing abortion or fetal or early neonatal

death; and the CNS. The type of nucleic acid and genomic structure are used to classify viruses into RNA or DNA viruses (Table 11.13). This section describes disease resulting from infections with members of the Togaviridae family of viruses (eastern, western, and Venezuelan encephalitis) and CNS infections caused by viruses from miscellaneous viral families.[506]

TOGAVIRIDAE
Equine alphaviruses[a]
- Eastern equine encephalomyelitis (EEE) virus
- Western equine encephalomyelitis (WEE) virus
- Venezuelan equine encephalomyelitis (VEE) virus
- Ross River virus
- Getah virus

[a]May also affect humans.

Togaviral Encephalitis

Togaviruses are small lipid- and protein-enveloped RNA viruses. Viruses in the family Togaviridae include the genera *Alphavirus* and *Rubivirus. Rubivirus* exclusively affects humans (rubella virus). The alphavirus equine encephalitides are mosquito-borne infections that cause neurologic disease and death in humans and horses (Table 11.14). Togaviral encephalitis can cause severe encephalitis and has been commonly referred to as sleeping sickness due to the degree of obtundation that affected horses develop. The incubation period is variable and depends on virus type but usually ranges from 5 to 14 days.

EEE, WEE, and Venezuelan (VEE) equine encephalitis viruses are the most frequently isolated alphaviruses from epidemics of encephalitis in horses and human beings in the Western Hemisphere (see Table 11.14). The first recorded epidemic of EEE in North America likely occurred in Massachusetts in 1831.[507] The viruses have been isolated from infected mosquitoes, horses, humans, birds, and rodents and are transmitted by hematophagous arthropods.[508]

Epizootiology

The alphaviruses EEE and WEE are specific and discrete togaviral species; North and South American antigenic variants of EEE exist.[509] WEE is a recombinant between an EEE-like virus and a Sindbis-like virus.[510] Two antigenic subtypes of WEE virus exist: (1) WEE and (2) Highlands J viruses. The Highlands J virus causes most infections that occur east of the Mississippi River. Although these alphaviruses have different antigenic properties, there is extensive overlap in geographic distribution.[506,511] VEE virus has six distinct subtypes designated by Roman numerals I through VI. Subtypes IAB, IC, and IE have been responsible for large outbreaks of encephalitis in horses in the Western Hemisphere in the past 20 years. Subtypes ID and IF have been reported in Central America and Brazil, respectively; type II (Everglades) virus in Florida; and types II, IV, V, and VI viruses.[512-515] Encephalitis has had a high morbidity and mortality in the United States.[516-519] Horses immunized with strains of virus isolated from infected horses from the East or West were protected when vaccinated with attenuated virus.[519-522] Table 11.15 summarizes the most common types of alphaviruses associated with encephalitic disease in horses and their geographic distribution.

Distribution

Disease associated with EEE, WEE, and VEE is restricted to the Western Hemisphere and ranges from temperate to desert climates. Many seropositive horses do not have recognizable clinical disease.[522-549] The presence of EEE virus has

TABLE **11.13 Properties of Viral Families**

Family	Genome	Configuration	Size (kb)	Envelope	Morphology	Virion size (nM)
Herpesviridae	dsDNA	1 linear	125–240	+	Isometric	150
Reoviridae	dsRNA	10–12 segments	19–32	–	Isometric	60–80
Rhabdoviridae	NssRNA	1 – segment	11–15	+	Bullet-shaped	100–430 × 45–100

Virus	Major Disease Vector	Zoonotic Potential	Amplification from Horses	Disease Spread	Viremia	Equine Mortality
EEE	*Aedes* spp.	Unlikely	Unlikely	Vector	Low	75%–100%
WEE	*Culex tarsalis*	Unlikely	Unlikely	Vector ± secretions	Low	20%–50%
VEE	*Culex melanconium, Aedes* spp. *Phosphora* spp.	Occurs	Occurs	Vector ± secretions	High	40%–80%

EEE, Eastern equine encephalitis virus; *WEE,* western equine encephalitis virus; *VEE,* Venezuelan equine encephalitis virus.
[a]The statements made are generalizations, and some degree of variation occurs.

been reported from Canada to Central and South America. In the United States disease has been reported primarily in the southeastern states, some western states, and east of the Mississippi River. Other parts of the world include the Philippines and some areas in Europe.[550,551] Historically large outbreaks of WEE have been described in horses in California and other western states, and uncommonly in eastern states.[552] Venezuelan equine encephalitis is a very important human and veterinary pathogen in the Western Hemisphere that can cause large outbreaks of disease in human beings and horses over large geographic areas. Disease due to VEE virus has been reported in Mexico, Venezuela, Colombia, Trinidad, French Guiana, Peru, and Brazil.

Epidemic

For outbreaks to occur several factors play a role such as presence of reservoir animals, intermediate hosts, insect vectors, and susceptible horse and human populations.[450,553] Prediction of outbreaks has been attempted but without success,[507,524,546] which indicates that other unknown factors may exist. In the environment, Togaviridae persist by asymptomatically infecting wild animals (sylvatic hosts) such as birds, small mammals, and reptiles.[554] The viruses may survive during the winter or nonvector season in sylvatic populations.[524,555]

Vectors

Specificity of the viruses for particular vectors occurs. The vectors for EEE include *Culiseta melanura, Aedes* spp., and *C. melanura.*[522,539,556,557] *Aedes* spp. appear to be more important in epizootics and epidemics. *Culex tarsalis* is the primary vector that maintains WEE virus. *Dermacentor andersoni* ticks,[558,559] *Triatoma sanguisuga* (assassin bug),[560,561] and the cliff swallow bug *(Oeciacus vicarius)*[558,562] may also be involved as vectors or overwintering reservoirs for WEE. Several species of mosquitoes from at least 11 genera have been determined to be naturally infected with epidemic strains of VEE virus, including *Culex melanconium,* and *Mansonia, Aedes,* and *Psorophora* spp.[526,527,534,535] Ticks may also be capable of virus transmission. Although less likely, EEE and VEE may spread by nasal secretions.[526,527,561,563] Vectors transmit viral particles between sylvatic hosts when taking a blood meal. Mosquitoes remain infected for life.[557,564] Seasonal incidence depends on peak of seasonal vectors. The highest number of cases occurs between June and November in temperate climates. If vector season is longer such as in warmer climates, disease outbreaks last longer.[565]

Outbreaks of disease because of EEE have been described in emus, ostriches, and swine, with isolated cases in cattle, sheep, and nondomestic ungulates.[566,567] Pigs may also be affected by VEE.[567] The signs of disease in these species are similar but are milder than disease in horses for the respective viruses. Burros and mules may contract all three diseases, and the disease is as severe as that identified in horses.[568] Experimental models of infection have included mice, hamsters, guinea pigs, and rhesus monkeys.[507]

TABLE **11.15 Alphavirus Types and Geographic Distributions**

Eastern Equine Encephalomyelitis Virus
- Multiple lineages
  - Lineage 1, subtype I in North America
  - Lineage 2, subtypes II to IV in South America
- Horse is a dead-end host

Western Equine Encephalomyelitis Virus
- North American and South American lineages with multiple variants
- Primarily found in western United States
- Highlands J variant in eastern North America
- Horse is a dead-end host

Venezuelan Equine Encephalomyelitis Virus
- Genetically diverse with six primary subtypes (I–VI)
- Epidemic or "epizootic" subtypes (IAB, IC, IE) in Central America and South America
- Endemic subtype II (Everglades) in Florida has low pathogenicity
- Horse is amplifying host

Pathogenesis

Alphaviruses can replicate to very high titers and cause severe cytopathic changes in many cells of vertebrates.[506] In mammalians and birds, infection causes complete shutdown of host-cell protein and nucleic acid synthesis. In mosquitoes, cell division can continue, with cells becoming persistently infected and continuously shedding virus.[506] After viruses are inoculated, they multiply in muscle, enter the lymphatic circulation, and localize in lymph nodes. Viruses replicate in macrophages and neutrophils and subsequently are shed in small numbers. Many of the viral particles are cleared at this time. If clearance mechanisms are successful, no further clinical signs develop. Neutralizing antibodies still will be produced. Several mechanisms of viral immunologic avoidance exist and include erythrocyte and leukocyte absorption. If viral elimination is not complete, the remaining viruses infect endothelial cells and concentrate in highly vascular organs such as the liver and spleen. Viral replication in these tissues subsequently is associated with circulating virus. The second viremic period often is associated with early clinical signs of disease. Infection of the CNS occurs within 3 to 5 days.[514,527,569,570]

Clinical Signs

Alphavirus clinical infection in humans is associated with insect vector contact and usually involves old or young persons.[507] Morbidity and mortality rates are virus specific.[571] Clinical signs in human beings include acute fulminant encephalitis, headache, altered consciousness, and seizures. The mortality rate in human patients varies depending on specific virus.[571] Human beings and horses are terminal hosts for WEE. A transient viremia occurs in horses in the acute stages of disease.

EEE virus is probably the most virulent of the alphaviruses with a case fatality in humans of 50% to 70%.[508,571] In humans, the virus causes fever, muscle pain, headache, disorientation, stupor, vomiting, respiratory signs, leukocytosis, hematuria, seizures, and coma.[508,571] MRI has shown lesions in the basal ganglia and thalamus.[508] Horses could be a natural amplifier of EEE, and infection in equines precedes human cases by 2 to 5 weeks.[572,573] Thus horses are sentinels for human beings in a given area. In animals, acute clinical signs of EEE and WEE include mild fever to severe pyrexia, anorexia, and stiffness. Viremia occurs during this period. The incubation period (1–3 weeks) is often shorter with EEE than WEE. Early signs of the disease include fever and mild obtundation. With EEE, progression is more common. Once nervous signs develop, the viremia is past, and animals are unlikely to be able to amplify the disease. Cerebrothalamic signs such as compulsive walking, altered behavior, hyperesthesia, excitability, and obtundation occur. Cranial nerve dysfunction can also occur, with signs such as vestibular, facial, pharyngeal, laryngeal, and tongue dysfunction. Death often is preceded by recumbency for 1 to 7 days. Comatose animals rarely survive. If animals survive, slow gradual improvement is observed over weeks to months.[574-577] Clinical signs are more profound in unvaccinated animals.[573,576]

VEE virus circulates in enzootic cycles between rodent host and mosquito vector.[578] Clinical signs with VEE vary depending on virus subtype from mild to severe to fatal. In general, severe encephalitis in humans infected with VEE virus is less common than with EEE and WEE virus infection. Neurologic disease in humans can be detected in up to 14% of cases, mainly children, and fatality rate is about 1%.[508,571] VEE viral infections in human epidemics and equine epizootics have been associated with subtypes ID and IE, which are less virulent for horses. In contrast, subtypes IAB and IC are highly pathogenic to horses with case fatality of 20% to 80%. Epidemic strains are associated with severe pyrexia and leukopenia.[514,570] Neurologic signs occur at approximately 4 days after infection and include severe obtundation and recumbency. Diarrhea can occur before neurologic deficits. Other associated signs include abortion, oral ulceration, pulmonary hemorrhage, and epistaxis.[526,527] Horses with VEE have sufficient circulating viral concentrations that act as amplifiers of disease.[534,579] Ocular and nasal secretions from infected horses contain high concentrations of VEE virus.[526,527] Infection via entry through the respiratory tract may occur by direct contact with infected animals. Equine and human survivors of VEE infection and clinical disease may develop chronic relapsing viremias and serve as chronic disease amplifiers.[566] Clinical signs in human beings include fever, headache, myalgia, and pharyngitis.

Accidental cases in humans have occurred in laboratory conditions.[508] Viral load in infected tissue could be high, therefore, precautions must be taken when performing necropsies or handling tissue from diseased animals. Alphavirus infections are reportable diseases to state health officials.[507,579] EEE virus has poor ability to replicate in lymphoid tissues, whereas VEE does so efficiently. Therefore EEE virus can avoid IFN-α and IFN-β induction in vivo, which may allow EEE to evade the host's innate immune responses and thereby enhance neurovirulence. Inhibition of genome translation restricts EEE infectivity for myeloid but not mesenchymal cells. This factor likely contributes to the observed differences in disease cause and presentation.[580]

Diagnosis

The diagnosis of equine encephalitides can be made by viral isolation or detection through virus-specific antibody response, viral nucleic acid, and presence of viral antigen in tissue samples. Clinically, a presumptive diagnosis is based on clinical findings of acute onset of altered behavior, obtundation, preceded by fever; season of the year, presence of vectors and hosts. IgM antibody-capture enzyme-linked immunosorbent assay can detect recently infected horses and humans.[508] These antibodies are not produced in response to vaccine.[581] The antibodies disappear by 21 days after infection.[582] The assay for confirming acute VEE infection should be used when one cannot collect convalescent serum samples. Detection of IgG antibodies is not predictive of recent infection and may be confused with vaccine-induced antibodies.[506] Viral antibodies are commonly present within 24 hours after the initial viremia, and their presence often precedes clinical encephalitis.[551] The concentration of antibodies increases rapidly and then decreases over 6 months.[582] An initial sample often is taken when encephalitic signs are present, which may be after titers have peaked. Therefore a second sample possibly may have a decreased titer compared with the initial sample. Hemagglutination-inhibition and neutralization assay can also detect within a few days after onset of infection.[578] Fourfold antibody rise in IgG antibody 10 days to 2 weeks apart supports infection. Complement fixation has also been used for the diagnosis of alphaviruses.[583] The virus can also be isolated from vertebrates and mosquitos. Immunohistochemistry of brain tissue can be done for the detection of virus. More recently, RT-PCR has been used for the diagnosis.[584] Viral cultures are unlikely to be fruitful, except in the case of acute VEE. One may isolate the virus from CSF of horses with acute infections.[527] The usefulness of CSF viral titers in light of a negative viral isolation is questionable. Fluorescent antibody, ELISA, and viral isolation are useful in identifying virus in brain tissue.[585,586]

Colostral antibodies may interfere with diagnosis in foals. The antibody titers to VEE, WEE, and EEE viruses in the sera of 2- to 8-day-old foals are similar to those of dams. The serum half-life of maternal antibodies in foals is approximately 20 days.[587]

Clinical Pathology

The CSF changes associated with togaviral infections are similar to those of other viral encephalitides and include most commonly lymphocytic pleocytosis (50–400 mononuclear cells/μL) and protein concentration (100–200 mg/dL).

Necropsy Findings

With any of the alphaviral equine encephalitides, sufficient viral particles for infection may be present in CNS and other tissues, and one should take precautions when performing a necropsy examination on suspect cases. The brain and spinal cord often have a normal gross appearance. In some cases

TABLE **11.16** **Vaccination Protocol for EEE/WEE Recommended by the American Association of Equine Practitioners Guidelines 2015**

Horse Group	Unvaccinated or Unknown (EEE/WEE)	Seasonal Exposure	Year-Round Exposure
Adults	2 doses 4–6 weeks apart	Annual before vector season	Every 6 months
Pregnant mares	2 doses 4–6 weeks apart	4–6 weeks before foaling or before vector season	
Foals (vaccinated mare)	3 doses at 4–6 months of age with a 4–6-week interval between 1st and 2nd vaccination; if high risk start at 2–3 months of age	Third dose at 10–12 months of age or before vector season	
Foals (unvaccinated mare)	3 doses with a 4-week interval	4th dose at 10–12 months of age or before vector season	

vascular congestion and discoloration of the CNS is evident. Histologic findings include nonseptic mononuclear cell and neutrophilic inflammation of the entire brain.[526,588-590] Severe lesions are evident in the cerebral cortex, thalamus, and hypothalamus. Specific lesions include significant perivascular cuffing with mononuclear and neutrophil cell infiltration, gliosis, neuronal degeneration, and mononuclear cell meningeal inflammation. With VEE, liquefactive necrosis and hemorrhage of the cerebral cortex, atrophy of the pancreatic acinar cells, and hyperplasia of the pancreatic duct cells commonly occur.[589] Immunohistochemistry can be diagnostic on necropsy samples.[591,592]

Differential Diagnosis

The differential diagnosis for EEE, WEE, and VEE should include other acute conditions associated with diffuse or multifocal neurologic deficits such as other viral diseases including other togaviral encephalitides, trauma, hepatoencephalopathy, rabies, WNV, and leukoencephalomalacia. Others such as bacterial meningoencephalitis, EPM, and verminous encephalitis should also be considered.

Treatment

There is no specific treatment for alphavirus infection. However, appropriate management includes supportive therapy, treatment of other concurrent disease, and prevention of complications. Supportive therapy includes meeting needs of hydration, nutrition, urination, defecation, and bedding. NSAIDs (phenylbutazone, 2–4 mg/kg every 12 hours; flunixin meglumine, 1 mg/kg every 12–24 hours) control pyrexia, inflammation, and discomfort. DMSO given at 1 g/kg intravenously in a 20% solution may be useful in controlling inflammation. The use of corticosteroids is controversial because beneficial effects are short term, and the risk of developing secondary bacterial infections increases. One might control seizures as described in this chapter previously. One should monitor hydration and administer balanced isotonic fluid solutions orally or intravenously as needed. Other supportive care should include dietary supplementation and administration of laxatives to minimize the risk of gastrointestinal impaction. If anorexia persists for more than 48 hours, enteral or parenteral supplementation should be used. For the short term, pelleted feeds may be put into suspension for oral administration. Protection from self-induced trauma may require protective limb wraps and head protection. If the horse is recumbent, one should attempt to provide support in a sling, and all animals should be bedded heavily.

Prognosis

Complete recoveries from the neurologic deficits associated with these viruses are reported, but they are rare.[591] Animals that have recovered from EEE often have residual neurologic deficits that commonly include ataxia, obtundation, and abnormal behavior. Neurologic sequelae are similar but less common in horses that recover from WEE. For horses that develop neurologic disease, the mortality rate for EEE is between 75% and 100%; for WEE, 20% and 50%; and for VEE, 40% and 80%.[526,551] If horses recover from any of the diseases, they seem to be protected variably for up to 2 years after infection. One would wisely assume that infection affords no protection.

Prevention

Prevention of alphavirus encephalitis should aim at reducing the concentration of insect vectors and implementing vaccination programs.[543-545,568,593-596] EEE, WEE, VEE are included as core vaccines in endemic areas as defined by the American Veterinary Medical Association. Current commercial vaccines are formalin inactivated viruses (Table 11.16). Significant increases in antibody titer occur at 3 days after vaccination.[526,527,595-598] One should vaccinate susceptible horse populations with monovalent, divalent, or trivalent vaccines containing EEE, WEE, or VEE. Administration of trivalent vaccines increases specific antibody production to all viruses. Some cross-protection exists between EEE and WEE and between EEE and VEE, but none exists between WEE and VEE.[587,599,600] If one is to give VEE vaccine, simultaneous administration of all three vaccines is recommended.[601-603] The response to VEE vaccination alone is poorer in horses previously vaccinated against WEE and EEE.[597,598,602,603] VEE vaccination does not seem to interfere with responses to EEE or WEE vaccination.[604] One should complete annual vaccinations in late spring or several months before the beginning of the encephalitis season. Adequate titers appear to last for 6 to 8 months. In areas in which the mosquito problem is prolonged or continuous, biannual or triannual vaccination is suggested. Vaccination of susceptible horses in the face of an outbreak is recommended. If vaccinated horses develop disease, the affected individuals are often young or old. Vaccination of mares 1 month before foaling enhances colostral antibody concentrations. Antibody concentrations in foals born to immunized mares appear by 3 hours after colostrum is fed and persist for 6 to 7 months.[592] Vaccination may begin at any age, but if they are vaccinated early, one should revaccinate foals at 6 months

and 1 year to ensure adequate protection. Foals respond to vaccination with VEE in utero.[605] A prospective study to determine the serologic response of previously vaccinated horses to revaccination against EEE and WEE identified that horses responded variably to each antigen, and some horses had low or undetectable antibodies 6 months after vaccination. Some horses did not develop increasing titers to EEE or WEE despite recent vaccination. Geometric mean titers peaked 2 weeks after revaccination and were significantly increased from before revaccination.[606,607]

Novel vaccines have been developed experimentally, such as modified live, chimeric gene-deleted live mutants, DNA, and adenovirus-vectored alphavirus vaccines.[581] The results have appeared promising. The development in new vaccines has been the result of concerns involved in the production of inactivated vaccines. These concerns mainly involve the manipulation of large quantities of viral particles under biosafety level 3 containment laboratories, which poses a possible risk of infection for operators producing vaccines. Further, these vaccines have not been able to induce long-lasting immunity.

Owners should use insecticides and repellents when possible and practical, should eliminate standing water, and in endemic areas or during an outbreak should implement environmental insecticide application and should screen stalls. Horses with VEE can be persistently viremic and should be quarantined for 3 weeks after complete recovery. Cases of VEE must be reported to regulatory authorities in the United States. Public health officials may institute other measures of disease control.

Flavivirus Encephalitis

Monica Aleman

The family *Flaviviridae* comprises three genera: *Flavivirus, Pestivirus,* and *Hepacivirus.*[608-620] Although these viruses have similar genomic organization, they are genetically and biologically different. At least half of the members of *Flaviviridae* are zoonotic. The genus *Flavivirus* has at least 70 viruses. Of importance in equine species are Japanese encephalitis, St. Louis encephalitis, West Nile, Powassan, and louping ill viruses. Arthropod-borne (e.g., *Culex* spp.) diseases include Japanese encephalitis, St. Louis encephalitis, and West Nile virus infection. Powassan and louping ill viruses are transmitted as tick-borne (*Ixodes* spp.) diseases.[608-614] The mosquito- and tick-borne flaviviruses are maintained in nature in arthropod-vertebrate-arthropod cycles, whereas the nonarthropod-borne viruses are transmitted directly among bats or rodents.[608]

Serocomplex Japanese encephalitis viruses include Japanese encephalitis, St. Louis encephalitis, Murray Valley encephalitis, Kunjin virus, and West Nile virus. These group of viruses are vector borne, with transmission occurring to avian and mammalian hosts from blood meal–seeking mosquitoes.[621] Virus is either maintained or cycled between vectors, and biologic amplification occurs within the vector species. Vertical transmission within vectors must occur for maintenance of virus within a geographic area.[621] The distribution of Japanese encephalitis occurs in most countries of southeast Asia and has extended to India, Pacific islands, and northern Australia. Japanese encephalitis virus causes between 30,000 and 50,000 human encephalitis cases annually worldwide, with endemic areas including China, the southeast region of the Russian Federation, South and Southeast Asia, and Australia. Exact numbers of horses with clinical Japanese encephalitis are difficult to ascertain; however, reports exist of Japanese encephalitis isolation from horses in Taiwan, China, Pakistan, and Australia in the literature since the 1980s. Outbreaks in horses have also been reported in India, Nepal, the Philippines, Sri Lanka, and northern Thailand. Seroconversion of young horses over their first year of exposure in Hong Kong is as high as 63% in some locales. The disease has a high mortality rate of 10% to 40%, with 40% to 70% of survivors having permanent neurologic deficits.[621] Japanese encephalitis should be suspected in horses with compatible clinical signs that reside in an area of virus activity. Diagnostic confirmatory tests include serologic assays such as neutralizing, complement fixation, hemagglutination inhibition, and ELISA tests.[621] All single sera testing, including IgM assays, must be interpreted with caution in horses from areas with other endemic flaviviruses. In fatal Japanese encephalitis cases, viral isolation, PCR assays, and immunohistochemistry for detection of virus in CNS tissues are confirmatory.

St. Louis encephalitis virus is associated most commonly with encephalitis in human beings and may rarely be involved in equine disease. Experimental inoculation in horses produces viremia but no clinical signs. Neutralizing antibody is often present. *Culex pipiens* and *C. tarsalis* are the major vectors. Wild birds seem to be the primary reservoir.[608,613]

Experimental infection with Murray Valley virus results in transient pyrexia, myalgia, and ataxia. Horses are unlikely to be efficient amplifiers of this virus.[610-612] In Australia, the virus is more commonly a disease of human beings. An epidemic in human beings was associated with significant titers in horses. Some horses with clinical signs, significant titers, and histologic evidence of viral encephalitis were identified.[611,612]

Powassan virus has been associated with nonsuppurative, focal necrotizing meningoencephalitis in horses.[609] Antibodies for Powassan virus commonly are identified in Ontario and the eastern United States. *Ixodes cookei, I. marxi,* and *Dermacentor andersoni* appear to be important vectors, with snowshoe hares and striped skunks as major reservoirs. Zoonoses occur after bites by infected ticks. Approximately 13% of horses sampled across Ontario in 1983 were serologically positive for the virus.[609] Experimental infection with Powassan virus strain M794 in horses was associated with neurologic deficits within 8 days. A nonsuppurative encephalomyelitis, neuronal necrosis, and focal parenchymal necrosis occur. Signs include tremors of the head and neck, ptyalism, myalgia, ataxia, and recumbency. No clinical signs were identified in inoculated rabbits, but widespread encephalitis characterized by lymphoid perivascular cuffing, lymphocytic meningitis, and lymphocytic choroiditis occurred.[609]

The other two genera have viruses of veterinary and human importance, with the genus *Pestivirus* containing the ubiquitous bovine diarrhea virus (BVD) and *Hepacivirus* containing the human pathogen hepatitis C virus (HCV). There was no known *Pestivirus* affecting the nervous system in horses until recently when a *Hepacivirus* was implicated as causing central nervous system disease in horses as previously mentioned in this chapter.[622]

West Nile Virus

Monica Aleman

West Nile virus (WNV) is an important cause of neurologic disease in humans and horses worldwide.[506,620,623] The virus is neurotropic, and access to the brain is proposed to

be hematogenous and transneural through the disruption of the blood-brain barrier and retrograde axonal transport. Historically, WNV was first recognized in humans in Uganda in 1937 and the Middle East as a febrile illness. Since then, the infection has spread globally to other parts of Africa, the Middle East, Asia, Australia, Eastern Europe, and North, Central, and South America.[506,623] The first reports of encephalitis in humans from North America occurred in August 1999 in Queens, New York.[506] These patients developed fever, altered mental status, flaccid paralysis causing respiratory failure, and weakness. All patients were over 50 years old, spent time outdoors, and lived close to mosquito-breeding sites. These patients were positive for IgM on ELISA testing on CSF. There are two major genetic lineages (1 and 2) of West Nile virus. Kunjin virus is a variant of lineage 1 WNV. WNV lineage in North America is 1. Before 1999 veterinarians, trainers, and horse owners on the American continent had little familiarity with flaviviruses. Since that time, several thousands of equine cases have been reported to have disease, with an estimated 30% to 40% case fatality rate in the United States. Horses represent 96.9% of all reported nonhuman mammalian cases of WNV.

Etiology. All flaviviridae are positive-sense single-stranded RNA viruses measuring approximately 50 nm.[506] The virions are spherical and enveloped with the C protein, making up a nucleocapsid of about 25 nm. Electron microscopy reveals an icosahedral symmetry of the envelope and capsid of these viruses. An approximately 11-kb genome contains a single open reading frame that is translated in its entirety and cleaved into 10 viral proteins by both cell and viral proteases.[506] Three structural and seven nonstructural proteins exist; the structural proteins include the capsid (C), premembrane (prM) and membrane (M), and envelop (E) proteins. The nonstructural (NS) proteins, numbered 1 through 5, are cleaved after translation and are required for viral replication and assembly.

The final M protein and the E protein are important for virulence.[506,620,623] The M protein is formed from a precursor protein (prM protein) that is modified as immature virions are secreted through the Golgi network of the cell. The E protein is only secreted in its native conformation through association with the prM protein. The E protein is the immunodominant viral protein and is important in receptor ligand binding and fusion to host cells.

Epidemiology. WNV is generally transmitted via bite from infected mosquitoes. There are several species of mosquito capable of acquiring the virus after feeding in infected vertebrate amplifying hosts (most common birds), but the most important in the United States include *Culex* genus *(C. pipiens, C. restuans, C. salinarius, C. tarsalis)*.[506,620,624-626] WNV penetrates the mosquito gut and replicates in multiple tissues including nervous system and salivary glands, infecting the mosquito for life. The virus is transmitted from females transovarially to offspring, continuing its persistence in the environment. Mosquitoes transmit WNV to over 300 species of birds and at least 30 vertebrates.[627] Birds include crows, magpies, jays, house sparrows, finches, and grackles. Vertebrates include humans, horses, mules, donkeys, camelids, pigs, dogs, cats, birds, and harbor seal, among others.[506,620] Seropositive free-ranging mammals include the big brown bat, little brown bat, eastern chipmunk, eastern gray squirrel, eastern striped skunk, white-tailed deer, and the brown bear.[506,620,627] Neurologic disease has been confirmed as WNV in gray squirrels and fox squirrels. Alligators can have an extremely high titer of viremia and may be an important reservoir for WNV in the Southeast. Reports exist of both farmed and free-ranging alligators with neurologic signs from which WNV has been isolated. In farm-raised alligators, cloacal shedding of virus has been demonstrated with oral infection likely.

The virus may also be transmitted through contaminated blood transfusion or organ transplantation if donors are viremic. Vertical transmission through placenta and milk has been demonstrated in people.[628-630]

The outbreaks are seasonal and reflect mosquito activity. In the northeastern United States, more than half of the WNV-positive mosquito pools are *C. pipiens.*[506] In the West, populations of the highly efficient *C. tarsalis* constitute the majority of positive pools, with *C. pipiens* the next most commonly found *Culex* spp.[506,624,626] In the Southeast, *C. quinquefasciatus* and *C. nigripalpus* have the highest WNV infection rates. In the Southwest, epidemics are most commonly associated with positive mosquito pools of *C. quinquefasciatus, C. tarsalis,* and *C. pipiens.*

A reservoir host (mostly birds) is one in which a pathogen is amplified in vivo so that it can be transmitted to a vector species.[631] Horses and human beings are considered dead-end (nonreservoir) hosts for WNV.[631] To date, more than 300 species of birds have been reported WNV-positive in the United States. High levels of viral amplification occur in many bird species.

Because transmission is via vectors, transmission could be seasonal in temperate regions and year-round in subtropical regions. Intense virus activity in the United States begins in July, with a peak incidence in September and October.[506,620] A drop in ambient temperature with soft frost usually results in a rapid decrease in reporting activity.

Older people appear more susceptible to neuroinvasive disease from WNV. Similarly, older horses appeared to be more susceptible.[632] Although men are more frequently affected with neuroinvasive disease, there appears to be no breed or gender predilection in horses. In one study of horses with WNV encephalomyelitis, female horses were 2.9 times more likely to die than male horses with neurologic signs.[633]

Clinical Signs. Neurologic disease has been reported in horses naturally and experimentally infected.[634-639] Most horses seroconvert without clinical disease after infection with WNV. However, approximately 8% to 10% of infected naïve horses develop clinical disease with neurologic signs.[623] Neurologic signs usually develop 5 to 22 days post infection. The most common clinical signs are weakness (94–100%), ataxia (72%), altered mentation (67%), fever early in disease (65%), fasciculations (61%), cranial nerve deficits (44%), and recumbency (30%). Other common signs include anorexia (47%) and bruxism (20%).[634,636,637]

Alterations in behavior such as hyperexcitability, apprehension, aggression, and compliance occur mainly due to thalamic involvement. Interspersed during periods of hyperexcitability, some horses appear to have abnormalities of sudden sleeplike activity resembling narcolepsy. This can occur to the point of cataplexy, and horses may partially or completely collapse for a short period of time. Because WNV affects predominantly the brainstem, signs such as abnormal state of consciousness, mainly obtundation due to injury to the reticular formation, is common. In some horses a change

of mentation is persistent, and a state of nonresponsiveness resembling coma results. Both gray and white matter can be infected. In the brain, gray matter of the midbrain and hindbrain is affected, resulting in cranial nerve deficits (mainly VII, IX, and XII) along with altered mentation.[4,639] Injury to these cranial nerves results for short periods of time in weakness of the tongue, muzzle deviation, and head tilt. Dysphagia has been reported with choke as a sequela. A cauda equina syndrome consisting of stranguria and rectal impaction is infrequently reported. Involvement of lower motor neurons in the spinal cord results in weakness, gait abnormalities, and proprioceptive deficits.

WNV can affect sensory and motor tracts within the spinal cord, and the signs could be diffuse or multifocal symmetric or asymmetric. However, motor and sensory deficits could also be caused by involvement of relay tracts and centers within the brain (thalamus and basal nuclei).[635-637,639-642] These two clinical signs are likely a reflection of brain and spinal cord disease through direct infection of the spinal cord, interruption of motor tracts in the hindbrain, and loss of fine motor control through infection of the large nuclei of the thalamus and the basal nuclei. General proprioceptive ataxia, paresis, weakness, and proprioceptive deficits result from lesions in the spinal cord. Many horses might have difficulty standing primarily because of profound weakness.

Involuntary skin and muscle fasciculations, tremors, and hyperesthesia, extremely common in this disease, likely result from loss of fine motor control, which is regulated mainly by the basal nuclei.[643,644] Movement disorders are detected with flavivirus infection in a long-term Parkinson-like syndrome in rats and experimental infection in monkeys.[644] Fine and coarse fasciculations of the muscles of the face and neck are very common. Fasciculations can be quite severe and involve all four limbs and trunk, affecting normal activities such as walking, eating, and interactions with handlers and other horses. The fasciculations are most notable at the muzzle and eyelids. Eyelid activity during this period is enhanced with light, and at times it appears that horses are quite photophobic.

Horses develop clinical signs when infected with the neurally invasive lineage type I WNV, whereas infection with the African lineage type II viruses is universally subclinical in nature. A mild to moderate increase in rectal temperature (38.6°C–39.4°C), anorexia, and depression are the most common initial systemic signs.[634] Abdominal pain is not an uncommon initial presenting complaint.[631,633,634,636] Gait abnormalities, including overt lameness or dragging of a limb before development of an obvious neurologic syndrome, have also been reported.

Overall, the combination, severity, and duration of clinical signs can be highly variable. After initial signs abate, about 30% of horses experience a recrudescence in clinical signs within the first 7 to 10 days of apparent recovery. Irrespective of recrudescence, about 30% of affected horses progress to complete paralysis of one or more limbs overall. Most of these horses are euthanized for humane reasons or die spontaneously.

Many horses will improve within 3 to 7 days of displaying clinical signs. If the horse demonstrates significant improvement, full recovery within 1 to 6 months can be expected in 90% of patients. Residual weakness and ataxia appear to be common, with long-term loss of the use of one or more limbs infrequently described. Mild to moderate persistent fatigue on exercise has been observed.

Diagnosis. CBC and serum biochemistry profiles are usually within reference values. Occasionally, creatine kinase might be elevated due to trauma and/or recumbency. A frequent finding is hyponatremia, which has also been described in human beings with encephalitis, potentially caused by inappropriate release of antidiuretic hormone.[645,646] CSF analysis could be normal or reflect lymphocytic pleocytosis with elevated protein. In contrast, the most numerous cells in the CSF of horses with EEE are neutrophils, especially during the initial stages of disease.[647]

Differential diagnosis should include alphavirus encephalitis, rabies, EPM, EHV-1, botulism, and verminous meningoencephalomyelitis (e.g., *Halicephalobus gingivalis, Setaria* spp., *Strongylus vulgaris*). Noninfectious causes to consider include hypocalcemia, tremorgenic toxicities, hepatoencephalopathy, and leukoencephalomalacia.

Confirmation of WNV infection with encephalitis in horses begins with assessment of whether or not a horse meets the case definition based on clinical signs, as well as whether or not the horse resides in an area in which WNV has been confirmed in the current calendar year in mosquitoes, birds, human beings, or horses.[641] Serologic testing developed by the National Veterinary Services Laboratory (NVSL) is based on detection of the IgM antibody response that uniformly occurs in acutely infected horses. The preferred test is an IgM capture ELISA (MAC-ELISA).[648] Horses develop a very intense IgM response on exposure to WNV that lasts approximately 6 weeks. This immunologic reaction is much more reliable than in human infection in which a more persistent IgM response is common. Most diagnostic laboratories use the WNV IgM capture ELISA (MAC) for actual confirmation of disease (increases in IgM rarely occur after vaccination). The sensitivity and specificity of this test are 81% and 100%, respectively.

In nonvaccinated horses, a fourfold increase in neutralizing antibody titers is confirmatory of a diagnosis of WNV infection. The most common neutralizing antibody test formats are the classic plaque reduction neutralizing antibody response (PRNT) and a more recently developed microwell format.[648,649] Vaccination induces formation of neutralizing antibody that likely confounds interpretation of the PRNT.

Other methods for confirmation of a diagnosis of WNV include postmortem detection of WNV by PCR, culture, and immunohistochemistry in tissues of the CNS. Nested PCR targeting the E protein has demonstrated sensitivity for relatively low viral load in equine tissues.[650,651] Real-time PCR methodology has been used to detect WNV in equine tissues.[651] The E-protein target appears less sensitive; however, the NS5 target has detected WNV nucleic acids in CNS tissues, heart, and intestine of clinically affected horses.

Pathologic Findings. Flaviviruses cause polioencephalomyelitis (inflammation of the gray matter) with lesions that increase in number from the diencephalon through the hindbrain and frequently increase in severity caudally through the spinal cord. The basal nuclei, thalamus, pons, and medulla have the highest numbers of lesions with two to several cell layers of mononuclear perivascular cuffing. Neuronal damage includes chromatolytic neurons and neuronophagia. In long-standing disease, areas of neuronal dropout may exist. By contrast, lesions are limited in the cortex and cerebellum. In the spinal cord, perivascular cuffing, gliosis, and damaged neurons may be seen.

Therapy. The goals of therapy are supportive and preventive. Treatment is mainly supportive care as there are no

known antiviral medications.[634,636,652-654] Survival of horses with WNV is higher compared with other viral encephalitis. Horses might start recovering between 3 to 5 days post onset of clinical signs. Most cases that have been euthanized have been the result of progressive disease resulting in recumbency. Therapy of recumbent horses is generally more aggressive and might include dexamethasone sodium (0.05–0.1 mg/kg IV every 24 hours) and mannitol (0.25–2.0 g/kg IV every 24 hours). Controversy remains as to whether corticosteroids enhance peripheral and CNS viral load.[655-658] Detomidine hydrochloride (0.02–0.04 mg/kg IV or IM) is effective for prolonged tranquilization. Low doses of acepromazine (0.02 mg/kg IV or 0.05 mg/kg IM) provide excellent relief from anxiety in both recumbent and standing horses. In addition, treatment of concurrent disease is recommended. IFN-α has been used in humans and veterinary medicine. However, studies on its efficacy are limited.[653,654,659-661] Plasma containing WNV-specific immunoglobulins for intravenous administration has been used, but plasma treatment did not change outcome and severity of WNV disease.

Prevention. Experimental models of disease have shown that 70% to 100% of nonvaccinated healthy horses become viremic upon viral challenge through mosquitoes, needle, or intrathecal injection. Epidemiologic and experimental evidence exists regarding the effectiveness of vaccination.[648,662] Several commercially available vaccines are licensed by the USDA as an aid in prevention of viremia, encephalitis, and mortality and reduction of viremia, encephalitis, and mortality. Available vaccines are inactivated whole WNV or a nonreplicating live canary pox recombinant vector vaccine. An inactivated flavivirus chimera vaccine is no longer commercially available. Vaccination before the mosquito season is critical. Manufacturer's labeling instructions must be followed for induction of immunity with initial immunization. All available vaccines are labeled for administration every 12 months after the initial series; however, only the modified live chimera vaccine has published 12-month efficacy data.[663] More frequent vaccination in areas with year-round mosquito seasons is recommended for most vaccines because it is not expected that the initial vaccine series will provide long-term protection, especially with killed virus vaccines with which antibody levels rapidly decrease after 4 to 6 months. Where these viruses are endemic, vaccination schedules should be maintained even when a decrease in the incidence of overt disease exists.

Public Health Considerations. WNV is a zoonotic disease. Bird reservoirs maintain the virus in an endemic life cycle, allowing for transmission by mosquitoes to human beings. Therefore control of the mosquito population is important. Little risk exists of disease by direct contact with an infected horse, except during postmortem examination with inappropriate handling of infected tissues. Blood-borne transmission can occur between viremic hosts. In addition, occupational infection has occurred through necropsy of avian hosts.

Bornavirus

Borna disease was first described in the town of Borna in Saxony, Germany, in 1766 as "sad horse disease" due to the obtunded appearance of diseased horses. However, the virus was not identified until 1926. The virus is a member of the *Bornavirus* genus of the Bornaviridae family, a group of enveloped viruses with a nonsegmented, negative-sense, single-stranded RNA genome. It is the cause of a naturally occurring infectious, usually fatal (80%–100% mortality rate), progressive meningopolioencephalitis that affects horses and sheep most commonly.[664] Less often the virus affects other equids, cattle, goats, camelids, fox, dogs, cats, rabbits, rodents, birds, primates, and humans. The disease is recognized to date in Germany, Switzerland, Liechtenstein, and Austria. Antibody-positive horses are present in the Middle East, Asia, Australia, and the United States. Reservoirs include rodents, rabbits, and deer. The route of transmission includes nasal secretions and saliva, and vectors are believed to be rodents. Virus is shed in body secretions, gaining entrance to a new host through exposed nerve endings in the nasal and pharyngeal mucosa.[665,666]

Borna disease is caused by a virus-induced immunopathologic reaction.[665-667] The virus is a noncytolytic, neurotropic, single-stranded RNA virus. The glycoproteins GP43 and GP84 are important in pathogenesis of disease. GP84 serves for attachment to cells and GP43 for the internalization to cells via endocytosis. The virus gets access to nasal mucosa and migrates to olfactory bulbs via axonal transport mechanisms. The virus has tropism for the limbic system, particularly the hippocampus. Once in the central nervous system, the virus migrates centrifugal to the peripheral nervous system. Main histologic lesions occur in Ammon's horn, olfactory bulb, caudate nuclei, thalamus, and less commonly the cerebellar nuclei. The virus causes progressive severe immune-mediated nonsuppurative meningoencephalitis. Natural infection in horses results in peracute, acute, or subacute meningoencephalitis leading to death in 1 to 4 weeks of affected animals. In endemic areas (Germany), the prevalence of disease is estimated to be 12%.[664,665] There can be subclinical carriers. Specific neurologic signs are variable but may include slow-motion eating, chewing motions of the mouth, head pressing, somnolence and stupor, hyperexcitability, fearfulness, aggressiveness, hypokinesia, abnormal posture, hyporeflexia, head tilt, neurogenic torticollis, and inability to swallow. Diagnosis is made through serology such as Western blot, ELISA, IFAT; virus isolation; IMHC; and RT-PCR.

Miscellaneous Viral Encephalitides

Other mosquito-borne encephalitides reported in California have been caused by a group of closely related viruses belonging to the *Orthobunyavirus* genus of the Bunyaviridae family.[506,668] Snowshoe hare and Jamestown Canyon viruses have been isolated in Canada and California.[669-672] Snowshoe hare virus is the most widely occurring arbovirus in Canada and is maintained in an amplification cycle involving small mammals and mosquitoes primarily of the *Aedes* genus.[669,671] Seroconversion without clinical disease is widespread. One report exists of acute encephalitis with complete recovery in a horse that seroconverted to the snowshoe hare serotype of California encephalitis viruses.[669] Jamestown Canyon virus has been isolated from vesicular lesions in a horse.[670,672]

Main drain virus, a member of the *Orthobunyavirus* genus of the Bunyaviridae family that is not part of the California encephalitis serogroup, was isolated from the brain of a horse with encephalitis in Sacramento County, California.[673] Signs included incoordination, ataxia, stiffness of the neck, head pressing, dysphagia, fever, and tachycardia. The major vector is *Culicoides variipennis,* which transmits the virus from infected rabbits and rodents.[673] The Cache Valley virus, a member of the *Bunyamweravirus* genus of the Bunyaviridae

family, has been isolated from a clinically normal horse; a high seroprevalence exists for this virus among horses in some geographic areas.[674]

Nipah virus, a member of the *Henipavirus* genus of the Paramyxoviridae family, causes encephalitis in human beings and pigs in Southeast Asia. It is transmitted from bats to pigs and then spreads horizontally to other pigs and human beings. One anecdotal report exists of dilated meningeal vessels in a horse from which Nipah virus was isolated.[675]

Equine encephalosis virus, a member of the *Orbivirus* genus of the Reoviridae family, is an insect-borne virus transmitted by a variety of *Culicoides* spp.[676] Horses, donkeys, and zebra in Southern Africa are frequently seropositive. The clinical importance of equine encephalosis virus as a cause of neurologic disease in equids appears to be limited despite the fact that it was originally isolated from a horse with clinical neurologic disease. Clinical signs that have been attributed to equine encephalosis virus include fever, depression, edema of the lips, acute neurologic signs, enteritis, and abortion.

Other viruses, identified in areas around the world, that have been implicated in equine encephalitis or that are associated with encephalitis in other species and for which significant titers have been identified in horses include the louping ill,[677,678] Maguari,[679,680] Aura,[680] Una,[680] Highlands J,[681] Semliki forest,[682] and Getah[619] viruses.

Three recently identified viruses (anellovirus, hepacivirus, and parvovirus) were found through PCR in CSF from horses with neurologic signs predominantly involving brainstem and spinal cord (personal observation, Aleman).[622] Cytologic analysis of CSF showed lymphocytic pleocytosis in these horses.

RABIES

Monica Aleman

The family *Rhabdoviridae* includes six genera of viruses that infect a variety of species such as mammals, birds, fish, insects, and plants. The genera consist of *Lyssavirus, Vesiculovirus, Ephemerovirus, Novirhabdovirus, Cytorhabdovirus,* and *Nucleorhabdovirus.* There are other unclassified rhabdoviruses. Rhabdoviruses are enveloped with single-stranded RNA.[506,683] The family *Rhabdoviridae* includes viruses of importance to animal and human disease such as rabies, vesicular stomatitis, and bovine ephemeral fever viruses. Rabies virus belongs to the genus *Lyssavirus.*[506] Other related viruses such as Mokola, Lagos bat, European bat lyssaviruses 1 and 2, and Australian bat lyssavirus also belong to the genus *Lyssavirus* and cause rabies-like disease in animals and humans. The rabies virus is a large, cylindric, bullet-shaped neurotropic rhabdovirus.[683] Rhabdoviruses are relatively stable in the environment. However, rabies virus is inactivated by detergent-based disinfectants, iodine-containing solutions, radiation, strong acids, alkalis, lipid solvents, and anionic solvents.[506,683]

Rabies was first recognized as a fatal disease in Egypt before 2300 BC and in ancient Greece. The virus has a worldwide distribution except for Australia, New Zealand, Japan, Antarctica, and certain islands. The virus was recently eradicated from portions of Europe (e.g., Switzerland, France) and Scandinavia.[506] Although rabies is uncommonly diagnosed in equids due to its zoonotic potential, it should be considered as a differential diagnosis in horses with acute progressive neurologic signs. Rabies is estimated to cause 35,000 to 70,000 human deaths worldwide annually.[506] Rabies surveillance in 2009 showed that 49 states and Puerto Rico reported 6690 rabid animals and 4 human rabies.[684]

The most common route of transmission of the virus is via saliva-contaminated wounds or bites from a wild carnivorous or insectivorous bat carrying the virus. In Africa and Asia most of the human cases result from bites from rabid dogs, whereas in North America they result more commonly from wildlife.[506] The most common reservoir hosts in the United States are skunks, raccoons, and the red fox.[683] However, domestic dogs, cats, and other horses may transmit rabies to horses by bite wounds. An important reservoir of rabies in the Caribbean islands is the gray mongoose. Furthermore, rabies virus can be transmitted by droplet inhalation, orally, or transplacentally. Droplet transmission has been reported to have occurred in foxes, coyotes, opossums, and raccoons in a bat cave in Texas. In that report the virus was isolated from the air in the cave.[685] Aerosolization of the virus also caused an outbreak of rabies in a laboratory. Transmission via aerosol has also been reported in a few humans working in bat caves.[506] Transplacental transmission of the virus has occurred in naturally infected cattle and experimentally infected mice and bats.[683]

Virus entry into host cells occurs by receptor-mediated endocytosis via coated pits, pH-dependent fusion of the viral envelope with the endosomal membrane releasing the viral nucleocapsid into the cytoplasm where replication occurs.[506] Rabies virus infects and replicates in myocytes at the inoculation site and might remain undetectable for weeks or months before moving centrally. The virus infects peripheral nerves by traversing neuromuscular and neurotendinous spindles. Progression along the nerve is thought to occur in the tissue spaces of the nerve fasciculus.[685] After progressing centripetally up the peripheral nerve by axoplasmic flow, the virus replicates in spinal and dorsal root ganglia of the corresponding peripheral nerve. Once the virus reaches the CNS, spread occurs rapidly through multiplication in neurons of the brain, spinal cord, sympathetic trunk, and glial cells. Spread of rabies virus also can occur through passive transport within CSF or blood.[683] Finally, the virus reaches tissues outside the CNS via centrifugal movement of the virus along nerve axons.[683]

The incubation period is usually between 14 and 90 days, but it could be longer, up to a year. The incubation period can be affected by the virus strain, host species, inoculum size, and proximity of the inoculation site to the CNS.[683] Retention of virus in myocytes at the inoculation site may be a mechanism for variation in the incubation period. A shorter incubation period also might be explained by the virus entering peripheral nerves soon after exposure and rapidly migrating centripetally to the CNS without replication in non-neural tissue.[683]

Clinical Signs

No signs are pathognomonic for rabies infection in horses. There is usually a prodromal phase on which signs are often overlooked or not appearing as neurologic in origin. This also occurs in horses. Clinical signs on presentation vary and range from lameness to sudden death.[686-689] Hyperesthesia, ataxia, behavior change, anorexia, paralysis or paresis, and

colic have been reported as initial clinical signs.[686-691] One rarely finds a bite wound, and the horse might or might not be febrile. The site of inoculation and its proximity to the CNS influence what clinical signs one observes.[683,687,688] The neurologic signs exhibited in rabies-infected horses can be classified into three forms, depending on the neuroanatomic location in the CNS infected by the virus. First, in the cerebral or furious form, one might see aggressive behavior, photophobia, hydrophobia, hyperesthesia, self-mutilation, straining, muscular tremors, convulsions, and blindness.[4] Second, in the brainstem or dumb form, one commonly sees obtundation, anorexia, head tilt, circling, excess salivation, facial and pharyngeal paralysis (giving the name of "hydrophobia").[4,690] Finally, in the paralytic or spinal form, one sees progressing ascending paralysis, ataxia, shifting lameness with hyperesthesia, self-mutilation of an extremity, flaccid tail and anus, and urinary incontinence.[4,691,692] Most affected animals with the paralytic form become recumbent in 3 to 5 days. The neurologic signs may vary as the virus spreads to other portions of the CNS. Thus horses may have clinical signs of two or all forms of rabies. Regardless of form presented, progression occurs to severe altered behavior and mentation and paralysis leading to recumbence. Antiinflammatory therapy can delay virus progression,[4] but death usually occurs within 5 to 10 days after onset of clinical signs.[506,689]

Diagnosis

Antemortem diagnosis of rabies is difficult, but one should consider the disease in horses showing rapidly progressing or diffuse neurologic signs. Other diseases that one should consider include other viral encephalitis such as togaviral encephalitis, hepatoencephalopathy, protozoal encephalomyelitis, nigropallidal encephalomalacia, botulism, lead poisoning, polyneuritis, meningitis, space-occupying mass, trauma to the brain or spinal cord, and esophageal obstruction.[685] Clinical laboratory data of body fluids are nonspecific. CSF might be within normal reference range or might show a moderate increase in total protein concentration (60–200 mg/dL) and lymphocytic pleocytosis (5–200 mg/dL).[685] Fluorescent antibody testing of tactile hair follicles of facial skin taken on biopsy or from corneal epithelium might help diagnose rabies antemortem. The fluorescent antibody technique detects the rabies virus antigen in these tissues. However, a negative test does not exclude rabies as a differential diagnosis.[689] One can achieve definitive postmortem diagnosis by submitting half the brain in 10% formaldehyde for histologic examination and the other half frozen to a public health diagnostic laboratory for direct immunofluorescent antibody tests, mouse inoculation, and monoclonal antibody techniques. The whole brain might be shipped unfrozen on ice for further rabies evaluation and testing. One should examine the rest of the carcass only with careful precautions against transmission of the virus, if present, by wearing gloves, caps, and masks until a negative rabies diagnosis is made.

Common histopathologic changes are a mild, nonsuppurative encephalomyelitis; perivascular cuffing by mononuclear cells; gliosis; glial nodules; and neuronal degeneration. These lesions occur most commonly in the hippocampus, brainstem, cerebellum, and gray matter of the spinal cord. Large intracytoplasmic eosinophilic inclusions within neurons and ganglion cells, known as *Negri bodies,* are pathognomonic for rabies.[683] However, in 15% to 30% of confirmed rabies cases, Negri bodies are not present in histopathologic sections, especially if the animal died or was euthanized early in the disease process.[683] The most commonly used and fastest diagnostic test for rabies is the direct fluorescent antibody test. This technique may identify 98% of infected brain specimens.

A recent histologic study characterized the lesions caused by rabies virus in cattle and horses.[693] Inflammatory lesions in horses were moderate at the thoracic, lumbar, and sacral levels, and marked at the lumbar enlargement level. Gitter cells were present in large numbers in the lumbar enlargement region. Immunohistochemistry staining intensity ranged from moderate to strong in the spinal cord. Only two horses exhibited lesions in the brain, which were located mainly in the obex and cerebellum. The study concluded that the odds of detecting lesions in horses with rabies are 3.5 times higher in spinal cord compared with brain alone.[693]

The mouse inoculation test is the most accurate method for diagnosing rabies virus infection but requires 5 to 6 days to complete. The mouse inoculation test involves the injection of suspect brain or salivary gland tissue homogenates intracerebrally in mice and observation of clinical and neurologic signs or death.[683] The monoclonal antibody test has been used most recently for rabies diagnosis in horses. The test can differentiate specific street, fixed, or vaccinal strains of rabies virus by their glycoprotein or nucleocapsid antigens.[683] This is important in postexposure vaccination of human beings and animals when using the specific strain of virus.

Rapid and accurate laboratory diagnosis of rabies is essential for timely administration of postexposure prophylaxis in humans and control of the disease in animals. RT-qPCR assays have been developed and proved to be a fast and useful diagnostic method. One study evaluated 211 biologic samples from humans including saliva, skin, and brain biopsies. RT-qPCR had a sensitivity of 91.5% for skin biopsies and 54% for saliva. This methodology has been implemented in a few countries as an antemortem diagnostic aid.[694]

This method was also evaluated for the diagnosis of human rabies on 211 biologic samples (positive $n = 76$ and negative $n = 135$) including saliva, skin, and brain biopsies. It detected all 41 human cases of rabies tested and confirmed the sensitivity and the interest of skin biopsy (91.5%) and saliva (54%) samples for intra vitam diagnosis of human rabies. Finally, this method was successfully implemented in two rabies reference laboratories in enzootic countries (Cambodia and Morocco). This combined RT-qPCR method constitutes a relevant, useful, validated tool for the diagnosis of rabies in both humans and animals and represents a promising tool for lyssavirus surveillance.

Recently a pan-lyssavirus (multiplex) Taqman RT-PCR assay named LN34 for the detection of highly variable rabies virus and other lyssaviruses was developed. LN34 assay uses a combination of degenerate primers and probes along with probe modifications to achieve identification of the *Lyssavirus* genus. The LN34 assay was successfully used for both antemortem and postmortem diagnosis of over 200 clinical samples.[695]

Treatment and Prevention

As for most viral encephalitis, there is no specific treatment for rabies. Aggressive supportive therapy might prolong the disease course. However, this increases the risk of exposure

to those involved with the horse's care. Rabies should always be considered as a differential diagnosis for acute progressive neurologic disease, and all measures to minimize exposure to personnel must be taken. These measures include isolation of the animal and minimal handling of the animal. Horses that are known to have been exposed to rabies should have all wounds cleaned and lavaged with iodine or quaternary ammonium disinfectant (and rabies antiserum, if available, infiltrated around the bite wound). No postexposure protocol exists for unvaccinated or vaccinated horses. However, exposed horses should be quarantined for 6 months and observed for the occurrence of neurologic signs. Unvaccinated horses should not receive postexposure prophylaxis until after the 6 months of quarantine.

Currently, there are three inactivated (tissue culture–derived products with an adjuvant) vaccines licensed for rabies to be administered intramuscularly. The American Association of Equine Practitioners recommends that all horses in the United States be vaccinated against rabies. Foals from vaccinated mares should be vaccinated no earlier than 6 months of age. The second dose of vaccine should be given 4 to 6 weeks after the first. A third dose should be given at 10 to 12 months of age. The first dose of vaccine should be given to foals from unvaccinated mares at 3 to 4 months of age. A second dose should be given at 10 to 12 months of age. Adult horses should receive annual revaccination. Pregnant mares might be vaccinated annually before breeding or 4 to 6 weeks before foaling. Testing for rabies antibodies using the rapid fluorescence focus inhibition test (RFFIT) is available through the Kansas State Veterinary Diagnostic Laboratory.

Recently a study investigating the serologic response to vaccination in 48 horses with undocumented vaccination history was conducted.[696] These horses were vaccinated and blood collected before, 3 to 7 weeks, and at 6-month intervals for 2 to 3 years post vaccination. Serum rabies virus–neutralizing antibody (RVNA) values were measured. A protective RVNA value (≥0.5 U/mL) as defined by the World Health Organization for humans was maintained for 2 to 3 years in horses inferred to have been previously vaccinated on the basis of prevaccination RVNA values. The authors found significant differences between horses inferred to have been previously vaccinated and horses inferred to be naïve before the study. Based on these results, the conclusion was that a rabies vaccination interval greater than 1 year may be appropriate for previously vaccinated horses but not for horses vaccinated only once.[696]

EQUINE MOTOR NEURON DISEASE

Yvette S. Nout-Lomas

Equine motor neuron disease (EMND) is an acquired neurodegenerative disease of adult horses that has been reported in North and South America, Japan, and Europe.[697-700] Lower motor neuron disease was first recognized in 1988 based on histologic changes in skeletal muscle,[701] and EMND was first described in 1990.[697] In the 1990s, EMND was recognized worldwide in an apparently increasing frequency that was estimated to have peaked in 1997.[3] A study conducted between 1997 and 2007 suggested incidence was still decreasing,[702] and currently the disease is seen only sporadically. The decrease may be the result of preventive management measures taken for horses at risk of developing the disease.

The disease affects primarily the motor neurons in the spinal cord ventral horn cells and brainstem and leads to characteristic clinical signs, including generalized neuromuscular weakness and neurogenic muscle atrophy.[697,699,703] EMND closely resembles progressive spinal muscular atrophy, a variant of *amyotrophic lateral sclerosis (ALS)* or Lou Gehrig's disease.[697,704] However, EMND only affects lower motor neurons, which is not the case in ALS. A chronic lack of antioxidants is implicated in the pathogenesis of EMND, but experimental and clinical studies also suggest that there is an individual predisposition to this neurodegenerative disease.[705]

Clinical Signs

EMND occurs in adult horses 2 years and older with a mean age of onset of clinical signs of 9 years.[704] The risk for EMND increases with age, peaking at around 15 years.[706] No gender predilection is apparent, and although initial studies showed the Quarter Horse to be at increased risk for disease, this likely was a reflection of management factors.[706]

Clinical signs reflect motor denervation of skeletal muscles. Muscle wasting despite a normal or ravenous appetite, trembling or muscle fasciculations, and excessive recumbency are the predominant signs of EMND, and each of these was shown to be present in greater than 90% of 77 cases.[705] Muscle wasting is most noticeable in the quadriceps, triceps, and gluteal areas. Onset of muscle wasting usually occurs before the other clinical signs do, but sometimes signs of muscle weakness are seen in normally muscled horses. Generally onset is acute, and, in addition to the aforementioned signs, gait abnormalities such as short-stridedness and weight shifting in the pelvic limbs are frequently seen. Ataxia is not a clinical sign of EMND. A horse with EMND is said to move better than it stands. Other abnormalities that are seen in horses with EMND include a base-narrow stance and abnormal sweating. Also, in more than 50% of cases, horses may display a lower than normal head carriage with muscle wasting of the cervical musculature (hangdog appearance) and an elevated tail head carriage (Fig. 11.40).[697,699] Elevated tail head carriage is likely secondary to denervation atrophy and fibrotic contracture of the sacrococcygeus dorsalis medialis muscle. Occasionally horses are presented for poor performance or development of noncharacteristic gait

FIG. **11.40** Characteristic appearance of a horse with equine motor neuron disease (EMND), including muscle wasting, sweating, base-narrow stance, low head carriage (hangdog appearance), and tailhead elevation.

abnormalities (stringhalt-like movement). Despite the frequent occurrence of cranial nerve nuclei pathology clinical signs of cranial nerve dysfunction are very uncommon; in 2013 a case of acute-onset EMND was discussed that had marked reduction of tongue tone.[707] In nearly 40% of EMND cases ocular funduscopic examination reveals a yellow-brown-black pigment that has a reticulated appearance and is located in a horizontal band above the optic disc at the tapetal-nontapetel junction.[705,708] Loss of vision has not been reported.

Pathologic Findings

Gross necropsy findings in EMND include diffuse muscle atrophy and pallor (especially of the intermediate vastus and medial head of the triceps muscles). Despite the obvious weight loss seen in horses with EMND, fat deposits are usually within normal limits.[697,703] The CNS and peripheral nerves are grossly normal.

Histologically, one may detect noninflammatory neuronal degeneration and neuronal loss at all levels of the spinal cord, but such loss is most obvious in the cervical and lumbar intumescence. In addition, degenerative axonal changes can be found in the ventral roots and peripheral nerves. Degenerative lesions and neuronal loss are found in the ventral horn cells (lower motor neurons) of the spinal cord gray matter; the nucleus ambiguous, and all brainstem cranial nerve somatic motor nuclei, except III, IV, and VI. Most affected neurons are swollen, markedly chromatolytic, and diffusely argyrophilic, and severely affected neurons are shrunken or vacuolated. In chronic cases there are glial scars consisting of astrocytes and lipofuscin-laden microglia. In the retinal epithelium, liver, and intestine additional deposits of ceroid-lipofuscin can be found.

Skeletal muscle changes include nonspecific myopathic changes such as excessive fiber size variation, internal nuclei, and cytoarchitectural alterations. Scattered fiber degeneration and necrosis are consistent findings in EMND. Atrophy of type I and type II muscle fibers occurs in severely affected muscles in EMND and is pathognomonic of denervation atrophy.[697,703] EMND predominantly affects type I fibers, in contrast to denervating diseases in other species, and has not been reported in ALS. Motor neurons supplying the type I fibers have a higher oxidative activity and thus may be more susceptible to oxidative injury. Similar to ALS, in which at least 30% of motor axons must be destroyed before clinical evidence of atrophy occurs, in horses with muscle wasting caused by EMND, a mean motor neuron loss of 31% was recorded.[709] There have been some reports of horses with EMND having small intestinal lesions including evidence of lymphocytic or eosinophilic-lymphocytic infiltration, edema, and catarrhal enteritis.[699,710]

Pathogenesis

The clinical signs of neuromuscular weakness result from the generalized denervation muscle atrophy found in horses with EMND. Oxidative stress is believed to be the underlying mechanism for development of EMND, either through a deficiency in antioxidant elements, such as vitamin E, and/or an excess of prooxidant elements such as copper and iron.[706,711-714] However, besides oxidative stress it appears there must be other factors involved in the pathogenesis of this disease.

A chronic vitamin E deficiency is thought to be the most important contributor to the state of oxidative stress in horses with EMND, although recently it has been shown that EMND occurred in a horse with high tissue iron concentrations,[715] and in five horses that were on pasture at the onset of the disease.[716] The latter studies suggest that, besides inadequate intake of vitamin E, abnormal bioavailability or excessive utilization of vitamin E may play a role in the pathogenesis of EMND. Evidence of chronic oxidative stress in horses with EMND includes the pronounced type I muscle fiber atrophy and the lipopigment deposition in the capillaries of the spinal cord and the epithelium of the retina. In addition, there is overwhelming epidemiologic and experimental evidence that a diet low in vitamin E is a strong risk factor for EMND.[705,713,717]

Although EMND is the only naturally occurring model for ALS and oxidative injury is implicated in the cause of both diseases, some important differences exist between the two.[703] In contrast to EMND, in which the disease process is limited to the lower motor neurons, ALS affects upper and lower motor neurons. Only mild degeneration of the pyramidal tracts is present in horses with EMND, but the pyramidal tracts in horses are less extensive and poorly developed compared with human beings. Why both these diseases affect motor neurons so selectively is unclear. Motor neurons are particularly susceptible to oxidative injury by having high energy requirements associated with the maintenance of long axons. The high concentration of polyunsaturated fatty acids in neuronal cell membranes make these cells particularly susceptible to lipid peroxidation.[718] About 10% of human ALS cases are considered familial, of which about 20% are associated with mutations in the Cu/Zn superoxide dismutase gene. Mutations of this gene were not found in horses with EMND.[711] Pathologic protein aggregates that are found in neural tissues of humans with ALS or other neurodegenerative diseases may reflect a common pathway for a variety of destructive processes, including oxidative injury. In 2012, one of those proteins, transactive response DNA binding protein of 43 kDa, was shown to be present in neural tissues of EMND-affected horses but not in those of control horses.[719] In addition to gene mutations, other causal factors for ALS include excess iron and copper intake and exposure to lead, solvents, and chemicals. For some of these there is evidence these may play a role in the pathogenesis of EMND as well. For example, a case report and an experimental feeding trial have shown that excessive copper and iron may increase the risk of development of EMND.[715,717] Moreover, elevated copper concentrations were found in the spinal cords of EMND-affected horses compared with controls.[720] Further, similarities in the clinicopathologic features of EMND and lead toxicosis suggest a trace element toxicosis is possible.[721] Another recent hypothesis involved a neurotoxin called β-*N*-methylamino-L-alanine, which can be found in the brains of human patients with ALS or other neurodegenerative conditions such as Alzheimer disease and Parkinson dementia complex. This toxin is produced by cyanobacteria that can be present in the intestinal tract of humans and horses. Altered intestinal conditions may lead to overgrowth of cyanobacteria and resultant toxin production.[722]

A temporal vitamin E deficiency is also implicated in the pathophysiology of NAD/EDM. NAD/EDM develops in genetically susceptible animals if vitamin E deficiency occurs during the first year of life,[279,723] whereas EMND occurs in adult horses after an extended period of vitamin E deficiency.[713] Clinical signs and histopathologic findings are very different in these two diseases, and they are therefore considered distinct entities. However, recently evidence was provided for the concurrent presence of NAD/EDM and EMND

in three young horses.[292] Although the authors did not find evidence of mutations in the superoxide dismutase gene, they did suggest that there could be overlap in genetic susceptibility to developing both NAD/EDM and EMND in certain families when a nutritional vitamin E deficiency is present.

Diagnosis

Clinical signs and a history of other EMND cases in the stable and absence of pasture or green hay may lead to a tentative diagnosis of EMND. One must be aware of the fact that a recent European study showed EMND to occur in horses that did have access to pasture.[716] Ophthalmoscopic examination may reveal fundic lesions in approximately 30% of cases. Serum enzyme activities of AST and CK are generally mildly to moderately increased. The plasma vitamin E concentration is consistently low (less than 1 μg/mL); however, a 2006 case report described a horse with EMND that had normal serum vitamin E concentrations and was hypothesized to have developed the disease secondary to high tissue iron concentrations.[715] CSF analysis has been performed in horses with EMND and demonstrated elevated IgG concentrations in approximately 50% of cases. Intrathecal production of IgG also occurs in ALS; however, in both diseases this is considered a secondary effect of the disease process rather than a cause. The AQ was normal in most horses examined, indicative of normal blood-brain barrier function.[699] EMG of cervical, facial, triceps, rear limb, and tailhead muscles may be useful in acute cases. However, the electromyographic changes, which include positive sharp waves and fibrillation potentials, may be difficult to evaluate because they are expected in any peripheral nerve disease, myopathy, or myositis.[697,724] In approximately 50% of horses with EMND, the plasma glucose curve is decreased after oral glucose tolerance testing, whereas results of xylose absorption tests are normal or only slightly abnormal.[699,725] Research suggests that increased glucose metabolism, rather than reduced intestinal absorption, is the cause of abnormal glucose tolerance in horses with EMND.[726] The clinical significance of this finding is unknown.

An antemortem diagnosis of EMND can be reached through examination of muscle and/or nerve biopsies. A biopsy of the sacrocaudalis dorsalis muscle is easy to obtain in a standing horse, and histopathologic examination of this muscle reveals changes consistent with denervation muscle atrophy and scattered muscle necrosis.[703] This test has a sensitivity of approximately 90%, and it has recently been hypothesized that horses with a syndrome of vitamin E–responsive muscle atrophy and weakness may account for the less than 10% of false negatives. This is because vitamin E–related pathology is only detectable using mitochondrial stainings in fresh frozen sections, and not in formalin-fixed tissue, whereas evidence of denervation can be seen in formalin-fixed tissue. Horses with this syndrome have clinical signs of EMND but do not have evidence of lower motor neuron involvement in biopsies.[727] Advanced quantitative analytical techniques have shown that muscle biopsy samples from EMND-affected horses have a lower percentage of type I fibers and higher percentages of type II fibers, reduced oxidative capacity, increased glycolytic capacity, diminished intramuscular glycogen, lower capillary-to-fiber ratio, a higher ratio of myofibers expressing sarcoendoplasmic Ca^{2+}-ATPase 1a to the 2a isoform, and a lower percentage of fibers expressing phospholamban. The extent of the changes observed in this study appeared to be related to the duration of the disease.[728]

Examination of a biopsy of the ventral branch of the spinal accessory nerve may be more sensitive in chronic cases. Nerve biopsies must be placed on a tongue depressor and in 10% formalin or another fixative suitable for electron microscopy. An experienced neuropathologist should examine nerve biopsies carefully; wallerian degeneration, Schwann cell proliferation, and sometimes only evidence of smaller Bungner's bands (columns of proliferated Schwann cells) can be detected.[703,729] This nerve biopsy technique is described postmortem and in horses under general anesthesia, but it is also possible in standing sedated horses.[730]

A definitive diagnosis is based on postmortem examination of spinal cord, brainstem, nucleus ambiguus, and skeletal muscle. The most important differential diagnoses that one should consider are laminitis, rhabdomyolysis, and colic. Other diseases that may cause similar signs are botulism, EPM, polysaccharide storage myopathy, iliac thrombosis, equine grass sickness, and lead toxicosis.[502,721]

Treatment, Prognosis, and Prevention

The only recommended treatment is based on the idea that this disorder is caused by oxidative injury and on the fact that horses with EMND consistently have low plasma vitamin E concentrations. Supplementation with vitamin E (5000–7000 IU/horse/day) results in an increase of plasma vitamin E concentrations to 2.0 μg/mL or greater after 4 to 6 weeks.[502] Treatment with vitamin E has been associated with improvement of clinical signs in about 40% of cases within 6 weeks of treatment, of which many horses can make a near full recovery in 3 months[502]; however, no published studies examining the effect of treatment exist at this time. Response to treatment is thought to depend on the number of neurons that are damaged versus those that are dead; in the case of neuronal death, full recovery is unlikely because this is irreversible.

The prognosis is poor for return to performance and guarded for life. Although no published investigations exist regarding the survival rate and follow-up of horses with EMND, horses with EMND generally have been shown to follow one of three possible clinical courses.[502] Approximately 20% of horses continue to deteriorate, and the severe weakness and excessive recumbency necessitate humane euthanasia. In approximately 40% of horses, clinical signs appear to stabilize; however, these horses do not regain muscle mass and may develop severe gait abnormalities. Continued clinical abnormalities frequently lead to euthanasia within 1 year of onset of clinical signs. The third group of horses (approximately 40%) show dramatic improvement after treatment with vitamin E, and many may regain a normal muscle mass. These horses may remain stabilized, that is, appear normal, for 1 to 6 years or more; however, many relapse, resulting in euthanasia. This relapse appears associated with return to exercise, training, and competition. The group of horses that recover and appear normal may be affected by a more recently discovered syndrome of vitamin E–responsive muscle atrophy and weakness that may be a separate disease entity or a predecessor to development of EMND.[727] Horses affected by this syndrome have clinical signs of EMND but they lack evidence of neurogenic atrophy in the sacrocaudalis dorsalis medialis muscle. It is suggested that such undiagnosed cases may be the result of a specific myogenic presentation of vitamin E deficiency that can only be identified in mitochondrial stains of frozen sacrocaudalis dorsalis medialis muscle.[727]

In healthy young and middle-aged horses receiving adequate dietary vitamin E intake, there is no research-based evidence for the need for additional vitamin E supplementation above 500 IU/day.[305] The goal of vitamin E supplementation in horses at risk of developing EMND (horses at risk for oxidative stress) is to increase α-tocopherol concentrations in the CNS. A dose of 10,000 IU RRR-α-tocopherol/500-kg horse/day was shown to do this[303]; however, it is important to consider that this dose equals the NRC upper limit safety recommendation.[305] Periodic monitoring of blood antioxidant status is recommended in horses that are at risk for developing EMND.[713,731]

TETANUS

Yvette S. Nout-Lomas

Tetanus is an infectious disease of all domestic animals and human beings. Tetanus has been recognized since ancient times, including mention in the writings of Hippocrates. Tetanus (from the Greek *tetanos,* to contract) was first identified as a neurologic disease more than 20 centuries ago by Greek physicians. A causative infectious agent was first hypothesized in the 1860s. In 1884 Nicolaire produced tetanus with injections of garden soil into mice and transfer of tetanus by injection of infected material from a human wound into a rabbit was demonstrated. Reinforcing the transmissible nature of an infectious agent, smears of wounds from infected patients showed a bacillus-like organism under microscopy. Pure culture of the toxigenic organism was obtained by Kitasato in 1889, and it was subsequently shown that animals immunized with modified tetanus toxin generated neutralizing serum antibodies.[732] Passive immunization of horses against tetanus using horse serum antitoxin was practiced by Nocard as early as 1892. In 1986 the amino acid sequence of tetanus toxin was revealed,[733] with the mechanism of action elucidated in 1992.[734]

Although equine tetanus is an increasingly rare disease, tetanus occurs worldwide and is considered enzootic in many warmer countries in the developing world where vaccination programs for both man and equids are not established. Tetanus is a distressing and often-fatal disease caused by 3 protein exotoxins liberated by the bacterium *Clostridium tetani* of the family Bacillaceae. Equids are particularly susceptible to the tetanus exotoxin.

Biology of *Clostridium Tetani*

C. tetani is a large gram-positive bacillus and is an obligate anaerobic spore former. It is part of the normal flora of the intestinal tract of humans and animals and can be readily isolated from the intestinal tract and feces of a wide range of animals, with fecal surveys in North America, Brazil, and Canada revealing between 30% and 42% positive samples.[732] *C. tetani* is found ubiquitously and in adverse environmental conditions, *C. tetani* produces round terminal spores able to survive in the environment for a prolonged period (years) in the absence of direct sunlight. Spores are highly resistant to environmental changes, acid, alkali, boiling water, and many standard disinfection techniques. The vegetative form is susceptible to heat and numerous disinfectants. *C. tetani* spores are terminal and oval, giving the bacillus a characteristic drumstick or tennis racket appearance.[732] The organisms may occur singly or in filamentous chains. Organisms are highly motile by means of flagellae uniformly distributed over the entire bacterial surface, allowing them to swarm over a culture plate. Optimal growth occurs at 37°C. Colonies have irregular margins and are flat, translucent, and gray with a matte surface on blood agar. Colonies are 4 to 6 mm in diameter with a narrow zone of clear (β-type) hemolysis.

Toxins

Under anaerobic conditions, *C. tetani* spores germinate and produce three exotoxins: tetanolysin, tetanospasmin, and nonspasmogenic toxin. Tetanospasmin is the most powerful and most important clinically.

Tetanospasmin

Tetanospasmin is produced in the bacterial cell as a single polypeptide chain of 1315 amino acids[733] with a molecular mass of approximately 150 kd.[735] The amino acid sequence of tetanus toxin shares marked similarities to the amino acid sequences of botulinum toxins A, B, and E, suggesting that, although neurotoxins from *C. tetani* and *C. botulinum* have different clinical effects, they are derived from a common ancestral gene.[733] After release from the cell, the molecule is cleaved into two polypeptide fragments by proteases produced by the organism—a heavy chain of about 100 kd and a light chain of about 50 kd that remain joined by a disulfide bond.[736] Toxin spreads from the infected site by diffusing into the adjacent tissues and is subsequently transported by the lymphatic system, allowing entrance to the bloodstream.[732] Toxin also travels up (centripetal transport) peripheral nerve endings, sensory and autonomic fibers, into the central nervous system through retrograde axonal transport.[732] Tetanospasmin localizes in the ventral horn of the gray matter of the spinal cord and binds to inhibitory interneurons, called Renshaw cells. There are three steps that result in action of this toxin: (1) binding to the neuronal cell membrane; (2) internalization by endocytosis; and (3) the intracellular blockade of neurotransmitter release.[737] Binding of the toxin to receptors on the nerve endings is the initial step in the paralytic process. Membrane receptors for these toxins consist of membrane gangliosides GT and GD1b and a receptor protein. This binding is almost irreversible and thus accounts for the prolonged nature of the signs. Once toxin is bound, it is internalized by endocytosis. The light chain, where it displays its zinc-endopeptidase activity specific for protein components of the neuroexocytosis apparatus, is translocated into the cytosol where it can exert its effect.[738,739] This process of internalization makes toxin unavailable to be bound and neutralized by circulating antibodies. Finally, tetanospasmin blocks the postsynaptic inhibitory signal of the spinal cord motor neurons by preventing release of the inhibitory neurotransmitters glycine and GABA. This disinhibition leads to continued stimulation of motor and reflex arcs, which results in the characteristic muscular spasms and contractions, hyperesthesia, and eventually convulsions, respiratory arrest, and death seen in patients with tetanus.

The specific target of tetanus toxin is synaptobrevin, also known as vesicle-associated membrane protein (VAMP).[740] This is one of three proteins that comprise the soluble *N*-ethylmaleimide-sensitive factor attachment receptor (SNARE), an integral membrane protein of the synaptic vesicles of nerve cell terminals crucial for normal vesicle physiology.[737,741] SNAREs are essential for a variety of vesicle docking and

fusion events,[739] and mutant studies have shown that any alteration in synaptobrevin leads to disturbed vesicle function.[741] Two copies of a nine-residue motif situated in tandem, each with three negatively charged residues, appear to be responsible for toxin specificity.[741] Cleavage of synaptobrevin by proteolytic action of the zinc-dependent endopeptidase of tetanospasmin light chain is the mechanism of toxicity, incapacitating cellular exocytotic machinery and blocking neurotransmitter release.[742] Both binding and internalization are mediated only by the heavy chain of the toxin, whereas the intracellular blockade of neurotransmitter release involves the light chain alone.[737]

Tetanospasmin is poorly absorbed across mucous membranes, is destroyed by gastric juices, and is unable to cross the placenta as result of its high molecular weight.

Tetanolysin and Nonspasmogenic Toxin

The effect of tetanospasmin is amplified by tetanolysin and nonspasmogenic toxin. Tetanolysin facilitates the spread of infection by increasing the amount of local tissue necrosis. The mechanism of action is to cause permeability changes in liposomes and biologic membranes resulting in cell lysis.[743] Tetanolysin is an oxygen-sensitive hemolysin similar to streptolysin and can affect a variety of cells including erythrocytes, neutrophils, macrophages, fibroblasts, and platelets. Tetanolysin has an affinity for cholesterol and related sterols that inhibit its lytic and lethal actions. The amount of tetanolysin produced by the organism in vivo is unknown.[732] The role of nonspasmogenic toxin in the pathogenesis of tetanus is not fully known but may involve blocking transmission in peripheral neuromuscular junctions.

Risk Factors for Disease

A 2007 report on tetanus in equids in a group of clinics in Morocco showed that tetanus cases represented 0.07% of the total patient load and 2% of all hospitalized patients.[744]

Animal species vary in their susceptibility to tetanus toxin. The horse is the most susceptible animal, and the cow is among the least. Neither age nor sex influences susceptibility. Incidence of disease depends on susceptibility and opportunity for exposure to the organism. Entry of organisms into the animal is usually by inoculation into a contaminated deep-penetrating wound. From two retrospective studies it appears that tetanus in equids is mostly associated with wounds to the distal limbs and hooves, which were found in 32 out of a combined 74 cases.[744,745] Other sites of wounds that were found in these studies were the head, proximal limbs, tail, hobble wounds, fistulous withers, rectal prolapse, and castration wounds. Other potential sites of entry include lacerations, surgical sites, the umbilicus of the neonatal foal, and the postfoaling reproductive tract. What may complicate or delay the diagnosis of tetanus is that the wound that served as the initial site of introduction of *C. tetani* may involve unbroken skin or be healed by the time clinical signs are observed. In fact, one study showed this had occurred in 2 out of 18 cases,[745] and another series showed that 18 out of 56 equids with tetanus had no visible wound at presentation.[744] Devitalized tissue is essential for development of tetanus. Once traumatized or devitalized tissue has become contaminated with spores, the spores can remain dormant until necrosis of the tissue provides the strict anaerobic environment necessary for germination to the vegetative, toxin-producing form.

Clinical Signs and Course of Disease

Tetanus is manifest as hypertonia of the striated muscles, with clonic paroxysmal muscular spasms superimposed. Muscular activity may be increased to the point that rectal temperature becomes markedly elevated. Clinical signs may be generalized or localized. Localized tetanus involves muscular rigidity and spasms in the vicinity of the infected wound. With time, this usually progresses to a more generalized tetanus affecting the entire body; however, the initial manifestation of tetanus is most often generalized rather than localized.[732] With generalized tetanus, a characteristic "sawhorse" stance, with an extended, rigid tail, may be present, and the gait is stiff if the horse remains ambulatory (Fig. 11.41). Difficulty in standing or lying down is due to extensor muscle rigidity that is exacerbated by external stimuli. As a result of hyperesthesia, painful reflex muscle spasms progressing to generalized tonic contractions with opisthotonus may be the result of even mild stimulation. Progression of the disease makes voluntary movement impossible because of marked extensor rigidity of all four limbs, often leading to recumbency.

Tetanospasmin affects both the sympathetic and parasympathetic nervous systems. Sympathetic hyperactivity

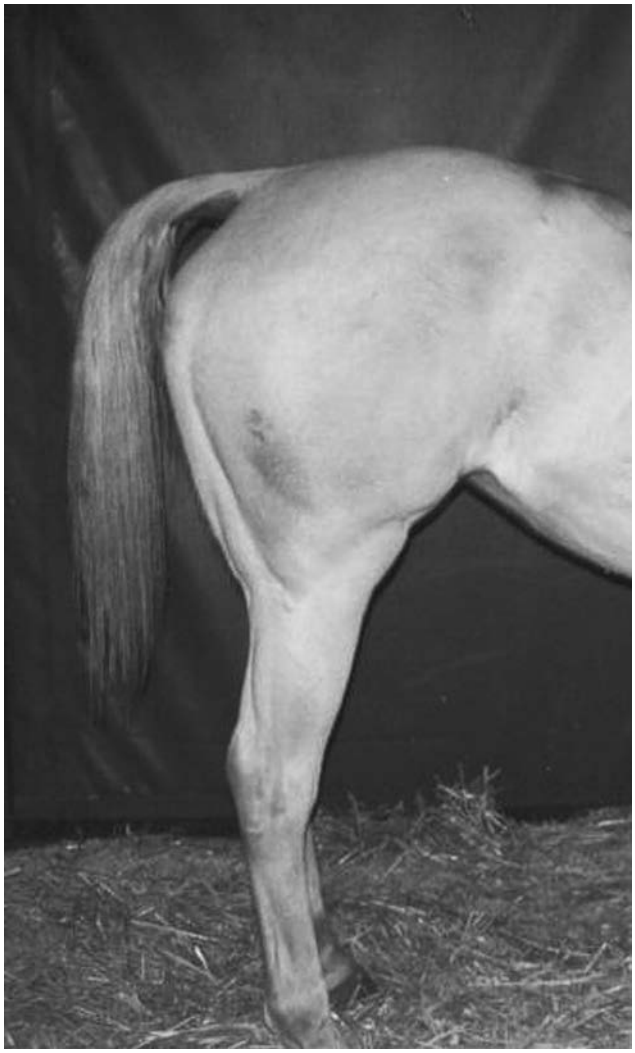

FIG. **11.41** The extended, rigid tail seen in this horse is characteristic of generalized tetanus.

associated with adrenergic stimulation may lead to tachycardia, cardiac arrhythmias, and peripheral vasoconstriction. Parasympathetic hyperactivity increases vagal tone that may result in bradyarrhythmias, atrioventricular block, and sinus arrest. Furthermore, tetanospasmin can act upon cranial motor nuclei, resulting in spasms of cranial muscles. Trismus is due to contraction of the masticatory muscles, with sustained facial muscle contracture and lip retraction resulting in risus sardonicus (a sardonic grin). Dorsomedial retraction of the ears and excessive wrinkling of the skin of the forehead can be seen. Prolapse of the nictitating membrane and enophthalmos is due to retraction of the globe by the hypertonic extraocular muscles (Fig. 11.42). Miosis, dysphagia, ptyalism, and laryngeal spasm may also occur.

A series of 20 cases showed that hyperesthesia (17 of 20, 85%) and prolapse of the third eyelid (17 of 20, 85%) were the most consistently observed clinical signs. A stiff gait, fever, tachycardia, tachypnea, erect ears and tail, elevated head, trismus, extensor spasms, sweating, and convulsions were seen in 50% (10 of 20) of the horses.[745] In an attempt to correlate clinical signs to survival a disease severity scoring system has been proposed using a clinical score from 1 indicating mild disease to 4 indicating terminal disease (Table 11.17).[744]

Complications from tetanus include decubital ulcers after periods of recumbency, regurgitation because of dysphagia, dysuria because of a hypertonic urethral sphincter, and constipation with gaseous distention because of a hypertonic anal sphincter and lack of exercise. Death may result from respiratory failure secondary to the spasm of respiratory muscles or central respiratory arrest from medullary intoxication. Aspiration pneumonia secondary to dysphagia or increased airway secretions may also be fatal. No characteristic necropsy lesions can be ascribed to the tetanus toxins themselves.

FIG. **11.42** This horse exhibits enophthalmus, prolapsed nictitans, and rigidity of facial muscles, typical of generalized tetanus.

The prognosis for survival from this disease is reported to depend on several factors, including the immune and vaccination status of the host, the dose of clostridial organism inoculated, and the availability and duration of aggressive treatment and supportive care.[745] From the three reports available on survival of equine tetanus, the oldest describes a case fatality rate of 75%, with previous vaccination strongly associated with survival.[745] Two other reports describe a mortality rate of 68%[746] and 59%.[744] Severity of clinical signs is clearly associated with survival across these three studies.[744-746] In particular, the presence of dyspnea, dysphagia, and recumbency were significantly more common in nonsurvivors than survivors and can be considered indicators of a poor prognosis.[746] When using the clinical scoring system (see Table 11.17), animals categorized as grade 1 or 2 had a survival rate of over 60%, whereas this was less than 10% for animals categorized in grade 3.[744] One report showed that younger horses were significantly less likely to survive than older horses[746]; however, this was not the case in the other study that looked at this.[744] A study involving 56 cases showed that factors such as sex, age, and chronicity at presentation had little relationship with prognosis.[744] Heart rate at presentation had little value as a prognostic indicator, except where elevated above 80 beats/min. Furthermore, survival was not different among donkeys, horses, and mules.

Diagnosis

There is no definitive antemortem test for tetanus. There are also no postmortem findings pathognomonic for the disease. Finding microscopic evidence of the bacteria or its toxin at the site of a wound is an unreliable diagnostic indicator. A biologic assay for antemortem diagnosis is possible in some cases by injecting infected material into the tail base of mice and observing for onset of clinical signs. A presumptive diagnosis of tetanus is based on history, clinical signs, and response to treatment. Confirmation is difficult. On physical examination, a recent or healed wound may be found; however, absence of a detectable wound at the time of clinical onset is not

TABLE **11.17** **Clinical Scoring System for Equids with Tetanus, According to Kay and Knottenbelt**

Clinical Score	Disease Severity	Clinical Signs
1	Mild	Nictitans membrane flashing, ears pulled caudally, slightly stiff gait but still walking and eating without difficulty
2	Moderate	Nictitans membrane flashing, ears pulled caudally, limbs stiff and walking with difficulty, trismus and generalized muscle spasm, animal still capable of eating and drinking voluntarily albeit slowly
3	Severe	Capable of standing but incapable of walking, severe trismus, difficulty with prehension, mastication and swallowing of food, and drinking voluntarily
4	Terminal	Animal recumbent, incapable of standing, incapable of eating; animals presenting in this situation are considered candidates for immediate euthanasia

From Kay G, Knottenbelt DC. Tetanus in equids: a report of 56 cases. *Equine Vet Educ*. 2007;19:107-112.

uncommon. Devitalization of deep tissue undetectable externally may be the site of toxin production.

Gram staining of samples from the wound is of limited diagnostic value. Sporulated and vegetative forms of *C. tetani* appear similar to other anaerobic bacteria. Furthermore, *C. tetani* may be present as a wound contaminant, with some strains of *C. tetani* nontoxigenic because they lack the 75-kilobase plasmid containing the toxin gene.[733,741] Bacteriologic confirmation of tetanus is not often attempted but would be obtained by isolating *C. tetani* from the infected wound. However, isolation of *C. tetani* can be difficult and often fails because of low concentration of organisms present in the wound and strict anaerobic conditions required for culture.

Hematology, serum chemistry, and CSF analysis are usually unremarkable. If a wound or aspiration pneumonia is present, neutrophilic leukocytosis with a left shift may be observed. Muscle enzymes may be elevated (CK and AST) because of muscle trauma from sustained contracture and prolonged recumbency.

Treatment

The binding of tetanospasmin to the Renshaw cells via ganglioside receptors is almost irreversible. Recovery is slow and does not occur until new interneuronal synapses develop to replace those that were inactivated by toxin. Therapeutic management of clinical cases of tetanus is centered around the following five goals.

Elimination of the Source of the Toxin

Local and parenteral antibiotic therapy is initiated to prevent further production of tetanospasmin by eradication of the vegetative form of *C. tetani* at the site of infection. Penicillin is the drug of choice for eliminating the vegetative form and is recommended to be administered at high dosages. Other antimicrobials that may be effective include the tetracyclines, macrolides (to be avoided in adults), and metronidazole. Metronidazole is indicated for deep and contaminated wounds because it is able to penetrate necrotic tissues without losing efficacy. Any visible wounds should be systematically cleaned, meticulously debrided, and lavaged thoroughly. If possible, aerobic conditions should be established at the infection site.

Neutralizing Unbound Toxin

Neutralizing any toxin that is not already bound to the ganglioside receptors is of primary importance. Tetanus antitoxin (TAT) is produced by hyperimmunization of horses with tetanus toxoid. Administration of 1500 U of antitoxin to unvaccinated horses provides immediate passive protection lasting approximately 3 weeks.[747] Higher doses result in longer duration of protection. In one study monitoring antitoxin levels as a measure of protection, combined active-passive immunization (tetanus toxoid concurrently with TAT) was effective at providing rapid and prolonged protection for previously unvaccinated horses.[748] Administration in separate, remotely located sites on the horse was recommended. Subclinical and clinical hepatic disease after TAT administration has been reported.[749,750] Known as idiopathic acute hepatic disease, this condition has also been called Theiler's disease, serum hepatitis, serum sickness, and postvaccinal hepatitis. Signs vary from hepatic enzyme elevation to hepatic encephalopathy in severe cases. Occurrence of this disease is rare and sporadic, but prognosis is poor in most affected horses.

Once TAT is administered to the affected horse, the passively acquired antibodies neutralize unbound toxin both circulating in the blood and present in the wound. Injection of TAT, both around and proximal to the wound site, has been suggested to be beneficial in neutralizing unbound toxin. It is important to realize that once the toxin is bound and then internalized into the neurons it can no longer be neutralized by antitoxin. Therefore the disease will likely continue to progress after the administration of TAT. Although the use of TAT for neutralization of unbound toxin has been reported to be an effective adjunct to therapy, dosages and routes of administration vary and there are few data for evidence-based therapy. Currently, recommended doses range from a single administration of 5000 to 2.5×10^6 IU/animal followed by lower doses over 5 days.[744] The use of TAT administered into the subarachnoid space (intrathecally) has also been advocated. One of the first reports to use this method showed a recovery rate of 77.5% in horses treated with 30,000 to 50,000 IU TAT intrathecally.[751] Such success has not been repeated in more recent reports.[744,745,752] The advantages of the intrathecal route seem to be questionable, and it appears that early diagnosis, nursing care, high doses of parenteral penicillin, and establishing aerobic conditions at the infected site may be the most important aspects of treatment.[744]

Relief of Pain and Control of Neuromuscular Derangements

Generalized muscle contractions can be painful and result in hyperthermia that must be managed. Typically a combination of sedatives and muscle relaxants is used to achieve the goals of pain relief and control of muscle spasms. Phenothiazine drugs are commonly used for sedation and relieve of muscle spasms. The relaxing effects appear to allow some affected animals to eat and drink again, which are considered good prognostic indicators. Phenothiazine drugs work at the level of the brainstem, depressing descending excitatory input on the lower motor neurons within the spinal cord. Although these medications have been reported to lower the seizure threshold, their effectiveness in the management of clinical cases strongly supports the use of these drugs. Phenothiazines potentiate barbiturates, which are also useful in the management of tetanus cases because of their ability to depress the motor areas of the brain and abolish spontaneous spinal cord activity. Muscle relaxants such as the benzodiazepines indirectly antagonize the effects of tetanospasmin. Diazepam has glycine mimetic effects and potentiates release of GABA, an inhibitory neurotransmitter. The combination of benzodiazepines and α_2-agonists such as xylazine may also be very effective in controlling muscle spasms. Methocarbamol or other central-acting muscle relaxants, such as guaifenesin or baclofen, would also be considered rational and useful therapeutic agents. Magnesium sulfate may also have beneficial effects in the treatment of tetanus.

Supportive Care

Supportive care is of utmost importance in the successful treatment of tetanus. Patients should be placed in a dark, quiet environment, with minimal stimulation and handling. Ear plugs can be placed to reduce auditory stimulation. If recumbent, supportive care for down horses needs to be provided.[9] Maintaining adequate hydration and nutritional status is of critical importance for care in these horses. In addition, providing deep soft bedding and regular turning (every 4 hours) to minimize decubital ulcers and pulmonary congestion are essential. Urinary catheterization, enemas, and manual rectal evacuation of feces may be required

because of hypertonic urethral and anal sphincters and lack of an effective abdominal press. If dysphagic, an esophagostomy or gastrostomy tube may be required for feeding. Tracheostomy may be required should laryngeal spasm and respiratory obstruction occur.

Generation of Active Immunity to Tetanus Toxins

Unfortunately, the concentration of tetanus toxin required to cause overt neurologic disease is insufficient to generate a protective immunologic response. Therefore at the initiation of treatment for tetanus, all horses should be immunized with tetanus toxoid to initiate a protective antibody response. An antibody response may take 2 to 4 weeks to develop.

Prognosis

Mortality rates of 54% to 75% have been reported for horses with tetanus.[744-746] The prognosis for survival depends on several factors such as the immune and vaccination status of the horse, the dose of clostridial organisms, and the availability and duration of treatment and supportive care. A short incubation period, short duration of onset, and rapid progression of signs is often associated with a poor prognosis. When attempting to treat clinical cases, it must be realized that the required supportive care is prolonged, labor intensive, and costly. One study reported an association between survival and previous prophylactic vaccination with tetanus toxoid; in that study none of the nonvaccinated horses survived.[745] One study showed that there was no association between sex, age, and duration of disease at presentation. However, what did affect prognosis was severity of clinical signs: animals with severe clinical signs (grade 3) had the lowest survival rate (less than 10%).[744]

Prevention

Where possible, management of contaminated or necrotic wounds should include thorough debridement, large volume flushing, aeration, and comprehensive cleansing. After this, rational antibiotic therapy should be instituted. Together these procedures, in conjunction with the following, should greatly minimize the occurrence of tetanus.

Low concentrations of tetanospasmin are capable of inducing clinical signs. As a result, neither exposure to tetanospasmin nor recovery from clinical disease induces the development of immunity. Prophylactic antibody formation and generation of immunity is stimulated by vaccination with tetanus toxoid, derived from inactivation of tetanospasmin with formaldehyde. Tetanus is a preventable disease, and vaccination with tetanus toxoid markedly reduces the occurrence of clinical disease. However, no vaccination is absolute,[745] with protection being dependent on proper administration and subject to breakdown in the face of overwhelming challenge. The adjuvanted tetanus toxoid vaccine is highly immunogenic, but efficacy of the vaccine relies heavily on the vaccination program. Current recommendations for adult horses are an initial vaccination followed by a booster 4 to 6 weeks later with annual revaccination. Significant differences have been found in antibody response (IgG titers) between commercially available multivalent vaccines,[753] and it was suggested that these differences were the result of variations in antigenic mass. Recently a prospective seroconversion study demonstrated that protective titers against tetanus were present up to 3 years after a series of vaccinations were administered (initial booster 4–6 weeks after primary vaccination and a second booster 15–17 months after the second vaccination).[754] The authors suggested our vaccination guidelines may need to be revisited and annual revaccination may not be necessary. In clinical cases of tetanus, experts recommend that tetanus toxoid be administered to horses with susceptible wounds if longer than 6 months since vaccination.

In foals, tetanus-specific IgG antibodies inhibiting the foal's response to tetanus toxoid are passively transferred via colostrum. High titers of IgGa, IgGb, and IgG(T) subisotypes were detected in postsuckling serum samples collected from foals born to mares that had received booster doses of multicomponent vaccines during the past 2 months of gestation. In addition, antibody response to vaccination of younger foals has been shown to be poor, necessitating multiple doses of toxoid. Current recommendations are to vaccinate foals born to vaccinated mares at 4 to 6 months of age with boosters 4 to 6 weeks later and a third vaccine at 10 to 12 months of age. Vaccination for foals born to unvaccinated mares should begin at a younger age: the current recommendations are to start at 1 to 4 months of age with a booster 4 weeks after the first dose and a third vaccine 4 weeks after the second dose.

BOTULISM

Yvette S. Nout-Lomas, (Stephen M. Reed)

Botulism is a severe neuroparalytic disease caused by botulinum neurotoxins (BoNTs) that are produced by BoNT-producing clostridia. The neurospecificity and toxic potency of BoNTs make them the most powerful known toxins, and they are potential bioterrorism weapons.[755,756] Horses are more susceptible to botulism than other species such as cattle, dogs, and humans, which are relatively resistant.[757] In horses, botulism has been most commonly associated with BoNT serotype B (BoNT/B) and BoNT/C, followed by BoNT/A and less commonly by BoNT/D.[755,758-760] The disease course is related to total toxin exposure and most commonly results in death unless the horse is treated promptly with specific antitoxin. A fast and accurate diagnosis is crucial because of the necessity of rapid treatment and the large potential of botulism outbreaks linked to a common feed source. Unfortunately, laboratory diagnosis has proven difficult in horses, and botulism is generally considered to be a clinical diagnosis.[758,759]

Biology of Bont-Producing Clostridia and their Toxins

There are six phylogenetically distinct groups of BoNT-producing clostridia (*Clostridium botulinum* groups I–III, *Clostridium argentinense* group IV, and some strains of *Clostridium baratii* and *Clostridium butyricum*) that produce seven serotypically distinct BoNTs (serotypes A–G).[755,756] The number of subtypes has grown in recent years, owing to the increased use of whole-genome sequencing and mass spectrometry, as well as the availability of high-affinity monoclonal antibodies. This has revealed the striking variety of distinct BoNT subtypes that are produced by clostridial species.[756] Notably, *C. botulinum* strains from groups I and II produce the widest range of neurotoxins; group I proteolytic *C. botulinum* produces BoNT/A, BoNT/B, and BoNT/F; and group

II nonproteolytic *C. botulinum* produces BoNT/B, BoNT/E, and BoNT/F. Group III *C. botulinum* produces BoNT/C, BoNT/D, and their mosaic BoNT/CD and BoNT/DC. Group IV *C. argentinense* produces BoNT/G, *C. butyricum* produces BoNT/E, and *C. baratti* produces BoNT/F. Each toxin serotype is categorized into various subtypes on the basis of their amino acid sequences, and, although most strains of *C. botulinum* express a single toxin serotype, some isolates produce more than one serotype; for example, some proteolytic *C. botulinum* group I isolates produce a mixture of Ab, Af, Ba, and Bf subtypes.[756] Investigators have shown that there are now more than 40 different BoNTs.[756]

Clostridia are sporulating and anaerobic gram-positive, rod-shaped bacteria that are widely distributed in the environment and in anaerobic regions of the intestines of several animals, where they are typically found as spores. Spores are resistant to physical and chemical stresses and can persist for long periods of time until favorable conditions enable germination. Under appropriate environmental conditions (such as humidity, nutrients, and the absence of oxygen), spores germinate into vegetative cells; conversely, exposure to oxygen, as well as water and nutrient deprivation, trigger sporulation.[756] Botulism outbreaks typically occur in environments that contain *C. botulinum* spores, which can germinate in decomposing organic material under anaerobic conditions. Environmental conditions that favor botulism outbreaks include warm temperatures, shallow alkaline waters that contain abundant invertebrate populations, and decomposing vertebrate carcasses.[755,756]

Human botulism is much rarer than animal botulism and is mostly caused by BoNT/A, BoNT/B, BoNT/E, and rarely by BoNT/F. Botulism mostly affects wild and domesticated animals, and outbreaks of animal botulism can spread rapidly, leading to the intoxication of hundreds of thousands of animals in just a few days. The primary contamination route for both humans and animals is the ingestion of preformed toxins in foods or feeds. Raw material, such as grass, hay, rotting vegetation, and slaughterhouse waste, as well as decay of vertebrate carcasses, invertebrates, and sewage may support BoNT-producing clostridial growth and toxin production. Animals may directly ingest decaying organic matter containing toxin, or they may ingest toxins through the consumption of zooplankton or invertebrates, such as larvae, that have consumed toxic material. Fly larvae and other invertebrates are unaffected by the toxin, but feeding on toxigenic carcasses may concentrate toxin. Ingestion of a single toxigenic maggot could be lethal. This is described as the carcass-maggot cycle of botulism.[755] Typically carrion-associated (birds, small animals) botulism is associated with contaminated water, feed, or the environment involving BoNT/C and BoNT/D. Non–carrion-associated botulism is caused by BoNT/A and BoNT/B.

In North America, over 85% of equine botulism cases are caused by BoNT/B.[757] BoNT/A and BoNT/C have been associated with fewer cases, although studies suggest that BoNT/A botulism may be more common in horses than previously assumed.[761] BoNT/D botulism has been suspected in horses and cattle in the United States[757] but has only been confirmed in equine botulism in Senegal.[762] Equine botulism in Europe appears to be mostly associated with BoNT/B and BoNT/C.[763] In North America, BoNT/B botulism is endemic in the mid-Atlantic states and Kentucky, and BoNT/A botulism is more common in the western states. This geographic distribution is consistent with outcomes from soil surveys, which have demonstrated a predominance of BoNT/B-producing clostridial spores in the northeast and central states, from Kentucky to Pennsylvania, whereas BoNT/A-producing clostridial spores were found in samples from western states.[764] BoNT/A and B botulism are associated with forage, whereas BoNT/C botulism is associated with decomposing carcasses. Ravens have been shown to serve as transport vectors by feeding off a decomposing animal carcass and then transporting the toxin to the feed buckets or feed troughs of horses up to 1.5 miles distant from the decomposing carcass.[765]

Mechanisms of Intoxication

Three routes of BoNT intoxication have been described in the horse: (1) food-borne botulism, (2) toxicoinfectious botulism, and (3) wound botulism. Food-borne botulism is caused by ingestion of the preformed toxin present in feed materials, most commonly roughage (hay, haylage, silage) but occasionally grain by adult horses. Typically, BoNT/B-producing clostridia directly proliferate and produce toxins in decaying vegetable matter. In contrast, BoNT/C-producing clostridial spores that can be present in the intestinal tract of animals or birds can undergo germination and toxin production in a decomposing carcass, which provides an excellent anaerobic environment. Toxins produced in the carcass over time leach out and contaminate the hay or other feed material.[757]

Toxicoinfectious botulism, or "shaker foal syndrome," is usually associated with BoNT/B and occurs in foals between 2 weeks and 8 months of age.[757] The syndrome is similar to what is seen in human infants whereby spores are ingested, germinate, and produce toxin once in the gastrointestinal tract. Under normal circumstances, the intestinal flora of adult animals and humans inhibits the intestinal proliferation of BoNT-producing clostridia, thereby limiting the occurrence of toxicoinfectious botulism to neonates.[766] Endemic foal botulism is thus considered to occur from ingestion of spores present in contaminated soil. Toxin can be detected in the feces of approximately 30% to 40% of foals with botulism but only during the acute clinical phase.[757,767]

Wound botulism occurs in horses when BoNT/B-producing clostridia infect a wound, germinate, proliferate, and release toxin under anaerobic conditions. In adult horses, wound botulism has been associated with an injection abscess and castration, and in foals, it has been diagnosed in conjunction with infected umbilical remnants and an infected limb wound.[757]

Mechanism of BoNT-Induced Neuroparalysis

BoNT-producing clostridia secrete toxins during their vegetative growth as progenitor, inactive, single-chain polypeptide toxins of approximately 150 kDa. Toxins are produced as heterodimers with proteins that effectively decrease the exposure of BoNT to external damaging agents. These proteins may also facilitate crossing epithelial cells.[755,756] BoNTs cross the intestinal epithelial barrier, disperse in extracellular fluid, and enter the lymphatic system and the blood circulation where they can remain for many days. They are unable to cross the blood-brain barrier. BoNTs are very specific and only bind to peripheral nerve terminals, particularly those of skeletal and autonomic cholinergic nerves.[768]

BoNT mature toxins consist of a light chain and a heavy chain. Internalization of the BoNT into nerve terminals occurs through binding of the carboxy-terminal end of the HC domain of the light chain to a polysialoganglioside (PSG) receptor that is present on the presynaptic membrane, followed

by binding to a protein receptor (either synaptotagmin or SV2) that is located either inside the exocytosed synaptic vesicle or on the presynaptic membrane. The light chain encodes the toxic moiety, which is a metalloprotease domain that specifically cleaves the SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) proteins that are necessary for neurotransmitter exocytosis. Some BoNTs cleave VAMP, some cleave SNAP25, and some cleave both SNAP25 and syntaxin. BoNTs thus act presynaptically at the peripheral cholinergic neuromuscular junction and result in the inhibition of neurotransmitter (acetylcholine) release and consequent neuroparalysis.[756]

The action of BoNTs is reversible likely because BoNTs do not cause neuronal death. The duration of BoNT-induced neuroparalysis is quite variable, depending in part on the lifetime of the metalloprotease within the nerve terminal cytosol, which is different for the different BoNTs (BoNT/A > BoNT/C > BoNT/B > BoNT/D). Also, the activity of the affected muscle and toxin dose determine duration of BoNT action. Duration of action determines the severity of disease, and in humans and horses there are data to suggest that BoNT/A causes more severe disease than BoNT/B.[756,761] Once the toxin is bound, improvement in clinical signs is achieved after sprouting of the presynaptic axon terminal and subsequent formation of a new synapse.[769]
