lacerate the vaginal roof, and in extreme cases it can result in a rectovaginal fistula. A fistula is all that occurs if the foal withdraws its hoof from the rectum before delivery. A third-degree perineal laceration occurs if the strong expulsive efforts of the mare cause the limb that has penetrated the rectum to dissect through the caudal rectovaginal shelf and rupture through the anal sphincter, creating a cloaca.[820,821]

Carpal flexion is a common cause of dystocia. It may be unilateral or bilateral, and typically the affected carpus is located at the pelvic inlet.[802] To safely correct this malposture, the fetal body must first be repelled into the uterus. If the dystocia is prolonged, then the amount of uterine contraction may preclude meaningful repulsion of the fetus back into the uterus. Because the fetus is likely to be dead in these cases, a relatively simple fetotomy cut can be made at the level of the distal row of carpal bones. This permits safe delivery of the foal without the need to traumatize the reproductive tract and generally facilitates extraction within minutes.[813,815,817] If the foal is alive, then repulsion into the uterus will permit the flexed limb to be grasped at the level of the fetlock and pastern. By rotating the wrist, the obstetrician can rotate the carpus laterally while bringing the flexed fetlock medially and caudally into the birth canal. This maneuver allows maximal use of available space by obliquing the extremity through the pelvic inlet. The obstetrician should be aware that flexural deformities are considered to be the most common congenital anomaly of foals and that the rigid deformity often means that a cesarean section or fetotomy must be performed.[178,591,797,813,814] Limb contractures are generally bilateral. Contracture is more common in the forelimbs than the hindlimbs but can involve all four limbs.[797,802] Severely affected limbs cannot be straightened, and needless trauma can be inflicted on the genital tract by unrewarding attempts to manually correct the malposture. It is important that the clinician cup the hand over the bottom of the fetal hoof at all times while attempting to straighten the limb. Failure to do so may result in injury to the reproductive tract. Application of an obstetric chain or rope to the distal limb can be a useful aid. This permits traction to be applied to the distal limb while the hand covers and guides the hoof.

The single most common abnormality in referral hospital dystocia populations is a reflected head and neck.[726,797,816] Unfortunately, these malpostures are often iatrogenic in that a viable fetus has pulled back from the initial vaginal intervention that aimed to correct a minor postural problem. If the mare strains while the foal's head is pulled back, it is then possible for the muzzle to engage the wall or floor of the pelvic inlet. The mare's forceful expulsive efforts may then drive the head and neck ventrally or laterally along the thorax while the forelimbs are pushed farther into the vaginal canal. Ventral or lateral displacements of the head and neck can be very difficult to correct. The length of the foal's neck often makes it impossible to reach the head. Inexperienced clinicians should consider referral as soon as the condition is diagnosed, because prolonged unrewarding manipulations can easily jeopardize the mare's future fertility. A relatively simple fetotomy cut can resolve these cases quite atraumatically if the fetus is dead when the veterinarian arrives. The author believes that this approach is preferable to prolonged and often unsuccessful attempts at manual correction of this extremely difficult malposture.

If the fetus is alive, then an attempt can be made to place eye hooks or to loop a snare around the mandible. Some obstetricians even suggest applying a clamp on an ear to pull the head back enough to place a snare. The author prefers to use a snare whenever possible. If traction can be applied to the head, then the foal's body must be carefully repelled while attempts are made to bring the head and neck around into a normal posture for delivery. Factors influencing the successful outcome include uterine tonicity, clinician arm length and skill, and the presence or absence of torticollis and facial scoliosis. As with contracted tendons, it is essential that the practitioner consider the possibility of a wry neck. This condition is not amenable to correction by mutation, and needless trauma can be inflicted on the genital tract by unrewarding attempts at correction. Ventral deviation of the head is relatively easy to correct if the fetal nose is just below the brim of the pelvis (poll posture). It is generally easier to rotate the head laterally before attempting to bring the muzzle up over the pelvic brim. In more severe cases the neck is tucked down between the forelimbs and the head is often beyond reach (nape posture). If attempts to reposition the head and neck are unsuccessful, then cesarean section or fetotomy are indicated.

Shoulder flexion posture may be unilateral ("swimming" posture) or bilateral ("diving" posture). To gain access to the retained limb, it is usually necessary to repel the head and neck into the uterus. An immediate cesarean section may be preferable if the foal is alive, because correction of this malposture can be difficult and time consuming. If this is not an option, it is then recommended that a soft rope snare be placed on the fetal head (behind ears and into mouth) so that the head can be readily retrieved once the shoulder flexion has been corrected. If the limb can be reached, then correction of this malposture is performed in two stages. Initially, the shoulder flexion is converted to a carpal flexion when the limb is grasped in the area of the humerus working down to the distal radius. The limb is then pulled caudally and medially as the fetal body is repelled. The carpus is then hooked over the brim of the pelvis to create a carpal flexion, which is then corrected as previously described. It must be remembered that it is not always possible to repel the head sufficiently to gain access to the retained forelimb. In these cases cesarean section is the only option for delivery of a live foal. If the fetus is dead, then a fetotomy cut to remove the head and neck may provide sufficient room to correct the malposture.

Caudal (Posterior) Presentation

A foal in posterior presentation will have the soles of the hooves facing up. Although the author has seen dystocias in which an anteriorly presented foal was in a dorsopubic position with both forelimbs extended, this is a very unusual complication. Foaling attendants should be instructed to wash the mare's perineum and then to use a clean arm to check for the hocks somewhere in the vaginal canal. Gentle traction on the hindlimbs in conjunction with the mare's expulsive efforts may facilitate delivery of a live foal. However, approximately half of the fetuses may be malpositioned as well, and they often require veterinary assistance to permit an atraumatic delivery. Foals in a caudal (posterior) presentation are more likely to be in a dorsoilial position than foals in a cranial (anterior) presentation.[726] Although a normally positioned fetus in a caudal presentation may not be particularly difficult to deliver, it is more likely to suffer hypoxia because of compression of the umbilical cord under the fetal thorax or because of premature rupture of the umbilical cord.[802] Although only about 1% of foals are presented posteriorly, this malpresentation accounts for between 14% and 16% of referral hospital dystocia cases because any postural abnormalities create a major

complication.[726,797,800] Typically both hindlimbs are involved, and these types of dystocia cases (hock flexion and hip flexion) are extremely difficult to correct under field conditions. Hock flexion malposture accounts for about one quarter of referred posterior cases.[726,797,800] Correction of a hock flexion is dangerous because of the risk of perforation of the dorsal aspect of the uterus. The fetus must be repelled into the uterus while one hock is pushed dorsolaterally and the distal limb is directed medially. The procedure for obliquing the extremity into the birth canal is similar to that previously described for correction of a carpal flexion. An obstetric chain or strap can be used to apply traction to the limb while the hoof is cupped in the hand. Straightening a flexed hock entails considerable risk because the hock is invariably forced against the dorsal uterine wall. When the uterus is contracted, there is a real possibility of causing a laceration or perforation. Cesarean section may be preferable for delivery of a live fetus. The author strongly believes that fetotomy is a safer procedure than attempts at mutation if the fetus is dead. Approximately half of referred posterior presentation cases are breech (bilateral hip flexion posture).[726,797] A cesarean section is indicated if the fetus is alive because the manipulations involved in correcting this malposture are time consuming and extremely difficult. The comments for managing a hock flexion apply because if mutation is attempted, the hip flexion must first be converted into a flexed hock posture. A key point is to remember to flex both hocks before attempting to straighten a limb. If one limb is extended into the vaginal canal while the other hip remains flexed, then the fetal body will move back into the pelvic canal, and this will make it extremely difficult to access the retained limb. If the fetus is dead, the author recommends attempting to convert the bilateral hip flexion into a hock flexion posture, followed by correction with two fetotomy cuts through the distal row of tarsal bones. This may be safer and less traumatic than attempting to straighten the limbs, provided that the clinician is experienced in the use of a fetotome. Attempts to correct a bilateral hip flexion by fetotomy, without first creating a bilateral hock flexion, are often unrewarding because of the difficulty in correctly placing the fetotomy wire. Referral for cesarean section will often provide the best prognosis for future fertility in these cases.

Transverse Presentation

Only about 1 in 1000 foals is presented transversely. Successful resolution of these dystocia cases requires a significant amount of obstetric experience, which explains why these rare presentations account for between 10% and 20% of referral hospital dystocia cases.[726,797,809] Most transverse presentations are ventral transverse, with the abdomen and limbs of the fetus presented toward the birth canal. Although the widespread adoption of ultrasonography has markedly reduced the likelihood of a twin birth, this possibility must always be explored when more than two limbs are present in the birth canal.[178,591] In some instances it may be possible to repel the head and forequarters of the fetus while extending the two hindlimbs into the pelvic canal. If the manipulations are successful, the transverse presentation is thus converted into a posterior presentation for vaginal delivery. The likelihood of successfully resolving one of these cases is improved if the mare has been anesthetized and the hindquarters elevated.[802] Transverse presentations may be associated with flexural limb deformities, angular limb deformity, and spinal deformity. If the fetus is alive, then the delivery method of choice is cesarean section. Dorsal transverse presentations, with the spinal column of the fetus presented toward the birth canal, are very rare. These cases warrant an immediate referral for cesarean section even if the foal is dead. Although an experienced obstetrician may be able to deliver a transversely presented fetus by fetotomy, the owner should be advised that this will be a difficult and time-consuming procedure, with a high risk of trauma that will likely impede the mare's future fertility.[802,813,814]

Fetal Anomalies

Hydrocephalus is not uncommon in equine fetuses, especially in pony breeds.[726,797,822] The condition occurs when increased intracranial pressure causes the bones of the skull to enlarge, sometimes almost doubling the size of the head. The skull is often very thin, and many affected foals can be delivered after incising the soft portion of the skull with a finger knife, allowing the skull to collapse. The trunk of the hydrocephalic fetus is generally smaller than normal and seldom interferes with delivery. If the enlarged cranium is bony, then a fetotomy cut may be necessary to reduce the size of the head.

CARE OF THE POSTPARTUM MARE

The fetal membranes should be examined after every delivery to ensure that they have been passed intact and to check for any placental anomalies that may indicate impending problems in the neonate. The chorioallantois often has tears that can be misleading, especially if the mare has trod on the membranes repeatedly. Examining the allantoic side of the membrane may be helpful in that the blood vessels can be pieced together and will give some idea as to whether a portion is actually missing.[431] Ideally, all foaling mares should receive a brief physical examination within 24 hours of parturition. If the mare's attitude is normal and she displays typical maternal behavior toward the foal, then the udder should be checked and the perineal area inspected for evidence of trauma.

A detailed reproductive examination is usually unwarranted because it may unnecessarily disrupt the normal mare-foal bond that is developing at this time.[823] Routine postpartum use of oxytocin or prostaglandin (cloprostenol) therapy is not warranted because there is no apparent benefit for uterine involution in normally foaling mares.[824] If the mare has a foal that is unable to suckle from the mare, or the mare and foal must be housed in stalls with limited exercise, treatment with oxytocin (10–20 IU IM) every 6 hours should be considered. All mares should receive a thorough reproductive examination at the foal heat.

Occasionally an enlarged ovary is detected. This may be a GTCT that has enlarged during the course of the previous pregnancy or an ovarian hematoma due to intrapartum bleeding. Prompt diagnosis and surgical intervention may permit the mare to resume normal cyclicity and conceive during the current breeding season.

Abdominal discomfort in the peripartum mare may be due to uterine contractions, especially if the mare has been treated with oxytocin to promote passage of the fetal membranes. However, other causes of abdominal pain should not be discounted.[736,825-827] When a postpartum mare displays abdominal discomfort, transabdominal ultrasound and/or abdominocentesis may be indicated, especially if the mare does not respond to an analgesic dose of flunixin meglumine. The normal foaling process does not alter the composition of the peritoneal fluid from within the normal range. Even

a dystocia does not necessarily cause significant changes in the peritoneal fluid. If an experienced obstetrician performs the vaginal manipulations or fetotomy, then the fluid should remain normal.[197] If the peritoneal fluid is normal, then the mare should be monitored closely for signs of clinical deterioration. Repeated abdominocentesis or ultrasound may be indicated when clinical signs suggest that a parturient-related abdominal lesion may be present because the peritoneal fluid constituents can change within hours.[197] A single elevated peritoneal fluid value (total protein, white cell count, or percent neutrophils) may be an incidental finding. Elevation of two or more values often signals the onset of clinical abnormalities. If a postpartum peritoneal fluid sample has a total protein value above 3.0 g/dL in conjunction with a white blood cell count greater than 15,000 cells/μL and a white blood cell differential count greater than 80% neutrophils (especially if degenerative changes are present), then the presence of a potentially life-threatening lesion is likely.[197] The peritoneal fluid analysis should not be viewed in isolation and must be considered in conjunction with the history and clinical signs being exhibited by the mare. Detection of changes in the peritoneal fluid almost invariably indicates the presence of foaling-related trauma in either the reproductive or the gastrointestinal tract. An early diagnosis followed by appropriate medical or surgical intervention (or both) will often result in a favorable outcome. If treatment is not implemented until the affected mare has become depressed and febrile, with accompanying signs of shock and toxemia, then the prognosis may be more guarded.

Periparturient Hemorrhage

The arterial supply to the uterus is supported by the mesometrium (broad ligament). The major blood supply to the uterus is from the uterine artery, a branch of the external iliac artery. It forms a cranial branch that supplies the proximal uterine horn and a caudal branch that supplies the distal uterine horn and uterine body. The smaller ovarian artery gives off a uterine branch that anastomoses in the proximal horn with the cranial vessels from the uterine artery. The urogenital artery is a branch off the internal pudendal artery, and it gives rise to the caudal uterine artery along with vessels to the rectum, ureter, bladder, urethra, and vagina. The caudal uterine artery supplies the lateral side of the cranial vagina and continues past the cervix to ramify on the uterine body, in which it anastomoses with the caudal branch of the uterine artery.[4,828,829] Hemorrhage from these vessels, especially the large-diameter uterine artery, is a significant cause of periparturient colic signs and death in older multiparous mares.[811,826,829-831] However, a retrospective study of 73 cases suggests that periparturient hemorrhage can occur in mares of any age or parity, and the condition may occasionally occur before foaling.[832] In a study of 98 postpartum deaths, almost 40% were caused by uterine artery rupture.[826] The rupture may be anywhere along the vessel and is typically 2 cm or 3 cm in length and oriented parallel to the long axis of the vessel. Generally, there is no evidence of a predisposing aneurysm.[826] An association with low serum copper levels has been proposed as a reason for vessel fragility in aged mares.[833]

There appears to be a predilection for right-sided uterine vessel rupture. It has been suggested that the extent of cecal displacement of the gravid uterus to the left may be sufficient to place increased tension on the vessels in the right broad ligament.[826,830] Although the added stress of dystocia may increase the chances of arterial rupture, many cases occur in mares that appeared to have an uneventful delivery. Hemorrhage from the hypertrophied vessels that supply the gravid uterus may be rapidly fatal, especially if the artery ruptures directly into the peritoneal cavity. The mare may be found dead or moribund with pale mucous membranes, tachycardia (up to 140 beats/min), and tachypnea. Heroic attempts to administer blood transfusions, plasma expanders, and associated fluid therapy may save the life of some valuable mares, but costs may be prohibitive.[204]

If the bleeding is contained within the broad ligament, then the mare may be trembling and will exhibit signs of extreme pain (anxiety, sweating, and colic), presumably as a result of the stretching of the broad ligament as the hematoma develops.[204,811,826] The color of the mucous membranes may not change initially because of vascular compensation, and often these initial colic signs are mistaken for the typical discomfort experienced by postpartum mares as the uterus contracts. However, if significant hemorrhage is present, the color of the mucous membranes will eventually become pale, and capillary refill will be delayed. These mares must be monitored closely because the hematoma can subsequently rupture out of the mesometrium and lead to rapid exsanguination.[830]

If a ruptured artery is suspected, then the mare should not be disturbed any more than is necessary to perform an examination. In many cases, postponing, or even forgoing, rectal palpation may be prudent. Although an internal examination will reveal valuable diagnostic information, transabdominal ultrasound, abdominocentesis, and assessment of packed cell volume may be all that is necessary to confirm that an acute hemorrhagic episode has occurred. Transabdominal ultrasonographic evaluation will reveal free blood in the abdominal cavity if the hematoma has torn the broad ligament. If the broad ligament tears after a uterine artery rupture, then a bloody tap invariably results, with an elevated red blood cell count in the peritoneal fluid.[197] The centrifuged sample will have a pink or hemolyzed appearance if hemoperitoneum is present. A smear that reveals phagocytosed erythrocytes indicates hemorrhage rather than contamination during sampling. Even if a clot has contained most of the hemorrhage within the broad ligament, there is often considerable blood loss into the peritoneal cavity. The initial hemogram during an acute hemorrhagic episode can be confusing because the relative loss of erythrocytes and plasma may not alter the hematocrit immediately. Splenic contraction will also temporarily increase the hematocrit.

Ideally, mares suspected to have acute hemorrhage should not be transported because movement could destabilize the clot and prove fatal. Any supportive therapy should be administered at the stall until the mare has stabilized. The foal should be kept safely nearby so that the mare does not become unduly distressed.

Most recommendations for the management of postpartum hemorrhage in mares are based on the collective wisdom of experienced clinicians and from methodologies that have been extrapolated from the human trauma literature. The approach taken will be governed by the facilities and expertise available and financial constraints. In some instances an extreme hypotensive state may actually offer the best chance for survival (conservative approach), whereas in other cases an attempt to restore intravascular pressures and circulatory volume could be indicated. The conservative approach is to confine the hypotensive mare to a dark, quiet stall with minimal disturbances. In some cases a platelet–fibrin plug allows the rent in the vessel to be sealed once the arterial pressure

falls. Tranquilizers (especially acetylpromazine) should be used with caution, because any induced drop in blood pressure may exacerbate the hypovolemic shock. Some clinicians use hypotensive resuscitation by administering a vasodilating agent in conjunction with IV fluid therapy. The idea in this instance is to provide lifesaving volume replacement while maintaining a low mean arterial pressure. In life-threatening situations anything that may stabilize the mare is worthwhile, but the clinician should consider the possibility of impeding resolution of the hematoma by rapid expansion of blood volume and elevation of blood pressure. The need to support cardiac output and ensure oxygen delivery must be balanced against the prospect of the increased arterial pressure promoting further hemorrhage.

Although costly, an aggressive therapeutic approach can occasionally save the life of a valuable mare. If the mare presents in shock and appears to be deteriorating rapidly, then a large IV catheter should be inserted and substantial fluid therapy begun. Whole-blood transfusions must be given slowly and thus are of little benefit for resuscitative purposes when rapid volume expansion is required. One option is rapid administration of 2 to 3 L of hypertonic saline followed with 10 to 20 L of LRS over a period of 2 to 4 hours. An alternative to the hypertonic saline is the high oncotic pressure exerted by colloids (e.g., 3 L hydroxyethyl starch). Synthetic oxygen-carrying fluids are commercially available but extremely expensive. Supplemental oxygen can be provided by nasal insufflation at a flow rate of 5 to 10 L/min. If the hematocrit continues to drop to under 15%, then whole-blood transfusions (6–8 L over several hours) may be warranted. Benefits include provision of oxygen-carrying cells, clotting factors, and oncotic pressure (albumin).

A shock dose of corticosteroid is indicated. Because hemorrhagic shock can cause ischemic-reperfusion damage to the gut and lungs (multiple organ failure), broad-spectrum antibiotics, antioxidant drugs, and antiinflammatory medication may be warranted if the mare survives the initial hemorrhagic crisis. Flunixin meglumine (1.1 mg/kg) is administered to reduce the inflammatory cascades activated by ischemia and may help to alleviate the mare's discomfort. Low-dose (10–20 IU) oxytocin therapy is controversial, and some feel it aids uterine involution, reducing the weight supported by the ligaments. Higher doses should be avoided because an induced colic episode may precipitate a fatal hemorrhage. Antifibrinolytic drugs (aminocaproic acid and tranexamic acid) may assist with clot stabilization. Pentoxifylline increases erythrocyte flexibility and may increase oxygen delivery to ischemic tissues. It should be remembered that there is little refereed veterinary literature to validate the use of some of these medications in the horse. For instance, a conjugated estrogen product has been proposed on the basis of its ability to shorten prolonged bleeding times in humans. However, the benefit, if any, would not be realized until several days after the crisis has passed. Likewise, anecdotal reports suggest that naloxone (8 mg) may be efficacious, but the concept has been extrapolated from small animals, and controlled equine studies are lacking. A controversial historical therapy to promote hemostasis in the horse is the use of IV buffered 10% formalin, which is thought to enhance the activation of the clotting cascade. However, controlled studies were not able to demonstrate an effect on coagulation parameters or template bleeding times in normal horses.[203] Broad-spectrum antibiotics should be administered to prevent infection of the hematoma. Yunnan Baiyao, an herbal supplement, has been used by some practitioners to facilitate hemostasis.

If hemorrhage is contained within the wall of the uterus, then the intramural hematoma may be an incidental finding at the foal heat examination. However, some mares may exhibit variable signs of abdominal discomfort, even to the extent of warranting an exploratory celiotomy.[834-836] If an endometrial laceration severs an artery in the uterine wall, then substantial hemorrhage may ensue, often with blood escaping from the vagina. The mare should be confined to a stall and low-dose oxytocin therapy instituted. Uterine irrigation is contraindicated because it will disrupt clot formation and prolong the hemorrhagic episode. The internal pudendal artery, one of the terminal branches of the internal iliac artery, gives rise to the umbilical artery and the urogenital artery before terminating in branches to the perineal area and the vestibular bulb. The small cranial vesicular artery supplies the apex of the bladder before the remainder of the umbilical artery terminates into the cordlike round ligament of the bladder. The urogenital artery gives rise to a caudal uterine branch that runs cranially on the side of the vagina and ramifies with the caudal branch of the uterine artery on the body of the uterus. The urogenital artery also supplies branches to the rectum, ureter, caudal bladder, and urethra and continues as the vaginal artery to the caudal portion of the reproductive tract.[4,828,829] A hematoma arising from these vessels may dissect along the fascial plane within the pelvic cavity and present as a large unilateral vulvar swelling.[811] Affected mares typically will experience violent colic. Abscessation of a retroperitoneal hematoma can become a life-threatening complication after a dystocia; thus prophylactic broad-spectrum antibiotic coverage is warranted.[826] Mares with an infected retroperitoneal hematoma often develop signs of toxemia. In these cases the peritoneal fluid has an increased total protein content (3.0–5.0 g/dL) with a massive increase in the white blood cell count (often exceeding 100,000 cells/μL).[197]

Uterine Prolapse (Eversion)

Uterine prolapse, or eversion, is an uncommon complication of equine parturition that may occur up to several hours (and occasionally several days) after fetal delivery.[837] The condition may be complicated by bladder eversion (or prolapse), uterine rupture, or intestinal herniation and may be rapidly fatal if the uterine artery is ruptured.[200,800,812,826] If the mare is standing and personnel are available, then instructions should be given to place the uterus in a large plastic bag and elevate it to the level of the vulva. This may prevent further damage to the endometrium and, more important, will relieve the tension on the uterine vessels.[837] Fluid therapy may be indicated, and any calcium deficit must be corrected. Epidural anesthesia may reduce the amount of reflex straining provoked by vaginal manipulations, but it will not eliminate the mare's strong abdominal press.[801] General anesthesia may be necessary if the mare exhibits violent discomfort or if straining is excessive. Any uterine lacerations should be closed with absorbable sutures. The well-lubricated uterus is then pushed back through the vagina with a kneading motion. The fingertips can easily damage the edematous tissue, and manipulating the uterus through a plastic bag will reduce the likelihood of a finger rupturing the wall.[204] Ultrasonography is useful to evaluate any suspicious contents. A trapped bladder may be aspirated through a large-diameter needle, but a loop of bowel may require a ventral midline celiotomy.

The replaced uterus should be distended with sterile saline to ensure that the tips of both horns are fully extended. Repeated low doses (10–20 IU every 2 hours) of oxytocin should be administered to promote uterine involution. Failure to ensure complete extension of the uterine horns into a normal position within the abdomen may result in discomfort, straining, and recurrence of the prolapse.[204] Vulvar retention sutures should not be necessary provided that the uterus has been completely returned to its normal position, the calcium deficit has been corrected, and low-dose oxytocin therapy has been administered. Broad-spectrum antibiotics, NSAIDs, and tetanus prophylaxis are indicated. The mare should be closely monitored for evidence of internal hemorrhage. Affected mares may exsanguinate after the uterus has been replaced. Ischemic damage to trapped bowel is a potential complication. The clinician should be cognizant of the potential risks of endometritis-metritis, septicemia, endotoxemia, and laminitis. Between 2 and 3 days of intrauterine therapy may be warranted, depending on the condition of the exposed endometrium.

Partial Inversion (Intussusception) of the Uterine Horn

Injudicious traction on a retained fetal membrane remnant may invert the tip of the uterine horn, and this may progress to complete uterine prolapse.[204] If only the horn is affected, then compromised circulation and pressure on nerve endings may produce signs of abdominal discomfort; thus the tips of both uterine horns should be rectally palpated when a postpartum colic case is evaluated. The affected horn will be shorter than normal and extremely thickened.[800,812] Manual reduction by pressure from within the uterine lumen may be possible in some cases, and infusion of several liters of saline solution will usually ensure extension of the affected horn.[800] Oxytocin (10–20 IU) should then be administered and the fluid drained from the uterus as it contracts. Resolution of the problem should be confirmed by rectal palpation.

Uterine Rupture

In any dystocia case there is a risk for iatrogenic tears, and the uterus should always be checked for any obvious lacerations immediately after extraction of the fetus. Early recognition is important because the prognosis is worse once peritonitis develops.[197,810,811,826,838] However, obstetric intervention is not always the cause of uterine tears. Occasionally, the foal's hoof may be forced through the dorsal uterine wall during the mare's expulsive efforts, and the mare may be found with a loop of bowel protruding through the vulvar lips. The exposed bowel should be rinsed with sterile saline and replaced, but a ventral midline celiotomy may be warranted to fully evaluate intestinal damage and to repair the uterine laceration. A more common lesion in unassisted deliveries is a tear toward the tip of the gravid uterine horn.[199,838] Although the fetal hooves are covered with hard gel-like pads that presumably protect the placenta and uterine wall, the vigorous piston-like thrusts of the hindlimbs may occasionally cause a rupture.[402,675,839] Affected mares generally experience bouts of colic and become depressed, febrile, and anorectic as peritonitis develops. The interval from occurrence of the tear to diagnosis and initiation of therapy has a marked impact on the prognosis for survival.[197,199,204,811,826,838] It may not be possible to ascertain uterine integrity by vaginal palpation alone. The tips of the horns may be especially difficult to palpate from within the postpartum uterus. The changes in the peritoneal cavity depend on the duration of the condition, but generally one can expect to see serosanguineous to sanguineous fluid containing elevated total protein, increased white blood cell counts, and often extracellular and intracellular bacteria.[197,198,838,840]

Laparoscopic evaluation of the uterus may confirm the diagnosis and provide useful information when determining the need for surgery.[841] Complete perforation of the uterine wall is not necessary for peritonitis to develop if traumatic obstetric manipulations have damaged the uterine wall.[842] However, a fetotomy procedure does not alter the composition of the postpartum peritoneal fluid if it is performed correctly.[197]

If a uterine laceration is suspected (partial or full), then the mare should receive systemic broad-spectrum antibiotic coverage along with nonsteroidal antiinflammatory medications in an effort to prevent development of endotoxemia or other systemic infections. Oxytocin therapy (10–20 IU every 2 hours) will promote uterine involution. The dose can be increased if the mare does not become uncomfortable. Fluid therapy should be administered as necessary, ensuring that calcium levels are within the normal range. Intensive medical management may suffice for small dorsal uterine tears, but most warrant suturing if costs are not a limitation.[199,838,840,841] Opinions vary on the need for—and usefulness of—peritoneal lavage.[838,841] Large full-thickness tears warrant surgical intervention. In some instances a laceration in the uterine body can be sutured blindly in situ, but often a ventral midline celiotomy is the preferred approach.[204,736,810,840]

Retained Fetal Membranes and Toxic Metritis

Once the umbilical cord ruptures, there is a sudden cessation in blood flow through the capillary network in the placenta.[200] This causes a reduction in the tissue volume of the microcotyledons, and the rhythmic tubocervical contraction waves cause the membrane tips to separate and invaginate into the horn. The ongoing tubocervical detachment process causes the membranes to be passed inside out with the allantoic surface exposed. The membranes should be expelled within 3 hours after parturition, and the incidence of retention has been reported to range between 2% and 10% of foalings.[727,843,844] Membrane retention tends to be most commonly associated with the tip of the nongravid horn and appears to be associated with dysfunction of the initial separation process.[432]

In circumstances in which tissue inflammation is common (e.g., abortion, dystocia, cesarean section), it is more likely that membrane retention will occur. In these cases the endometrial edema may trap the microcotyledons within the endometrial crypts. Mares with membrane retention may have a significantly lower serum calcium level.[845] The number of endometrial mast cells observed during the puerperal period is significantly lower in the endometrium of mares with retained fetal membranes.[846] It is likely that some dysfunction of the normal endocrine-related maturational processes within the microcotyledons is involved. There may be an association between inbreeding and the high incidence of fetal membrane retention in Friesian mares.[763,847]

Appropriate management of a mare with fetal membrane retention varies depending on the time since foaling.[848] Although some mares, especially those foaling in a natural environment, may not experience any complications, prophylactic medication is recommended under intensive husbandry

conditions.[844,849] Bacterial contamination in this environment is highly likely. If a severe metritis develops, then inflammation of the uterine wall permits bacteria and toxins to enter the systemic circulation, producing septicemia and endotoxemia.[842,850] Laminitis is a frequent sequela.[204]

The approach to treating RFMs varies considerably, depending on the duration of membrane retention and the presence or absence of metritis with septicemia. In normal, unassisted foalings, one or two treatments with oxytocin may be all that is required to facilitate passage of the RFMs. The protruding placental remnants should be tied in a knot above the mare's hocks. An initial low dose (10–20 IU) of oxytocin is recommended because some postpartum mares are especially sensitive to this hormone and may experience a severe bout of colic within minutes of treatment. Higher doses are likely to be counterproductive because myometrial spasm will occur instead of the desired rhythmic tubocervical contractions. If colic does occur, then the mare should be sedated so that she does not roll and possibly injure the neonate. In these cases the next dosage of oxytocin should be reduced. Each mare's response to the initial treatment governs the subsequent dose recommendations of 10- to 20-IU incremental increases every 30 minutes to 2 hours.

Distention of the chorioallantoic sac with fluid, known as the *Burns technique,*[851] promotes membrane expulsion (5–30 minutes) in most postdystocia mares. A major advantage is that expulsion of the intact fetal membranes will remove any contaminants that may have been introduced by the obstetric procedures.[851] The technique works only if a sterile nasogastric tube can be passed beyond the torn distal fragments and is best performed while the membranes are still fresh. In more protracted cases the rapidly autolyzing chorioallantois becomes friable and generally tears once the fluid pressure increases. When the procedure is performed the exposed fetal membranes are held tightly around the tube while 12 to 15 L of solution are infused. The opening is then tied off with umbilical tape. The exact mechanism is unknown, but expansion of the uterine lumen may dilate the endometrial crypts such that the weight of the membranes can atraumatically pull the microcotyledons free. Endogenous oxytocin release can be supplemented to enhance uterine contractions.

Because the uterine response to oxytocin wanes during the postpartum period, the dose may be increased in small increments every 2 hours in mares that retain their fetal membranes despite the initial therapy. If a hospitalized mare is receiving IV fluids, then each oxytocin treatment can be added to the fluid line. Another option is to add oxytocin to the fluid bag at a dose that is calculated on the basis of the flow rate (1 IU/min).[204] However, a disadvantage of this approach is that these fluids must be discarded if the mare becomes uncomfortable yet still requires rehydration. The calcium ion plays a vital role in myometrial contractility, and it is important to ensure that calcium levels are within the normal range.[768,852] Supplemental calcium can markedly expedite the rate of passage, which suggests that uterine hypomotility is a component in some of these cases.[844] Controlled exercise is often beneficial in promoting uterine involution but is not always feasible if the mare is hospitalized or is being kept in a stall while a compromised neonate is being medicated.

It is widely accepted that excessive traction on the fetal membranes is contraindicated, but a recent study suggests that cautious manual removal of the membranes may not be as deleterious as previously thought.[853] When the membranes are extracted by force there is inevitably disruption of the epithelial barrier, making the traumatized uterine lining more susceptible to bacterial invasion and the development of metritis.[850] Endometrial trauma is also likely to contribute to the development of periglandular fibrosis. It is not uncommon for the membrane tip to tear off and remain firmly attached within the nongravid horn.[432] Injudicious traction on the membranes can also cause an inversion of the tip of the uterine horn, and this can progress to a complete uterine prolapse.

If the fetal membranes have not been expelled after 2 days of supportive therapy, then the autolytic tissue becomes less firmly embedded. A gentle twisting technique, with minimal traction, applied within the attached horn will often result in successful removal of the entire chorioallantois. This procedure works best while the uterus is being distended during a uterine lavage. A potentially effective treatment for RFMs in mares may be intraplacental injections of collagenase.[854,855]

If the membranes have been retained for 6 to 8 hours when the mare is first examined, then systemic antibiotic therapy is indicated.[204] Drugs that have been recommended for systemic administration include ampicillin, gentamicin, kanamycin, penicillin, ticarcillin, and trimethoprim-sulfamethoxazole. If a remnant is missing when the membranes are examined, then the approach to therapy should proceed as if the entire membrane were still present. Characteristic signs of toxic metritis are fever, depression, anorexia, tachycardia, and injected mucous membranes. The foal will not be receiving adequate milk intake, and many of these mares will have bounding digital pulses and evidence of laminitis.

Transrectal palpation will reveal a large, thin-walled, atonic uterus that contains moderate to large amounts of fetid fluid. A large volume of toxic, red-brown, watery fluid can accumulate within the pendulous postpartum uterus before any obvious vaginal discharge becomes evident. Often the history will reveal that the fetal membranes were discarded without being checked to ensure that they were passed intact.

Because the endometrium is likely to be necrotic, therapy should include broad-spectrum antibiotics, antiinflammatory drugs, and IV fluids if indicated. Tetanus prophylaxis is advisable. A combination of penicillin and gentamicin is widely used to provide broad-spectrum systemic coverage, especially against the coliforms that frequently contribute to endotoxemia and laminitis.[856] Flunixin meglumine should be administered to ameliorate the effects of endotoxemia. It is commonly administered IV at a reduced dose (0.25 mg/kg, t.i.d.).[204] Phenylbutazone (2–4 mg/kg) and provision of deep, soft bedding and padded shoe support are useful to alleviate pain when laminitis appears to be imminent. Radiographs can be useful to monitor changes in the position of the pedal bone. Vasodilators such as acetylpromazine maleate may be administered by IM injection (0.02–0.04 mg/kg every 4–6 hours).[856] Further discussion of the diagnosis and treatment of endotoxemia and laminitis are found in Chapters 10 and 12, respectively.

The uterus should be lavaged with sterile saline or very dilute ("weak tea") povidone-iodine solution. If povidone-iodine is used, then the final concentration should not exceed 0.1%; this is equivalent to 10 mL of 10% povidone-iodine solution (e.g., Betadine) in 1 L of saline. If costs are a concern, then 90 mL in a 9-L bucket of clean water may suffice. Extreme caution should be exercised to keep from puncturing the inflamed uterine wall with the tube. The lavage should be repeated until the returning fluid is relatively clear. The goal of

therapy is to eliminate toxins and to prevent the rapid proliferation of bacteria, especially coliforms and possibly anaerobes. The administration of intrauterine antibiotics in the postpartum mare is controversial because little scientific validation has been performed. Intrauterine administration of antibiotics and antiseptics may depress the phagocytic activity of uterine neutrophils, and many chemicals are known to irritate the endometrium in mares being infused for endometritis.

The pharmacokinetic properties of each drug will influence its efficacy in the postpartum uterus. Most of the studies of intrauterine therapy in mares have addressed therapy for endometritis in nonparturient animals. The efficacy of antibiotic formulations in the presence of the mixed bacterial population and tissue debris associated with fetal membrane retention in the mare remains to be established. The antibiotic of choice should be added to a large infusion volume (2–3 L) to ensure uniform distribution across the inflamed endometrial surface once a lavage has removed the toxic fluid and necrotic debris. Infusion of 2 g of amikacin after a uterine lavage is often clinically effective. Polymyxin B may have some merit because of its endotoxin-binding ability. Powdered and propylene glycol–based oxytetracycline formulations are known to be irritating when infused into the involuted uterus and should be avoided.[6,857] Other antibiotics that have been suggested for postpartum intrauterine therapy include ampicillin (3 g), ticarcillin and clavulanic acid (1–3 g), and gentamicin (2–3 g). Fewer than 60% of isolates from metritis fluid appear to be sensitive to ampicillin. The authors do not support intrauterine antimicrobial therapy in the postpartum mare.

Recently a technique has been described that is believed to cause immediate placental release. This technique consists of cannulating the umbilical cord vessels and using an adaptor to connect the catheter to a garden hose. Water is pumped into the mare uterus until the chorioallantois is detached from the endometrium.[858] A success rate of 93% for immediate release of the placenta is reported.

Gastrointestinal Complications

Prolonged straining during dystocia can lead to variable amounts of rectal mucosa being forced out through the anal sphincter (type I rectal prolapse). The tissue then becomes subject to trauma, contamination, and vascular compromise. If not promptly corrected, then pressure from the anal sphincter will cause venous congestion and swelling. This promotes more straining, and the condition can deteriorate rapidly. A type II prolapse involves all or part of the ampulla recti. An epidural anesthetic may help decrease straining. Topical glycerin or dextrose may be applied to the prolapsed tissue to reduce edema.[204] A purse-string suture can cause additional straining and will impede defecation.[859] Fecal softeners should be administered and the diet modified (e.g., pellets, pasture) to help produce soft feces.[569]

Chronic prolapses may warrant surgical resection of the devitalized mucosal mass. In a type III prolapse, there is a full-thickness rectal prolapse and an intussusception of the peritoneal rectum or small colon. In a type IV prolapse the intussuscepted bowel protrudes through the anus such that there is a palpable trench that may extend several meters into the rectum, depending on the length of the intussusception.[859-861] Midventral celiotomy is usually necessary to reduce the intussusception, although some smaller prolapses will reduce after an attendant has extracted the foal. The short mesentery that supports this section of bowel is often torn from the colon. These cases have a guarded prognosis, dependent on the vascular integrity of the affected small colon. This condition can develop when as little as 6 to 10 inches of bowel appear to be prolapsed. The avulsion most likely occurs when the mare's intermittent straining forces an extra 4 to 6 inches of bowel in and out of the rectum. Thus it is imperative to prevent straining as soon as possible. If the foal has not yet been extracted, it may be best to immediately anesthetize the mare and then elevate the hindquarters before attempting to correct the cause of the dystocia.

In rectal prolapse cases that have been managed conservatively, one of the first postpartum clinical signs may be discomfort attributable to impaction colic. If avulsion of the mesocolon has occurred, then ischemic necrosis of the affected bowel will cause a delayed peritonitis. Because early intervention is essential, sequential abdominocentesis is indicated when a type III or IV rectal prolapse is being conservatively managed. Initially, there may be negligible changes in the composition of the peritoneal fluid. However, if an avulsion has occurred, the compromised segment of bowel will soon lose its integrity, and a massively increased white blood cell count can occur within 24 to 48 hours as peritonitis ensues.[197] Laparoscopic evaluation of the abdomen can provide an immediate assessment of bowel integrity and permit an accurate prognosis to be given to the owner. The affected colon is not readily accessible for resection and anastomosis, so the prognosis in most cases is guarded.

Variable degrees of uncomplicated impaction are not uncommon in the postparturient mare, possibly as a result of localized perineal pain causing reluctance to defecate.[204] Astute managers will note an absence of fecal matter in the stall. Treatment with fecal softeners (e.g., mineral oil) and analgesics generally corrects the problem. Laxative feeds (e.g., bran mash) are effective in reducing the incidence of constipation in foaling mares.[800] Postpartum mares appear to be at an increased risk for development of a large colon torsion.[570,826,862] This condition presents as an especially violent colic with readily discernible abdominal distention. Extensive ischemic damage affects the prognosis, but early surgical intervention can increase the survival rate.[863] Bruising of the abdominal viscera can occur during foaling, with subsequent development of moderate to severe signs of impaction colic and peritonitis. Occasionally, the mesentery may be torn from a segment of intestine, leading to ischemic necrosis and peritonitis. An early diagnosis and prompt surgical intervention may save the mare's life.[197,737,825-827,864] A rent in the mesentery or broad ligament at the time of foaling may permit a segment of bowel to become incarcerated even weeks later.[568,820,826,827,865] Owners should be advised that surgical correction is feasible only if the segment of devitalized bowel is accessible.

Although mares tend to reduce their feed intake in the days leading up to foaling, ensuring a reduction in the amount of available roughage may help reduce the incidence of bowel rupture.[800] The tip of the cecum is the most likely site of a foaling-related rupture in the alimentary tract. On rectal palpation the inflamed serosal surfaces will feel roughened, with a discernible crepitus. Abdominocentesis will reveal dark green-brown gastrointestinal fluid that contains plant material and massively increased neutrophil numbers. Humane euthanasia is indicated because the leaking ingesta incites a severe peritonitis with accompanying septic shock, and the condition is likely to be rapidly fatal.[826,866-869] Diaphragmatic herniation has been reported as a rare parturient complication in heavily

pregnant mares.[735,870-872] Colic symptoms are attributable to strangulating obstruction or tension on the mesentery. Some mares may exhibit respiratory distress. Transthoracic ultrasonography can help confirm the presence of bowel within the thorax.[873] Surgical repair of the defect may not be possible, and assisted ventilation will be required.[871,872]

Vaginal Lacerations and Bladder Prolapse

Primiparous mares are especially susceptible to vaginal trauma. Vaginal lacerations are most likely to occur during injudicious attempts to relieve dystocia. Although most lacerations are retroperitoneal, they still may contribute to severe vaginitis, fibrosis, and possibly abscessation. If ventral trauma is present, then a urinary catheter should be passed to check for urethral integrity. In some instances ligation of a severed artery will be necessary. Emollient creams, tetanus prophylaxis, broad-spectrum antibiotics, and antiinflammatory drugs are indicated. A major concern is the possibility of herniation of intestine into the vagina if the tear is located just caudal to the cervix in the vicinity of the urogenital pouch.[826,874] If eventration has occurred, the bowel should be cleansed and examined for evidence of vascular compromise. If the involved intestine appears to be grossly normal, it should be rinsed with sterile saline and returned to the abdominal cavity. If vascular compromise is detected at the time of the initial examination, then the prognosis is guarded and a ventral midline celiotomy to facilitate resection is warranted. A bladder prolapse occurs when the bladder is forced up through a vaginal laceration. The viscus rapidly becomes distended as a result of the continued accumulation of urine from the ureters and an inability to void urine because of kinking of the urethra. The edematous serosal surface of the bladder may protrude through the vulvar lips. The exposed organ should be thoroughly cleansed and gently returned to the abdominal cavity. It may be necessary to administer an epidural and aspirate urine to facilitate replacement. If possible, the vaginal laceration should be sutured once any viscera have been returned to the abdominal cavity. In some cases the severity of the trauma precludes successful closure, and the wound must heal by second intention.[874] Placement of a Caslick suture reduces the possibility of bacterial aspiration. Mares may be cross-tied for several days to decrease the risk of eventration brought about by elevation of intraabdominal pressure as the mare lies down.[204] The mare should be treated for impending peritonitis (e.g., broad-spectrum antibiotics, NSAIDs). Tetanus prophylaxis is indicated. If severe colic symptoms develop, bowel compromise should be suspected.

Eversion of the Urinary Bladder

The mare's urethra has a large diameter, and occasionally the bladder may be everted up into the vagina after severe straining.[875] If the everted bladder protrudes through the vulvar lips, then the exposed mucosal surface will rapidly become edematous, and urine may be seen to drip from the ventral surface. Closer inspection will reveal that the urine is dribbling from the exposed papilliform openings of the ureters on the dorsal surface of the neck of the bladder.[876] A lip chain and epidural may provide adequate restraint to facilitate replacement. The mucosal surface should be thoroughly cleansed and any defects repaired. Sterile lubricant should be applied and the friable organ gently massaged back through the urethra. In some instances it may be necessary to incise the urethral sphincter if the bladder mucosa is especially thickened.[876] This incision should be closed once the bladder has been replaced. A Foley catheter can be inserted to lavage the bladder lumen and ensure complete repositioning. Broad-spectrum antibiotic coverage, NSAIDs, and tetanus prophylaxis are indicated.

Rupture of the Urinary Bladder

Occasionally, the bladder may rupture as a consequence of increased intraabdominal pressure in the foaling mare or because of direct trauma during parturition.[877-879] Clinical signs are delayed and are associated with electrolyte imbalances. Affected mares may be depressed and inappetent, with failure to void urine. Clinical examination will reveal tachycardia, tachypnea, and decreased gastrointestinal activity. Blood chemistry will reveal elevated serum levels of creatinine, blood urea nitrogen, and potassium in addition to decreased sodium and chloride levels. Evaluation of a peritoneal fluid sample helps confirm the diagnosis. The fluid will contain elevated urea and creatinine levels and calcium carbonate crystals. Cystoscopy is useful to evaluate the size and extent of the bladder injury. Once the mare's medical condition has been stabilized, surgical repair is indicated.[820,877-879] A standing vaginal approach eliminates the need for general anesthesia and allows excellent observation and repair of bladder tears in adult mares.[879]

Rectovaginal Fistulas and Perineal Lacerations

A first-degree perineal laceration involves the mucous membrane of the vestibule and the skin of the vulvar lips. In second-degree perineal lacerations, the deeper tissues of the perineal body are involved. Both of these conditions may be associated with unassisted delivery of a large foal or may be a sequela of dystocia. The laceration may be amenable to immediate repair and placement of a Caslick suture, or the clinician may elect to wait until the wound has granulated. The mare should be treated with broad-spectrum antibiotics, antiinflammatory medication, and tetanus prophylaxis. Provision of a bran mash diet and administration of mineral oil or stool softeners may facilitate defecation during the initial inflammatory period.

Third-degree perineal lacerations generally occur during unassisted foalings when the fetal hoof catches on the vaginal roof at the vestibulovaginal junction. Forceful straining by the mare can drive the hoof through the rectovaginal shelf such that the fetal hoof comes to lie within the rectum. If the fetus is viable, it may remove the affected limb and delivery will proceed unimpeded, but a rectovaginal fistula results. If the limb remains within the rectum, then continued passage of the fetus causes the trapped limb to tear out the perineal body and anal sphincter. The resulting defect is called a *third-degree perineal laceration.* These injuries do not respond well to immediate surgical intervention, and the general recommendation is to wait 4 to 6 weeks before attempting reconstructive surgery.[820,875,880] In the interim the mare should be treated with broad-spectrum antibiotics, antiinflammatory medication, tetanus prophylaxis, and fecal softeners.

Grade IV (full-thickness) rectal tears that communicate directly with the peritoneal cavity have a poor prognosis and can occur as a result of parturition.[881,882] Tears tend to occur just cranial to the caudal peritoneal reflection. Such cases warrant immediate intervention, and the rectum should be packed to prevent abdominal contamination during transport to a referral hospital. A standing technique that permits an easy and effective stapled primary closure repair has been described.[881]

Perineal Bruising and Vulvar Hematomas

Much of the swelling after prolonged obstetric manipulations is edematous. Fecal softeners such as oral mineral oil and bran mash are recommended to ease the passage of feces through the swollen and bruised perineal area.[735,806] Hematomas in the vaginal wall and vulvar lips are not uncommon, especially in primiparous mares and mares that have delivered an extremely large foal. It is important to differentiate a bulging vestibular hematoma from an everted or prolapsed bladder.[800,829] Needle aspiration of vulvar hematomas is not recommended because of the risk of abscessation. Broad-spectrum antibiotics and tetanus prophylaxis are indicated. Most hematomas will resolve uneventfully, but some vulvar, vaginal, or pelvic hematomas may warrant drainage in 7 to 10 days.[735]

Postpartum Eclampsia (Lactation Tetany)

Postpartum eclampsia, or lactation tetany, is extremely rare in mares but may occur in animals that are lactating heavily. The highest incidence is reported in draft breeds, but the author has encountered a case in a pony mare. Equine eclampsia is generally associated with some type of stress (e.g., change in surroundings). Early signs include restlessness, tachypnea, staring eyes, twitching, trembling, and clonic spasms (especially diaphragmatic). The clonic spasms gradually become more tonic, and eventually the mare may be unable to stand. The differential diagnosis is tetanus, but the nictitating membrane is not prolapsed. The condition responds well to intravenous calcium gluconate administration.[200]

Assisted Reproductive Techniques for the Mare

E.A. Bradecamp

The development of new assisted reproductive techniques for the mare has allowed production of offspring from mares that are infertile using standard breeding techniques or embryo transfer.

INTRACYTOPLASMIC SPERM INJECTION

Currently, intracytoplasmic sperm injection (ICSI) has become the most common assisted reproductive technique used to obtain pregnancies from mares that have failed to produce pregnancies themselves or via embryo transfer. ICSI is also used to obtain pregnancies from stallions that have very poor fertility or from which there is a limited amount of semen available. During ICSI a single sperm is selected, aspirated into a fine-bore needle, and injected into a mature oocyte. The injected oocyte can be transferred into a recipient's oviduct or cultured to allow embryo development[883] and then transferred into a recipient once it reaches blastocyst stage. Cochran et al. reported the first successful ICSI of an equine oocyte that was matured in vitro. Foals have been produced by ICSI using oocytes matured in vivo or in vitro.[884,885]

Currently, there are several commercial ICSI labs to which mares can be shipped for management for oocyte aspiration and ICSI, or oocytes can be collected at a remote location and shipped for ICSI. Subsequently, the fertilized oocytes are cultured until the blastocyst stage is reached. The embryos can then be transferred into on-site recipients, if available, or shipped to an off-site recipient herd.

Oocytes can be collected from preovulatory dominant or nondominant follicles. Oocytes from preovulatory follicles are collected between 24 and 36 hours after the administration of hCG (1500–2500 IU, IV) or deslorelin (1.5 mg, IM) to the donor, with the oocytes collected between 18 and 20 hours before anticipated ovulation. Therefore oocytes are probably at metaphase I or II. Criteria for hCG administration are as follows: (1) a follicle greater than 35 mm in diameter, (2) relaxed cervical and uterine tone, and (3) uterine edema or estrous behavior for a minimum of 2 days. Some mares, especially old mares, do not consistently respond to hCG. In these cases the authors use a combination of deslorelin acetate (1.5 mg, IM) and hCG (2000 IU, IV), with hCG administered between 4 and 5 hours after deslorelin. Oocytes have been collected from the follicles of mares by laparotomy,[886] colpotomy,[887] flank puncture,[888,889] and ultrasound-guided follicular aspiration.[890,891] Currently, most laboratories collect oocytes through the flank or with transvaginal ultrasound-guided punctures.

For the collection of oocytes using flank puncture, the trocar is placed through the flank ipsilateral to the preovulatory follicle at approximately the position of the ovary. The ovary is manipulated per rectum to position the preovulatory follicle against the end of the cannula. While stabilizing the ovary per rectum, the clinician places a needle (12–17 gauge) through the cannula and into the follicular antrum and removes the follicular fluid and oocyte by gentle suction and lavage of the follicle. Transvaginal ultrasound-guided follicular aspiration requires use of an ultrasound machine and a probe fitted to a special needle case. Linear, curvilinear, and sector transducers have been used. The transducer is placed in a casing containing a needle guide. Rectal contractions may be minimized by administration of propantheline bromide (0.04 mg/kg, IV)[892] or *N*-butylscopolamine or intrarectal use of lidocaine before the procedure. The clinician applies a nontoxic lubricant to the transducer and positions it against the anterior vaginal wall, lateral and dorsal to the external cervical os and ipsilateral to the follicle to be aspirated. The follicle must be carefully positioned through transrectal manipulations with the follicular apex juxtaposed to the needle guide. The needle is advanced through the needle guide to puncture the vaginal and follicular walls. In the authors' laboratory, a 12-gauge double-lumen needle is used. The follicular fluid is aspirated from the follicle using a pump set at approximately 150 mm Hg or with suction from a large syringe. After removing the follicular fluid, the clinician lavages the lumen with between 50 and 100 mL of flushing liquid. Typically, modified Dulbecco's phosphate-buffered solution or a sterile commercial embryo flush solution is used. Heparin (10 IU/mL) is added to the flush solution to prevent coagulation of blood in the aspirate. By use of this technique, oocytes were typically collected successfully from between 70% and 80% of the follicles in client donors.[892]

The major clinical advantage of ICSI is that limited sperm numbers or poor-quality sperm can be used to produce offspring, and pregnancies can be obtained from infertile mares that failed to produce embryos and pregnancies through embryo transfer.

OOCYTE TRANSFER

Although the first successful oocyte transfer was performed in 1988, the technique was not used for commercial transfers

until the late 1990s.[892-894] Oocyte transfer involves the transfer of an oocyte from a donor into the oviduct of a recipient, and the recipient is inseminated within the uterus. Fertilization, embryo development, and fetal development occur within the recipient, preventing problems associated with ovulation or the tubular genitalia of donors. The incidence of ovulatory failure increases with age and during the autumn months.[704,895] Prolonged exposure to an abnormal follicular environment results in aging and death of the oocyte. Some types of ovulatory failures can be detected with ultrasound as an atypical morphology of the follicle or ovulatory site. Mares that repeatedly fail to ovulate can provide oocytes for transfer successfully if oocytes are collected before deleterious changes occur within the follicle.[892]

Historically, the uterus has been considered the primary cause of reduced fertility in the mare. Mares with pyometra or persistent endometritis are expensive to treat and frequently do not provide embryos. Mares with cervical lacerations, cervical or uterine adhesions, or urine pooling often fail as embryo donors. Oviduct dysfunction is a rare impediment to fertility and can occur in young or aged mares. When the oviducts of old mares (>20 years) and young mares (2–9 years) were flushed between 1 and 4 days after ovulation, collection rates of recently ovulated oocytes or oviductal embryos were significantly higher in the young mares than in the old ones (26 of 27 [96%] vs. 17 of 29 [59%], respectively).[547] In subfertile mares pathologic changes of the oviducts were imaged using scanning electron microscopy, and significantly fewer sperm were detected in the caudal isthmus in subfertile mares than in fertile mares. Few sperm found in the oviducts of subfertile mares were motile, whereas oviducts of the normal mares contained highly motile sperm.[896] Obstructions of the oviductal lumen are postulated to be the cause of subfertility in some mares. Globular masses composed of type I collagen were found more frequently in older than in younger mares.[206] Oviductal masses were found in the oviducts in 73% (16 of 22) of mares between 2 and 22 years of age; in a small number of mares (3 of 43), the masses occupied and distended the oviductal lumen and could have resulted in infertility. The equine embryo remains in the oviduct for 5 or 6 days before entering the uterus; therefore oviductal problems such as inflammation could affect embryo viability.[897]

Oocyte Donors

Requirements for oocyte donors are minimal. Uterine infections in donor mares should be treated to prevent introduction of a pathogen into the abdominal cavity during transvaginal oocyte collections. Donors should have regular estrous cycles with growth of a preovulatory follicle. The age of the donor affects success rates. When oocytes were collected from the follicles of young donors (6–10 years) and old donors (20–26 years) and transferred into the oviducts of young recipients (3–7 years), significantly more oocytes from young than old donors developed into embryonic vesicles (11 of 12 [92%] vs. 8 of 26 [31%], respectively).[552] A higher incidence of morphologic anomalies was observed in oocytes from older than from younger mares.[551] Although younger mares are better candidates for oocyte donors, older (≥20 years) mares frequently are presented to commercial oocyte transfer programs, and pregnancies are obtainable through repeated transfers.[884]

Oocyte Culture and Transfer

Oocytes are sensitive to temperature changes; therefore the clinician should warm media and equipment for handling the oocyte to 38.5°C. On collection the flushing solution is poured into large search dishes and examined under a dissecting microscope to locate the oocyte. One can transfer oocytes collected at least 30 hours after hCG administration to the donor immediately into a recipient's oviduct. Oocytes are usually collected 24 hours after administration to the donor and between 12 and 16 hours before transfer. Most oocytes are cultured in medium similar to that first described by Carnevale and Ginther.[552] The timing of oocyte collection (24 vs. 36 hours after administration of hCG to donors) did not affect pregnancy rates.[898] A modification of these procedures was to collect oocytes 24 hours after hCG administration and immediately transfer them into the recipient's oviduct. Oocyte maturation was completed within the oviduct, and recipients were inseminated after oocyte maturation should have been completed (at 16 hours after transfer). Pregnancy rates were not statistically different for oocytes matured within the oviduct or within an incubator (43% vs. 57%).[899]

Because the reproductive tract of the recipient provides the environment for sperm transport, fertilization, and embryo development, recipient mares should be young (optimally 4–10 years) and have normal reproductive tracts. Cyclic and noncyclic hormone-treated mares have been used as oocyte recipients. When cyclic mares are used, recipients are synchronized with the donor, and the recipient's own oocyte is removed by transvaginal or flank aspiration before transfer of the donor's oocytes.[900] Anestrous and early transitional mares are used as recipients during the nonovulatory season.[892,901] During the breeding season a high dose of a GnRH agonist (4.2 mg deslorelin acetate)[902] or injections of progesterone and estrogen (150 mg progesterone and 10 mg estradiol)[894] have been administered to reduce follicular development in potential recipients. The endocrine environment of the cyclic mare is imitated in the noncyclic recipient with administration of estradiol (1.5–5 mg daily for 3–7 days) before transfer. Estradiol often is given to obtain a recipient with a relaxed, open cervix and moderate endometrial edema. Progesterone (150–200 mg daily) or a progestin is administered after transfer. Pregnancies are maintained through the administration of exogenous progesterone or progestins.[892]

Because oocytes are transferred surgically, adequate exposure of the oviduct is essential, and mares with short, thick flanks or short, broad ligaments are not good candidates for recipients. Most oocyte transfers are performed through a standing flank laparotomy. Tranquilization, preparation, closure, and aftercare of recipients are similar to previously described methods for embryo transfer.[903] The authors generally use a fire-polished glass pipette to transfer oocytes. The oviductal os is located by following the outline of the oviduct along the external surface of the infundibulum. The end of the structure is identified and the pipette containing the oocyte is inserted into the os, and the pipette is carefully advanced 2 to 3 cm. The oocyte and a minimal amount of medium (<0.1 mL) are deposited into the ampullary region of the oviduct, the ovary is gently returned to the abdominal cavity, and the surgical site is closed.

Insemination of Recipients

In a commercial oocyte transfer program, use of stallions with good fertility is essential for success, but cooled, transported semen frequently is provided from stallions of variable fertility.[892,904] The equine oocyte remains viable for approximately

12 hours after a natural ovulation.[4] Because of this limited life span, recipients must be inseminated before or directly after oocyte transfer or both. Pregnancies have occurred when recipients were inseminated only before[905,906] or after[899] the transfer of oocytes. However, for most experimental transfers, recipients were inseminated before transfer (approximately 12 hours) and after transfer (approximately 2 hours), with a total of 2×10^9 motile sperm. In a commercial program using older donors and cooled semen from numerous stallions of variable fertility, pregnancy rates when recipients were inseminated before or before and after oocyte transfer were significantly higher than when recipients were inseminated only after transfer (18 of 45 [40%], 27 of 53 [51%], and 0 of 10 [0%], respectively).[904] The results suggest that insemination of a recipient once before transfer with at least 1×10^9 progressively motile sperm from a fertile stallion is sufficient. However, if fertility of the stallion is not optimal, then insemination of the recipient before and after transfer could be beneficial.

After insemination and transfer, the uterus of the recipient should be examined with ultrasound to detect intrauterine fluid collections. Recipients with intrauterine fluid collections are treated like an ovulating mare, with oxytocin or PGs to stimulate uterine contractions or with uterine lavage and antimicrobial infusion.

Success of Oocyte Transfer

Pregnancy rates for commercial transfers using older donors and semen of variable quality ranged between 27% and 40% per transfer.[892,904] In contrast, experimental transfers under similar conditions using oocytes from young mares and fertile stallions resulted in pregnancy rates between 54% and 83% per transfer.[27] However, one or more pregnancies were obtained for more than 80% of donors during the breeding season in a commercial oocyte transfer program.[892] All mares in the program had histories of reproductive failure in breeding and embryo transfer programs, with a mean of 7 years (range of 3–15 years) from the last successful pregnancy or embryo collection.[892]

In Vitro Maturation and Fertilization of Oocytes

In vitro fertilization is not as repeatedly successful in the mare as it is in many other species, with only two foals born after in vitro fertilization.[907,908] One problem in trying to study procedures such as in vitro fertilization in the horse is the paucity of equine oocytes. Oocytes often are collected from the preovulatory follicles of live mares. Collection of oocytes from small follicles during diestrus results in reduced collection rates compared with collection of oocytes from preovulatory follicles.[909] In one study,[908] oocytes were collected from small follicles and preovulatory follicles. Oocytes collected from small follicles were matured in vitro for 36 to 38 hours before transfer, whereas oocytes collected from preovulatory follicles were transferred immediately into a recipient's oviduct. Embryo development rates after transfers were 9% for in vitro maturation and 82% for in vivo. In contrast, some laboratories have been very successful in developing methods to collect and mature oocytes from small follicles. Colleoni et al. reported an oocyte recovery rate of 58%, or 11 oocytes per ovum pick-up session.[910] At this time, in vitro embryo production is best achieved with oocyte aspiration, followed by ICSI to achieve fertilization, then embryo maturation in vitro, and transfer at the blastocyst stage into a recipient.

Research involving oocytes from excised ovaries is aimed at developing a method for salvaging gametes from the ovaries of valuable mares that have died or been euthanized. One can collect ovaries from mares immediately after death and ship them to a facility for oocyte recovery, maturation, and transfer. This technique was first attempted in 1999,[892] and a pregnancy was established that later underwent embryonic death. However, more recent attempts have resulted in pregnancies and healthy foals after shipment of ovaries from mares that were euthanized for various medical reasons.[911,912] Currently obtaining a late-term pregnancy or pregnancies from about one of four sets of ovaries that are shipped to a laboratory for oocyte recovery is anticipated.

Cryopreservation of Oocytes and Embryos

Cryopreservation of the equine oocyte results in the preservation of female genetics, whereas cryopreservation of the embryo results in the preservation of the female and male genome. The first foal was produced from a cryopreserved embryo in 1982.[913] Procedures for embryo cryopreservation have been reviewed.[914] Cryopreservation of small embryos (morulae or early blastocysts <300 μm) has consistently resulted in acceptable pregnancy rates close to 50%.[915,916] Cryopreservation of larger embryos (≥300 μm) is usually unsuccessful. Embryo collection is recommended on day 6 or 6.5 after ovulation.[914] Embryo donors are examined twice daily for ovulation, or embryo collections are timed from administration of an ovulation-inducing agent.[917] In recent years vitrification procedures have been used to successfully cryopreserve small equine embryos.[917-919] The advantage of vitrification over traditional slow-cooling methods include cryopreservation, which is a rapid procedure (<15 minutes) that requires minimal equipment and results in better pregnancy rates post thaw. Recently a technique that involves aspiration of fluid from the blastocele cavity before vitrification in larger embryos has been reported to have reasonable success rates.[920]

Although cryopreservation of the oocyte is difficult, successful fertilization of cryopreserved oocytes has been described.[921, 922] In 2001, the first foals were born after cryopreservation of oocytes.[906] Clinical use of oocyte cryopreservation has not been reported and is currently not used in a clinical setting.

ASSISTED REPRODUCTIVE TECHNIQUES FOR THE STALLION

Maximum fertility was obtained when fertile mares were inseminated every other day during estrus with 500×10^6 progressively motile sperm.[923] Insemination of low numbers of sperm would be beneficial for frozen semen that is of limited supply, semen from subfertile stallions with low sperm numbers, and insemination of sex-sorted sperm. The following discussion summarizes techniques for low-dose or assisted inseminations. A more complete discussion on stallion semen processing will be found in a later section.

Deep Intrauterine Insemination

Uterine contractions move sperm into the tips of the uterine horns within 20 minutes of routine AI.[924] The aim of deep uterine insemination (also known as "deep-horn insemination")

is to increase the number of sperm entering the oviduct ipsilateral to ovulation.[925-927] A flexible insemination pipette is passed through the cervix and into the uterine horn ipsilateral to the preovulatory follicle. Then rectal manipulation is used to advance and position the catheter at the tip of the uterine horn in which the sperm are then deposited. Fresh, cooled, and sex-sorted sperm in volumes ranging from 0.2 to 1.0 mL of commercial semen extender have been used for deep intrauterine inseminations. Pregnancy rates after deep intrauterine inseminations with 5×10^6 progressively motile sperm were between 30% and 50%,[923,928] and inseminations with 25×10^6 progressively motile sperm ranged between 57% and 63%.[929,930] However, in a study by Woods et al.,[930] control mares were inseminated with 25×10^6 progressively motile sperm in the uterine body, and pregnancy rates were not significantly different between standard and deep uterine inseminations. Because control inseminations were not done in many studies, the true benefit of deep uterine insemination has not been determined.

Hysteroscopic Insemination

Hysteroscopic insemination involves deposition of sperm directly onto the papilla of the uterotubal junction. A minute volume of extended sperm (approximately 0.05–0.25 mL) is desired for hysteroscopic insemination. Sperm are centrifuged through a density gradient to select a sperm population with a high percentage of motility. Numbers of fresh sperm inseminated ranged between 1 and 10×10^6 progressively motile sperm, with pregnancy rates between 40% and 75%.[928,931-933] Studies have been conducted using higher volumes[931] or lower sperm numbers,[931] but fertility was reduced.

With hysteroscopic insemination, semen is aspirated into an equine gamete intrafallopian transfer (GIFT) catheter (Cook Animal Health, Bloomington, IN) protected by an outer polypropylene cannula and loaded into the working channel of the videoendoscope. With a sterile gloved arm in the vagina of the mare, the operator guides the flexible endoscope (1.6 m in length) through the cervix and uterine lumen; directs the endoscope along the uterine horn ipsilateral to the preovulatory follicle; and on imaging the papilla of the uterotubal junction, extrudes the outer cannula and then the inner GIFT catheter containing the sperm suspension from the working channel of the endoscope. When the tip of the GIFT catheter touches the papilla, the operator bubbles the inseminate onto the surface of the papilla.[931]

Low-dose insemination with frozen-thawed sperm maximizes the use of a conventional dose of frozen sperm (800–1000×10^6 progressively motile sperm) by reducing the number of sperm needed for insemination. Using 5 or 10×10^6 frozen-thawed progressively motile sperm, different investigators obtained pregnancy rates between 33% and 47%.[932,934,935] Alvarenga et al.[936] inseminated client mares with 100 to 150×10^6 frozen-thawed sperm from 15 Warmblood stallions and obtained an overall pregnancy rate of 57%, demonstrating that hysteroscopic insemination can be applied immediately in the horse industry. Current rates for sorting sperm into X chromosome–bearing or Y chromosome–bearing populations are approximately 10 million sperm per hour, meaning that low-dose inseminations are necessary for sex-sorted sperm. Several studies have been conducted using hysteroscopic insemination of sex-sorted sperm, resulting in pregnancy rates between 25% and 44%.[932,934]

Gamete Intrafallopian Transfer

GIFT involves transfer of oocytes and sperm into the recipient's oviduct. Compared with oocyte transfer, GIFT requires low numbers of sperm. The first successful GIFT in the horse was reported in 1998.[901] GIFT sperm are often selected through a density gradient to select a population with a high percentage of morphologically normal, motile sperm, free of debris and seminal plasma, with 1 to 5×10^5 progressively motile sperm transferred with an oocyte into the recipient's oviduct. Optimal procedures for GIFT have probably not been established, although pregnancy rates between 27% and 82% have been reported.[899,937] GIFT is a potentially valuable technique to produce pregnancies from subfertile stallions, frozen semen, and sex-sorted sperm. However, the type of sperm and even extenders may have an effect on the success of GIFT. Pregnancy rates with GIFT were lower when cooled or frozen semen was used for GIFT (pregnancy rates of 25% and 8%, respectively) compared with pregnancy rates with fresh semen (82%).[938]

CONCLUSION

New assisted reproductive techniques have been developed that allow for the production of offspring from mares and stallions that would be considered subfertile or infertile when more standard breeding procedures are used. Although cost, expertise, and availability of these procedures may be limiting factors in their widespread use at this time, their clinical potential for preservation of valuable equine genetics is important to recognize.

The Stallion

Charles F. Scoggin

This section will describe the relevant anatomy, physiology, and management of the stallion and discuss pathology associated with the reproductive tract of male horses.

Medical conditions affecting stallions are generally no different from what we see in other horses, with the obvious exception being those pertaining to the reproductive organs. The incidence of problems associated with the genitalia or gonads is inherently low because there are proportionally fewer intact male horses compared with female horses and geldings. Nonetheless, on the vast majority of farms and ranches, stallions are one of—if not the—most valuable assets of the breeding operation and represent a very large financial investment. Time off in the breeding shed because of illness or injury can have significant and negative effects on both the stud farm and the stallion. Problems must thus be addressed efficiently and appropriately to minimize financial losses and maximize fertility. Understanding the relationship between the reproductive system and other organs in the stallion allows for a thorough evaluation with the intent of achieving a timely diagnosis and therapeutic plan.

Stallions are considered by some to be the most coveted and financially relevant assets of a breeding farm. Consequently, the importance of keeping them happy and healthy cannot be overemphasized. Understanding the various anatomic and physiologic attributes of breeding stallions allows for proper reproductive management and health care.

REPRODUCTIVE ANATOMY

Internal Genitalia

Testicles

Reproductively normal stallions should have paired testes that are readily palpable within the scrotum. Normal equine testes are relatively ovoid in shape. Each is oriented mostly in the horizontal plane, with the head *(caput)* and tail *(cauda)* of the epididymis located on the cranial and caudal poles, respectively, of the testis. The body *(corpus)* of the epididymis runs along the dorsal aspect of each testis. Occasionally, the testes may rotate up to 180 degrees without any apparent signs of discomfort or swelling. Such rotation is usually temporary but may occasionally become permanent. It should also be distinguished from spermatic cord rotation, which is a pathologic condition described later. This condition strays from normal and may adversely affect perfusion to the testis. As such, this finding should be taken into consideration when performing a reproductive evaluation on a breeding stallion and duly noted within the records. An important landmark is the *proper ligament of the tail of the epididymis,* which is a remnant of the fetal gubernaculum. The proper ligament attaches the tail of the epididymis to the caudal pole of the testis. Clinically, this ligament is palpable as a fibrous nodule that can be large in newborn colts and mistaken for the testis, and it may also be a useful reference in determining the relative orientation of the testis. The *ligament of the tail of the epididymis* is another gubernacular remnant that attaches the tail of the epididymis to the parietal vaginal tunic of the scrotum and anchors the testis and epididymis to the scrotum.

Each testicle is encapsulated by the tunica albuginea. This tough collagenous membrane contains smooth muscle that sends supporting trabeculae into the testicular parenchyma, dividing the testis in adjoining lobules. Functionally, this muscular investment is thought to assist with sperm transport and determine the relative tone and turgidity of the testicle.[939] Normal testes should be firm but resilient on palpation. Soft or hard testes are abnormal and may be associated with myriad conditions, including neoplasia, degeneration, infection, and trauma.

Each testis is composed of several different cell types. Some of these have endocrine functions, whereas others have exocrine or homeostatic functions. The parenchyma of the testis accounts for 85% to 90% of the testicular volume. It is composed of the seminiferous tubules and the interstitial tissue. These work in tandem to manufacture, mature, and deliver spermatozoa for fertilization of female gametes.

The seminiferous tubules are lined with an epithelial layer (seminiferous epithelium) composed of germ cells and Sertoli cells. Germ cells will be present at various stages of development, from early spermatogonia to mature spermatids, and are the most prominent cell types. The interstitium is formed by Leydig and myoid cells and comprises ~15% of the parenchyma.[940]

Because of the complexities of the spermatogenic process, it and the various stages of germ cells involved in spermatogenesis will be covered in a separate section. What follows immediately is a brief description of the other cells involved in testicular function.

Sertoli Cells. Sertoli cells are pivotal for germ cell maturation, serving as nurse cells and forming the blood-testis border. These cells help nurture and support developing germ cells through their exocrine secretions that bathe the developing germ cells. These cells also have important endocrine functions, and by secreting androgen binding protein (ABP), activin, and inhibin, they can affect the hormonal milieu of the testis. The former's role is to bind dihydrotestosterone (DHT; the bioactive form of testosterone) to maintain proper concentrations of DHT in the seminiferous tubules and epididymis, whereas the latter two are responsible for stimulating or suppressing FSH, respectively. Sertoli cells also produce other proteins that are necessary to support and regulate spermatogenesis. Examples include ceruloplasmin and transferrin, which act as carrier proteins for copper and iron, respectively, and are necessary for proper testis function.

The blood-testis barrier divides the seminiferous epithelium into basal and adluminal compartments via tight gap junctions formed between Sertoli cells. This barrier functions primarily to protect the haploid spermatozoa found in the seminiferous tubules from the host immune system that would recognize them as foreign; thus its primary function is one of providing immune privilege to the adluminal compartment of the seminiferous tubules.

The number of spermatogenic cells and ultimately the total sperm production of a given stallion are determined by the number of cells that can be accommodated between the tight gap junctions between two Sertoli cells. Sertoli cell numbers increase steadily during puberty and continue to rise with maturity. The number of Sertoli cells within the adult stallion's testes was once thought to be finite. However, recent research suggests that Sertoli cells are not stable; instead, their numbers fluctuate with season.[941]

Leydig Cells. Leydig, or interstitial, cells are the main source of testosterone production. Androgen production is mediated primarily via pituitary secretion of LH, and Leydig cells contain an abundance of LH receptors. Through steroid production, Leydig cells provide the feedback mechanisms on the pituitary necessary to maintain spermatogenesis, secondary sex characteristics, and libido. Testosterone concentration in the testicular microcirculation is at least 10 times higher than that in the systemic circulation. Season and not age appear to affect the testosterone production in adult stallions, which is mediated through a change in total number of Leydig cells rather than total volume of cells per testis. In contrast to Sertoli cells, Leydig cell numbers do not increase dramatically with age, but both number and size of these cells can vary with season.[942]

Myoid Cells. Myoid cells appear essential for proper testicular function. They provide architectural support to the seminiferous tubules and likely play an important role in intratesticular movement of sperm. In addition, myoid cells also modulate Sertoli and Leydig cell function via paracrine factors. One example is production of the mesenchymal factor PmodS, which has been shown in vitro to stimulate release of transferrin from Sertoli cells.[943]

Germ Cells. In contrast to mares, normal stallions continually produce germ cells. This process of development of a diploid germ cell to a haploid spermatozoa capable of fertilization requires approximately 57 days, and the number of germ cells produced is directly correlated with the total volume of the testes.[944] Germ cells line the seminiferous tubules and can be found in different stages of maturation from early diploid stem cell spermatogonia to almost fully mature haploid spermatids. The process by which these primordial cells transform into spermatozoa is referred to as *spermatogenesis.*

Spermatogenesis follows a chronologic order in the development of germ cells yet is also a highly complex process. The spermatogenic process will be reviewed later in the discussion of stallion physiology.

Testis Cell Interactions. The importance of the relationship between the individual cells within the testes cannot be overstated. For example, Sertoli, or "nurse," cells have a direct interaction with germ cells, and Leydig cells interact with Sertoli and germinal cells through hormonal signals. The myoid cell produces at least one paracrine factor that interacts directly with the Sertoli cell. Paracrine and autocrine modulating factors, products of the peritubular cell, appear to have an effect on ABP function. In turn, the myoid cell is under the regulatory influence of transforming growth factors α (stimulatory) and β (inhibitory). Other factors involved in cell-to-cell communication of the cells of the testis include collagen, plasminogen activator, vitamin A, pyruvate, and carbohydrates.[945] Most of these products and mechanisms have not been investigated extensively in the stallion.

Epididymides

The specific absorptive and secretory functions of each segment of the stallion epididymis remain the subject of considerable debate and investigation. The histologic structure of the epididymis changes as it continues through its different regions, with epithelial height being greatest proximally and smooth muscle components greatest distally.[946] As spermatozoa are transported from the excurrent ducts into the head, along the body, and into the tail, they undergo a number of morphologic and physiologic changes that ultimately render them motile and fertile. Specific maturational changes that occur include (1) acquiring the capacity for progressive motility, (2) shedding of the cytoplasmic droplet, (3) plasma and acrosomal membrane alterations, (4) DNA stabilization, and (5) metabolic changes.[947] All these changes occur primarily at the level of the mid to distal corpus.[947,948] The tail of the epididymis serves primarily as a storage site for nearly competent spermatozoa that are ready for ejaculation.

Fluid resorption occurs throughout the epididymis and at a steady rate, which results in a significant increase in sperm concentration. Stallions with high-volume ejaculates with relatively low sperm concentration and poor sperm morphology may have epididymal dysfunction. However, the association has yet to be clearly defined.

Spermatic Cord

The spermatic cord supplying each testis is enveloped in the parietal layer of the vaginal tunic, which extends distally from the internal inguinal ring. Within each cord are the corresponding deferent duct, testicular artery, testicular veins, lymphatic vessels, and nerves. The cremaster muscle is situated in the caudolateral borders of each spermatic cord. The testicular artery, a branch of the abdominal aorta, descends through the inguinal ring into the cranial border of the spermatic cord in a tortuous manner and divides near the testis into several branches to supply the testis and epididymis. These small branches, embedded in the tunica albuginea, enter the parenchyma by way of the trabeculae and septae of the testis. A corresponding network of veins leaves the testis and surrounds the testicular artery in a tortuous manner, forming the *pampiniform plexus.* This arrangement of artery and veins serves a critical role in thermoregulation of the testis in the stallion. The pampiniform plexus allows for heat exchange from the testicular artery to the venous side, resulting in testicular arterial blood being several degrees cooler than systemic blood temperature. Abnormal distention of the veins of the pampiniform plexus is termed a *varicocele* and is an uncommon condition in stallions. Palpation of the spermatic cord of an affected stallion reveals the dilated and often tortuous vessels. Varicoceles are usually not painful but can result in fluid accumulation around the vaginal tunics, most often involve only one side of the spermatic cord, and usually are diagnosed by the observation of the dilation of the vessels from the pampiniform plexus with ultrasonography. The condition has been identified in stallions with normal semen parameters.[949]

Accessory Sex Glands

In the stallion, the *accessory sex glands* are composed of the bulbourethral glands, prostate gland, seminal vesicles, and ampullae. Their secretions produce the seminal plasma that makes up most of the ejaculate volume. The ampullae, which are dilations of the vas deferens before opening in the colliculus seminalis, are also considered a storage site for sperm.

Short exposure to seminal plasma appears to be important for sperm function, but long-term exposure to seminal plasma components may be detrimental to spermatozoa survival for some stallions. Often termed "toxic" seminal plasma, spermatozoa exposed to certain stallions' seminal plasma quickly lose their viability, leading to subfertility. AI programs deal with this potential detrimental effect by dilution of semen with semen extenders in fresh or fresh-chilled programs and by centrifugation to remove seminal plasma in frozen semen programs and some chilled-shipped programs. Live-cover operations may counter toxic seminal plasma by infusing semen extender into the mare's uterus before or after mating.

Seminal plasma appears to suppress the inflammatory response of the endometrium of the mare to sperm after insemination or natural mating. Although the functions of the specific components of the seminal plasma remain rather obscure, the fluid suspends the ejaculated sperm and also is thought to be a source of energy, protein, and other macromolecules required for sperm functions and metabolism.[950-952]

Next is a brief discussion on the anatomy and functionality of the stallion's accessory sex glands.

Bulbourethral Glands. Multiple ductules from the bulbourethral glands enter the dorsomedial wall of the pelvic urethra caudal to the prostatic ductules. Bulbourethral gland secretions compose most of the presperm or first fraction of the ejaculate and serve as a cleanser and pH stabilizer in the urethra before ejaculation.

Prostate Gland. In the stallion the prostate is formed by a central isthmus and two lateral lobes located on the caudolateral borders of each vesicular gland. Multiple ductules from the prostate enter the lumen of the pelvic urethra in the dorsal urethral wall lateral to the colliculus seminalis. The watery secretions of the prostate contribute to the presperm fraction of the ejaculate.

Ampullae. The ampullae are the enlarged distal portions of the deferent ducts. They converge caudad and pass beneath the prostate gland but lie dorsal to the pelvic urethra. At their distal ends they continue through the dorsal wall of the urethra, opening into the colliculus seminalis alongside the excretory ducts of the seminal vesicles. The ampullae, in addition to serving as a sperm storage area, have many branched tubular glands located within the thickened wall.[953]

The ampullae are a common site for blockage caused by stasis of sperm (as would be seen in a sexually inactive stallion) or an inability to effectively void spermatozoa. This condition is referred to as *spermiostasis* or *plugged ampullae* and can cause subfertility if not properly managed. This condition will be discussed later.

Seminal Vesicles. The seminal vesicles or vesicular glands are paired, pyriform, and thin-walled structures lying lateral to the ampullae. On occasion they may extend far cranially to hang over the brim of the pelvis. The caudal ends of the glands converge, passing under the prostate as they lie parallel to the ampullae, terminating in the seminal colliculus in the dorsal wall of the urethra. The excurrent ducts of the vesicular glands open lateral to the excurrent ducts of the ampullae at the colliculus seminalis of the urethra. Secretions of the vesicular glands compose the gel fraction of the ejaculate. Higher gel volumes can be collected with increased sexual stimulation and season. The specific function of the gel fraction is unclear, and it should be removed when processing semen for evaluation or AI. The seminal vesicles are the glands that are most prone to bacterial infections. Diagnosis is based on the cytologic evaluation of the semen with the presence of white blood cells. Treatment and management typically involve both local and systemic antibiotics based on culture and sensitivity results.

External Genitalia

The penis and scrotum comprise the extent of a normal stallion's external genitalia. The penis is comprised of smooth muscle and encased in a sheath of tissue, often referred to as the prepuce. The penis of the stallion is composed of a root, a body, and a glans penis and is musculocavernous. The penile base arises at the ischial arch in the form of two crura that fuse distally to form the single dorsal corpus cavernosum penis (CCP) enclosed by a thick tunica albuginea. The corpus cavernosum, corpus spongiosum, and corpus spongiosum glandis are the three spaces that make up the erectile tissue of the penis. Engorgement of these spaces with blood from branches of the internal and external pudendal arteries and obturator arteries is responsible for an erection. The cavernous spaces within the penis are continuous with the veins responsible for drainage. The corpus spongiosum originates in the pelvic area and surrounds the penile urethra within a groove on the ventral side of the penis and forms the corpus spongiosum glandis at the distal end of the penis.[954] The corpus spongiosum glandis creates the distinct bell shape of the stallion penis after ejaculation.

The distal end of the urethra contains a distinct urethral process, which is visible within the center of the glans penis and surrounded by an invagination known as the fossa glandis. Within the fossa glandis are diverticulae and a urethral sinus. Accumulation of secretions in these areas can occur to form "smegma," and further coalescence can form semifirm concretions ("beans") within one or all of these sites. Therefore careful examination and cleansing of this area are imperative during the reproductive evaluation of a stallion or before breeding.

The bulbospongiosus muscle and two retractor penis muscles are located ventrad on the stallion penis and run the length of the organ. The former is responsible for providing rhythmic contractions or pulsations to assist in moving the penile urethral contents (semen and urine) distally during ejaculation; the latter are responsible for returning the penis to the sheath after detumescence.

The prepuce is formed by a double fold of skin that is hairless and well supplied with sebaceous and sweat glands. The primary preputial function is to contain and protect the nonerect penis. The external part of the prepuce, or sheath, begins at the scrotum and is continuous with the scrotal raphae. The internal layer of the prepuce extends caudally from the orifice to line the internal side of the sheath and then reflects cranially toward the orifice again before reflecting caudally to form the internal preputial fold and preputial ring. This additional internal fold allows the considerable lengthening (approximately 50%) of the penis during erection. During erection the preputial orifice is visible at the base of the penis just in front of the scrotum, and the preputial ring is visible at approximately the midshaft of the penis.

The penis and prepuce of a breeding stallion can best be examined after teasing with an estrous mare, when one can observe the stallion drop the penis and attain a full erection. The prepuce and penis should be free of vesicular, proliferative, or inflammatory lesions such as those found in horses with coital exanthema, squamous cell carcinoma, or cutaneous habronemiasis. Removal of smegma accumulations is necessary for a complete examination of the skin surfaces.

REPRODUCTIVE PHYSIOLOGY OF THE STALLION

Sexual Differentiation

Mammalian sexual differentiation is a complex process. Timing is crucial, and an intricate series of intracellular and extracellular signaling events during specific periods of embryonic and fetal development must occur for sexual differentiation to proceed normally. Sexual differentiation is established by the chromosomal sex at fertilization when oocytes comprising the X chromosome encounter the X-bearing or Y-bearing sperm. Ovarian or testicular development pathways are initiated by the bipotential embryonic gland, which is a diverse population of somatic cells and germ cells. The testis-determining factor, located on the Y-region, is known as the sex-determining region (*SRY* in humans, and *Sry* in horses and other mammals). The presence of *SRY* activates the testis-specific pathway and suppresses the ovary-specific genetic development pathway in most mammals, and the reader is referred to more comprehensive reviews on this topic.[955-959] The protein product SRY is expressed in XY somatic cell precursors and in conjunction with steroidogenic factor 1 *(SF1)* acts as a molecular switch specifically to upregulate expression of *SOX9* in the *SOX* (*SRY*-related high-mobility group box) gene family.[957] Initially, *SOX9* is expressed in the bipotential gonad of both sexes, whereas *SOX9* expression in XX gonads is downregulated, and expression of *SOX9* in XY gonads is significantly upregulated. On reaching a certain threshold, somatic cell precursors differentiate into testis-specific Sertoli cells.[957] Upregulation of *SOX9* protein expression also leads to a series of molecular events to advance testis differentiation by promoting cellular and structural organization. Protein expression of *SOX9* is also responsible for a negative-feedback loop to repress *SRY* expression. Despite cessation of *SRY* expression, expression of the *SOX9* and *SF1* proteins continues and is maintained at high levels in Sertoli cells to further promote Sertoli cell development. Factors and signaling pathways that also play an important role in Sertoli cell differentiation include the signaling molecule *FGF9* (fibroblast growth factor) and its

receptor *FGFR2,* as well as prostaglandin D2 (PGD2). Expression of *FGF9* is activated downstream of *SOX9* and *SRY.* Both *FGF9* and *SOX9* work together in a positive feedforward loop in which SOX9 protein is required to upregulate *FGF9* expression. This then maintains *SOX9* expression to further promote differentiation into Sertoli cells.[960] In the absence of *FGF9* or *FGFR2* expression in XY mice, *SOX9* expression was lost and Sertoli cells did not develop, resulting in sex reversal.[961,962] Upregulation of *FGF9* during testis development also actively represses the female gene wingless-related MMTV integration site 4 *(WNT4),* which is required for ovarian development.[963] Thus *FGF9* expression is critical for testis development.

Another autoregulatory loop that works independently from *FGF9* and promotes Sertoli cell development is the PGD2-mediated signaling pathway. Sertoli cells secrete PGD2, causing neighboring somatic cell precursors to express and accumulate *SOX9,* spawning more Sertoli cells,[964] but this particular signaling pathway is not essential for testis development.

Testicular Descent

Normal descent of the testes into the scrotum is somewhat variable and typically occurs between the last 30 days' gestation and the first 10 days of birth. In some colts the testes may descend into the inguinal region and remain there for some time before fully descending. Both endocrine and anatomic events must occur for proper migration of the testes into the scrotum. Androgens and AMH are involved in the signaling for testicular descent.[965-968] Traction of the gubernaculum, which attaches the caudal pole of the testis to the parietal vaginal tunic of the scrotum, is believed to draw the developing testis and epididymis into and through the inguinal ring.[2]

Cryptorchidism is the condition in which one or both testes fail to descend into the scrotum by 2 years of age. It is one of the most common congenital defects occurring in colts, yet the causes remain obscure and are presumably multifactorial. A true genetic link has not been found, but anecdotal evidence abounds about certain family lines in particular breeds whose males are prone to the condition. Diagnosis and management of this condition will be discussed later.

Puberty

This period is defined as the age at which a colt is able to mount, copulate, and successfully impregnate a mare and generally occurs during the second spring after the year of birth in the Northern Hemisphere. It should be noted that in some cases colts as young as 8 months have been able to achieve pregnancies. In some large breed horses (e.g., draft breeds) there may be a delay in puberty. Puberty should not be confused with sexual maturity. Whereas puberty signifies the time in which a male can successfully impregnate a female, sexual maturity indicates the time period after which a stallion has fully developed secondary sexual characteristics and fully developed genitalia. Puberty occurs earlier (e.g., ~2 years of age), whereas sexual maturity is reached at approximately 5 years of age.

The hypothalamic pulse generator is a group of cells located in the arcuate nucleus of the hypothalamus.[965] Neuroendocrine activity from this generator stimulates the onset of puberty via pulsatile secretion of GnRH from the hypothalamus, which stimulates the secretion of LH and FSH from the anterior pituitary. Season, age, breed, nutritional status, and external hormones affect puberty. In horses, onset of puberty occurs around 12 to 18 months and is complete by 18 to 24 months, as previously mentioned.[969]

Endocrinology

The pineal gland plays a significant role in the seasonality of the horse. Specifically, the retina captures photoperiod information and transports it by way of nerve fibers to the pineal gland. In horses, photoperiod stimulation (i.e., long days) inhibits the production of melatonin. Because melatonin inhibits GnRH release in horses, suppression of melatonin leads to increased pulses of GnRH from the hypothalamus. Unlike mares, stallions do not undergo a complete reproductive quiescence during short days and will continue to produce sperm year round. The cause for this partial refractoriness of the stallion to changes in photoperiod is not well understood but likely clinically insignificant in normal fertile stallions.

The hypothalamus, pituitary, and testes (HPG axis) must work in synchrony for a stallion to be able to start and sustain sperm production. The primary role of the hypothalamus is the production of the 10-amino-acid peptide GnRH, which is secreted in multiple daily pulses and then transported via the hypothalamic-pituitary portal system to the anterior pituitary. In addition to melatonin-mediated stimuli, the hypothalamus responds to tactile, olfactory, and visual stimuli.[970]

The pituitary, which is connected to the hypothalamus by neural fibers, has two lobes. The anterior lobe possesses GnRH receptors. Binding of GnRH activates these receptors and induces secretion of FSH or LH. FSH and LH act on the Sertoli and Leydig cells, respectively, stimulating production of steroids and other protein hormones. The peptide hormones inhibin and activin regulate FSH secretion at the level of the pituitary. Steroid hormones produced in the testis (e.g., estradiol, testosterone) feed back at the level of the pituitary to inhibit FSH and LH secretion and to regulate GnRH secretion from the hypothalamus.

Because of the complexity of interactions among hormones, their target tissues and other important physiologic events, current methods do not exist to accurately predict infertility in stallions. As will be discussed later, pharmaceutical therapy, particularly supplementation with exogenous hormones, is empiric, somewhat unreliable, and only of benefit in certain instances.

Spermatogenesis

Spermatogenesis describes a series of chronologic changes occurring within the seminiferous tubule that transforms a large, round diploid spermatogonium into a haploid spermatozoon capable of fertilization. This process takes approximately 57 days in stallions and is not affected by frequency of ejaculation or sexual stimulation. Next will be a brief review of the spermatogenic process. However, many of the complexities are beyond the scope of this chapter, so the reader is directed to reviews on this subject for more in-depth information.[939,949,971]

The process starts when an A_1 stem cell spermatogonia undergoes mitosis, giving rise to (1) a second A_1 spermatogonia to maintain a constant population of stem cells and (2) an A_2 spermatogonia. In turn, the A_2 spermatogonia gives rise to A_3, A_3 to B_1, and B_1 to B_2. Spermatogenesis can be divided into three phases of similar length: *spermatocytogenesis, meiotic divisions,* and *spermiogenesis.*

Spermatocytogenesis is characterized by the mitotic divisions of A and B spermatogonia. Meiotic divisions result in the

formation of primary spermatocytes from B_2 spermatogonia, followed by formation of secondary spermatids. Leptotene spermatocytes that form immediately after the first meiotic division are shielded from the host's immune system by the blood-testis barrier. Spermiogenesis is characterized by the transformation of round spermatogonia to elongated spermatids and, ultimately, spermatozoa. During spermiogenesis, the acrosome arises from the Golgi complex, and compaction of DNA occurs because of expression of protamine genes at the spermatid stage. The end of spermatogenesis is characterized by *spermiation,* which is the release of elongated spermatids into the lumen of the seminiferous tubule and represents the transition to a spermatozoa.[972]

Seasonality

Stallions are subject to seasonal influences. For example, concentrations of LH and testosterone, DSO, and libido all increase during times of the year that coincide with periods of longer exposure to light, or "long days."[973-975] However, stallion reproduction does not appear to be as tightly regulated by season as that of mares. When given the opportunity, stallions will breed year round and are capable of ejaculating normal sperm and achieving adequate pregnancy rates.[973]

Because stallions are seasonal long-day breeders, exposure to artificial lighting programs has been used in the management of commercial breeding stallions. It is thought that it can hasten the onset of improved breeding behavior and sperm production. Such strategies are used on several commercial stud farms in the United States. Two studies reported no detrimental effect on photostimulated stallions.[975] Another study demonstrated that light therapy increased testicular size and sperm production, but changes were transient.[976,977] In addition, some stallions experienced a reduction in testis size and circulating testosterone concentrations by June, which could potentially have a negative effect on reproductive efficiency, especially in stallions of already questionable fertility.

Sexual Behavior

Stallions will demonstrate sexual behavior in many ways. Vocalization, snorting, bowing of the neck, biting/nipping, striking, and the flehmen response are all typical signs associated with normal breeding behavior. Depending on the individual stallion, these precopulatory signs will be expressed with various frequencies and intensities. *Libido* or "sex drive" is the vigor with which stallions display breeding behavior. Strength of libido is dependent on numerous factors such as genetics, farm and breeding management, season, and external stimuli (olfactory, visual, and auditory) and is highly variable among individual stallions. When exposed to an estrous mare, stallions should drop their penis within 2 minutes, which is referred to as the "latency to erection" period, and attempt to mount the mare or phantom mount in 3 to 5 minutes. Once intromission occurs, stallions give several (five to eight) vigorous pelvic thrusts, followed by three to five short thrusts immediately before ejaculation. External signs of ejaculation that are used to determine whether ejaculation has occurred are rhythmic and frequent urethral pulsations in the penis (fremitus), flagging of the tail, and head relaxation. A single stallion tends to be consistent in his breeding behavior, provided that the conditions under which he usually mates are the same.[978] Exceptions to these rules are stallions that have never bred before (i.e., *novice stallions*). Their behavior can be somewhat erratic because of inexperience but will evolve and stabilize with increased breeding frequency. Management of the abnormal behavior and the novice stallion will be discussed later.

CLINICAL EVALUATION OF THE STALLION

Assessments of stallions for their suitability as breeding animals are called breeding soundness evaluations (BSEs). However, the author prefers the term *stallion reproductive evaluations* (SREs) because BSE is commonly associated with examination of bulls for their relative virility. The criteria used to determine the value of and measure the reproductive performance of males are vastly different between the two species. Thus it seems reasonable to use a separate term to avoid confusion.

Many SREs are performed as either part of a prepurchase examination or as annual evaluations (typically performed before the breeding season) to monitor reproductive capacity. Other indications for SREs would be a precipitous drop in fertility or as partial fulfillment of an insurance examination. An example of a typical form to record findings from an SRE is shown in Fig. 19.25.

Recommendations for determining whether a stallion met the criteria to be considered *satisfactory* for breeding were outlined in the (no longer available) *Manual for Clinical Fertility Evaluation* published by the Society for Theriogenology in 1983.

Standards by which a stallion is judged to be a satisfactory breeder include the ability to

1. Render 75% of 40 mares pregnant via live cover (or 120 mares by AI) in one breeding season;
2. Produce ≥1 billion progressively motile, morphologically normal sperm in the second of two ejaculates collected an hour apart;
3. Have a total scrotal width of 8 cm; and
4. Be free of undesirable/hereditable defects.

Stallions failing to meet these requirements are given either *differed* or *unsatisfactory* status based on findings from the evaluation. Much advancement in our knowledge of reproductive physiology and breeding management has been made since this manual's publication, and some theriogenologists have acknowledged the need for updating the requirements.[979] Moreover, problems often arise when trying to quantify biologic systems, especially when there is more "skin in the game" than just finances. For example, there are certain intangibles a stallion may represent that prove nearly impossible to calculate. Farm management practices, whether knowingly or unknowingly, can also influence reproductive efficiency. Therefore data obtained from the SRE should always be interpreted with respect to individual farms and stakeholders.

Breeding Records

The importance of maintaining accurate and current breeding records cannot be overstated. Both computer-generated and manual records can be used to evaluate and track a stallion's reproductive efficiency. In addition, these records are invaluable to clinicians when asked to assess a stallion for his reproductive performance.

In central Kentucky, "Horse Farm Management," provided by the Jockey Club Information Systems (Jockey Club Information Systems, Lexington, KY) is an example of a digital

program that can track and compile data about past and current reproductive parameters. For example, this program can generate reports on the numbers of mares bred, mare information, and seasonal summary reports for individual stallions or the stud farm as a whole. This information can then be tallied to evaluate breeding efficiency and/or factors associated with poor performance.

Physical Examination

Stallions should be sound in both mind and body to be suitable for breeding. Organ systems should be evaluated for signs of diseases or disorders that could adversely affect breeding performance. In particular, diseases of the musculoskeletal system can significantly impede reproductive efficiency, and chronic disorders (e.g., arthritis, laminitis) can drastically shorten a stallion's breeding career. When or if possible, baseline radiographs of the distal limbs can prove useful for screening, monitoring, and treating orthopedic issues.

Careful attention should be paid to the external genitalia. Visual and manual inspection of the entire penis, sheath, and scrotum for size, texture, consistency, and signs of dermatitis are indicated. Measurement of total scrotal width using calipers or ultrasonography is useful for measuring reproductive efficiency. As will be discussed in the next section, ultrasonography is a highly useful means to assess the internal anatomy of the stallion, especially the testes.

Evaluation of the External Genitalia

Ultrasonography of the testes is a useful diagnostic tool for screening for pathology, monitoring progression of disease, and predicting reproductive capacity. Pathology of the testes will be discussed later, but at a minimum ultrasound and

palpation of the testes should be performed to determine the size, tone, orientation, and character of the testes and associated structures. Measurements of the *height, width,* and *length* of each testis can be obtained with a standard 5-MHz or 7.5-MHz linear rectal probe. These values can be used to calculate testicular volume and then the estimated DSO[980] and breeding frequency expected for testes of that size.[981] Table 19.11 shows the relationship among testicular volume, DSO, and expected number of daily breedings determined in Thoroughbred stallions performing in a commercial live-cover program.

Specific techniques for examination of the testis have been previously discussed.[982,983] Beginning at the proximolateral aspect of the scrotal neck with the long axis of the probe parallel to the ground, the spermatic cord can be imaged. The arrangement of the pampiniform plexus results in the mottled, heterogeneous appearance of the spermatic cord, and the testicular artery and veins are identifiable in cross-sectional images. If the ultrasound machine is equipped with a power Doppler function, then evaluation of the vasculature can be performed and compared with previously established values.[984,985] Slowly moving distal and cranial toward the cranial pole of the testis, the probe can then be oriented in a vertical position (i.e., long axis perpendicular to the ground) and moved caudad. Visualization of the scrotum reveals a thin, echogenic uniform layer. Minimal, if any, fluid is visible between the scrotal skin and testicular parenchyma in the normal stallion. In the cranial third of the scrotum, the head of the epididymis, testicular parenchyma, blood vessels of the spermatic cord, and central vein of the testis are visible.

As the probe is moved caudal, the spermatic cord vessels disappear, and the head of the epididymis continues into the body of the epididymis. The head and body of the epididymis appear as heterogeneous areas just below the spermatic cord. Further caudad, the body of the epididymis becomes indistinct. With the exception of the central vein, the testicular parenchyma appears uniformly echogenic and homogeneous. The central vein appears as a small anechoic area within the testicular parenchyma at the cranial third of the testis and should not be mistaken for a pathologic lesion. Dilation of the central vein may be visible in cases of varicocele or spermatic cord torsions and usually is accompanied by detectable dilations of the vessels of the spermatic cord. Well-defined and hypoechoic or hyperechoic lesions within the parenchyma suggest testicular tumors.

FIG. **19.25, Cont'd**

Continued

After reaching the most caudal aspect of the testis, the clinician rotates the probe to face cranially in a vertical position to allow examination of the tail of the epididymis. This structure appears as a heterogeneous area with a Swiss cheese–like appearance. Identification of the epididymal tail may assist in diagnosis of testicular rotations. In horses with 360-degree torsions, the tail of the epididymis, although in its caudal position, is more dorsal because of the tension on the ligament of the tail of the epididymis by the deferent duct.

ROOD & RIDDLE EQUINE HOSPITAL

Overall Evaluation
Based upon the above findings, including—but not limited to—a careful physical examination, a thorough review of past and present breeding ability, and a systematic evaluation of the genitalia and seminal characteristic of this stallion, it is my professional opinion that this stallion:

Sincerely,

FIG. **19.25, Cont'd**

TABLE **19.11** **Relationship Between Testicular Volume, Daily Sperm Output, and Expected Daily Breeding Frequency in Thoroughbred Stallions in a Commercial Live-Cover Breeding Operation**[981]

	Estimating Breeding Book Size Based on Testicular Measurements	
Testicular Volume (mL)	Range in Predicted Daily Sperm Output (x 10^9)	Number of Covers per Day
200	3.54–4.04	2.36–2.69
250	4.74–5.24	3.16–3.49
300	5.97–6.44	3.96–4.29
350	7.14–7.64	4.76–5.09

Some stallions may have only a single testicle because the other one is either retained or removed. Most of these stallions can perform adequately as breeding stallions. The functional testis will grow in size (i.e., hypertrophy) and usually produce adequate numbers of sperm. The developmental disorder of *cryptorchidism* will be discussed in a later section.

Evaluation of the Internal Genitalia

The majority of the internal reproductive structures of interest can best be evaluated and imaged using rectal palpation and ultrasonography. Most stallions tolerate transrectal palpation well with adequate restraint. The important structures are located relatively close to the anus in the caudal pelvic region, usually requiring the operator to insert only the hand into the rectum. The accessory sex glands, ampullae, and pelvic urethra are much easier to palpate and visualize on sexually stimulated stallions. Next are descriptions of the appearance of these structures, and the reader is referred to several publications for more detailed information.[986] Thorough evaluation of the urethra is best accomplished using endoscopy, although ultrasonography can be used to supplement endoscopic findings.

Bulbourethral Glands. The paired bulbourethral glands, although not usually palpable rectally because of the urethralis and bulboglandularis muscles close to the ischiatic arch, are easy to evaluate by ultrasonography. They are located 3 to 4 cm cranial to the anus, lateral to the pelvic urethra, and will appear as variably sized yet distinct ovoid structures with multiple hypoechoic regions throughout the parenchyma.

Prostate Gland. In the stallion, the prostate is formed by a central isthmus and two lateral lobes located on the caudolateral borders of each vesicular gland. Although not always palpable rectally, the prostate is lobulated or nodular and firm, distinguishing it from the smooth, thin-walled vesicular glands lying medial to the prostatic lobes. Each prostatic lobe measures 5 to 9 cm long, 2 to 6 cm wide, and 1 to 2 cm thick. They appear as two symmetric and homogeneously echogenic lobes visible lateral to the area in which the penile urethra merges with the neck of the bladder. Hypoechoic dilations within the gland's parenchyma are usually evident in a teased stallion.

Ampullae. The ampullae are the enlarged distal portions of the deferent ducts measuring 1 to 2 cm in diameter and 10 to 25 cm in length. Palpable along the midline of the pelvic floor over the neck of the bladder, they converge caudally and pass beneath the prostatic isthmus to terminate in the seminal colliculus in the dorsal wall of the pelvic urethra. Because of the longitudinal orientation of the ampullae, sometimes they are easier to find on rectal palpation. One can identify them by ultrasonography by their hypoechoic central lumen surrounded by a uniformly echogenic wall and a hyperechogenic outer muscular layer. Orienting the transducer in a transverse position inside the rectum can provide a good cross-sectional image of the ampullae.

Seminal Vesicles. Palpation of the vesicular glands may be easier after considerable teasing of the stallion. With adequate stimulation, the vesicular glands can be felt as dilated and elongated structures measuring 12 to 20 cm long and 5 cm in diameter. The glands also are readily palpable in instances of pathologic enlargement. With ultrasonography the vesicular glands appear in a longitudinal section as a flattened oval to triangular sacs, depending on the degree of sexual stimulation. A thin echogenic wall surrounds a lumen containing fluid of

variable echogenicity. Increased echogenicity of vesicular gland fluid is associated with the highly viscous gel fraction produced by some stallions. The seminal vesicles are the accessory sex glands most prone to bacterial infections. Diagnosis is based on the cytologic evaluation of the semen with the presence of leukocytes, which are often most elevated in the gel fraction of the ejaculate.

Pelvic and Penile Urethra. Although the pelvic urethra can be evaluated by transrectal ultrasonography, in most cases little to no pathology is identified. Endoscopic examination is often more reliable in identifying sites of hemorrhage, rents, or abnormal mucosal surfaces, as well as allowing excellent visualization of the bladder.[987,988] The procedure is performed by gently passing a 1-m endoscope with an outer diameter of 8 to 9 mm into the urethra of a sedated horse. The penis is washed, and lidocaine gel and/or sterile lubricant are applied to the endoscope to facilitate passage. The clinician applies gentle and constant pressure to pass 70 to 80 cm of the endoscope into the urethra. Care must be taken not to inflate the bladder with too much air because of a slight risk of rupture.

The ductules to the bulbourethral glands, which are conduits from the gland to the urethral lumen, are arranged as two rows of 6 to 10 small openings dorsal and abaxial along the urethra. The prostatic ductules are arranged in a similar way and are visible as two groups of small openings lateral to the ejaculatory orifices of the seminal colliculus. The ductules to the bulbourethral gland are grouped about 2.5 to 3 cm caudal to the prostatic openings.

One can identify the colliculus seminalis as a rounded prominent structure found on the medial aspect of the dorsal wall of the urethra approximately 5 cm caudal to the internal opening of the urethra from the bladder. On either side of the colliculus is an ejaculatory duct orifice, which is a small slit-like diverticulum within which the ampullary ducts and ducts of the seminal vesicles open. By passing the endoscope into this orifice, one can visualize and evaluate the seminal vesicles. Samples can be collected for culture in cases of suspected seminal vesiculitis.[989] Ventral and cranial to the seminal colliculus are the openings of the urethral glands. These are visible laterad on the widened pelvic portion of the urethra at the level of the prostatic gland openings.

Endoscopic examination of the urethra is indicated in stallions with clinical signs suggestive of pathology of the urethra and accessory sex glands. In cases of hemospermia the bleeding area may be visualized with the endoscope. These lesions are most readily identified in the region of the ischiatic arch and distal urethra. One should take care to assess the urethral mucosa as the endoscope is passed forward because some irritation and erythema of the mucosal lining often results from the endoscopic examination. A false diagnosis of urethritis may result if one assesses the mucosa while withdrawing the endoscope.

Semen Collection and Evaluation

When a reproductive evaluation of a stallion is performed, two ejaculates are collected approximately 1 hour apart. Semen samples are collected with the use of an artificial vagina (AV). Ejaculates are collected either with the stallion mounted on an estrous mare or a breeding mount/phantom. Some stallions will not ejaculate into an AV, in which case they are allowed to breed a mare in estrus, and the drippings are collected from the stallion as he dismounts the mare. Other means of semen collection include aspiration of semen from the uterus and vagina of a recently bred mare, use of a large condom, and pharmacologically induced ejaculation.

Artificial Vaginas

Several different types of AVs are commercially available. Considerations for selecting an AV include size, cost, frequency of use, and stallion preference. Temperature and pressure of the AV are two important factors, and these can be adjusted accordingly for individual stallions. Most stallions favor warmer temperatures, such as 44°C to 48°C, for adequate stimulation. Adequate pressure and nonspermicidal lubrication are also necessary and important factors for successfully collecting semen.

If experiencing difficulty in obtaining an ejaculate, troubleshooting the various aspects of the process is useful for identifying the problem(s). Some instances can be caused by incorrect positioning of the AV, which places the penis at an awkward angle. Other instances include low AV temperature, poor lubrication, or inadequate size. Manual pressure to the glans and/or base of the penis or use of a warm compress can increase stimulation. Jump mare selection can also be important in that some stallions may prefer a mare in natural estrus as opposed to an ovariectomized mare receiving exogenous estrogen.

Colorado State University Model Artificial Vagina. The Colorado State University (CSU) model is essentially a large piece of PVC piping with a water bladder and a removable liner. It has an inline filter to remove debris and the gel fraction from the ejaculate. Advantages include its size and ability to maintain proper temperatures in cold weather and for extended periods. Additionally, the relative rigidity of the CSU model provides the operator better control over particularly aggressive stallions. However, the size is also a disadvantage, making it heavy and cumbersome. Heat shock is also a concern when using this model because ejaculated semen is exposed to the liner inside the AV (~46°C), which is hotter than normal and enough to cause thermal damage to spermatozoa. Finally, the CSU model requires fairly precise assembly before use, causing it to be somewhat higher maintenance than other models discussed below.

Missouri Model Artificial Vagina. The Missouri equine AV is likely the most popular type of AV in the United States. Unlike the CSU model, it requires less assembly and is made by two molded layers of latex forming a water jacket. It also can be fitted with an inline filter and is held in place with a leather or neoprene case. The Missouri model is much less rigid than the CSU model, and most stallions will ejaculate beyond the water jacket, preventing semen from being exposed to increased temperatures. This AV also allows for application of pressure on the glans or base of the penis, which can be difficult with the CSU model due to its relative rigidity.

Hanover Model Artificial Vagina. The Hanover model AV is more common in Europe, is shorter and smaller in diameter than the CSU AV, and is made of a hard rubber casing and inner rubber liner. This AV should work well for most stallions. Ejaculation occurs at or near the end of the water jacket. Pressure of the Hanover model AV is critical. This AV has an eccentric opening. If the AV is too loose, then the nonengorged glans can come through the ring, and glans dilation occurs on the other side of the opening, which is painful for the stallion.

Polish or Open-Ended Model Artificial Vagina. The Polish model is substantially different from other models on the market. Using the open-ended AV, one can visualize the process of

ejaculation and can collect individual jets of presperm, sperm-rich, or gel fraction of the ejaculate. This AV has been valuable in the diagnosis of hemospermia, urospermia, internal genital tract infections, and ejaculatory failure.[990] Additionally, this AV has been useful in obtaining semen for commercial use from stallions with hemospermia and urospermia, because most of these affected stallions ejaculate the blood or urine after the initial jets of sperm-rich semen. The open-ended AV also has been useful in cryopreservation programs for obtaining sperm-rich and bacteria-free ejaculates from stallions. This method of collection is also used to obtain "clean" ejaculates from stallions that are untrained and intolerant of penile washing. The Polish AV also allows the use of high internal AV temperatures without the risk of sperm cell damage because the ejaculate usually is emitted directly into a funnel with an attached receptacle held by a second person. Open-ended AVs are not currently available in the United States but can be made by hand from plastic or polyvinyl chloride tubing or by removing the coned portion of the Missouri University model AV and using only the innermost rubber liner to form a water jacket.

Disposable Artificial Vagina Liners. Sterile, plastic disposable liners have become commercially available for most types of AVs. These can be useful to reduce the risk of semen being exposed to chemical residues or latex. Many stallions object to these liners, however, and the number of mounts per ejaculation increases. Breakage of the plastic liner may occur during thrusting, and complete eversion of the liner may occur during dismount. If stallions ejaculate on first entry into an AV fitted with a disposable liner, the bacterial contamination of semen is reduced sharply. As the number of entries into the AV or the number of thrusts in the AV increases, however, the bacterial contamination of semen also increases. As such, ensuring that the stallion is properly stimulated and prepared to breed is useful for limiting the number of mounts.

Care of Artificial Vaginas. The AV should be cleaned immediately after each use, rinsed thoroughly with hot water, and wiped clear of dirt, debris, and smegma. If disposable liners are not used, then the rubber liners should be immersed in 70% alcohol for 1 hour or more, rinsed thoroughly with hot water, and hung in a dust-free, dry environment. To prevent the accumulation of chemical residue, soaps and disinfectants should not be used on the rubber equipment. If disposable AV liners are not used or the AV and its liners are not thoroughly cleaned, then the AV may become an effective fomite for spread of infectious or venereal disease. For these reasons, many farms maintain an individual AV for each stallion at the breeding farm.

Pharmacologically Induced Ejaculation

Several protocols have been published for the *ex copula* ejaculation of stallions using various pharmacologic agents alone or in tandem. The most commonly used drugs include xylazine, imipramine, and prostaglandins.[991-994] Semen collected in this fashion is generally of low volume and high concentration because of the decreased contribution from the accessory sex glands. One can use the resulting ejaculate for evaluation, AI, or cryopreservation. The inability to obtain ejaculates on a predictable schedule limits the commercial usefulness of these methods. In one experiment, ponies were collected in 10 of 24 attempts using imipramine and xylazine.[992] In selected cases in which the stallion is physically unable to mount and copulate, it is possible to obtain semen specimens with the aid of pharmacologic agents. Under farm conditions, semen is obtained in 25% to 30% of attempts. Keeping the stallion quiet and undisturbed is important, especially after xylazine has been administered.

A common protocol is to administer imipramine (2.2 mg/kg, PO, once) approximately 2 hours before anticipated semen collection.[995] Xylazine (0.2–0.3 mg/kg, IV) is then given. Ejaculation typically occurs shortly after xylazine administration (e.g., 1–3 minutes) or as the stallion begins to wake up from sedation (15–20 minutes). Although successful about 25% of the time, the procedure is time consuming and unpredictable for mare owners. The success rate may increase if the dosages are altered for individual stallions.

Miscellaneous Methods of Semen Collection

Condoms have been used in stallions that have an aversion to ejaculating into an AV. Condoms should be large and nonspermicidal. Disadvantages of this method are the high risk of the condom rupturing and contamination with debris. Aspiration from the uterus and vagina of recently bred mares is another option, but it is prone to contamination and does not lend well for achieving an accurate volume of the ejaculate.

Semen Evaluation

This process involves the collection of stallions' ejaculates and analysis of various seminal parameters as follows:

1. Volume and color: One should record the color and volume (in milliliters) of the ejaculate. Generally the color of the normal ejaculate ranges from watery to creamy white opalescent and depends on the sperm concentration per milliliter. Abnormal colors or volumes can indicate contamination of the ejaculate with blood, urine, or white cells. Normal volumes of light horse ejaculates range from 20 to 250 mL, with an average of 50 to 60 mL.[996] Factors influencing the volume are degree of sexual stimulation before collection, breeding conditions, and foreign material in the ejaculate. The volume of the ejaculate does not always reflect the quality of the ejaculate, and other parameters should be considered in light of the volume. When possible, distinction should be made between the volume of the gel and gel-free portions of the ejaculate. Most AVs can be fitted with an inline filter to separate these two fractions.
2. Sperm concentration: The number of sperm per milliliter must be accurately estimated to calculate total sperm numbers in the ejaculate and how best to process semen for further use. Sperm concentration, or density, is reported in millions of sperm cells per milliliter. Average counts are between 100 and 300 million, but there are many factors that can influence concentration, including season, frequency of collection, testicular size, and age. Although subject to as high as 10% variation, the Neubauer chamber or hemocytometer is regarded as the gold standard for evaluation of sperm concentration.[997] Even though the hemocytometer is regarded as the most accurate method to measure sperm concentration, it is time consuming and therefore not regularly used for routine counting of raw semen. The NucleoCounter SP-100 (Chemometec, Allerod, Denmark) counts sperm cell nuclei stained with the DNA-specific fluorescent dye propidium iodide.[997] The primary advantage to the NucleoCounter is that it retains its accuracy even when samples are contaminated with other debris, such as blood or urine. It is also capable of evaluating sperm viability via

detection of nonmembrane intact spermatozoa. The main disadvantage of this system is its significant cost. Other systems, such as the SpermaCue (MiniTube, Tieffenbach Germany), Equine Densimeter (Animal Reproduction Systems, Chino, CA,USA, or the Accucell (IMV Technologies, L'Aigle, France), are used. With all these systems it is critical to have a very clean sample free of foreign particles, debris, or extender. All these systems are accurate and repeatable at the 100 to 300 million sperm range, but their accuracy diminishes out of this range.[997] The computer-assisted sperm analysis (CASA) systems can also be used for concentration determination with an accuracy comparable to densimetry methods. In addition to providing sperm numbers, the CASA system reports sperm motility and the number of fast-moving and progressively motile sperm.

3. Osmolarity and pH: Osmolarity of stallion semen ranges between 290 and 310 mOsm. Values greater than 350 mOsm may indicate urospermia, and one should measure the level of creatinine (normal semen creatinine concentration <2 ng/mL). Values less than 250 mOsm suggest water contamination, and values over 500 mOsm reflect possible lubricant contamination. Seminal pH ranges between 6.9 and 7.5, and values higher than those should warn the clinician that there may be extraneous material in the ejaculate or an infectious process in the reproductive tract of the stallion.
4. Spermatozoal motility: Sperm motility has long been used as a method to estimate the percentage of viable sperm in the ejaculate. Several methods have been used to evaluate sperm motility, but all are used to determine the percentage of *total motile sperm* (the percentage of sperm in the ejaculate with any movement) and the percentage of *progressively motile sperm* (the percentage of sperm in the ejaculate moving in a linear or progressive line). The CASA system is the gold standard by which equine spermatozoal motility is evaluated. This modality generates objective values for sperm motility by counting and measuring individual cells in set frames. It also provides data on sperm characteristics such as linear velocity, linearity, path velocity, and lateral head displacement. The relative expense of the CASA system may preclude its use by some practitioners. Another common method is visual assessment of sperm motility. This involves placing a drop of semen on a microscope slide with a coverslip and evaluating cell movement at 200 to 400× magnification using phase contrast microscopy. This is the most widely used assay for evaluating sperm motility because of its simplicity and low cost. However, many factors can influence this mode of evaluation: individual judgment, volume of the drop used, concentration of sperm in the ejaculate, degree of contamination, degree of agglutination, and temperature. Even under the most tightly controlled conditions, repeatability of visual motility assessment is poor between technicians and laboratories. Visual motility estimates of freshly ejaculated stallion sperm have been reported to account for only 50% to 70% of the variation of fertility in that sample. The correlation is even worse ($r = 0.3$) when trying to predict fertility of a frozen-thawed sample of semen based on postthaw motility.[998] Although analysis of sperm motion with a computer is more objective and provides a highly consistent way of evaluating spermatozoa, the motility is but one factor influencing stallion fertility and should not be overinterpreted. In addition the formulas or settings for calculating the various motility parameters can differ between CASA systems, so analysis of one ejaculate may differ between the CASA systems used for each ejaculate.
5. Longevity of sperm motility: Duration of sperm motility can be determined using raw, undiluted semen or extended semen. For raw semen, a sample should be held at room temperature and evaluated every hour until <10% motility is observed. Semen from most normal stallions will maintain >10% motility for at least 4 hours. For extended semen, it should be processed, cooled, and stored appropriately. It can then be evaluated every 24 hours for the percentage of total and progressively motile spermatozoa.
6. Sperm morphology: For any sperm morphology evaluation, a minimum of 200 cells should be counted. Normal sperm cells, as well as those with acrosomal, head, midpiece, droplet, and tail defects, should be recorded, with the specific type of defect noted for each part. Although only 200 cells are counted routinely, sperm cells with more than one defect should be recorded as such to help the clinician evaluate the incidence of defects in a particular semen sample. One can evaluate cells as wet mounts under phase-contrast microscopy or differential interference contrast (DIC) microscopy after fixation in buffered formal saline or 4% glutaraldehyde. An antibiotic should be added to the fixative if samples are to be preserved for longer periods. Alternatively, cells can be evaluated after staining. One drop of semen is well mixed with the stain and smeared on a glass slide. Common stains currently used include India ink, eosin-nigrosin, eosin-aniline blue, Giemsa, Wright, and several others. The clinician should be aware that severe changes in the osmolarity of the stain as well as mechanical damage to the sperm could alter the normal morphology of the cells. Morphologic assessment of the sperm may aid in the diagnosis of certain pathologies because some defects are associated with different anatomic regions or suggest a specific reproductive pathology. Several attempts have been made to try to correlate the percentage of morphologically normal sperm present in a given ejaculate with fertility. Unfortunately, there appears to be a lack of consistency among clinicians in reporting sperm morphology. Among the problems that clinicians encounter are the definition of normal and abnormal in light of the tremendous range of normality and the fact that little knowledge exists regarding specific sperm defects that interfere with fertility. This problem is even more vexing when a clinician is trying to interpret the results from a referring veterinarian or a veterinary technician. Some of these inconsistencies can be avoided by recording specific morphologic defects rather than grouping defects into primary and secondary, because this last method erroneously assumes the origin of sperm defects (testis and posttesticular, respectively).

Semen evaluation thus provides a slew of data to supplement other examination findings. Calculation of the ejaculate's total volume and concentration will yield the total number of sperm cells in the ejaculate. Determination of concentration can be determined by manual, photometric, and fluorescence-based studies. Assessment of individual sperm cells (i.e., morphology) is performed to determine the number of normal looking sperm cells. Longevity studies are useful when planning matings and frequency of collections, but caution should be exercised in interpreting results because they do not adequately represent the environment within the mare's reproductive tract.

More advanced techniques exist for evaluation of stallion spermatozoa. These include testing the function of spermatozoa using the sperm chromatin structure assay, hyperosmotic swelling test, acrosomal reaction, and mitochondrial activity. Alternatively or in addition, transmission electron microscopy is useful for ultrastructural evaluation of individual sperm. It is capable of identifying subtle yet serious lesions within individual spermatozoa.

Hematologic and Endocrine Testing

Blood is commonly collected for evaluation as part of the BSE and typically consists of a complete blood count (CBC), fibrinogen, biochemistry profile, and testing for equine arteritis virus (EAV) if indicated. Endocrine testing is also commonly performed and concentrations of resting testosterone, estradiol, FSH, and LH are evaluated. In addition to screening for underlying diseases or disorders, these tests are also useful for establishing a baseline of normal values should an illness arise at some separate point in time.

Endocrine testing is often considered an adjunctive test but is nonetheless useful in the diagnosis of specific disorders. In particular, it allows for detection of primary testicular issues such as testicular degeneration. Because spermatogenesis relies on an intricate network of various autocrine, paracrine, and endocrine signals, aberrations in circulating gonadotropins and sex steroids may signal the onset of testicular dysfunction. Shown in Table 19.12 are examples of how serum concentrations of LH, FSH, testosterone, and estrogen conjugate can differ by season in normal stallions. Differences are also seen when comparing the concentrations of these hormones between fertile and subfertile stallions. Subfertile stallions have higher circulating gonadotropin concentrations, whereas estrogen conjugate is lower and testosterone remains relatively steady regardless of season.[999]

Microbiologic Testing

Screening for STDs should also be performed. Specific disease screening recommendations depend on the country where the horse has lived, currently resides, or where the horse may be shipped following the evaluation. Generally culture swabs of the penis/prepuce, urethral fossa, and urethra (both preejaculation and postejaculation) are taken and submitted for aerobic culture as a minimum in an SRE. During the breeding season, serial testing is performed to monitor for potentially pathogenic agents, such as *Klebsiella* spp. and *P. aeruginosa.* In certain areas of the United States, novice stallions will need a negative EVA serum titer either periodically or immediately before vaccination. Recently imported stallions will be subject to testing mandated by the USDA-APHIS as described earlier. Imported stallions are routinely tested for CEM by collecting swab samples of the external genitalia. In accordance with the USDA-APHIS, previously active breeding stallions also require test breeding of at least two mares, from which serial swabs are collected before and after breeding. Twenty-one days after the last test breeding, serum is collected for a CF test. The reader is directed to the USDA-APHIS *Contagious equine metritis* fact sheet[1000] for more information on the testing protocol. Again, the clinician is referred to the country's regulating body and regulations regarding sexually transmissible diseases of stallions when it comes to determining what testing must be performed.

Cytogenetic Testing for Markers of Fertility

This particular means of evaluating the breeding potential and soundness of stallions is still in its infancy. Since the horse genome project was completed in 2007, equine researchers are now discovering key relationships between DNA and the onset of certain diseases and disorders. This has allowed for the development of sensitive testing techniques to monitor or diagnose various hereditary diseases. These will all be discussed in another chapter, but one important disorder is a genetic link that has been found for impaired acrosome reaction (IAR), which is a known cause of infertility in many mammalian species. Researchers at Texas A&M University recently identified a susceptibility gene in horse chromosome 13 in FK506 binding protein 6 *(FKBP6)* in horses with IAR.[1001] This test can be useful as either a screening test for a prospective stallion or a diagnostic test in cases of unknown subfertility. The author currently uses the Animal Genetics Inc. (Tallahassee, FL) laboratory for most genetic testing, whereas the testing for IAR is done exclusively at the Department of Integrative Biosciences, Texas A&M University (College Station, TX).

TABLE **19.12** **Seasonal Effects of Luteinizing Hormone, Follicle-Stimulating Hormone, Testosterone, and Estrogen Conjugate in Fertile and Subfertile Stallions**

	Fertile (n = 8)		Subfertile (n = 6)	
Hormone (ng/mL)	**Nonbreeding Season**	**Breeding Season**	**Nonbreeding Season**	**Breeding Season**
Luteinizing hormone	2.4 ± 0.8	6.6 ± 0.8	9.2 ± 1.4	12.6 ± 2.8
Follicle-stimulating hormone	4.7 ± 0.5	6.1 ± 0.7	13.6 ± 3.1	14.5 ± 3.3
Testosterone	0.69 ± 0.14	1.14 ± 0.17	0.75 ± 0.08	0.88 ± 0.13
Estrogen conjugate	232 ± 29	216 ± 20	169 ± 45	186 ± 59

Values are presented as the mean ± SEM.

Summary and Epicrisis for Stallion Reproductive Evaluations

As mentioned at the beginning of this section, stallion reproduction involves many different factors. Attempting to account for all of them and predict fertility is currently impossible. Consequently, it now seems common practice not to assign stallions a particular status (e.g., satisfactory, unsatisfactory, status deferred) but to summarize the findings and offer recommendations for future management.

MANAGEMENT OF BREEDING STALLIONS

Nutrition

Specific feeding programs are at the discretion of the stud farm. General horse husbandry practices apply, and it is important to account for the method of breeding (e.g., in-hand, pasture, collection with an AV). Stallions in live-cover programs with book sizes of 60 or more mares may be asked to breed two to three times a day for several days in a row, creating a significant caloric demand. Providing adequate forage, a balanced concentrate, and fresh water ad libitum is the principal concern in the management of stallions. Average breeding stallions (500–600 kg) will usually consume 6 to 10 quarts of concentrate (12%–14% protein) a day. New rations and supplements should be introduced gradually to avoid gastrointestinal upset.

Healthy and active stallions should enter the breeding season approximately one body condition score higher (on a scale of 1–9) than normal, realizing they shed this weight quickly. For most stallions, an ideal body score is 5 to 5.5 of 9, so starting out at 6 to 6.5 of 9 is generally acceptable and unlikely to have ill effects if the stallion is otherwise healthy.

Care should be taken not to overfeed stallions. Obesity can have negative and often serious consequences (e.g., predisposition to colic, laminitis, metabolic disease) that can adversely affect a stallion's breeding performance. Moreover, stallions should not experience extreme weight fluctuations because dramatic swings can hinder both health and fertility.

There is some evidence supporting the efficacy of certain supplements to improve seminal quality in stallions. Feeding OM3FAs is supported by evidence-based research demonstrating their positive effects. For example, Brinsko et al. reported improvement in sperm motion characteristics in cooled and frozen semen after stallions were fed a DHA-enriched nutraceutical for 14 weeks.[301] Another study demonstrated increased concentrations of OM3FAs in seminal plasma and total sperm output in stallions fed an OM3FA supplement but no improvement in sperm motility. Both of these studies used a marine-based source of OM3FAs.[1002] Algae-based supplements and flaxseed are other sources of OM3FAs and, at least anecdotally, appear more palatable than those that are marine based. Studies describing a direct relationship of feeding OM3FAs and improved fertility are lacking.

Other nutritional supplements used in the breeding management of stallions are antioxidants (e.g., vitamins C and E) and acetyl-L-carnitine. The former may be beneficial in reducing oxidative stress on spermatozoa, whereas the latter is thought to enhance motility by stimulating β-lipid oxidation in sperm mitochondria. Scientific evidence supporting the use of these products is lacking, but anecdotal reports are mostly favorable. The efficacy of antioxidants is somewhat curious in that one study showed that the most fertile ejaculates from dismount samples collected from live-cover matings were those with the highest level of oxidative stress.[1003] Nevertheless a plasma membrane surrounds the entire spermatozoon, so the relative intactness of this membrane is thought to be closely related to sperm quality. Because antioxidants may suppress or quench the damaging effects of free radicals on lipid peroxidation,[1004] supplementation, in theory, may assist in improving sperm quality.

Exercise

Exercise is an important yet sometimes overlooked part of stallion management. Programs should be based on the individual stallion and account for his current and desired weight, soundness, anticipated book size, environment, and other health issues that may preclude the stallion from receiving adequate exercise. Methods for exercise include forced (e.g., riding, lunging, mechanized walkers) and passive (e.g., turnout in a large paddock for several hours a day). The means of exercise will vary from farm to farm, but the objective should be to keep stallions fit and their mind occupied, because exercise engages them both mentally and physically. In humans, physical fitness has proven advantages in maintaining vigor and preventing disease. It thus seems logical, albeit a bit anthropomorphic, that horses can reap the same benefits.

Length of forced exercise is usually predicated on the horse's level of fitness, whereas turnout should be kept on a regular schedule and consist of several hours of free grazing. Numerous large-scale breeding operations keep their stallions in training or continue to exercise them throughout their stud careers. One experiment showed stallions subjected to a moderate amount of exercise had a decline in number of morphologically normal spermatozoa post exercise compared with those obtained preexercise. No other seminal parameters (e.g., concentration, gel volume, total sperm) differed between the preexercise and postexercise samples.[1005]

If farm management practices or the horse's physical condition preclude active exercise, then paddock or round-pen turnout can be used. Paddock size is usually relegated to no more than a few acres. It can be helpful to place water and feed buckets in different areas to encourage increased movement. Turnout during inclement weather is at the discretion of the farm, but most horses are very resilient to adverse environmental conditions.

Herd Health Management

Routine hoof and dental care, as well as targeted vaccinations and dewormings, provide a solid foundation to manage the overall health of stallions. Similar to the previous considerations, herd health management will vary based on the particular farm and location.

Timing of vaccinations is important when managing active breeding stallions. Although a relatively low risk, especially considering the advancements made in vaccine quality over the past two decades, adverse events can still occur following immunizations. Untoward effects, whether local or systemic in nature, can hinder breeding performance. For example, local swelling at the site of an injection can cause soreness and reluctance to breed. Alternatively or in addition, a fever can negatively affect spermatogenesis because of secondary thermal stress.

Some practitioners choose to limit or postpone vaccinations during the breeding season. The author usually gives booster

vaccines in late December or early January so that any issue resulting from vaccination can be resolved before the beginning of the breeding season (mid-February). Boosters are also given, but evenly spaced out, in the summer and fall. Since stallions are at risk for acquiring infectious diseases because of contact with outside mares, vaccination against equine rhinopneumonitis can be performed every 2 to 3 months.

Vaccination against EAV, the causative agent of EVA, is required in some states for active breeding stallions because this virus can be shed in bodily fluids such as semen and respiratory secretions. The most pressing concern with EAV is the potential to cause abortion storms or neonatal death in naive pregnant mares.[243] The reader is encouraged to contact his or her state veterinarian's office for rules and requirements pertaining to vaccination against EVA in breeding stallions. Some stallions can transmit EAV in their semen (i.e., shedding stallions), so the stud farm should disclose if a stallion is a chronic shedder of EAV. Guidelines for breeding a mare to an EAV-shedding stallion are provided by the American Association of Equine Practitioners.[1006]

Breeding Methods

Live Cover

Also referred to as *natural service* or *in-hand* mating, live-cover breedings are commonly performed in commercial Thoroughbred operations throughout the world. Briefly, when an estrous mare is identified and deemed suitable for mating, she is brought to the breeding shed where she is teased and prepared routinely for breeding by washing of the perineum. Mares are usually restrained with a lead shank and a nose twitch, and padded leather "kick" boots are placed on the hind feet. Some sheds apply a neck shield or "cape" around the mare's cervical spine to provide extra protection. An example of typical preparation of a mare for a live-cover mating is shown in Fig. 19.26. The stallion is presented to the mare and teased until properly stimulated. He is then given a cue to mount, and, on doing so, an attendant will direct his penis into the mare's vagina. When ejaculation occurs, the attendant will apply his fingers to the base of the penis to feel for characteristic pulsations and fremitus of emission and ejaculation. As the stallion dismounts, the attendant will collect the drippings from the penis, which will undergo microscopic evaluation for the presence of live sperm, offering further confirmation of ejaculation. The sequence of events is shown in Fig. 19.27.

Semen Collection Using a Live Mare as a Mount

Selection of a suitable mount or "jump" mare depends on the experience and breeding mannerisms of the stallion and farm resources. For example, the inexperienced stallion may need to be taught to mount the mare from the rear quarters. This training requires a disciplined, cooperative mare that will tolerate being mounted from the side. Some stallions vocalize loudly in the breeding shed and may frighten maiden or timid mares. The mount mare needs to tolerate a certain amount of nipping and biting of the neck, shoulders, flank region, and hocks to be suitable for some stallions. Mares with foals at their sides are frequently protective of their foals and less cooperative than barren mares. The mount mare also should be an appropriate size match for the stallion. For routine breeding farm activities, the reliance on an estrous mare as a mount has significant shortcomings because the mare must be followed with

FIG. **19.26** Example of a mare being restrained for a live-cover mating.

teasing and ultrasound to ensure she is in estrus. Additionally, in a cooled, shipped semen program, the breeding farm may not have access to nonpregnant mares, particularly at the end of the breeding season. Therefore some breeding farms maintain one or more ovariectomized mares as mount mares. One should select from these ovariectomized mount mare candidates based on their size, tolerant attitude toward handling, and strong estrous behavioral signs as intact mares. A mare with gonadal dysgenesis, karyotype (XO), may be a good mount mare candidate without requiring an ovariectomy. Most ovariectomized mares perform well as mount mares while being restrained with a twitch or lip chain placed on the upper gum. In some cases it may be necessary to administer a low dose of estradiol cypionate (0.5–4 mg, IM) at intervals of 3 days to 3 weeks to maintain receptivity by the mare.

During the semen collection process, the mount mare usually is restrained using a twitch. Hobbles also may be applied to rear pasterns or hocks, but there is risk of the stallion becoming entangled in the hobbles if the collection procedure goes awry. Protective boots can also be placed on the hind feet to minimize damage if the mare does kick, and hind shoes should always be removed. The long tail hairs at the base of the mount mare should be wrapped to prevent the tail from interfering with deflection and entry of the penis into the AV.

Breeding Phantom

The breeding phantom, dummy, or mount consists of a structure suitable for stallion mounting that is usually a cylindrical barrel or tube mounted in a stationary position that is the approximate size of the body of a mare the stallion would breed (Fig. 19.28). The barrel is usually covered with 1 to 2 inches of firm padding. The padded cylinder then is covered by a tough, nonabrasive cover that is free of wrinkles. Stallions that repeatedly mount and dismount a phantom can abrade the medial aspects of their forearms and carpi. Wraps can be applied to minimize trauma. The stallion should be taught to dismount the phantom in a controlled manner by backing off of the mount rather than making a side dismount. The diameter, length, and height of the phantom should be dictated by stallion size and preference, with most light horse stallions tolerating a total diameter of 20 to 24 inches. The struts of the phantom should be far enough from the mounting end to prevent injury to the hindlegs of the stallion during mounting and

FIG. **19.27** Sequence of events for a live-cover mating.

dismounting. The height and the angle of the phantom should be adjustable to accommodate older stallions, stallions with hindlimb lameness or musculoskeletal issues, and stallions of varying stature.[970,1007]

Adequate space should surround the phantom for the safety of the handlers and to allow a teaser mare to be positioned alongside or in front of the phantom if additional stimulation is needed. Many stallions are trained to mount the phantom even when the teaser mare is not close to it.

When a phantom is used to collect semen from a stallion, the stallion should approach the mount in a controlled fashion, mount the rear of the phantom, and use his forelimbs to stabilize himself by grasping the padded barrel of the mount. Once the stallion is properly situated, the operator approaches from the left or near side of the stallion, deflects the penis into the AV using a right, overhand grip, and stabilizes him- or herself on the near side of the phantom as the stallion services the AV. While on the left side of

FIG. **19.28** Example of a breeding phantom used for collection of stallion semen in an artificial insemination program. The phantom is secured in the ground by a single and sold strut. The body or barrel of the phantom is reinforced with soft, nonabrasive material for comfort.

the stallion (and phantom), the operator deflects and stabilizes the base of the penis with the right hand. This practice minimizes potential injury to the penis and prepuce during thrusting by the stallion. Some phantom mounts are fitted with an AV installed within the posterior end, which works well for some stallions and requires only one person for the collection procedure. The only disadvantage of indwelling AVs is that occasionally the stallion's penis can be traumatized by incorrect insertion. In addition, some stallions need manual stimulation of the glans penis, which is easier to provide when the operator has control of the AV. Stallions regularly used for live-cover breedings can be difficult to train to a phantom. For this reason, certain circumstances may require access to an estrous mare to facilitate semen collection.

Measuring Reproductive Performance

Formulas for evaluating reproductive efficiency of stallions are presented below. These measures are useful for comparing stallions among and within farms. They also offer insight into breeding and farm management and can help identify areas of concern.

$$\text{Per Cycle Pregnancy Rate} = [(\text{No. in Foal}) / (\text{No. Covers}) (\text{No. Doubles})] (100\,\%)$$

$$\text{Seasonal Pregnancy Rate} = [(\text{Total No. Pregnancies}) / (\text{Total No. Mares Bred})] (100\,\%)$$

$$\text{First Cycle Pregnancy Rate} = [(\text{No. in Foal on First Cover}) / (\text{Total No. Mares Bred on First Cycle})] (100\,\%)$$

$$\text{Covers Per Pregnancy} = \frac{\text{Total No. Covers}}{\text{Total No. Pregnancies}}$$

Organization and tabulation of these data are most commonly done electronically. Computerized spreadsheets can assist with data collection and analysis. Charts and graphs comparing various reproductive parameters are useful for summarizing and comparing findings in a concise yet comprehensive manner and can be used to monitor patterns of breeding performance.

Novice or Maiden Stallion

The arrival of a new stallion to a breeding farm is usually an exciting time. These stallions have proven superior in their respective disciplines and are thus of high value both financially and emotionally. Although the urge exists to "see what they're made of" with respect to breeding behavior, good managers believe it is best to give them time to familiarize themselves with their surroundings before initiating breeding activity. Documenting and addressing previous health issues or injuries should also be done so that the stallion remains fit and sound for breeding. This transition, or *let-down*, period is variable (2 weeks to 2 months) and should remain fluid to allow the stallion to settle into his new career. The let-down period typically includes the following:

- Quarantine to reduce risk of transmissible disease
- Conditioning and acclimatization to new surroundings
- Establishment of a routine
- Diagnostic testing

Most stallion managers are also cognizant of the various mental adjustments that a stallion goes through as he transitions to a new environment. Moreover, each stallion is an individual and should be treated as such. Stallions must remain respectful to prevent aggression toward their handlers and other horses.[1008] Novice stallions must be treated with patience, positive reinforcement, and in some instances, perseverance. Unnecessary punishment and rough handling can aggravate a problem and may result in breeding disinterest.

Following the let-down period, maiden stallions are introduced to mating via test breeding of estrous mares. This process allows for conditioning of the stallion to the farm's breeding procedure and for evaluation of the stallion's breeding behavior and seminal characteristics. A test mare recently screened for EVA and CEM is prepared as for a normal live cover. The stallion is introduced to the mare and allowed to sniff and interact with the mare in a respectful manner. Both patience and repetition are required during the test breeding process because mating is a new experience for these stallions. Some stallions may require only a few breeding sessions before management is adequately satisfied that the stallion is trained; others may require several attempts before they display any interest in breeding. Dismount samples are routinely evaluated for the presence of live, motile, and morphologically normal spermatozoa. A stallion is considered "trained" once he willingly breeds a mare in an efficient and proper manner. Shown in Video 19.3 is a novice stallion presented to an estrous mare for the first time. This stallion displayed excellent libido and bred the mare in the relatively short period. For stallions destined for live-cover operations, the author prefers to train stallions to the mare first. The collection of entire ejaculates via an AV can be performed at a later date.

Starting novice stallions under lights is used in some programs. No proven benefits have been demonstrated from this practice. Anecdotally, and as discussed previously, the additional photoperiod may stimulate reproductive function and prepare the stallion for success early in the breeding season.

DISEASES AND DISORDERS OF INTACT MALE HORSES

Abnormal Behavior

Manifestations of abnormal behavior are numerous. Examples are provided in Table 19.13 along with potential causes for deviant sexual behavior. McDonnell reviewed the incidence of behavioral problems in 250 stallions over a 5-year period.[978] More than 50% of the cases had complaints related to poor libido or excessive aggressiveness. Of those, nearly half were described in stallions with no previous sexual experience. The rest were divided evenly between experienced stallions with low sexual interest and those with increased aggressiveness. Mounting and erection dysfunction accounted for 11% of complaints, whereas ejaculatory problems accounted for 25% of the total cases. Other problems, such as self-mutilation and various stereotypies accounted for 11% of the reported cases.[978]

For clinicians, it is important that dysfunctional behavior is interpreted relative to the expectations of the breeding outfit.[1009] For example, stallions requiring 30 minutes or more to mount and ejaculate or those needing several mounts before ejaculation may be considered unacceptable in some intensive management situations. On the other hand, a stallion that takes several hours to achieve an erection, mount, and ejaculate may be considered normal if he breeds only two or three mares during the entire breeding season in pasture conditions.

Low Libido

Lack of adequate sex drive is the most common behavioral issue in breeding stallions.[978] Many factors can be at play, including management practices and environmental cues. For example, timid stallions housed next to dominant stallions may show a lack of libido because of perceived subordination to the dominant stallion. Other stallions may have an aversion to or preference for a particular color of mare. Lack of libido may be observed in experienced stallions toward the end of the breeding season, particularly in heavily used or overused animals. This problem can be corrected by decreasing the frequency of service or collection. Stallions that have been kicked by mares or negatively reinforced for displaying sexual behavior during performance may demonstrate reduced sexual desire. It is thus prudent to consider the history, health, and management of the stallion from many different perspectives when determining the cause of low libido.

Treatment of a stallion with low sexual drive is best directed at correction of the underlying problem, but assessment of the nature of the problem is often difficult. One may try several alternatives, including

- Change of stimulus mare or environment
- Breeding or collecting another stallion in the presence of the low-libido animal
- IV administration of GnRH, 50 μg, 1 to 2 hours before breeding or hCG, 5000 to 10,000 IU, 1 hour before breeding
- IV administration of diazepam or midazolam at a dosage of 0.05 mg/kg (maximum 20 mg) 10 to 15 minutes before breeding to reduce inhibition of sexual behavior in some stallions
- Single injection of a short-acting testosterone

The efficacy of most of these treatments is dependent on the individual stallion and the primary problem(s). Some of these treatments may have adverse effects. For example, chronic administration of steroids, particularly androgens, is well documented to negatively affect spermatogenesis.[970] Therefore treatment of stallions with exogenous steroids and particularly androgens to improve libido should be measured carefully with respect to the risks and potential benefits. Consequently, treatment is typically reserved for use when other means of increasing arousal have failed. Current recommendations are treatment with an initial dose 80 to 100 mg (IM) of testosterone cypionate and maintaining serum concentrations at 2 to 4 ng/mL. The effect typically lags a significant time following treatment (5–8 days). Anecdotal reports of topical application of testosterone cream to the penis to improve tactile stimulation have been reported but not rigorously studied.

TABLE **19.13 Signs of Abnormal Stallion Behavior and Potential Causes**

Signs	Causes
Low libido	Pain
Paraphilia	Secondary health issues
Timidness	Mare preference
Erectile failure	Environmental changes
Ejaculatory failure	Management changes
Self-mutilation	Previous adverse experience

Erection Failure

The inability of a stallion to develop and maintain a normal erection despite normal libido may be related to anatomic issues. Possible problems include vascular damage associated with traumatic injuries or neurologic problems associated with other penile or lumbosacral compromise.[991]

Medical (e.g., administration of vasoactive substances) and surgical (e.g., penile implants) options may be considered. Unfortunately, evidence-based research supporting these methods is lacking. Sildenafil (Viagra, Pfizer, New York, NY) has long been discussed but does not currently have a reported dose or effect in horses.

Ejaculatory Failure

Some stallions show normal precopulatory behavior, mounting, and intromission but fail to ejaculate. These stallions may become exhausted or frustrated, displaying aggressiveness to the mare or handler. For this condition it is important to rule out musculoskeletal or orthopedic pain such as degenerative joint disease. If suspected, trial treatment with an appropriate dose of a nonsteroidal agent can be of benefit. Circulatory disorders, such as iliac thrombosis, have also been associated with ejaculatory failure.

Despite being difficult to diagnose, psychological problems can lead to ejaculatory dysfunction. In many instances, a history of a traumatic incident while breeding is closely associated with the onset of ejaculatory failure. If the stallion refuses to ejaculate only under specific circumstances, such as into an AV or when breeding a mare, then a systematic approach is important to determine the problem.

A variety of behavioral and managerial aids have been used to help stallions ejaculate.[1010] One should adapt these aids according to the physical condition of the stallion (i.e., stallions that cannot achieve a full erection; stallions that have difficulty mounting; stallions that refuse to ejaculate after normal erection, mounting, thrusting, and belling of the glans).

Neither mounting nor full erection is necessary for ejaculation. Stallions that have difficulty mounting can be taught to ejaculate on the ground by manual stimulation of the penis or with an AV. Stallions with erection problems can ejaculate if proper stimulation is given to the penis. One can achieve proper stimulation to the penis by raising the temperature of the AV or by applying hot towels to the base of the penis during thrusting. It is also important to consider changes in footing and surroundings, stimulus mare, and handlers before implementing pharmacologic therapy.

Therapeutic regimens for ejaculatory dysfunction are empirical and include those already mentioned for the treatment of low-libido stallions. In addition, PGs, oxytocin, and xylazine have been used to aid stallions in the process of ejaculation. Oxytocin and PG also have been used to treat azoospermia caused by ampullary blockage.[1011] The tricyclic antidepressant imipramine can be given to lower the threshold for ejaculation in stallions.[995] As discussed previously, varying success rates are obtained when using these agents for either short-term or long-term management of ejaculatory failure.

Self-Mutilation

Self-mutilation is a highly complex behavioral syndrome that can include self-biting, stomping and kicking, rubbing, and lunging at objects. According to McDonnell, three distinct types of self-mutilation occur.[1012] Type I represents a normal behavioral response to continuous or intermittent unrelieved physical discomfort. Type II, seen in stallions and geldings, can be recognized as self-directed intermale aggression. This behavior includes certain elements of the natural interactions typical of encounters between two stallions, except that the stallion himself is the target of his intermale behavior. Type III involves a quieter, often rhythmically repetitive or methodical behavioral sequence of a stereotypy (e.g., nipping at various areas of the body in a relatively consistent pattern, stomping or kicking rhythmically against an object). Some researchers have speculated that self-mutilation has a genetic component. The prevalence of self-mutilation of one form or another has been observed in as many as 2% of domestic stallions.[1013] Among and between stallions, self-mutilation varies in frequency and intensity and can reach levels that threaten the stallion's fertility and even his life.

Careful evaluation of the horse's behavior is often necessary to distinguish the specific type of self-mutilation. Type I self-mutilation can be eliminated by relieving the source of discomfort. For types II and III, understanding of intermale interactive behavior of horses and the environmental factors triggering the self-mutilating form can be useful in guiding humane management or behavior modification. Pharmacologic manipulation and nutritional changes may be useful adjuncts in the management of this condition.

Although self-mutilation is usually limited to postpubertal horses in type II or type III, it is not limited to confined animals like some stereotypies. In some animals the problem is exacerbated on presentation of a mare to a confined stallion or breeding in the presence of another stallion.[1014] The compulsive behavior seems to be more dramatic during the breeding season.

Self-mutilation may be a problem exacerbated by olfactory stimuli. In some horses, smelling their manure triggers this behavior. The stallions often mistakenly recognize themselves as a threat, triggering the compulsive behavior.

Therapy of this complex syndrome depends on the type of self-mutilation and its underlying causes. Potential strategies include pain management, surgery, regular exercise, stall toys, and companion animals. Products to reduce the olfactory stimuli can be used, and diet modification to decrease carbohydrates have been used with some success. Treatment with behavior supplements, such as a milk-protein–based product (Zylkene; Vetoquinol USA, Inc., Fort Worth, TX) or pheromone mimic (Confidence EQ; Ceva Animal Health, Lenexa, KS) may help some stallions, but their efficacy is unproven. Physical restraints such as head cradles or muzzles most likely lead to development of another self-mutilating behavior. In extreme, inhumane, and refractory cases, castration of the stallion has eliminated the problem for type III self-mutilation but not for the other types. Therefore an accurate diagnosis is a critical component of the treatment protocol.

Other Behavioral Problems

Some stallions may have behavioral traits or vices that adversely affect their breeding ability. Overly aggressive stallions may be too dangerous to handle because of savaging the handlers or the mare. This aggression may be caused by frustration, past breeding experience, and/or potentially paraphilia. Aggression is best managed with an experienced and patient handler and identification and elimination of potential management and environmental cues that lead to adverse behavior.

Stereotypies can also affect reproductive performance. Cribbing, weaving, stomping, and wall kicking are all examples that can lead to secondary health issues (e.g., colic, weight loss, lameness). Because these are thought to be born of boredom, providing mental stimulation via enrichment activities (e.g., rubber ball, companion animal) may help. Some stereotypies are a result of physical discomfort (ulcers, laminitis, and neuropathic pain), and general health causes for discomfort should always be ruled out.

Abnormalities of the Penis and Prepuce

Clinicians must be able to accurately identify pathologic conditions of the external genitalia to make sound decisions regarding the therapy and management of stallions. Acquired conditions may be reversible by surgical or other means, but diagnosis of irreversible or terminal conditions must be well substantiated because they could have a significant effect on the viability of the breeding operation. Ethical considerations are also pertinent because some genetic diseases can have a significant effect on the breed as a whole.

Developmental Conditions

As reviewed previously, the sexual development of the equine embryo to a mature normal stallion capable of successfully breeding requires multiple genetic factors, pathways, and endocrine events to occur and proceed normally. Horses with genetic abnormalities can vary in their genotype, anatomic features, and behavior. The most common causes of congenital defects are hermaphroditism, XY sex reversal, and testicular feminization or androgen insensitivity. Previously described as intersex conditions, they are now referred to as *disorders of sexual development* (DSD).[1015,1016]

Hermaphrodites are classified on the basis of the type of gonadal tissue present. True hermaphrodites have testicular and ovarian tissue, whereas pseudohermaphrodites have either testes (male pseudohermaphrodite) or ovaries (female pseudohermaphrodite). Various combinations of male and

female internal and external reproductive organs can exist and have been described.[1017,1018] The most commonly diagnosed DSD is the male pseudohermaphrodite, which has a mostly female phenotype but testes instead of ovaries. A common clinical presentation is a "mare" with a small vulva and an extremely large clitoris or what appears to be a glans penis with an increased anogenital distance. Behaviorally, the horse may display stallion-like behavior because of the presence of testicular tissue. Female pseudohermaphrodites are much less common and are characterized by a male phenotype, but the animal's internal gonads are ovaries instead of testes.

Horses with XY sex reversal syndrome are characterized by female external genitalia but a normal 64XY karyotype. Androgen insensitivity or testicular feminization syndrome is a well-characterized genetic disease in human beings and in some domestic species. Animals have a normal XY karyotype and display male behavior but have a female phenotype. The syndrome has two possible causes: a mutation at the level of the gene that codes for the androgen receptor or a deficiency in 5α-reductase, the enzyme responsible for conversion of testosterone to the active androgen DHT.[1019] In either situation the reproductive tract is underdeveloped and the female phenotype predominates.

Genetic defects can be tentatively diagnosed by visual inspection of the external genitalia, rectal palpation, and ultrasonography. However, a definitive diagnosis requires cytogenetic evaluation by a commercial molecular and cytogenetics laboratory.

Segmental aplasia of the vas deferens or the epididymal duct has also been reported.[1020] These conditions can render the stallion sterile in the case of bilateral aplasia, due to the inability to emit and ejaculate spermatozoa. Other aberrations in gonadal development can potentially lead to improper germ cell development and/or maturation.

Phimosis is the inability to protrude the penis and can be congenital. In neonatal colts, the penile frenulum is commonly broken down early in life but can occasionally persist. The most common presenting complaint is an abnormal urine stream; inspection of the colt's prepuce and penis reveals a palpable frenulum and the glans penis is reflected caudally. This condition is usually self-limiting, but transection of the band can be performed to hasten resolution.

Acquired Conditions

Paraphimosis occurs when the penis is unable to retract back into the sheath. This condition is seen in cases of severe malnourishment or exhaustion, neurologic disease, administration of certain psychoactive drugs, and trauma. Whether alone or in combination, these causes culminate in chronic flaccidity and extensive edema of the penis.[1021,1022] Because venous return is impaired, the condition can progress to balanoposthitis, which includes the development of skin ulcerations, secondary infections, and penile necrosis. Treatment aims are to restore venous blood flow and reduce swelling and inflammation. Hydrotherapy, massage, application of topical emollients, antiinflammatory drugs, and diuretics can all be useful therapies. Antimicrobials and corticosteroids may also be indicated to prevent secondary infections and manage the edema. Support of the penis and prepuce are important to prevent microthrombi from forming and can be accomplished using mesh support, a probang device, or purse-string suture (as shown in Fig. 19.29).[1023,1024] In some instances flushing of the CCP with heparinized saline or intracavernous injection of phenylephrine may aid in blood drainage and penile retraction. Traumatic accidents involving the penis are not uncommon. Cuts with mare tail hair, poorly constructed breeding phantoms with fixed AVs, and severe bending of the erect penis may result in abrasions, lacerations, and severe hematomas. These wounds are treated with supportive therapy and surgery, when indicated. Prevention of secondary contamination and adhesion formation is important. It is also essential in cases of paraphimosis that the stallion's ability to urinate is assessed and addressed, because this can quickly become a life-threatening condition if the damage to the penile urethra prevents urination.

FIG. **19.29** Example of a penile sling using women's undergarments. Lacy material is ideal to allow for passage of urine and exudate. The sling is secured with rubber tubing.

Acquired conditions causing *phimosis,* or the inability to extrude the penis from the prepuce, include those conditions that cause stenosis of the preputial orifice. Strictures can arise from trauma or neoplastic growths. Horses experience difficulty urinating or have an inappropriate urine stream. Surgical resection of the stricture and/or debulking of the growths and lesions can help resolve the condition. Some breeding stallions may achieve an erection before full protrusion from the sheath. This condition can cause mild discomfort and even self-trauma. This condition is resolved by calming the stallion via removing the sexual stimulus and allowing the penis to detumesce.

Priapism is a persistent erection in the absence of sexual stimulation. It has been commonly associated with phenothiazine-derivative tranquilizers,[1021,1025,1026] but it can occur following the administration of any sedative or tranquilizer (though this is uncommon). Medical management with the IV administration of benztropine mesylate (8 mg, IV) or direct injection of the CCP with 1% phenylephrine (10 mg diluted in 10 mL physiologic saline) have been used successfully to resolve this condition. Surgical treatment is usually instituted when medical therapy fails. It consists of evacuating and flushing the CCP with heparinized saline. A partial phallectomy can also be used to manage this condition in geldings.

Neoplastic Conditions

The most common form of neoplasia affecting the penis is squamous cell carcinoma. Smegma accumulation on the penis may be a predisposing factor for this type of neoplasia.[1027] The

tumors start as small, keratinized plaques that slowly progress into necrotic foci with foul-smelling exudate from secondary bacterial contamination. The papillomavirus has been suggested as a predisposing factor, which is a hypothesis that warrants further investigation.[1028] Conclusive diagnosis is based on histopathologic examination of tissue from the affected region. The condition is treated with cryosurgery, reefing, or phallectomy.

Warts or squamous papillomas, sarcoids, melanomas, fibromas, and lipomas may also occur on the penis. Cryotherapy, autogenous vaccines, chemotherapeutic agents, and surgical debulking have been used with varying degrees of success to treat these conditions.

Infectious Conditions

The most common infections involving the penises of stallions are habronemiasis, EHV-3, and bovine papillomavirus (BPV). Dermatologic lesions secondary to *Habronema* spp. and the microfilaria *Onchocerca cervicalis* result in characteristic lesions commonly referred to as "summer sores." Diagnosis of habronemiasis is usually straightforward by observing characteristic lesions on the urethral process, glans, and sheath. Enteral and topical therapy with ivermectin is often useful. Affected horses are prone to recurrence, and severely affected horses may benefit from treatment with corticosteroids. While the occurrence of habronemiasis waned with the advent and ubiquitous use of avermectin anthelmintics, this disease has seen a mild reemergence in recent years that has been attributed at least in part to possible resistance of the organisms to common dewormers.

Coital exanthema caused by EHV-3 is a contagious venereal disease affecting stallions and broodmares. It causes characteristic lesions and can be readily transmitted by both horses and fomites. EHV-3 and other venereal diseases are covered in a separate section.

Infection with BPV is an interesting concept because it has been implicated in the onset of equine sarcoids.[1029] Consequently, treatment with topical antiviral agents (e.g., acyclovir) may be of benefit in arresting and even reducing growth.

Bacterial infections of the penis should always be interpreted in light of both clinical signs and breeding records. For example, the external genitalia of commercial Thoroughbred stallions are cultured routinely to screen for potential pathogens. It is not uncommon to obtain positive growth of various organisms, including *E. coli, S. zooepidemicus, S. equisimilis, Staphylococcus aureus, Bacillus* spp., *K. pneumoniae,* and *P. aeruginosa.*[1030] Despite positive growth, many stallions will remain unaffected as evidenced by a lack of clinical signs and adequate pregnancy rates. However, when the normal flora is disrupted, potentially pathogenic bacteria, particularly *P. aeruginosa* and *K. pneumoniae,* can colonize the penis and prepuce. These organisms rarely produce clinical disease in stallions, but controversy exists regarding the risk of transmission to the mare at the time of breeding and the potential for causing IE and associated subfertility. Factors contributing to the colonization of the penis by these bacteria have not been clearly determined. Normal bacterial microflora of the external genitalia of the stallion may combat proliferation of pathogens, and frequent washing of the penis, especially with soaps, may remove these nonpathogenic resident bacteria, increasing the susceptibility of the penis and prepuce to colonization by pathogenic organisms.[1031] Others dispute this concept, asserting that repeated washing of the external genitalia alone does not contribute to overgrowth of pathogenic microorganisms. The environment in which a stallion is housed may influence the types of organisms harbored on the external genitalia. The stallion also can acquire these organisms at the time of coitus with a mare that has a genital infection.[1008] Diagnosis of pathogenic colonization of the stallion's penis begins with careful evaluation of breeding records and early pregnancy rates. A sudden and unexplained drop in reproductive efficiency should warn the stallion manager about a possible problem. Definitive diagnosis requires isolation of the pathogenic microorganisms from cultures of the genitalia. In addition, isolation of the same microorganism with a similar sensitivity pattern from recently bred mares may help confirm the diagnosis.

Treatment of pathogenic bacterial colonization of the penis depends on the type of bacteria isolated and method of breeding. For stallions breeding by AI, a thorough penile wash before semen collection is recommended. Collected semen should be filtered and diluted appropriately in extender containing an antibiotic to which the bacteria is sensitive. Stallions breeding by live cover should have their penis washed and dried before or after mating. Aggressive management of the mare may also be pursued (e.g., uterine lavage, antibiotic infusions, and/or systemic antimicrobials) if growth is of significant concern and/or the mare is susceptible to postmating-induced endometritis. Stallions with penile colonization by *Klebsiella* or *Pseudomonas* spp. can be washed with a weak solution of HCl or sodium hypochlorite. Systemic treatment is not recommended because it has proved unrewarding in most cases.

Abnormalities of the Scrotum

The scrotum in the horse is a pliable and thin-skinned pouch with a fine layer of short hair, numerous sweat glands, and the thick muscular layer (tunica dartos). The scrotum is usually darkly pigmented. Functional integrity of the scrotum is vital because of its role in thermoregulation of the testes.[1032] Abnormal conformation, trauma, and increased thickness can have a dramatic and deleterious effects on spermatogenesis. The scrotum is easily accessible for examination by visual inspection and palpation, and most stallions allow evaluation and palpation with mild restraint.

Developmental Conditions

The most common developmental condition of the scrotum is a reduction in size secondary to unilateral or bilateral cryptorchidism (discussed later). Stallions affected with DSDs may also display smaller than expected scrotal size or an unusual location of the scrotum.

Acquired Conditions

Traumatic insults to the scrotum or the scrotal area and other inflammatory processes in the genital area often result in scrotal edema. The clinician must identify the causes of the swelling to initiate adequate therapy. Chronic edema of the scrotum can result in abrasions or wounds that can be complicated further by bacterial contamination. Differential diagnoses for scrotal swelling include systemic infectious processes, scrotal herniae, spermatic cord torsion, scrotal abscess or hematoma, hemorrhagic processes associated with the testes or spermatic cords, and ascites or peritonitis.

An ultrasonographic study is indicated in stallions with scrotal edema or swelling to evaluate the scrotal tissues and

contents. Percutaneous aspiration of fluid in the scrotal tissue or between the visceral and parietal vaginal tunics can prove useful for further characterization of the fluid but does carry risk of iatrogenic infection.

Therapy is directed toward removing the primary cause of scrotal swelling and controlling any ongoing inflammation and edema. Antiinflammatory drugs (e.g., NSAIDs, corticosteroids), diuretics, and frequent hydrotherapy are all measures that should be implemented to counteract swelling and reestablish circulation. Broad-spectrum antibiotic therapy can be instituted, and application of lubricants and emollients is useful for preventing dermatitis and countering secondary bacterial infection.[1033]

Quick resolution of scrotal edema and swelling is of paramount importance. Acute systemic (e.g., fever) or local inflammation can lead to thermal insult of the testes, which can adversely affect spermatogenesis and translate into poor semen quality and reproductive efficiency. Chronic inflammation can also be detrimental, leading to fibrosis and testicular degeneration.

Neoplastic Conditions

Cancers of the scrotum are similar to those affecting the skin. Sarcoids, squamous cell carcinoma and papillomas, and melanoma have all been reported.[1034] Diagnosis is made based on both clinical signs and histopathology of the affected tissue. Combination therapy with surgical removal and chemotherapeutic agents appears to be the most common mode of treatment.[1035]

Infectious Conditions

EIA or other infectious diseases causing severe hypoproteinemia can result in scrotal edema and affect stallion fertility. The acute phase of EVA can cause different degrees of ventral or dependent abdominal edema that may involve the scrotum. Coital exanthema caused by EHV-3 can also affect the scrotum and is discussed later.

Infection with *T. equiperdum,* the causative agent of dourine, can also cause scrotal edema. It is considered an FAD in the United States but is found in equids located in parts of Africa, Asia, and possibly South America.[246] As will be discussed later, dourine is transmitted almost exclusively by coitus. Habronemiasis is another parasitic disease that infrequently affects the scrotum and can be managed as described for similar lesions affecting the penis.

Abnormalities of the Testes

As previously reviewed, the major cell types of the testes are Sertoli, Leydig, myoid, and germ (sperm) cells. Congenital, acquired, neoplastic, and infectious conditions affecting these cells, whether alone or in combination, can have significant consequences on fertility. Early diagnosis and management are key to a resolution.

Developmental Conditions

Discussed next are various developmental disorders of the testes. In addition to these, monorchidism, anorchidism, and polyorchidism have been described in stallions.[1036]

Ectopic Testis. A gonad that fails to reach the scrotum and deviates from the normal path of descent is termed an *ectopic testis.* These testes may be located in subcutaneous tissues within the inner thigh, abdomen, or perineal region. Cryptorchid testes are sometimes referred to as ectopic testes.[1037] Splenic-testicular fusion has also been reported and represents an extreme case of ectopic testis.

Cryptorchidism. This condition refers to the failure of one (unilateral) or both (bilateral) testes to fully descended into the scrotum by 2 years of age. Cryptorchidism is a fairly common congenital defect of horses and is further characterized by the location of the retained testis (inguinal or abdominal). Two retrospective studies documented 350 cases over a 14-year period[1038] and 500 cases over a 23-year period.[1039] Diagnosis is fairly straightforward and involves both palpation and ultrasonography. The former is useful for confirming the lack of a testis or testes, whereas the latter aids in locating the retained testicle, which is beneficial when planning a particular surgical approach.

When the castration status of a horse is unknown, endocrine analyses are relatively sensitive methods for detecting the presence of testicular tissue. Evaluation of resting testosterone concentration, hCG stimulation test, estrone sulfate concentrations, and AMH serum concentrations have all been described. The most common endocrine test performed to evaluate whether testicular tissue is present is baseline testosterone concentrations, with values <50 pg/mL suggesting an absence of functional testicular tissue, 50 to 100 pg/mL being inconclusive, and values >100 pg/mL suggesting the presence of functional testicular tissue. If this test is inconclusive, then an hCG stimulation test is performed that induces an increase in testosterone secretion and production from the Leydig cells within the testes. This test involves collection of a baseline serum sample, followed by IV administration of 5000 to 10,000 IU hCG and collection of serum at 24 and 48 hours later. A 2- to 3-fold increase in circulating testosterone concentration from baseline indicates the presences of active testicular tissue. Unfortunately, this test can yield equivocal results when posttreatment samples are collected too early.[1040] The current recommendation for those using this test is to collect the posttreatment sample 2 days after hCG stimulation.[1041] Detection of AMH is proving to be just as—if not more—sensitive for the diagnosis of cryptorchidism.[968] This test only requires a single serum sample but is subjected to seasonal influences.[1040]

Nonsurgical treatment for cryptorchidism should be initiated early and cases selected appropriately to increase the likelihood of success.[1042] When the testis is located within the abdomen, surgical removal is the only means of removal. Retained testicles should be dealt with at an early age for the following reasons:

1. Trainers believe the retained testicle can be a periodic source of discomfort.
2. A retained testicle, while unlikely to produce viable spermatozoa, remains hormonally active, which can have suppressive effects on the descended testis.
3. Retained testes can become neoplastic with advancing age.

To further the last point, the relative incidence of testicular cancer in stallions is difficult to precisely quantify because of the relatively low number of older intact males. Nevertheless, neoplasia of the testes can have serious consequences on breeding efficiency and overall health. Surgical removal is often curative, with the risk of metastatic disease relatively low, although not entirely uncommon.

Breeding stallions with only one functional testis can often be managed successfully. Generally speaking, the functional testis will hypertrophy. Young fertile stallions can often perform adequately with only one testicle. Appropriate

management of book size and selecting young mares can all favor a stallion, especially early in his career.

Gonadal Hypoplasia. Small testes may result from a number of underlying complex processes such as spermatogenic arrest and germ cell deficiencies. Testicular hypoplasia is the failure of the gonads to reach their full adult size and must be differentiated from gonadal atrophy or testicular degeneration, which is the reduction in testicular size after the gonad has reached full adult size. The cause of the hypoplastic gonad is complex and is thought to be congenital or acquired. Although not clear for horses, a genetic component has been identified in other species.[1016] Generally testicular hyperthermia, malnutrition, and endocrine imbalances—particularly in steroid-treated young stallions—can negatively affect testicular size. It is important to remember that the testes do not start to enlarge until 15 to 18 months of age, and they continue to increase in size until 4 to 5 years of age. Testicular hypoplasia should not be confirmed before the stallion is 2 to 3 years old. The breeding of mares to stallions with hypoplastic gonads is discouraged, but the value and performance record often trump breeding soundness. In these cases, implementation of managerial practices to maximize the reproductive performance of the animal is important and should include reducing the number of mares in the book and breeding mares only once when they are close to ovulation.

Gonadal Atrophy. Also known as *testicular degeneration,* gonadal atrophy is most common in the mature stallion and can lead to profound disruptions in spermatogenesis. Gonadal atrophy and gonadal hypoplasia must be differentiated because they represent distinct disease processes. A thorough reproductive examination and an accurate history are fundamental in differentiating the two conditions. One should note inconsistencies between measured sperm output and estimated sperm output (DSO) based on testis size. Small testes in relation to the epididymis indicate atrophy. However, developmental abnormalities such as a small penis and enlarged inguinal rings associated with small testicular size often indicate hypoplasia. Atrophy or degeneration is considered an acquired condition that may or may not be reversible, depending on the cause.

Testicular atrophy can be caused by exogenous hormone administration. Historically, colts or stallions given anabolic steroids to improve recovery and muscle mass experienced reduction in testicular size caused by suppression of endogenous testosterone production. The use of anabolic steroids is no longer common in the United States. The synthetic progestin, altrenogest, can also cause testicular atrophy and a reduction in seminal quality and quantity.[1043] The detrimental effects on spermatogenesis are caused by an increase in the circulating levels of androgens, which in turn provide negative feedback on LH secretion by the pituitary with a consequent decline in testosterone production. As a consequence, testicular function is compromised, leading to a significant reduction in sperm production. Fortunately, the negative effects of steroids on testicular function are generally considered to be reversible, at least with respect to short-term use.[123] Long-term effects are unknown and need further study.

Diagnosis of gonadal atrophy requires a multimodal approach consisting of an accurate history, physical examination, evaluation of the external genitalia, semen analysis, and endocrine testing. An early indication of testicular degeneration is poor spermatogenic efficiency or decreased sperm output relative to what is expected based on calculations from testis size. More specifically, these stallions can have adequate-sized testes, but the quantity and/or quality of spermatozoa within the ejaculate is low or unusually poor, and during the initial phases the testes can feel softer. With chronicity, the testicular parenchyma is replaced by connective tissue, which makes the testes feel firmer. Leydig and Sertoli cells and spermatogonia and spermatozoa are more resistant to degeneration than cells of the intermediate stages of spermatogenesis; therefore semen analysis varies depending on the extent of damage. In most cases gonadal atrophy does not affect libido.

Endocrine testing can help confirm a diagnosis of gonadal atrophy. In many instances stallions will have increased circulating FSH concentrations but decreased concentrations of other sex hormones, such as LH, estradiol, testosterone, and inhibin.[1044] The use of AMH is an interesting concept, but to the author's knowledge, the usefulness of this endocrine assay in evaluating stallions with possible testicular degeneration has yet to be determined.[968]

Treatment of gonadal atrophy revolves around determining the cause of degeneration. Resumption of normal testicular function can be expected in instances in which damage was mild and relatively short lived. Chronic disease and idiopathic causes carry a more guarded prognosis. Reduction in book size, maintaining a selective book, and advanced semen processing and insemination techniques may help achieve acceptable pregnancy rates. Administration of GnRH has anecdotally been reported to be of benefit in early cases but is unlikely to be of benefit in reversing degenerative changes. For further information on management strategies for gonadal atrophy the reader is directed to an excellent review.[1045]

Acquired Conditions

Any condition causing hyperthermia or hypothermia can lead to damage and abnormal testicular function. Examples of conditions implicated as possible causes of testicular degeneration include prolonged recumbency, trauma, torsions of the spermatic cord, disruption of the blood-testis barrier and the consequent production of antisperm antibodies, inappropriate or prolonged steroid therapy, accumulations of fluids such as in hydroceles, and advanced age. Scrotal lesions that impair the normal testicular thermoregulation may be a significant factor causing gonadal atrophy. Other acquired disorders of the testes include radiation exposure; nutritional disorders, particularly those of vitamin A and zinc; and toxicity with heavy metals or nitrogen, phosphorus, and halogenated compounds.

Immune-mediated orchitis is rare in stallions. As soon as spermatogonia enter the leptotene stage during the meiotic phase, they become isolated from the general immune system by tight junctions between adjacent Sertoli cells. As mentioned previously, these gap junctions form the blood-testis barrier. A fine balance is maintained so that maturing spermatids can migrate toward the adluminal compartment without eliciting an immunologic response. In addition to the blood-testis barrier, local immunosuppressors are present in the testicular interstitium. Factors that disrupt the blood-testis barrier with the consequent formation of antisperm antibodies include tumors, trauma, biopsies, and spermatic cord torsions of more than 360 degrees. The association between antisperm antibodies and infertility, although reported for the stallion, warrants further investigation.[1046]

Hypertrophy refers to a condition in which the individual cells of the testes increase in size. The most common cause of testicular hypertrophy is removal of one testis or the abdominal

retention of one that triggers a compensatory growth of the contralateral gonad. *Hyperplasia* refers to an increase in the number of cells and can be focal or generalized. Testicular hyperplasia is rare in stallions.

Neoplastic Conditions

With an estimated frequency of approximately 4%, testicular cancer in stallions is relatively rare. The low occurrence is likely related to the relatively low number of sexually mature intact males compared with females. Teratomas were the most common (37%), followed by interstitial cell tumors (30%), seminomas (23%), lipomas (7%), and mast cell tumors (3%).[1047] Teratomas are commonly found in juvenile colts at the time of castration, which may explain their overrepresentation in incidence. Cryptorchid testes appear to have a predisposition for neoplasia, especially germ cell tumors, such as seminomas.[1047] Risk of metastasis is generally considered low, but one author has known two stallions that experienced secondary complications and subsequent death from malignancies arising from confirmed seminomas. Consequently, ensuring adequate excisional margins by histopathologic evaluation of excised tissue and evaluating regional lymph nodes provide useful information related to prognosis for that stallion.

Diagnosis of testicular neoplasia is based on a careful examination of the testes and related structures. One should palpate the scrotal contents and note soft or firm spots, nodules, or asymmetry. Ultrasonographic examination is crucial for the identification of fluid-filled or solid nonpalpable lesions embedded deep in the testicular stroma. The spermiogram often yields nonspecific findings but can demonstrate a high incidence of teratozoospermia (abnormal morphology), asthenozoospermia (poor motility), and/or the presence of round spermatids and other testicular cells. Abdominally retained testes can be diagnosed by transrectal and transabdominal palpation and ultrasonography. Unilateral or bilateral orchiectomy is the treatment of choice regardless of the type of tumor. Depending on the size and location of the testis, an inguinal, flank, or ventral midline incision is recommended. Ligation and removal of as much of the cord as possible are strongly recommended, and sampling of regional lymph nodes can be useful for determining the risk of metastatic disease. The gross appearance of testicular neoplasia can vary with the primary cell type. Interstitial cell tumors are usually soft, orange, and nodular, with no clear demarcation with the adjacent testicular tissue. Seminomas can vary in color from white to dark gray with a glistening appearance; the neoplastic area frequently bulges above the adjacent testicular tissue. Fluid-filled cysts often are present. Sertoli cell tumors are usually firm, nodular, and pale gray. Teratomas are easily identifiable by the presence of tissue of different origins (e.g., bone, hair). Ultimately, diagnosis is confirmed by histopathologic examination of the affected tissue.

Infectious Conditions

Inflammation of one or both testes is referred to as *orchitis.* Causes may be bacterial, viral, parasitic, or aseptic after trauma. Orchitis can be primary or secondary to another disorder. It is important to differentiate this condition from the more common conditions of periorchitis or scrotal edema, although the two conditions may be present simultaneously. Bacterial orchitis in horses may be caused by *Brucella abortus, Actinobacillus equuli, Pseudomonas pseudomallei, S. zooepidemicus, S. equisimilis, Salmonella* spp., *E. coli,* and *Staphylococcus* spp.[1048] The viral diseases EVA and EIA affect the testes because of associated fevers and edema. These agents can also be shed in the semen of affected stallions. Focal lymphocytic infiltrations may be observed in affected stallions. Parasitic orchitis is usually a sequela of migratory larvae of the parasite *Strongylus* spp.[1049] The condition can affect descended or undescended testicles and the tunics and spermatic cords. A possible secondary lesion associated with larvae is known as focal lymphocytic orchitis, which occurs around the seminiferous tubules.[1050] It is different from the condition of autoimmune orchitis reported for the mouse in which foci of lymphocytes are localized exclusively at the rete testis and efferent ductules. Initial diagnosis of the granulomatous-type lesions in the testicle caused by strongylosis sometimes can be done by ultrasonography, but histopathologic identification is necessary for a definitive diagnosis. Regular deworming programs with ivermectin can help control both of these conditions.

Abnormalities of the Epididymides

Congenital Conditions

Blind-ended ductules can form within the epididymis and likely represent failure of fusion of the ducts during embryonic or fetal development. If sufficient numbers of tubules are blocked, then the condition may lead to spermiostasis with development of cystic dilations, formation of epididymal sperm granulomas, and reduction of fertility. These cystic dilations may be diagnosed by palpation and ultrasonography.

Segmental aplasia of the mesonephric duct or epididymal agenesis is rarely reported in horses. Interestingly, the epididymis in the stallion is not fused completely with the testicle as in other species, which may predispose them to epididymal pathology such as spermatoceles and cystic dilations. Other, less common conditions include adenomyosis and tumors.[1051] Palpation and ultrasonography may be useful in diagnosis of these conditions.

Acquired Conditions

Other causes of epididymal dysfunction can manifest as abnormal accumulation of sperm in the cauda epididymides or generalized dysfunction of the epididymal epithelium associated with deficiencies in electrolyte, protein, or steroid secretion or resorption. Accumulated material may become inspissated and clog the normograde flow of sperm. Epididymal dysfunction, whether primary or secondary, can create changes in pH and osmolarity of the seminal plasma that might adversely affect maturation and viability of sperm. These conditions can be diagnosed by frequent semen collections (once or twice daily for 7–10 days) and evaluation of sperm morphology and motility, as well as seminal pH and metabolite analysis. Oligospermia and varying degrees of teratospermia are common. Morphologies from stallions with plugged cauda epididymides often have an unusually high percentage of detached heads and clumps of spermatozoa. Normal stallions ejaculate semen with a pH of 7.4, whereas those with decreased circulating testosterone and estradiol concentrations tend to have higher pH levels.[1052] Because the accessory sex glands contribute a significant portion of volume to semen, disorders affecting these structures also need to be ruled out.

Infectious Conditions

Bacteria or trauma to the scrotal area may cause inflammation of the epididymides. Infectious epididymitis as a primary

disease is rare in stallions and is considered a sequela to orchitis or to deep lacerations of the scrotal area. Migration of *Strongylus edentatus* larvae also may cause epididymitis with the consequent formation of granulomas.[1053] One confirms a diagnosis of epididymitis by palpation, ultrasonography, the presence of inflammatory cells in the ejaculate, and bacterial growth on culture.

Abnormalities of the Spermatic Cord

Congenital Conditions

The terms *inguinal hernia* and *scrotal hernia* are often used interchangeably. These involve protrusion of intestines or omentum through the vaginal ring and into the vaginal cavity. Ruptures of the vaginal sac can also occur. Inguinal hernias are more common in intact males because of the rapid closure of the rings following castration. Congenital and hereditary causes have been identified,[1054] and one of the authors (CFS) has seen them most often in Standardbred horses. Percutaneous and transrectal palpation and ultrasonography are ideal for diagnosing inguinal hernias and ruptures. In foals, many will spontaneously resolve by 6 months of age. Application of a truss or frequent manual reduction may hasten resolution in some affected horses. Occasionally, the bowel may become incarcerated and undergo ischemic insult, necessitating surgical closure of the rings and possible resection of bowel.

Acquired Conditions

Vascular problems associated with the cord include torsion, varicoceles, and thrombosis.[1055,1056] Torsion of the cord is significant when the cord has rotated more than 180 degrees. Torsions of less than 180 degrees are usually an incidental finding in young horses and are usually transient but occasionally permanent. Oftentimes torsions of less than 180 degrees are of little clinical significance, especially when no other clinical signs are evident. Torsions greater than 270 degrees are associated with scrotal swelling, pain on palpation, an abnormal gait, and acute abdominal pain. Diagnosis is made by a combination of clinical signs, palpation, and ultrasonography. The latter modality is very useful in differentiating spermatic cord torsions from scrotal hernias. The treatment of choice in spermatic cord torsion is hemiorchiectomy because the affected testicle will likely necrose and become nonfunctional.

Varicoceles in stallions are of questionable significance, especially if unilateral. Nevertheless, they have been associated with poor seminal quality and subfertility in other species.[1057,1058] If severe enough, the function of the pampiniform plexus (the mechanism responsible for countercurrent heat exchange of blood entering and exiting the testes) can be altered, predisposing the developing sperm cells to hyperthermia. Thrombosis of the cord is a more serious condition. The clinical signs resemble those of pathologic spermatic cord torsions, and unilateral castration is recommended. Ultrasonography is a useful means of diagnosis, and color flow Doppler can be used to evaluate blood flow when restriction, thrombosis, or infarction is suspected.

Infectious Conditions

Diseases and disorders of the spermatic cord involving older horses are primarily limited to infections and vascular issues. In intact horses, the most common infectious causes would be aberrant parasite migration and vasculitis secondary to local or generalized sepsis. Infection of the spermatic cord can occur following castration and is referred to as *septic funiculitis, scirrhous cord,* or *champignon.* Treatment consists of systemic broad-spectrum antibiotic therapy and supportive care. Surgical debridement and removal of the necrotic foci are also necessary because most cases do not resolve with medical management only.

Aberrant parasite migration into the pampiniform plexus can occasionally occur. However, it is now uncommon because of the widespread use of the avermectins, which have effectively resolved large strongyle infections.

Neoplastic Conditions

Neoplastic conditions are rare and usually secondary to invasion or metastases. Seminomas can invade the cord, and blood-borne cancers such as lymphoma may also metastasize to the spermatic cord. Diagnosis is made based on accompanying clinical signs, imaging, and histopathology.

Abnormalities of the Accessory Sex Glands

Congenital Conditions

Congenital disorders of the accessory sex glands in intact male horses are rare. In cases of DSDs, infantile or hypoplastic glands may be noted in the absence of androgen stimulation.

Acquired Conditions

The most common acquired condition of the accessory sex glands is spermiostasis or plugged ampullae. Stallions with this condition are referred to as *sperm accumulators.* Current theory holds that these stallions, when subject to prolonged periods of sexual rest, accumulate an abnormal amount of sperm and seminal secretions in their ampullae and deferent ducts. The incidence is estimated at ~25% (DD Varner, personal communication, 2015), and Thoroughbred stallions are overrepresented in most estimates. Possible causes include stallions failing to void "stale" sperm in their urine (unconfirmed observation) and/or anatomic variations causing narrowing of the lumen of the deferent ducts.[83,86]

Diagnosis entails collection of sequential semen samples and evaluation of the spermiogram. Ejaculates can range from oligospermic to containing unusually high (>30 billion) total sperm cells. In stallions producing a large amount of sperm, a characteristic finding is a high frequency of detached heads as determined by DIC microscopy. "Clumps" of sperm aggregates may also be seen. Ultrasonography per rectum can also be used to evaluate the accessory sex glands. Blocked ampullae can have a distended lumen and even hyperechoic regions proximal to the seminal colliculus, suggesting inspissation of seminal material.

The most common treatments for spermiostasis are frequent and consistent collections or breedings. Stallions initially diagnosed with this condition may take 1 to 2 weeks for seminal quality to improve. It is important to maintain accumulating stallions on a regular breeding schedule when possible. Other treatment strategies include administration of ecbolic agents (oxytocin [10–20 IU, IM/IV] or $PGF_{2\alpha}$ [cloprostenol; 25–250 µg, IM]) and manual massage of the ampullae per rectum. Severe cases can be treated with normograde or retrograde flushing of the ampullae and deferent ducts. One author (CFS) has used phenylephrine (20 mg, diluted in 1 L LRS, IV) in a horse with refractory plugged ampullae with positive results. This treatment, however, did cause moderate colic-like signs and intense full-body contractions during and shortly after

treatment and should only be administered with caution and informed consent from owners.

Neoplastic Conditions

Neoplasia of the accessory sex glands is rare. A recent report from the University of Pennsylvania described two cases of prostatic masses that were confirmed as either prostatic cystadenoma or adenocarcinoma.[1059] Surgical debulking was performed in one horse, but both horses died within 9 months of diagnosis.

Infectious Conditions

Although infections of the accessory sex glands are uncommon, unilateral or bilateral seminal vesiculitis can occur. Bacterial infection of the seminal vesicles is usually not accompanied by any external clinical signs. The ejaculate, however, is often turbid and discolored, and evaluation reveals a significant number of degenerate white blood cells. The glands may be enlarged, firm, and painful on palpation if the condition is acute. Ultrasonography can be used, but results need to be interpreted with caution because the size of the seminal vesicle can vary with breed, season, and sexual stimulation. Diagnosis of seminal vesiculitis is best made by rectal palpation, observation of large numbers of neutrophils in the semen (gel fraction), bacterial culture of semen and/or gel fraction, and endoscopy of the urethra and seminal vesicles. Direct culture of the seminal vesicles during endoscopy increases the clinician's confidence in the significance of organisms cultured. Treatment is difficult, and the prognosis is guarded. Reported treatments include systemic and local antibiotic therapy as well as the addition of extenders containing appropriate antibiotics to the semen of the affected stallion. Endoscopic evaluation is highly useful and can be followed by lavage and local antibiotic infusion.

Sexually mature stallions can harbor EAV in their accessory sex glands. This leads to chronic shedding and transmission of the virus to mares. This virus and its disease (EVA) will be discussed later in a separate section on equine venereal disease.

Abnormalities of Semen and Spermatozoa

Azoospermia and *oligospermia* describe the absence or abnormally low numbers of spermatozoa in an ejaculate, respectively. *Teratospermia* refers to the presence of an unusually large number of individual sperm defects, whereas *asthenospermia* refers to sperm with poor motility. Causes can be characterized as developmental, acquired, and infectious.

Developmental Conditions

Azoospermia is usually secondary to a gonadal or epididymal disorder. Cryptorchidism, anorchidism, and testicular hypoplasia secondary to a DSD can lead to low sperm production. Hypoplasia of the epididymides and deferent ducts leading to outflow obstructions can also lead to little to no sperm cells within an ejaculate. Diagnosis and treatment of cryptorchidism have previously been discussed. Developmental abnormalities are often diagnosed via exclusion and genetic testing (e.g., karyotyping and molecular studies).

Infectious and Acquired Conditions

Pyospermia. The hallmark of this condition is the presence of purulent debris, white blood cells, and pathogenic organisms in an ejaculate. This condition is usually secondary to infection or inflammation of the deferent ducts, accessory sex glands (e.g., seminal vesicles), and/or urethra. Following a live-cover, normal dismount, samples may be "contaminated" with cellular debris and microorganisms. Caution should thus be exercised not to overinterpret the findings in these samples, which should be analyzed with respect to current reproductive performance. Aerobic cultures of the stallion's penis, fossa glandis, urethral sinus, and preejaculate and postejaculate urethra can help with localization of the infection. Further characterization of the source can be aided by fractionation of the ejaculate using an open-ended AV. If the clinician suspects that the stallion is the cause of bacteria-related fertility problems in a group of mares, then it is important to culture the mares to determine whether the mares are harboring the same pathogens as the stallion. Giemsa, Wright, or Diff-Quik stains of the semen aid in identifying the type of white blood cell present. Treatment of pyospermia consists of resolving the primary issue, use of semen extenders with appropriate antibiotics, and isolation of the sperm-rich fraction using centrifugation or filtration.

Urospermia. General causes of urospermia include neurologic disease, orthopedic conditions, psychogenic or behavioral problems, and idiopathic causes. Although uncommon, retrograde ejaculation can also occur.[1060] Urine-contaminated semen is often readily detectable because of changes in color (yellow), odor (urea), and volume (increased). However, when urine is not obvious but suspected to be a contaminant, the concentrations of urea nitrogen >30 mg/dL and creatinine >2 mg/dL in the semen are diagnostic of urospermia. The effect of urine on the sperm cells is not well documented. However, the reduction in motility and fertility is significant because of the effects of hyperosmotic medium and water removal from the sperm cells. One author (JCS) has observed several cases of urospermia associated with self-mutilating stallions. Pharmacologic therapy of the problem is purely empiric and limited to drugs that act to close the neck of the bladder, such as β-blockers. A more common approach is to use managerial procedures such as encouraging urination before semen collection and the collection of semen directly into an extender and immediate centrifugation. The ideal procedure is to fractionate the ejaculate during collection with an open-ended AV. In breeds for which AI is not allowed, an extender may be infused into the uterus and flushed out 4 to 6 hours later. Holding stallions in a freshly bedded stall or placing feces from another stallion in their stall before semen collection can sometimes stimulate the stallion to void urine and can thus be used to limit the risk of urospermia.

Hemospermia. Hemospermia is typified by an unusually large amount of blood (fresh or dried) in an ejaculate. The presence of erythrocytes in semen can adversely affect seminal quality and subsequent fertility.[1061] Decreased progressive motility and plasma membrane integrity were lower in ejaculates incubated in whole blood compared with controls. In a recent report on eight cases, causes of hemospermia included urethral rents (3), urethral process lesions (2), squamous cell carcinoma (1), kick to the penis (1), and unknown origin (1).[1062] Penile lacerations and habronemiasis are other potential causes of hemospermia. Interestingly, stallions collected for AI were overrepresented in reviews on this condition.[1062,1063] If the bleeding site cannot be found externally, another common site is where the pelvic urethra folds over the ischium. Urethroscopy performed immediately after ejaculation can be used to visualize the penile and pelvic urethra and identify the

location of a rent. If the source of bleeding can be identified in the urethra, a common approach to treatment is sexual rest to allow for tissue remodeling. Alternatively, a urethrostomy of the area is indicated for horses that fail to respond with conservative therapy. The urethrostomy relieves pressure and allows the rent in the urethra to heal by second intention. Some of the management procedures described for urospermia, such as fractionation and extension, also may be considered.

Sexually Transmitted Diseases

There are several STDs that are relevant from both clinical and regulatory standpoints. Readers are strongly encouraged to contact their local regulatory official for updated information or whenever a reportable or foreign animal disease (FAD) is suspected. Questions pertaining to handling of potentially infected gametes (e.g., spermatozoa, embryos) should be directed to local regulatory officials.

Contagious Equine Metritis

CEM is a true venereal disease caused by the bacterium *T. equigenitalis,* a highly contagious gram-negative coccobacillus.[240] Transmission via fomites is possible and was implicated in a recent outbreak in the United States.[1064] Clinical signs vary from relatively inapparent to copious vulvar discharge originating from the uterus.[241] Stallions rarely display clinical signs but are unapparent carriers and are the most common means of transmission because they are much more sexually active. Significant drops in reproductive efficiency ensue, leading to increased costs associated with management and veterinary care. Diagnosis is made by isolation of the organism. Because of the organism's rather fastidious nature, samples should be sent to laboratories familiar with culturing techniques. Treatment for *T. equigenitalis* is fairly straightforward and consists of careful cleansing of the internal and external genitalia and application of local antiinfective agents. The United States has undergone a reclassification in its status as a CEM-free country because of the previously mentioned outbreak. Readers are thus encouraged to contact their local USDA official for current recommendations. All breeding activity should be withheld until proper screening and prophylactic treatments have been performed before introduction of the animal into a local breeding population.

Equine Viral Arteritis

EVA is another disease that has important regulatory implications. The causative agent is EAV, which is an enveloped, single-stranded RNA virus.[242] Clinical signs include vasculitis, distal limb edema, pyrexia, rhinitis, conjunctivitis, and anorexia. The virus can also cause abortion outbreaks and severe neonatal pneumonia in naïve herds. It is transmitted via respiratory secretions and other body fluids, including semen and fetal fluids/tissues, and fomites. Current estimates suggest that 30% to 70% of exposed stallions will become persistently infected when exposed to the virus, and they are referred to as shedder stallions.[243] Consequently, prevention of the disease is key and has even been nearly eradicated in commercial North American Thoroughbreds by screening and vaccination. A modified-live virus vaccine is commercially available in the United States (Arvac; Zoetis, Parsippany, NJ) and approved for use in breeding stallions. In some breeds that allow AI, breeding with EAV-infected semen is permissible with proper documentation of the mare's vaccination status. Certain breed registries and state agricultural departments have restrictions regarding vaccination of breeding stock and use of EAV-infected semen. State requirements can be obtained by contacting local regulatory officials.

Equine Herpesvirus Type 3

EHV-3 is the causative agent of *equine coital exanthema,* characterized by vesicular or poxlike lesions on the genitalia that eventually progress to depigmented regions of skin. It is not currently considered a reportable disease in the United States. Transmission is most common via coitus but can also occur via fomites. Clinical disease is primarily manifested as vesicular and painful lesions on the external genitalia of both mares and stallions. During the acute phase, these lesions can cause discomfort during reproductive evaluations and during live-cover matings, but infection has no lasting or impressionable effects on fertility.[244] Lesions will take 4 to 6 weeks to heal and are characterized by focal areas of depigmentation. Gentle cleansing of active lesions may soothe and reduce inflammation. Reports of antiviral treatments are sparse. One author (CFS) has used docosanol cream (Abreva; Zoetis, Florham Park, NJ) in four cases with seemingly good results in resolving the acute inflammation associated with the lesions. However, no comparison was made regarding the length of the convalescent period between treated and control groups. Transmission to other animals is a concern and seems to be highest during the acute phase of this disease. A period of 4 to 6 weeks of sexual rest is recommended to prevent further transmission and allow the lesions to heal. Resumption of breeding activity can occur once the lesions have healed. Natural recrudescence of this particular herpesvirus is unknown,[245] but experimental administration of dexamethasone has been shown to cause reactivation of the virus.[1065] Control is aimed at early detection and sexual rest until lesions have subsided. There is no commercially available vaccine against EHV-3 in the United States.

Dourine

Dourine is a venereal disease of significance because of its high level of morbidity and its effect on international transport of equids. The etiologic agent is the protozoa *T. equiperdum.* Clinical signs include intermittent fever, swelling of and discharge from the genitalia, cutaneous plaques, and neurologic signs.[246] Generally considered a chronic and progressive disease, the onset of recumbency usually indicates terminal disease. Dourine has been eradicated in the United States, but it is still present in Africa, the Middle East, South America, and Central America. Sporadic outbreaks have been reported in Asia and Germany.[240] Diagnosis is made via compatible clinical signs and laboratory testing. The CF test is prone to false positives from other species of *Trypanosoma,* and newer methods of diagnostics, including ELISA and PCR technologies, are currently being explored for both testing and screening purposes. Infected animals should be removed from breeding and culled. Treatment with antiprotozoal drugs has been performed in some endemic areas, but they are unproven and even discouraged because of concern about inapparent shedding animals. Suspected cases of dourine should be reported immediately to local regulatory officials.

Piroplasmosis

Previously eradicated in the United States, cases of piroplasmosis have sporadically occurred over the past few years. This disease is caused by the protozoa *Theileria equi* (formerly *Babesia equi*) and *B. caballi.* Transmission occurs either via

an insect vector (e.g., ticks) or mechanically (e.g., improperly sanitized instruments). It also has the potential to be transmitted venereally in cases of hemospermia. Piroplasmosis creates disturbances in several body systems. Clinical signs are often nonspecific and vary based on the severity of disease and chronicity. Horses surviving the acute phase can become carriers. Diagnosis is confirmed based on observation of the organism on blood smears and serologic testing. Treatment with antiprotozoan medications is unproven, and recrudescence is a concern.[240] Similar to other reportable diseases, suspect cases should be directed to the local USDA-APHIS office.

Opportunistic Pathogens

Several aerobic bacteria have been associated with poor reproductive efficiency. These include β strep, *E. coli, P. aeruginosa,* and *Klebsiella* spp. Although rarely a cause for clinical disease,[1066] overgrowth of these bacteria may occasionally influence pregnancy rates in, for example, susceptible mares. Serial collection of aerobic cultures of the external genitalia (e.g., penis/prepuce, urethral fossa, and preejaculate and postejaculate urethra) is common to monitor for pathogens. Cleansing with lukewarm water and drying the penis before and after breeding are useful preventive measures, and they also allow for inspection of the genitalia for abnormalities. Treatment with local and/or systemic antibiotics is usually not indicated for fear of disrupting the normal flora on the genitalia. Washing with soaps or antiseptics may remove the normal flora and select for more resistant and pathogenic strains. The environment in which a stallion is housed may influence the types of microorganisms harbored on the external genitalia and should also be considered. When there is concern about transmission of potentially pathogenic bacteria, breeding strategies can be implemented to abate the risk. In the case of stallions used for live cover, semen extender containing an appropriate antibiotic can be infused into the uterus before or after mating. Semen from stallions used for AI should be screened for microorganisms and extended in an appropriate semen extender. For mares bred to these stallions, postbreeding management could entail uterine lavages, infusions, and ecbolics.

Conclusion

Whether developmental or acquired in nature, there are many conditions that can affect the reproductive tract of intact male horses. Careful evaluation of all body systems is indicated when disorders of the reproductive tract are suspected because of its interrelationship with other organs. This also holds true when examining a breeding stallion for fertility issues. In these particular cases, the sense of immediacy is ratcheted up a few notches to obtain a timely diagnosis and implement effective management strategies to improve reproductive efficiency. Clinical examination, diagnostic imaging, endocrine testing, and semen evaluation are all useful in meeting these goals.

CHAPTER 20

Disorders of Foals

Harold C. McKenzie III

EQUINE NEONATOLOGY

Tremendous advances have been made in the medical care of newborn foals over the past 50 years, thanks to the pioneering efforts of many individuals and research groups and the increasing sophistication of veterinary medicine as a whole. Although the field of human neonatology has provided critically important guidance regarding the physiology and pathophysiology of the neonatal foal, and will continue to do so, fundamental insights have been achieved into the unique characteristics of this special population. The foundations of equine neonatology were built on the earliest descriptions of specific conditions in foals by clinician researchers, such as septicemia, joint ill, and hemolytic icterus,[1-4] as well as the "dummy foal" syndrome and the respiratory distress syndrome (RDS) associated with primary surfactant deficiency.[5,6] Significant strides were also being made in the understanding of the physiology of the equine fetus and neonate, in large part because of the efforts of a group of researchers working in the UK.[5-23] As the knowledge base grew dramatically,[24-29] there was increasing interest in providing improved care for the equine neonate, in large part because of the substantial investments of time, energy, and equity involved in the lengthy process of conception, gestation, parturition, and juvenile development. Owners were very interested in optimizing foal survival, and this interest, along with the increasing capability for providing effective critical care for foals, led to the development of neonatal intensive care units (ICUs) worldwide in the 1980s. Since that time there has been a steady increase in our understanding and ability to successfully treat and manage the critically ill foal. The result has been a dramatic improvement not only in the likelihood of survival but also the ability of surviving foals to mature into sound, healthy individuals that are able to perform their intended function.[30] Our knowledge base in equine neonatology continues to grow, and the goal of this chapter is to provide an overview of the current knowledge in this field as well as to provide some insights derived from human medicine.

FETAL ASSESSMENT, MONITORING, AND MANAGEMENT

The efforts of owners, managers, and veterinarians to maximize equine reproductive success extend far beyond successful conception. Close attention must be paid to a variety of influences before, during, and after pregnancy. These influences include numerous maternal, placental, and fetal risk factors. By assessing these variables and monitoring for changes during the course of pregnancy, it may be possible to implement medical therapies to minimize some risks, or at least to ensure that management strategies are in place to reduce the risk of problems during or after delivery.

Regarding maternal risk factors one must begin with a detailed assessment of the mare's reproductive history including endometrial health before breeding; problems during conception; vaccination history; possibility of twinning; previous gestational length; number of previous foals; the number of successful deliveries; history of and types of dystocia; and the occurrence of any problems with previous foals after birth, such as neonatal isoerythrolysis.[31] In addition, a number of maternal factors during pregnancy should be assessed, including maternal under- or overnutrition, maternal illnesses (especially colic or other severe stressors), and endocrine or metabolic maternal abnormalities. Physical abnormalities, such as abdominal wall muscular tears or prepubic tendon rupture, represent serious risks to both the dam and the fetus. Uterine torsion represents a life-threatening situation for the mare and the fetus, and if correction is successful the fetus must be regarded at high risk for the duration of the pregnancy.

Although it can be very difficult to appreciate placental risk factors, this is a critical issue given the complete dependence of the fetus on the dam for energy and oxygen supplies. Conditions such as endometriosis or twinning can reduce the available surface area for placental attachment, resulting in impaired transfer of nutrients and waste products between the fetus and the dam and potentially causing intrauterine growth retardation (IUGR). Placental dysfunction can result from abnormalities such as placental detachment, placentitis, placental edema, hydrops, and vascular inflammation or injury.[31] Exposure of the mare to any possible infectious causes of abortion or maternal ingestion of endophyte-infested fescue also can represent serious risk factors to the fetus.[32,33] Although there are often no outward signs of placental abnormalities, the development of excessive abdominal distention, vulvar discharge, or premature udder development may suggest their presence. A number of fetal factors can complicate pregnancy as well, including fetal malformations (congenital or developmental), fetal malpositioning, twinning, exposure to infectious agents, and neonatal isoerythrolysis.

If any potential risk factors are identified then the pregnancy should be characterized as high risk, requiring assessment of

the mare, the placenta, and the fetus. Evaluation of the mare should include a thorough physical examination, paying particular attention to the external genitalia and the udder. The abdomen should be evaluated for signs of excessive enlargement, ventral edema, or a pendulous appearance. Evidence of systemic illness (fever, tachycardia, tachypnea, abnormal mucous membranes, etc.) will serve as an indication for additional diagnostic evaluation to ascertain the focus and severity of the inflammation. A complete blood count and serum chemistry profile may be helpful in that regard. Evaluation of the reproductive tract should include a rectal examination, if feasible, as well as a vaginal examination and transrectal and transabdominal ultrasound examinations. These will allow for detection of abnormalities such as cervical discharge, uterine torsion, hydrops, and prepubic tendon rupture.

Ultrasound examination will provide the opportunity to thoroughly evaluate the placenta to assess placental attachment, placental thickness, and the echogenicity of the fetal fluids.[34-36] The transabdominal approach allows for prolonged periods of examination and allows for a thorough assessment of the uterus, placenta, and fetus.[37] After 4 months' gestation both transabdominal and transrectal ultrasonographic examinations should be performed to ensure thorough assessment. After 6 months of gestation transrectal ultrasonography can also be used to regularly monitor variables such as fetal heart rate, eye diameter, and fetal activity.[38] Although transrectal ultrasound examination does not allow visualization of all fetal structures, it is very useful during late gestation, because the caudal uterine body is the most common site for ascending placentitis to develop.[35] Measurement of the combined thickness of the uterus and placenta (CTUP) is a useful indicator of placental abnormalities, but this assessment should only be performed in areas of the placenta not in contact with the fetus. Although the CTUP can be measured transabdominally, this approach is more challenging because of the variations in the location measured as well as the potential for fetal contact compressing the placenta.[39] It is preferred to measure the CTUP transrectally at a site near the cervicoplacental junction, at which a branch of the uterine can be visualized between the uterus and the bladder, using the average of several measurements.[36] Normal measurements of the CTUP have been reported to be 0.6 cm at 7 months' gestation, less than 0.8 cm at 9 months, less than 1.0 cm at 10 months, and up to 1.0 to 1.2 cm at the end of gestation.[36,40] It is important to remember that even though an increased CTUP may suggest placental abnormalities it does not represent a definitive finding. There are reports of increased CTUP measurements that were not associated with placental pathology, and conversely ascending placentitis is not always associated with an increase in CTUP.[35,36,41] Although there may also be breed and parity influences on CTUP measurements, the 1.2-cm upper limit represents a reasonable cutoff for most Light Horse and Warmblood breeds.[42] Placental detachment may be associated with accumulation of exudate between the placental and uterine surfaces, which is typically hyperechoic in ultrasonographic appearance.

In addition to CTUP there are a number of other ultrasonographic parameters that can be used for assessment and monitoring of the high-risk fetus. Fetal viability can be assessed using fetal heart rate and rhythm, as well as fetal activity patterns and fetal responses to stimulation. Fetal heart rates change throughout gestation, trending from a high of 135 ± 6 beats per minute at 91 to 120 days' gestation to 67 ± 12 beats per minute at 330 to 360 days' gestation.[43] Transient alterations in fetal heart rate may be observed but do not likely indicate fetal distress unless they persist. Persistent tachycardia or bradycardia may be an indication of impending fetal death.[44,45] Fetal heart rate should increase during periods of fetal activity and return to normal ranges thereafter. Fetal electrocardiography can be used for monitoring fetal heart rate and rhythm as well and was widely used several decades ago but has fallen out of favor because of the ready availability, ease of use, and diagnostic yield associated with ultrasonographic fetal assessment. A recent report described the use of telemetric electrocardiography equipment for monitoring fetal heart rate and fetal heart rate variability, and this tool may hold some promise for fetal assessment in the future.[46] A biophysical profile based on ultrasonographic fetal assessment has been developed for use in late gestation, and this includes fetal heart rate, fetal activity, fetal aortic diameter, CTUP, uteroplacental contact, and maximal allantoic fluid depth.[43,45,47]

Once the determination has been made that the pregnancy is high risk, and particularly if there are uteroplacental or fetal abnormalities indicative of the risk or presence of fetal compromise, the next challenge is if, when, and how to intervene appropriately. Because of the very late maturation of the equine fetus in the last 1 to 2 weeks of gestation, combined with the difficulty of determining fetal readiness for birth, it is rarely advisable to induce delivery. It is far better in most situations to attempt to support the fetus in utero as best as possible while awaiting natural delivery.[48] If there are complications that threaten the survival of the dam, then cesarean section or induction of parturition may be indicated, although the survival of the foal should be considered highly unlikely. The other situation in which intervention may be indicated is if the fetus is thought to be near term and the mare suffers from a condition such as severe colic that is endangering fetal survival, although the prognosis for foal survival again remains poor.

Medical management of the high-risk pregnancy has two goals: the first is treatment of the primary condition, if possible, and the second is treatment intended to support the fetus in utero and maintain the pregnancy. The primary condition most commonly encountered in the mare is placentitis, and specific treatment consists of antimicrobial therapy and antiinflammatory therapy. Antimicrobial therapy, although typically empiric in nature, should ideally rely on drugs that are capable of reaching therapeutic concentrations within the uterus. Trimethoprim-sulfamethoxazole, penicillin, and gentamicin have all been shown to reach appropriate levels within the allantoic fluid, but trimethoprim-sulfamethoxazole is most commonly used because of the ease of oral administration and low cost.[49,50] Ceftiofur crystalline-free acid (CCFA), although appealing from the perspective of ease of administration and expense, did not achieve therapeutic concentrations within the placenta or fetal fluids and was not effective in an experimental model of bacterial placentitis.[51]

Antiinflammatory therapy in most cases consists of flunixin meglumine and pentoxifylline, although other agents such as aspirin and corticosteroids have been investigated. Although the efficacy of antiinflammatory therapy in placentitis is uncertain, they are commonly used. Flunixin meglumine is the most common agent used, because it is a potent nonsteroidal antiinflammatory drug (NSAID), but it is not clear that it reaches therapeutic concentrations within the placenta or uterus.[52] Other antiinflammatory drugs have been of interest,

although one study did not find any benefit to the addition of an antiinflammatory (dexamethasone and aspirin) to trimethoprim-sulfamethoxazole therapy in experimentally induced bacterial placentitis.[53] In addition to the potential antiinflammatory effects of corticosteroids, their use has been of interest because of the widespread use of this treatment to accelerate fetal maturation in human patients.[54] The administration of corticosteroids to mares in late gestation was shown to accelerate fetal maturation in one experimental study, but there are no reports regarding the use of this therapeutic approach in clinical practice.[55]

Treatments that may be beneficial in supporting gestation include exogenous progestagens, tocolytics, and agents promoting oxygen delivery to the fetus. Progestagen supplementation may have a multitude of effects, including antiprostaglandin effects, but primarily it is thought to function as a tocolytic. This is typically accomplished using altrenogest, a synthetic progestin, although injectable progesterone is sometimes used.[43] Although the use of these agents has been somewhat controversial, altrenogest therapy has shown some indications of efficacy in reducing fetal losses from bacterial placentitis.[56-58] Clenbuterol, a β_2-sympathomimetic drug, has been shown to induce uterine relaxation during late gestation but is short-acting, with only 2 hours' duration of effect.[52] For this reason clenbuterol is most useful in the acute situation, such as in the management of dystocia while preparing for cesarean section or assisted delivery.[59]

Treatments that may improve fetal oxygen delivery in utero and during an assisted delivery include pentoxifylline and intranasal oxygen administration to the mare. In addition to its antiinflammatory effects, pentoxifylline has rheologic effects that may enhance oxygen delivery to the placenta by improving microcirculation.[60] Intranasal oxygen administration (10–15 L/min) to the pregnant mare will increase the partial pressure of oxygen and oxygen saturation in the arterial blood supplying the placenta and may improve oxygen delivery to the fetus.[30] Vitamin E has been used in the management of high-risk pregnancy as an antioxidant and is administered orally to the pregnant mare.[30]

At this time the combination of trimethoprim-sulfamethoxazole, flunixin meglumine, and pentoxifylline remain the most commonly used treatment protocol for the medical management of bacterial placentitis in the mare. Generally, when managing mares with high-risk pregnancies it is critical that a well-formed plan is developed for dealing not only with parturition but also the high-risk foal after delivery, if it survives. Ideally these mares will be housed in a facility that is able to provide 24-hour monitoring and that has a team available to deal with any eventualities appropriately and in a timely manner. All necessary equipment needs to be organized and readily available. Thorough discussions with owners and agents need to occur before any crises so that all involved know the priorities regarding what procedures are authorized and whether the mare's life or the foal's life is the focus of the teams' efforts.

EXAMINATION OF THE NEWBORN FOAL

When assessing an equine neonate, it is important to remember that the first minutes and hours after birth are a profound adaptive period and that the normal parameters used in assessment are continually changing during this time. All of the foal's body systems are transitioning from the protected intrauterine environment in which many of their functions were primarily performed by the mare via the placenta, to the external environment in which these systems assume full responsibility for maintaining homeostasis. The time required for this transition varies by body system, and the adaptations required of the cardiopulmonary system are the most time critical. At birth the lungs must expand and clear themselves of fluid for gas exchange to occur, and this process must be coordinated with a shift in blood flow into the pulmonary circulation. If all elements of this transition do not occur within a few minutes, the foal will not be able to survive in the external environment. The adaptations required of the nervous, musculoskeletal, endocrine, alimentary, and thermoregulatory systems are similarly critical but occur over a longer period of time following birth.

There are a number of endocrine changes occurring in the periparturient period, and these changes are critical in readying a number of body systems, such as the lungs, gastrointestinal tract, kidneys, and liver, for the functions they will be responsible for following birth.[61] The most critical of these appears to be the activation of the hypothalamic-pituitary-adrenal (HPA) axis. This process begins in the period starting approximately 5 days before birth, when the fetal cortisol concentration rapidly begins to rise.[17] This increase prepares the body for many of the processes that may have little or no role in utero but are critical for survival after birth, such as respiration, renal sodium conservation, and glucose metabolism.[62] Serum cortisol concentrations continue to rise in the first few hours after birth before decreasing to normal basal values by approximately 1 day of age in healthy foals.[63] Very premature foals (<320 days' gestation) have low cortisol concentrations at birth, and these do not increase appropriately in the first 2 hours of life.[64] In addition to changes in the HPA axis there are also increases in circulating catecholamines, insulin, and glucagon, as well as thyroid hormones (T_3, T_4) associated with the immediate postpartum period.[62]

The neurologic system of the equine fetus is fully developed and functional because the precocious nature of foals at birth requires the immediate ability to ambulate and function independently.[65] The fetus is maintained in a sleeping state in utero through a combination of inhibitory factors, which include physical factors such as warmth, cushioned tactile stimulation, and buoyancy, as well as chemical factors, which include high circulating and/or cerebral concentrations of adenosine, prostaglandin D_2, and the pregnane neurosteroids allopregnanolone and pregnanolone.[65,66] These inhibitory neurosteroids are synthesized from progesterone primarily within the placenta during late gestation, and following delivery their concentrations within the normal neonate decline rapidly, usually over the first 48 hours of life.[67,68] This loss of cerebral inhibition, in combination with potent stimulation arising from transiting the birth canal, the onset of breathing, and the onset of multiple external stimuli (light, cold, hard surfaces, unlimited space, gravity, etc.), lead to a rapid increase in activity and awareness in the neonate.[66]

As the foal passes through the birth canal the chest undergoes significant compression, which aids in shifting fluid out of the airways. Once the lungs begin to inflate the action of surfactant contributes to further clearance of airway fluid and the maintenance of alveolar stability and lung inflation. Before birth the fetal circulation functionally bypasses the pulmonary

circulation by shunting through the ductus arteriosus and the foramen ovale. Once the foal begins to breathe the resistance in the pulmonary vasculature dramatically decreases, allowing blood from the pulmonary artery to enter the pulmonary vasculature rather than passing through the ductus arteriosus into the aorta. As the pressure in the left side of the heart increases, the foramen ovale closes, preventing the shunting of blood from the right atrium to the left atrium. Complete closure of the ductus arteriosus may take several days, and it is not unusual to hear a "machinery"-type murmur associated with patency of the ductus arteriosus in foals during the first 1 to 3 days of life. It is rare for the foramen ovale to remain patent in foals.

The foal's initial respirations primarily occur in response to the rapid rise of carbon dioxide in the bloodstream following the loss of placental gas exchange. The loss of placentally derived prostaglandins that suppress breathing in utero likely contributes as well, along with the initiation of cold and tactile stimuli associated with the external environment.[69] Spontaneous breathing may begin as soon as the chest clears the birth canal and should begin within 1 minute of birth. The first few breaths may be quite exaggerated in nature because of high carbon dioxide levels and the degree of effort required for initial lung expansion. Following these initial breaths most foals will continue to exhibit elevated respiratory rates of 50 to 75 breaths per minute for the first 20 to 30 minutes of life. The respiratory rate will then decrease to around 30 to 40 breaths per minute, and this remains fairly stable for the remainder of the first 2 days of life. By 2 to 3 days of age most foals will exhibit respiratory rates of approximately 20 breaths per minute. Foals show a much more exaggerated respiratory pattern than adult horses, with both inspiration and expiration requiring active respiratory effort because of the foal's highly compliant thoracic wall.

Immediately following birth the foal will typically exhibit bradycardia, with heart rates of 60 to 80 beats per minute.[8] The heart rate rapidly increases, peaking at 150 to 175 beats per minute around 40 to 60 minutes after birth, with the highest heart rates often observed in association with the foal's first attempts to stand.[70] The heart rate then gradually decreases, with a resting rate of 120 to 150 beats per minute from 1 to 2 hours after birth followed by a rate of 100 to 120 beats per minute by 3 hours after birth. By 1 day of age the normal resting heart rate will be in the range of 80 to 100 beats per minute. Because of the relatively late maturation of the HPA axis in the fetal foal, the cardiovascular system at birth does not appear to be as fully developed in the horse compared with other species.[71] As a result the neonatal foal does not have well-developed baroreceptor responses and is at risk for hypotension, especially if premature.[71]

The mare will begin interacting with the foal shortly after parturition, using both vocal and tactile stimuli. The normal foal should be responsive to stimulation shortly after birth, and by 20 to 30 minutes of age the foal should respond to visual stimuli by appropriate ocular and head movements.[72] Within 40 minutes the foal should be responding to auditory stimuli with independent orientation of the ears in the direction of the stimulus.[72] Because of the risks associated with prolonged recumbency for foals born in a natural environment, there is a strong imperative for foals to be able to stand quickly and become ambulatory. The normal foal will move into sternal recumbency within a few minutes after birth. It will begin making efforts to stand within 30 minutes after birth, and should be able to stand unassisted within 60 to 120 minutes.[73] There can be breed differences in the time to stand, with pony foals standing in less than 60 minutes and larger breed foals, such as Thoroughbreds, typically requiring 30 to 60 minutes longer.[9] When first standing the foal will exhibit some degree of incoordination and dysmetria and will assume a braced position, with all limbs spread laterally, the forelimbs positioned forward, and the hindlimbs extended posteriorly.[72] Once standing the normal foal will rapidly gain coordination and will begin circling the mare and attempting bursts of speed within 1 to 2 hours.[74]

Some foals will display flexor tendon laxity at birth, primarily noted in the form of dropped fetlocks.[75] Most foals with flexor tendon laxity will only demonstrate mild to moderate abnormalities, typically consisting of rocking back onto the heels and caudal hoof wall, which leads to pastern hyperextension and upward flipping of the toe.[76] Affected foals usually recover rapidly, with increasing strength and activity over the first few days of life.[77] Rarely, foals may demonstrate more dramatic musculoskeletal abnormalities, such as a "windswept" conformation, with either the front or hindlimbs affected by matching angular limb deformities. One limb will have a valgus deformity, whereas the opposite limb will exhibit a matching varus deformity. Unless there are underlying bony abnormalities most of these foals will also self-correct with time and activity.

The normal foal will begin displaying suckling behavior shortly after birth, even while still recumbent, and should be able to nurse unassisted within 1 hour of standing. Foals requiring more than 3 hours to suckle are considered abnormal. Successful nursing presents several challenges to the newborn foal, beginning with the absolute requirement for successful standing and ambulation to access the udder. Very weak foals, or those suffering from musculoskeletal or neurologic problems, will have great difficulty in nursing for this reason. Once able to stand successfully, the foal must locate the udder, which likely requires a combination of visual and olfactory abilities on the part of the foal. The ingestion of milk is a fairly complex neurologic process, beginning with successful capture of the teat by the lips, followed by coordination of the tongue, pharynx, larynx, epiglottis, and esophagus to ensure that milk enters the gastrointestinal tract rather than the respiratory tract. In addition to the potential adverse impact of muscular weakness or neurologic dysfunction on this process there may be physical abnormalities, such as cleft palate or subepiglottic cysts that may interfere with the normal passage of milk.

The gastrointestinal tract must undergo a number of changes to accommodate and use ingested colostrum and milk. During the first 12 to 24 hours after birth the small intestine remains permeable to macromolecules, most importantly immunoglobulins, allowing for the absorption of ingested antibodies contained in colostrum. Absorption occurs by a number of mechanisms, including pinocytosis, lymphatic transport, and exocytosis. The period of maximal absorption is the first 12 hours after birth, with approximately 50% of ingested immunoglobulins able to be absorbed during that time period.[78] From 12 to 18 hours after birth the efficiency of absorption decreases substantially, with only 28% of ingested immunoglobulins able to be absorbed, and this rate of absorption is not adversely affected by the prior ingestion of macromolecules.[78] Although some absorption may be possible after 18 hours, the efficiency of absorption continues to decrease and absorption is essentially absent by 36 hours of age.

Following the loss of maternally derived glucose supplied via the placenta, the foal must take control of glucose homeostasis. This is particularly challenging because nutrient intake transitions from a continuous mode, in which the dam ensures a continuous, regulated supply of glucose at all times, to intermittent energy intake based on milk ingestion. The pancreas must assume responsibility for the maintenance of normoglycemia through the differential production of glucagon and insulin. These dramatic alterations in energy metabolism may not always occur smoothly, and unfortunately the foal possesses limited energy reserves in the form of glycogen and fat. The result is that hypoglycemia occurs over the first 1 to 2 hours of life even in the normal neonatal foal, and the sick foal is at risk of profound hypoglycemia if deprived of energy intake for even a few hours. The metabolic response of the foal is to increase production of glucagon, epinephrine, and cortisol and suppress insulin production, increasing circulating blood glucose concentrations. Glycogenolysis provides a ready source of glucose, but hepatic glycogen stores are minimal in the foal, so gluconeogenesis rapidly becomes the primary route of endogenous glucose production. Premature or dysmature foals often have impaired glucose regulation and are susceptible to pathologic hypoglycemia in the absence of appropriate dietary or parenteral supplementation.

At birth the foal transitions from the normally sterile intrauterine environment into an environment teeming with nonpathogenic and pathogenic organisms. Colonization of the various tissues exposed to the outside environment occurs rapidly, beginning during the birthing process. This phenomenon is particularly important in the gastrointestinal tract, in which microbial activity is critical for full functionality of the local immune system and digestion. Colonization occurs through environmental exposure and is likely facilitated by the coprophagic behavior routinely exhibited by foals. Colostral immunoglobulins and oligosaccharides may play a role in regulating the composition of the gastrointestinal flora by affecting the ability of certain bacteria to attach to the mucosal surface and by opsonizing certain bacteria, facilitating the mucosal immune response to these organisms.[79] By 2 to 4 weeks of age the microbial population has become similar in composition and complexity to that of the foal's dam, which indicates a transition to an adult pattern in readiness for the dietary transition from a milk-based diet to a roughage-based diet.[80,81]

Thermoregulation can be a challenge for the neonatal foal as it transitions from the uterine environment into what is typically a much colder external environment. This challenge is increased by the presence of an initially wet hair coat, which enhances thermal losses to the environment as well as a large surface area to body mass ratio and minimal stores of fat. The healthy foal has a high resting metabolic rate compared with the adult, and in the immediate neonatal period the metabolic rate will be increased at two to three times the basal rate, in association with high concentrations of T_3, T_4, and cortisol.[82] This high metabolic rate allows for substantial endogenous heat production to achieve and maintain normothermia. This metabolic heat production requires substantial inputs of energy in the form of fats and carbohydrates derived from colostrum and milk, reinforcing the critical need for early successful nursing in foals. Another important mechanism that foals rely on for heat production in the immediate neonatal period is shivering thermogenesis. This appears to be particularly important, because foals do not appear to use nonshivering thermogenesis because of minimal or nonexistent stores of brown fat.[83] Foals also use behavioral approaches to thermoregulation, ranging from maintenance of sternal recumbency to minimize heat losses to vigorous activity when attempting to stand and once ambulatory, which generates substantial additional heat.

PREMATURITY, DYSMATURITY, AND INTRAUTERINE GROWTH RETARDATION

Abnormalities of gestation are associated with substantial risk for affected foals, both as a primary syndrome and as a risk factor for a number of other syndromes. Unfortunately, these abnormalities of gestation, which have also been termed *unreadiness for birth*, can be difficult to characterize because of the highly variable duration of equine gestation.[84] In humans the generally accepted definition of prematurity is birth more than 21 days before full term. This concept has been applied to horses as well, with delivery before 320 days' gestation considered premature.[85] Unfortunately gestational duration in the horse is much less consistent than in humans, with reported gestational lengths resulting in live foals ranging from 286 to 380 days (mean 344 days) in Thoroughbred mares and from 313 to 370 days (mean 339 days) in Warmblood mares.[86-88] Pony breeds typically have similar gestational lengths, ranging from 337 to 343 days.[89] Although there are anecdotal reports of draft mares routinely having gestational lengths over 365 days in duration, one recent report suggests that median duration of gestation in heavy horses is only 5 days longer than in light breeds.[90] In addition to the influence of breed there are a number of other variables that impact the duration of gestation including fetal gender; fetal weight; maternal age and parity; and environmental factors such as month of conception or foaling, maternal nutrition, and climate.[88]

Because of the difficulty in defining a specific time point that would be indicative of fetal maturity, equine prematurity should be considered as much a physical and functional characterization as a temporal one. The foal's size and physical appearance are important characteristics related to prematurity. Small body size and low birth weight, along with a prominent rounded forehead, silky hair coat, entropion, and floppy ears, are all common findings in premature foals. Some affected foals may have a prominent reddish discoloration of the tongue, and the mucous membranes may appear somewhat pale. Flexor and periarticular laxity are also common, although some premature foals may exhibit carpal or fetlock contracture. Incomplete ossification of the cuboidal bones in the carpus and tarsus is also a common finding in premature foals, and these areas are at risk of crushing injury when affected foals stand and ambulate. This risk can be minimized by limiting the amount of time that these foals are allowed to stand and by minimizing their activity level.

From a functional perspective premature foals typically exhibit generalized weakness and have great difficulty in standing without assistance. Affected foals often have impaired thermoregulation and abnormal glucose metabolism, as well as impaired cardiovascular, pulmonary, gastrointestinal, and renal function. Impaired thermoregulation is likely caused by inadequate endocrine responses to the change from the uterine environment to the external environment. Abnormal glucose regulation is also indicative

of endocrine dysfunction, potentially caused by impaired insulin production or peripheral insulin insensitivity. Cardiovascular dysfunction most often presents as persistent hypotension that is poorly responsive to pressor therapy. Increased vascular permeability may be present as well, potentially resulting in fluid shifts from the vasculature to the interstitium. For these reasons fluid, inotrope, and pressor support should target the maintenance of perfusion, rather than a target blood pressure range. Failure to use this approach will put the patient at risk of fluid overload and other complications. Respiratory dysfunction may be caused by surfactant deficiency but is also frequently associated with decreased respiratory drive, weak muscles of respiration, a highly compliant chest wall, and poorly compliant lungs. Gastrointestinal dysfunction is typically caused by inadequate motility, which can result in distention, colic, and diarrhea. Renal dysfunction may manifest primarily as decreased urine output rather than azotemia, and care must be taken to avoid fluid overload in these patients.

Clinicopathologic assessment may aid in characterizing these foals. Leukopenia caused by neutropenia combined with lymphocytosis leads to a neutrophil:lymphocyte ratio (N:L ratio) of less than 1.0, as opposed to a normal ratio of greater than 2.0. This reversal of the N:L ratio is a commonly used defining characteristic of equine prematurity and is directly associated with impaired adrenocortical function.[91] This impairment of adrenal function happens because maturation of the HPA axis normally occurs in the last several days of gestation and continues in the first weeks, and perhaps even months, after birth.[64,92-95] As a result, premature foals exhibit low serum cortisol concentrations at birth, in combination with elevated serum adrenocorticotropic hormone (ACTH) concentrations.[92] The inability of premature foals to produce appropriate concentrations of cortisol is caused by an impaired adrenal response to endogenous ACTH, and they exhibit impaired response to exogenous ACTH as well. Assessment of the response to exogenous ACTH may be helpful in characterizing foals as premature, although there is a subset of clinically ill full-term foals that may also exhibit impaired responses to ACTH stimulation testing.[96-98] Although not specific for prematurity, other clinicopathologic changes may include arterial hypoxemia and hypercapnia; hypoglycemia; acidosis; and low-grade macrocytic, normochromic anemia.

Dysmaturity typically refers to foals that are delivered at what appears to be full term but exhibit the characteristics of premature foals discussed earlier. Dysmaturity is most common secondary to placental insufficiency resulting in IUGR.[99] Placental insufficiency can be caused by placental disease, placental separation, or twinning. Other causes of IUGR may include maternal undernutrition or systemic disease. Postmaturity should be distinguished from dysmaturity, and refers to foals born postterm. These foals have been in utero for an excessive length of time, most commonly secondary to maternal ingestion of fescue infected with the endophyte fungus *Acremonium coenophialum*.[32] Physical characteristics associated with postmaturity include a normal to high birth weight associated with a large frame size but with poor body condition. Affected foals may also display flexor contracture, a long hair coat, and fully erupted incisors. They may share a number of other functional characteristics with premature foals, including impaired thermoregulation and abnormal glucose metabolism, as well as impaired gastrointestinal and renal function.

The severity of the abnormalities associated with prematurity are to some extent associated with the duration of the predisposing disease process that led to premature delivery. Foals that have suffered prolonged in utero stress caused by placental disease may be surprisingly "ready for birth" because of stimulation of endogenous cortisol production and early maturation of the endocrine system.[100] In rare cases such foals may survive with aggressive medical intervention even if born as early as 286 days of gestational age, based on the author's personal experience. Foals that have not experienced in utero stress and that suffer from some acute onset condition resulting in premature delivery are much more likely to be "unready" for birth and will exhibit the most dramatic clinical abnormalities. These foals are unlikely to survive if born more than 2 weeks before their expected due date.

Most premature and dysmature foals will require medical intervention and supportive care to survive. These conditions affect all body systems, so thorough evaluation is indicated. Because of substantial crossover in the clinical presentation of these foals with that of the term, septic foal it can be difficult to discriminate among syndromes. Given that premature and dysmature foals are also at heightened risk of sepsis the clinician should reasonably assume that bacterial infection is present at presentation in most cases. Appropriate broad-spectrum antimicrobial therapy is indicated. Specific recommendations for the treatment and support of the critically ill foal will be discussed in detail in the relevant sections of this chapter.

The prognosis for survival of foals suffering from prematurity, postmaturity, and dysmaturity is good with appropriate care. Survival rates can be as high as 80% to 85%, and many of these foals will "catch up" with their peers and attain a normal adult size and normal function. It is important, however, for the owners of foals born profoundly premature (less than 300 days' gestation) to understand that if they survive to adulthood these foals will not likely reach a normal adult size and morphology, and they are unlikely to be able to function as athletes.

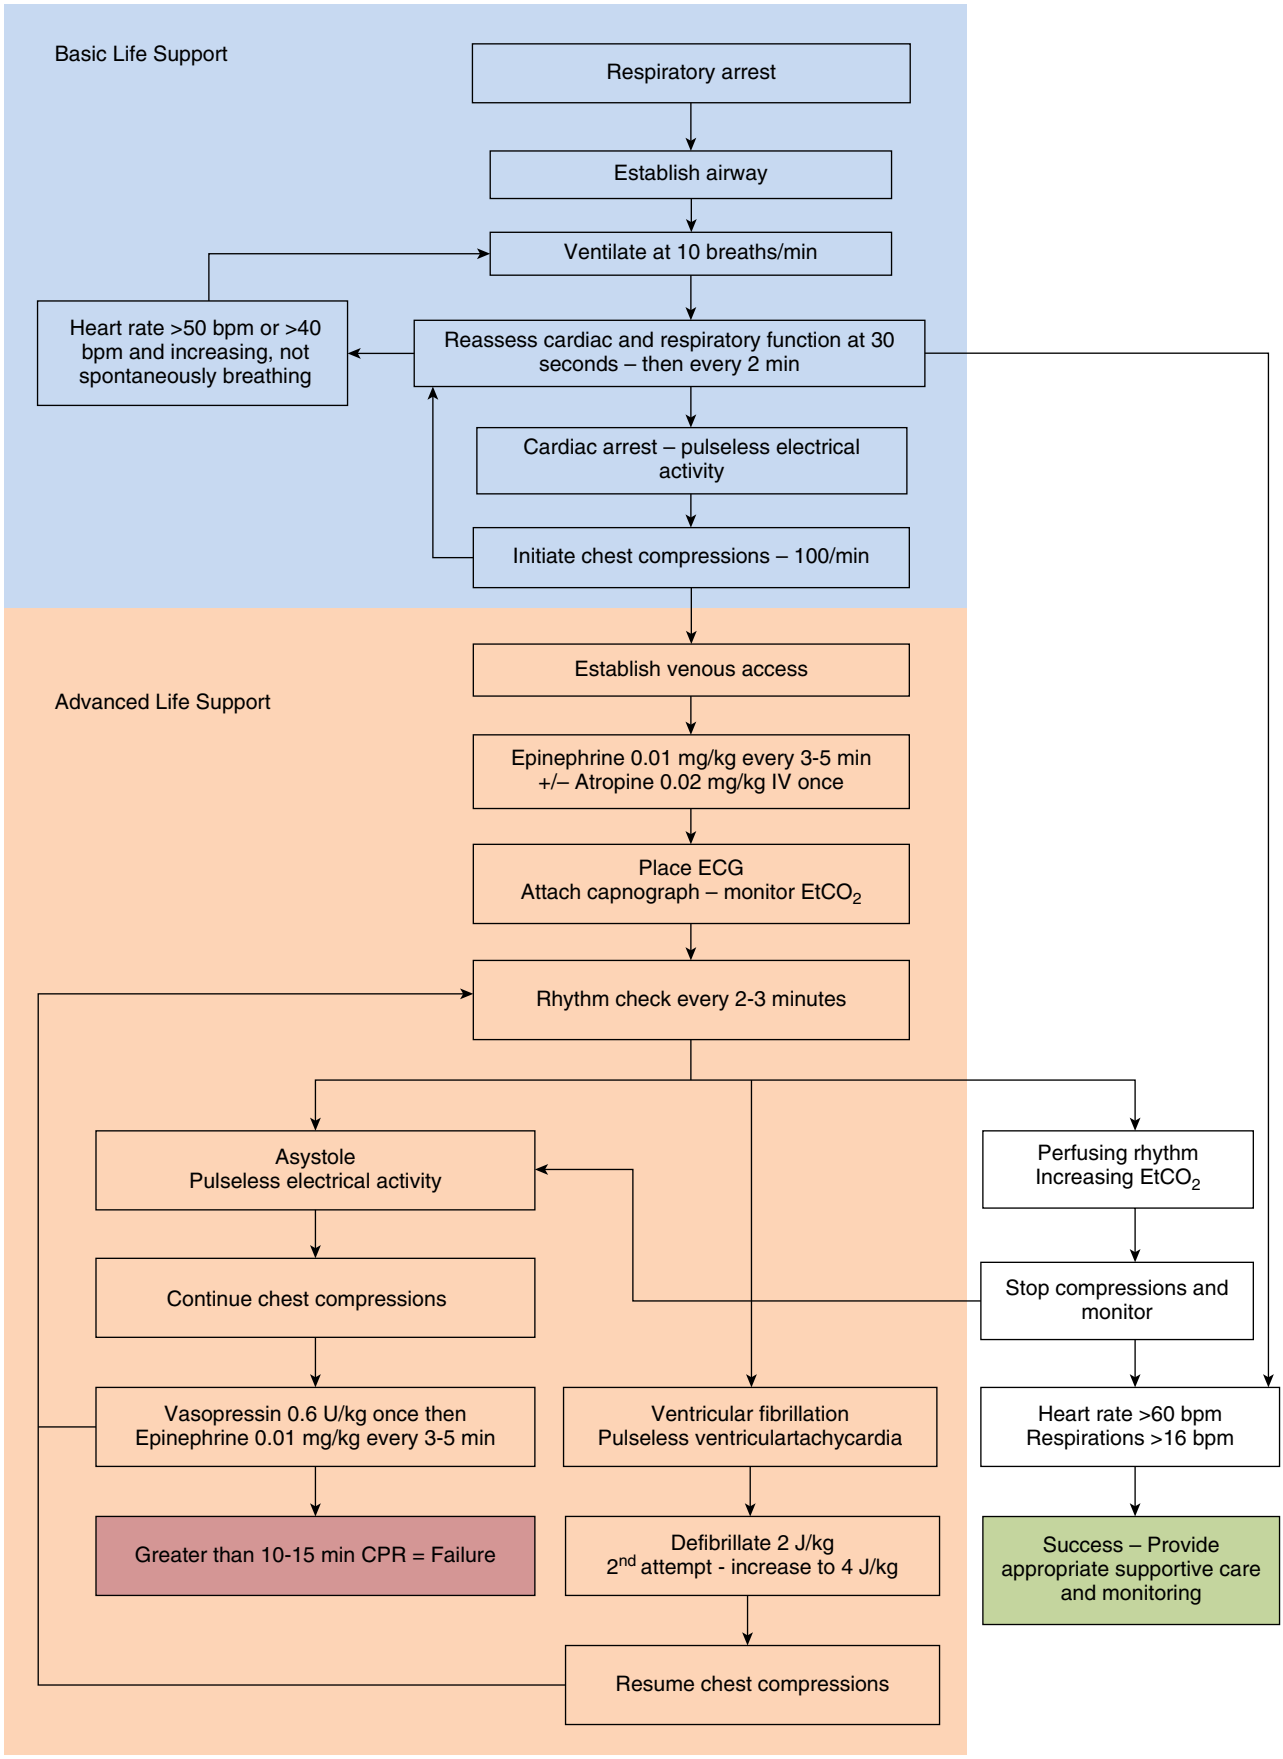
Prevention

The best approach for preventing abnormalities of gestation is close monitoring of the pregnancy to identify any conditions that may affect fetal viability or that may lead to premature delivery. Early treatment of placental infections with antimicrobials, antiinflammatories, and progesterone (altrenogest) may allow for prolongation of gestation and minimization of the abnormalities associated with premature delivery. Induction of parturition should be avoided if at all possible, but if it must be performed then care should be taken to avoid induction of delivery in mares unless the gestational length is known with great certainty. Removing mares from pastures containing endophyte-infected fescue, in combination with administration of dopamine receptor antagonists (domperidone), can decrease the risk of dysmaturity.

NEONATAL RESUSCITATION

Although the need to resuscitate a foal is uncommon, the critical and time-sensitive nature of this intervention requires that all those involved are appropriately trained in recognizing when and how to implement resuscitation efforts. It also requires that the appropriate equipment and drugs are organized and readily available before the event so that there are no delays in implementation. Cardiopulmonary arrest (CPA)

in foals most commonly begins with respiratory arrest, which subsequently leads to cardiac arrest caused by asphyxia, because primary cardiac disease is very rare in foals. This is a very different situation from that seen in most human patients, in which cardiac arrest is usually the primary initiating factor.[101] Because of this the protocol for resuscitation of foals differs substantially from the approach used in human patients. Establishment of a patent airway and the provision of ventilatory support is the initial priority in foals, rather than cardiac compressions (Box 20.1).



The first challenge is in recognizing which foals require resuscitation, because early intervention before cardiac arrest is associated with a much higher likelihood of successful resuscitation, potentially as high as 50%.[102] The situation in which foals are most likely to require resuscitation is parturition, because asphyxia can occur in utero or during dystocia, and the foal may have been in arrest for a prolonged period of time and will be unable to establish normal respirations without resuscitation.[30] The clinical signs that may indicate the need for resuscitation in the immediate postparturient period include absence of breathing, irregular gasping, respiratory rate less than 10 breaths per minute, heart rate less than 40 beats per minute, irregular or absent muscle flaccidity, or lack of response to tactile stimulation.[103] Other situations in which resuscitation may be required include primary lung disease, septic shock, hypovolemia, metabolic acidosis, hyperkalemia, hypoglycemia, vasovagal reflex, and hypothermia.[102,104] It is important to recognize that the prognosis for successful resuscitation and patient survival is much lower with these disease processes because of the severity of systemic illness and likelihood of multiple organ failure. Although it may be possible to resuscitate the patient, unless the underlying disease can be effectively addressed, the likelihood of survival is very low. Cardiac causes of CPA in foals may include secondary myocardial damage associated with severe hypoxia or sepsis, myocarditis, congenital cardiac defects, endocarditis with coronary artery embolism, and cardiac tamponade.[102,104]

Direct monitoring of the foal during delivery by veterinary staff is unlikely except in cases of dystocia and hospitalized high-risk pregnancies. When foaling is attended the assessment of the foal's respiratory and cardiovascular function should begin during delivery. If the foal is noted to be meconium stained the upper respiratory tract should be suctioned immediately, preferably while still in the birth canal and before the first breath. After delivery suctioning of the trachea may be required if the foal is heavily meconium stained or if meconium is detected in the upper respiratory tract. Mechanical suction is discouraged because it is often too aggressive and may actually worsen hypoxemia and potentiate bradycardia caused by vagal reflexes, and if used it should be limited to no more than 5 to 10 seconds of suction time. Following delivery the foal may gasp a few times but should establish a regular breathing pattern within 30 seconds. Persistent gasping, open-mouth breathing, or severe respiratory distress may be an indication of severe or total upper airway obstruction, such as bilateral choanal atresia, dorsal displacement of the soft palate, or stenotic nares. Tactile stimulation, such as vigorous drying with towels, may aid in stimulating the initiation of respiration. A rapid examination should be performed during this time to identify any congenital defects that would render resuscitation inappropriate or inhumane. If the foal fails to begin breathing spontaneously and regularly then an airway needs to be established immediately and basic life support (BLS) should be implemented. The best approach to establishing an airway is to pass a cuffed nasotracheal tube, which is facilitated by placing the foal's head in an extended position. Because of the urgency of the situation a maximum of two attempts to place a nasotracheal tube should be allowed, up to a maximum of 15 seconds. If nasotracheal intubation is unsuccessful then one should immediately proceed with orotracheal intubation or placement of a tracheotomy tube. If nasotracheal tubes are not available then mouth-to-nose ventilation can be used, because the foal is an obligate nasal breather. Care should be taken to occlude the opposite nostril manually to prevent air leakage from that site when ventilation is attempted, and the effectiveness of ventilation can be easily gauged by monitoring the chest rise during ventilation.[104]

After intubation ventilation should be provided with a self-inflating valved manual resuscitation device (Ambu Inc., Ballerup, Denmark) at 10 breaths per minute with a tidal volume of 10 mL/kg.[104] It is very difficult to limit breaths to this low rate, however, because of the stress and excitement of the resuscitation effort, which often leads to ventilation rates upward of 60 breaths per minute. Unfortunately excessive ventilation negatively affects cardiac return and coronary perfusion and has been associated with worsened outcomes.[105] Another challenge is associated with monitoring tidal volume, because there is a tremendous range of manual resuscitation bags available, all of which have different internal volumes and deliver variable amounts of air depending on how fully they are compressed. For this reason it is best to monitor ventilation by observing chest excursion during ventilation, keeping in mind that aggressive ventilation is contraindicated. Although somewhat controversial there may be some benefit to ventilating the newborn foal with 100% oxygen for a brief period of time (1 minute) immediately after delivery to encourage the reversal of persistent fetal circulation.[30,106] However, there is no indication for continued administration of supraphysiologic oxygen concentrations, because these may actually be harmful, and the delivery of room air is most appropriate in foals without underlying respiratory dysfunction.[104] Following 30 seconds of assisted ventilation discontinue ventilation, and observe the foal for spontaneous breathing while also assessing cardiovascular function by monitoring for a heartbeat. If a heart rate of 50 or greater (or between 40 and 50 but increasing)[104] is present but respirations are not, then resume ventilations, stopping every 2 minutes to monitor for spontaneous efforts or sooner if such efforts are obvious. As many as 90% of foals that require resuscitation at birth will respond to ventilatory support alone and require no additional therapy.[30]

If a heartbeat is absent or the rate is too low then immediately initiate thoracic compressions, because any delay may be very deleterious. No more than 10 seconds should be spent trying to assess cardiac function, and the risk associated with unnecessary thoracic compressions is less than that associated with the failure to provide compressions to an animal that needs them. Place the foal in lateral recumbency on a firm surface and quickly palpate for rib fractures before initiating compressions. If there are unilateral rib fractures position the foal with the affected side facing down, and if there are bilateral rib fractures place the side with more cranial rib fractures facing down.[104] The person providing compressions should position themselves to the dorsal aspect of the foal, with their knees against the spine, which will prevent the foal from shifting during compressions. Both hands should be used, with one closed in a fist and placed with the palm down over the

BOX 20.1 Cardiopulmonary Resuscitation Flowchart

Bpm, beats per minute; *$EtCO_2$*, end-tidal CO_2.

foal's heart, and the other hand placed on top of the closed fist. The arms should be kept straight, with the upper body weight being used to drive compressions. A rapid rate of 100 compressions per minute is advised.[102] The depth of compression is difficult to gauge, but "pushing hard" is recommended.[104] Chest compressions should be briefly stopped every 2 to 3 minutes to monitor for the presence of a heartbeat but should be resumed within 10 seconds. If there is only a single individual available to initiate resuscitation for a patient requiring chest compressions, then adjustments must be made. If the patient is not intubated, then it is recommended to provide 30 chest compressions to 2 ventilations, whereas for the intubated patient it is recommended to provide continuous chest compressions and no ventilatory efforts.[104] Although it is not feasible in single-rescuer resuscitation, if multiple individuals are participating in the resuscitation effort then an intravenous (IV) catheter should be placed while resuscitation efforts are ongoing to have IV access for administration of drugs or fluids.

If the foal is not responding to BLS then more aggressive measures (advanced life support) are indicated. These may include administration of pharmacologic agents and implementation of improved monitoring. Many drugs have been used empirically in foal resuscitation, but none has been specifically studied in the foal. The utility of many of these agents is debatable, either because they are directed toward primary cardiac dysfunction, which is rare in foals, or because their use in human cardiopulmonary resuscitation (CPR) has been discontinued. The drug that is most likely to be used is epinephrine, although this is the subject of ongoing debate in the human literature.[107] Epinephrine is administered at 0.01 mg/kg IV every 3 to 5 minutes. If IV access is not available then epinephrine can be administered intratracheally at 0.1 mg/kg, preferably diluted in a small volume (3–5 mL) of sterile water or saline.[104] Vasopressin has been used either in place of, or in combination with, epinephrine in CPR.[108] If used it should be given as a single dose of 0.6 U/kg IV following the first dose of epinephrine.[102] Doxapram has been commonly used in foal resuscitation as a respiratory stimulant, but it is contraindicated because it does not reverse secondary apnea and has been shown to decrease cerebral blood flow and increase cerebral oxygen consumption.[104,109] Atropine and glycopyrrolate have also been used in foal resuscitation, but as high vagal tone is an unlikely cause of bradycardia the benefit of these treatments is unclear. The administration of a single dose of atropine seems unlikely to be harmful, however, and if used atropine should be administered at 0.02 mg/kg IV. Corticosteroids, calcium gluconate, lidocaine, magnesium sulfate, and sodium bicarbonate, while potentially indicated in the treatment of primary cardiac arrest, are not recommended in routine resuscitation of neonatal foals at this time.[104]

Defibrillation

Defibrillation is indicated in cases of ventricular fibrillation and pulseless ventricular tachycardia. Access to appropriate equipment is often limited, however. The widespread availability of human automated electrical defibrillators may alter this situation, but at this time there are no published studies regarding their use in foals. When performing defibrillation the cardiac compressions and ventilation should continue until the moment of defibrillation and resumed immediately afterward. The initial charge should be 2 J/kg, which should be increased to 4 J/kg for subsequent attempts.[102] Defibrillation presents danger to the operator and anyone in contact with the foal, and operators should receive appropriate training before using a defibrillator.

Monitoring Resuscitation

Patient status during resuscitation is extremely dynamic, requiring constant reassessment, and it can be difficult to monitor for return of spontaneous circulation and spontaneous respiration without interfering with the process of resuscitation itself. Following initiation of resuscitation efforts cardiac and respiratory function should be reassessed at 2- to 3-minute intervals unless the foal shows obvious signs of response (Box 20.1). Monitoring via electrocardiography can be challenging, because electrical activity does not necessarily represent effective cardiac contractility, which is a phenomenon termed *pulseless electrical activity*. Respiratory efforts are much more readily observed and their effectiveness subjectively evaluated. One technique that can greatly facilitate monitoring during resuscitation is the monitoring of end-tidal CO_2 ($EtCO_2$), if capnography is available. The sensor is placed on the endotracheal tube and real-time monitoring is readily performed. Normal resting $EtCO_2$ in a healthy spontaneously breathing patient is approximately 40 mm Hg (35–45 mm Hg), whereas the CO_2 in room air is 0.3 mm Hg. During resuscitation a reasonable target for $EtCO_2$ is 10 mm Hg, because this indicates that an adequate degree of perfusion and ventilation is being achieved. If resuscitation is successful then a rapid increase in $EtCO_2$ toward the normal range will be observed, indicating that both perfusion and ventilation are improving. A decrease in $EtCO_2$ during resuscitation indicates inadequate ventilation and perfusion, requiring reevaluation of how resuscitation is being performed. If no response is detected after 10 to 15 minutes of resuscitation it is extremely unlikely that the patient will respond with further efforts.

Postresuscitation Support

Following successful resuscitation the patient should be considered at high risk because of the presence of any primary, initiating diseases and the likelihood of secondary hypoxic injury.[110] Appropriate medical care and monitoring are critical during this period of time. Foals should receive intranasal insufflation of humidified oxygen at 5 to 10 L/min until they have been demonstrated to be stable with adequate cardiopulmonary function. Fluid therapy will likely be of benefit in ensuring normovolemia and supporting cardiovascular function. Care should be taken to avoid overhydration, because these patients may be at risk of pulmonary edema. Pressor and inotrope therapy may be indicated if cardiovascular function is inadequate. Glucose support is important, especially in neonates, but care should be taken to avoid hyperglycemia. If resuscitation occurred in the field then serious consideration should be given to immediately referring the foal to a facility equipped to provide intensive care.

NEONATAL SEPSIS

The management of critically equine neonates is extremely challenging, but there have been tremendous advancements in the care of these foals over the past several decades. The gradual decline in mortality rates for hospitalized foals over the past 30 years, although likely because of a number of factors in addition to advances in treatment, serves as strong evidence of the progress that has been achieved. Reported survival rates

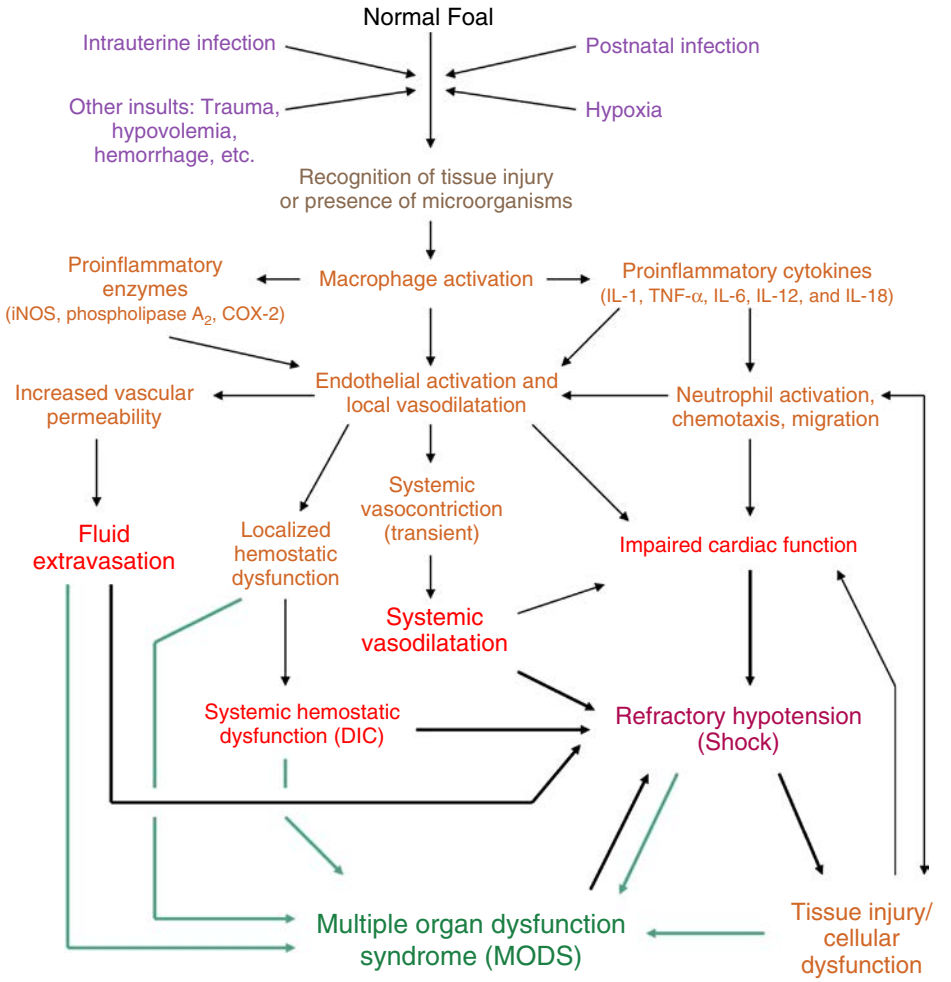
for hospitalized foals in North America have slowly trended upward from approximately 60% in the 1980s to around 70% in the 1990s and then 70% to 80% in the 2000s.[111-116] As encouraging as these numbers are it is important to note that the survival rates for foals suffering from sepsis are lower than those for all sick foals presenting to a hospital. In the 1980s it was reported that only 26% of septicemic foals survived, whereas a more recent study in 2006 reported that 57% of septic foals survived.[117,118] This is compared with reported survival rates of hospitalized sick, nonseptic foals of 75% to 95%.[118-122] The relatively poor prognosis for septic foals is caused by many factors, not least of which is the fact that sepsis represents a systemic inflammatory response to infection or injury and can rapidly progress to septic shock and death despite aggressive treatment. Traditionally, the term *septicemia* is used to refer to this process in the equine neonate and describes a systemic disease process involving the presence of pathogenic microorganisms and/or their toxins in the blood.[123,124] Historically the typical presentation of sepsis in foals was that of disseminated gram-negative bacterial infections; however, it has become clear that an identical syndrome may occur in patients with gram-positive or mixed bacterial infections, viral infections, trauma, hypovolemia, hemorrhage, and immunologic and drug reactions.[125-127]

Pathophysiology

The abnormalities associated with the clinical syndrome of sepsis result from a nonspecific innate inflammatory response, which has been termed the *systemic inflammatory response syndrome* (SIRS).[125] SIRS represents a common terminal phase of the inflammatory response characterized by malignant global activation of multiple proinflammatory pathways and is characterized by parameters that can be readily defined in clinical patients. These manifestations of disease are the same as those previously used to define sepsis, but the appreciation that many different stimuli can induce this response has resulted in sepsis being redefined as SIRS because of infection (Table 20.1).[128,129] The changes associated with SIRS can lead to shock, which is characterized by severe hypotension not responsive to IV fluid therapy (Box 20.2). Shock can result in hypoperfusion and organ dysfunction such that homeostasis cannot be maintained without intervention. This process is termed *multiple organ dysfunction syndrome* (MODS).[125] MODS represents a progressive syndrome with initial dysfunction seen in the cardiovascular system, followed by involvement of the respiratory, hepatic, gastrointestinal, renal, cardiac, and neurologic systems. These processes result in the development of refractory hypotension, lactic acidosis, and oliguria and may progress to death. SIRS criteria were proposed 15 years ago for the neonatal foal population and are based on human criteria using information regarding normal values in foals.[124,130] SIRS criteria have been used in a number of studies of clinically ill foals since that time and have been correlated with increases in both lactate concentration and mortality.[130,131] A recent report has proposed a revised set of SIRS criteria that are age dependent and based on insight from revised human pediatric SIRS criteria and that incorporate the changes in normal values that occur with increasing age in foals (Table 20.2).[132]

Inflammation represents the response of tissues to either injury or the presence of microorganisms. It serves a vital role because it enhances the movement of phagocytic cells and defensive molecules, such as immunoglobulin and complement, from the bloodstream to the site of infection or injury.

TABLE **20.1 Definitions of Terms Used to Describe Clinical Syndromes Associated with Systemic Inflammation**



Infection	Inflammatory Response to the Presence of Microorganisms or the Invasion of Normally Sterile Host Tissue by Microorganisms
Bacteremia/septicemia	Presence of viable bacteria in the bloodstream
SIRS	Systemic response to an array of severe clinical insults
Shock	SIRS-induced hypotension refractory to fluid resuscitation in association with hypoperfusion
Sepsis	SIRS caused by infection
Severe sepsis	Sepsis associated with organ dysfunction, hypoperfusion, or hypotension
Septic shock	Sepsis-induced shock
MODS	Altered organ function in an acutely ill patient requiring intervention to maintain homeostasis

MODS, multiple organ dysfunction syndrome; *SIRS,* systemic inflammatory response syndrome.
Adapted from Nathens AB, Marshall, JC. Sepsis, SIRS, and MODS: What's in a name? *World J Surg*. 1996;20(4):386-391; Bone RC, Grodzin CJ, Balk RA. Sepsis: a new hypothesis for pathogenesis of the disease process. *Chest*. 1997;112(1):235-343.

The first step in this process is the recognition of tissue injury or microbial invasion. Trauma or microbial invasion results in tissue injury, and injured cells then release or produce damage-associated molecular patterns, and these mediators can initiate a nonspecific inflammatory response.[133] Alternatively, specific bacterial cell components, termed *pathogen-associated molecular patterns* (PAMPs), may be recognized by immune cells that produce inflammatory mediators, leading to the initiation of an inflammatory response and subsequent amplification of that response.[133,134] Some of the PAMPs that can be recognized by the immune system include lipopolysaccharide (LPS; endotoxin), exotoxins from gram-negative bacteria, peptidoglycan, lipoteichoic acids, enterotoxins, or superantigenic exotoxins from gram-positive bacteria.[124,135] The development of an inflammatory response is dependent on the production, primarily by the activated mononuclear phagocyte, of numerous inflammatory mediators, including proinflammatory cytokines (tumor necrosis factor-α [TNF-α,] interleukin [IL]-1, IL-6), proinflammatory enzymes (inducible nitric oxide synthase, phospholipase A_2, cyclooxygenase-2 [COX-2]) and adhesion molecules (selectins and intercellular adhesion molecules).[136] The transcription of many of the genes encoding for these mediators, or the enzymes that produce them, is dependent on the transcription activator nuclear factor-κB, and this molecule may be a potential target for intervention in SIRS.[137-139]

It is important to understand that although bacterial infection may be responsible for the initiation of an inflammatory response, the inflammatory process itself results solely from the production of endogenous mediators. The initial changes seen in an inflammatory response are primarily the result of local vasodilatation and increased vascular permeability

BOX 20.2 Pathophysiology of Shock in the Neonatal Foal

caused by the effects of vasoactive mediators released by the injured or infected cell. On their arrival at the site of tissue injury, neutrophils and macrophages phagocytose foreign material and injured or dead tissue cells and attempt to destroy the phagocytosed material. In addition, macrophages release a number of factors that augment the immune response, including the proinflammatory cytokines IL-1, TNF-α, IL-6, IL-12, and IL-18. These proinflammatory cytokines increase the production of secondary inflammatory mediators, including phospholipid derivatives (prostaglandins, thromboxane A_2, and leukotrienes), and reactive oxygen species (ROS), further increasing the activity of the inflammatory response. The systemic manifestations of inflammation/infection (fever, lethargy, malaise, loss of appetite, and cachexia) are primarily caused by TNF-α and IL-1. The cytokines IL-6, IL-1, and TNF-α initiate the acute phase response in which the liver increases production of acute-phase proteins (fibrinogen, serum amyloid A, plasminogen, complement, haptoglobin, ceruloplasmin, ferritin, C-reactive protein, etc.).[140] These substances are important in many phases of the response to inflammatory stimuli, including complement activation, coagulation, fibrinolysis, transport of substances within the bloodstream, inhibition of neutrophil proteases, and modulation of the inflammatory response.[141] The acute phase response is critical in inflammation, healing, and adaptation to noxious stimuli. Also included in the acute phase response is a counterregulatory antiinflammatory component that normally functions to minimize and resolve the inflammatory response to localized stimuli. This counterregulatory response consists of antiinflammatory mediators that inhibit macrophage activation (IL-4, IL-10, IL-13, adrenal corticosteroids, transforming growth factor-β and prostaglandin-E_2), antagonists to the receptors for proinflammatory cytokines (IL-1 receptor antagonists), and soluble receptors of proinflammatory cytokines (soluble IL-1 receptor type II and soluble TNF receptors).[142] The balance between these proinflammatory and antiinflammatory components is very important in determining the characteristics of the inflammatory response, because excessive activity of the antiinflammatory component may result in immunosuppression during or after a severe inflammatory response, which has been termed the *compensatory antiinflammatory response syndrome*.[125]

In moderation the changes associated with an inflammatory response are protective, resulting in the enhanced killing of microbes by antigen-specific and nonspecific mechanisms, generalized immune stimulation, and increased activity of the systems required for healing damaged tissue. SIRS, the excessive, malignant form of the inflammatory and acute-phase responses, is characterized by the systemic activity of numerous proinflammatory mediators. These mediators all represent components of the normal inflammatory response to a localized stimulus, but the systemic activity of these proinflammatory mediators may result in an excessive, and often detrimental, response. One of the first effects seen in SIRS is widespread endothelial activation, resulting in the increased production of vasoactive mediators and alteration of vascular homeostasis. Inflammatory cytokines are responsible for activation of the endothelium, and the activated cells produce inflammatory cytokines, as well as increased amounts of nitric oxide (NO), prostaglandins, and endothelin-1.[143] Activated endothelial cells retract from one another, increasing the size of the intercellular pores and allowing for increased vascular permeability, and increase their production of tissue factor and von Willebrand factor, resulting in localized thrombosis and platelet adherence.[144]

One of the earliest systemic effects is pulmonary vasoconstriction leading to pulmonary hypertension.[145] This phase is followed by systemic hypotension caused by decreased arterial tone resulting in decreased left ventricular afterload, combined with venous vasodilatation in the large-capacity vessels that decreases venous return and right ventricular preload. These effects can progress to the syndrome of hyperdynamic shock, with increases in heart rate and cardiac output developing as compensatory mechanisms to maintain tissue perfusion.[146] This compensatory response is impaired by the reduction in left ventricular preload resulting from decreased peripheral vascular resistance, combined with decreased cardiac contractility.[147] Changes occurring in the microvasculature further contribute to the impairment of tissue perfusion. Arteriolar vasoconstriction develops because of the impairment of the normal autoregulatory systems caused by inflammatory cytokines and endothelin-1, combined with the increased production of vasoconstrictive substances. Adherence of neutrophils to the endothelium and endothelial cell swelling further reduces blood flow. Accumulation of fibrin and aggregation of platelets and red blood cells secondary to activation of the clotting system results in occlusion of the vasculature, resulting in tissue hypoperfusion. Arteriovenous shunting occurs in some tissues, whereas increased vascular permeability results in leakage of intravascular fluid into the interstitial space, further contributing to hypotension and hypovolemia and contributing to the development of tissue edema. Progressive alteration of the microcirculation leading to failure may represent the "common final pathway" of SIRS-related injury contributing to or resulting in MODS.[148]

Activation of coagulation occurs primarily through the extrinsic pathway, and endothelial injury secondary to neutrophil degranulation results in increased platelet adhesion.[149] In the normal state the accumulation of the resulting excessive amounts of fibrin would be prevented by the action of plasmin, the primary mediator of fibrinolysis. In the presence of SIRS the fibrinolytic system is suppressed because of the increased plasma concentration of plasminogen-activator inhibitor type 1, the primary inhibitor of fibrinolysis.[150] The widespread activation of the clotting system combined with impairment of fibrinolysis and depression of the inhibitors of coagulation can result in a consumptive coagulopathy potentially leading to disseminated intravascular coagulation (DIC).[150,151] Several reports have demonstrated that clinicopathologic and histopathologic evidence of coagulopathy is common in septic foals, and these findings are associated with a worsened prognosis for survival.[152-156]

The progression of these processes affecting the cardiovascular system ultimately results in shock. Shock occurs when cardiovascular function is severely impaired to the point that hypotension cannot be corrected with IV fluid administration, requiring the use of inotropic and/or vasopressor agents.[157] Shock represents severe cardiovascular dysfunction associated with SIRS and is a primary component of MODS. The development of MODS is likely the result of cardiovascular dysfunction leading to tissue hypoperfusion combined with changes in cellular metabolism that result in impairment of oxygen delivery and uptake.[158] Tissue hypoxia is manifested by increased oxygen extraction ratios and metabolic acidosis caused by increased lactate production. Pulmonary dysfunction is manifested by refractory hypoxemia, potentially caused

by increased pulmonary vascular permeability, microthrombi formation, pulmonary epithelial injury, pulmonary edema, and impairment of surfactant production.[159] Renal dysfunction is manifested by the development of azotemia and oliguria, and this acute renal failure is likely caused by alterations in the distribution of intrarenal blood flow arising from microvascular alterations with or without systemic hypotension.[158] Gastrointestinal dysfunction is primarily manifested by the presence of ileus but may also result in loss of the normal barrier function of the gastrointestinal mucosa. Impairment of the mucosal barrier may further contribute to the pathogenesis of MODS caused by bacterial translocation or endotoxin absorption.[160] Hepatic dysfunction is manifested by the development of hyperbilirubinemia and in some cases increased serum activities of hepatic enzymes (sorbitol dehydrogenase [SDH] and aspartate aminotransferase [AST]).[158] Hepatic dysfunction may result from hypoperfusion but may be heightened by the production of inflammatory mediators by the hepatic Kupffer cells secondary to the actions of systemic mediators or stimuli derived from the gastrointestinal tract.[161] Dysfunction of the central nervous system (CNS) is frequently present and may manifest as depression, which can progress to septic encephalopathy with extensive neuronal injury.[162] The development of consumptive coagulopathy (DIC) could also be considered a component of MODS, rather than merely a pathophysiologic process contributing to the development of organ failure.

Risk Factors for Neonatal Sepsis

A number of factors have been identified that increase the likelihood of septicemia in equine neonates. These risk factors may include history of placentitis, prenatal vulvar discharge, dystocia, maternal illness, premature or delayed parturition, premature placental separation, induced parturition, partial or complete failure of transfer of passive immunity (FTPI), poor sanitary conditions, improper umbilical care, prolonged transport of the pregnant mare, and the presence of localized disease in the neonate (anterior uveitis, diarrhea, pneumonia, infectious arthritis, and open wounds).[163,164] Inadequate transfer of passive immunity (serum IgG concentration of <800 mg/dL) represents a critical risk factor for septicemia and death in foals, with the risk of infection and death increasing proportionally with decreasing IgG concentrations (see later section Immunologic Disorders).[165] Pathogenic organisms can infect the equine neonate by numerous routes, although in the intrauterine environment the fetus may be exposed to organisms that have invaded the placenta or that cross the placentochorial barrier and gain direct access to the foal's bloodstream. Bacteria associated with placental disease may enter the amniotic fluid and gain access to the respiratory and gastrointestinal tracts of the fetus. After birth, infection can occur following contamination of the umbilical stump, ingestion, inhalation, or secondary to wounds.[123,164]

Clinical Presentation and Identification of the Septic Neonate

The presenting signs associated with sepsis in the neonatal foal are often vague and nonspecific. Foals may exhibit depression, lethargy, and partial or complete absence of nursing behavior. Tachycardia and tachypnea are also common initial signs but are not consistently present. Signs of systemic inflammation may include abnormal mucous membranes, with a prolonged capillary refill time, and a dark red or injected appearance. Petechiation of the mucous membranes or the skin of the inner pinnae may be present. Fever is not consistently present, because neonatal foals may exhibit impaired thermoregulation, and hypothermia is not uncommon in this population. There may be additional signs of localized infection, such as diarrhea, joint effusion (with or without lameness), respiratory disease or distress, lameness, uveitis, seizures, subcutaneous abscesses, omphalitis, or patent urachus.[164] Additional diagnostic evaluation using ultrasonography may be useful in identifying the presence of pulmonary inflammation or infection, joint or physeal infection, and internal involvement of the umbilical remnants.

Clinicopathologic evaluation of the clinically ill foal can be helpful in supporting the clinical suspicion of sepsis. Septic neonatal foals have been demonstrated to exhibit lower white blood cell (WBC), neutrophil and lymphocyte counts, and higher band neutrophil and monocyte counts compared with healthy age-matched control foals.[152] Azotemia is commonly encountered in this population but may reflect placental insufficiency (spurious hypercreatininemia) rather than neonatal sepsis or renal insufficiency.[114,166] Azotemia typically resolves rapidly with standard treatment unless underlying renal disease or uroperitoneum is present.[166] Blood glucose abnormalities are common in septic foals, with hypoglycemia being the most common.[131] This is likely caused by decreased milk intake combined with limited endogenous energy stores but may also be associated with SIRS. Arterial blood gas evaluation is extremely useful and often reveals the presence of acidosis, which may be metabolic, respiratory, or mixed in nature. Hypoxemia and/or hypercapnia may also be identified, typically in more severely affected patients. The measurement of blood lactate concentration is increasingly performed because of the availability of handheld lactate meters, and hyperlactatemia is a common finding.[167-169] Blood lactate concentrations are consistently higher in normal neonatal foals than normal adult horses for the first 24 to 72 hours of life, with normal foals exhibiting values of up to 5.0 mmol/L in the first 24 hours,[20,64] with a recent report finding values as high as 10.2 mmol/L immediately after birth.[167] In that study lactate concentrations steadily decreased over the first 3 days of life, but the median concentration at 72 hours remained slightly increased relative to normal adult concentrations, at 1.7 mmol/L. Serial measurement of blood lactate may be useful in assessing the foal's response to therapy, because the failure to normalize lactate over time has been associated with a poor prognosis for survival.[170]

The most definitive test for antemortem identification of the septicemic equine neonate remains blood culture, which should be performed at presentation in any equine neonate with a clinical suspicion of sepsis, ideally before the administration of antimicrobial therapy. This test has been reported to have fairly poor sensitivity, with false negative results obtained in up to 37% of cases of fatal septicemia.[171] It is likely that the false negative rate would be much higher in less severely ill foals that recover with antimicrobial therapy. For this reason, it has been recommended that multiple samples be collected to maximize the sensitivity of blood culture, but the majority of isolates have been reported to be present in the first culture sample, and the need for immediate antimicrobial therapy usually results in only one sample being obtained. Although it is recommended that blood culture sampling should occur before the initiation of antimicrobial therapy, there is evidence

in human patients that a delay in the initiation of antimicrobial therapy of more than 3 hours from the onset of clinical signs is associated with increased morbidity and mortality, and current recommendations suggest a delay of no more than 1 hour.[172-175] In the referral setting most foals will have been exhibiting signs of sepsis for longer than that period of time, so early blood culture collection and initiation of antimicrobial therapy is critical. For this reason when a case is being referred from the field it is advisable to initiate antimicrobial therapy on the farm before referral if transport to the referral center is likely to require more than 30 minutes. Although this may decrease the likelihood of obtaining a positive blood culture, the benefit of early treatment likely outweighs the loss of diagnostic information. It is also important to obtain bacterial cultures from suspected areas of infection during the course of treatment because the blood culture may be falsely negative or nosocomial infection may have developed during the course of treatment. The appropriate samples are dependent on the system affected but could include transtracheal aspirate, blood, urine, synovial fluid, peritoneal fluid, cerebrospinal fluid (CSF), and umbilical remnants following surgical resection.

Although historically gram-positive organisms were most commonly associated with neonatal infections, over the past 30 years the most common bacteria isolated from infected foals have been gram-negative organisms (Table 20.3).[120,171,176-182] Gram-positive organisms isolated from infected foals are often present in mixed infections with gram-negative organisms, and streptococcal species are most common. Other organisms associated with severe systemic inflammation in the equine neonate include equine herpesvirus type 1 (EHV-1) and equine viral arteritis.[183,184] It is also possible that severe hypoxia leading to hypoxic ischemic encephalopathy (HIE; neonatal encephalopathy [NE], neonatal asphyxia, and dummy foal syndrome) represents a causative factor for induction of SIRS in the equine neonate.[185]

Rapid identification of the septic neonate is critically important in ensuring that appropriate treatment is administered and in determining the prognosis for survival. The identification of the septic neonate remains problematic, however, because neonates presenting with clinical abnormalities consistent with sepsis (SIRS) may be negative on blood culture with no evidence of a focal site of infection. Attempts to identify equine neonates with septicemia have included the development of a sepsis scoring system combining historical information, objective data, and subjective measures to derive a numerical representation of the patient's condition.[24,117] Using a cutoff of ≥12 the sensitivity and specificity of the modified version of this scoring system were reported to be 93% and 86%, respectively. Unfortunately the specificity and sensitivity may not always be this high; a subsequent study found that the modified sepsis score yielded sensitivity of 67%, a specificity of 76%, a positive predictive value (PPV) of 84%, and an NPV of 55%.[186] The authors of that report suggested that it might be that this scoring system must be adapted to each ICU in which it is applied to achieve reasonably high levels of sensitivity and specificity. In another study the modified sepsis scoring system failed to predict sepsis in 49% of bacteremic foals.[178] A more recent study investing the application of the modified sepsis scoring system in a large population of 1065 foals proposed a revised cutoff value of >7, resulting in a sensitivity of 84.4% and a specificity of 41.8%, compared with the original cutoff of ≥12, which had a sensitivity of 56.4% and specificity of 73.4%.[187]

TABLE **20.3 Organisms Isolated from Foals with Sepsis/ Septicemia with Frequency of Isolation**

	Organism	Pre-2000 Isolates	Post-2000 Isolates
Gram negative	*Escherichia coli*	30.6–56	22.4
	Klebsiella pneumoniae	3.7–12.9	0.8–5.7
	Actinobacillus spp.	8–30	6.5–12.4
	Enterobacter spp.	3.5–14	3.2–8.1
	Pseudomonas aeruginosa	2–4.7	2.9
	Citrobacter spp.	4.7	—
	Pasteurella spp.	3.7	—
	Salmonella spp.	2.8–5	3.4
	Serratia marcescens	2.8–3.7	—
	Acinetobacter spp.		5.6
Gram positive	β-Hemolytic streptococci	1.2–8.8	10.6
	Other streptococci	5.9–7.1	4.1
	Staphylococcus spp.	2.8–4.8	6.3–9.7
	Clostridium spp.	2.4–3.7	1.6
	Enterococcus spp.	4.6–14	12.0–12.1

Ultimately, no sepsis score can substitute for clinical judgment, and these scores should be used as a diagnostic aid in the identification of high-risk individuals, with full consideration given to their limitations.[163,188] There has been interest in the use of serum amyloid A (SAA) as an early and accurate biomarker of bacterial infection in neonatal foals, and an early report suggested a cutoff of >100 mg/L as being highly suggestive of infection.[189] A recent unpublished study by Jokisalo et al.[104] found that using the cutoff point of >100 mg/L yielded a sensitivity of 68.6% and specificity of 68.5%, and the NPV was 87%.[190] Unfortunately 11 of 36 foals considered to be septic in that study had SAA concentrations below 25 mg/L, and 9 of 36 septic foals had SAA concentrations less than 10 mg/L, which indicates that low SAA concentrations do not rule out the possibility of bacterial sepsis.[190] Other potential biomarkers of sepsis in foals, such as IL-1β, plasma C-reactive protein, and haptoglobin, have been investigated but do not appear to be strong or accurate predictors of sepsis.[191,192] Although abnormalities of blood glucose concentration and lactate concentration are common in septic foals, these biomarkers appear to be most useful in prognostication rather than identification of the septic neonate.[126,131,193]

Because of the difficulty of definitively identifying neonates with bacterial infection it is appropriate to make the assumption that all high-risk neonatal foals presenting with clinical illness are septic.[194] Aggressive, early antimicrobial therapy is indicated, and although there are some risks associated with antimicrobial therapy these are greatly outweighed by the risks associated with withholding antimicrobial therapy from a patient with sepsis secondary to bacterial infection. An initial antimicrobial regimen should provide broad-spectrum coverage including organisms commonly identified in the practice population or region. While a detailed discussion of antimicrobial therapy can be found in the antimicrobial section of this chapter, a reasonable initial approach is the use of penicillin or ampicillin in combination with an aminoglycoside, typically amikacin. If there are concerns regarding renal insufficiency then the aminoglycoside can be replaced by a third-generation cephalosporin. Monotherapy with a third- or fourth-generation cephalosporin may be a reasonable alternative to combination therapy, particularly in the severely dehydrated patient, but may not provide full coverage for gram-positive pathogens.

Management

Management of the septic neonate can be challenging because of the requirement for constant monitoring and the need for substantial nursing care. Fluid therapy is indicated in the resuscitation and stabilization of clinically ill foals and can initially take the form of intermittent 20-mL/kg boluses given over 10 to 30 minutes. This typically needs to be accompanied by appropriate maintenance fluid therapy (see later section Fluid Therapy in the Foal). The presence of fluid-refractory hypotension may require the use of inotropic and vasopressor therapies (see later section Inotrope and Vasopressor Therapy). Respiratory support is beneficial, and in most cases it consists of intranasal insufflation of humidified oxygen at 5 to 10 L/min using a nasal cannula. Respiratory stimulants (caffeine and doxapram) may be beneficial in foals with decreased respiratory drive. If these interventions are not adequate then mechanical ventilation may be necessary. Additional therapies may include the administration of hyperimmune plasma, either for supplementation of immunoglobulins, colloidal support, or the treatment of SIRS. Antiinflammatory therapies are sometimes used, primarily consisting of nonsteroidals, but these sometimes including corticosteroid therapy if critical illness–associated corticosteroid insufficiency (CIRCI) is suspected (see later sections Antiinflammatory and Analgesic Therapy and Endocrine Disorders). Care should be taken regarding the use of antiinflammatory therapies in critically ill foals, however, because of the risk of gastrointestinal ulceration or renal injury. Gastroprotectant therapy using proton pump inhibitors is generally not used in the first few days of life because of concerns regarding increased susceptibility to nosocomial infections, but sucralfate may be a reasonable option to those drugs (see later section Gastrointestinal Disorders). The use of low-molecular-weight heparin and/or the administration of fresh or fresh frozen plasma have been suggested to address coagulopathies in the critically ill foal.[190,195]

Nursing care is one of the most important aspects of treating septic foals. Foals should be kept warm and dry, which can be difficult in the recumbent patient because of frequent urination and defecation. The placement of a urinary catheter should be considered in these patients, even though it may present a risk regarding urinary tract infections, because it greatly facilitates their nursing care, decreases the risk of decubital ulceration, and provides a means of monitoring urine output. Recumbent foals should be kept in a sternal position as much as possible to minimize the development of atelectasis in the dependent lung, and they should be turned at no longer than 2-hour intervals. Feeding septic foals can be a challenge if gastrointestinal function is abnormal, and parenteral nutrition may be needed (see the later section Nutritional Support for the Foal). Blood glucose levels should be monitored frequently, especially in foals receiving parenteral nutritional support. The development of persistent hyperglycemia may require the institution of insulin therapy. If at all possible, foals should be weighed daily; this can be another means of monitoring for fluid retention.

Prognosis

The costs associated with the intensive care of affected foals are substantial, and for that reason it is important to strive to provide an accurate prognosis for survival as well as for long-term athletic function. Given the broad range of prognostic indicators that one can use to assess the odds for survival of a critically ill foal, it can be challenging to provide an accurate and timely prognosis for the owner of such a patient. Experienced clinicians are able to provide accurate predictions for survival, but given that there will always be variations in clinician experience level and performance there has been substantial interest in developing a scoring system that could be used prospectively to enhance prognostic accuracy. In 1992 Hoffman et al. performed a study of predictive variables for survival in hospitalized neonatal foals.[111] In that study they retrospectively identified two predictive variables, anion gap and the venous partial pressure of oxygen (Pvo_2), and when these were applied prospectively in a population of 48 foals their model showed a PPV for survival of 62% and an NPV of 100%. In 1997 Furr et al. performed a similar study, developing a predictive equation for outcome in a population of 99 hospitalized neonatal foals.[112] They identified several variables associated with nonsurvival, but their model ultimately retained a different set of predictive variables, which were heart rate, rectal temperature, and neutrophil count. This model yielded a PPV of 78% and an NPV of 78% in the retrospective population. When applied prospectively to two populations of hospitalized foals the model performed differently in the two populations, with a PPV of 93% and an NPV of 72% in one population as opposed to a PPV of 83% and an NPV of 44% in the other. This was likely caused by fundamental differences in the types of cases referred and the timing of presentation to the two different hospitals.

Rohrbach et al. performed a large, multicenter study to create a predictive model for the probability of hospital discharge in hospitalized foals less than 7 days of age.[196] The variables retained in their model were foal age, ability to stand, presence of a suckle reflex, WBC count, serum creatinine concentration, and anion gap. This model yielded a PPV of 95% and an NPV of 65% in the retrospective population. When applied prospectively the model demonstrated a PPV of 90% and an NPV of 46%. Rohrbach et al. also reported the accuracy of clinician prediction of outcome, which was 83% in the retrospective population, as opposed to 81% accuracy for the mathematical model; however, the predictions were not well correlated. Interestingly, by combining the clinician's initial prediction with the model output they were able to improve the accuracy of

TABLE **20.4 Survival Scoring System Proposed by Dembek et al.**[115]

Variable	Value	Points	Value	Points	Score
Cold extremities	No	2	Yes	0	
Prematurity (<320 days)	No	1	Yes	0	
>2 infection/inflammatory sites	No	1	Yes	0	
IgG (mg/dL)	<400	0	≥400	1	
Glucose (mg/dL)	<80	0	≥80	1

From Dembek KA, et al. Development of a likelihood of survival scoring system for hospitalized equine neonates using generalized boosted regression modeling. *PLoS One*. 2014;9(10):e109212.

the survival estimate by 12%.[196] Another multicenter study was performed by Dembek et al., in which they developed a survival scoring system for critically ill foals.[115] Their final model retained six variables, which were cold extremities, prematurity, ≥2 infection/inflammation sites, IgG concentration, glucose concentration, and WBC count. These variables were assigned scores depending on their respective values, and totaling of the individual scores yields the final survival score (Table 20.4). A score of 0 was associated with a 3% probability of survival, whereas the maximum score of 7 was associated with a 97% probability of survival (Table 20.5). They validated their foal survival score (FSS) prospectively using score cutoffs of ≥4 for foals predicted to survive and <4 for foals predicted to die, which resulted in values for a PPV of 91% and an NPV of 86%. Foals with an FSS of 4 to 5 were 24.2 more likely to survive than foals with a score <4, and foals with a score of 6 to 7 were 91 times more likely to survive.[115] Most recently, Giguère et al. reported a retrospective study examining factors associated with survival in a population of 1065 hospitalized foals over 26 years at one academic referral hospital.[116] The variables retained in their model included positive blood culture, neutropenia, hypothermia, bicarbonate, P_{CO_2}, presence of infectious orthopedic disorders, and sepsis score. The reported sensitivity of their model was 97%, and the specificity was 75%. Of particular interest was the increase in the odds of survival for foals born in the 1990s, which were 2.2 times greater compared with those born in the1980s, whereas foals born in the 2000s had a 3.4 times greater odds of survival compared with those born in the 1980s.[116]

NEUROLOGIC DISORDERS

Weakness and abnormal behavior are common presenting signs in clinically ill foals and may be associated with neurologic dysfunction; however, they may also be caused by a myriad of other conditions. For this reason thorough evaluation and assessment of abnormal foals is extremely important. This evaluation should include the collection of a thorough history (to include maternal health and reproductive history) and performance of a complete physical examination, which should include a detailed neurologic assessment. The first objective of neurologic assessment is to ascertain whether true neurologic dysfunction is present and, subsequently, to establish neuroanatomic localization of any lesions. This information is then used to direct further diagnostic and therapeutic efforts.

The first stage of the neurologic examination should be assessment of the foal's behavior and level of alertness, but when doing so it is important to remember the normal development and progression of foal behavior. In the first few hours after parturition foals exhibit fairly dramatic increases in consciousness, strength, and coordination, as well as awareness of and interaction with their environment. Thus it is important to understand at what point they should be along that continuum based on the time since birth. Most foals will be able to stand within 1 to 2 hours of birth, and it is typical for the initial efforts at standing to be poorly coordinated and at times unsuccessful. The initial stance will be base wide, with prominent swaying back and forth. However, once the foal stands successfully rapid improvement in ambulation should be noted and the foal will begin seeking the mare's udder. A suckle reflex should be present within minutes after birth, and foals will actively engage in suckling behavior even while recumbent and without access to the udder. Most foals suckle successfully within 1 to 3 hours after birth, but this can range from 0.5 to 7 hours. Nursing episodes should last from 1 to 5 minutes and are typically followed by periods of drowsiness, recumbency, and sleep.[197] Foals become increasingly coordinated and confident over the first few days of life and will avoid handlers if possible. Once restrained they typically struggle vigorously but will become limp when compressed along their long axis.[198] This relaxation response in response to squeezing is particularly pronounced in the first several hours after birth.[199]

The next stage of the examination is an assessment of the foal's conformation, posture, and gait. The head should be above the horizontal plane when foals are standing, and no head tilt or rotation should be noted.[197] Foals carry their heads with pronounced flexion of the atlantooccipital joint and tend to move their heads with jerky motions that may resemble cerebellar dysfunction in the adult.[198] The foal's gait should be evaluated by observing the foal in unrestrained, spontaneous movement, and this can be facilitated by leading the dam and observing the foal as it follows.[200] The neonatal foal may appear somewhat dysmetric compared with an adult, but this typically improves with exercise.[201] Foals typically have a somewhat exaggerated "bouncy" and hypermetric gait compared with an adult.[197]

Examination of the cranial nerves is similar to the adult, and begins by observation of facial expression, muscle tone, and symmetry. Touching the nasal septum and the inside of the ear canal, which should elicit avoidance behavior, will aid in the assessment of facial sensation. The flick reflexes should be evaluated by gently touching the tip of a hemostat to the pinna of the ear, the medial and lateral canthi of the eyes, and the commissure of the lips.[197] The eyes should be examined for orientation, pupillary size, and pupillary light reflexes. The globe typically shows a ventromedial deviation that will resolve by 1 month of age.[198] The pupil is somewhat round at birth, but direct and consensual pupillary light reflexes, although somewhat slow initially after birth, should be present in normal foals in the first day of life.[202] Dazzle reflexes should be present as well. A menace response is not present at birth but will develop within 1 to 2 weeks of life.[202] Even though a menace response is not present, most foals will show visual avoidance by moving their head away from a threatening gesture toward the eye.[197] The eyes should be assessed for the presence of nystagmus, and although lateral movements of the head will elicit normal physiologic nystagmus, spontaneous nystagmus with the head stationary is abnormal.[197] The suckle reflex and jaw tone should be assessed by inserting a gloved finger into the mouth. The foal should also be observed to nurse, paying close attention to swallowing movements in the pharyngeal region and observing for nasal regurgitation after nursing.

Testing the cervicofacial reflex along the neck and the cutaneous trunci reflex along the thorax will allow assessment of the long spinal reflexes. If these are abnormal, then segmental cutaneous sensation should be assessed. Further assessment of spinal reflexes is best accomplished after placing the foal into lateral recumbency, which also allows for better assessment of muscle tone in the limbs. There should be substantial extensor tone, but the limbs should be able to be flexed with persistent gentle pressure. The triceps, extensor carpi radialis, biceps, patellar, sciatic, and gastrocnemius reflexes should all be able to be reliably elicited and are more pronounced than in adults. The foal should respond to pressure on the sole of the hoof and flexion of the upper limb with an extensor response, known as the extensor thrust reflex.[197] A flexor or withdrawal reflex should be present in response to pinching of the skin of the distal limb, and most foals will exhibit a crossed extensor response by extending the opposite limb at the same time.[197] This crossed extensor reflex should be absent after the first 3 weeks of life.[200]

Although most foals with neurologic dysfunction will display generalized signs, such as abnormal behavior, seizures, depression, poor affinity for the mare, and loss of suckle, the findings of the neurologic examination can be used to assess the nature and severity of the dysfunction and to provide neuroanatomic localization of any lesions that may be present (Table 20.6).

Selected Disorders

Neonatal Encephalopathy and Hypoxic Ischemic Encephalopathy

NE in humans is a clinically defined syndrome of neonatal brain dysfunction, manifested by difficulty with the initiation and maintenance of respiration, depression of tone and reflexes, subnormal levels of consciousness, and frequently seizures.[203] NE represents a very broad categorization that encompasses any neonate with neurologic signs, regardless of etiology. This term has recently come into use in the equine literature as well.[65,185,197,204] HIE is a specific type of NE typically associated with adverse peripartum events that result in episodes of cerebral hypoxia and ischemia. A wide variety of terms have been used synonymously with HIE in reference to affected foals, including neonatal maladjustment syndrome, perinatal asphyxia syndrome, dummy foal, wanderer, and barker foal.[185,205] The clinical presentation associated with HIE in foals can range quite dramatically from mild behavioral abnormalities to severe neurologic abnormalities including central blindness, seizures, coma, and death.[206] Unfortunately these clinical signs are not specific for HIE, and diagnosis is typically made based on elimination of other potential etiologies. Indeed, the confusion associated with the nomenclature reflects the clinical challenges associated with determining the etiology of neurologic dysfunction in the neonatal foal, because it has long been recognized that many foals presenting with the clinical signs typically associated with HIE have no documented evidence of asphyxiation or a hypoxic-ischemic event.[65,207] The fact that many affected foals recover rapidly and demonstrate no neurologic sequelae, in contrast to the situation in human infants, further reinforces this dilemma.[65] There is evidence that elevations in neurosteroid concentrations may be associated with NE in some cases, particularly those with no discernible history of a hypoxic insult.[65,67,68,205,208,209] A novel "squeeze" technique has been reported primarily as an aid in foal restraint and, although only anecdotal, in time this technique may have some benefit in moderating excessive inhibitory neurosteroid concentrations and improving foal consciousness.[199]

With the introduction of the term *NE* in human medicine there has been an effort toward restricting the term *HIE* to the subset of cases of NE in which there is evidence of a hypoxic-ischemic cause, and that approach will be used here.[203] Multiple conditions have been associated with peripartum asphyxia and HIE in foals, including dystocia, induction of parturition, cesarean section, placentitis, premature placental separation, meconium aspiration, twinning, in utero infection, severe maternal illness or surgery, and postterm pregnancy.[185,210,211] Affected foals may appear normal at birth but will typically demonstrate neurologic dysfunction within the first 72 hours of life.[65] The clinical signs of HIE can be highly variable but may include behavioral changes (loss of affinity for the mare, inappropriate nursing behavior, loss of awareness of the environment, head-pressing, and abnormal vocalization), altered mentation (depression, stupor, somnolence, difficult to arouse, and coma), cranial nerve dysfunction (loss of suckle reflex, weak tongue tone, tongue protrusion, and dysphagia), and CNS dysfunction (hypotonia, tremors, hypertonia, proprioceptive deficits, central blindness, irregular respiratory patterns, opisthotonus, and seizures).[65,185,210-213] Two major categories of HIE-affected foals have been described, with Category 1 foals born normally but then developing signs within the first 48 hours of life, and Category 2 foals being abnormal from birth, usually in association with documented risk factors for HIE.[197] It is common to see multisystem involvement, because hypoxic injury will adversely affect most body systems. The gastrointestinal tract and renal system appear most susceptible, but the cardiovascular system, pulmonary system, and liver and endocrine systems may all be involved.

The pathophysiology of hypoxic injury is complex and may vary to some extent in different body systems, but the focus will be on the nervous system here. The initial insult of tissue

TABLE **20.6** **Neuroanatomic Localization Based on Results of the Neurologic Examination**

Evaluation	Pathways	Major Signs of Disorder
Behavior	Forebrain (primarily cerebrum)	Reduced affinity for dam, restlessness, head pressing, compulsive walking
Alertness	All of brain	Lethargy, stupor, semicoma, coma
Avoidance, nasal	Cranial nerve Va, pons, cerebral cortex	Facial hypoalgesia
Avoidance, visual	Cranial nerve II, thalamus, cerebral cortex	Blindness
Head position	Cranial nerve VIII, hindbrain	Head tilt, turn, body lean, walking in circles, ataxia, nystagmus
Eye position and movement	Cranial nerves III, IV, VI, and VIII, midbrain, hindbrain	Strabismus, nystagmus
Flick reflexes	Cranial nerves V and VII, pons, hindbrain	Facial paralysis, facial hypoalgesia, absent flick reflexes
Dazzle reflex	Cranial nerve II, subcortex, midbrain, cranial nerve VII	Absent dazzle reflex
Pupillary light reflex	Cranial nerve II, midbrain, cranial nerve III	Absent pupillary light reflex
Suckle	Cranial nerves V, VII, and XII, pons, hindbrain, cerebrum	Weak or absent suckle
Swallow	Cranial nerves IX and X, hindbrain	Flow of milk from the nose
Cervicofacial reflex	Cervical spinal nerves and spinal cord, cranial nerve, VII, (hindbrain)	Diminished cervicofacial reflex
Cutaneous trunci reflex	Thoracic spinal nerves and spinal cord, brachial plexus, lateral thoracic nerve	Diminished reflex caudal to spinal cord lesion
Cutaneous sensation	Peripheral nerves, spinal cord, cerebral cortex	Cutaneous hypoalgesia/anesthesia
Gait	Cranial nerve VIII, cerebellum, hindbrain, spinal cord, peripheral nerves	Ataxia
Limb strength	Spinal cord, peripheral nerves	Limb weakness at or caudal to the level of the lesion
Flexor reflex (pelvic), patella, sciatic reflexes	Spinal cord, peripheral nerves (L3-S2)	Pelvic limb weakness, diminished or absent reflexes
Flexor reflex (thoracic), biceps, triceps reflexes	Spinal cord, peripheral nerves (C6-T2)	Weakness of thoracic with or without pelvic limbs, diminished or absent reflexes
Anal/tail clamp reflex	Spinal cord, cauda equine, peripheral nerves (S2-Coccyx)	Reduced or absent anal/tail clamp reflex

hypoxia initiates a cascade of deleterious events. First, there is a shift toward anaerobic metabolism that leads to depletion of high-energy phosphate (adenosine triphosphate [ATP]) reserves, accumulation of lactate, and a failure of cellular homeostasis.[204] Decreased activity of transcellular pumps that depend on ATP leads to intracellular accumulation of sodium, calcium, and water.[214] Membrane depolarization leads to release of the potent excitatory amino acid glutamate, which accumulates in the extracellular space. Glutamate then acts on the *N*-methyl-D-aspartate (NMDA) receptor, opening NMDA channels, potentiating calcium influx into the neurons, and contributing to neuronal injury.[215] This cascade of events results in the development and perpetuation of excitotoxicity, which ultimately leads to neuronal cell death and brain injury.[204,214] Hypoxia and subsequent reperfusion also initiate the increased production of ROS and NO, ultimately resulting in the process known as *reperfusion injury* and leading to further tissue damage via cell death and activation of apoptotic cascades.[204,214] Tissue injury initiates an inflammatory response, leading to increased local blood flow and vascular permeability, which may result in the development of edema. Inflammatory cell infiltration leads to further tissue injury and upregulation of ROS production.[185,216] Increased concentrations of neurosteroids have been documented in affected foals, but their role in the pathophysiology of HIE is unclear because they may actually have a neuroprotective effect.[65,66,68] In situations where the degree or duration of hypoxia is not overwhelming, a biphasic pattern of injury may be observed in which the initial acute phase of injury is stabilized, followed by an ongoing latent phase of injury that results in more severe clinical deterioration several hours later.[214]

The diagnosis of HIE is challenging because of the substantial overlap between the clinical signs associated with HIE and other causes of NE, as previously discussed. Unfortunately

there is no definitive test for HIE, so diagnosis is typically made based on historical information, clinical presentation, and the elimination of other potential causes. Additional diagnostics that are used in human infants include electroencephalography (EEG) as well as imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI).[204] An EEG is difficult to accomplish in the unsedated foal, and interpretation can be confounded by patient movement or sedation, rendering this modality of limited use in foals. Brainstem auditory evoked response testing is widely used in human neonatal ICUs to aid in the assessment of CNS function and the diagnosis of HIE, and this technique has been described and validated in foals.[217,218] A recent report described the MRI findings associated with a presumptive case of NE in a foal, and the increasing availability of MRI in equine referral centers may render this modality of utility in the future.[219] There has been tremendous interest in identifying biomarkers of HIE in human infants, and two potential biomarkers of HIE have been investigated in foals.[206,220] A recent study measured the plasma concentration of the phosphorylated axonal forms of neurofilament H (pNF-H) and ubiquitin C-terminal hydrolase 1 (UCHL1) and found that the diagnostic performance of UCHL1 was significantly higher than that of pNF-H, with the sensitivity and specificity of UCHL1 for diagnosis of neonatal HIE reported as 70% and 94%, respectively.[206] This test is not available for clinical use at this time, however.

Prevention of HIE is difficult because of the occult nature of the injury in many cases, but all efforts should be made to identify mares at risk of maternal or placental disease during pregnancy and to implement appropriate treatment and monitoring. Close observation of at-risk mares during parturition may allow for early intervention and assistance, if needed. Foals should be closely observed during and after parturition for signs of distress or neurologic dysfunction and appropriate supportive care or resuscitation provided.[185] Foals that exhibit seizure activity within the first 24 hours of hospitalization have been shown to have poorer outcomes than foals that do not exhibit seizure activity.[205] The prognosis for survival for foals with uncomplicated disease that survive the first 5 days of life and demonstrate neurologic improvement during that time appears to be good.[185]

Sepsis-Associated Encephalopathy

Brain dysfunction occurring as a result of severe systemic inflammation secondary to infection, but not involving overt CNS infection or other types of encephalopathies, has been termed *sepsis-associated encephalopathy* (SAE).[221] This syndrome has also been referred to as septic encephalopathy and sepsis-associated brain dysfunction.[222] SAE is thought to represent a neglected cause of neurologic dysfunction in human patients because of the difficulty in diagnosing a condition that has no precise clinical or biological markers, and the situation is likely similar in NE of foals.[223] In humans the clinical spectrum of SAE may include signs ranging from mild behavioral abnormalities and altered sleep states to severe disturbances of consciousness and even coma.[224] The pathophysiology of SAE appears to involve direct neuronal cell injury, mitochondrial and endothelial dysfunction, disturbances of neurotransmission, and derangements of neuronal calcium homeostasis.[223,224] Given the substantial overlap between the presentations of HIE and SAE, and the frequent involvement of sepsis in the critically ill foal population, SAE should be considered as a potential cause of NE in foals.

Seizure Disorders

Seizures are a common manifestation of neurologic dysfunction in human neonates and in foals.[65,225] Seizures in foals can be idiopathic, the result of primary CNS disorders, or secondary to numerous conditions involving other body systems or diffuse disease. Seizures are defined as abnormal, stereotyped, and paroxysmal alterations in neurologic function and may include behavioral changes, motor dysfunction, autonomic dysfunction, and loss of consciousness.[226] Seizure activity indicates neurologic dysfunction of the forebrain associated with abnormal electrical activity. Neonates appear to be at increased risk of seizure activity because of the relative excitability of the developing brain combined with the high risk of brain injury in the neonatal period.[227] Diagnosis of seizure activity is primarily based on clinical signs but can be challenging because of the subtle signs in some cases, the potential confounding effects of other conditions altering patient behavior, neurologic function, or level of consciousness. Subtle signs may include abnormal eye movements, tremors, excessive stretching, excessive extensor tone, hyperesthesia, and apneustic breathing, whereas overt signs of seizures typically include rapid nystagmus, paddling, hyperextension, and excessive movements of the mouth.[198] Unexplained physical trauma may represent evidence of unobserved seizure activity. Confirmation of seizure activity is achieved by EEG examination, but this can be challenging in foals. Specific treatment may not be required in individuals with very subtle or rare signs of seizure activity but is clearly indicated in patients with repeated, generalized seizure activity. Foals that exhibit seizure activity within the first 24 hours of hospitalization have been shown to have poorer outcomes than foals that do not exhibit seizure activity.[205]

Bacterial Meningitis

Bacterial meningitis is an uncommon condition but appears to be more frequent in foals than adults.[228] It has been reported to occur in 2.6% to 10% of foals suffering from sepsis and is associated with high mortality rates.[25,176,228,229] The most common clinical findings in foals with bacterial meningitis are lethargy, weakness, recumbency, decreased suckling reflex, abnormal pupillary light reflexes, hyperesthesia, cervical pain, fever, blindness, seizures, and coma.[228,230,231] Clinicopathologic findings may include FTPI, neutropenia or neutrophilia, and hyperfibrinogenemia and most often reflects systemic inflammation related to sepsis.[197,228,230,231] Definitive diagnosis is by means of CSF analysis, with neutrophilic pleocytosis (total nucleated cell count >7 cells/μL) and increased total protein (TP) concentration (TP >120 mg/dL) being present in most cases.[232,233] Cellular degeneration is frequently observed in the CSF, along with intracellular bacteria.[197,233] Meningitis is most commonly associated with the same types of bacteria associated with neonatal sepsis, and *Escherichia coli, Actinobacillus* spp., *Klebsiella* spp., *Streptococcus* spp., and *Salmonella* spp. are the most commonly reported.[228,233,234] Treatment depends on intensive antimicrobial therapy using drugs capable of achieving therapeutic concentrations within the CNS and is ideally guided by culture results.[235] Drugs such as penicillin, ceftiofur, and the aminoglycosides are unlikely to be effective because of poor penetration, so consideration should be given to other treatments such as ceftriaxone, cefepime, cefotaxime, imipenem, chloramphenicol, and rifampin (as an adjunct).[235] Because

much of the damage occurring in the CNS in meningitis is secondary to the inflammatory response, there is a rationale for using antiinflammatory therapy in these cases. The use of corticosteroids as adjunct therapy in human patients has been associated with a reduction in neurologic sequelae but did not alter mortality.[236,237] The prognosis for survival in foals with appropriate treatment is fair to poor, depending on the severity of the presenting signs.[228]

Trauma

Trauma should always be considered when evaluating the foal with acute onset of neurologic signs. Brain trauma may be associated with blunt force trauma in the region of the frontal or parietal bones or may be secondary to trauma to the poll or temporal region secondary to the foal flipping over backward.[197] Vertebral injury can occur as well and may be associated with the foal running into an immobile object. Outward signs of trauma may not be obvious, and imaging studies may be required for confirmation. Examination may reveal superficial abrasions, pain on palpation of affected areas, soft tissue swelling, crepitus, or bleeding from the nares or ears. Treatment is supportive in nature along with stabilization of bony injuries if possible. Antiinflammatory and antioxidant therapy may be of some benefit, but corticosteroid administration is not recommended. Appropriate antimicrobial therapy is indicated when there is the possibility that the CNS may have been contaminated.

Botulism

Botulism is a syndrome of flaccid paralysis caused by the neurotoxins produced by *Clostridium botulinum,* colloquially known as "shaker foal syndrome." Most equine cases are associated with toxin types B and C, although type A cases have been reported.[238] The syndrome in foals is thought to be toxicoinfectious in nature, in which the foal ingests spores from the environment that germinate in the gastrointestinal tract and spread toxin, as opposed to the more common form of "forage poisoning" associated with ingestion of a preformed toxin as seen in adults.[239] Botulism toxin acts presynaptically at the neuromuscular junction by inhibiting the release of the neurotransmitter acetylcholine. Severely affected foals may be found dead, but more commonly there is a sudden development of weakness, trembling, and dysphagia in a previously healthy foal.[238] Progressive deterioration is typically observed, even with appropriate treatment, and respiratory paralysis is the cause of death in most cases. Diagnosis is typically presumptive based on the history and clinical presentation because confirmation requires demonstration of spores and/or toxin in the feces of affected animals, which can be difficult. A mouse bioassay has been validated for the diagnosis of botulism in horses and foals.[240] This assay is highly specific in foals, with specificity and PPV reported as 100%, but it exhibits low sensitivity (53%) and NPV (52%).[240] Treatment is based on the administration of antitoxin and the provision of supportive care. Foals that become recumbent will likely die unless they receive ventilatory support in the form of mechanical ventilation, which may be required for as long as 2 weeks.[238] With early and appropriate care the prognosis for survival in cases of types B and C botulism is reported to be good.[238] Type A botulism has been associated with more severe clinical signs and a higher case fatality rate, but a recent report described the successful treatment of a foal affected by type A botulism.[241]

Tetanus

Tetanus is a syndrome of spastic paralysis caused by the neurotoxin tetanospasmin produced by *C. tetani.* Although rare because of the widespread use of tetanus toxoid vaccines, recent cases have been reported in foals.[242,243] This syndrome usually affects foals over 7 days of age and is associated with the development of an anaerobic site of infection, reportedly most often within the umbilical remnants.[244] Tetanospasmin acts to prevent the release of the inhibitory neurotransmitter GABA by spinal interneurons, leading to disinhibition of spinal motor neurons, resulting in excessive motor activity and spastic paralysis.[245] The primary clinical signs are rigidity, excessive autonomic activity, and episodic muscle spasms, which lead to trismus, facial spasm, third-eyelid protrusion, and dysphagia. Progression leads to recumbency, and death is usually caused by respiratory failure. Treatment of tetanus depends on the administration of tetanus antitoxin, supportive care, control of muscle spasms, and source control.[242,246] Control of muscle spasms is often accomplished using benzodiazepines, either administered as needed or by continuous rate infusion (CRI). Magnesium sulfate represents an affordable and viable option to benzodiazepines in humans and may be a reasonable option in foals as well.[197] Source control may involve surgical excision or drainage of the site of infection in combination with antimicrobial therapy. Penicillin has been the standard treatment, but metronidazole may also be used. The prognosis for survival is good in cases that do not progress to recumbency, but it is guarded to poor once recumbency occurs, although recent success has been reported.[242,243]

Metabolic Encephalopathies

There are a number of metabolic derangements that have the potential to adversely affect neurologic function and potentially cause neurologic injury in foals. These include hypoglycemia, hyponatremia and hypernatremia, hypocalcemia, hyperbilirubinemia, and hyperammonemia. Hypoglycemia is common in critically ill foals, and severe hypoglycemia is associated with nonsurvival to hospital discharge.[131] Persistent, severe hypoglycemia is associated with neuronal degeneration in both the central and peripheral nervous systems, but interestingly this phenomenon is only seen in human patients receiving insulin therapy or suffering from hyperinsulinemias.[247,248] Although short-term hypoglycemia may not cause permanent injury, it certainly can cause neurologic dysfunction and adversely affects other body systems and should therefore be addressed with dextrose supplementation.[249,250]

Sodium disorders are fairly common in critically ill foals, but they are not typically associated with neurologic dysfunction unless the derangements are very severe or there are dramatic, acute changes in the serum sodium concentration. These rapid changes in sodium concentration cause dramatic fluid shifts in the tissues of the CNS, with hyponatremia potentially being associated with the development of cerebral edema, whereas hypernatremia may cause an osmotic demyelination syndrome.[250] Hyponatremia is more common than hypernatremia, and neurologic signs are most typically associated with sodium concentrations less than 120 mEq/L.[249,251] The neurologic manifestations of hyponatremia may include an abnormal stance or gait, depression, blindness, or seizures.[252,253] Treatment of these disorders involves correction of the underlying whole body sodium/water imbalances, because hyponatremia represents a free-water excess and hypernatremia a free-water deficit.[254] Hyponatremia should be addressed

by administering fluids that are relatively hypertonic compared with the plasma osmolality, and although the literature suggests that initial correction should be rapid followed by slower correction, a more conservative approach may be appropriate in foals.[249] Hypernatremia should be addressed using fluids that are relatively hypotonic but should be gradual (<0.5 mEq/L/h).[249]

Hypocalcemia is often asymptomatic but can be associated with tetany and seizures.[254] Rapid decreases in the ionized calcium concentration appear more likely to be associated with clinical signs in critically ill foals.[250] A syndrome of hypocalcemic seizures has been described in young foals, typically from 2 to 5 weeks of age.[255,256] This condition is thought to be caused by primary hypoparathyroidism.[249,256]

Bilirubin is capable of crossing the blood-brain barrier, especially when plasma concentrations of bilirubin are very high and in neonates where the blood-brain barrier is more permeable. Bilirubin is neurotoxic and can cause neurologic dysfunction and irreversible brain damage, which is a clinical syndrome termed *kernicterus*.[257,258] The most important cause of clinical icterus in equine neonates is neonatal isoerythrolysis (NI). Treatment of NI is discussed elsewhere in this chapter, but primarily it consists of supportive care and blood transfusions. These treatments do not address the hyperbilirubinemia, which can only be reduced using therapeutic plasma exchange.[258]

Hyperammonemia has been associated with neurologic dysfunction in foals and adult horses, and the clinical signs associated with hyperammonemia include depression, blindness, aimless wandering, head pressing, ataxia, circling, recumbency, and death.[259-262] Hyperammonemia may develop secondary to hepatic insufficiency, portosystemic shunts, or increased gastrointestinal production (intestinal hyperammonemia).[259-262] A disorder suspected to represent hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome, a genetic defect in the urea cycle resulting in persistent hyperammonemia, has been reported in Morgan foals.[263] Intestinal hyperammonemia is typically seen in association with clinical signs of gastrointestinal disease.[261]

Congenital Disorders

Hydrocephalus

Hydrocephalus is a condition resulting from impaired drainage of CSF caused by congenital defects or inflammation that results in the compression of the brain caused by increased intracranial pressure.[264,265] This condition is considered to be uniformly fatal and is rare in horses but may be more frequent in the Friesian breed.[265] Diagnosis is typically presumptive and confirmed on postmortem examination, but CT and MRI can be used for definitive antemortem diagnosis if necessary.[266]

Occipitoatlantoaxial Malformation

Foals born with occipitoatlantoaxial malformation typically exhibit paresis and ataxia of all four limbs, but in some cases foals may be born dead or comatose.[197] Foals may have a head tilt or abnormal head carriage, movement of the head may reveal a clicking sound, and neurologic deficits may range from inapparent to severe enough to result in quadriplegia.[197,267] The condition is familial in the Arabian breed but may occur in other breeds as well.[267] Diagnosis is typically confirmed radiographically, although contrast myelography, CT, or MRI may be useful in some cases.[268,269] Foals exhibiting clinical signs are typically euthanized because of the poor long-term prognosis.

Cerebellar Abiotrophy

Equine cerebellar abiotrophy is a neurodegenerative condition affecting the cerebellum, which results in ataxia, head tremors, and loss of equilibrium.[270,271] Cerebellar abiotrophy is relatively rare in horses, and, although it can occur in multiple breeds, it is most common in Arabian horses. It is inherited as an autosomal recessive trait, with clinical signs generally detectable between 4 weeks and 6 months of age.[270-272] Diagnosis is typically presumptive based on breed association and clinical presentation because definitive antemortem diagnosis is difficult.

Epilepsy

A syndrome of juvenile idiopathic epilepsy (JIE) has been described in Arabian foals of Egyptian lineage.[273,274] This syndrome is characterized by recurrent tonic-clonic seizures and resembles benign-familial neonatal convulsion syndrome in humans.[275] JIE exhibits an early onset of clinical signs in the first days to months of life but appears to be self-limiting and resolves by 1 to 2 years of age.[273,275]

Narcolepsy and Cataplexy

Narcolepsy in the horse is characterized by paroxysmal sleep attacks, and affected animals may remain standing, whereas cataplexy represents the complete loss of muscle tone combined with areflexia leading to recumbency.[276] Narcolepsy without cataplexy has been described in Thoroughbred, Warmblood, and Icelandic horses, and in some cases there may be a familial component.[276,277] Narcolepsy with cataplexy is very rare, but it has been described in horses.[276,278]

Treatment of Neonatal Encephalopathy

Because of the broad range of disease processes associated with the development of NE in foals, there is no single treatment strategy. This discussion will focus on treatments directed toward the prevention of CNS injury and normalization of nervous system function. Foals with NE are typically suffering from severe systemic inflammation as well, and specific treatment recommendations for supportive care; infection control; correction of metabolic disorders; and normalization of cardiovascular, pulmonary, gastrointestinal, and renal function in critically ill foals is covered in detail elsewhere in this chapter.

The first objective is stabilization of the patient systemically, because the restoration and maintenance of CNS perfusion is critical in ensuring adequate delivery of oxygen and glucose. IV fluid therapy is often required to correct hypovolemia and support cardiovascular function, but vasopressors and inotropes may be required to normalize blood pressure. It is important to avoid overhydration or hypertension, however, because these may potentiate CNS injury.[185,279] Normalization of blood glucose concentrations is important as well, but care must be taken to avoid hyperglycemia, because critically ill foals may be intolerant of dextrose infusions. Intranasal oxygen supplementation is recommended in weak or recumbent foals, or those with documented arterial hypoxemia, to support oxygen delivery, and blood transfusions may be needed in anemic patients for the same reason.

The second objective is to control seizure activity, if present. Specific treatment may not be required in individuals with very subtle or rare signs of seizure activity, but it is clearly

TABLE **20.7 Drugs Used for the Control of Seizures in Foals**

Drug	Dosage	Route	Frequency	Comments
Diazepam	0.1–0.4 mg/kg	IV	As needed	Short-term seizure control
Midazolam	0.04–0.1 mg/kg 0.02–0.06 mg/kg/h	IV IV	As needed CRI	Short-term seizure control For persistent seizures
Phenobarbital	2–10 mg/kg 3–10 mg/kg	IV PO	12 h 12 h	For persistent seizures Monitor serum concentrations
Pentobarbital	2–10 mg/kg	IV	Single dose	For status epilepticus—use caution
Phenytoin	1–5 mg/kg 1–5 mg/kg	IV, PO PO	4 h, up to 6 doses 12 h	—
Potassium bromide	10 mg/kg 60 mg/kg	PO PO	8 24 h	Monitor serum concentrations

CRI, Continuous rate infusion; *IV,* intravenously; *PO,* orally.

indicated in patients with repeated, generalized seizure activity. Benzodiazepines (diazepam and midazolam) represent the first-choice therapy for control of acute seizures in foals because of their rapid onset of action and minimal depressive effects (Table 20.7).[30,198] Bolus IV doses are used for the control of single seizure episodes, but CRI of midazolam can be used to control persistent seizures. Other options for the control of persistent seizures include phenobarbital, pentobarbital, and potassium bromide. Phenobarbital can cause substantial CNS depression when first administered but is generally well tolerated, even with prolonged use. Serum phenobarbital levels should be monitored when used long term to ensure that concentrations remain within the therapeutic range, which has been reported to be 5 to 30 μg/mL in foals.[280] Pentobarbital should only be used in cases with status epilepticus that cannot be controlled with other medications and is associated with substantial risk caused by profound respiratory and cardiovascular depression. Phenytoin has unpredictable kinetics and is not widely used but has been suggested for anticonvulsant use in foals. Potassium bromide may be useful for long-term maintenance in foals with epilepsy because it has fewer side effects than phenobarbital and is well tolerated. Reported effective plasma concentrations of bromide in other species are 70 to 240 mg/dL, but this has not been validated in foals.[281]

The next goal is to control ongoing CNS injury and prevent further damage. Hypothermia is considered the standard of care in the treatment of human neonates suffering from HIE. This involves cooling the patient to 92.3 to 95.0°F using whole body hypothermia, although selective head-cooling approaches can be used as well.[214] A recent systematic review confirmed that therapeutic hypothermia is beneficial in human infants suffering from HIE, because hypothermia reduced mortality without increasing long-term neurologic disability in survivors.[282] There are some complications associated with hypothermia, most notably overcooling, skin problems, altered drug metabolism, and an increased risk of seizure during rewarming.[283] The logistics of providing therapeutic hypothermia in foals, including the appropriate techniques of cooling, patient selection, and duration of cooling remain, is to be defined before clinical application of this approach in equine medicine.

A number of pharmacologic approaches to neuroprotection have been used empirically in foals with HIE, but their use has not been validated (Table 20.8). One of the most widely used drugs for decades has been dimethyl sulfoxide (DMSO), which has been used because of its purported free radical scavenging and antiinflammatory effects, which are perhaps reinforced by ease of administration and low cost.[284] DMSO has osmotic and diuretic effects, which may be helpful in reducing intracranial pressure, and reportedly blocks sodium channel activation, suppresses calcium influx and prevents glutamate excitotoxic cell death.[284] As promising as this appears, there is actually little to no scientific evidence of efficacy regarding DMSO treatment of HIE, and clinical consensus on its use is lacking.[30,211] Mannitol has been administered to reduce cerebral edema, but evidence of efficacy is also lacking for this treatment modality, and it is not commonly used.[185] Magnesium sulfate treatment has been of interest because of its NMDA-receptor antagonist effects, and magnesium may also stabilize cell membranes, inhibit free radical production, and reduce secondary CNS inflammation and associated injury.[285] The use of magnesium sulfate in foals with HIE has been reported, and treatment appears to be well tolerated, although excessive doses can cause muscular weakness and hyotension.[279] No data are available regarding efficacy in foals and, although there are some studies with encouraging results, this therapeutic approach currently remains preclinical in human infants with HIE.[285,286] Pentoxifylline, a phosphodiesterase inhibitor, has antiinflammatory and immune-modulating effects and may improve local tissue perfusion.[287] It has been suggested that pentoxifylline may inhibit TNF-α production in foals with NE.[185] Antioxidant administration may be of some benefit in addressing CNS inflammation, and vitamins C and E and thiamine (vitamin B_1) have all been administered to foals with HIE.[65] Allopurinol is an antioxidant that has shown promise in human infants, but it remains preclinical at this time.[288] Allopurinol administration has been suggested for foals with HIE, but there are no reports of its use.[185] A myriad of additional treatments have been investigated in human neonatal HIE, and some of those that appear promising include inhaled xenon as an antiexcitotoxic agent, melatonin as an antioxidant, erythropoietin as a growth factor, and stem cell therapy.[204,289,290]

RESPIRATORY DISORDERS

Lower respiratory tract disease is common in foals and accounts for substantial morbidity and mortality. Foals are at risk for the development of respiratory disease caused by

complex interactions between innate immunologic factors and a number of risk factors. Immunologic factors include possible FPTI, delayed endogenous immunoglobulin production, and potentially impaired immunologic responses. Risk factors in neonates include systemic sepsis, congenital abnormalities, meconium aspiration, milk aspiration, and birth trauma. Risk factors in older foals include the stresses of weaning, sales preparation, and transport, as well as confinement in crowded or dusty conditions that result in heavy exposure to potential respiratory pathogens.

Respiratory Distress

There are several syndromes associated with respiratory distress in the foal, and these syndromes can result from a variety of initiating causes. The defining characteristics change with age, caused by the normal maturation of pulmonary function in the newborn foal, and to some extent caused by the changing nature of the insults that result in respiratory distress. The finding of acute respiratory distress immediately after birth is likely associated with extrapulmonary disorders causing upper respiratory obstruction, such as bilateral choanal atresia, stenosis of the nares, severe laryngeal edema or collapse, dorsal displacement of the soft palate, subepiglottic cysts, or severe congenital pulmonary abnormalities.[30] Congenital cardiac anomalies, such as malpositioning of the great vessels, resulting in severe right-to-left shunts may also be involved.[30]

Acute Lung Injury and Acute Respiratory Distress Syndrome

When dealing with respiratory distress in foals beyond the immediate postpartum period the situation can become confusing because of the broad range of etiologies involved and the broad spectrum of the clinical syndromes. Although this has been appreciated in human and veterinary medicine for many years, it is only in the past decade that a consensus approach to this situation has been developed in veterinary medicine.[291] The terms *acute lung injury* (ALI) and acute RDS (ARDS) were originally developed in human medicine to refer to a syndrome of respiratory failure associated with noncardiogenic pulmonary edema, decreased pulmonary compliance, and ventilation/perfusion mismatching.[292,293] These syndromes are associated with an exaggerated and self-perpetuating inflammatory response, which results in severe tissue damage within the lungs. Protein-rich edema fluid accumulates within the alveoli and interstitium, resulting in impairment of gas exchange leading to hypoxemia.[294] ALI and ARDS are not primary disease syndromes and always occur secondary to other disease processes. Risk factors for ALI and ARDS in human patients include processes resulting in both direct pulmonary injury (pneumonia, aspiration of gastric contents, smoke inhalation, pulmonary contusion, and drowning) and indirect pulmonary injury (nonpulmonary sepsis, pancreatitis, multiple transfusions, and major trauma).[294]

Accurate assessment of respiratory function in the neonate requires arterial blood gas analysis, and the ready availability of portable blood gas analyzers has greatly improved access to this important diagnostic tool. Management of critically ill foals without this information is extremely difficult, because it is important in initial evaluation, formulation of an appropriate treatment plan, monitoring the response to treatment, and prognostication. Foals are most readily sampled in lateral recumbency using the lateral metatarsal artery and the brachial or transverse facial artery. Sampling should be performed quickly after placing the foal in lateral recumbency, and the patient should be returned to a sternal or standing position as soon as possible, because positioning in lateral recumbency has a substantial negative impact on arterial oxygenation (10–14 mm Hg). Diagnostically this impact can be addressed by using appropriate reference ranges derived from foals sampled in lateral recumbency (Table 20.9). The other major element that has to be factored in to interpretation of arterial blood gas data in neonatal foals is the changes in pulmonary function that occur over the course of the first several days of life, because newborn foals have a small degree of shunt fraction that renders them relatively hypoxemic and less responsive to oxygen supplementation than adults. This phenomenon is also addressed in Table 20.9.

The most common arterial blood gas abnormalities identified in neonatal foals are hypoxemia with normocapnia or hypocapnia and hypoxemia with hypercapnia. Hypoxemia can result from several mechanisms: hypoventilation, ventilation/perfusion mismatching, impaired diffusion, intrapulmonary or extrapulmonary (cardiac) shunts, and decreased

TABLE **20.9** **Normal Arterial Blood Gas Values for Foals**[a]

Gestational Age	Postnatal Age	Pa_{O_2}	Pa_{CO_2}	pH

concentration of oxygen in the inspired air (high altitude or inappropriate ventilator setting). Weak, recumbent neonatal foals will frequently suffer from hypoventilation, whereas the presence of intrapulmonary inflammation or surfactant deficiency will cause substantial ventilation/perfusion mismatching with intrapulmonary shunting of blood. Severe inflammation or pulmonary edema can cause diffusion impairment, whereas extrapulmonary shunts are most commonly associated with persistent fetal circulation or cardiac anomalies. Foals suffering from pneumonia typically show profound hypoxemia initially, but the development of hypercapnia and respiratory acidosis indicates substantial worsening of pulmonary function and is associated with a poorer prognosis for survival.[111,295]

ALI in human patients is characterized by an acute onset, the presence of bilateral pulmonary infiltrates on thoracic radiographs, a decreased ratio of the partial pressure of oxygen in arterial blood (Pa_{O_2}) to the fraction of inspired oxygen (Fi_{O_2}) of ≤300 mm Hg, and a pulmonary arterial wedge pressure of less than 18 mm Hg or the absence of clinical evidence of left atrial hypertension.[292] ARDS represents a more severe degree of dysfunction and is characterized by the same criteria but with a lower Pa_{O_2}/Fi_{O_2} ratio of ≤200 mm Hg.[292] Similar terminology and definitions have been proposed for foals suffering from respiratory distress.[291] Multiple classifications have been defined, including neonatal equine RDS (NERDS), equine neonatal ALI (EqNALI) and equine neonatal ARDS (EqNARDS), and veterinary ALI (VetALI) and veterinary ARDS (VetARDS).[291] The diagnostic criteria for these syndromes are provided in tabular form (Boxes 20.3–20.5).

Although the term *NERDS* is new, the syndrome of severe, progressive respiratory distress in foals within the first 24 hours of life has been recognized for at least 50 years.[5] NERDS is very similar to infant RDS in human infants, which is caused by primary surfactant deficiency associated with premature delivery.[291] Surfactant has three primary roles within the lung: to prevent atelectasis at the end of expiration, to increase

BOX 20.3 **Definition of Neonatal Equine Respiratory Distress Syndrome**

Etiology: Primary surfactant deficiency caused by the failure of final fetal pulmonary surfactant metabolism maturation. Diagnosis requires meeting all criteria listed next:

1. Persistent hypoxemia in combination with progressive hypercapnia
   a. Hypoxemia defined as Pa_{O_2} <60 mm Hg with the foal breathing room air and in lateral recumbency
2. The presence of at least one of three appropriate risk factors:
   a. Very early gestational age: less than 290 days' gestational age or less than 88% of the average of the dam's previous gestation lengths
   b. Induction of parturition
   c. Caesarean section
3. Failure to develop normal immediate postpartum respiratory patterns: development/persistence of paradoxic breathing over the first several hours of life, persistent tachypnea
4. Ground glass appearance of lateral thoracic radiographs at ≤24 hours of age (standing or lateral recumbency)
5. Absence of evidence of fetal inflammation
   a. Normal white blood cell count, differential, and fibrinogen concentration for gestational age
6. Congenital cardiac disease ruled out as a cause of hypoxemia

Adapted from Wilkins PA, Otto CM, Baumgardner JE, et al. Acute lung injury and acute respiratory distress syndromes in veterinary medicine: consensus definitions: the Dorothy Russell Havemeyer Working Group on ALI and ARDS in Veterinary Medicine. *J Vet Emerg Crit Care*. 2007;17:333-339.

pulmonary compliance, and to facilitate recruitment of collapsed airways.[296] Surfactant deficiency leads to progressive atelectasis and decreased pulmonary compliance, worsening of ventilation/perfusion mismatching caused by intrapulmonary and possibly extrapulmonary shunting of blood, hypoventilation, and increased work of breathing. If not addressed the end result is progressive hypoxia and hypercapnia and ultimately respiratory failure.[296]

Treatment of NERDS is challenging, because the primary interventions used in human infants are not readily available in equine medicine (exogenous surfactant) or are only available in tertiary care referral centers (mechanical ventilation). Given the benefits of surfactant therapy in human respiratory distress syndrome (RDS) patients,[297] this intervention is of great interest in affected foals, but the author's personal experience and the limited references to this therapy in the literature suggest that the effect of this therapy has a short duration and needs to be repeated frequently, making it difficult to justify the significant expense, if surfactant is even available.[298,299] Interestingly, one of the primary changes in the management of human neonates with RDS has been driven by the recognition that mechanical ventilation via endotracheal intubation, although life-saving in many cases, is also associated with the potential for serious acute complications and long-term pulmonary dysfunction.[300] The acute complications may include trauma to the upper respiratory tract associated with intubation, increased risk of lower respiratory tract infections, pulmonary barotrauma

BOX 20.4 Definition of Veterinary Acute Lung Injury and Acute Respiratory Distress Syndrome

Must meet at least one each of the first four criteria; criterion five is a recommended but optional measure.

1. Acute onset (<72 hours) of tachypnea and labored breathing at rest
2. Known risk factors
3. Evidence of pulmonary capillary leak without increased pulmonary capillary pressure[a] (any one or more of the following):
   a. Bilateral/diffuse infiltrates on thoracic radiographs (more than one quadrant per lobe)
   b. Bilateral dependent density gradient on CT
   c. Proteinaceous fluid within the conducting airways
   d. Increased extravascular lung water
4. Evidence of inefficient gas exchange (any one or more of the following):
   a. Hypoxemia without PEEP or CPAP and known Fio_2
      i. Pao_2/Fio_2 ratio
      ii. ≤300 mm Hg for VetALI
      iii. ≤200 mm Hg for VetARDS
      iv. Increased alveolar-arterial oxygen gradient
      v. Venous admixture (noncardiac shunt)
   b. Increased "dead-space" ventilation
5. Evidence of diffuse pulmonary inflammation
   a. Transtracheal wash/bronchoalveolar lavage sample neutrophilia
   b. Transtracheal wash/bronchoalveolar lavage biomarkers of inflammation
   c. Molecular imaging (PET)

[a]No evidence of cardiogenic edema (one or more of the following): PAOP <18 mm Hg (adult horse). No clinical or diagnostic evidence supporting left heart failure, including echocardiography.

CPAP, Continuous positive airway pressure; *CT,* computed tomography; *Fio_2,* fraction inspired oxygen; *PAOP,* pulmonary artery occlusion pressure; *PEEP,* positive end expiratory pressure; *PET,* positron emission tomography; *VetARDS,* veterinary acute respiratory distress syndrome; *VetALI,* veterinary acute lung injury.

BOX 20.5 Definition of Equine Neonatal Acute Lung Injury/ Respiratory Distress Syndrome

Postnatal Age	Normal Pao_2 (mm Hg)	Normal Pao_2/Fio_2 Ratio (mm Hg)	NALI Pao_2/Fio_2 Cutoff (mm Hg)	NARDS Pao_2/Fio_2 Cutoff (mm Hg)
60 min	60.9 ± 2.7	>300	<175	<115
12 h	73.5 ± 3.0	>350	<200	<140
24 h	67.6 ± 4.4	>350	<200	<140
48 h	74.9 ± 3.3	>350	<200	<140
4 days	81.2 ± 3.1	>400	<250	<160
7 days	90.0 ± 3.1	>430	<280	<190

This is for VetALI/VetARDS but adheres to the following age-dependent adaptation of the Pao_2/Fio_2 ratio in term foals in lateral recumbency breathing room air (Fio_2 = 0.21) based on age-dependent normal values for Pao_2 under similar conditions.

Fio_2, fraction inspired oxygen; *NALI,* neonatal acute lung injury; *NARDS,* neonatal acute respiratory distress syndromes; *VetALI,* veterinary acute lung injury; *VetARDS,* veterinary acute respiratory distress syndrome.

From Wilkins PA, Otto CM, Baumgardner JE, et al. Acute lung injury and acute respiratory distress syndromes in veterinary medicine: consensus definitions: the Dorothy Russell Havemeyer Working Group on ALI and ARDS in Veterinary Medicine. *J Vet Emerg Crit Care.* 2007;17:333-339.

and volutrauma, air leak syndromes (pneumothorax), and hemodynamic complications caused by impaired venous return, whereas the primary long-term complication is bronchopulmonary dysplasia.[301] Because of these concerns noninvasive forms of respiratory support are widely used in human infants with RDS, which include all forms of respiratory support not delivered with an endotracheal tube.[302] The simplest and most readily implemented form of noninvasive respiratory support in foals is the intranasal administration of humidified oxygen via intranasal cannula. Although a single cannula is most often used, this may not provide sufficient oxygen flow rates, in which case a second cannula can be placed in the opposite nostril, and combined flow rates of up to 20 L/minute can be readily delivered.[303] A potential downside to bilateral cannula placement is that this may cause some degree of upper respiratory obstruction in small foals, potentially impairing exhalation and CO_2 elimination, although this effect was not detected when this technique was investigated in healthy foals.[303] If nasal cannulation is not possible or is not achieving adequate flow rates, then an intratracheal catheter can be used for oxygen insufflation, but this rarely represents anything more than a short-term solution.[304]

Although oxygen insufflation can be tremendously helpful, it is unlikely to be sufficient in foals with severe respiratory impairment secondary to surfactant deficiency caused by progressive alveolar collapse and worsening ventilation/perfusion mismatching. In the most severely affected cases mechanical ventilation will represent the only viable means of respiratory support, and this technique is discussed in detail later in this section. However, noninvasive respiratory support strategies that provide continuous positive distending pressure, such as continuous positive airway pressure (CPAP), are widely used in human neonates with RDS and have been shown to reduce respiratory failure and mortality.[305] There are a few older reports of noninvasive ventilatory support techniques for foals that used mechanical ventilators and either nasal prongs or face masks.[306,307] A recent report described the adaptation of a commercial human CPAP device and face mask to provide CPAP to foals.[308] The authors reported that although both CPAP and nonpressurized oxygen supplementation with a face mask normalized pretreatment hypoxemia, oxygen extraction and CO_2 elimination were highest with CPAP at a lower respiratory rate than nonpressurized oxygen administration. Both treatments were associated with the development of modest hypercarbia, but this was not associated with adverse effects. This treatment modality holds promise for foals suffering from NERDS, but further evaluation in affected foals is needed.

The syndromes of EqNALI and EqNARDS represent a subset of ALI and ARDS that occurs in foals in the first week of life. The criteria for EqNALI/EqNARDS differ from those for ALI/ARDS because of the changes that occur in the efficiency of pulmonary gas exchange as foals develop

during this time frame. Diagnosis of these syndromes is fundamentally similar to that of VetALI and VetARDS with the exception of the use of an age-specific scale of Pao_2/Fio_2 ratios based on blood gas values obtained from foals breathing room air and positioned in lateral recumbency, as is typically encountered in clinical practice. It is important to remember that EqNALI/EqNARDS is not a primary diagnosis, and affected foals may be suffering from a broad range of disease processes. There certainly may be overlap with NERDS, but bacterial sepsis and bacterial pneumonia will be the most common disease processes in foals of this age. Other potential etiologies include meconium aspiration, milk aspiration, viral pneumonia, fungal pneumonia, or thoracic trauma, all of which are covered in detail in the following sections.

Treatment of EqNALI/EqNARDS is primarily focused on addressing hypoxemia and hypercapnia while pursuing correction of the primary etiology where possible. Respiratory support may involve the provision of intranasal oxygen, CPAP, or mechanical ventilation, depending on the severity of pulmonary dysfunction. Because of the substantial inflammation present, there may be an indication for antiinflammatory therapy. Nonsteroidal antiinflammatories are unlikely to be sufficient, but there is evidence in adult humans with ARDS[309,310] and in older foals with VetARDS[311,312] that corticosteroid therapy may be beneficial. Although specific therapeutic protocols have not been defined, recent work has suggested that hydrocortisone administration at a dosage of 1 to 4 mg/kg per day IV divided into four to six doses may be appropriate for septic foals with CIRCI, but this approach has not been investigated in septic foals or foals with EqNALI/EqNARDS.[313-315] Because of the likelihood that bacterial infection may be involved in this age group, broad-spectrum antimicrobial therapy is also indicated along with judicious fluid therapy and supportive care.

The most definitive descriptions of acute respiratory distress in foals have been associated with bronchointerstitial pneumonia in foals 1 to 12 months of age.[311,312,316,317] Affected foals often appear clinically normal until they are found in acute respiratory distress or dead.[311] Some cases may have a history of previous respiratory disease associated with sudden clinical deterioration.[293] Physical examination finds affected foals depressed, lethargic, and inappetent, with severe respiratory distress characterized by tachycardia, tachypnea, and nostril flare. A paradoxic breathing pattern may be present, in which the thorax and abdomen move opposite from one another, rather than synchronously, during inspiration and expiration. Auscultation may reveal widespread abnormal sounds, with prominent wheezes and crackles, or lung sounds may be very quiet to absent with only large airway sounds detectable. Fever and injected mucous membranes are common as well. Care should be taken to auscult the heart thoroughly, which may be difficult in the presence of diffuse abnormal respiratory sounds, to rule out a cardiac cause of pulmonary edema. Clinicopathologic evaluation is important both for assessment of pulmonary function and identification of the primary underlying disease process. Arterial blood gas analysis is extremely helpful and should be performed before initiation of intranasal oxygen insufflation, if clinically appropriate. Complete blood count, fibrinogen concentration, and SAA concentration are all helpful in characterizing the severity of systemic inflammation, and very high WBC counts, fibrinogen, or SAA concentrations, although not definitive, may be suggestive of *Rhodococcus equi* infection.[318,319]

Thoracic imaging is extremely helpful in staging the degree of pulmonary inflammation and identifying underlying primary disease processes. Thoracic ultrasonography is readily performed and may provide useful information, such as the presence of severe atelectasis, pleural effusion, or pulmonary abscesses. Diffuse lung inflammation, such as occurs in ALI, will be seen as thickening of the visceral pleura and the appearance of echogenic projections arrayed perpendicular to the surface of the lung (comet-tail artifacts).[320] Thoracic radiographs provide much more detailed information regarding the severity and extent of pulmonary inflammation, and reasonable image quality can be obtained with stall-side digital radiographic equipment.[321] The radiographic abnormalities observed in affected foals may range from a diffuse interstitial pattern to a focal or diffuse coalescing alveolar pattern with multiple air bronchograms, and serial radiography can be very helpful in monitoring the progression of disease and response to treatment.[293,321] The presence of pulmonary abscesses on thoracic ultrasonographic examination or in thoracic radiographs is strongly suggestive of *R. equi* involvement but is not definitive.[318] CT imaging of the thorax for the evaluation of foals with pulmonary disease has been recently reported as well.[321,322] CT imaging provides much more detailed information regarding the nature and degree of pulmonary changes but is only available in a few specialty referral settings at this time.

Foals affected with VetALI/VetARDS most commonly suffer from a primary bacterial pneumonia, but other causes such as viral pneumonia are possible. A transtracheal aspirate should be performed unless the patient is too unstable to undergo the procedure; this sample can provide important cytologic evidence regarding the type and severity of pulmonary inflammation and the presence of extracellular and intracellular bacteria and should also be submitted for bacterial culture and sensitivity. Neutrophilic inflammation is typically present, and the detection of intracellular gram-positive coccobacilli within pulmonary macrophages is strong evidence of the presence of *R. equi.*[318] Polymerase chain reaction (PCR) testing of tracheal aspirates may be helpful in confirming rhodococcal involvement.[323] Treatment of ALI/ARDS-affected foals should focus on addressing the hypoxemia, treating the primary underlying disease process, controlling the excessive inflammatory response, and providing supportive care. Intranasal oxygen insufflation, as described previously, should be initiated as soon as possible in foals suffering from respiratory distress and represents the primary means of respiratory support in these older foals. Antimicrobial therapy should target the most likely bacterial pathogens based on the overall assessment. In younger foals in which sepsis may be playing a primary role, broad-spectrum antimicrobial therapy is recommended. In older foals empiric treatment should address the possible involvement of *R. equi.* Aggressive systemic antiinflammatory therapy using potent corticosteroids, such as dexamethasone and methylprednisolone sodium succinate, has been shown to be the most important intervention in effecting survival of affected foals.[311,312,324] Corticosteroid therapy should be gradually tapered as the clinical condition improves, rather than rapidly withdrawn. Prolonged therapy has been shown to be beneficial in human ARDS patients.[310] Bronchodilator therapy has been used in affected foals because of the severity of

respiratory distress, but bronchoconstriction is not a prominent feature of ARDS, and bronchodilator administration may actually worsen the ventilation/perfusion mismatching and result in clinical deterioration or even death.[293] If used, bronchodilator therapy should only be administered after nasal insufflation of oxygen has been instituted, and the clinician should be prepared to address sudden changes in clinical status. The use of the inhalational route for the administration of corticosteroids and bronchodilators in patients suffering from severe pulmonary dysfunction with substantial ventilation/perfusion mismatching is often unrewarding because of poor pulmonary penetration and delivery, so the systemic route is recommended. The prognosis for survival in affected foals is poor to guarded, with early and aggressive corticosteroid and antimicrobial therapy offering the best chance of survival.[324]

Persistent Pulmonary Hypertension

Persistent pulmonary hypertension of the newborn (PPHN), also known as persistent fetal circulation or reversion to fetal circulation, is a syndrome characterized by sustained increases in pulmonary vascular resistance. Increased pulmonary vascular resistance, possibly combined with decreased right ventricular function, results in right-to-left shunting through the ductus arteriosus and/or foramen ovale.[325] PPHN can be idiopathic, but in human infants it is more commonly associated with pulmonary disease, such as meconium aspiration, perinatal asphyxia, surfactant deficiency, and pneumonia.[326] In foals PPHN may also develop secondary to systemic sepsis, hypoxemia, or acidosis.[327,328] The pathophysiology of PPHN is complex but fundamentally represents dysfunction of the factors that regulate pulmonary vascular tone. PPHN should be suspected in any neonatal foal exhibiting progressive or refractory hypercapnic hypoxemia. Care should be taken to rule out the presence of congenital cardiac anomalies that may be causing extrapulmonary shunting of blood and other causes of hypoxemic respiratory failure, such as sepsis or infectious pneumonia. PPHN should be suspected in cases of hypoxemia that do not show a significant increase in Pao_2 following the institution of intranasal oxygen therapy. Definitive diagnosis can be challenging, but ultrasonography can be very helpful in ruling out congenital cardiac anomalies and detecting primary pulmonary disease.

Treatment of PPHN is challenging but depends on addressing any predisposing or underlying factors while addressing the severe hypoxia. Foals that do not respond well to nasal insufflation of oxygen will require intubation and mechanical ventilation with 100% oxygen.[30] This can be useful both in addressing the hypoxia and in potentially stimulating pulmonary vascular relaxation.[327,328] Following a brief period of hyperoxia, it is recommended to taper the inhaled oxygen concentration to target a Pao_2 of 60 to 100 mm Hg.[325] Therapeutic agents that directly address the pulmonary vasoconstriction are widely used in human neonates, but inhaled nitric oxide (iNO) is the only approved pulmonary vasodilator for human use. The successful use of iNO therapy in foals has been reported,[327] but unfortunately it is impractical in most settings because it requires mechanical ventilation along with specialized equipment for introducing the NO gas into the ventilator circuit.[328] Sildenafil (Viagra, Pfizer Inc., New York), a phosphodiesterase type 5 inhibitor, has been used in humans and is reported to be effective.[326,329] There are anecdotal reports of the use of sildenafil in foals with PPHN, at a dosage rate of 0.5 to 2.5 mg/kg PO, up to every 4 hours, starting at the lower end of the dosage range to avoid systemic hypotension.[330] Although supported by only one case report in humans, the use of pentoxifylline, a nonselective phosphodiesterase inhibitor, as an adjunctive therapy may be worthy of consideration in foals because of availability, low cost, and an accepted safety profile.[331,332]

Congenital Upper Respiratory Tract Disorders

There are a number of congenital upper respiratory tract disorders in foals, although none is common. These can include wry nose, choanal atresia, cleft palate, nasopharyngeal cysts, and subepiglottic cysts.[333] Wry nose involves lateral and rotational deviations in the structure of the nose; in moderate to severe cases it will cause significant upper airway obstruction.[334] Surgical repair is possible, but this must be regarded as a salvage procedure, because the prognosis for athletic function is poor.[334] Choanal atresia is rare in foals but involves unilateral or bilateral soft tissue narrowing or complete obstruction of the caudal aspect of the nasal passages.[335] Foals born with bilateral complete obstruction will die without rapid intervention to establish an airway because of the obligate nasal breathing nature of equines.[333] Foals with unilateral choanal atresia often remain undiagnosed until later in life.[336] Diagnosis is most often made using endoscopy, but CT examinations have been useful in some cases.[336] Surgical correction is feasible, but the prognosis for performance remains guarded because of the persistent airway narrowing in many cases. Cleft palate deformities are rare and are reported in only 0.1% to 0.8% of foals.[337] Most affected foals will show clinical signs of dysphagia when nursing, including coughing or nasal milk drainage, but this is inconsistent.[338] Aspiration pneumonia is a common complication. The primary site of involvement is the soft palate, and the defect can range from a small, focal site to essentially the absence of the entire soft palate. Diagnosis is most readily made endoscopically, although surgical correction is theoretically possible; the approach is difficult and the outcome uncertain, especially with large defects.[337] There is one recent report of successful transoral endoscopically assisted repair in a foal.[339] Subepiglottic cysts are also rare in foals, but when present they can interfere with epiglottal placement, resulting in persistent palate displacement and severe dysphagia and aspiration pneumonia.[333,340] Diagnosis is primarily by endoscopic examination, although visualization may be difficult if the cyst is positioned below the palate. Radiographs or CT may be helpful in detecting these lesions. Treatment is by cyst removal, either via laryngotomy or by nasal or oral endoscopic approaches.[333]

Meconium Aspiration

Meconium aspiration syndrome (MAS) is defined as respiratory distress in a foal born through amniotic fluid stained with meconium in which the symptoms cannot be explained by other etiologies. Meconium staining can occur before, during, or immediately after parturition, and meconium passage in utero is thought to primarily occur in response to fetal hypoxia leading to fetal stress. Fetal hypoxia also may result in fetal gasping, facilitating introduction of meconium into the respiratory tract while in utero. Meconium aspiration may also occur in association with the first few breaths after birth. The presence of meconium-stained amniotic fluid does not guarantee that MAS will occur, however, because only

2% to 9% of human infants born through meconium-stained amniotic fluid develop MAS.[341] When meconium contamination of the lower respiratory tract occurs there are a number of pathophysiologic mechanisms leading to pulmonary dysfunction, including mechanical airway obstruction, regional air trapping, surfactant inactivation, surfactant displacement, chemical pneumonitis and alveolitis, and persistent pulmonary hypertension.[327,341]

If meconium aspiration is suspected then aspiration of the material from the nasal passages and pharynx can be performed, even while the foal is in the birth canal, if the birth is attended. If more severe contamination is suspected then nasotracheal intubation followed by aseptic suctioning is suggested, although care must be taken to avoid contamination of the lower respiratory tract or overly zealous suction. Intranasal oxygen supplementation is recommended in affected foals, but mechanical ventilation will be required in more severely affected cases and is associated with a worsened prognosis. Mechanical ventilation is challenging in these cases because of the degree of pulmonary inflammation and airway compromise as well as the severity of ventilation/perfusion mismatching and strategies to minimize barotrauma, such as CPAP ventilation and synchronized intermittent mandatory ventilation (SIMV), which may be helpful.[342,343] Surfactant administration and lung lavage with dilute surfactant appear to be effective in human neonates with MAS but are not routinely used in foals.[344] Antiinflammatory therapy may be beneficial because of the substantial pulmonary inflammation associated with MAS. Pentoxifylline has shown some promise in animal models, appears safe in foals, and is easily administered.[345,346] Corticosteroids, either inhaled or systemically administered, are commonly used in human infants with MAS.[347,348] Although meconium aspiration is not associated with primary bacterial pneumonia, affected foals are at risk of secondary bacterial infection, and broad-spectrum antimicrobial therapy is recommended.

Milk Aspiration

Neonatal foals may aspirate milk into the lower respiratory tract secondary to a number of conditions, although this is most common secondary to generalized weakness, a poor suckle reflex, or dysphagia related to prematurity or NE.[349] This risk may be exacerbated by attempts at bottle feeding foals affected with these problems. Other potential causes of aspiration include physical abnormalities such as subepiglottic cysts, cleft palate, megaesophagus, esophageal stenosis, esophageal compression by vascular anomalies, or persistent dorsal displacement of the soft palate.[342,349,350] Functional abnormalities of the pharynx, larynx, and esophagus resulting in aspiration have been associated with pharyngeal dysfunction of unknown etiology, botulism, and hyperkalemic periodic paralysis.[342,349,351] Incorrect placement of nasoesophageal feeding tubes has also been associated with direct instillation of milk into the lungs, leading to aspiration pneumonia. Detection of milk aspiration can be difficult because some affected foals may not cough or show nasal milk regurgitation. Diagnosis is based on historic information that may reveal episodes of nasal milk regurgitation, physical examination findings demonstrating abnormal lower respiratory sounds, and clinicopathologic evidence of systemic inflammation (inflammatory leukogram and hyperfibrinogenemia or increased SAA) and pulmonary dysfunction (arterial hypoxemia).[342] Endoscopic examination of the upper respiratory tract may reveal structural abnormalities of the pharynx, larynx, or esophagus suggestive of aspiration, or pharyngeal dysfunction may be observed. Thoracic radiographs typically reveal an alveolar pattern with or without air bronchograms in the caudoventral lung, but this may be localized to the perihilar region.[321] It is important to pursue the identification and correction of the cause of aspiration, if possible, to prevent further aspiration. Placement of a nasoesophageal feeding tube will allow for the safe delivery of milk pending correction of the underlying disorder. Broad-spectrum antimicrobial therapy is indicated to address the bacterial pneumonia accompanying milk aspiration, and successful treatment may require several weeks of treatment.

Transient Tachypnea

Idiopathic or transient tachypnea has been reported in Clydesdale, Thoroughbred, and Arabian foals and is generally seen during hot, humid weather conditions.[352] This condition is believed to be the result of immature or dysfunctional thermoregulatory mechanisms.[327] Affected foals are usually normal at birth and of a normal gestational age, but they develop hyperthermia and tachypnea at variable times following birth.[342] It is critical that other potential causes of respiratory disease are ruled out before making the diagnosis of idiopathic tachypnea, because the consequences of withholding antimicrobial treatment could be severe. Treatment is primarily directed at controlling the hyperthermia and may include body clipping; alcohol baths; and movement to a cool, shady environment.[342] In most foals the condition is self-limiting and will resolve within a few days to a few weeks.

Rib Fractures, Pneumothorax, and Hemothorax

Rib fractures are a fairly common problem, having been reported in 3% to 5% of the general population of neonatal foals and as many as 30% of foals presenting to a neonatal ICU.[353] Fractured ribs can cause a number of traumatic insults to the thoracic viscera, including pulmonary contusions and lacerations of the lungs, major arteries, heart, or diaphragm. Pneumothorax, hemothorax, and diaphragmatic herniation may all occur as a result of these traumatic insults, and myocardial injury is typically fatal. Rib fractures can be single, but are often multiple, most often affecting adjacent ribs on one side of the chest. The most common site of injury is at the costochondral junction or immediately dorsal to it.[354] Flail chest, or paradoxic thoracic wall motion, may occur when multiple ribs are fractured, and the affected region will move inward during inspiration and outward during expiration, counter to the movements of the intact portions of the thoracic wall. Rib fractures are commonly found on physical examination by palpation of the fracture itself or by the detection of crepitus at the site of the fracture. Auscultation may reveal grinding or "clicking" sounds in the area of the fracture as well. Confirmation of the diagnosis is best accomplished ultrasonographically because this modality is much more sensitive than radiography for this purpose.[355] Ultrasonography may also be used to document the presence of air, blood, or abdominal viscera within the thoracic cavity, although radiography may be helpful in this evaluation. Treatment depends on the structures involved and the severity of the complications observed. Most minimally displaced rib fractures, particularly those involving the costochondral junction, can be managed conservatively with stall rest and avoidance of pressure on the affected area when the foal is handled. Mild to moderate pneumothorax may not

require intervention, but if substantial air is presented within the pleural cavity it will cause respiratory distress and should be evacuated. Placement of an indwelling thoracic catheter will facilitate ongoing drainage. If multiple ribs are fractured, and particularly if sharp bony projections are exposed and threatening internal injury, then surgical repair may be indicated.[356] Hemothorax can be life-threatening because of pulmonary compression and/or severe blood loss anemia, and treatment should focus on addressing the primary cause of hemorrhage and patient stabilization and support.[357]

Viral Infections

Viral pneumonia is uncommon in neonatal foals but has been associated with EHV-1, EHV-4, equine influenza virus (EIV), equine arteritis virus (EAV), and equine adenovirus (EAdV). EHV-1 infections in neonatal foals are severe and typically fatal, despite aggressive treatment. One of the challenges associated with these cases is the difficulty of ascertaining EHV-1 involvement, because the presenting signs are very similar to neonatal sepsis. Foals may be delivered somewhat early and with little or no warning of impending parturition, and the placenta is usually grossly normal.[328] Farm outbreaks have been reported.[184,358,359] Clinical signs are of cardiovascular and respiratory insufficiency, and the mucous membranes are severely congested and icteric. Clinicopathologic abnormalities include severe leukopenia with neutropenia, toxic neutrophil morphology, and lymphopenia. The combination of severe leukopenia and icterus may be suggestive of EHV-1 infection.[183] Bone marrow examination will reveal depletion of the myeloid cell lines. Many affected foals will display dilation of the retinal vasculature with reddish discoloration of the optic disk. Diagnostic confirmation is most readily accomplished by PCR testing of nasal secretions or whole blood. Treatment of affected foals with acyclovir has been attempted, and this appeared to have some efficacy in less severely affected foals.[184] Given the superior bioavailability of valacyclovir in adult horses, this drug may represent a more suitable choice for use in EHV-1–infected foals.[328,360] EHV-4 appears to be a rare cause of neonatal disease and is more commonly associated with abortion or stillbirth, but it has been associated with neonatal mortality caused by multisystemic disease.[361,362]

Infections with EIV in neonatal foals are not common, particularly in endemic areas in which mares are routinely vaccinated and foals are typically protected by maternal colostral antibodies.[363-366] Outbreaks have been reported when EIV has been introduced into naïve populations.[364,366] EIV infection in susceptible foals is associated with severe bronchointerstitial pneumonia leading to respiratory distress.[364] Antemortem diagnosis is by PCR of nasal secretions. There is no specific treatment for EIV infection.

Neonatal infections with EAV are associated with severe interstitial pneumonia, which has been reported to be uniformly fatal.[367-369] Both solitary cases and farm outbreaks have been reported.[367,368,370-372] The clinical signs associated with neonatal EAV infection are severe and primarily respiratory and initially include edema, weakness, and depression, ultimately progressing to terminal respiratory distress, although acute death has also been reported.[368,372] Gastrointestinal involvement has been reported in some cases but is not consistently present.[367,369] Clinicopathologic abnormalities are not specific to EAV infection but often include leukopenia and thrombocytopenia.[368] There is no specific antiviral treatment for EAV, and despite attempts at aggressive medical therapy there are no reports of successful treatment of neonatal EAV infections. Diagnostic confirmation of EAV involvement is most readily achieved by PCR testing of blood, respiratory secretions, or tissues (lung, kidney, and spleen).[372]

EAdV infections are rare in immunocompetent foals, and the primary concern is in immunocompromised foals. The best described syndrome associated with EAdV infections is in Arabian foals with severe combined immunodeficiency syndrome, although a similar syndrome may occur in Fell pony foals with an unidentified immunodeficiency.[373-375] Two distinct EAdVs have been identified, with EAdV1 being ubiquitous and readily isolated from normal and diseased foals and horses, whereas EAdV2 is only isolated from foals with upper respiratory tract disease and diarrhea.[373,376,377] Experimental infection of healthy foals with EAdV has been associated with pneumonia regardless of breed.[378,379] PCR testing for EAdV1 and EAdV2 is available, but care must be taken with interpretation because EAdV1 is frequently detected in normal animals. Confirmation of diagnosis may require histopathologic evidence of EAdV infection or virus isolation.[373]

Viral respiratory infections are more common in older foals than in neonatal foals, and respiratory disease in this age group has been associated with EHV-1, EHV-4, EIV, and EAV.[380] The clinical signs associated with EHV and EIV infections in this age group are very similar and are consistent with those reported in adult horses. Clinical signs typically include a dry cough and fever, although a mucopurulent nasal discharge may be present as well. The presence of such a discharge may be suggestive of secondary bacterial involvement, however. EIV and EHV infections in older foals are typically much less severe than in neonates and ultimately self-limiting. A rare, fatal pulmonary vasculotropic form of EHV-1 infection has also been described in young horses.[381] EAV infections typically show similar respiratory signs and fever, but affected individuals often exhibit substantial ventral and limb edema secondary to vasculitis.[369]

The potential role of the gammaherpesviruses, EHV-2 and EHV-5, in foal pneumonia is intriguing but currently unclear. Both of these viruses are ubiquitous in equine populations worldwide, and foals become infected within the first several months of life.[382] Infection in foals is generally considered to occur without clinical signs, but EHV-2 infection has been associated with mild to severe chronic pharyngitis of foals following natural and experimental infection.[383] Other signs of upper respiratory tract disease, such as lymphadenopathy, mild pyrexia, and rhinitis may be associated with natural infections.[384-387] Some intriguing evidence exists that EHV-2 may play a role in potentiating lower respiratory bacterial infections; there are reports that use of an EHV-2 vaccine protected foals from *R. equi* pneumonia.[388,389] Natural infection of foals with EHV-2 has been associated with fever and immunopathologic changes similar to those observed in human adolescents suffering from infectious mononucleosis following infection with Epstein-Barr virus.[390] In addition, the EHV-2 genome contains an IL-10 homolog as well as encoding for several other proteins that may have immunomodulatory effects that could predispose a patient to bacterial infections.[382] The case for a pathogenic role for EHV-5 is stronger, because this virus has been convincingly associated with the syndrome of equine multinodular pulmonary fibrosis.[391-394]

Fungal Diseases

Although fungal pneumonia is very rare in neonatal foals, there are a few conditions to be aware of in this population. In utero infection with *Histoplasma capsulatum* has been associated with placentitis, abortion, and the birth of infected foals.[395,396] Affected foals have multisystemic disease, including granulomatous pneumonia.[395] Antemortem diagnosis is challenging but may be facilitated by tracheal aspirate or bronchoalveolar lavage cytology, in which characteristic yeastlike organisms (3- to 5-μm diameter) may be detected within the macrophages.[342] Serology is useful as well. The mare and foal should be positive for anti-*Histoplasma* antibodies, which can be detected using an agar gel immunodiffusion test.[328] Although successful treatment of infected adults has been reported using amphotericin B, there are no reports of successful treatment in neonatal foals.[328]

Although *Candida* spp. infections are a major problem in human intensive care patients, they appear to be an infrequent problem in foals. Systemic candidiasis has been reported in foals, but superficial infections of the mucous membranes (thrush) appear to be more common.[397-400] The presence of superficial infections may be related to the development of systemic infections, so these lesions should be taken seriously and treatment implemented in a timely manner. This concern is reinforced by the fact that the clinical signs associated with systemic candidiasis are indistinguishable from those seen in bacterial sepsis.[400] Confirmation of the diagnosis of systemic candidiasis is by blood culture of the organism. Successful treatment has been reported with IV amphotericin B and/or oral fluconazole, with fluconazole preferred.[400]

Parasitic Pneumonia

Following ingestion of the larvated eggs of *Parascaris equorum* the infective larvae emerge in the intestinal lumen and migrate through the liver and lungs before being coughed up and reingested, returning to the small intestine in which they mature into adults.[401] Passage through the lungs is associated with substantial inflammation, and infected foals may present with clinical signs of lower respiratory disease when the larvae are migrating through the lungs.[402] Infestation is ultimately self-limiting, and the pulmonary signs rarely require medical treatment. Because of concerns regarding possible colic secondary to intestinal obstruction by the adult parasites, it is recommended that foals suspected of parasitic pneumonia be dewormed. Ivermectin has been recommended traditionally, but the widespread emergence of macrocyclic lactone–resistant strains has led to the recommendation that benzimidazole or pyrimidine anthelmintics should be used.[401] Resistance has been demonstrated in these classes as well, unfortunately, requiring individuals to be monitored with fecal egg counts to ensure efficacy of anthelmintic therapy.[403]

Bacterial Infections

Neonatal Foals

Bacterial pneumonia in neonates is most often associated with hematogenous spread secondary to bacteremia, but it may also occur secondary to infection in utero or meconium or milk aspiration. The bacteria associated with neonatal pneumonia are typically the same as those involved in neonatal sepsis, and gram-negative bacteria are the organisms most commonly involved. Gram-positive infections appear to be increasing in prevalence, however, and mixed infections occur as well.[404] The most common isolate is *E. coli,* with *Klebsiella* spp., *Actinobacillus* spp., *Pasteurella* spp. *Salmonella* spp., *Streptococcus* spp., *Enterococcus* spp., and *Staphylococcus* spp. also occurring with some frequency.[25,171,176,178,180,181] Successful treatment depends on early and effective support of respiratory function with correction of hypoxemia, control of systemic and pulmonary inflammation, and appropriate antimicrobial therapy. Unfortunately antimicrobial selection is almost always empiric initially, but collection of blood culture samples before initiation of antimicrobial therapy is encouraged to provide confirmation of bacterial involvement and to guide future antimicrobial therapy on the basis of antimicrobial sensitivity patterns. Transtracheal aspirates are not commonly performed in neonatal foals because they can be technically challenging and may worsen the foal's respiratory distress. They can be very useful diagnostically, especially when the respiratory infection is secondary to aspiration.[404] Because of the possibility of polymicrobial and mixed infections, broad-spectrum therapy is recommended initially. This often consists of a β-lactam (penicillin) in combination with an aminoglycoside, but a third-generation cephalosporin, such as ceftiofur, may represent a better choice because of its superior pulmonary penetration.[328]

Older Foals

Pneumonia is common in foals from 1 to 6 months of age and is the most common cause of death in this age group.[405] The most common etiologic agent of bacterial pneumonia in these older foals is *Streptococcus equi* subsp. *zooepidemicus,* which is a normal upper respiratory commensal organism. This age group of foals may be at risk for the development of respiratory infections caused by decaying levels of maternal immunoglobulins in conjunction with delayed endogenous immunoglobulin production and possibly impaired immunologic responses to pathogen exposure. Additional risk factors in older foals include the stresses of weaning and sales preparation and transport, as well as confinement in crowded or dusty conditions that result in heavy exposure to potential respiratory pathogens. Secondary infection with gram-negative organisms is not uncommon, and foals in which this occurs may exhibit a poor response to treatment or deteriorate clinically in the face of treatment. Viral infections such as EHV-1, EHV-4, and EIA may cause pulmonary inflammation and injury, whereas other viral infections such as EHV-2 may directly impair pulmonary immune responses, facilitating the development of secondary bacterial pneumonia.

The second most common agent of pneumonia in this age group is *R. equi,* which is a facultative, intracellular gram-positive coccobacillus. This organism was first isolated from foals with pyogranulomatous pneumonia in Sweden in 1923 and was originally named *Corynebacterium equi.*[406] Although it has been known as *R. equi* for several decades, the taxonomic nomenclature for this organism is a matter of ongoing debate, and the alternative names *Prescottella equi* and *Prescottia equi* have been recently proposed.[407,408] The conventional terminology *R. equi* will be used here. *R. equi* is considered to be a ubiquitous bacterium with a worldwide distribution,[409] although a recent study suggests that it may not be present in Iceland.[410] All isolates capable of causing disease in foals carry a plasmid encoding a virulence-associated protein (VapA). Although VapA is required for virulence, it alone is not sufficient, and other plasmid-encoded genes also influence virulence.[349] Rhodococcal pneumonia is occasionally seen as a

sporadic disease but is more common on endemic farms, on which there is often substantial variation in the incidence of disease on an annual basis.[411] On endemic farms as many as one third of the foals are affected with clinical disease, and up to 50% of affected foals may die.[412] The most likely route of infection in foals is by inhalation, and increased airborne concentrations of virulent *R. equi* are positively associated with the development of pneumonia.[413,414] High stocking densities of mares and foals have also been associated with an increased incidence of rhodococcal pneumonia.[415,416] Higher concentrations of *R. equi* have been detected in stalls and barns, as opposed to pastures and paddocks,[417,418] and this could lend support to the suggestion that dusty conditions are associated with an increased incidence of rhodococcal infection.[419]

R. equi infections are rare in adult horses unless they are suffering from some form of immunodeficiency. Given the ubiquitous nature of *R. equi* in the environment, this suggests that foals are in some way uniquely susceptible to infection by this organism. Several studies have investigated the immune responses of foals, but the results have been inconclusive and there is no clear evidence of an age-related immunodeficiency that renders them susceptible.[420,421] Recent studies have investigated the potential for genetic predispositions to rhodococcal infections, with some intriguing findings. Polymorphisms in the transferrin and *SLC11A1* genes have been associated with rhodococcal pneumonia in Thoroughbred and Arabian foals, respectively.[422,423] More recently a genetic region on chromosome 26 that contains the *TRPM2* gene, which is associated with neutrophil function, was found to be positively associated with rhodococcal pneumonia, and foals with a single nucleotide polymorphism in this region were three to four times more likely to be clinically affected than their herdmates.[424]

Because of the occult nature of this disease, there has been tremendous interest in identifying infected foals as early as possible so that treatment can be implemented early in the disease process. To this end a number of screening programs for early detection of infected foals have been investigated, including serial monitoring of physical examinations, WBC concentration, fibrinogen assays, SAA concentration, and quantitative fecal VapA PCR testing, but none has proven to be clinically effective.[349,425] Serology has been unrewarding as well,[426] although there are recent reports that VapA-specific serum IgG(T) measurement may be useful in identifying infected foals, although this requires further validation in the field setting.[410,427] Ultrasonographic screening programs were developed, and these demonstrated that large numbers of foals had pulmonary lesions in the absence of clinical signs.[428] Because of the widespread implementation of these ultrasonographic screening protocols on endemic farms, subclinical *R. equi* infections have become the most common form of this disease.[429] This approach has also resulted in the treatment of many foals in which the pulmonary lesions would likely have resolved spontaneously, contributing to the development of macrolide resistance.[430,431]

Clinically evident rhodococcal pneumonia is often insidious, ultimately presenting with signs consistent with lower respiratory tract infection, and fever, lethargy, coughing, tachypnea, and dyspnea are common clinical signs. Dyspnea can be severe, with nostril flaring and prominent abdominal expiratory effort. Although relatively rare, some foals may present with a subacute, severe form of respiratory disease, consistent with ARDS, and severely affected foals may be found dead.[429] Auscultation typically reveals diffuse crackles and wheezes, with prominent large airway sounds (rattles) caused by the accumulation of exudate in the cranial thoracic region. Rebreathing examination is typically not necessary because of the prominence of the abnormal lung sounds, and it is contraindicated in animals in respiratory distress. It is important to perform a thorough examination in affected foals, because extrapulmonary disorders are common.[432] The most common of these are diarrhea, ulcerative enterotyphlocolitis, presumed immunomediated synovitis, intraabdominal lymphadenitis, or abscessation and uveitis.[432] Arterial blood gas analysis is extremely helpful in assessing the degree of pulmonary dysfunction and should be performed before initiation of intranasal oxygen insufflation if clinically appropriate. Complete blood count, fibrinogen concentration, and SAA concentration are all helpful in characterizing the severity of systemic inflammation, and very high WBC counts, fibrinogen, or SAA concentrations, although not definitive, may be suggestive of *R. equi* infection.[318,319] Serial monitoring of these values can be helpful in assessing the response to treatment and in determining the duration of therapy.

Thoracic imaging is extremely helpful in staging the degree of pulmonary inflammation and supporting the diagnosis of rhodococcal involvement, and serial imaging studies can be very helpful in monitoring the progression of disease and response to treatment. Thoracic ultrasonography is readily performed and is very effective for the detection of peripheral pulmonary consolidation or abscesses, but it is unable to detect axial lesions unless peripheral lesions are present.[349] Despite these limitations ultrasonography is the most widely used imaging technique in evaluating foals suspected to have rhodococcal pneumonia because of the combination of ready availability, ease of performance, and diagnostic utility. Abdominal ultrasonography should also be performed in foals with suspected rhodococcal pneumonia because of the frequency of abdominal extrapulmonary disorders. Thoracic radiographs provide more detailed information regarding the severity and extent of pulmonary disease, however, and should be considered in more severely affected cases, particularly given that reasonable image quality can be obtained with stall-side digital radiographic equipment.[321] The radiographic abnormalities observed in affected foals may include a diffuse interstitial or alveolar pattern, tracheobronchial lymphadenopathy, intrapulmonary abscesses, and pleural effusion. A scoring system has been developed to assess the severity of alveolar pattern, interstitial pattern, tracheobronchial lymphadenopathy, pleural effusion, and the number of nodular opacities and cavitary lesions in affected foals.[433] Foals with higher median scores (≥15) were less likely to survive (odds ratio [OR] 6.15, 95% confidence interval [CI]: 1.35–28.2) than foals with a lower score, with only the severity of the alveolar pattern and number of cavitary lesions being associated with decreased survival. Care should be taken to avoid overinterpretation of imaging studies, especially thoracic ultrasonography, because many of the lesions detected may resolve without therapeutic intervention. A recent study on an endemic farm found that 80% of foals developed ultrasonographic evidence of pulmonary consolidation or abscess formation, but only 21% developed clinically apparent *R. equi* pneumonia.[434] As a result of this concern a thoracic ultrasonographic scoring system has been used in several prospective studies of rhodococcal pneumonia therapies in an effort to more effectively identify foals that require treatment.[431,435-438] This scoring

system defines a pulmonary abscess as a focal hypoechoic area with a diameter of ≥1.0 cm, and the number of abscesses identified is recorded along with the diameter of each abscess. The diameter of each individual abscess is totaled to generate a total abscess score in centimeters, with foals that have a total score less than 8 cm or 10 cm typically not receiving treatment.

Following the completion of any imaging studies a transtracheal aspirate should be performed unless the patient is too unstable to undergo the procedure; this sample can provide important cytologic evidence regarding the type and severity of pulmonary inflammation and presence of extracellular and intracellular bacteria. This sample should also be submitted for bacterial culture and sensitivity. Profound neutrophilic inflammation with degranulation of neutrophils is typically present, and the detection of intracellular gram-positive coccobacilli within pulmonary macrophages is strong evidence of the presence of *R. equi*.[318] PCR testing of tracheal aspirates may also be helpful in confirming rhodococcal involvement, because the culture is frequently negative even when intracellular bacteria are seen on cytologic examination.[323] Quantitative PCR testing of feces was recently investigated on an endemic farm and was found to be useful in diagnosing *R. equi* in foals with clinical signs of pneumonia and, although these results are preliminary, this technique may prove useful in situations where tracheal aspirates cannot be collected.[439]

Treatment of foals with rhodococcal pneumonia should focus on addressing respiratory distress, if present, and treatment of the infection. Oxygen insufflation should be provided, if possible, to animals with dyspnea. Nonsteroidal antiinflammatory therapy may be helpful in controlling the fever, and affected animals should be kept in a cool, shaded area if possible because of the risk of exacerbation of physiologic hyperthermia. Antimicrobial therapy of rhodococcal pneumonia has been based on the combination of a macrolide and rifampin for over 30 years, which is an approach that was validated by a recent ACVIM consensus statement.[440] Although erythromycin was initially the primary macrolide used, it has been supplanted by azithromycin and clarithromycin for a variety of reasons, including less frequent administration, superior drug distribution, and pharmacokinetics as well as evidence of superior efficacy in a retrospective study.[420,441,442] There has been interest in the use of gamithromycin for the treatment of *R. equi* infections in foals because the pharmacokinetics support once-weekly intramuscular administration.[443] A recent study reported that gamithromycin therapy was noninferior to the combination of azithromycin and rifampin, although they also reported that 58% of foals treated with gamithromycin showed adverse reactions consisting of either colic or hindlimb lameness following drug administration, which is likely caused by tissue irritation from the drug.[435] The potential efficacy of the macrolide tulathromycin has been investigated, but despite early reports of efficacy[437] it has unacceptable pharmacokinetics and has subsequently been demonstrated to be ineffective.[436]

Rifampin has been used in combination with macrolide therapy on the basis of in vitro evidence of synergistic effects with erythromycin and limited evidence of enhanced treatment efficacy.[440] A recent study compared the efficacy of an azithromycin-rifampin combination to azithromycin alone and found that both treatments were superior to placebo, but there was no difference in efficacy between treatments.[436] Despite this evidence of efficacy the combination has been called into question because of the interference of rifampin with macrolide absorption after coadministration.[444,445] It is still recommended to use rifampin in combination with a macrolide to aid in minimizing the development of resistant strains, because these combinations have been shown to have lower mutant prevention concentrations than any of the individual macrolides or rifampin alone.[440,446] Reports of the emergence of macrolide-resistant and rifampin-resistant strains of *R. equi,* especially on endemic farms in which large numbers of foals have received treatment for subclinical pulmonary lesions identified on survey ultrasonographic examination, reinforce the need for this approach.[430,447,448] Indeed, one can reasonably question the need to treat foals that are not suffering from more severe forms of the clinical disease; recent studies examining treatment efficacy have also reported that 78% to 88% of foals in the untreated control groups recovered without intervention.[431,435] The prognosis for survival and athletic function in foals with *R. equi* pneumonia are good, at 60% and 54%, respectively.[349] Unfortunately the odds of survival are approximately sevenfold lower in foals infected with macrolide-resistant strains.[448]

There has been tremendous interest in reducing the incidence of rhodococcal infections on endemic farms for many years, but no highly effective approaches have been identified. The mainstay of prevention on many farms has been the administration of hyperimmune plasma, despite some conflicting evidence regarding efficacy, and widespread acceptance that even in the best-case scenario protection is incomplete.[449-453] Despite the expense, difficulty of administration, and potential for complications, the administration of hyperimmune plasma will likely continue to be used in prevention efforts until better approaches become available. Chemoprophylactic strategies have been investigated using azithromycin and gallium maltolate, with azithromycin yielding conflicting results and gallium showing no evidence of efficacy.[438,454,455] The prophylactic use of macrolides should be discouraged, however, because of the emergence of resistant strains on farms in which large numbers of foals receive these drugs.[430] Ultimately vaccination represents the ideal prevention strategy, but despite intensive investigation no effective vaccine is yet available.[420,456]

Respiratory Therapeutics

Bronchodilators

In foals suffering from respiratory dysfunction or respiratory distress there may be some utility in using bronchodilators to increase the airway diameter, decreasing the work of breathing and improving ventilation. The clinical utility of this approach is limited, however, because bronchoconstriction does not appear to play a prominent role in ARDS.[457] The other factor limiting the utility of bronchodilator therapy is the risk that the resulting increase in ventilation may actually worsen the degree of ventilation/perfusion mismatching caused by increased ventilation of areas of the lung that are poorly perfused. To determine whether bronchodilator therapy may be beneficial, one can perform a bronchodilator response test under close clinical monitoring. Because of the risk of worsening hypoxemia, it is best if the foal is already receiving oxygen by nasal insufflation, but at the very least oxygen should be readily available in case of clinical deterioration. Administer a single dose of a short-acting bronchodilator, preferably by inhalation rather than systemically, and then monitor the response using clinical assessment and ideally with repeated arterial blood gas analysis.[324] If the patient responds favorably,

TABLE **20.10 Inhaled Drugs Used for Treating the Respiratory Tract**

Class	Drug	Dose	Route	Frequency (h)
Bronchodilator	Albuterol	90–180 μg (young foals) 360 μg (weanlings)	MDI, Neb	2–6
	Ipratropium bromide	18–36 μg	MDI, Neb	8–12
	Ipratropium bromide with albuterol	18–36 μg ipratropium, 90–180 μg albuterol	MDI, Neb	8–12
Aerosolized antimicrobial	Ceftiofur	2.2 mg/kg	Neb	24
	Gentamicin	2.2 mg/kg	Neb	24

MDI, Metered dose inhaler; *Neb,* nebulization.

with decreased respiratory effort and improved arterial oxygenation, then it may be reasonable to continue bronchodilator therapy. Regarding the choice of bronchodilator, the methylxanthines (aminophylline and theophylline), although readily available, are not recommended because of their systemic effects and narrow therapeutic index.[458] Generally, the use of the aerosol route is preferred; this targeted application allows for the use of smaller dosages, reducing the risk of systemic toxicity. β_2-Adrenergic agonists (albuterol and clenbuterol) are easily administered and may have additional benefits including enhancement of mucociliary clearance. Albuterol is inexpensive and the metered dose inhaler (MDI) formulation is most often used (Table 20.10). This drug has a fairly short duration of action of 1 to 2 hours. The anticholinergic bronchodilator ipratropium bromide (Atrovent, Boehringer Ingelheim) has a longer duration of action than albuterol (6–8 hours) and can be used alone or in combination with a β_2-agonist (Combivent, Boehringer Ingelheim). Ipratropium is only available as an aerosol preparation, either as an MDI or a solution for nebulization.

Aerosolized Antimicrobials

The targeted administration of antimicrobial drugs to the respiratory tract is of interest because it achieves very high local drug concentrations, which may allow for a more rapid response while minimizing the risk of systemic toxicity.[459] Although controlled studies in horses are lacking, there is evidence in human medicine that the use of aerosolized antimicrobials as an adjunct to systemic therapy is well tolerated and may improve outcomes in certain subsets of patients.[460,461] Although a number of antimicrobial drugs have been administered via nebulization empirically in the clinical setting, only a few drugs have been investigated for aerosolized administration in horses, including ceftiofur, cefquinome, gentamicin, and marbofloxacin.[459,462-466] Aerosol administration of these drugs to horses has been shown to achieve high respiratory drug concentrations, is well tolerated, and appears safe. Anecdotally, the two most widely used inhaled antimicrobials in horses are ceftiofur and gentamicin[458] (Table 20.10). A variety of devices have been used to aerosolize these drugs, including jet and ultrasonic nebulizers, but the recently developed vibrating mesh nebulizers yield the most uniform and appropriately sized aerosols with a wide variety of drugs. The availability of a vibrating mesh nebulizer that is integrated into a face mask device specifically designed for horses (Flexineb, Nortev, Galway, Ireland) has greatly facilitated the ability to routinely deliver aerosolized medications in the clinical or field setting.

Mechanical Ventilation

The goals of mechanical ventilatory support are to achieve and maintain adequate pulmonary gas exchange, reduce the work of breathing, and minimize patient discomfort and distress.[467,468] Mechanical ventilation provides pressure and volume support to ensure that adequate minute ventilation is achieved and also provides control over the composition of the inspired gases to provide sufficient oxygen to support arterial oxygenation. Patients requiring mechanical ventilation typically are suffering from arterial hypercapnia and/or arterial hypoxemia. Treatment of hypercapnia, defined as a $Paco_2$ of greater than 60 mm Hg, is fundamentally to increase the patient's alveolar ventilation by increasing the rate and/or depth of breathing. For initial therapy some clinicians will use respiratory stimulants to increase the patient's ventilatory efforts and try to avoid the need for mechanical ventilation, but if respiratory stimulant therapy is unsuccessful at resolving the hypercapnia, or if the hypercapnia is more severe ($Paco_2$ > 70 mm Hg) one should consider instituting mechanical ventilation. Early intervention is preferable, because there is no benefit to the patient from prolonged hypercapnia and the duration of the requirement for mechanical ventilation is usually shorter with early intervention.

Treatment of hypoxemia, defined here as a Pao_2 of less than 60 mm Hg, is initially by increasing the fraction of inspired oxygen (Fio_2) through the provision of supplemental oxygen by intranasal insufflation, but this will be inadequate in patients with significant hypoventilation or ventilation/perfusion mismatching. Mechanical ventilation allows for much higher Fio_2 than can be achieved with insufflation, up to 100%, dramatically increasing alveolar oxygen tension. Mechanical ventilation is also useful in terms of increasing minute ventilation through controlled respiratory rate and volume and in recruitment of alveoli for participation in gas exchange. An additional benefit is the decrease in the effort required for respiration, which can be dramatically increased in the face of pulmonary disease, which allows for a substantial decrease in the patient's energy and oxygen needs. This can also ease patient distress and increase patient comfort.

In equine patients the provision of mechanical ventilatory support is indicated in only a few basic situations. The first of these is the patient lacking normal respiratory drive, such as the obtunded or comatose neonatal foal, or the patient with impaired ventilatory effort, such as a patient with botulism. These types of patients are fairly easy to ventilate because the lungs are not diseased and pulmonary function is relatively normal. The prognosis for survival of these foals is excellent if

mechanical ventilation is instituted early.[469,470] A fundamentally different situation is present in the patient with severe pulmonary disease resulting in respiratory failure, such as a foal with severe sepsis, ARDS, meconium aspiration, or severe pneumonia. In these patients the presence of pulmonary disease results in profound alterations in pulmonary function, primarily in the form of increased pulmonary resistance and decreased dynamic compliance, making these patients much more challenging to ventilate. The prognosis for survival in this population of foals is much more guarded. The decision to initiate mechanical ventilation can be an agonizing one because of concerns regarding prognosis, client cost, potential complications, and the intimidation factor associated with managing the ventilator. Unfortunately this can result in delays in the initiation of therapy that dramatically decrease the likelihood of a successful outcome. The development of some familiarity with the process of mechanical ventilation on the part of the neonatal intensive care team often results in a willingness to use mechanical ventilation earlier. Training sessions that provide familiarity with ventilator setup and initial settings are extremely useful, and so is a pictorial guide to setting up a circuit and attaching it to the patient.

PPV functions by generating a positive pressure within the patient's airways, which is used to overcome the resistance to airflow arising from the airways themselves, the lungs, and the thoracic wall. Invasive PPV relies on intubation for the establishment of an airway for gas exchange and aids in preventing the aspiration of upper respiratory secretions or refluxed stomach contents. Intubation is best achieved in the conscious patient by the nasal route, and this is easiest to do with the head fully extended. Nasotracheal tubes in the range of 7 to 10 mm outside diameter will accommodate most horse foals, and these tubes should be cuffed. The largest tube that can be passed through the upper respiratory tract without trauma should be used. Care should be taken to ensure that the tip of the tube is located in the cervical portion of the trachea, because it is possible to insert the tube too deeply, resulting in placement within a mainstem bronchus and ventilation of only one lung. After final positioning of the tube the cuff should be inflated with only enough pressure to maintain a seal during PPV, because excessive cuff pressure can cause tracheal injury and necrosis. The tube should be anchored to the patient's head to prevent inadvertent removal resulting from patient movement, and this can be done by tying a section of umbilical tape to the hub of the tube and anchoring the ends of the tape to an elastic tape bandage placed around the muzzle or to a soft cotton halter around the patient's head. Endotracheal tubes should be changed at least every 12 to 24 hours, because respiratory secretions and exudate will accumulate within the lumen of the tube, impeding gas flow and potentially causing obstruction of the tube. The presence of large amounts of pulmonary exudate may require even more frequent changing of the tube.

The ventilator gases must be appropriately pretreated before delivery to the patient to ensure that the gases are humidified and warmed and avoid injury to the respiratory mucosa. This can be achieved with an active humidifier, which is typically a component of the mechanical ventilator, and these devices are very effective in humidifying and warming the large volumes of gases involved. Unfortunately the gases tend to cool as they pass through the tubing from the ventilator to the patient, resulting in substantial condensation (rain out) within the circuit that must be periodically drained. This effect is accentuated if the hospital environmental temperature is low. Alternatively a passive humidifier can be used, which consists of a heat–moisture exchange (HME) filter device placed in between the ventilator circuit and the patient.[469] These devices are effective with small foals but may not be adequate for foals over 70 kg and may need to be supplemented with a cold active humidifier in the ventilator circuit.[469] The primary limitation to HME filters is that they tend to clog with airway discharge, which can result in obstruction and failure of mechanical ventilation.[470,471] For these reasons the author typically uses HME filters only for short periods of time, such as when first initiating mechanical ventilation, and relies on active humidification for the duration of ventilation.

The settings on the ventilator should be established before attaching the patient to the ventilator to avoid inadvertent overinflation of the lungs. Although there are several different ventilator modes to select from, on most ventilators there are some basic settings that are fairly universal including Fio_2, tidal volume, peak flow, and breath rate. Fio_2 should be set to the minimum level required to maintain an adequate Pao_2 but no lower than atmospheric O_2 (0.21% or 21%). The tidal volume is the volume of gas delivered with each machine-controlled breath, and this should be set such that the peak inspiratory pressure (PIP) does not exceed 25 to 35 cm H_2O to avoid trauma to the pulmonary tissues. Peak flow is the maximal gas flow rate delivered by the ventilator during the inspiratory phase of ventilation. Excessive peak flow rates will result in overly rapid inflation of the lungs and high peak airway pressures. Low peak flow rates will result in an overly long inspiratory phase, resulting in a loss of synchrony with the ventilator, especially at high respiratory rates. Reasonable initial settings for these parameters are an Fio_2 of 0.5 (0.3–1.0), a tidal volume of 5 mL/kg (up to 8 mL/kg), a peak flow of 70 L/min (60–80 L/min) and a breath rate of 20 to 30 breaths/min.[469] These values may require adjustment once ventilation is instituted, and the response to ventilation should be closely monitored. Additional variables that may be controlled with the ventilator are positive end-expiratory pressure (PEEP), which should be set at 3 to 5 cm H_2O, trigger sensitivity (−2 cm H_2O), pressure support (8–10 cm H_2O), and inspiration:expiration ratio (I:E ratio = 1:2).

When considering mechanical ventilation one encounters a bewildering array of modes of ventilation, but the ideal mode is one that maintains consistent and adequate tidal volume and minute ventilation at moderate airway pressures, is synchronized to the patient's respiratory efforts, responds to patient demands, and allows for the lowest possible work of breathing.[468] This discussion will be limited to the most commonly used modes of mechanical ventilation. SIMV is a modification of assist-control ventilation that still delivers a set minimum rate of mandatory breaths, which are rigidly controlled; however, the ventilator attempts to synchronize these breaths with the patient's inspiratory efforts if possible. The primary advantage of this mode is that it is well tolerated by the patient because of the synchronization of mandatory breaths with patient effort. In addition, SIMV ensures a minimum breath rate in patients with variable respiratory efforts or that are exhibiting periods of apnea. The limitation of SIMV is that the spontaneous breaths are not supported by the ventilator and require a large degree of patient inspiratory effort. Pressure support ventilation (PSV) allows the patient complete control over all aspects of the ventilatory cycle except for the pressure limit. In this mode each patient breath is supported by a preset assist pressure, which is stopped when the flow rate decreases below a set fraction of peak flow at end inspiration. This allows

the patient to determine the size of the breath and the inspiratory flow rate, substantially decreasing the work of breathing. The risk of PSV is that there is no mandatory minimal breath rate guaranteed by the ventilator. The limitations of SIMV and PSV can be overcome by using SIMV with pressure support. SIMV provides a guaranteed minimal breath rate, and the PS provides pressure support of the patient-initiated breaths to overcome the inherent resistance of the ventilator circuit and endotracheal tube. CPAP is used to provide for a positive airway pressure throughout the ventilatory cycle. The pressure provided is typically the clinician-selected PEEP level. CPAP is often combined with PS to aid in overcoming the resistance of the circuit and decreasing the work of breathing.

It is generally desirable when ventilating a patient to not only provide for the minimal ventilatory needs of the patient but to use the ventilator to recruit poorly ventilated regions of the lung back into participating in gas exchange. The most commonly utilized recruitment maneuver is PEEP, which functions to maintain positive pressure within the ventilatory circuit during exhalation and between breaths to prevent alveolar collapse that might result during periods of negative pressure. Over time the presence of PEEP will keep open the alveoli that are "recruited" during the inspiratory cycle, and this allows for gradual improvement in the functional capacity of the lungs. This can result in substantial increases in Pao_2 and may allow for a decrease in the Fio_2.[472] By preventing cyclical alveolar collapse and reopening PEEP, the amount of shear stress-induced pulmonary injury may also decreased.[472] The use of PEEP is not always benign, however, because it can cause compression of the intrathoracic venous system and impair cardiac return with detrimental effects on cardiac output. When first initiating mechanical ventilation it is reasonable to use PEEP in most patients, especially at moderate settings, because the benefits appear to outweigh the potential negative effects.

The provision of mechanical ventilation is a very dynamic process requiring substantial involvement of the clinician in the supervision of ventilator setup and adjustment. Appropriate monitoring is critical to effective mechanical ventilation, and this cannot be overemphasized. The two most important aspects of monitoring are the assessment of pulmonary mechanics and pulmonary function. When considering the assessment of pulmonary mechanics one is really analyzing the interaction of the mechanical ventilator and the patient, and the three most important parameters are the driving pressure, the tidal volume, and the tidal airflow. The primary parameters of ventilator function and ventilator/patient interaction are the PIP and tidal volume (V_T). These parameters are interrelated, because increasing pressures will be associated with increasing tidal volume in normal lungs within normal physiologic limits. In ventilated patients, especially those with substantial pulmonary disease, one will often find that this relationship is abnormal, with normal pressures resulting in inadequate tidal volumes, or excessively high pressures being required to achieve a desired V_T. Continuous monitoring of PIP is extremely important, because sudden decreases may indicate a circuit leak, ventilator failure, inadequate gas supply, or a leak in the endotracheal tube cuff.[469] Increases in PIP may indicate obstruction of the endotracheal tube caused by kinking or accumulation of exudate, bronchospasm, or pneumothorax.[469]

The other critical aspect of monitoring involves monitoring pulmonary function, which fundamentally consists of the evaluation of pulmonary ventilation, in the form of elimination of CO_2, and pulmonary oxygenation, in the form of arterial oxygen tension. Assessment of pulmonary oxygenation relies primarily on the measured Pao_2, because the Fio_2 is known. In the patient with normal pulmonary function there should be a linear increase in Pao_2 with increasing Fio_2, but this relationship breaks down in the presence of pulmonary disease caused by ventilation/perfusion mismatching. The presence of intrapulmonary shunts, resulting from the perfusion of poorly ventilated regions of the lungs, will cause the Pao_2 to be lower than expected. A reasonable target for Pao_2 is 80 to 100 mm Hg or slightly higher, because values above 150 mm Hg are not beneficial and are an indication to decrease the Fio_2. The goal is to use the Fio_2 closest to room air (0.21) that achieves the desired Pao_2, and Fio_2 values above 50% are associated with oxygen toxicity to the respiratory mucosa. Additional information can be derived from knowledge of the exhaled $EtCO_2$ concentration, which is measured using capnography. The $EtCO_2$ is representative of the $Paco_2$ in patients with normal pulmonary function, usually with a value 2 to 5 mm Hg less than the $Paco_2$.[469] Decreases in $EtCO_2$ indicate decreased pulmonary perfusion secondary to decreases in cardiac output or increases in pulmonary vascular resistance.[469]

An important aspect of clinical monitoring is to check the endotracheal tube for exudate accumulation when the tube is changed, which should be done at least daily (more often if copious exudate is present). An increase in the amount of exudate within the tube, or a change in the character of the exudate to a more purulent appearance, may be an early indication of ventilator-associated pneumonia (VAP). A hemorrhagic appearance to the tube exudate may suggest ventilator-associated lung injury (VILI) or worsening of pulmonary inflammation caused by other insults.

The administration of mechanical ventilation is inherently unnatural and unphysiologic and has the potential to disrupt the normal functioning of many body systems. The provision of PPV, especially in the form of excess PEEP, has the potential to substantially decrease venous return, leading to impaired cardiac output. This is a serious concern, especially in the critical patient where cardiac output is often already impaired. The presence of an endotracheal tube has a number of potential adverse effects. First, the tube causes an increase in airway resistance because of its long narrow lumen and increases the work of breathing associated with spontaneous respirations. Second, the presence of the endotracheal tube results in a bypass of the normal protective functions of the upper respiratory tract and can allow access to the respiratory tract for pathogenic organisms. Infections arising by this route are termed *VAP*, and the likelihood of VAP developing is increased with prolonged duration of mechanical ventilation. The presence of inflammation secondary to the process of mechanical ventilation itself will also increase the likelihood of VAP, as will impairment of the patient's immune function associated with systemic illness. The organisms involved in VAP are often nosocomial in nature, which can be associated with a pattern of increased resistance to antimicrobials, complicating treatment of the condition. Aerosolized ceftazidime has been shown to be effective in the prevention of VAP in human patients, while also attenuating the proinflammatory response in the lung.[473] The author has subjectively observed a decreased rate of VAP in mechanically ventilated foals when aerosolized amikacin is nebulized into the ventilator circuit starting within 24 hours of the initiation of mechanical ventilation.

Ventilator-induced lung injury (VILI) should be considered to be inevitable, and the clinician's goal is fundamentally

to minimize the severity of this effect. There are three fundamental types of VILIs: barotrauma, volutrauma, and atelectotrauma.[474] In patients with poor pulmonary compliance and areas of pulmonary atelectasis, high positive inspiratory pressure may be required to achieve adequate ventilation, and this causes overdistention of the ventilated regions of the lung (local volutrauma).[475] Volutrauma results from exceeding the normal physiologic functional residual capacity of the ventilated regions of the lung, resulting in the development of pulmonary edema and initiation/amplification of the local inflammatory response. PEEP is somewhat protective in that it appears to slow the development of pulmonary edema unless it too is excessive, at which point it contributes to overinflation and causes further harm.[476] Atelectotrauma is caused by the repeated opening and closing of lung units during tidal ventilation and essentially represents a syndrome of low-volume injury resulting in the initiation of an inflammatory response.[474] By appreciating that the lungs are susceptible to both high- and low-volume injury it is apparent that optimal mechanical ventilation is achieved within a fairly narrow range of tidal volumes and that this range may vary dramatically from patient to patient.

The discontinuation of mechanical ventilation *(weaning)* can be the most challenging part of the entire process, and in human patients this phase may constitute as much as 50% of the time the patient is being mechanically ventilated.[477] Arguably the process or weaning begins as soon as the patient is placed on the ventilator, because the clinician constantly strives to identify the minimum level of support required to maintain adequate ventilation and oxygenation. By minimizing the degree of support, one can accelerate the patient's recovery of strength and stamina in the muscles of respiration (or minimize its loss) while also increasing the clinician's ability to identify when the patient no longer requires ventilatory support. Gradually decreasing the level of pressure support provided and increasing the trigger sensitivity level can accomplish progressive challenge of the patient's ability to ventilate on its own. Ultimately, however, the determination of readiness to be removed from the ventilator is a subjective one, and the question can only be answered by an extubation challenge. This is preferable to simply removing the patient from the ventilator while leaving the endotracheal tube in place, because the tube causes significant resistance to airflow and increases the patient's work of breathing. Intranasal oxygen insufflation should be provided immediately following tube removal in most cases, unless the patient has been maintaining normal oxygenation at an Fio_2 of 0.21 while on the ventilator. Care must also be taken so that one is fully prepared to immediately reintubate the patient if the challenge is not successful and mechanical ventilation must be reinstituted. The primary endpoints of the challenge are respiratory rate, respiratory effort, and arterial blood gas evaluation, and some patients may fail within minutes while others fail over several hours. Several challenges may be required over a period of hours to days before one is certain that the patient is able be maintained without ventilatory support.

GASTROINTESTINAL DISORDERS

Colic

Colic is a common presenting complaint in foals.[478,479] Unfortunately the evaluation of foals with colic can be frustrating because of the common clinical presentation associated with acute abdominal pain, despite the many possible underlying etiologies. Foals are typically more demonstrative of abdominal pain than adult horses, and signs of colic in foals may range from very nonspecific signs such as tachycardia, tachypnea, anorexia, agitation, and bruxism to more classic signs such as abdominal distention, recumbency, rolling, and lying in dorsal recumbency.[480] Causes of colic in neonatal foals can include meconium impaction, infectious and noninfectious enterocolitis, dysmotility associated with other disease processes, small intestinal strangulating obstructions, congenital abnormalities, intussusceptions, hernias, gastric or duodenal ulceration, aerophagia, foreign body obstructions, lactose intolerance, hypoxic injury, and ovarian or testicular torsion.[480] Causes of colic in older foals are similar but also include conditions such as ascarid impactions, displacements, pyloric or duodenal strictures, abdominal adhesions, and nonstrangulating obstructions such as fecaliths. Nonintestinal pain may cause clinical signs indistinguishable from true colic in foals, and this may result from pain in the thorax, liver, or urogenital tract; distention associated with uroperitoneum; or nongastrointestinal inflammation such as peritonitis.

Examination of foals with colic is somewhat facilitated by their small size, which allows for repositioning and external abdominal palpation, as well as thorough ultrasonographic examination. The inability to perform a rectal examination beyond digital palpation can be a frustrating limitation, however. Just as in adults the initial goals of colic evaluation are stabilization of the patient and differentiation of cases requiring surgical versus medical management. Although most cases of colic in foals can be successfully managed medically, there are cases in which prompt surgical intervention will be required, and small intestinal strangulating obstruction is the most common.[479] The presence of diarrhea is usually an indication that medical management will be sufficient, but this may be present in association with a surgical problem. Unrelenting pain that is poorly controlled with analgesics is a strong indication of a surgical problem, just as in adults. Severe intestinal distention on ultrasonographic examination, particularly caused by fluid or mixed fluid and gas rather than gas alone, may also suggest the presence of a surgical lesion.

The most common cause of intestinal obstruction in neonatal foals is meconium impaction.[480,481] Meconium is a mixture of glandular secretions, mucus, bile, digested amniotic fluid, and epithelial cells and should normally be expelled within the first few hours of life following the foal's first feedings. Colostrum feeding may be helpful in the expulsion of meconium because of the laxative effects of colostrum, but the lack of colostrum intake in a recent study had no effect on meconium release compared with foals fed milk replacer.[482] If the meconium is not passed by 12 hours of age it will likely cause intestinal obstruction, typically at the level of the small colon or the pelvic inlet.[481,483] Progressive intestinal and abdominal distention will develop over the next several hours secondary to gas accumulation orad to the obstruction. Identification of the mass of meconium may be possible on manual palpation of the abdomen, but ultrasonography is a more sensitive and specific means of identifying meconium obstructions. In some cases retrograde contrast radiography may be helpful in confirming the presence and level of the obstruction and in ruling out other causes of obstruction such as congenital defects. Administration of an enema can be useful both as a therapeutic intervention and a diagnostic test and is indicated in all cases of suspected meconium impaction. Sodium phosphate

enemas are widely used because of their ready availability in a premixed human preparation that is easily administered. Care must be taken to avoid hyperphosphatemia caused by excessive administration, however, and for this reason this type of enema should be administered no more than twice in the first 24 hours of life. Soapy water enemas given by gravity flow have also been frequently used, but because of the likelihood of rectal irritation and limited efficacy they should not be used repeatedly.

The most effective type of enema for the treatment of meconium impaction is the acetylcysteine retention enema.[481] These enemas can be prepared using commercially available acetylcysteine (*N*-acetyl-L-cysteine powder, Sigma-Aldrich, St. Louis, MO) by adding 8 g of acetylcysteine to a solution of 20 g of baking soda in 200 mL of water. Commercially prepared acetylcysteine enemas for foals are also available (http://www.scahealth.com/e-z-pass-foal-enema-kit.html). The foal is placed in lateral recumbency and restrained and sedated, if necessary. A 30-Fr Foley catheter with a 30-mL balloon is placed 2.5 to 5 cm into the rectum, and the balloon is filled, taking care not to overinflate. The acetylcysteine solution is infused using gravity flow to a volume of 100 to 200 mL and left within the rectum for 30 to 45 minutes.[481] Because this type of enema does not seem to be highly irritating, this procedure can be repeated as many as three times, usually at 12- to 24-hour intervals. Additional treatments that are helpful in managing affected foals include IV fluid therapy to address any deficits and ongoing maintenance needs, as well as analgesic therapy. Butorphanol administration may be sufficient to control discomfort in many foals, but individuals with more pain may require flunixin administration to control their pain while medical management is pursued. Cases refractory to medical management may require surgical correction of the meconium impaction, but this is uncommon since the introduction of acetylcysteine enemas.[481]

Roundworm *(P. equorum)* infestation is a common condition among foals, with a reported prevalence around 40%.[484] Most foals will not show evidence of infestation, but the clinical signs associated with the presence of this parasite may include lethargy, anorexia, decreased weight gain, coughing, hypoproteinemia, nasal discharge, colic from gastrointestinal impaction, and occasionally rupture or perforation of the small intestine.[485,486] The colic signs result from acute small intestinal obstruction caused by a large burden of the parasite, and in most cases the colic is associated with recent administration of anthelmintic medications but may be associated with a stressor such as transportation or weaning.[485] Horses with impaction of the small intestine caused by *P. equorum* commonly suffer from secondary intestinal abnormalities caused by luminal obstruction, including small intestinal volvulus or intussusception, and surgical intervention is typically required to prevent intestinal rupture.[486,487] As a result of the increasing resistance of *P. equorum* to commonly used anthelmintics, especially the macrocyclic lactones, it seems likely that the prevalence of this condition will increase.[403,488-490]

Although congenital defects of the gastrointestinal tract are rare, they must be ruled out when evaluating the neonatal foal with colic because of the similarities in clinical presentation with meconium impaction. The most common congenital defects are atresia of the colon, rectum, or anus. Affected foals typically present within the first 2 to 48 hours of life and exhibit signs of acute, progressive colic and abdominal distention.[338] In addition to signs of colic (tachycardia, tachypnea, recumbency, rolling, and anorexia), tenesmus may be noted. No fecal material will have been passed, and there will be no meconium staining noted in enema fluids that have been administered. Atresia ani is readily diagnosed on visual examination and digital palpation, whereas rectal and colonic lesions are more challenging to identify.[491] Ultrasonography may be useful in demonstrating distention orad to the site of the lesion but rarely is able to characterize the lesion. Retrograde contrast radiography can be helpful in further characterizing the lesion and differentiating atresia from meconium impaction. Colonoscopy may aid in diagnosing lesions in the terminal colon and rectum. This procedure can be performed under standing sedation, and the use of *n*-butyl scopolamine bromide (Buscopan, Boehringer Ingelheim Vetmedica Inc., St. Joseph, MO) has been shown to aid visualization.[492] Ultimately surgical exploration may be the only way a definitive diagnosis of atresia coli can be made. Surgical correction of atresia ani is straightforward and typically successful, although anal sphincter function may not be normal.[491] Atresia ani may be accompanied by penile malformations (hypospadias) that will also require surgical correction.[493] Surgical resection and anastomosis has been attempted in some cases of atresia coli in which the lesion was accessible, but outcomes have been poor.[491] This is likely caused by additional underlying neurologic and motility disorders and means that this condition should be considered typically fatal.

Congenital aganglionosis, or overo lethal white syndrome, is a syndrome that affects white American Paint Horse foals born from overo-overo matings, although it has been reported in one foal with one solid color Quarter Horse parent.[494] This syndrome occurs when foals receive one copy of the mutated endothelin receptor B gene (*EDNRB,* overo lethal white gene) from each parent.[495,496] Affected foals suffer from aganglionosis of the distal small intestine and large intestine, which results in a lack of intestinal motility leading to colic.[494] Recent work suggests that the extrinsic innervation may be affected as well.[497] Not all foals born from overo-overo matings will be affected, so care should be taken to ensure that the foal is not simply suffering from meconium impaction before making a potentially terminal decision. A mutagenically separated PCR was recently developed for the detection of the *EDNRB* genotype in horses.[498]

Diarrhea

Diarrhea is a common problem in foals, with substantial morbidity and mortality.[405] It is associated with a number of potential pathophysiologic mechanisms and many etiologies, making diagnosis and management challenging. Syndromes involving noninfectious etiologies as well as bacterial, viral, protozoal, and parasitic etiologies are all reported in foals. Although many of the conditions associated with diarrhea can affect foals of any age, some conditions, such as necrotizing enterocolitis (NEC) and asphyxia-associated enteric dysfunction, are primarily seen in neonates, whereas others, such as proliferative enteropathy, are seen in older, weanling age foals.

Foal heat diarrhea is a mild, self-limiting condition seen in foals from 5 to 15 days of age, and is temporally associated with the occurrence of the mare's first heat following parturition. This temporal association has implied causation, but this is not the case. Foals raised on milk replacer also exhibit diarrhea during this time frame, and analysis of the composition of mares' milk has not revealed any changes that might precipitate the development of foal diarrhea.[499] Affected foals are

clinically normal with the exception of diarrhea and remain bright with good appetites. It appears more likely that changes occurring within the gastrointestinal tract in relation to solid feed ingestion and development of the fecal microbiota are responsible.[500,501] Additionally there may be hypersecretion of the small intestinal mucosa that is inadequately compensated for by immature colonic absorption that contributes to foal heat diarrhea.[502] Diarrhea in a foal of this age should not be taken lightly, however, because rapid clinical progression is possible. Any sign of systemic illness, dullness, or inappetence should prompt rapid assessment for a more severe condition than foal heat diarrhea that may warrant medical intervention.

A common cause of diarrhea in hospitalized neonatal foals is perinatal asphyxia-associated gastrointestinal dysfunction. Affected foals typically have associated risk factors such as dystocia, delivery by cesarean section, umbilical problems during delivery, or some cause of inadequate oxygenation immediately postpartum.[503] These foals may exhibit dysmotilities leading to ileus, gastroduodenal reflux, intolerance of enteral feeding, abdominal distention, colic, and diarrhea.[503] Evidence of perinatal asphyxia syndrome may be observed in other body systems, especially the neurologic system. Affected foals should be considered at risk for developing sepsis, and a similar presentation may be observed in foals suffering from sepsis, likely caused by the presence of severe systemic inflammation. For these reasons appropriate broad-spectrum antimicrobial therapy is indicated in these cases.

Another condition affecting hospitalized neonatal foals is NEC. This syndrome is the most frequent and lethal disorder affecting preterm human infants and is associated with disruption of the intestinal barrier leading to intestinal necrosis, multiorgan failure, and death.[504] NEC has been sporadically reported in foals for many years, but it appears likely that it represents an underdiagnosed condition.[505-511] A broad variety of infectious agents, including not only bacteria but also viruses and fungal species, have been associated with NEC in humans.[512] Although most of the cases reported in foals have been linked to the presence of a variety of pathogenic bacteria, the cause of NEC remains the subject of much discussion in human literature, and it is not clear if it is primarily an infectious condition. It appears likely that the pathophysiology is truly multifactorial, involving a complex interplay between intestinal immaturity, hemodynamic instability, inflammation, genetic factors, formula feeding, and dysbiosis.[513-515] The clinical presentation may be similar to that described for the asphyxia-associated disorders mentioned previously, and certainly those foals may be considered at risk for NEC. In a recent report foals diagnosed with NEC presented most commonly with colic or diarrhea, but these signs were absent in the majority of affected foals.[511] Other abnormalities observed in association with NEC included prematurity, gastric reflux, abdominal distention, bloody feces, and pneumonia.[511] Interestingly, the authors of that report found no evidence of an association of *C. difficile, C. perfringens,* or *Salmonella* species with NEC.

The diagnosis of NEC is made through radiographic or ultrasonographic evidence of intramural gas in the intestinal wall (pneumatosis intestinalis) or surgical or postmortem evidence of gastrointestinal necrosis.[511] Although as many as 80% of affected human neonates are reported to survive, the presence of NEC is associated with a poor prognosis for survival in foals.[511,513] Treatment of foals with NEC will be as for any critically ill foal and will likely include IV fluid therapy and broad-spectrum antimicrobial therapy. Because of concerns that enteral feeding may precipitate or worsen NEC, it has been recommended that enteral feeding should be avoided, which is generally recommended in the foal with colic, ileus, or reflux. Parenteral nutrition will be required until enteral feeding can be gradually reintroduced. Human studies have suggested that a minimal enteral nutrition approach, rather than complete withdrawal of enteral feeding, using less than 20 mL/kg per day for the first several days, then gradually advancing to normal intake levels over several days, appears to be well tolerated and safe.[516,517] Human studies have shown that breast milk is protective against NEC in low-birth-weight infants, and for this reason it makes sense to use the mare's milk for feeding the foal if possible.[503,518] Metronidazole therapy may be indicated because of the reported association of NEC with clostridial infection in foals, although a recent human report found that metronidazole therapy may not prevent clinical deterioration in cases of NEC.[519]

Other causes of noninfectious diarrhea can include dietary intolerance, particularly when milk replacers are fed rather than mare's milk.[503,520] This can be the result of products used in the milk replacers that are poorly digested by foals, such as maltodextrins, corn syrup, oligosaccharides, or glucose polymers.[520] Gastrointestinal irritation secondary to ingestion of sand, grit, or dirt may also result in diarrhea caused by mechanical irritation of the mucosa.[521]

Infectious Causes of Diarrhea

The most common cause of infectious diarrhea in foals is rotavirus, which is detected in the feces of foals with diarrhea in 20% to 77% of cases.[522-524] Equine coronavirus has been associated with clinical disease in adult horses[525] and has been detected in the feces of diarrheic foals, but the role of this virus in foal disease is unclear.[524,526-528] EAdV2 has also been detected in the feces of foals with diarrhea, but the actual involvement of adenovirus in the development of disease is unclear, especially in the immunocompetent individual.[529-532] There are older reports of parvovirus-like particles identified in foals with diarrhea, but no further evidence has emerged regarding the potential pathogenic role of such organisms in the foal.[533,534]

The pathogenesis of rotaviral diarrhea is multifactorial, and this organism is frequently detected in combination with other potential gastrointestinal pathogens. Rotavirus infects the epithelial tips of the villi of the duodenum, jejunum, and ileum, but it does not affect the crypt epithelium.[523] The virus replicates within the villous epithelium and is released following cell lysis, which results in destruction of the infected cell and desquamation of the villous tips. This leads to a loss of the normal absorptive capacity of the villi, but the secretory crypt epithelium is unharmed, resulting in malabsorption that likely contributes to the development of diarrhea. Villous injury also results in the decreased production of disaccharidases, particularly lactase, which may impair the digestion of lactose and contribute to the development of diarrhea by osmotic mechanisms. Other factors contributing to the development of rotaviral diarrhea may be the activity of viral enterotoxins, inhibition of sodium-glucose cotransport, dysregulation of calcium homeostasis, and activation of the enteric nervous system.[523]

Clinically rotaviral diarrhea often occurs in large, comingled groups of mares and foals, and affected foals are typically from 5 to 35 days of age.[535] Foals initially exhibit anorexia and

depression, which quickly progresses to acute, profuse watery diarrhea. Affected foals may become rapidly dehydrated and frequently develop electrolyte abnormalities and metabolic acidosis. Although the morbidity associated with rotavirus infections is high, which is caused by the highly contagious nature of the virus, the prognosis for survival is good. Treatment is generally supportive and symptomatic, but IV fluid therapy is often needed to effectively address the fluid and electrolyte deficits. Balanced electrolyte replacement solutions are most effective given the frequent involvement of hyponatremia and hypochloremia. Severely affected foals may also benefit from a brief period of enteral rest (1–2 days), which necessitates the provision of parenteral nutrition until feeding can be reintroduced. Supplementation with lactase enzymes (Lactaid, McNeil Nutritionals, LLC, Ft. Washington, PA) at 9000 U (one tablet) PO every 3 to 8 hours may be helpful in improving milk digestion in foals that remain on the mare, or when nursing is reintroduced.[503] The diagnosis of rotaviral diarrhea is by detection of viral particles using electron microscopy, virus isolation, enzyme-linked immunosorbent assay (ELISA), immunochromatography tests, and real-time reverse-transcriptase PCR (RT-PCR). Of these the immunochromatography tests and RT-PCR are the most rapid and simplest to perform and provide high sensitivity and specificity.[523,536] Control of rotaviral diarrheal outbreaks can be challenging, especially in crowded environments because of the highly contagious nature of the virus, its persistence in the environment, and the resistance to disinfectants.[523] Prevention can be facilitated by the use of maternal vaccination, which has been associated with a reduction in the frequency and severity of rotaviral diarrhea on endemic farms, and a conditionally licensed commercial vaccine is available for provisional use (equine rotavirus vaccine, Zoetis, Kalamazoo, MI).

The primary bacterial agents of concern in foal diarrhea are *C. difficile* and *C. perfringens*. Discerning the relationship between these organisms and clinical disease has been challenging because either or both organisms can be identified in normal animals as well as diseased animals, but both organisms are isolated significantly more frequently from foals with enterocolitis than from healthy foals.[506,509,522,537-540] *C. difficile*–associated diarrhea (CDAD) is commonly associated with a history of antimicrobial therapy and likely represents the primary agent of antimicrobial-associated diarrhea (AAD) in foals.[541] Spontaneous cases of CDAD can occur without exposure to antimicrobials, however, both sporadically and in outbreaks.[509,537,542,543] Additional risk factors that may predispose foals to CDAD include hospitalization, stress, dietary alterations or starvation, transportation, nasogastric intubation, and surgical or medical treatment.[544] Clinically CDAD can be quite variable both in terms of the clinical signs and the severity of the disease. The primary clinical sign of CDAD is diarrhea, which may be watery or bloody, typically accompanied by signs of systemic inflammation and hypovolemia (hyperemic mucous membranes, prolonged capillary refill time, pyrexia, tachycardia, and tachypnea) and occasionally by abdominal distention and colic.[545] Unfortunately these signs are nonspecific, and although CDAD may be suspected on the basis of history and clinical presentation, diagnostic testing is required for confirmation of the diagnosis. Because normal animals may carry the organism and these often represent nonpathogenic strains, culture is not useful for diagnosis of CDAD. Virulence of *C. difficile* depends on the elaboration of toxin A (TcdA) and toxin B (TcdB), and there is evidence to suggest that both toxins are important in the development of clinical disease.[546,547] An additional toxin, termed *C. difficile transferase* (CDT), appears to play a role in virulence as well; CDT-producing strains have been associated with increased mortality in human patients.[547] Confirmation of a diagnosis of CDAD is based on the detection of TcdA and/or TcdB in the feces of the affected individual, and this is most often performed using a commercial ELISA (*C. difficile* Tox A/B II, Techlab, Inc., Blacksburg, VA) or RT-PCR.[524,541]

C. perfringens has also been associated with enterocolitis in foals, and this syndrome is typically quite severe in nature, with high mortality rates.[508] Both type A and type C *C. perfringens* have been implicated in these cases, but the more severe form of the disease is typically associated with type C, and affected foals do not typically respond to treatment.[508] *C. perfringens* produces four major toxins, but the β-toxin appears to be the primary one responsible for intestinal injury.[509] A novel β-pore-forming toxin, NetF, has recently been described and has been associated with severe NEC in dogs and foals.[548,549] Risk factors may include birth on dirt, sand, or gravel and housing in stalls or dry lots in the first few days of life. Clinical signs are similar to CDAD, but because of enterotoxemia affected foals may show more pronounced signs of systemic inflammation and shock. Hemorrhagic diarrhea has been reported in some cases but may be transient in nature. Diagnosis of *C. perfringens* enterocolitis can be challenging, because the organism may be present in the feces of healthy foals. A positive fecal culture in combination with appropriate signalment and clinical presentation may be supportive, however, because healthy foals will generally shed very low numbers of the organism. Fecal Gram stain may also be supportive if it demonstrates large numbers of large gram-positive rods or spores. Commercial assays are available for detection of fecal enterotoxin, but they lack sensitivity.

Treatment of CDAD and *C. perfringens* enterocolitis is primarily supportive in nature, similar to other causes of enterocolitis. Broad-spectrum antimicrobial coverage is indicated, even in situations in which AAD is suspected, because of the risk of bacteremia secondary to bowel wall inflammation and injury. Metronidazole therapy represents the primary specific therapy for clostridial infections, but metronidazole-resistant strains of *C. difficile* have been reported.[550] A recent pharmacokinetic study suggests that the metronidazole dosing regimens used in foals should be revised to 10 mg/kg orally every 12 hours for newborn foals and 15 mg/kg orally every 12 hours for the 10- to 12-day-old foal.[551] After that age the current recommendation of 15 mg/kg orally every 8 hours remains unchanged. Additional therapies that may be of some benefit in CDAD include enterally administered adsorbents, such as di-tri-octahedral smectite.[552] Probiotic therapy is of interest because of the positive results reported in human patients, but the limited studies do not support the efficacy of probiotics in foal diarrhea at this time.[553,554]

A number of other bacteria have been associated with diarrhea in foals, including *Salmonella* spp., *E. coli, Enterococcus* spp., *Aeromonas* spp., and *Bacteroides fragilis,* although causation can be difficult to establish.[531,555-558] Given that diarrhea is a common clinical abnormality associated with sepsis in foals, it is important to be aware that bacterial involvement may be present, even if not in the form of a primary enteric pathogen. One retrospective study found that of foals less than 30 days of age presenting with diarrhea, 50% were bacteremic at admission, further reinforcing this concern.[120] Blood cultures

should be collected routinely at admission in this population, not only to confirm bacteremia but also to yield information regarding antimicrobial sensitivities.

R. equi, although primarily a respiratory pathogen, commonly exhibits extrapulmonary involvement and has been associated with enteric disease, primarily in older foals.[558] Diarrhea, ulcerative enterotyphlocolitis, abdominal abscessation, mesenteric lymphadenitis, and peritonitis have all been reported.[432] In one study 33% of foals with *R. equi* infections were reported to have diarrhea, and in half of those foals diarrhea only began following the initiation of treatment for the primary infection.[432]

Equine proliferative enteropathy (EPE) is an infectious disease affecting young horses, primarily foals from 2 to 8 months in age.[559,560] EPE is caused by the obligate intracellular bacterium *Lawsonia intracellularis.* This disease causes dramatic structural changes in the mucosal epithelium of the small intestine caused by proliferation of the crypt epithelial cells. These alterations lead to a protein-losing enteropathy that can result in variable degrees of hypoalbuminemia, hypoproteinemia, ventral edema, lethargy, diarrhea, fever, weight loss, and colic.[561,562] Diagnosis of proliferative enteropathy is by a combination of clinical signs (ventral edema), clinicopathologic abnormalities (hypoalbuminemia), abdominal ultrasonographic examination, immunoperoxidase monolayer assay serology, and fecal PCR testing for *Lawsonia* DNA.[563] Treatment is best accomplished using lipophilic antimicrobials administered for 3 weeks, such as tetracyclines (oxytetracycline, doxycycline, or minocycline), macrolides (azithromycin and clarithromycin), or chloramphenicol.[564] Rifampin has been used in combination with macrolides but does not appear necessary to achieve a positive clinical response. Regarding prevention, unfortunately passively acquired antibodies have been demonstrated to have no effect on the occurrence of subclinical or clinical EPE.[565] Promising results regarding prevention have been seen with the intrarectal administration of a commercial avirulent porcine vaccine against *L. intracellularis,* which has been demonstrated to result in complete protection against EPE and reduces fecal shedding.[566] The prognosis for survival with appropriate treatment is good, but affected animals often exhibit a decrease in growth rate and as a result may be at a slight disadvantage relative to their peers for several months.[560] Recent reports have detailed a more severe form of EPE that is associated with fatal outcomes, but these cases appear to be unusual.[567,568]

The pathogenic role of *Cryptosporidium* spp. in foal diarrhea has been the subject of debate because normal foals have been shown to shed the organism, but there have been several studies that implicate this organism in both sporadic and outbreak situations.[569-572] Although the most commonly identified species has been *C. parvum,* another *Cryptosporidium* (the horse genotype) has been identified in horses, humans, and a calf.[573,574] Affected foals usually do not exhibit substantial systemic inflammation, and the disease is typically self-limiting. Profuse watery diarrhea may necessitate IV fluid therapy in addition to routine supportive therapy. This disease has clear zoonotic potential, so appropriate biosecurity precautions are indicated to protect in-contact individuals. Indeed, a recent report detailed an outbreak of human cryptosporidiosis in veterinary students associated with exposure to infected foals in an equine perinatology unit.[575] Diagnosis has traditionally relied on the identification of oocysts in the feces using acid-fast staining techniques, but RT-PCR testing can be performed, and rapid and easily performed immunofluorescence assays are commercially available (Xpect Giardia/Cryptosporidium Test, Thermo Scientific, Waltham, MA; Merifluor Cryptosporidium/Giardia, Meridian Bioscience, Inc., Cincinnati, OH).

Strongyloides westeri is a nematode primarily transmitted to foals by the transmammary route. Although this organism has been suspected as a cause of diarrhea in young foals, it appears likely that clinical disease would only be present when the parasite is present in very high numbers.[503,569] Control is typically by means of ivermectin administration to the mare shortly after delivery, but the prevalence of this parasite appears to be increasing, perhaps related to the decrease in ivermectin administration to foals because of concerns for ivermectin resistance in *P. equorum.*[576]

Gastric Ulceration

Gastric ulceration has been frequently reported in foals, with prevalence ranging from 22% to 57%.[577-580] The clinical signs associated with gastric ulceration in foals are often nonspecific and may include diarrhea, colic, rolling, restlessness, lying in dorsal recumbency, excessive salivation, bruxism, and anorexia.[581] For this reason diagnosis should not be made on clinical grounds alone but should rely on gastroscopic examination. In addition to confirming the presence of gastric ulceration, gastroscopic examination allows for thorough characterization of the site(s) involved and the severity of the lesions present. Noninvasive techniques for diagnosing gastric ulceration in foals are of interest but are not well validated and would not provide detailed information regarding the extent and severity of gastric ulceration.

The greatest challenge associated with the diagnosis and treatment of gastric ulceration in foals is the fact that many of the animals with endoscopically evident ulceration do not show any clinical signs suggesting that the ulcers are causing dysfunction or discomfort.[580] Therefore the clinical significance of gastric ulceration in some foals, and the need for treatment, is unclear. Despite this fact there has been substantial concern related to the risk of intestinal perforation secondary to the progression of clinically silent gastric ulcers, because this condition is fatal when it occurs.[582] For this reason prophylactic antiulcer therapy has often been administered to clinically ill foals or those receiving nonsteroidal therapies. The efficacy of these prophylactic approaches has not been confirmed in clinically ill foals, however, and the response of sick foals to acid-suppressive therapy is less consistent than in healthy foals.[583] Indeed, two large retrospective studies reported that the prevalence of gastric ulceration on postmortem examination of hospitalized foals was not related to whether or not prophylactic treatments were administered.[578,584] Unfortunately prophylactic acid suppression may be associated with some risks, and human studies have documented an increased risk of pneumonia and CDAD in non-ICU hospitalized patients treated with acid-suppressive drugs.[585,586] Proton-pump inhibitors (PPIs) are more potent inhibitors of acid suppression than histamine 2-receptor antagonists (H2RAs), and for this reason PPIs appear to be associated with a greater risk of these complications.[587,588] In human ICU patients there does not appear to be an increased risk of pneumonia or differences in overall mortality associated with acid suppression, but the use of PPIs is associated with an increased risk of CDAD.[586] A recent multicenter study found that the use of acid-suppressive therapy in hospitalized foals was associated with an increased risk of

undifferentiated diarrhea but not of CDAD.[589] Together these concerns suggest that such use should be avoided and that treatment be limited to those foals with documented disease requiring treatment.

The pathophysiology of gastric ulceration in the foal is likely complex and multifactorial and may differ between the squamous and glandular mucosal regions of the stomach. Within the stomach there is a constant interplay between protective factors and aggressive factors. The protective factors maintain a healthy gastric mucosa by promotion of mucosal blood flow, mucus and bicarbonate production, prostaglandin E2 production, promotion of epithelial growth factors, epithelial cell restitution, gastric afferent innervation, and gastroduodenal motility. The aggressive factors, which include gastric acid, bile salts, pepsin, and numerous enzymes, act to induce and potentiate gastric epithelial injury. As gastric acid production is highly variable in neonatal foals and the intragastric environment is often alkaline,[583] it seems likely that ulceration results most commonly from suppression of the protective factors rather than from excess acid production. Perinatal hypoxia, systemic illness, or the administration of nonsteroidal antiinflammatory medications may lead to gastric mucosal hypoxia or ischemia, impairing the local protective factors and predisposing the patient to mucosal ulceration. Ulceration may occur in the squamous mucosa, the glandular mucosa, or both, and may extend to involve the duodenum and/or the esophagus. The clinical syndromes associated with ulceration include subclinical, clinically significant ulceration, perforating ulceration, and gastroduodenal ulcer syndrome (GDUS). This scheme should perhaps be expanded to include gastroesophageal ulceration, although this is most commonly associated with reflux esophagitis secondary to GDUS-induced delayed gastric emptying. The classification of ulceration as subclinical or clinical may be challenging and cannot be based solely on the number and severity of lesions identified on gastroscopic evaluation. Instead, it must involve consideration of the history and clinical signs associated with those findings. The diagnosis of perforation may also be difficult and cannot be based on gastroscopic assessment alone because of the sometimes benign surface appearance of these lesions. For this reason abdominal ultrasonography and abdominocentesis are important in confirming the presence of perforation. The diagnosis of GDUS is based on gastroscopic evaluation combined with the presence of one or more of the signs of gastric ulceration listed previously, although signs of gastric-outflow obstruction, such as ptyalism and bruxism, are typically more common with this diagnosis.

GDUS is most commonly seen in foals 2 to 6 months of age and is often associated with an unthrifty, pot-bellied appearance and foals being small relative to their peers.[590] Ultrasonographic examination is indicated in foals suspected to be suffering from GDUS because it allows for noninvasive assessment for gastric and duodenal distention. When gastric distention is present a nasogastric tube should be passed to extract the fluid and facilitate gastroscopic evaluation. Gastroscopic abnormalities commonly observed with GDUS include esophagitis, gastric squamous and glandular ulceration, pyloric ulceration, and pyloric stricture. Examination of the duodenum is usually not possible because of the presence of pyloric stricture. Treatment of affected foals is challenging and requires intensive management. Frequent gastric decompression is required, and parenteral nutrition is typically necessary because of the inability of the foal to eat. Supportive care including IV fluids, antimicrobials, and analgesics is also indicated. Acid-suppressive therapy is required, and this is usually accompanied by gastroprotectants and prokinetics. Although medical management may be helpful in resolving delayed gastric emptying, many affected foals will have severe fibrosis and constriction of the pylorus and duodenum, necessitating surgical correction. The goal of surgical correction is to bypass the pylorus and proximal duodenum, which typically involves gastrojejunostomy. Surgery is challenging, and success likely depends on early intervention, surgical expertise, and appropriate postoperative care.[590] Reported surgical outcomes have improved over time, with the most recent report demonstrating 100% survival to hospital discharge and 50% long-term survival.[591]

The cornerstones of treatment of gastric ulceration in foals are acid-suppressive drugs, primarily the H2RA drugs cimetidine and ranitidine and the PPI omeprazole (Table 20.11). The acid-suppressive effects of the H2RAs are variable and less dramatic than those seen with PPIs, but these drugs may suppress acid production sufficiently to facilitate ulcer healing.[592] Because of the more consistent and pronounced acid-suppressive effects of the PPI omeprazole, this drug has become the mainstay of gastric ulcer therapy in horses.[593] Dosing for foals can be challenging, because there is no labeled form specifically designed for use in foals, but the product marketed for use in adults can be measured out on a volume basis and administered orally at a body weight–appropriate dosage to foals. An IV formulation of omeprazole is not readily available for administration to foals that cannot take medications orally, but the IV pharmacokinetics of the PPI pantoprazole have been determined in foals.[594] Other treatments include

TABLE **20.11** **Drugs Used in the Prophylaxis and Treatment of Gastric Disorders in Foals**

Drug Class	Drug	Dosage (mg/kg)	Route	Frequency (h)
H2RA	Ranitidine	6.6	PO	8
		1.5–2.0	IV	6
PPI	Omeprazole—treatment	4	PO	24
	Omeprazole—prevention	1	PO	24
	Pantoprazole	1.5	IV	24
Mucosal protectant	Sucralfate	20–80	PO	6–12
Prostaglandin E1 analog	Misoprostol	2–5 μg/kg	PO	8–12
Antacids	Aluminum/magnesium hydroxide	120–240 mL	PO	4–8

H2RA, Histamine 2-receptor antagonists; *IV,* intravenously; *PO,* orally; *PPI,* proton pump inhibitor.

mucosal adherents, such as sucralfate, and oral antacids, such as aluminum hydroxide and magnesium. Sucralfate dissociates in the acidic environment of the stomach to sucrose octasulfate and aluminum hydroxide. Sucrose octasulfate binds to the ulcerated mucosa and decreases tissue exposure to hydrochloric acid and may also interfere with the activity of peptic enzymes.[595] Sucralfate appears safe and is well tolerated and likely represents a safer approach for ulcer prevention in hospitalized neonatal foals compared with the use of a PPI. The prostaglandin E1 analog misoprostol has been used in an effort to enhance ulcer healing by increasing epithelial mucous secretion, bicarbonate secretion, and mucosal blood flow.[596] Misoprostol may also enhance epithelial repair via closure of tight junctions following epithelial restitution of denuded regions of the mucosa.[597]

UROGENITAL DISORDERS

Abnormalities involving the urogenital tract are common in foals and can be congenital or acquired in nature. Acquired conditions may occur secondary to infectious, toxic, traumatic, or iatrogenic causes. The presence of urogenital disorders may represent the primary disease process or may occur secondary to other disease processes. In some cases the presenting signs may be directly associated with the urogenital disorder, but often these cases present with nonspecific signs such as depression and poor body condition. Clinicopathologic evaluation may be normal, but cases involving impaired renal function or urine retention are typically associated with azotemia and electrolyte abnormalities. Azotemia most often presents as an elevation in serum creatinine concentration, but with more chronic or insidious conditions an elevation in blood urea nitrogen (BUN) may be more prominent. Serum electrolyte abnormalities may include hyponatremia, hypochloremia, and hyperkalemia. Metabolic acidosis is also common. Urinalysis in normal foals will demonstrate hyposthenuria, because they produce dilute urine with a specific gravity 1.010 or less. Foals with renal dysfunction may have hyposthenuric, isosthenuric (specific gravity of 1.010), or concentrated, hypersthenuric urine (specific gravity >1.010), depending on the nature of dysfunction. Transient proteinuria is typical at birth, but this should resolve in the first few days of life in normal foals, and casts should not be present.

Congenital Disorders

Congenital urinary tract disorders are quite rare in foals, but of these renal dysplasia or hypoplasia is the most commonly reported.[598-604] No familial or breed predisposition has been demonstrated for this condition in horses. In utero exposure to therapeutic drugs or toxins may cause renal dysplasia, and there are reports of renal dysplasia in foals born to mares treated for equine protozoal myeloencephalitis with pyrimethamine, trimethoprim, sulfonamides, folic acid, and vitamin E.[605] Renal dysplasia or hypoplasia may represent an incidental finding in a foal or young adult horse presented for evaluation of other problems. Azotemia is typically not present unless renal function has been impaired by at least 65% to 75%, because of the substantial reserves of renal function that are normally present. Cases with bilateral renal involvement, urine retention, or suffering from acute-on-chronic disease are more likely to be associated with clinical and clinicopathologic findings consistent with renal insufficiency. Patients with unilateral involvement often remain asymptomatic, whereas treatment of renal dysplasia or hypoplasia is usually unrewarding if bilateral renal involvement is present.

Pollakiuria, dysuria, stranguria, and incontinence may be observed with renal dysplasia/hypoplasia, but these are more commonly associated with conditions such as ectopic ureters.[606-608] Ectopic ureters may be associated with urine scald caused by urinary incontinence. Surgical intervention, while often challenging, is the only option for addressing cases of ectopic ureter, with relocation of the ureteral opening being the primary intervention. Hematuria is uncommonly associated with congenital urogenital disorders but may be present in association with renal arteriovenous malformations.[609] Congenital abnormalities of the bladder have been suspected in some cases of uroperitoneum,[610,611] but evidence of a true congenital origin is lacking in horses or other species.[612] Umbilical hernias may be present at birth but are usually small and will resolve without intervention. Larger hernias, typically over 3 cm in size, may require surgical repair, but there is no rush to perform this procedure as long as the hernia remains easily reducible. Inguinal hernias may also be present at birth but are also typically small and easily reducible. Conservative medical management consisting of frequent, repeated reduction, or bandaging to maintain reduction, is often successful in resolving small hernias. Larger inguinal hernias may allow for substantial herniation of the small intestine and often require surgical repair.

Uroperitoneum

Accumulations of urine within the peritoneal cavity represent one of the most common urogenital conditions in young foals, involving as many as 2.5% of hospitalized neonates.[613] Most cases are observed within the first few days of life and are associated with bladder wall rupture.[614,615] The most common site of bladder wall failure is the dorsal wall, and it is believed that most cases occur during parturition. The proposed etiology is that the fetus has a very full bladder, which ruptures under the intense pressures occurring during transit through the birth canal. Obstruction of urine outflow via the urachus during delivery may contribute to high intravesicular pressures. This theory is supported by anecdotal reports of bladder distention identified on fetal ultrasonographic examination in foals that subsequently developed bladder rupture after birth. There may be some sex predilection for bladder rupture, with colts being overrepresented in cases presenting shortly after birth, but in cases developing later there does not seem to be a difference between the sexes.[612] Not all cases of uroperitoneum are associated with primary bladder rupture, however, because ureteral tears and urachal rupture can also result in uroperitoneum. Although ureteral tears initially result in urine accumulation in the retroperitoneal space, this typically progresses to uroperitoneum after several days. Urachal rupture may be associated with infection and necrosis of the umbilical remnant, and for this reason these foals may present slightly later than foals with bladder rupture.

Diagnosis of uroperitoneum is made on the basis of history, physical examination, clinical pathology, and ultrasound examination. The clinical signs associated with uroperitoneum may vary based on the site of leakage, but affected foals most often present with depression and weakness and signs of hypovolemia. It can be difficult to differentiate these foals from those suffering from neonatal sepsis, and indeed many affected foals may be suffering from sepsis in addition to uroperitoneum.[613] The rate at which clinical signs develop is often

associated with the size of the defect and the associated rate of urine leakage into the peritoneal space, with small defects in the bladder or retroperitoneal ureteral leakage often not becoming clinically obvious for several days to a week post foaling. Some foals with uroperitoneum will present with ventral edema, although this is most dramatic in foals with umbilical trauma and associated subcutaneous urine leakage. Foals with retroperitoneal urine accumulation may present with stranguria before the development of uroperitoneum, and foals with urethral defects most often demonstrate substantial subcutaneous edema in the perineal region. Some foals with uroperitoneum will present with abdominal distention or abdominal discomfort but will otherwise be in good physical condition. Palpation or ballottement of the abdomen may aid in detecting fluid accumulation within the peritoneal cavity.

The classic clinicopathologic presentation of the foal with uroperitoneum is that of azotemia, with increases in serum creatinine and (less reliably) BUN. Azotemia is typically accompanied by hyperkalemia, hyponatremia, hypochloremia, and metabolic acidosis. Hyperkalemia is caused by the reabsorption of substantial amounts of potassium, whereas hyponatremia and hypochloremia are caused by reabsorption of water from the urine within the abdomen. These changes are likely more pronounced because of the milk-based diet of foals; milk contains relatively high concentrations of potassium (25 mEq/L) and is relatively low in sodium (12 mEq/L).[616] Hyperkalemia is potentially life-threatening because of the possibility of fatal bradyarrhythmias. An electrocardiogram (ECG) should be performed in all foals with uroperitoneum or hyperkalemia of any cause. Typical ECG findings in hyperkalemia will progress from peaked T waves and a shortened QT interval to lengthening PR interval and loss of P waves, followed by widening of the QRS complex, and potentially leading to cardiac arrest and death.[617] Other potential cardiac sequelae associated with hyperkalemia include third-degree atrioventricular block, ventricular fibrillation, and ventricular premature contractions. This classic pattern of electrolyte abnormalities is not typically observed, however, in hospitalized foals that develop uroperitoneum while being treated with IV fluid therapy with balanced electrolyte solutions.[612,613]

Ultrasonographic examination is the most useful ancillary diagnostic test in the evaluation of uroperitoneum. Not only can one confirm the presence of free fluid within the peritoneal space, but one can also assess the degree of fluid accumulation and investigate possible sites of urine leakage. The free fluid within the abdomen is typically hypoechoic to mildly hyperechoic, and numerous loops of small intestine or other intraabdominal structures may be suspended in the free fluid contained within the abdomen. The dorsal bladder wall is the most common site of bladder rupture, and this area should be thoroughly investigated because in some cases the free margins of the defect can be readily observed. It is important to remember that there may be more than one site of urine leakage, however, either from the bladder itself or potentially involving the urachus, ureters, or urethra. Although ultrasound examination is typically less useful when evaluating ureteral or urethral defects, it is important to perform a complete examination of the urinary tract to detect any defects in the kidneys or ureters that might be missed if only the bladder and urachus are examined. Contrast radiography may be required to identify sites of leakage other than the bladder or urachus.

Definitive confirmation of uroperitoneum requires abdominocentesis. Creatinine diffuses poorly across the semipermeable peritoneal membrane, so the creatinine concentration in the peritoneal fluid will be at least twofold higher than the creatinine concentration in the serum. Abdominocentesis is both a diagnostically important technique and a therapeutic technique, because it allows for the drainage of accumulated urine from the peritoneal cavity. Removal of this fluid will aid in controlling hyperkalemia, and it will minimize further potassium absorption from the peritoneal cavity. Drainage will also decrease the pressure being exerted on the diaphragm and thoracic cavity, aiding in the resolution of any tachypnea, dyspnea, or respiratory distress. Abdominocentesis should be performed with a teat cannula or stainless bitch catheter or with an indwelling type of catheter such as a Foley or mushroom-tip peritoneal catheter. This approach minimizes the risk of trauma to the abdominal viscera and allows for safe manipulation and maintenance of the catheter while the abdomen is being drained. Care should be taken to administer appropriate fluid therapy before and during the drainage of the abdomen to avoid hypovolemia resulting from the removal of this third-space fluid. Drainage should be continued until surgical repair is performed, because premature discontinuation will simply allow for reaccumulation of urine within the abdomen.

Although medical management has been described, the treatment of uroperitoneum is primarily surgical because the site of urine leakage must be identified and addressed by surgical repair or removal. Correction of hypovolemia and electrolyte disturbances before surgery is important in minimizing the risk of anesthetic complications. The most critical of these disturbances is hyperkalemia because of the risk of cardiac disturbances. Hyperkalemia is addressed by the administration of IV fluids that do not contain potassium, and isotonic (0.9%) or hypotonic (0.45%) saline solutions are most commonly used. Dextrose is typically added to the fluids at a rate of 5%, and this will aid in lowering serum potassium concentrations by encouraging movement of potassium from the extracellular to the intracellular compartment, but in severe cases the administration of exogenous insulin (0.1 U/kg) may be necessary to substantially reduce serum potassium concentrations. Sodium bicarbonate therapy may aid in lowering serum potassium concentrations and may be helpful in addressing the concurrent hyponatremic metabolic acidosis.[617] Administration of calcium gluconate may also be helpful in decreasing the negative effects of hyperkalemia.[617] Recent reports have suggested that the frequency of anesthetic complications during surgical correction of uroperitoneum is less common than previously reported, perhaps because of less severe electrolyte disturbances, better preoperative stabilization, or the use of safer inhalant anesthetics (primarily isoflurane).[612]

The prognosis for survival in foals with uncomplicated uroperitoneum secondary to bladder rupture is good, whereas the prognosis for foals suffering from ureteral or urethral disorders is less favorable. Delays in the identification of affected foals and the presence of concurrent disease, especially sepsis, will result in worsening of the prognosis for survival.[612,613]

Umbilical Disorders

The umbilicus represents the primary channel for exchange of nutrients and oxygen between the dam and the fetus and the primary outlet for fetal urine. The umbilical cord consists of two arteries carrying poorly oxygenated blood away from the fetal heart and one vein carrying relatively better oxygenated blood from the placenta toward the fetal heart and the

urachus, which connects the fetal urinary bladder to the allantoic cavity.[618] Following second-stage parturition the umbilicus will narrow and separate at a point 2 to 3 cm from the body wall, typically within about 10 minutes if the mare and foal are undisturbed.[619] A small amount of neonatal blood loss may occur normally following separation of the cord, but it should be of minimal volume and should cease within a few minutes. If the mare stands too soon, then premature separation of the umbilical cord or umbilical cord damage may occur. Subcutaneous rupture of the urachus can result in substantial accumulation of urine in the tissues of the abdominal wall, which will likely require surgical resection of the umbilical remnants. Following separation from the placenta the umbilical structures immediately become vestigial, and in the normal foal the umbilical remnants will atrophy over the first few months of life.

One of the most common umbilical disorders is patent urachus, in which the urachal remnant is open and urine drains to the external environment. Although this may occur immediately following cord separation, it is more typically seen several days after birth and is most often associated with umbilical infections. Systemic illness and the associated stress of handling involved in the management of sick foals may also predispose the patient to the resumption of patency. Patent urachus may present simply as moistness of the external umbilical remnant or may be associated with a streaming flow of urine. Urine scald of the abdominal wall and the medial aspect of the hindlimbs may occur secondarily. It is important that an ultrasound examination be performed in these cases to determine whether there are internal abnormalities, such as umbilical remnant infections, associated with a patent urachus. Conservative management consisting of topical cleansing of the external umbilicus and close monitoring for the development of infection is often sufficient, although complete resolution may take days to weeks in some cases. If any infectious component is suspected then appropriate systemic antimicrobial therapy is indicated. Chemical cautery using silver nitrate sticks is often used and may accelerate closure of the urachal remnant, especially in early, mild cases. Excessive use of silver nitrate may result in local tissue necrosis, however, and may precipitate the development of infection. If conservative management fails then surgical excision of the umbilical remnants is indicated, but this is rarely a problem that needs to be addressed urgently, especially in a foal suffering from systemic illness or other disease processes.

Umbilical remnant infections are also common and can take several forms. Affected foals may appear clinically normal or they may exhibit signs of systemic inflammation (fever, leukocytosis, hyperfibrinogenemia, and elevated SAA). Infection of the external umbilical structures will result in local abscess formation, which presents as swelling, inflammation, and often discharge from the area of the external umbilicus, but it can become more locally invasive, involving the body wall. External umbilical abscesses can often be treated with the establishment of drainage combined with appropriate systemic antimicrobial therapy. Internal umbilical remnant infections can occur in all three of the distinct umbilical structures: the urachus (infection of the urachus is called *urachitis*), the umbilical arteries (infection of the umbilical arteries is called *omphaloarteritis*), and the umbilical vein (infection of the umbilical vein is called *omphalophlebitis*). It has traditionally been thought that umbilical remnant infections occurred secondary to external contamination of the umbilicus, with ascending migration of bacteria. This is likely true in some cases, and for this reason it is important to practice appropriate routine cleaning and disinfection of the external remnant. Excessive cleansing or treatment with caustic agents may actually increase the risk of ascending infection, so moderation is key. It is very possible that bacteremia occurs secondary to umbilical infections, resulting in seeding of other sites. Infection of remote structures, especially synovial structures and growth plates, has been frequently associated with the presence of umbilical remnant infections. Although the umbilical structures may represent the primary site of infection, it is also possible that some umbilical remnant infections actually develop secondary to systemic illness and bacteremia, rather than secondary to external contamination.

Ultrasonographic examination of the umbilical remnants is well described and can be performed readily with either a linear or curved probe using a frequency of 5 to 7.5 MHz, although higher quality imaging can be obtained with a linear 10- to 12-MHz probe.[620] All four umbilical structures (urachus, vein, and paired arteries) can be readily imaged in the external remnant as it courses out of the body wall. Internally the paired umbilical arteries are found ventral and lateral to the urachus and bladder, and they course caudally and deep toward their origins from the iliac arteries. They are thick-walled structures and should have a diameter of less than 13 mm.[621] Although the arteries may still be observed to pulsate in very young foals, they should contract down and be immobile by 24 hours of age. The lumen may be filled with clotted blood in some cases. The urachus extends from the apex of the bladder outward to the umbilical stump, and the lumen is typically collapsed and difficult to appreciate. A transverse view of the urachus and umbilical arteries taken at the apex of the bladder should normally measure less than 25 mm in total diameter.[621] The umbilical vein courses cranially from the site of the external umbilicus to the liver and is located along the midline very close to the abdominal wall. The vein is a thin-walled structure and may contain anechoic fluid within its lumen. The vein should measure less than 5 to 10 mm in diameter.[621] Infection involving these structures will typically manifest as filling of the lumen with material of variable echogenicity, thickening of the wall, and an increase in the overall size of the structure.[622,623] Thorough assessment is important, because multiple structures may be involved in the infectious process.

Treatment of umbilical remnant infections can be medical or surgical in nature. Medical management is generally preferred, and treatment with appropriate broad-spectrum antimicrobials is often successful in resolving the infection. Prolonged treatment of several weeks' duration and ongoing ultrasonographic monitoring is required to ensure complete resolution. In cases suffering from a combination of umbilical remnant infection and infections in other sites the clinician may feel a sense of urgency to surgically remove the umbilical remnants, but the stress of general anesthesia and abdominal surgery may be counterproductive. Stabilization of the patient and the institution of antimicrobial therapy before surgery may be beneficial in these cases. Broad-spectrum antimicrobial therapy is indicated, preferably using oral medications because of the need for prolonged therapy in most cases. The presence of gas within the internal structures on ultrasonographic examination or a fetid order represents an indication for the addition of metronidazole to the treatment regimen. In cases refractory to medical therapy, surgical excision of the affected

internal umbilical remnants is indicated. Thorough ultrasonographic examination preoperatively is helpful in developing the surgical plan and may reveal areas of infection deep in the umbilical arteries or vein that may not be able to be surgically removed. Continued medical management may be indicated in such a situation, but marsupialization of the umbilical vein or arteries can be performed to allow for external drainage and possible lavage of the infected structures.[624-626]

Acute Kidney Injury and Acute Renal Failure

Acute kidney injury can occur in foals secondary to systemic disease, toxin exposure, or postrenal obstruction. The most common of these etiologies is systemic disease, which has previously been termed *vasomotor nephropathy*, although the actual pathophysiology involved in these cases is not well understood.[627] It appears likely that there is a complex interaction among systemic cardiovascular responses, local vasomotor tone, systemic and local inflammatory mediators, microvascular dysfunction, and local renal tissue responses that result in decreased renal function. This decrease in renal function may represent a self-protective response by the kidneys in which decreased energy and oxygen demands within the kidney may help to improve tissue survival and recovery.[628] The most common toxic causes of renal injury in foals are iatrogenic in nature—namely, aminoglycoside antimicrobials and oxytetracycline (administered as a treatment for tendon contracture).[629] Nonsteroidal-associated renal injury is relatively uncommon in foals and is likely because these drugs are not commonly used in foals at this time, although this may change with increasing use of COX-2–specific NSAIDs in foals. Other causes of toxin-induced renal injury are hemoglobin released because of NI and myoglobin released because of myopathies, most commonly white muscle disease. Postrenal obstruction is very rare in foals and is primarily associated with congenital abnormalities.

Diagnosis of acute kidney injury is complicated by the poor sensitivity of the commonly used biomarkers of renal function—namely, serum creatinine and BUN. Because of the substantial renal reserve, it is likely that substantial injury has occurred by the time changes in these markers are detected clinically. BUN is so insensitive that it is of limited use in evaluation of acute kidney injury in foals, but one should be concerned when substantial simultaneous increases in BUN and serum creatinine are observed. Serum creatinine, despite its poor sensitivity, remains the best biomarker for renal function in foals. Although there is tremendous interest in identifying more sensitive biomarkers of renal function, none has yet been characterized in foals. Interpretation of serum creatinine concentrations in neonatal foals is complicated by spurious hypercreatininemia, which can be caused by placental insufficiency or neonatal hypoxia.[166] Although foals presenting with spurious hypercreatininemia had similar elevations of serum creatinine concentration compared with foals presenting with acute renal failure, serum creatinine concentrations in foals with spurious hypercreatininemia typically decrease by 50% within 24 hours of initiation of treatment and normalize by 72 hours.[166] The most effective way of improving the sensitivity of serum creatinine is to become more critical about evaluation of changes in the serum concentration. Even though the values may remain within the published normal range, an elevation of as little as 0.3 mg/dL above baseline may be indicative of decreased renal function. Because serum creatinine may be elevated from prerenal causes at presentation, it is important to evaluate the serum creatinine concentration frequently to assess the response to therapy and detect upward trends as early as possible.

Given the limitations of serum creatinine concentration as a marker of renal function, and more specifically glomerular filtration rate (GFR), it may be helpful in some cases to obtain a more accurate assessment of GFR. The exogenous marker iohexol has been validated in foals, but iohexol assays are not readily available.[630] Endogenous creatinine clearance is actually fairly simple to perform in foals with an indwelling urinary catheter and urine collection system. This involves obtaining a baseline serum sample for creatinine determination and simultaneous emptying of the urine collection bag, followed by a timed urine collection over at least several hours, but ideally over 24 hours. At the end of that time a second serum sample is obtained for serum creatinine measurement. The volume of urine collected is accurately measured, and a representative sample of urine is collected for creatinine determination. The endogenous creatinine clearance is calculated using the formula[631]:

$$\text{endogenous creatinine clearance (mL/min/kg)} = (\text{urine [creatinine]/plasma [creatinine]}) \times (\text{urine output [mL]/time [minutes]})/\text{body weight [kg]}$$

Reported values for endogenous creatinine clearance in normal foals are 1.78 to 2.17 mL/min per kilogram.[630,632,633]

Urinalysis can be helpful in detecting acute kidney injury, but interpretation can be challenging because of temporal changes in the composition of neonatal urine and the influences of fluid therapy and other treatments on urine constituents. Urine specific gravity is normally hyposthenuric (<1.010) in foals that are well hydrated and should increase appropriately (>1.012) in foals that are dehydrated. Isosthenuria (specific gravity of 1.010) may indicate a loss of renal function, but serial determination may be required to confirm the inability of the kidneys to dilute or concentrate the urine with changes in hydration status. Proteinuria is normally present in the first 24 hours of life but should then be absent unless there is renal injury. If the urine is alkaline, then mild spurious proteinuria (1+) may be observed on dipstick examination. Sick foals often will have acidic urine, making this less of an issue of interpretation than in adults. Examination for enzymuria has been advocated as an early indicator of renal injury in foals, primarily regarding urine γ-glutamyl transferase (GGT). This is assessed using the GGT-to-creatinine ratio (urine GGT/urine creatinine × 100), which corrects for dilutional effects. Elevations of the urine GGT:creatinine ratio above 25 are suggestive of proximal tubular injury, but this test does not have good specificity. Unfortunately elevations of the GGT:creatinine ratio are to be expected in foals receiving systemic aminoglycoside therapy, and the magnitude of the increase is not well correlated with the degree of renal injury.[634]

Treatment of acute renal failure is primarily supportive in nature. All efforts should be made to remove exposure to the potential initiating cause of acute kidney injury, if possible. Fluid therapy is typically indicated, both to correct any existing dehydration or hypovolemia and to induce diuresis. Carefully monitoring of urine output is indicated to be sure that the patient is not oliguric or anuric, and placement of a urinary catheter and urine collection system is extremely helpful in this regard. This may be difficult to achieve in the ambulatory

patient but is readily accomplished in recumbent foals. Urine output in a normal 4-day-old foal is approximately 6 mL/kg per hour, but this value should increase in response to fluid therapy.[632] Monitoring of "ins" versus "outs" should be routinely performed, with the goal of at least two thirds of fluid intake being excreted. If this is not achieved, then fluid overload is likely to develop. If urine output is inadequate after restoration of normovolemia and correction of systemic hypotension, then diuretic therapy is indicated. Furosemide appears safe and is well tolerated. In addition to its loop diuretic effects, furosemide may actually lessen renal metabolic demands by suppression of tubuloglomerular feedback. Recommended dosing of furosemide ranges from 0.5 to 1.0 mg/kg IV q 8–12 h to 1 to 2 mg/kg every 30 to 120 minutes over 6 hours.[185,635] CRIs have also been used in foals based on dosing regimens developed for adult horses, starting with a loading dose of 0.12 mg/kg IV, followed by 0.12 mg/kg per hour CRI.[636] If furosemide is ineffective, then osmotic diuretics can be used. DMSO is commonly administered to foals suspected of suffering from NE, and in addition to its free radical scavenging effects it does have some osmotic diuretic effects. Mannitol can be used as a more potent osmotic diuretic, at a dosage of 0.5 to 1.0 g/kg IV as a 20% solution over 20 minutes.[185] If medical therapy is not effective, then renal replacement therapy (dialysis) can be considered. Hemodialysis is the gold standard therapy and has been performed in foals, but it is rarely available for equine patients because of the expense and lack of access to the appropriate equipment.[629] Although typically less effective than hemodialysis, peritoneal dialysis and thoracic dialysis have been performed in foals and are much more feasible in most clinical settings.[635]

ENDOCRINE DISORDERS

The critically ill foal undergoes severe physiologic stress, and the body responds to this stress with a complex, integrated series of neuroendocrine and humoral adaptations that are directed toward support of critical hemodynamic, immune, and metabolic functions. The HPA axis, sympathetic-adrenomedullary axis, hypothalamic-pituitary-thyroid (HPT) axis, and the somatotropic axis are all of critical importance in this response.

Hypothalamic-Pituitary-Adrenal Axis Function and Dysfunction

Activation of the HPA axis leads to increased secretion of corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP) from the paraventricular nucleus of the hypothalamus. CRH is the primary stimulus for the production and secretion of ACTH by the anterior pituitary, whereas AVP acts synergistically with CRH to increase ACTH secretion. ACTH is secreted into the systemic circulation and interacts with the cells of the zona fasciculata of the adrenal glands, which subsequently produce cortisol. Cortisol is not stored in the adrenal glands; it is released into the systemic circulation immediately after it is produced. Only the unbound, or "free," cortisol is biologically active, and in the normal adult state the vast majority of the cortisol in circulation is bound to cortisol binding globulin (CBG), with much smaller amounts bound to albumin.[637] Foals have been shown to have a much greater free cortisol fraction (58 ± 8 at birth to 33 ± 6 at 7 days of age) than adult horses (7 ± 3) or human infants (32% at birth to 19% by 3 months of age).[638] Increases in the free cortisol fraction can be associated with localized or systemic inflammation, because bound cortisol can be released from CBG by the neutrophil elastase.[639] The concentration of active cortisol is also regulated at the tissue level by the action of two isoforms of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD). 11β-HSD1 primarily generates active cortisol from inactive cortisone, whereas 11β-HSD2 primarily converts active cortisol to inactive cortisone.[640] Unbound cortisol reaches the tissues by diffusion and enters the cell, in which it binds to the intracellular glucocorticoid receptor (GR). The cortisol–GR complex then translocates to the nucleus in which it is able to exert both genomic (regulation of gene transcription) and nongenomic (protein–protein) effects.[309] In critical illness cortisol is important in supporting cardiovascular function, regulating immune responses, and increasing the availability of glucose as an energy source.

A variety of approaches has been used to assess the function of the HPA axis in both health and disease. These include the determination of neutrophil:lymphocyte ratios, basal serum cortisol concentrations, basal serum ACTH concentrations, ACTH/cortisol ratios, and ACTH stimulation tests that measure the ability of the adrenal glands to produce cortisol (delta cortisol). There are a number of challenges associated with HPA axis assessment, however.[641] The first is that the activation and response of the HPA axis are highly dynamic, with rapid changes in a short period of time and substantial variation even on an hour-to-hour basis. The second challenge is that measurement of total serum cortisol concentrations does not reflect the biologically active free portion, and determination of the active, free cortisol fraction is technically challenging, time-consuming, and not readily available in the clinical setting. The third is that the concentration of cortisol in the circulation provides no information related to the concentration of cortisol at the tissue or intracellular levels, in which it is active. The fourth challenge is that ACTH stimulation testing, either high or low dose, may not represent an accurate assessment of HPA axis function in critical illness. Finally, there may be substantial variation among cortisol assays, rendering it extremely difficult to compare the results of studies using different assays[114] and calling into question the use of specific values of serum cortisol as indicators of HPA axis function or dysfunction.

The maturation of HPA axis function in the equine fetus occurs very late in gestation, in the last few days before birth, and continues for the first several weeks of life.[64,92,93,642] As a result, foals delivered prematurely often suffer from inadequate HPA axis function, manifested by inappropriately low serum cortisol concentrations despite increased serum ACTH concentrations. These findings are indicative of a decreased response to ACTH at the level of the adrenal gland, and this is supported by the fact that these premature foals also show impaired responses to ACTH stimulation testing.[64,91,92] The neutrophil:lymphocyte ratio was noted by Rossdale et al. to be an easily determined surrogate marker for basal cortisol concentration in foals, with a ratio of <1.0 suggestive of impaired HPA axis function in premature foals, whereas a ratio of >2.0 was associated with adequate HPA function in term foals.[92] Normal term foals also show some evidence of incomplete HPA axis development, however, because they exhibit impaired responses to endogenous ACTH and both low- and high-dose ACTH stimulation tests, compared with adult horses.[64,642] Following birth the serum cortisol and

ACTH concentrations peak in the first hour of life and then gradually decline over 6 to 12 hours to levels lower than normally seen in adult horses.[638,643]

The correlation between HPA axis dysfunction and equine prematurity led to an early interest in this area of equine medicine, but little work was done in this area until the past decade. This renewal of interest was primarily the result of extensive work done in humans regarding the role of the HPA axis in critical illness.[644] The concept of relative adrenocortical insufficiency (RAI) was developed and defined as an inadequate cortisol response for the degree of illness.[645] RAI is considered to be a transient, reversible condition and has been associated with exaggerated proinflammatory responses in conditions such as sepsis, ARDS, and severe trauma. Potential mechanisms of RAI include suppression of the HPA axis at the level of the hypothalamus, the pituitary, or the adrenal gland.[646] RAI has been associated in a number of studies with an increase in the risk of death in critically ill human patients.[647] Subsequent studies using corticosteroid supplementation demonstrated a trend toward decreased mortality and improved vasopressor responsiveness, which further supported the concept of RAI in critical illness.[648-650] The diagnosis of RAI remained challenging, however, because of the wide range of diagnostic criteria used in different studies. The most widely accepted criteria was a random total serum cortisol of <10 mg/dL or a delta cortisol of <9 mg/dL following ACTH stimulation.[651]

Several studies have been performed in healthy foals to characterize normal HPA axis function in this population.[95,642,652] Substantial age-related changes in basal cortisol concentrations were found, and normal age-based ranges were reported. Unfortunately the rapid changes over time and the high variability of a single cortisol measurement mean that the application of basal cortisol concentration as a clinical marker of RAI cannot be recommended at this time.[315] The response to both low- and high-dose ACTH stimulation testing has also been examined, and although the dosages of ACTH varied among some studies there was a consistent pattern of age-related differences in the response to ACTH, with the most profound responses observed immediately after birth.[95,642,653] Age-related reference ranges for both low-dose and paired low- and high-dose ACTH stimulation testing have been reported.[95,642]

Several studies have been performed in clinically ill foals to determine whether RAI occurs in the septic foal. The first report of transient adrenal insufficiency in a septic foal was published in 1998, and the foal in that report had a low basal serum cortisol concentration and an inadequate response to high-dose ACTH stimulation testing.[654] Gold et al. reported that septic foals had higher mean cortisol and ACTH concentrations than normal foals, and the septic foals also had higher ACTH/cortisol ratios than normal foals.[655] Castagnetti et al. reported that nonsurviving septic foals had higher ACTH and ACTH/cortisol ratios at admission than healthy foals or surviving septic foals.[656] Interestingly, Wong et al. reported no difference in baseline cortisol or ACTH concentrations or ACTH/cortisol ratios between normal and clinically ill foals.[96] A small number of foals in that study did exhibit low baseline cortisol and ACTH concentrations or inadequate responses to ACTH stimulation suggestive of RAI, however. Hurcombe et al. reported that ACTH, cortisol, and AVP concentrations were increased in septic foals, compared with sick, nonseptic foals and normal foals.[121] They also found that ACTH, cortisol, and AVP concentrations were higher in sick, nonseptic foals than in healthy foals. Some septic foals in that study exhibited low or normal serum cortisol concentrations despite an increased ACTH concentration, which was considered to be suggestive of RAI.[657] Hart et al. examined a population of hospitalized foals and an age-matched population of healthy foals.[97] They found that 46% of hospitalized foals had an inappropriately low baseline cortisol concentration, and 52% had an inadequate response to high-dose ACTH stimulation. A significant correlation was observed between an inadequate response to high-dose ACTH stimulation and both shock and MODS in hospitalized foals as well as a correlation with decreased survival in a subset of septic foals. Armengou et al. reported that nonsurviving septic foals have higher cortisol concentrations and ACTH/cortisol ratios than surviving foals.[114] Although there are no reports examining the role of peripheral tissue corticosteroid resistance in the development of CIRCI in foals, a recent study performed in adult horses with SIRS found that decreased GR binding affinity was associated with nonsurvival and a trend toward an increased ACTH:cortisol ratio.[658] Investigation of the role of peripheral tissue corticosteroid resistance in foals may be warranted.

The variability seen in these equine studies mirrors the challenges observed in human medicine in applying basal cortisol concentrations and the results of high- and low-dose ACTH stimulation testing in the diagnosis of RAI. The use of baseline cortisol concentrations and ACTH stimulation testing is no longer recommended in human critical care patients.[659-661] Similarly, there is currently no consensus regarding the appropriate diagnostic features of this condition in foals.[662] Because of these difficulties and the increasing appreciation that it is not possible to determine the actual activity of cortisol at the tissue level, a new term was developed in human medicine: CIRCI. CIRCI is inadequate cellular corticosteroid activity for the severity of the patient's illness.[309] The current recommendations in human medicine regarding the diagnosis of CIRCI are based on clinical criteria rather than diagnostic testing. Patients with hypotension refractory to fluid replacement and vasopressor therapy should be suspected of suffering from CIRCI, and they should be treated with hydrocortisone. The positive response to hydrocortisone therapy is potentially supportive of a diagnosis of CIRCI.[309,660]

There is very little information available regarding the treatment of foals that may be suffering from CIRCI. The results of multiple studies in human patients have demonstrated that low-dose corticosteroid therapy in septic shock is associated with improved hemodynamics and a decreased requirement for vasopressor therapy, but it is not clear that there is a survival benefit associated with this intervention.[663] Based on the experience in human medicine, it appears reasonable to reserve corticosteroid therapy for those foals in which CIRCI is suspected and that demonstrate fluid-refractory, vasopressor-resistant hypotension.[190,662,664,665] The potential role of corticosteroid replacement therapy may be supported by the recent study regarding factors associated with nonsurvival in foals with NE. This study reported that persistent hypotension requiring vasopressor and/or inotrope therapy was significantly associated with nonsurvival.[666] Recommendations for corticosteroid therapy in foals are by necessity based primarily on the recommendations derived from human medicine, because no specific therapeutic protocols have been investigated in the foal.[667] Current human recommendations are for the use of physiologic dosages of hydrocortisone. This approach most closely mimics normal corticosteroid

dynamics rather than using high supraphysiologic dosages or long-acting drugs like prednisolone or dexamethasone.[315] A 3.5-day course of tapering dosages of hydrocortisone (1.3 mg/kg/day divided q 4 h IV) in healthy 2- to 6-day-old foals was reported to potentially have beneficial antiinflammatory effects without any apparent adverse effect on innate immunity.[313] The daily endogenous production of cortisol and the pharmacokinetics of hydrocortisone have been studied in neonatal foals, and it was determined that an appropriate dosage of hydrocortisone for foals suspected to have CIRCI might be in the range of 1 to 3 mg/kg per day.[314] This is slightly lower than the 2- to 4-mg/kg-per-day dosage (divided into two to four IV boluses per day) currently recommended in human medicine,[309] and it has since been suggested that a reasonable hydrocortisone dosage for foals may be 1 to 4 mg/kg per day divided into four to six IV boluses per day.[315] The appropriate duration of therapy is unknown in foals, but in humans it has been shown that early withdrawal of hydrocortisone therapy is deleterious, and prolonged treatment (7–10 days) with subsequent tapering of dosages is recommended.[646,668]

Hypothalamic-Pituitary-Thyroid Axis Function and Dysfunction

The production of thyroid hormones is regulated by the hypothalamus, which releases thyrotropin-releasing hormone (TRH) into the pituitary portal system. TRH then stimulates the thyrotropes of the anterior pituitary to release thyroid-stimulating hormone (TSH) into the systemic circulation. TSH regulates the synthesis and release of thyroid hormones by the thyroid gland. The thyroid hormones are stored within the thyroid gland as the precursor thyroglobulin, which is cleaved to produce triiodothyronine (T_3) and thyroxine (T_4) under the influence of TSH. T_3 and T_4 then enter the systemic circulation. In the circulation the thyroid hormones are bound to thyroid binding globulin and other proteins, including albumin. T_4 has minimal activity and essentially serves as a prohormone. It is converted to T_3, the primary active form of thyroid hormone, at the tissue level. Only the unbound, free thyroid hormones can be transported into the cell, in which they bind to thyroid hormone receptors in the nucleus and subsequently influence gene transcription. The effects of thyroid hormones are extensive but primarily involve increasing metabolic rate, enhancing cardiovascular function, and thermogenesis.[643]

The assessment of HPT function relies primarily on the measurement of TSH and/or the measurement of basal thyroid hormone concentrations (T_3, T_4, free T_3, free T_4, and reverse T_3). This approach is complicated by the age-related changes in these hormone concentrations that occur in newborn foals, as well as the myriad of influences of other nonthyroidal factors. The measurement of circulating concentrations is also poorly reflective of the activity of these hormones at the tissue level. Stimulation testing is difficult because of the lack of ready availability of TRH or TSH and is not practical in the clinical setting. In newborn foals thyroid hormone concentrations are substantially higher at birth than in adult horses.[669-674] These elevated concentrations gradually decrease to adult levels over several months' time. Only a few studies have measured TSH in neonatal foals, and they found that the concentrations were not elevated; instead, they were similar to the levels seen in adult horses.[674,675] This suggests that the HPT axis is different in foals, perhaps because of increased activity of TSH or increased receptor sensitivity to TSH. This alteration in the HPT axis may account for the rapid growth of foals in the first few months of life and their high neonatal thermogenic capacity.[669,674]

Dysfunction of the HPT axis has been described in neonatal foals and is caused by congenital hypothyroidism, prematurity, and systemic illness. A syndrome of congenital hypothyroidism and dysmaturity syndrome was first described in neonatal foals in Western Canada in 1981.[676,677] This syndrome is associated with thyroid hyperplasia (goiter), increased gestational length, dysmaturity, and numerous musculoskeletal abnormalities, including flexural limb deformities, rupture of the common digital extensor tendon, incomplete ossification of the cuboidal bones, mandibular prognathism, and incomplete closure of the abdominal wall.[676,678-684] This syndrome is also suspected to be associated with abortion in some cases.[685] Thyroid hormone levels in affected foals may be low or normal, but the response to TSH stimulation is consistently decreased.[686,687] Although the etiology is unknown, this syndrome is suspected to be associated with exposure to some causative agent, and epidemiologic investigations have suggested increased dietary nitrate intake or exposure to mustard plants could be involved.[643,678,682] Other potential risk factors could include inadequate iodine or selenium intake.[682,688] The prognosis for survival in affected foals is poor, and those that do survive are likely to suffer a variety of orthopedic abnormalities that render them unsound.[680] Congenital hypothyroidism has also been reported in foals whose dams suffered dietary iodine deficiency or excess, and affected foals typically exhibit prominent goiter.[689-691] In utero exposure of foals to endophyte *(A. coenophialum)*-infected fescue has been associated with clinical signs of hypothyroidism after birth and with decreased circulating concentrations of T_3.[32,692]

Premature foals exhibit hypothyroidism because they have substantially lower thyroid hormone concentrations compared with healthy, full-term foals.[82,671] This may be analogous to the syndrome of transient hypothyroxinemia of prematurity that has been described in premature human infants.[693,694] One report described that both premature and term hospitalized foals had lower T_3 concentrations compared with healthy term foals, whereas the premature foals had lower T_4 concentrations than either group of term foals.[674] The presence of systemic illness is also associated with hypothyroidism in both premature and term foals, and this has been termed the *sick euthyroid syndrome* or the *nonthyroidal illness syndrome* (NTIS). NTIS is well described in humans, dogs, and cats, and there is increasing evidence that it occurs in adult horses and foals.[671-674,695,696] NTIS in sick foals is characterized primarily by low T_3 concentrations.[674] The mechanisms underlying NTIS are thought to be associated with the proinflammatory state associated with illness, but they may also be related to decreased feed intake, because fasting induces NTIS in healthy humans.[697,698] It has been proposed that this phenomenon may represent an appropriate and beneficial response to critical illness, at least in the acute stages, and may not require any therapeutic intervention beyond addressing the primary disease.[697,699]

Dysfunction of the Somatotropic Axis and Energy Regulation

As previously discussed the maturation of the endocrine system of the foal is incomplete at birth, and development

continues for weeks to months after parturition. This is also the case for the systems regulating energy metabolism in foals.[700] These systems are very complex, involving neuroendocrine (cortisol, vasopressin, and thyroid hormone), somatotropic (growth hormone [GH] and insulin-like growth factor-1 [IGF-1]), sympathoadrenal (epinephrine and norepinephrine), and pancreatic (insulin and glucagon) responses, as well as signals derived from fat stores (leptin and adiponectin) and the gastrointestinal tract (ghrelin).[701] The somatotropic axis is stimulated by hypothalamic release of growth hormone-releasing hormone and inhibited by the release of somatostatin.[702] The somatotropic cells of the anterior pituitary respond to these signals by increasing or decreasing the release of GH. The effects of GH are primarily mediated by IGF-1, which is produced by the liver and has similar effects on insulin when regulating blood glucose concentrations by decreasing hepatic gluconeogenesis and stimulating the uptake, utilization, and storage of glucose.[703] The secretion of GH is stimulated by ghrelin and under negative feedback control of IGF-1 and leptin.

The sympathoadrenal response is stimulated by physiologic stress and hypoglycemia, leading to the release of epinephrine from the adrenal gland.[704] The metabolic effect of epinephrine is to increase energy substrate availability by inhibiting pancreatic insulin secretion and increasing glucagon secretion, interfering with the effects of insulin on the tissues, stimulating hepatic glycogenolysis, and increasing lipolysis. The pancreatic hormones insulin and glucagon are critical mediators of blood glucose concentrations, with insulin being produced by β cells in response to hyperglycemia and glucagon produced by α cells in response to hypoglycemia. Insulin has a multitude of effects, primarily focused on lowering blood glucose concentrations, and these include increasing glucose uptake in insulin-dependent tissues such as muscle and adipose tissue, increasing glycogen synthesis, increasing fat synthesis, and decreasing gluconeogenesis and lipolysis. Glucagon acts in opposition to insulin, primarily functioning to increase blood glucose concentrations by increasing glycogenolysis and gluconeogenesis, as well as by increasing lipolysis. The adipokine leptin is involved in the control of appetite, with increases seen following ingestion of a meal and with increasing total body fat, whereas adiponectin is negatively correlated with total body fat and has some activities similar to glucagon. Ghrelin mainly acts to increase feed intake and to stimulate GH secretion.

Hypoglycemia is a common finding in critically ill equine neonates, perhaps because of limited endogenous energy stores and decreased enteral intake.[131,705,706] Care should be taken in interpreting blood glucose concentrations in neonatal foals, however, because they typically have relatively low blood glucose concentrations (50–60% of maternal blood glucose) in the immediate postpartum period, especially before their first nursing.[707] Hypoglycemia has been repeatedly associated with an increased risk of nonsurvival in critically ill foals, although different diagnostic criteria have been used to define hypoglycemia.[118,131,708,709] In the study reported by Hollis et al. there was an association between the severity of hypoglycemia and the risk of nonsurvival, with each increase of 18 mg/dL from a cutoff of 50 mg/dL being associated with an increase of the odds of survival to discharge of 3.4 times (95% CI 2.1–5.4).[131] In one study the percentage of survivors was lower among foals with blood glucose values ≤120 mg/dL (31%) compared with foals with blood glucose concentrations >120 mg/dL (55.6%).[708] A second study, however, found no clinically relevant pattern of alteration in blood glucose concentration when comparing septic and sick, nonseptic neonatal foals to healthy controls.[114] Septic foals had slightly lower median blood glucose concentrations than controls, but this remained within the normal reference range. The treatment of hypoglycemia in sick foals is of critical importance when it is documented and should be addressed by the immediate provision of nutritional support, either enterally and/or parenterally, as is appropriate to the individual case (see the later section Nutritional Support for the Foal).

Hyperglycemia is common in critically ill foals as well, with one study reporting that 36.5% of foals demonstrated hyperglycemia at admission, which was similar to the rate of hypoglycemia (34.4%).[131] That study reported that extreme hyperglycemia (>180 mg/dL) was associated with an increased risk of nonsurvival, which is similar to the situation reported in human neonates and adult horses with acute abdominal disease.[710-713] Interestingly, Barsnick et al. reported different findings, because the septic foals with the highest blood glucose concentrations (up to 329 mg/dL) in their study all survived.[709] Insulin resistance may play a role in the development of hyperglycemia, although there are many other factors that may contribute to the development of hyperglycemia, as discussed previously. Increased insulin concentrations have been associated with mortality in critically ill foals, which might be an indication of insulin resistance in the most severely affected individuals.[709] Insulin resistance does not appear to be a common feature of critical illness in foals, however, because both sick nonseptic and septic foals have exhibited normal insulin sensitivity in the studies that have investigated this phenomenon.[114,709]

There has been tremendous interest and debate in human medicine regarding therapeutic interventions to control hyperglycemia in the critically ill. Tight regulation of blood glucose concentrations (between 80 and 110 mg/dL) was initially advocated in human medicine,[714] but this approach has been shown to be deleterious because of frequent hypoglycemia resulting from insulin administration. A more permissive approach is now recommended, in which blood glucose concentrations are maintained between 145 to 180 mg/dL.[715] This approach attempts to avoid the requirement for aggressive insulin therapy, minimizing hypoglycemic episodes, while also recognizing that stress hyperglycemia is a normal physiologic response that is important for maximizing energy delivery to noninsulin-dependent tissues, such as the brain, intestine, red blood cells, and kidney.[716,717] The primary goal should be the avoidance of severe hypoglycemia that exceeds the renal threshold, which in foals is likely to be above 180 mg/dL.[718] Insulin therapy may be required to accomplish this goal, and various regimens have been described, including intermittent bolus administration or continuous rate IV infusions[30,643,718-720] (see the later section Nutritional Support for the Foal). The institution of insulin therapy is not to be taken lightly, because it requires frequent monitoring of blood glucose concentrations and rapid intervention to avoid hypoglycemia until a stable blood glucose level is achieved, which may take several hours of fine-tuning.[720]

Other indicators of alterations of energy regulation that have been investigated in foals include triglycerides (TG), nonesterified fatty acids (NEFAs), GH, IGF-1, leptin, and glucagon. Although our understanding of the role of these factors in equine neonatal critical illness is still developing, these studies

give valuable insight into the complexities involved and provide some indication of the potential benefits of assaying these variables. Barsnick et al. reported that septic foals had higher glucagon and TG concentrations than healthy foals but found no difference in leptin concentrations between groups.[709] Lower leptin concentrations were associated with mortality in that study, however. In a later study Barsnick et al. found that septic foals had higher ghrelin, GH, and TG concentrations and lower IGF-1 and glucose concentrations compared with healthy foals, and these findings are likely related to inanition and a negative energy balance.[721] Sick, nonseptic foals in that study had higher GH and TG and lower IGF-1 concentrations than were observed in healthy foals. The GH:IGF-1 ratio was higher in septic and sick, nonseptic foals than healthy foals and was highest in nonsurvivors. This finding was indicative of somatotropic axis resistance in clinically ill foals.[721] Panzani et al. reported that IGF-1 concentrations did not differ between healthy and sick foals but increased over time in all groups, whereas NEFA concentrations were higher in sick foals at some time points.[672] Armengou et al. also reported that NEFA concentrations were higher in sick foals than in healthy foals but found no differences in TG concentrations between groups.[114] Although direct intervention in the somatotropic axis does not appear to be indicated, [722] these findings support the importance of correcting the negative energy balance that exists in many critically ill foals.

IMMUNOLOGIC DISORDERS

Failure of Transfer of Passive Immunity

The most common type of immunodeficiency disorder in horses is FTPI, which is the failure of the foal to ingest or absorb adequate immunoglobulin from colostrum.[723,724] This is critically important because foals are essentially agammaglobulinemic at birth from the inability of macromolecules to transfer across the diffuse epitheliochorial equine placenta from the dam to the fetus.[725] FTPI is regarded as the most important risk factor for the development of infection and death for foals within the first month of life, and the incidence of FTPI has been estimated at 3% to 24%.[726] FTPI can occur by several mechanisms, including failure of the foal to ingest adequate volumes of colostrum in the early neonatal period, loss of colostrum before ingestion because of premature lactation, low colostral immunoglobulin concentration, and inadequate absorption of colostrum by the neonatal gastrointestinal tract.[725,727] The timing of colostrum ingestion is critically important, because the ability of the neonatal gastrointestinal tract to absorb macromolecules is maximal at birth but rapidly declines over the first 24 hours of life.

The diagnosis of FTPI cannot be made on clinical grounds and requires determination of the foal's serum IgG concentration within the first 18 to 24 hours of life. The gold standard assay for the quantification of immunoglobulin quantification is the single radial immunodiffusion assay, but this test requires a prolonged incubation period, rendering it of little utility in the clinical setting. A number of types of rapid screening tests are available for estimating foal IgG concentrations, including glutaraldehyde coagulation, zinc sulfate turbidity, turbidimetric immunoassay, latex agglutination, and enzyme immunoassay tests, as well as serum globulin or TP concentrations.[727-735] The ultimate decision regarding which test to use is based on the consideration of each test's accuracy, time requirement, cost, and ease of implementation.[733] Several studies have indicated that serum globulin concentrations can be used to estimate the IgG concentration, but it appears that the cutoff points must be established in each individual clinical laboratory because of the variations in testing methodology.[733,736,737] The enzyme immunoassay test is widely used because of its acceptable diagnostic performance as a screening test (high sensitivity), combined with simple performance and rapid results.[733] The interpretation of the results of IgG testing has been the subject of tremendous interest over the past 40 years and can be a point of confusion because of the different diagnostic criteria and different test methodologies used over time. A recent report supported the traditional cutoff value of >800 mg/dL as indicative of adequate transfer of passive immunity (ATPI) and found that in a large population of hospitalized foals values <800 mg/dL were proportionally associated with mortality.[165] This study also reported a regression equation that could be used to estimate serum IgG concentration from serum TP, albumin, and globulin concentrations with good diagnostic performance (IgG = −241.4 × [albumin] + 462 × [globulin] + 222.8 × [TP] − 370.3).[165] This estimation may be helpful in situations where specific testing for serum IgG concentration is not readily available.

Treatment of FTPI depends to some extent on the clinical status of the foal and the foal's environment. If the foal is known or suspected to have ingested inadequate amounts of colostrum, then early enteral administration of maternal or banked colostrum may be effective; however, such treatment should not be assumed to result in ATPI, and monitoring of serum IgG is still indicated.[738] A clinically normal foal examined in the home farm environment may not require treatment if the IgG value is between 400 and 800 mg/dL (partial FTPI), whereas a value of less than 400 mg/dL (complete FTPI) represents grounds for treatment. If the foal shows any signs of clinical illness or is being examined in a hospital environment, then any IgG value of less than 800 mg/dL is an indication for treatment. Treatment consists of providing IgG supplementation, which most often is accomplished by IV administration of equine plasma, because test results are typically not available until after the time period in which enteral supplementation would likely be effective. The dosage for IV plasma administration is based on the severity of the foal's deficit, but it is not precise because of the tremendous variability in IgG content in commercial equine plasma.[724] In clinical practice the administration of 1 L of plasma can reasonably be expected to provide an approximately 200-mg/dL increase in serum IgG.[739] Unless plasma with a higher IgG concentration is used, it can be difficult to administer enough plasma to completely normalize serum IgG in severely affected foals because of the risk of volume overload as well as the expense of treatment, so the maximum initial dosage of plasma is typically 2 L.[740] It is important to monitor the effect of treatment by repeated measurement of serum IgG to ensure that further treatment is not required, especially in severely affected clinically ill foals that may have ongoing catabolism of IgG associated with their systemic illness.[740]

Neonatal Isoerythrolysis

NI is the most common cause of icterus in newborn foals. It is an immunogenetic disorder in which the foal's red blood cells are destroyed by preformed maternal anti–red blood cell antibodies ingested in the colostrum. These maternal antibodies are produced in response to exposure of the mare to "foreign"

red blood cell antigens by several possible routes, including placental pathology allowing exposure to fetal red blood cells during gestation, exposure to foal red blood cells during parturition, or blood transfusions administered to the mare.[741] Blood group incompatibilities between the mare and the foal are caused by the foal inheriting a blood group antigen from the sire that the mare does not possess. These incompatibilities are likely commonly caused by the multitude of equine blood group antigens, with an estimated incidence of 14%, yet the reported incidence of NI is only 1% in Thoroughbreds and 2% in Standardbreds.[122,742,743] This is because the majority of blood group antigens are not strongly immunogenic under these conditions of exposure. Some blood group factors are strongly immunogenic, and factor Aa in the A system and factor Qa in the Q system have historically been the factors associated with the majority of cases of NI.[742] More recent reports have documented the involvement of other alloantigens, perhaps as a result of an enhanced ability to detect these other factors or because of differences in the breed composition of the local horse population.[119,744] The incidence of NI in mules is much higher than in horses, with estimates as high as 10% because of the presence in these foals of a donkey-specific red blood cell antigen ("donkey factor") that horses lack.[745,746]

Foals affected with NI are typically born clinically normal and begin to show clinical signs within 2 to 5 days of birth, although intervals of as long as 12 days have been reported.[119] The clinical signs of NI result from anemia and tissue hypoxia and include progressive lethargy, weakness, tachypnea, and tachycardia. Affected foals will initially have pale mucous membranes but subsequently develop icterus, although in peracute cases foals may die before exhibiting icterus.[741] As the disease progresses foals will become dyspneic, and seizure-like activity may occur, potentially caused by kernicterus in cases with severe hyperbilirubinemia. Pigmenturia may be present, which is caused by severe hemolysis. Affected foals are anemic, although the magnitude of the anemia may be masked by concurrent hemoconcentration at presentation.[119] Although most foals will present with hematocrits between 10% and 20%, the anemia can be severe, with hematocrits as low as 5% reported.[119,741] Thrombocytopenia may be present as well, and this finding appears to be more common in mule foals.[741,747] Venous blood gas analysis reveals decreased venous oxygen concentration and saturation caused by increased oxygen extraction at the tissue level. There is metabolic acidosis caused by lactic acidosis, which is caused by anaerobic tissue metabolism, resulting in increased lactate production. Hyperbilirubinemia, primarily caused by increased indirect bilirubin concentrations, is a consistent feature, although increased direct bilirubin concentration is seen in some affected animals, potentially caused by hepatic injury secondary to hypoxia or iron toxicity associated with bilirubin accumulation.[119,122] Increased SDH concentrations have also been associated with severe anemia (hematocrit <11%) in foals with NI, further supporting that hepatocellular injury occurs in severely affected foals.[119] Hemoglobinemia and hemoglobinuria can be pronounced, and pigment nephropathy resulting in acute renal failure can occur in severely affected cases.

Diagnosis is often made based on the signalment, history, and clinical signs, but confirmation is important because there are other causes of hemolytic anemia in neonatal foals, including DIC associated with sepsis, bacteria-induced hemolysis, and iatrogenic causes such as incompatible transfusion of blood or plasma.[119] A definitive diagnosis is made by demonstrating the presence of antibodies in the mare's colostrum or serum directed against the foal's red blood cell antigens. This can be done using agglutination or lytic tests, with lytic tests regarded as more reliable.[743] The hemolytic crossmatch of mare serum with foal red blood cells using exogenous complement is considered the test of choice. Identification of the specific red blood cell factors involved can also be accomplished by testing panels of red cells that represent all the known blood groups.[741] Despite their limitations, agglutination tests are commonly used because they are more readily performed and provide more rapid results. A crossmatch of mare serum with foal red blood cells without the addition of exogenous complement has agglutination rather than hemolysis as the endpoint and is less sensitive than the hemolytic crossmatch. The direct antiglobulin (Coombs) test can be used to demonstrate the presence of antibodies on the surface of the foal's red blood cells, but this test can lack sensitivity. The most readily performed test is the jaundiced foal agglutination (JFA) test, which is simple and provides rapid results. The JFA test is performed using red blood cells from the foal and colostrum from the mare, with agglutination as the endpoint. Unfortunately the JFA test can lack both sensitivity and specificity and is most useful in prevention of NI rather than diagnosis of an affected foal.

The treatment for NI will be dictated by the severity of the anemia and the associated clinical signs. Moderately affected foals primarily require supportive care, exercise restriction, and close monitoring. Stress should be avoided in handling the foal. If the foal presents at less than 24 hours of age then it should be withheld from nursing until the risk of further antibody ingestion has passed. This time interval can be difficult to assess accurately, but it should not exceed 24 hours because of waning maternal antibody content in the milk and decreased gastrointestinal absorption in the foal. Serial monitoring of the JFA test can be used, if desired, to assess the decline of maternal alloantibodies in the milk and confirm that the introduction of nursing should be safe.[748] The foal will need to be provided with nutritional support during this time period, which is most readily performed using an indwelling feeding tube. IgG supplementation with colostrum from another mare or with frozen plasma will be necessary to ensure adequate passive transfer. Despite some concerns in the literature, withholding colostrum does not appear to have any deleterious effects on gastrointestinal development in foals.[749] IV fluid therapy is helpful in supporting cardiovascular function and tissue perfusion as well as ensuring diuresis, minimizing the potential nephrotoxic effects of hemoglobin. Fluid therapy should be administered conservatively, however, to avoid hemodilution, particularly in more severely affected foals. Plasma exchange has been successfully used to treat foals affected with severe hyperbilirubinemia secondary to NI.[258]

Further treatment is indicated if the affected foal shows evidence of shock caused by tissue hypoxia, which becomes more likely in foals with profoundly low hematocrits (<10–12%), but it should not be based on the hematocrit reading alone. The decision to treat in these cases may be supported by findings of persistent or progressive tachycardia and tachypnea and demonstration of decreased mixed venous oxygen tension.[750,751] Treatment in these foals is directed at the restoration of the oxygen-carrying capacity of the blood and improving tissue oxygen delivery. Intranasal oxygen insufflation is readily performed but may be of limited benefit because oxygen saturation is typically not adversely affected. The only other way to improve oxygen

delivery is by transfusion of red blood cells that will not be damaged by the maternal alloantibodies. The transfused red blood cells will likely only persist in the foal's circulation for a few days, but the goal of the transfusion is to provide support while the foal produces sufficient red blood cells to support itself. In the ideal situation a known Aa and Qa negative "universal" donor could be used, but these are very difficult to identify and not commonly available. In most cases the mare represents the most logical donor, and once her red blood cells have been washed to remove the alloantibodies present in her serum they can be transfused to the foal. The most effective way to wash the maternal red blood cells is by centrifugation, but this is often not readily available. Serial gravity sedimentations of anticoagulated maternal red blood cells using sterile isotonic saline to remove and discard the supernatant is readily performed and reasonably effective, but it does require a substantial period of time (several hours) during which the foal's clinical status may deteriorate. There are reports of the administration of polymerized bovine hemoglobin (Oxyglobin, Biopure Corporation, Cambridge, MA) as an alternative form of bolstering oxygen transport capacity. This is appealing because the product is shelf-stable and requires no delay in administration.[119,750,752] These reports provide some conflicting evidence regarding the potential safety of this approach because the administration of bovine hemoglobin was associated with poor outcomes in some instances. It is unclear if this is the result of the product administered or a result of case selection, in which the most severely affected foals were likely selected to receive this therapy.[752] When blood transfusions are used the volume of blood to be administered to the foal should be kept to a minimum; administration of greater than 4 L of blood is associated with the development of hepatic failure (OR 19.5).[122] Reinforcing this concern is the finding that the administration of each additional unit of blood was shown to increase the odds of nonsurvival 8.4 times.[122]

The most effective treatment for NI is prevention. Blood typing of the mare can be performed before breeding to fully characterize the mare's blood group, and if the mare lacks factors Aa and/or Qa she would be considered at risk for becoming sensitized in the future.[741] Testing to identify the specific alloantibodies produced by a mare that has produced an NI-affected foal can be used in combination with blood typing of the sire to predict future risk.[753] This is rarely done, however, and it is simpler to perform the JFA test at the time the foal is born and before the foal is allowed to nurse. When performed in this manner the JFA test is reasonably diagnostic, and a negative result supports allowing the foal to nurse.[748,754] In the absence of JFA test results, any foal born to a mare that has had a previous foal affected by NI should be considered at high risk, and the foal should be muzzled at birth and not allowed to nurse for the first 24 hours of life. Although clinically affected foals have likely received adequate passive transfer of immunoglobulins, any foals that are deprived of maternal colostrum as a preventive measure must receive immunoglobulins in the form of pooled colostrum administered enterally or fresh frozen plasma administered intravenously.

Neonatal Alloimmune Thrombocytopenia and Neutropenia

Neonatal alloimmune thrombocytopenia (NAIT) and neonatal alloimmune neutropenia (NAN) appear to be rare in the equine, but they have been reported in horse and mule foals.[747,755-759] A syndrome of ulcerative dermatitis, thrombocytopenia, and neutropenia has also been described in foals.[760] It is possible that the incidence of these conditions is underappreciated, however, because neutropenia and thrombocytopenia are common findings in critically ill patients secondary to a number of other mechanisms.[761] The pathophysiology of NAIT and NAN is very similar to that of NI: affected foals ingest maternal alloantibodies directed against antigens on platelets or neutrophils, resulting in their destruction or removal from circulation. Diagnosis of these conditions is based on the demonstration of persistent thrombocytopenia or neutropenia in the absence of other disease processes that might cause these abnormalities, such as bacterial sepsis. Foals affected by NAIT may appear clinically normal or they may exhibit petechial hemorrhages or prolonged bleeding from venipuncture sites. Foals with NAN are typically clinically normal, but they are predisposed to secondary bacterial infections that may lead them to exhibit clinical signs of local or systemic inflammation. Confirmation of the clinical diagnosis requires the demonstration of antibodies bound to the patient's platelets (NAIT) or neutrophils (NAN). Direct fluorescent antibody tests, ELISA, immunoradiometric tests, and flow cytometry have been used to confirm the diagnosis.[747,755-759,762]

Treatment of NAIT is supportive in most cases, although whole blood or platelet-rich plasma transfusions can be administered to foals exhibiting clinical bleeding diathesis.[763] Supportive care is indicated in foals with NAN, although recombinant human granulocyte colony-stimulating factor can be administered in an effort to increase endogenous neutrophil production.[758,759] Foals affected by NAIT and especially NAN appear to be at increased risk for secondary bacterial infections, so appropriate broad-spectrum antimicrobial therapy is indicated. Both conditions are ultimately self-limiting because the offending alloantibodies are consumed and eliminated from circulation. The use of immunosuppressive therapy has been proposed but does not appear to be indicated in these conditions.

HEPATIC DISORDERS

Hepatic disorders are uncommon in foals, but there are a wide range of possible etiologies. True hepatic failure is rare, and hepatic dysfunction is the most common disorder. Detection and diagnosis of hepatic disease in foals are challenging because the clinical signs are nonspecific and often related to a primary disease process. These nonspecific signs can include anorexia, depression, fever, weight loss, and abdominal pain. Icterus may be present but is not specific for hepatic dysfunction, and it may be secondary to anorexia, intravascular or extravascular hemolysis, sepsis, or severe systemic illness. With more severe hepatic involvement one may observe any or all of the following: CNS signs, bleeding disorders, edema, ascites, diarrhea, or dermatitis. A definitive diagnosis requires clinicopathologic examination consisting of serum enzyme activities and conjugated and unconjugated bilirubin at a minimum but potentially including serum bile acids, serum ammonia, and prothrombin time. Additional biochemical abnormalities that may be supportive of, but not specific for, hepatic disease include hypoglycemia, metabolic acidosis, low BUN, and polycythemia. Ultrasonographic examination also can be very helpful because it allows for the assessment of the hepatic parenchyma and may allow for the detection of structural abnormalities. Hepatic biopsy, although rarely performed

TABLE **20.12 Biochemical Parameters in Foals over the First Month of Life**

Biochemical Parameters	Units	1 Day	7 Days	1 Month
Alkaline phosphatase	IU/L	<2670	<1170	<866
γ-Glutamyl transferase	IU/L	<33	<98	<44
Sorbitol dehydrogenase	IU/L	<21	<18	<6
Aspartate aminotransferase	IU/L	<340	<620	<440
Glutamate dehydrogenase	IU/L	<27.5	<17	—
Total bilirubin	mg/dL	<4.5	<3.3	<1.7
Direct bilirubin	mg/dL	<0.35	<0.7	<0.6
Ammonia	μg/dL	—	<60	—
Bile acids	μmol/L	<82	<30	<17

in foals, may be useful in diagnosis, treatment planning, and prognostication.

The interpretation of the biochemistry profile can be challenging in young foals because the activities of some hepatic enzymes and other parameters are substantially different from those normally seen in adult horses (Table 20.12). Serum alkaline phosphatase (ALP) activity shows the most striking elevations compared with adults, with values as much as 10-fold greater in the first week of life. This is primarily caused by bone metabolism, which rapidly declines over the first month of life and then gradually decreases to the adult range by 6 months of age.[707,764,765] Serum GGT activity transiently increases during the second week of life and then returns to the normal adult range by 1 month of age.[766,767] AST concentrations increase slightly after the first week of life but then remain similar to adult values.[707,764] SDH and glutamate dehydrogenase (GLDH) values do not differ significantly with age.[707,768] Serum bile acid concentrations are also increased at birth but gradually decrease to normal adult ranges over the first 6 weeks of life.[769] Neonatal hyperbilirubinemia is well documented in foals and is primarily associated with increased total bilirubin concentration.[707] This elevation gradually resolves, and values are typically within normal adult ranges after the first week of life. Direct bilirubin concentrations are low at birth but increase to normal adult ranges after the first few days of life.[769] The serum enzymes that are liver specific—namely, SDH, GLDH, and GGT—are of greatest utility in evaluating the foal with hepatic dysfunction compared with the nonspecific enzymes ALP and AST. GGT is liver and biliary tract specific, whereas SDH and GLDH are of hepatocellular origin.

Acquired Disorders

Tyzzer's Disease

Tyzzer's disease is an enterohepatic syndrome affecting foals from 7 to 42 days of age that is associated with the rapid onset of septic shock and death, usually within 2 to 48 hours from the onset of clinical signs.[770,771] The primary manifestation of this disease is a peracute bacterial hepatitis. This disease is well described in foals, with numerous cases documented in the United States and other countries over the past 40 years.[772-778] The causative agent of Tyzzer's disease is *C. piliforme,* a soil- and manure-borne gram-negative, pleomorphic, motile, spore-forming, rod-shaped obligate intracellular bacterium.[779] The epidemiology is poorly understood, but as the disease does not affect adult horses it is likely that adult carriers contaminate the environment with subsequent fecal-oral transmission.[770] Risk factors for this disease include seasonality, with a 7.2 times greater risk between March 13 and April 13.[770] Foals born to young mares (<6 years of age) and nonresident mares are also at increased risk, possibly because of lack of previous exposure leading to poor colostral antibody production resulting in inadequate passive immunity in their foals.[770]

Tyzzer's disease often affects otherwise healthy foals, and affected individuals, especially younger foals, may simply be found dead. In foals presenting alive the clinical signs are often nonspecific, including lethargy, anorexia, dehydration, icterus, fever, colic, diarrhea, and seizures followed by the rapid onset of recumbency, weakness, coma, and death.[771,776] Antemortem diagnosis is difficult and is typically based on the signalment, history, clinical signs, and clinicopathologic findings. PCR testing may be useful for early and specific diagnosis,[771] but the results may not be available within a useful time frame because of the rapid progression of disease. Clinicopathologic examination typically demonstrates severe leukopenia with a left shift; thrombocytopenia; marked hypoglycemia; severe metabolic acidosis; elevated serum fibrinogen; and elevated total, indirect, and direct bilirubin concentrations.[771,779] The hepatocellular enzymes AST and SDH are markedly increased, but GGT and ALP are typically within normal limits.[768,771] Ultrasonographic examination of the liver reveals marked hepatomegaly with increased echogenicity of the hepatic parenchyma, or possibly an enhanced vascular pattern.[623,771] Treatment is extremely difficult because of the severe, acute nature of the disease, and the prognosis should be regarded as grave. There are, however, reports of successful treatment of three suspected and one confirmed case of the disease.[770,771,780] Treatment consists of antimicrobial therapy with penicillin or ampicillin in combination with an aminoglycoside, as well as fluid therapy, correction of electrolyte and acid-base disorders, parenteral nutritional support, and appropriate supportive care.[771,780]

Bacterial Hepatitis

Bacteria other than *C. piliforme* can cause hepatic disease, and are commonly associated with severe systemic inflammation and bacteremia, but these cases do not typically present with primary hepatic disease. These foals typically present as septic, critically ill foals, and the finding of hepatic involvement is secondary.[781] *Actinobacillus* spp. and *S. equi* subsp. *zooepidemicus* have been reported to be involved in acute bacterial hepatitis of young foals.[768,781] The spirochete *Bartonella henselae* was recently associated with severe suppurative cholangiohepatitis in a foal, which was successfully treated with trimethoprim-sulfamethoxazole and rifampin along with *S*-adenosylmethionine and pentoxifylline for their potential antifibrotic and antioxidant effects.[782] Leptospirosis has been associated with jaundice and death in a 10-day-old foal,[783] and *Leptospira interrogans* serovar Pomona appears to be a rare cause of hepatic disease in neonatal foals.[784] Ascending cholangiohepatitis and bile duct obstruction have been associated

with duodenal stenosis resulting from severe gastroduodenal ulcer disease (GDUD).[785-787] Effective surgical bypass procedures have been described for foals suffering from delayed gastric emptying associated with GDUD, but the prognosis for foals with hepatic involvement appears to be guarded.[591,787]

Equine Herpesvirus 1

EHV-1 infection of the near-term fetus can result in the delivery of a nonviable foal suffering from hepatic, respiratory, and/or gastrointestinal disease.[358,788] Most affected foals will be born premature and will be severely icteric on initial examination. Clinicopathologic examination typically demonstrates severe leukopenia caused by neutropenia and lymphopenia, which may be more severe than seen in septic foals.[183] Hyperbilirubinemia may be present, although the magnitude of hyperbilirubinemia may be less than one might expect based on the profound icterus observed clinically.[183,184] No increase is usually observed in the serum activity of the hepatic enzymes, which is surprising given the severity of the hepatic necrosis detected on postmortem examination.[183] Although hepatic involvement is prominent in most affected foals, death is usually caused by overwhelming respiratory disease within 1 to 5 days of birth.[184] Treatment with acyclovir was associated with an improvement in survival in one report, although valacyclovir may represent a superior choice given the superior bioavailability of that drug in adult horses after oral administration.[184,789]

Hepatic Lipidosis

Hepatic lipidosis can occur secondary to hyperlipemia in neonatal foals, but this appears to be most common in Miniature breeds.[790-792] Hypertriglyceridemia (>500 mg/dL) typically develops as a consequence of a negative energy balance resulting from inanition or anorexia caused by some other primary disease process and, if unresolved may progress to hyperlipemia, with characteristic grossly lipemic serum.[709,793] Fat accumulation in the liver can proceed rapidly, resulting in hepatic lipidosis. Hepatic enzyme activities may be increased, but this is not consistently observed.[790,791] Clinical signs of hepatic lipidosis may be referable to the primary disease process but can include severe depression, seizures, blindness, and ventral edema.[768] Treatment should be directed toward resolving any primary disease process and correction of the negative energy balance with parenteral nutrition. Insulin therapy is often critical in facilitating the resolution of the hyperlipemia and allowing for the administration of adequate amounts of parenteral nutrition.

Neonatal Isoerythrolysis

NI is the most common cause of hyperbilirubinemia in foals, and hepatic disease may develop because of hepatocellular injury resulting from excessive bilirubin accumulation, anemic hypoxia, and/or iron toxicosis.[119,122] Total and direct bilirubin, AST, ALP, and SDH activities may be increased in foals with NI. Foals with the lowest presenting packed cell volumes tend to have the highest SDH values, suggesting that hepatic injury was present at the time of presentation.[119] One study reported that foals receiving multiple blood transfusions (4 L or more) were 19.5 times more likely to develop hepatic failure than those receiving smaller volumes of blood products.[122] It is thought that multiple blood transfusions may cause iron overload leading to iron toxicity.[122,794] The administration of deferoxamine mesylate, an iron chelator, has been shown to decrease hepatic iron accumulation in healthy foals receiving blood transfusions.[794] Although the use of this drug in foals with NI has not been reported, the results of this study suggest that the administration of deferoxamine to foals with NI starting before blood administration may be beneficial in decreasing iron-associated hepatic injury.[784,794]

Iron Toxicity

The oral administration of iron fumarate is a very well-described cause of hepatic injury in foals. The greatest risk of toxicity is associated with iron administration before the foals first suckle, presumably caused by the presence of protective factors in colostrum or milk that decrease the hepatotoxicity of iron when administered after nursing has begun.[795-797] When iron is administered at birth and before colostrum ingestion, clinical signs will typically manifest within 2 to 5 days and are primarily associated with hepatoencephalopathy. Seizures, profound depression, head pressing, ataxia, and abnormal behavior are common. Icterus is usually present at the time of onset of neurologic signs. Clinicopathologic examination typically reveals elevated bilirubin, GGT, ALP, and SDH, as well as increased ammonia concentrations.

Inherited or Congenital Disorders

Glycogen Storage Disease Type IV

Glycogen storage disease type IV, a fatal recessive inherited deficiency of the glycogen branching enzyme, has been described in Quarter Horse foals.[798] The clinical signs associated with this disease are variable, ranging from stillbirth to progressive weakness, transient flexural limb deformities, persistent recumbency, seizures, and respiratory or cardiac failure.[798] Affected foals are leukopenic and typically have elevated AST and GGT activities, in addition to elevated creatine kinase (CK) caused by muscle pathology. The genetic lesion is a single base nonsense mutation in the glycogen branching enzyme encoded by the GBE1 gene.[799,800] One study reported that approximately 2.5% of fetal and early neonatal deaths in Quarter Horse–related breeds were homozygous for the mutant GBE1 allele, suggesting that this syndrome has a clinically relevant impact on the reproductive efficiency of these breeds.[801]

Persistent Hyperammonemia

Persistent hyperammonemia associated with encephalopathy has been described in Morgan foals 4 to 7 months of age.[263,802] Affected foals exhibit acute onset of clinical signs shortly after weaning, which can include coma, blindness, and seizures. Hepatic enzymes may be mildly elevated, but hepatic pathology is modest. Blood ammonia levels are extremely high in affected foals (300–600 μmol/L), and this syndrome is thought to be related to an inherited disorder of hepatic ammonia metabolism and possibly other amino acids.[803] The metabolic defect may resemble HHH syndrome in humans.[263] Although some foals may survive the first encephalopathic crisis, the syndrome is considered to be fatal and may end with a terminal hemolytic crisis.[768]

Congenital Fibrosis

A syndrome of congenital hepatic fibrosis has been described in the Swiss Franches-Montagnes and Swiss Frieberger breeds.[804,805] The onset of clinical signs is sudden, and affected foals are jaundiced and encephalopathic, with abdominal

distention and colic. Fever and tachypnea are also common. Leukocytosis caused by neutrophilia and increased GGT, ALP, and serum bile acid values are reported. Histopathology demonstrates diffuse bridging portal fibrosis with numerous small and irregular bile ducts, which are sometimes cystic.[805]

Portosystemic Shunts

Portosystemic shunts are an infrequent congenital anomaly in foals that allow for shunting of blood directly from the portal circulation to the systemic circulation.[806-808] The shunts can be located intra- or extrahepatic and may be single or multiple in number.[807] Clinical signs of encephalopathy often do not develop until foals are 6 to 12 weeks of age. The diagnosis is based on the signalment, particularly age of onset, and presence of encephalopathic signs with normal serum hepatic enzyme activities but marked elevations of serum ammonia. Confirmation of the diagnosis may be possible using hepatic ultrasonography, or by a "bubblegram" study involving the injection of 10 mL of agitated saline into the spleen while monitoring for the rapid appearance of bubbles via simultaneous echocardiography.[808] CT, positive contrast portography, and transrectal portoscintigraphy may also be useful in confirmation of the diagnosis.[784] Successful surgical repair using banding techniques that provide progressive occlusion has been described.[807,808]

MUSCULAR DISORDERS

Polysaccharide Storage Myopathy

Polysaccharide storage myopathy (PSSM) was first described in Quarter Horses and related breeds, such as Paint and Appaloosa horses, but is now recognized in some draft, Warmblood, and light horse breeds as well.[809-813] PSSM is characterized by abnormal glycogen accumulation in skeletal muscle associated with muscle damage following exertional exercise. This syndrome has been associated with an incompletely penetrant autosomal dominant mutation in the *GYS1* gene, which encodes the skeletal muscle glycogen synthase enzyme.[814] This mutation has been identified in more than 30 horse breeds, although at highly variable frequencies, with Quarter Horses and Belgians having the highest reported prevalences.[814-819] PSSM is rarely reported in foals because it remains subclinical, especially if foals are stall confined.[820] The only indication of the presence of the syndrome may be increased serum CK activity, unless the foals undergo a period of exertional activity or are affected by concurrent disease. Typically the disease is not recognized until affected individuals are mature enough to be put into training or work.[820] The clinical signs may range from muscle soreness and gait abnormalities in Warmbloods to progressive weakness and muscle atrophy in draft breeds, whereas Quarter Horses may suffer from acute exertional rhabdomyolysis.[815,821] Diagnosis in adults depends on muscle biopsy, but this may not be diagnostically useful in foals, and genetic testing is preferred.[822] Daily pasture exercise and appropriate feeding of a balanced, low-starch, fat-supplemented diet to both the foal and its dam will likely be beneficial in management of affected foals.[822]

Glycogen Branching Enzyme Deficiency

Glycogen branching enzyme deficiency represents an important cause of stillbirth and early neonatal death in the Quarter Horse and Paint breeds.[798,801,822] The syndrome is caused by a mutation in the *Gbe1* gene and results in severe impairment of glucose homeostasis.[800] The clinical presentation is variable, with foals born alive that are weak and hypothermic. Although they often respond positively when assisted to nurse or bottle-feed, intermittent hypoglycemia and seizures may develop unless they nurse regularly.[823] Other clinical signs can include fever, tachypnea, and tachycardia, and because of this very nonspecific spectrum of clinical signs it can be difficult to differentiate these foals from those suffering from neonatal sepsis.[824] Respiratory failure and sudden death can occur, even with only mild to moderate exercise.[823] Clinicopathologic evaluation may reveal leukopenia; intermittent hypoglycemia; and persistent elevations of CK, AST, and GGT activities.[822] Despite supportive care the condition is ultimately fatal, with most foals succumbing by 6 to 8 weeks and no reports of survival beyond 18 weeks of age.[822,823] A genetic test is available for diagnosis of this disease.[801]

Nutritional Myodegeneration (White Muscle Disease)

Nutritional myodegeneration (NMD) is a noninflammatory, degenerative disease primarily seen in foals less than 30 days of age. It affects skeletal as well as cardiac muscle and is associated with low serum selenium and vitamin E concentrations.[825-829] The primary deficiency of vitamin E and selenium appears to be in the mare, and for this reason NMD is most commonly seen in areas with selenium-deficient soils, forages, and grains.[830] These areas include the northeastern, northwestern, mid-Atlantic, and Great Lakes regions of the United States. The clinical presentation of NMD can be acute or subacute. The subacute form is associated with muscular weakness, whereas the acute form is associated with rapidly progressive weakness leading to recumbency and death within a few days.[831] Dysphagia is a common finding in the subacute form and is related to involvement of the muscles involved in prehension, mastication, and swallowing. It may contribute to the development of FTPI and aspiration pneumonia.[828] Severely affected foals typically have involvement of the myocardium and the respiratory musculature, contributing to cardiovascular and respiratory failure and leading to death.[822] Diagnosis of NMD is based on clinical signs in combination with increased muscle enzyme activities (CK and AST), decreased blood selenium, decreased glutathione peroxidase activity, and response to vitamin E and selenium treatment.[828,830] Profound electrolyte abnormalities may be present, including hyperkalemia, hyponatremia, hypochloremia, and hypocalcemia, with hyperkalemia potentially contributing to cardiac arrest in severely affected foals. Myoglobinuria may be present, and pigment nephropathy can lead to the development of acute renal failure. Muscle biopsies may be supportive of NMD, but a more definitive antemortem diagnosis requires assessment of vitamin E and selenium concentration or glutathione peroxidase activity.[828] Postmortem examination consistently reveals bilaterally symmetric myodegeneration with a dry appearance and pale discoloration of affected muscles. Treatment requires supportive care, IV fluid therapy for correction of hypovolemia, electrolyte derangements, metabolic acidosis, and diuresis. Dysphagic foals will require nutritional support, either by indwelling nasogastric feeding tube or parenterally. Vitamin E and selenium supplementation is essential in the treatment of affected foals (Table 20.13). The injectable form of selenium also contains vitamin E but at an insufficient concentration, requiring that foals also receive injectable or

TABLE **20.13 Treatments Drugs Used for Nutritional Myodegeneration**

Drug	Dosage	Route	Frequency (h)
Vitamin E (preferably in the form of DL-alpha-tocopheryl acetate)	2–6 IU/kg	PO	24
Selenium	0.055–0.067 mg/kg	IM (deep)	Once
	1 mg total dose	PO	24

IM, Intramuscularly; *IV,* intravenously; *PO,* orally.

oral vitamin E. Although the initial prognosis is guarded, foals that regain the ability to stand have a more favorable prognosis.[823] Prevention of NMD can be aided by ensuring that mares have adequate dietary vitamin E and selenium intake and by prophylactic parenteral administration of vitamin E and selenium to newborn foals in endemic areas.

FOAL ANTIMICROBIAL THERAPY

The presence of documented focal or systemic bacterial infection, such as septic arthritis, pneumonia, enterocolitis, meningitis, or umbilical remnant infections, represents a clear indication for the use of antimicrobial therapy in the foal. Unfortunately the clinical situation is not always so straightforward. Because of the risk of septicemia in any compromised neonatal foal, it is often better to make the assumption that bacterial infection is present rather than risk allowing the patient to deteriorate further while awaiting confirmation of the diagnosis.[194] In those situations in which bacterial infection is likely or suspected, aggressive therapy that includes antimicrobials is indicated. Although there are some risks associated with antimicrobial therapy, primarily AAD, these risks are greatly outweighed by the risks associated with withholding antimicrobial therapy from a patient with sepsis secondary to bacterial infection. Early appropriate empiric antimicrobial therapy has been shown to reduce mortality in human patients suffering from septic shock,[832] and although published evidence is lacking, clinical experience in neonatal foals supports this conclusion as well.[833]

When implementing antimicrobial therapy one must consider some basic pharmacologic concepts. The first concept is whether the antimicrobial selected is appropriate for the likely target of the therapy. To understand this, one must have a concept of the drug's mechanism of action and how that relates to the different classes of bacteria and their inherent susceptibilities. Second, how is the drug to be delivered, and is that route of delivery likely to achieve therapeutic concentrations of the drug at the affected site? There are key factors that profoundly affect our ability to effectively deliver antimicrobials to some sites of infection, and failure to take these into account will preclude effective treatment. The physical and pharmacologic characteristics of the different antimicrobials and their interactions with various tissues will also have a significant influence on the efficiency and efficacy of the treatment of bacterial infections. Consideration should also be given to the route of administration and frequency of dosing, particularly if treatment is to be administered by lay personnel or owners.

Achieving therapeutic concentrations at the site of infection can be challenging, especially when the drug has to cross an epithelial barrier (CNS, eye, lung, biliary, etc.). Drugs that are highly lipid soluble tend to distribute more fully to the tissues, whereas water-soluble drugs tend to distribute primarily within the extracellular water and penetrate epithelia poorly. The presence of inflammation will allow for increased tissue permeability of epithelial barriers; however, the resolution of inflammation allows for epithelial restitution. This may limit the ability of water-soluble drugs to maintain therapeutic respiratory concentrations as healing progresses, and recurrent infections may result.

The pharmacodynamic characteristics of the different antimicrobials also impact decisions regarding the route and frequency of administration. The two fundamental classes of drugs are the time-dependent and the concentration-dependent antimicrobials. Efficacy of time-dependent antimicrobials, such as the β-lactams, require that the concentration at the site of infection be maintained above the minimum inhibitory concentration (MIC) for as much of the treatment interval as possible. Time-dependent drugs benefit from intramuscular and oral administration because slower absorption yields lower serum concentrations, but therapeutic concentrations are typically maintained for longer periods of time. The use of CRIs for delivery of time-dependent drugs can yield optimal pharmacokinetics and is feasible in the hospital environment using electronic infusion pumps. The efficacy of concentration-dependent drugs requires high peak serum concentrations for maximal efficacy (greater than 10 times MIC for the aminoglycosides) but does not require high concentrations throughout the treatment interval. These compounds benefit from IV or topical administration to achieve high peak concentrations, with prolonged treatment intervals.

It is also important to remember that foals differ from adult horses in a number of ways that may impact the choice of antimicrobial therapy. First, foals have substantially greater total body water content than adult horses, typically requiring that the dosage of water-soluble drugs be increased. For example, doses of aminoglycosides are often increased as much as 100% in foals, compared with dosing in adults, to compensate for this increase in the volume of distribution. Also, neonatal foals do not have complete maturation of their hepatic and renal systems, especially during the first week of life, which may result in impaired elimination of certain drugs metabolized or eliminated by those routes. Different types of toxicities associated with antimicrobial use in foals must also be considered—for example, the risk of arthropathy associated with the administration of fluoroquinolones (because their rapidly growing cartilage tissue).

There are some advantages in designing foal antimicrobial therapy. Most orally administered antimicrobials are more effectively absorbed in foals compared with adults, which allows for wider use of this route. In addition, foals appear to be at reduced risk of AAD, which is likely because they have not yet fully transitioned to hindgut fermentation. Last, some antimicrobials used in in foals are cost-prohibitive in adult horses because of the total dose required; hence, the cost for foals is much less.

Therapeutic Targets

The most common isolates encountered will vary somewhat based on the specific site of infection and the predisposing factors associated with the infection. However, when looking at

retrospective studies of isolates from bacteremic neonatal foals some patterns become apparent. Over the past 30 years the most common bacteria isolated from blood cultures of infected foals have been gram-negative organisms.[25,123,171] Gram-positive organisms isolated from infected foals represented less than 20% of isolates and were typically present in mixed infections with gram-negative organisms.[25,123] Although some of the variance in the patterns of bacteria isolated from foals may result from regional differences, it does appear that more recently an increase in the percentage of gram-positive isolates has occurred.[177] Several studies have reported increased numbers of gram-positive isolates ranging from 30% to 43% of the total isolates.[180,181] This temporal change in patterns of isolates highlights the need to consider the likely pathogens present in the formulation of the initial empiric antimicrobial plan. Based on the most recent reports, *E. coli* remains the most common isolate followed by *Enterococcus* spp., *Actinobacillus* spp., β-hemolytic *Streptococci, Staphylococcus* spp., and *Enterobacter* spp.[180,834] Unfortunately there have also been temporal changes in the patterns of antimicrobial susceptibility observed in the bacteria isolated from bacteremic foals. Although there may be some debate as to the driving force behind these changing patterns of antimicrobial sensitivity, there is no doubt that the phenomenon is real. Some earlier reports mentioned the presence of a few isolates that were resistant to multiple antimicrobials,[120,177] but recent reports have demonstrated substantial numbers of multidrug-resistant (MDR) organisms (up to 38% of isolates).[180,182] Definitions vary somewhat among references, but generally speaking, MDR organisms display resistance to three or more of the core antimicrobials in a sensitivity panel. Recent studies in human medicine have characterized the most common and problematic of the MDR organisms as the ESKAPE group, which includes *Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumanii, Pseudomonas aeruginosa,* and *Enterobacter* spp.[835] This group of pathogens is responsible for the majority of nosocomial infections in human hospitals, and all routinely "escape" most currently used antimicrobial drugs.[836] The increasing prevalence of MDR organisms will require that antimicrobials are used judiciously and appropriately to limit the further spread of these organisms. The risk associated with these organisms also reinforces the need to perform appropriate culture sampling (blood, synovial fluid, CSF, body cavity effusions, etc.) to be sure of the pathogens involved and tailor antimicrobial therapy appropriately.

Antimicrobials

β-Lactams

β-Lactam antibiotics bind to penicillin binding proteins, interfering with bacterial cell wall synthesis. This leads to the formation of defective cell walls that are osmotically unstable, and cell death usually results from cell lysis. These drugs include the penicillins, synthetic penicillins, cephalosporins, and carbapenems. Modifications of the basic penicillin or cephalosporin molecule confer differences in antimicrobial activity, as seen with the synthetic penicillins and third-generation cephalosporins, which exhibit an increased gram-negative spectrum. Increased stability against β-lactamases may also be achieved, such as seen in the carbapenems. β-Lactam drugs are time-dependent antimicrobials and must be present in the tissues at concentrations greater than the MIC throughout most, preferably all, of the dosage interval to be effective.

Penicillin G is the most commonly used β-lactam antimicrobial in equine medicine, and it exhibits good efficacy against many gram-positive organisms and anaerobes, but it has a limited gram-negative spectrum. Penicillin G exhibits good synergy with aminoglycoside antimicrobials, making it a useful drug in a combination therapy approach. Procaine penicillin is administered intramuscularly, whereas the aqueous solutions of sodium or potassium penicillin are administered intravenously (Table 20.14). Procaine penicillin G is readily available and inexpensive, but the requirement for repeated intramuscular injections makes it less desirable for use in neonatal foals because of their minimal muscle mass. Potassium or sodium penicillins are substantially more expensive than procaine penicillin on a daily cost basis but are commonly used in hospitalized foals with ready venous access. There are reports of administering potassium or sodium penicillin as an IV CRI, which can provide favorable pharmacokinetics with these time-dependent compounds.[833] Toxicity is low for the penicillins and is primarily associated with adverse reactions to the inadvertent IV or intraarterial injection of the intramuscular preparation, procaine penicillin G, which likely represents adverse reactions to procaine rather than penicillin, although anaphylactic reactions have been reported.[837]

Ampicillin and amoxicillin are synthetic penicillins that exhibit better activity against gram-negative bacteria because of improved outer cell wall penetration. They do suffer some loss of efficacy compared with penicillin G regarding susceptible gram-positive bacteria. Ampicillin is widely used as an alternative to penicillin in the treatment of neonatal sepsis, typically in combination with amikacin.[177,194,834,838] Other β-lactam drugs that are occasionally used in foals include the antipseudomonal penicillins and the carbapenems. These drugs exhibit a superior gram-negative spectrum of action and are primarily used in cases where aminoglycosides cannot be administered or in the treatment of pathogens resistant to aminoglycosides. The use of these drugs should be restricted to cases with documented infections involving susceptible MDR organisms. The most commonly used antipseudomonal penicillin is ticarcillin, which is typically combined with clavulanic acid.[839,840] Clavulanic acid causes irreversible time-dependent inactivation of many of the β-lactamases, enhancing the activity of ticarcillin against organisms producing these enzymes. Imipenem, a carbapenem antimicrobial, has been used in foals for the treatment of MDR infections. Imipenem is used in combination with cilastatin, which slows renal elimination of imipenem and allows for a decreased frequency of dosing.[841]

Cephalosporins

Cephalosporins are traditionally grouped into "generations" according to their order of discovery and their spectrum of action. First-generation drugs exhibit a primarily gram-positive spectrum, whereas subsequent generations have an increasing gram-negative spectrum and corresponding decreases in the gram-positive spectrum. Fourth-generation drugs are considered to be truly broad spectrum. The primary cephalosporin administered to horses is ceftiofur, which is a third-generation drug.[842] It exhibits a fairly broad spectrum with an emphasis toward gram-negative coverage. Because of this spectrum of activity ceftiofur has often been used as the sole therapy in the initial treatment of foals. The relative safety of ceftiofur in foals has fostered this approach, because it allows the clinician to avoid using combined therapy including aminoglycosides. Unfortunately some recent studies have documented frequent

TABLE **20.14 Antimicrobial Dosages for Use in Foals**

Drug	Dosage	Route	Frequency (hours)
Acyclovir	16–20 mg/kg	PO	8
Amikacin	25–30 mg/kg (neonates) 20–25 mg/kg (2–4 weeks) 7–14.5 mg/kg (weanlings)	IV	24
Amikacin	8 mg/kg	Aerosol	24
Ampicillin sodium	10–20 mg/kg	IV, IM	8
Amoxicillin trihydrate	10–20 mg/kg 20–30 mg/kg	IM PO	8 6–8
Azithromycin	10 mg/kg	PO	24 h for 5 days, then every 48 h
Cefazolin	25 mg/kg	IM	6–8
Cefepime	11 mg/kg	IV, IM	8
Cefpodoxime proxetil	10 mg/kg	PO	6–12
Ceftiofur sodium	5 mg/kg	IV	12
	2.2 mg/kg	IM	12–24
	1.5 mg/kg/h	IV	CRI
	2.2 mg/kg	Aerosol	24
Ceftiofur crystalline-free acid	6.6 mg/kg	IM	96 (two doses)
Cefotaxime	50–100 mg/kg	IV	6
Cephalexin	30 mg/kg	PO	8
Ceftriaxone	25 mg/kg	IV	12
Chloramphenicol	50 mg/kg	PO	6
Clarithromycin	7.5 mg/kg	PO	12
Doxycycline	10 mg/kg	PO	12
Erythromycin	25 mg/kg	PO	6–8
Fluconazole	8 mg/kg (loading) 4 mg/kg (maintenance)	PO PO	Once 12
Gentamicin	11–13 mg/kg (neonates) 6.6 mg/kg (weanlings)	IV, IM	24
Gentamicin	2.2 mg/kg as a 50-mg/mL solution	Aerosol	24
Imipenem/cilastatin	5–10 mg/kg 10–20 mg/kg	IM IV	12 6
Metronidazole	10 mg/kg (neonates) 15 mg/kg (10–12 day old) 15 mg/kg (over 2 weeks)	PO PO PO	12 12 8
Minocycline	4 mg/kg	PO	12
Penicillin G	20,000 IU	IM (procaine penicillin) IV (K or Na penicillin)	12 (IM) 6 (IV)
Rifampin	5–10 mg/kg	PO	12–24

resistance to ceftiofur in organisms isolated from foals, and there does appear to be a trend toward increasing resistance over time, especially among gram-negative enteric bacteria.[180,834] The use of ceftiofur sodium as a CRI has also been investigated and appears to yield suitable pharmacokinetics.[843] Ceftiofur is also available in a sustained-release form, which contains CCFA. Subcutaneous administration of CCFA yields appropriate pharmacokinetics for highly susceptible bacteria in foals.[844] Self-limiting diarrhea was reported in 66% of the foals treated with CCFA, but this does not appear to be a clinical problem associated with this drug. Repeated subcutaneous dosing of CCFA (13.2 mg/kg) at 48-hour intervals for four doses has been reported to maintain appropriate therapeutic concentrations in foals.[845] Other cephalosporins may have utility in foals, such as cefquinome, ceftriaxone, cefpodoxime proxetil, cefotaxime, ceftazidime, and cefepime. Cefquinome

is a fourth-generation cephalosporin that is labeled in Europe for the treatment of foal septicemia caused by *E. coli,* but it is not available in the United States at this time.[846] Cefquinome is dosed at 1 mg/kg IV or intramuscularly every 12 hours, for very susceptible pathogens, but a higher dose of 4.5 mg/kg IV every 12 hours is indicated when dealing with pathogens with higher MIC values.[847] Cefpodoxime proxetil is a third-generation drug that is administered orally, but unfortunately the expense of this drug renders it of limited utility in most cases.[833] Cefepime is a fourth-generation drug that can be useful in the management of MDR infections.[848]

Aminoglycosides

The aminoglycosides continue to constitute a major component of the equine clinician's armamentarium, despite their well-described potential for nephrotoxicity. The primary reasons for this are that the aminoglycosides are bactericidal, exhibit primarily a gram-negative spectrum, and demonstrate good synergy with β-lactam antimicrobials.[634] The bacterial penetration of aminoglycosides is in part an oxygen-dependent transport process and partially accomplished by passive diffusion. This dependence on oxygen-driven transport renders anaerobes resistant to the aminoglycosides. The role of passive diffusion leads to a dependence on high tissue concentrations of the drug to achieve high intracellular concentrations. Routes of administration and/or dosage schedules associated with high peak concentrations at the site of infection, such as extended-interval dosing, are associated with improved clinical responses.[849] Prolonged treatment intervals decrease the risk of nephrotoxicity while still demonstrating clinical efficacy caused by the prolongation of bacterial killing, even after the aminoglycoside concentration drops below the MIC for the targeted organism. This phenomenon is termed the *postantibiotic effect.* The use of extended interval dosing also has been demonstrated to lessen the development of both acquired and adaptive antimicrobial resistance, which are caused by the high peak concentrations achieved and the period of time during which the drug is below the MIC.[634]

Neonatal foals have reduced rates of drug clearance, which necessitates prolonged treatment intervals, but their clearance increases to adult levels within the first few weeks of life.[634] They also have greater volumes of distribution, compared with adults, which necessitates substantially higher dosages to achieve the desired peak serum concentrations. A recent study examining the pharmacokinetics of gentamicin in foals indicated that gentamicin should be dosed at 12 mg/kg IV every 36 hours in foals less than 2 weeks of age, whereas a lower dose of 6.6 mg/kg IV every 24 hours was estimated to be adequate in foals 2 weeks of age or older.[850] Because of the unpredictability of aminoglycoside pharmacokinetics in sick foals, it is recommended that therapeutic drug monitoring be performed to ensure that both an adequate peak serum concentration is achieved as well as appropriate trough concentrations. Peak serum concentrations are typically monitored at 30 minutes after administration of the IV dose, and trough concentrations are monitored immediately before the subsequent dose. This approach is effective but may lack sensitivity in detecting impaired clearance of the drug. In addition, because of the timing of the sample collection the results of the assay will not be available until after the administration of the next dose, which may delay adjustment of the dosage or interval, if indicated. An alternative approach is to obtain serum samples at 30 minutes and 8 hours after drug administration, which can allow for estimation of drug clearance in a more timely manner, allowing for more rapid adjustment of the therapeutic protocol.[634]

Potentiated Sulfonamides

Potentiated sulfa compounds are very common in equine medicine because of their broad spectrum, oral route of administration, and affordability. These drugs exhibit time-dependent pharmacodynamics, and their effects are considered to be bactericidal. The potentiated sulfas distribute well to the tissues. Toxicity is most commonly associated with disturbance of gastrointestinal flora associated with the development of colitis. Although these drugs are not appropriate for initial therapy of septic foals, when organisms are documented to be susceptible they can be used quite effectively.

Tetracyclines

Tetracyclines are bacteriostatic and broad spectrum, possessing activity against a wide variety of bacteria and protozoa as well as *Mycoplasma* and *Rickettsia.* These compounds are time dependent in nature. The most commonly used compounds are oxytetracycline and minocycline. Toxicity has been reported from the disturbance of gastrointestinal flora in adults, but this appears to be rare in foals. Because the tetracyclines are primarily eliminated via the urinary tract, there is the risk for toxicity in animals with renal insufficiency. Very large dosages of oxytetracycline are administered to foals suffering from tendon contracture, and repeated or injudicious administration has been associated with nephrotoxicity.[629] Rapid IV injection of oxytetracycline has been associated with collapse in horses, perhaps caused by chelation of calcium in the blood. For this reason oxytetracycline is administered at 6 to 8 mg/kg slowly IV twice daily, usually diluted in 0.5 to 1 L of normal saline and administered over 30 minutes. Doxycycline is no longer widely used because of decreased availability and increased expense. Minocycline has come into widespread use in horses because of superior pharmacokinetics compared with doxycycline and a much more reasonable cost of treatment. Although no pharmacokinetic studies have been performed in foals, minocycline is empirically administered at adult dosages.[851]

Macrolides

Macrolides (erythromycin, azithromycin, and clarithromycin) are considered to be bacteriostatic; have a broad spectrum of action; and accumulate in tissues, particularly the lungs.[852] Their primary application is for the treatment of rhodococcal pneumonia in foals. Macrolides are eliminated by hepatic metabolism and can affect the pharmacokinetics of other drugs metabolized by the P450 system. Erythromycin administration in foals with rhodococcal pneumonia has been associated with frequent hyperthermia and diarrhea, and this drug is no longer used for this purpose in most areas of the United States. Azithromycin and clarithromycin are the most commonly used macrolides in foals at this time. Rifampin therapy is typically administered in conjunction with the macrolides in the treatment of rhodococcal pneumonia because of its potential synergistic effects. The combination of clarithromycin-rifampin has been shown to be more effective than erythromycin-rifampin or azithromycin-rifampin in the treatment of rhodococcal pneumonia.[441] Despite decades of clinical experience supporting the efficacy of the combination of macrolides and rifampin, there is recent evidence that coadministration of rifampin with macrolides substantially inhibits

macrolide absorption.[444,445] Current recommendations support the continued use of macrolide-rifampin combinations in the treatment of rhodococcal pneumonia in foals.[349] There has been recent interest in the use of the macrolide gamithromycin in foals because this drug exhibits favorable pharmacokinetics in foals following once-weekly intramuscular injections. It also has been shown to be noninferior to the combination of azithromycin and rifampin in the treatment of rhodococcal pneumonia in foals.[435,443]

Rifamycins

Rifampin is a macrocyclic antibiotic and is used primarily in foals as an adjunct therapy to the macrolides for treatment of rhodococcal pneumonia. It can be combined with other antibiotics for treatment of abscesses, but it should never be used alone because of the risk of rapidly developing antimicrobial resistance. In addition to using rifampin in the treatment of rhodococcal infections, it has been reported to be effective for the treatment of staphylococcal infections.

Chloramphenicol

Chloramphenicol is widely distributed to the tissues and has a wide spectrum of action including both gram-positive and gram-negative bacteria, as well as *Rickettsia, Mycoplasma,* and anaerobes. The half-life of chloramphenicol is short, and it is a time-dependent drug, requiring frequent dosing (6-hour intervals).[853] Human health concerns regarding possible chloramphenicol-associated nondose-dependent fatal aplastic anemia made it illegal to use this drug in food animals over the past 50 to 60 years. As a result of the minimal use of the drug there are low levels of resistance to chloramphenicol in many types of bacteria, which has created a potentially important role for chloramphenicol in the treatment of MDR organisms. Intriguingly, the usage of chloramphenicol has been proposed for human patients infected with MDR organisms, despite the risk of aplastic anemia.[854] Regardless, the potential risk of aplastic anemia to humans handling chloramphenicol necessitates thorough client education when dispensing this drug (avoid contact with aerosolized drug or direct contact with mucous membranes). Animal toxicity appears to be rare and is associated with reversible or irreversible bone marrow suppression. Florfenicol is closely related to chloramphenicol but has not been associated with aplastic anemia in humans and is labeled for use in food animals. Administration of florfenicol to adult horses has been associated with acute colitis and is contraindicated, but this has not been reported in foals. There are anecdotal reports of successful clinical use of florfenicol in foals at 24- to 48-hour dosing intervals; however, a recent pharmacokinetic study suggested that a shorter treatment interval of 10 hours may be appropriate.[833,855]

Fluoroquinolones

Fluoroquinolones have a relatively broad spectrum, with excellent activity against gram-negative organisms but minimal activity against streptococci. They are bactericidal and exhibit excellent tissue penetration. The fluoroquinolones exhibit peak concentration-dependent bactericidal effects and prolonged postantibiotic effects, which is similar to the aminoglycosides. As a result they can be given at relatively high doses at a decreased frequency. Enrofloxacin is the most widely used fluoroquinolone in horses, but its use is contraindicated in foals because of adverse effects on cartilage maturation.[856] Marbofloxacin has been used in foals and appears to be safe, although no controlled studies have been performed to confirm this clinical impression.[833,857]

Metronidazole

Metronidazole is a nitroimidazole antimicrobial that is highly effective against anaerobic organisms. Because of the limited anaerobic spectrum of most other antimicrobials used in foals, metronidazole is commonly used when anaerobic involvement is suspected or confirmed in foals. A recent pharmacokinetic study found that there were age-dependent influences on metronidazole kinetics in foals and suggested a range of dosages over the course of the first 2 weeks of life.[551]

Aerosol Administration

Aerosol administration of antimicrobials has been demonstrated to achieve high concentrations of antimicrobials at the respiratory mucosal surface while minimizing the development of systemic side effects. Other potential advantages to delivering medications to the lower respiratory tract by aerosolization include a decrease in the total dose administered, avoidance of systemic side effects, and a rapid onset of action.[463] The administration of antimicrobials by aerosolization does have limitations, however, including potential problems with drug delivery and pulmonary irritation, as well as the expense of the required equipment and the time required for administration. Several antimicrobials have been investigated for aerosol administration in horses, including gentamicin, ceftiofur, cefquinome, and marbofloxacin. Both gentamicin and ceftiofur are well tolerated and can be administered as aerosols.[459,466]

FLUID THERAPY IN THE FOAL

One of the fundamental dilemmas facing a clinician when evaluating a sick foal is whether or not fluid therapy is indicated. To determine the answer to that question one must consider the variety of indications for fluid therapy. The most common indication is for the correction of volume depletion or dehydration. Other indications for fluid therapy can be the correction of specific electrolyte imbalances, the provision of colloidal support, correction of acid-base disorders, restoration of oxygen-carrying capacity, and provision of immunoglobulins. In many cases more than one of these indications is present, and one must be careful in assessing the patient because changes in clinical status over time may result in one or more new indications for fluid therapy arising, even as others may have been resolved.

The next question regarding fluid therapy is what type of fluid does this patient need. The choice of fluid composition will depend on multiple variables, which include the primary goal of fluid therapy as well as patient-specific, route-specific, and practical considerations. The clinician must then determine the most appropriate route for administration of fluid therapy in the individual patient, and this may also factor into the decision-making process regarding the types of fluids to be administered. The amount of fluid therapy to be administered must also be determined, primarily based on the patient's fluid deficit and need for maintenance and replacement of ongoing losses. The anticipated duration of therapy can be more difficult to assess in the formulation of a treatment plan, but this represents an important factor in deciding how fluids will be administered and the potential costs to the client for fluid therapy. Finally, the clinician must develop a plan for monitoring ongoing fluid therapy and for determining when fluid therapy is no longer required.

Patient Requirement for Fluid Therapy

The first challenge in patient evaluation is the accurate assessment of hydration status. The typical parameters used in assessing clinical hydration during a physical examination are mucous membrane color, capillary refill time, jugular refill time, pulse quality, the temperature of the extremities, mental status, and urine production. Fundamentally these represent indicators of perfusion, rather than hydration, which is an important distinction given that there are situations, such as cardiogenic or vasodilatory shock, in which a well-hydrated patient can present with extremely poor perfusion. The term *dehydration* actually refers to situations in which there is a total body deficit of pure water. The clinical signs most commonly used for the assessment of dehydration are increased skin turgor, tacky mucous membranes, and sunken eyes. Unfortunately skin turgor is difficult to assess in foals, and a recent study in adult horses indicated that it was also not a reliable estimator of clinical hydration status in that population.[858] Further insight into hydration status can be gained by the measurement of urine specific gravity, which in the properly hydrated foal should be in the range of 1.010 to 1.001. Values greater than 1.010 indicate that the foal is retaining water and is likely not adequately hydrated. Urine output is another useful parameter, but it can be hard to gauge in foals that are not continuously monitored. The normal foal should urinate at least once every 2 hours. More accurate assessment of urine output is only possible in foals that have a urinary catheter in place, allowing for urine collection and measurement. Urine output should be greater than approximately two thirds of the total fluid intake including all IV infusions and any enteral fluids or feeding. Hypotension, considered a mean arterial pressure (MAP) less than 60 mm Hg, may be an indication of hypovolemia but can also result from decreased cardiac output or excessive venous capacitance. If the hypotensive patient does not respond to volume replacement then additional therapy in the form of vasopressors and/or inotropes is indicated (see the later section Inotrope and Vasopressor Therapy).

When attempting to determine whether hypovolemia and/or dehydration are present it is helpful to consider how fluid is distributed within the body. Neonatal foals have substantially higher total body water (TBW) content than adult horses, at 75% and 67%, respectively.[859] TBW is present in two primary compartments, the intracellular fluid (ICF) and ECF, with the ECF subdivided into the interstitial fluid and the plasma volume. In neonatal foals the ECF and ICF each represent approximately half of the TBW, and the plasma volume represents approximately one fourth of the ECF.[859] TBW is primarily determined by the total body sodium content, which is closely related to the sodium concentration within the ECF compartment and regulated by the ingestion or elimination of sodium.[860] Decreases in the plasma sodium concentration (hyponatremia) are indicative of a relative excess of free water and/or decreases in total body sodium content. The kidneys will respond by eliminating water while retaining sodium, restoring normal sodium concentration and TBW content. Increases in the plasma sodium concentration represent a loss of free water and will stimulate thirst, leading to water ingestion and correction of the TBW deficit.

Types of Fluids

Having determined that the patient needs fluids, the next challenge is determining the types of fluids that should be administered. There are many choices of fluids, and they fall into three broad categories: crystalloids, colloids, and oxygen-carrying solutions. Crystalloid solutions contain electrolytes and nonelectrolytes (such as dextrose) that are capable of diffusing through the capillary wall into the interstitium, whereas colloid solutions contain larger molecules that do not readily diffuse and tend to remain within the vascular lumen. Oxygen-carrying solutions contain either red blood cells or other substances capable of delivering oxygen from the lungs to the tissues. In the majority of situations the most appropriate fluid will be a crystalloid solution. These solutions are classified based on their tonicity relative to normal plasma and are isotonic, hypertonic, or hypotonic.

Isotonic electrolyte-containing fluids will have little influence on the ICF volume but will expand the ECF volume, expanding the circulating blood volume. Because these fluids contain large amounts of sodium, a substantial amount of the fluid will be retained in the body unless the kidneys excrete the sodium and water together. Sodium overload can result in hypernatremia, which has been associated with increased mortality and severity of illness in human patients.[861] In addition to the substantial sodium content of the isotonic electrolyte solutions, there is typically a substantial chloride content as well. This is most pronounced with isotonic saline (0.9%), which contains 154 mEq/L of both sodium and chloride (Table 20.15). Although the sodium content is only slightly supraphysiologic, the chloride content is dramatically greater than that present normally in the plasma. In some patients renal elimination of chloride is impaired and is not adequate to deal with this high chloride load.[862] Excessive chloride administration is associated with the development of hyperchloremic metabolic acidosis, inflammation, hypotension, and adverse renal outcomes in human patients.[861] More physiologic fluids, such as lactated Ringer's solution (LRS), Plasma-Lyte A, and Normosol-R, contain lower concentrations of chloride more closely mimicking normal serum concentrations. Dextrose 5% in water is an exception to these rules, because it is an isotonic crystalloid fluid that does not contain any electrolytes and is primarily used to replace total body water deficits.

Hypertonic crystalloid fluids have higher electrolyte concentrations than plasma and have fewer indications for their use. The most commonly used hypertonic crystalloid is hypertonic saline, which is primarily used to expand the circulating blood volume. This effect results from the shift of fluid from the interstitial space into the circulation, but it is very transient because of the rapid diffusion of the sodium load from the circulation into the interstitium. The other commonly used hypertonic crystalloid is hypertonic sodium bicarbonate, which is typically administered to correct metabolic acidosis. By providing sodium without any accompanying chloride this solution directly addresses strong ion acidosis, such as hyponatremic metabolic acidosis. It is less useful in addressing other types of metabolic acidosis, such as lactic acidosis, and care must be taken when administering this solution to foals with depressed ventilation because it will increase carbon dioxide production and potentially worsen respiratory acidosis.

Hypotonic crystalloid solutions contain much less sodium and chloride than the isotonic replacement fluids. This can be very helpful, because the lower sodium load decreases the risk of water retention and edema formation, and the lower chloride load decreases the risk of hyperchloremic metabolic acidosis. For these reasons hypotonic crystalloid solutions are most useful for maintenance fluid therapy, in which there is less need for electrolyte replacement and more need for the

TABLE **20.15 Composition of Intravenous Fluid Solutions Commonly Administered to Foals**

	Fluid Types							
Components	Plasma	0.9% Saline	Lactated Ringer's Solution	Plasma-Lyte A/Normosol-R	Plasma-Lyte 56/ Normosol-M with 5% dextrose	5% Dextrose in Water	50% Dextrose in water	7.2% Saline
Na^+ (mEq/L)	140	154	131	140	40	—	—	1232
Cl^- (mEq/L)	104	154	111	98	40	—	—	1232

Osmolarity (mOsm/L)	285	309	278	295	363	253	2525	—

provision of water. The use of resuscitation fluids, such as LRS and Normosol-R/Plasma-Lyte A, for maintenance therapy in foals has been associated with the development of hypernatremia and hyperchloremia, which reinforces this concern.[863] Because patients on maintenance fluid therapy often have reduced dietary intake, there is an increased need for potassium supplementation, and maintenance fluids have accordingly higher concentrations of potassium. There are concerns that the administration of hypotonic fluids could cause red blood cell lysis, and for this reason maintenance fluids often have dextrose added to bring the tonicity of the solution into a more appropriate physiologic range. Following administration the dextrose is metabolized and has no impact on fluid shifts within the body. The use of 5% dextrose in water (D5W) represents an alternative to hypotonic crystalloid fluids for maintenance therapy in foals; this solution will not contribute any sodium load because there are no electrolytes. This is problematic because there is an ongoing need for electrolytes caused by renal, gastrointestinal, and insensible losses. For this reason D5W should not be used alone and is typically combined with isotonic polyionic crystalloid solutions to provide for replacement of any electrolyte deficits as well as ongoing losses.

Colloids are fluids containing relatively large molecules less readily able to diffuse across the capillary membrane. This allows them to exert colloid oncotic pressure within the circulation, resulting in fluid shifts from the interstitium into the vasculature and expanding circulating blood volume. Colloids will also aid in retaining fluids that have been administered within the vasculature for a longer period of time than would be possible with crystalloids alone. The most commonly used colloid solution is fresh frozen equine plasma, which contains albumin as the primary colloid. Albumin, while the most physiologic colloid, also has a relatively small size and will diffuse into the interstitial fluid space in which it will then exert a colloidal effect, potentially exacerbating the development of edema. Blood is another natural colloid. In addition to the colloidal effect of the albumin that it contains, blood has the benefit of providing red blood cells to improve oxygen-carrying capacity and tissue oxygen delivery. Another solution with oxygen-carrying capacity is ultrapurified polymerized bovine hemoglobin. This product has colloidal effects, but they are not the primary reason that this product would be used. Polymerized hemoglobin has been used with apparent clinical efficacy in foals and horses at doses of 2 to 5 mL/kg.[750,752] This product is not currently available in the United States, but it is available in Europe (Oxyglobin, Dechra Veterinary Products, Shrewsbury, UK).

Synthetic colloids, such as hetastarch and pentastarch, are shelf-stable and do not require collection or thawing before administration, making them very useful in the critically ill patient. The synthetic colloids are typically less expensive than frozen equine plasma and also may provide a more long-lasting colloidal effect than albumin. There are concerns that synthetic colloids, especially hetastarch, may interfere with coagulation, especially in patients with severe systemic inflammation that may already be suffering from subclinical coagulative dysfunction. New-generation hetastarch preparations have lower molecular weight and lower degrees of molar substitution and may have improved safety profiles.[864] Of even greater concern is the recent evidence from human medicine that resuscitation with hetastarch solutions may be associated with an increased risk of acute kidney injury and mortality.[865] Although there are no studies addressing these concerns, in veterinary patients it is recommended that hetastarch solutions should only be used in patients with a demonstrated need for colloid therapy, and potentially in combination with equine plasma, rather than as the primary resuscitation fluid or the sole colloid. Hetastarch solutions should not be administered in doses of more than 5 to 10 mL/kg, and cumulative dosing should be restricted to no more than 20 mL/kg.

Route of Administration

The next challenge is determining the route by which fluids will be administered to the patient. The most physiologic route is the enteral route, but it can be easy to overlook the utility of this route, especially in hospitalized patients. Generally, if the gut is working it should be used for at least whatever component of the fluid therapy is appropriate. Enteral administration will be limited in both the volume that can be delivered and the rate at which the fluid will be absorbed, rendering it of limited utility in the critically ill patient, but it may be very useful in

delivering maintenance fluid therapy. Enteral therapy may also be less expensive and more practical in the field setting when treating the less severely compromised patient. IV administration will achieve the most rapid results because it allows for the rapid administration of large amounts of fluids and is the most commonly used route of administration in critically ill patients. IV access is associated with some risks, primarily catheter-associated complications such as thrombophlebitis and air embolus aspiration. Neither subcutaneous nor intraperitoneal fluid administration is well tolerated in equine patients, and these routes of administration are rarely used.

Practical considerations related to the ability to administer fluid therapy may impact all of these decisions. IV access can be challenging to establish in the sick neonatal foal, especially in a field setting. Although over-the-stylet catheters are commonly used, they can be difficult to place in hypotensive foals and are susceptible to kinking or displacement caused by foal movement and frequent handling. These catheters are best used for short-term fluid administration in normotensive foals. The most commonly used over-the-stylet catheters are made of Teflon, which can be more irritating to the vein than other materials, but polyurethane over-the-stylet catheters also are available (MILA International, Inc., Erlanger, KY; Arrow, Teleflex Inc., Wayne, PA). Over-the-wire catheters, although slightly more complex regarding placement, are easier to use in hypotensive patients and are easier to maintain for longer periods of time. These catheters are typically made of polyurethane, which is less thrombogenic than Teflon. Silicone over-the-wire catheters are the least thrombogenic and are rarely used in foals. Over-the-wire catheters are also available in longer lengths (20 cm) than over-the-stylet catheters (13 cm), which is helpful in critically ill foals because they can be placed almost as deep as a central venous line, potentially decreasing the risk of vascular irritation associated with delivery of hypertonic solutions or irritating medications. Multiple-lumen over-the-wire catheters are available that can be helpful in critically ill patients because they allow for parenteral nutrition or medications to be delivered through a separate catheter lumen than the one used for IV fluid administration. The downside to these multilumen catheters is primarily their large outer diameter, which can make them more challenging to place and may increase the risk of catheter site or vascular complications.

Enteral administration of fluids can be achieved using a nasogastric tube, but this approach is primarily useful for administration of a few doses of fluids, after which the requirement to repeatedly pass the tube may represent a very stressful intervention. Leaving the nasogastric tube in place is also problematic because of local irritation within the pharynx and interference with voluntary drinking and eating. If repeated enteral administration is anticipated, then serious consideration should be given to the placement of an indwelling enteral feeding tube (14 Fr × 125 cm, MILA International, Inc., Erlanger, KY). The small outer diameter of these tubes allows for ongoing voluntary intake of feed or water. Having one of these tubes in place makes it very simple to administer multiple small boluses of enteral fluids or milk with minimal patient stress. Further discussion of enteral feeding can be found in the section Nutritional Support for the Foal later in this chapter.

Dosage

The clinician must also determine the volume of fluids to be administered and the duration of fluid therapy. The factors that must be considered in determining the amount of fluids to administer are the volume needed for maintenance of normal bodily function, the magnitude of the existing fluid deficit, and the ongoing losses potentially associated with the disease process (diarrhea, reflux) as well as any insensible losses (sweat). When designing the fluid therapy plan it is important to consider the maintenance fluid plan as separate from the replacement fluid plan, which includes both replacement of existing deficits and ongoing losses. The types of fluids used for these purposes are typically different, and inadvertent use of maintenance fluids for replacement, or vice versa, can be deleterious to the patient. The calculation of maintenance fluid requirements in the foal can be approached in two ways. The traditional approach is based on the accepted value of 3 to 5 mL/kg per hour (75–120 mL/kg/day) as the maintenance fluid requirement. The primary problem with this approach is that it represents a very broad range of fluid rates and may result in fluid overload if not closely monitored. A second approach to the determination of maintenance fluid requirements has been proposed, based on the Holliday–Segar formula, which provides a "drier," more conservative rate of fluid administration. The calculation is as follows: for the first 10 kg of body weight, 100 mL/kg per day of fluids are administered, then 50 mL/kg per day for each kilogram from 11 to 20 kg body weight, and then 25 mL/kg per day for each kilogram of body weight >20 kg.[190,866] In a 50-kg foal this calculation yields a maintenance rate of 2250 mL/day, or 94 mL/h, which equates to 1.9 mL/kg per hour.[866] When formulating the fluid plan do not forget to incorporate other fluid sources that may be administered to the foal, which includes any enteral feedings, as well as fluids given as drug infusions or parenteral nutrition. It is easy to overlook these additional sources, yet they may constitute a significant proportion of the daily fluid intake.

The other consideration in the design of the maintenance fluid regimen is the ongoing need for electrolytes, particularly sodium and potassium. If isotonic replacement solutions are administered for maintenance purposes, then hypernatremia and hyperchloremia are likely complications.[863] Those solutions also contain inadequate amounts of potassium for maintenance. The use of hypotonic crystalloid maintenance solutions is, therefore, more appropriate. The recommended daily rate of sodium supplementation in foals is less than 3 mEq/kg, unless they have increased renal sodium losses.[866] Administration of a maintenance solution such as Plasma-Lyte 56 at 1.9 mL/kg per hour will provide approximately 2 mEq/kg per day of sodium. It is important to remember that the foal will likely be receiving other sources of sodium in the form of drug infusions and catheter flushes and in solutions such as parenteral nutrition, plasma, or synthetic colloids. Regarding potassium, the daily maintenance requirements are quite substantial in foals that are not nursing because milk contains high levels of potassium. Supplementation of potassium at 1 to 3 mEq/kg per day is a reasonable starting point. Hypotonic maintenance solutions, such as Plasma-Lyte 56, contain substantially more potassium than replacement solutions (13 mEq/L vs. 5 mEq/L, respectively), but this is still insufficient for the neonatal foal, and supplementation will be required. The addition of potassium chloride at 20 to 40 mEq/L to a hypotonic maintenance solution is a reasonable starting point for supplementation. Care should be taken not to administer a fluid with that amount of potassium supplementation at a high rate, however, because administration of potassium at a rate greater than 0.5 mEq/kg per hour may result in cardiac complications caused by hyperkalemia.

TABLE **20.16** Clinical Assessment of Hydration Status

Degree of Dehydration	Skin Tenting	Capillary Refill Time	Mucous Membranes
<5%	1–3 sec	<2 sec	Slightly tacky
5–10%	3–5 sec	2–3 sec	Tacky
>10%	>5 sec	>3 sec	Dry

TABLE **20.17** Clinical and Physiologic Parameters Useful in the Assessment and Monitoring of Hydration Status

Parameters	Overhydrated	Ideal	Underhydrated
Heart rate	—	80–120	>140
Respiratory rate/effort	Upward trend	<56	—
Hematocrit	20	35–45	>45 (increasing)

BUN/creatinine	—	Normal	Increasing

BUN, Blood urea nitrogen.

Using the clinical perfusion indicators mentioned previously (mucous membrane color, capillary refill time, jugular refill time, heart rate, and pulse quality) one can derive a rough estimate of the degree of clinical dehydration (Table 20.16). This approach yields estimates of dehydration ranging from 5% to >10%, and these values can be used when calculating the estimated fluid deficit. For example, a 50-kg foal with a clinical estimate of 5% dehydration will require 2.5 L of fluids (50 kg × 0.05 = 2.5 kg of fluid) to replace their deficit. Clinicopathologic testing can aid in refining the estimate of the fluid deficit, with variables such as packed cell volume, total plasma protein concentration, urine specific gravity, BUN concentration, serum creatinine concentration, and serum lactate concentration all potentially providing useful insight (Table 20.17). The packed cell volume will be increased with hypovolemia but may show less marked elevations with dehydration. Total protein concentration will typically increase with hypovolemia and dehydration as well, but this marker may lack sensitivity in patients with hypoalbuminemia and/or hypoglobulinemia. Urine specific gravity is a fairly sensitive marker of dehydration and is very clinically useful. BUN and creatinine concentrations are indicators of hypovolemia and decreased perfusion rather than dehydration. Both BUN and creatinine are relatively insensitive markers of decreased perfusion, especially BUN, and only begin to increase with substantial decreases in GFR. Serum lactate concentration may be a more sensitive marker of perfusion but can also be elevated in response to impaired tissue oxygen utilization or decreased hepatic lactate clearance. Measurement of central venous pressure (CVP) can be very useful in assessing the foal's fluid status. This technique is somewhat technically challenging but is feasible with limited equipment. If the foal has been catheterized with an over-the-wire 20-cm catheter, then the placement of the catheter tip will be fairly central, and this catheter can be used for the determination of an approximate CVP. With the foal in lateral recumbency all ingoing fluid therapy is stopped while the measurement is taken. A water manometer or electronic pressure transducer can be used, and the zero position on the manometer should be set at approximately the height of the base of the heart. The manometer is primed with sterile heparinized saline and then opened to the IV catheter. Slight fluctuations of pressure should be observed with respirations, and the measurement taken is the approximate mean of this range.

Once a determination of the existing fluid deficit has been made, a deficit fluid replacement plan can be formulated. Use of an isotonic replacement fluid (LRS, Normosol-R, and Plasma-Lyte A) is appropriate for this purpose, as previously discussed; remember that deficit therapy is given in addition to the ongoing maintenance fluid support described earlier. Rather than simply dividing up the calculated fluid deficit and administering it over a set period of time (i.e., 2.5 L over 12 hours), it is more useful to administer boluses of replacement fluids at 20 mL/kg (e.g., 1 L to a 50-kg foal) over 10 to 30 minutes and then reassess the patient's status and determine whether further boluses are required. Some foals may require more than replacement of their calculated deficit, but care should be taken not to exceed a 60-mL/kg total dose unless there are compelling clinical reasons that this is indicated, such as ongoing losses. Excessive administration of bolus fluid therapy has been associated with worsened outcomes in human patients.[867,868] If greater than 60 to 80 mL/kg of fluid replacement is required and the patient remains hypotensive, then they should be considered nonresponsive to fluid therapy, and the initiation of inotrope and/or vasopressor therapy should be seriously considered (see the next section Inotrope and Vasopressor Therapy). Reassessment of the patient's hydration status and response to fluid therapy involves the use of all the parameters discussed earlier, with serial measurements being critical to this process.

Replacement therapy is intended to address the patient's ongoing fluid losses, and determination of the magnitude of these losses is more art than science because they are difficult to measure. In many clinical situations the foal does not have a urinary catheter in place, so assessment of renal losses is entirely empiric based on frequency of urination and perceived volume. The assessment of gastrointestinal losses is similar in nature, whereas the losses caused by sweating are extremely difficult to estimate. The fluids used for replacement of losses should be isotonic balanced replacement solutions, because the fluids lost by these routes will be accompanied by electrolyte losses as well. If foals appear to be urinating and defecating normally and are not obviously sweating, then additional replacement fluids are not indicated. In those foals with increased losses associated with these systems one can add intermittent boluses of 10 to 20 mL/kg of replacement-type fluids to address the estimated loss. Monitoring of ongoing fluid therapy is very important and requires frequent assessment to

ensure that the goals for fluid therapy in the individual patient are being achieved and to avoid the development of adverse outcomes such as fluid overload. Repeated assessment of the clinical indicators of hydration status and perfusion is readily performed and extremely valuable in monitoring fluid therapy because normalization of these parameters is evidence of therapeutic efficacy.

INOTROPE AND VASOPRESSOR THERAPY

Hemodynamic factors, such as volume depletion, low cardiac output, or inappropriate vasodilation, lead to systemic hypotension, which may result in organ hypoperfusion through reductions in perfusion pressure with potentially deleterious consequences for the gastrointestinal and renal systems.[869] Tissue perfusion can be supported by the provision of IV fluids to address hypovolemia and improve venous return to the heart, providing adequate preload to support cardiac output, and fluid repletion is always the first intervention to be used in affected foals. Although many foals suffering from hypotension will respond well to IV fluid administration, a subset of these cases will be nonresponsive to fluids and will require additional blood pressure support. Treatment with inotropes and vasopressors may be indicated in these cases to increase cardiac contractility and afterload, respectively. Administration of these agents requires that the foal be in a hospital environment with close monitoring of hemodynamic function and the availability of electronic infusion pumps that can provide accurate CRIs. Blood pressure monitoring is absolutely essential, and this can be accomplished by direct (arterial catheter) or indirect (oscillometric tail cuff) means. In most situations the indirect approach will be used because the placement and maintenance of arterial catheters in foals can be extremely challenging. Although the data obtained from direct measurement are superior, the technical challenges render this approach impractical. Indirect techniques are not ideal because they can be affected by tail cuff size and placement and can be inaccurate, but they provide acceptable accuracy for clinical use, particularly in the monitoring of trends in MAP over time.[870,871]

It can be challenging to determine the point at which a patient requires additional blood pressure support. In human patients, exceeding the critical lower level for MAP, which is regarded as 60 to 65 mm Hg, is vital to maintain cerebral, coronary, and renal blood flow.[872] A major goal in the management of critically ill foals, therefore, is to maintain the MAP above 60 mm Hg, although this level does not necessarily indicate adequate tissue perfusion.[130,873,874] There is no apparent advantage to achieving higher MAP, and doing so may actually be deleterious because of altered distribution of blood flow resulting in decreased perfusion of some tissues.[718,872] It is critical to use other indicators of tissue perfusion, including heart rate, mentation, central venous oxygen tension, urine output, acid-base status, and trends in blood lactate concentration, because it has been suggested that neonatal foals may have a different physiologic response to hypotension than adult horses.[873] When implementing inotrope or vasopressor therapy it is advised to start at the lowest end of the dosage range (Table 20.18) and to monitor the response to therapy before increasing the dosage because it is impossible to predict the response of an individual patient. The short half-life of these agents means that the response to therapy can be assessed quickly, often in as little as 10 to 15 minutes, reinforcing the need for continual patient reevaluation.

TABLE **20.18 Dosages of Inotrope and Vasopressor Agents**

Agent	Dosage Range
Dopamine	3–20 μg/kg/min
Dobutamine	1–20 μg/kg/min
Norepinephrine	0.1–2 μg/kg/min
Vasopressin	0.1–2 mU/kg/min
Epinephrine	0.2–2 μg/kg/min

Dobutamine is a positive inotrope commonly used to treat hypotension in neonatal foals, and it often represents the first-line drug of choice[30,875] (Table 20.19). The β-adrenoceptor agonist increases myocardial contractility, and therefore cardiac output, via its action on β_1-receptors. Concurrent stimulation of β_2-receptors may also produce peripheral and splanchnic vasodilation. This vasodilatory effect may be unproductive because it can result in decreases in systemic vascular resistance and MAP, which means that dobutamine may not be the ideal choice as a single agent in the treatment of fluid-refractory hypotension.[876] For this reason dobutamine is normally used in combination with a vasopressor in human patients.[877] The positive benefit of the vasodilatory effect of dobutamine is that it may improve splanchnic perfusion when used concurrently with vasopressors.[876] By increasing myocardial contractility dobutamine also increases myocardial oxygen demand, which can be problematic in the patient with already impaired oxygen delivery. The other concern with dobutamine is that because of its stimulation of β_1-receptors it can cause tachycardia and arrhythmias, especially at higher doses.[877]

Dopamine was traditionally used as a first-line agent in human and veterinary medicine because it exhibits dose-dependent stimulation of a wide variety of receptors, with dopaminergic activity at low doses, β_1 and β_2 activity at moderate doses, and α_1 activity at high doses. Through the stimulation of dopaminergic receptors low-dose dopamine increases renal and splanchnic perfusion, although this has not

proven to be beneficial in preventing organ failure in human patients.[878] At higher doses dopamine increases cardiac contractility, vasoconstriction, and heart rate, all of which tend to increase MAP.[877] Unfortunately the vasopressor response to dopamine is less pronounced and less consistent than that achieved with norepinephrine.[879] When the inotropic effects of dopamine were compared with dobutamine in hypotensive human neonates, dopamine was less effective in restoring blood flow.[880] At high doses (greater than 20 μg/kg/min) dopamine can cause pulmonary venous vasoconstriction and reduced splanchnic perfusion.[30] For all of these reasons dopamine is now much less commonly used in human or equine critical care.

Norepinephrine is primarily an α-adrenergic receptor agonist, but it also has some limited β_1 and β_2 effects. Norepinephrine induces arterial and venous vasoconstriction, resulting in increases in MAP, effective circulating blood volume, and venous return and preload, with minimal increase of heart rate or stroke volume.[881] Despite historic concerns regarding potential splanchnic hypoperfusion, norepinephrine is now regarded as the first-line pressor agent in hypotensive human patients.[877] Current human guidelines recommended the administration of norepinephrine as a sole agent initially, with dobutamine added if hypoperfusion persists despite adequate MAP.[175] Norepinephrine has been reported to be effective in increasing MAP and urine output in hypotensive foals that were nonresponsive to both fluid administration and dobutamine therapy.[130] Another study compared the effects of norepinephrine alone and the combination of norepinephrine and dobutamine with a control treatment of saline infusion.[882] Both norepinephrine and norepinephrine-dobutamine increased arterial blood pressure and systemic vascular resistance and decreased heart rate and cardiac index compared with saline, but no effect was observed on renal function. Norepinephrine-dobutamine did result in higher arterial pressures than norepinephrine alone. This combination therapy approach is now commonly used for the treatment of foals with refractory hypotension.

In recent years in human medicine, AVP (antidiuretic hormone) has gained popularity in managing vasodilatory shock and cardiac arrest despite concerns regarding potential splanchnic hypoperfusion at higher dosages.[883] This concern regarding splanchnic hypoperfusion deserves consideration because this effect was observed at high doses of vasopressin in a study that examined the effects of dobutamine, norepinephrine, and vasopressin in healthy anesthetized foals with induced hypotension.[875] Although vasopressin has a myriad of effects involving numerous receptors and pathways, it controls blood pressure primarily by vasoconstriction via its actions on the vasopressin-1 receptor.[884] Vasopressin has stronger vasoconstrictive effects on large arterioles than norepinephrine, which may explain its effectiveness even in patients refractory to standard catecholamine therapy.[885] Vasopressin also has been shown to have a positive interaction with hydrocortisone therapy in the treatment of refractory shock in humans.[175] When used as a treatment for vasodilatory shock vasopressin has been shown to decrease heart rate, improve overall hemodynamics, and lead to a reduction in inotrope requirement.[886] A recent human meta-analysis determined that vasopressin therapy in human patients in septic shock was safe, useful in weaning patients off of catecholamines, and associated with decreased mortality.[887] The consensus in human medicine appears to be that vasopressin is a reasonable second-line choice as a vasopressor in patients not exhibiting a positive response to norepinephrine therapy.[877]

There are a few anecdotal reports of the use of vasopressin as a second-line vasopressor in equine critical care, with one reference, by Collins et al., indicating that vasopressin has begun to be used as the first-line therapy for foals with fluid-refractory hypotension.[30,718,888] At this time there is only one published report regarding vasopressin therapy in clinically ill foals.[889] In that report the effects of norepinephrine or vasopressin on cardiovascular responses and fluid balance were compared in a group of 34 foals with hypotension refractory to both fluid therapy and dobutamine. Eighteen foals were treated with vasopressin, whereas 16 foals received norepinephrine. Six of the foals in the vasopressin group had failed to respond to norepinephrine therapy, which was withdrawn before initiation of vasopressin therapy. The severity of illness was pronounced and similar between groups, with a mean lactate of 10.5 ± 4.4 mmol/L in the vasopressin group and 9.6 ± 4.6 mmol/L in the norepinephrine group. The two groups also had similar sepsis scores at admission, with a mean of 15.9 ± 6.1 in the vasopressin group and 16.1 ± 4.5 in the norepinephrine group. Vasopressin administration was associated with a significant increase in MAP and in urine output as well as a significant decrease in heart rate, whereas norepinephrine administration was associated with a significant increase in MAP. The overall survival rate in this study was only 38%, likely reflecting the severe systemic disease present in this population of foals evidenced by their admission sepsis scores and lactate concentrations, and was consistent with a previous report from the same institution, in which the survival rate for foals presenting with lactate concentrations greater than 6 mmol/L was reported to be only 40%.[126] The authors of this report also describe increased use of vasopressin as a first-line therapy for foals with refractory hypotension.[889]

Other pressor agents include epinephrine and phenylephrine, both of which are strong adrenergic receptor agonists and can have negative effects on splanchnic and renal perfusion.[890] Epinephrine is a catecholamine with potent activity at β-adrenergic and α-adrenergic receptors. Epinephrine increases MAP by increasing cardiac output and vascular tone, and in human patients it is regarded as the first alternative to the combination of norepinephrine and dobutamine.[877] However, epinephrine has been associated with hyperglycemia, hypokalemia, lipolysis, tachycardia, decreased splanchnic perfusion, increased lactate concentration, and increased platelet aggregation.[30,877] Phenylephrine has potent α_1 activity but has no cardiac effects, mediating its effects through the constriction of the peripheral arterial vasculature.[877] Phenylephrine is primarily of utility in patients with arrhythmias resulting from dobutamine and/or norepinephrine administration and has little application in equine neonatal critical care.

Although not a vasopressor per se, low-dose hydrocortisone therapy has been shown to improve the response to vasopressors and shorten the duration of vasopressor therapy in human shock patients.[891,892] The mechanisms responsible for this effect are unclear, but do not appear to be associated with primary corticosteroid insufficiency. Rather, it appears that corticosteroid therapy directly results in improved vasopressor responsiveness of peripheral vessels, because hydrocortisone raises blood volume, increases vascular tone, and enhances endothelial reactivity to vasopressors.[893] A thorough discussion of hydrocortisone replacement therapy can be found in the previous section Endocrine Disorders.

ANTIINFLAMMATORY AND ANALGESIC THERAPY

The indications for antiinflammatory therapy in the foal are numerous. Most often these compounds are used to regulate fever and local inflammation, reducing patient discomfort, but there are situations in which they are required for the control of systemic inflammation as well. The primary class of antiinflammatories used in foals is NSAIDs, which consists of drugs inhibiting arachidonic acid synthesis via COX inhibition. These drugs typically exhibit antipyretic, antiinflammatory, and analgesic effects.[894] There are also several drugs in the NSAID group that have effects on pathways other than arachidonic acid metabolism. The second class of antiinflammatory drugs is the corticosteroids (steroidal antiinflammatory drugs [SAIDs]). These drugs have potent dose-dependent antiinflammatory and immunosuppressive effects, but typically have little antipyretic or analgesic activity.[665] In situations where the primary goal is analgesia one can use NSAIDs, but opioid drugs provide analgesia without the concerns regarding gastrointestinal and renal toxicity associated with many NSAIDs. Although not commonly used in very young foals, alternative analgesics such as ketamine and lidocaine may be beneficial in managing older foals with severe, refractory pain.

The NSAIDs include nonspecific COX inhibitors such as phenylbutazone and flunixin meglumine, more selective COX-2 inhibitors such as ketoprofen, and COX-2–specific drugs like meloxicam and firocoxib. Nonspecific COX inhibition can be associated with side effects including gastrointestinal ulceration and renal injury.[895] Phenylbutazone has been associated experimentally and clinically with toxicity in foals[895,896] and appears to have a narrow therapeutic index in this population. In addition, it can be difficult to administer appropriate dosages of phenylbutazone to foals because of their small size and the composition of the forms of phenylbutazone that are available. For all of these reasons phenylbutazone is rarely used in foals. Flunixin meglumine, however, when given parenterally at appropriate dosages, has been demonstrated to be safe in foals, even when administered for several weeks,[897,898] and this is supported by clinical experience. Flunixin meglumine is primarily used in foals with severe systemic inflammation, severe discomfort, or persistent fevers. It is important to note that the metabolism and elimination of NSAIDs can be impaired in neonatal foals, potentially requiring increases in dosing or prolongation of the dosing interval.[899-901] For these reasons it is recommended that the nonspecific COX inhibitors be used with caution in the clinically ill neonatal foal, particularly in foals with severe systemic inflammation, hypovolemia, or the potential for gastric ulceration.

In theory, drugs like ketoprofen and carprofen should be safer for use in foals because they are more COX-2 selective than phenylbutazone and flunixin. Although there is no peer-reviewed evidence to support the claim of reduced toxicity, both of these drugs have been used in foals with apparent safety.[902,903] The pharmacokinetics of ketoprofen has been studied in foals, and the dosage and treatment intervals recommended in that report are both greater than those for adult horses[899] (Table 20.20). Ibuprofen has also been studied in foals and was found to be safe when administered for up to 6 days.[904] There are no published reports of the pharmacokinetics of carprofen in foals.

The mostly highly COX-2–specific NSAIDs that have been studied in horses and foals are meloxicam and firocoxib, with firocoxib demonstrating the greatest degree of COX-2 specificity. Firocoxib has favorable pharmacokinetics and is reported to be safe in foals when administered by the oral or IV routes.[905,906] Firocoxib has been demonstrated to be effective for musculoskeletal and visceral pain in horses,[907,908] but the analgesic efficacy of firocoxib has not been assessed in foals. Anecdotally it seems that firocoxib may be more effective for musculoskeletal pain than for visceral pain, but this has not been scientifically evaluated. Meloxicam is marketed for equine use in Europe but is currently only labeled for small-animal use in the United States. Meloxicam pharmacokinetics and safety have been evaluated in foals,[909] and no evidence of gastrointestinal or renal toxicity was detected. Interestingly, meloxicam was eliminated more rapidly in foals than in adult horses, which is quite different from what has been found with other NSAIDs. For that reason the authors of that study recommended that meloxicam be dosed every 12 hours in foals, rather than 24 hours.[909]

In addition to the COX inhibitors there are several antiinflammatory drugs that have been used in foals and may have some application. Dipyrone (metamizole) has been widely used in horses as an analgesic, antipyretic, and antispasmodic drug and clinically appears to be safe when used as a single dose in foals with abdominal pain. Acetaminophen has been used very little in horses because of concerns about the potential for hepatotoxicity, but recent reports suggest that this drug may be both safe and effective as an analgesic.[910] Although dipyrone and acetaminophen have some COX inhibitory effects, that pathway is not considered to be primarily responsible for the drugs' therapeutic effects.[911,912] The current hypothesis is that these drugs act primarily through other pathways, including the serotonergic, opioid, and cannabinoid systems.[913,914] Dipyrone or acetaminophen are sometimes combined with more traditional NSAIDs to achieve enhanced analgesic effects,[915] but there are limited reports regarding this approach in the horse.[912]

In addition to the NSAIDs there are other drugs that may exhibit antiinflammatory effects, such as pentoxifylline and DMSO. Pentoxifylline is a phosphodiesterase inhibitor that has been shown to have wide-ranging antiinflammatory effects and is frequently used in adult horses suffering from severe systemic inflammation.[916] Although the pharmacokinetics of pentoxifylline are not known in foals, it has been used in foals at adult dosages.[185] DMSO is a free radical scavenger that is widely used in horses and foals suffering from severe localized or systemic inflammation, despite a relative lack of evidence of efficacy.[917] When administered intravenously at an appropriate dilution DMSO appears to be safe and is frequently administered to foals suspected to be suffering from NE.[185] Although not a traditional antiinflammatory, the antimediator polymyxin B is sometimes used in foals with SIRS because it has the capability of binding circulating endotoxin and inhibiting the upregulation of the inflammatory response.[917,918] A recent study performed in healthy foals with experimentally induced endotoxemia found that administration of polymyxin B at 6000 U/kg IV every 8 hours attenuated some of the clinical and clinicopathologic effects of endotoxemia.[919] Polymyxin B is potentially nephrotoxic, however, so caution is indicated when considering the utilization of this therapy in the critically ill, hypovolemic foal.

The administration of SAIDs to foals is not frequently indicated and should be restricted to clinical syndromes in

TABLE **20.20 Dosages of Antiinflammatory and Analgesic Medications Used in Foals**

Drug	Dosage	Route	Frequency (h)
Aspirin	10–100 mg/kg	PO	24
Butorphanol	0.1 mg/kg (up to 8 weeks of age)	IV, IM	PRN
Carprofen	0.7 mg/kg (adults)	PO	24
Dexamethasone	0.01–0.02 mg/kg 0.05–0.2 mg/kg	IM, IV, PO	24–48
Dimethyl sulfoxide	0.5–1.0 mg/kg as a 10% solution over 30–60 min	IV	12–24
Firocoxib	0.1 mg/kg 0.09 mg/kg	PO IV	24
Flunixin	0.25–0.5 mg/kg 1.0 mg/kg	IV, PO	8 12–24
Hydrocortisone	0.17–0.67 mg/kg (total dose 1–4 mg/kg/day)	IV	4–6
Ibuprofen	25 mg/kg	PO	12
Ketamine	0.4–1.2 mg/kg/h	IV	CRI
Ketoprofen	2.2 mg/kg 3.3 mg/kg (<24 h)	IV	24
Lidocaine	1.3 mg/kg loading 0.05 mg/kg/min CRI	IV	CRI
Meloxicam	0.6 mg/kg	PO	12
Methylprednisolone sodium succinate	1 mg/kg	IM, IV (slow)	12–24
Phenylbutazone	1.1–2.2 mg/kg	IV, PO	12–24
Polymyxin B	6000 U/kg in saline	IV	8
Prednisolone sodium succinate	0.25–2.5 mg/kg 0.8–5.0 mg/kg	IV	6, PRN
Prednisolone	1–2.2 mg/kg	PO	12–24
Pentoxifylline	10 mg/kg (adults)	PO	12
Tramadol	3 mg/kg	IV	Not defined

CRI, Continuous rate infusion; *IM,* intramuscularly; *IV,* intravenously; *PO,* orally; *PRN,* as needed.

which overwhelming localized or systemic inflammation must be controlled. In foals with interstitial pneumonia, ALI, or ARDS, SAID therapy is critical in the downregulation of pulmonary inflammation and restoration of pulmonary function and represents the primary pharmacologic therapy for these conditions.[324] This syndrome is discussed in detail in the previous section Respiratory Disorders. Severely ill foals can suffer from CIRCI, which is associated with poor clinical outcomes.[667] This syndrome is discussed in detail in the previous section Immunologic Disorders. Cortisol replacement therapy using small doses of hydrocortisone administered frequently may provide antiinflammatory and physiologic benefits in CIRCI-affected foals and does not appear to interfere with the functioning of the innate immune system.[313,315]

If the primary goal of therapy is analgesia independent of antiinflammatory effects there are a number of alternative therapies available. For short-term analgesia the α_2-adrenergic agonists, such as xylazine and detomidine, are commonly used because they are very effective in controlling severe pain. The limitations of the α_2 drugs are profound sedation and decreases in gastrointestinal motility.[920] Alternatively, one could consider the use of an opioid agonist or agonist/antagonist. Butorphanol, an opioid agonist/antagonist, is the most commonly used drug because it is readily available and safe to administer. The limitations of butorphanol are primarily that it causes substantial sedation and only lasts for a short period of time when given as a bolus. Administering butorphanol as a CRI allows for a much more stable analgesic effect and may lessen the sedative effects. Opioid agonists, such as tramadol and fentanyl, are rarely used in foals but could have utility in managing chronic, severe musculoskeletal pain.[921,922] Lidocaine is a local anesthetic, but when administered systemically as a CRI it can provide effective analgesia, especially for visceral pain. It is not associated with sedative effects but can cause neurologic signs if given at an excessive rate. In a recent study lidocaine administration to foals achieved lower systemic concentrations than in adult horses but appeared to be safe and clinically effective.[923] Ketamine is a dissociative agent most commonly used for induction and/or maintenance of general anesthesia, but it has been reported to have analgesic effects when administered at lower doses as a CRI.[920]

NUTRITIONAL SUPPORT OF THE FOAL

Developing an appropriate nutritional plan when treating a sick foal can be challenging because one must ensure that the foal has adequate energy and nutrients for basal metabolism and immune function and ideally for growth as well. This should be a straightforward process in which the number of calories required by the foal is calculated, followed by a determination of the volume of the appropriate nutrient-containing solution and the administration of this nutritional source by

the appropriate route. Unfortunately the energy requirements for sick foals are not well understood and will vary among patients. Additionally, the ability of the foal to appropriately metabolize the nutrients provided is not guaranteed because both age and degree of illness impact the foal's ability to produce metabolic hormones as well as the ability of the tissues to respond to hormonal stimulation. Another difficulty arises because the energy content of mare's milk cannot be easily determined, and the exact formulation of substitutes such as artificial milk replacer is not always known. Ultimately the burden falls on the clinician to formulate the best plan possible with the information at hand and to ensure that the foal is closely monitored. This will ensure that the goals of the nutritional plan are met while the risk of complications is minimized.

The foal's nutritional requirements and dietary composition change substantially during the transition from neonate to weanling, requiring careful consideration of the foal's stage of growth when formulating a nutritional plan. At birth the foal transitions from a continuous supply of nutrients provided by the dam via the placenta to intermittent absorption of ingested nutrients. At the same time the metabolism of the neonate is no longer able to depend on the maternal glucose concentration to maintain normoglycemia, and the pancreas assumes responsibility for regulating glucose homeostasis. These dramatic alterations in energy metabolism do not always occur smoothly, and the foal possesses limited energy reserves in the form of glycogen and fat. The result is that hypoglycemia occurs frequently in even the normal neonatal foal, and clinically ill foals are at risk of profound hypoglycemia if deprived of energy intake for even a few hours.

The caloric requirements of the normal foal are sizable; they need to support not only their high basal metabolic needs but also maintain a rate of growth of as much as 2.5% of body weight per day in the neonatal period. This means that the neonates caloric requirement is as great as 150 kilocalories per kg body weight per day (kcal/kg/day) but decreases gradually to around 120 kcal/kg per day at 3 weeks of age and then to 80 to 100 kcal/kg per day by 1 to 2 months of age.[924,925] A more recent study has suggested that actual energy requirements of foals from 2 to 6 months of age may be 10% to 20% less than these values.[926] Because these measurements are given in terms of foal body weight, it is important to realize that as the energy requirement per kilogram is decreasing the foal's body weight is increasing; thus, the total caloric requirement increases with age. The initial energy source for the foal is mare's milk, which has substantially greater lactose content than cow's milk, with lower milk fat content. On a dry matter basis, mare's milk averages about 64%, 22%, and 13% sugar, protein, and fat, respectively, compared with 38%, 26%, and 30% sugar, protein, and fat, respectively, for cow's milk. Mare's milk therefore derives most of its energy content from carbohydrates, and an appropriate endogenous production of insulin by the pancreatic β cells is required for the foal to metabolize and utilize these carbohydrates appropriately.

Maturation of pancreatic β-cell function occurs very late in gestation in the fetal foal and is dependent on the normal rise in fetal circulating cortisol concentration, which occurs in the final days of gestation.[927] This preparturient cortisol rise is critical for many aspects of readying the foal for birth, both in terms of endocrine function as well as respiratory and cardiovascular function. Following birth there is a gradual maturation of the endocrine response to ingested carbohydrates. It has been shown that normal newborn pony foals demonstrated impaired glucose clearance following the administration of exogenous glucose on the first day of life, suggesting a degree of insulin resistance.[928] By 10 days of age foals demonstrate increased rates of glucose clearance, but this response remains lower than that seen in normal adult equines. This gradual maturation may be an appropriate response to changes in the composition of mare's milk, because colostrum contains little lactose, and in the volume of milk ingested, which is less on the first day of life than on subsequent days.[924,928]

Starting as early as the second day of life foals will begin ingesting small amounts of hay, grass, and grain while at the same time they are ingesting maternal feces, which likely provides the initial microbial flora required to support digestion of these feeds. It is unlikely that grain and roughage are thoroughly digested until several weeks of age, at which point the foal begins the gradual transition from a milk-based diet to a forage-based diet. The amount of milk produced by the mare peaks at around 2 months of lactation and then begins a steady decline, which continues until the time of weaning, necessitating that the foal begin relying on ingestion of solid food for an increasing proportion of its nutritional requirements. At the same time, the foal's hindgut function is increasing and is likely fully functional by around 3 to 4 months of age. By the age of 6 months the foal is receiving less than 30% of the total nutritional requirement in the form of milk, which allows for a fairly easy dietary transition when weaning occurs. As the foal's hindgut function increases, there is a corollary shift in the primary energy substrate from carbohydrates absorbed in the small intestine to volatile fatty acids absorbed from the large intestine.

When evaluating the sick neonatal foal one must always remember that the disease processes at work in the foal may have had their origins in utero. Maternal illness, maternal malnutrition, maternal toxin exposure, placentitis, and placental insufficiency all have the potential to profoundly influence the development and maturation of fetal metabolism. Studies investigating the role of a "restricted" uterine environment on fetal development have demonstrated lifelong impairment of growth and development in affected foals.[929] Conversely, the provision of a "luxurious" in utero environment can lead to enhanced growth rates out to 3 years of age.[929] The influence of maternal diet is important, because a diet high in soluble carbohydrates fed to the mare in late gestation contributed to a decrease in insulin sensitivity of the foals at 160 days of age.[930] It is clear that there is a potential for lifelong effects on metabolic function secondary to this "prenatal programming" effect, potentially contributing to the development of metabolic disease later in life.[931] This prenatal programming may affect the neonatal foal's ability to appropriately metabolize nutrients in the clinical setting, with foals from a compromised placental environment potentially exhibiting insulin resistance and carbohydrate intolerance.

As previously discussed the late gestation rise in fetal cortisol is critical in the final maturation of energy metabolism, and many foals delivered prematurely fail to undergo this rise in fetal cortisol concentration; therefore, they are unable to respond normally to the changes in metabolism that occur after birth. Hypoglycemia, complicated by decreased endogenous energy reserves and the impairment of nursing caused by concurrent weakness, depression, and/or difficulty standing, is a common problem in these foals. Following the successful delivery of nutrients by the enteral or parenteral routes

these foals are likely to be intolerant of carbohydrates, which is caused by impaired endogenous insulin production, and they may suffer profound hyperglycemia. Foals suffering from systemic inflammation, such as that associated with septicemia, may also exhibit hyperglycemia caused by insulin resistance and carbohydrate intolerance. Management of these foals may require lipid-containing parenteral nutrition solutions and/or the administration of exogenous insulin to achieve adequate caloric input.

Attempting to determine the true caloric needs of the clinically ill foal is one of the greatest challenges in designing a nutritional strategy. Historically it was believed that critical illness created a "hypermetabolic" situation in which the patient had increased energy needs caused by increased tissue energy consumption. The energy requirements of the sick foal do not appear to be as great as once was thought,[932] however, because there is a reduction in the overall metabolic rate from a decrease in activity level in combination with a temporary reduction in growth rate. Indirect calorimetry testing of clinically ill neonatal foals has shown that their resting energy requirement is only 45 to 50 kcal/kg per day, which is one third of the energy requirement for growing, active, normal foals.[933,934] As these foals recover, their energy requirements gradually increase to approximately 65 to 70 kcal/kg per day, which is similar to the energy requirements of age-matched control foals.[934]

When managing the critically ill neonatal foal it may be preferable to pursue a hypocaloric approach in which one endeavors to prevent the foal from entering a severely catabolic state while accepting that all of the nutritional needs of the patient may not be met.[935,936] This approach addresses the fact that aggressive nutritional support can result in overfeeding, the risks of which may easily outweigh the possible benefits of providing nutritional support. Excessive carbohydrate administration will lead to an increased generation of carbon dioxide and can worsen hypercapnia in foals with compromised respiratory function. Excessive carbohydrate delivery will also cause hyperglycemia, which is considered to be a proinflammatory stimulus and has been associated with worsening of outcome in human critical illness.[937,938] Overfeeding of protein will result in increased protein catabolism and can result in the potentiation and/or development of azotemia.[938] The excessive administration of lipids may result in hypertriglyceridemia.[719] In contrast to the risks of overfeeding, there is little evidence in human patients that short-term (several days) hypocaloric nutritional support results in worsened outcomes compared with regimens designed to meet the patient's metabolic needs.[935,936] There is some evidence to suggest that this approach, especially regarding the maintenance of appropriate control of blood glucose levels, is associated with decreased rates of complications and improved outcomes.[937]

The first step in the development of a nutritional plan involves selection of the route of nutrient delivery. Providing nutritional support by the enteral route is generally preferred for two reasons. First, this is the most natural and physiologically sound means of nutrient delivery. Second, the intestinal mucosa is partially dependent on the products of digestion for energy and nutrients. A thorough evaluation of gastrointestinal function is needed before the institution of enteral nutritional support. This will include abdominal auscultation, checking for gastric reflux, and possibly abdominal radiographs and ultrasonographic examination for the evaluation of bowel dimensions and motility. Foals with evidence of gastrointestinal dysfunction, such as gastric reflux, bowel distention, increased bowel wall thickness, and ileus, are unlikely to tolerate enteral feeding. A conservative approach to enteral feeding is also indicated for premature or immature foals in which there may be incomplete development of the gastrointestinal tract. Foals with perinatal asphyxia syndrome may be intolerant of enteral feeding caused by ileus and dysfunction as a result of intestinal ischemic injury.

Mare's milk is the preferred substrate for enteral feeding. It is highly digestible and obviously provides the correct balance of nutrients for normal growth and development. Commercial mare's milk replacers can be used, but it should be recognized that these products are bovine in origin and have lower digestibility compared with mare's milk. This increases the risk of intestinal dysfunction associated with enteral feeding. Semiskimmed (2% fat) cow's milk to which 20 g/L dextrose (equivalent to 40 mL of 50% dextrose solution per liter) has been added can be used if mare's milk or mare's milk replacer is unavailable. Foals that are unable to nurse the mare may be fed through a bottle, bowl, or nasogastric feeding tube. Many sick, recumbent foals have a weak and/or uncoordinated suckle reflex, and therefore, milk should be administered through a feeding tube.

Use of a small-bore, indwelling tube and feeding of small volumes at frequent intervals (e.g., every 20 minutes) is preferred over repeated passage of a nasogastric tube at 1- to 2-hour intervals. Large-bolus feedings may overwhelm digestive capacity, and repeated passage of a stomach tube is an unnecessary stress on the foal. Another advantage of small-bore indwelling tubes is that they do not interfere with voluntary feed and water intake. Therefore the tube may be left in place as the foal is transitioned to feeding from the mare. The feeding tube should be inserted with the foal in sternal recumbency, and correct placement within the esophagus should be confirmed by radiography or endoscopy. The tube may be fastened to the external nares by sutures. At each feeding, it is important to check that the tube is still in place and that there is no reflux. The foal should be in sternal recumbency or standing when it is fed. Milk should be administered by gravity flow followed by a small amount of clean water to flush the tube. The tube should be capped between feedings to prevent aspiration of air. Feeding tubes should be replaced every 1 to 2 days to reduce risk of gastrointestinal tract infection.

A suggested initial rate of milk delivery is 2 to 3 mL/kg body weight per hour, or 100 to 150 mL/h for a 50-kg foal (Table 20.21). This will provide 2.4 to 3.6 L of milk to a 50-kg foal during the first 24 hours of enteral support. Dextrose-containing fluids can be administered IV to provide additional calories during the transition to an adequate level of enteral feeding. The feeding rate can be gradually increased over the next 2 to 3 days (e.g., increase to 4–5 mL/kg/h on day 1 and then to 6–8 mL/kg/h on day 3), which represents a total daily intake of 10% to 15% of body weight. Simultaneously, IV caloric support (dextrose) can be gradually withdrawn. This feeding level will likely meet the resting energy requirements of hospitalized foals. Depending on the rate of clinical improvement and the length of hospitalization, it may be possible to increase the volume of feeding to 20% to 22% body weight per day, which approximates the milk intake of healthy neonatal foals. Clinical monitoring should include frequent assessments of gastrointestinal function, including gastric reflux, intestinal sounds, abdominal distention, and quantity and quality of feces. Gastric reflux, bloating, colic, diarrhea,

TABLE **20.21 Feeding Recommendations for Neonatal and Growing Foals**

Foal Age (Days)	Energy Requirement	Volume of Mare's Milk or Milk Replacer	Percentage of Body Weight Fed
0–1	50–150 kcal/kg/day	2–3 mL/kg/h	5–7%
2–3	100–150 kcal/kg/day	4–5 mL/kg/h	10–12%
4–7	150 kcal/kg/day	6–8 mL/kg/h	14–20%
8–30	120 kcal/kg/day	9–10 mL/kg/h	22%
30 to weaning	80–100 kcal/kg/day	Gradually decreasing and replaced with solid feed	—

or constipation can indicate intolerance to enteral feeding and the need for adjustments to the feeding program. This may involve a decrease in the volume or frequency of enteral feedings. In some situations there may be concerns regarding the ability of the foal's gastrointestinal tract to digest and absorb lactose, as in rotaviral infections during which production of lactase by the enterocytes is likely impaired. In these situations lactase enzyme can be added to the milk or milk replacer before feeding at the rate of 9000 U (one tablet) per feeding. Additional volumes of enteral fluid may be required in foals with diarrhea, and a simple balanced isotonic enteral solution can be formulated by adding 5.6 g of table salt (NaCl), 0.6 g of Lite Salt (50% NaCl, 50% KCl), and 3.4 g of baking soda ($NaHCO_3$) per liter of water.[939]

It is generally preferred to support foals via the enteral route,[940,941] both because this is the most natural and physiologically desirable route and because the epithelial cells lining the intestine are partially dependent on the products of digestion for energy and nutrients. Unfortunately there are a variety of situations in which a foal may be unable to receive enteral nutrition or is unable to tolerate the volume of enteral nutrition required to support basal metabolism and growth. These range from the critically ill neonate with gastrointestinal complications to the suckling foal with severe enterocolitis. The rapid institution of parenteral nutrition can aid in preventing the development of protein/calorie malnutrition and substantial energy deficits. The limitations of parenteral nutritional support are primarily caused by the expense of this therapy and the risk of secondary complications. These complications may include hyperglycemia, hypertriglyceridemia, thrombophlebitis, and an increased risk of bloodstream infections.

The primary goal of parenteral nutrition, as with any type of nutritional support, is to ensure that the patient is supplied with adequate calories to support basal metabolism at a minimum and ideally to provide additional support to allow for ongoing growth. A reasonable initial goal for parenteral nutrition administration in the foal is 30 to 40 kcal/kg per day. Although this level of caloric support does not fully meet the theoretic energy requirements of the healthy neonate, it comes close to meeting the resting energy requirement in hospitalized foals.[924,933] In this situation parenteral nutrition is used purely as a temporary support to prevent the foal from entering into a severely catabolic state, in which protein catabolism would increase and use amino acids for energy production.[720,924,942] Failure to provide adequate nutritional support may also have a substantial negative influence on the immune response.[942-944] Short-term parenteral supplementation (less than 24 hours) may consist of IV carbohydrate solutions and does not require the patient to receive a balanced nutritional source consisting of carbohydrates, amino acids, and lipids, but if parenteral nutrition is expected to be administered for a longer period then a more complete formula should be used.

Carbohydrate-containing solutions represent the simplest means of providing IV caloric support to foals. A solution containing 5% dextrose can be used, and there are several options available including D5W, LRS with 5% dextrose, 0.45% saline with 5% dextrose, Normosol-M with 5% dextrose (Hospira, Lake Forest, IL), and Plasma-Lyte 56 with 5% dextrose (Baxter Healthcare Corp., Deerfield, IL). Fluids containing dextrose should not be used for initial fluid resuscitation because this will almost certainly result in the delivery of excessive amounts of dextrose to a foal with any degree of dehydration, resulting in profound hyperglycemia. Following initial fluid resuscitation, solutions containing electrolytes as well as dextrose (0.45% saline with 5% dextrose, Normosol-M with 5% dextrose, and Plasma-Lyte 56 with 5% dextrose) may be used as the primary fluids for maintenance therapy in foals with minimal ongoing fluid losses. D5W is not an ideal choice as a maintenance solution because of the absence of electrolytes and is primarily useful in providing free water to patients suffering from hyperosmolar conditions. The caloric content of a 5% dextrose solution is 0.17 kcal/mL, so an infusion rate of 10 mL/kg per hour would be required to deliver approximately 40 kcal/kg per day (0.17 kcal/kg/h × 24 h/day = 41 kcal/kg/day). This rate of infusion is over twice that considered to be a maintenance rate for a neonatal foal. In addition, care must always be taken when adjusting the infusion rates of 5% dextrose-containing solutions in response to changes in the patient's fluid status to ensure that excessive amounts of dextrose are not infused, especially in premature or very sick foals that are likely to be poorly tolerant of dextrose infusions.

Alternatively, a 50% dextrose solution can be delivered without further dilution using an infusion pump, as long as additional isotonic fluids are being administered concurrently to provide dilution and avoid endothelial injury caused by the hypertonic nature of this solution. Use of 50% dextrose solution should be avoided if an infusion pump is not available because it is very easy to inadvertently administer an excessive amount of dextrose, leading to hyperglycemia. The caloric content of 50% dextrose solution is 1.7 kcal/mL, so an infusion rate of 1 mL/kg per hour of this solution will deliver approximately 40 kcal/kg per day (1.7 kcal/kg/h × 24 h/day = 41 kcal/kg/day). This low rate of infusion means that the primary fluid needs of the patient can be met with a dextrose-free isotonic electrolyte-containing fluid, the infusion rate of which can be altered in response to changes in patient fluid status without concerns related to the requirements of the nutritional plan. At the end of the first 24 hours of treatment the fluid therapy plan and nutritional plan should be revisited to determine whether the patient can begin to rely on enteral fluid and nutritional intake or if continued parenteral therapy is required. Because dextrose-containing fluids are a very incomplete nutritional source, they should not be used as the primary nutritional source for more than 24 hours. Continued

parenteral nutritional support will require the formulation of a more complete solution that provides amino acids and possibly lipids.

One important aspect of providing longer term (over 24 hours) parenteral nutrition to foals is the inclusion of a protein source. The metabolic response to injury and sepsis is to increase protein degradation in muscle tissue. This catabolic response can be reduced by supplying a source of nitrogen or by increasing energy intake. The recommended ratio for nonprotein calories to nitrogen is 100 to 200 nonprotein calories per gram of nitrogen.[945] The inclusion of lipids in the parenteral nutrition formulation allows for the provision of a larger number of calories per unit volume compared with solutions containing only dextrose. Another advantage of lipid emulsions is that they are isotonic, so they moderate the hypertonicity of the parenteral nutrition formulation and potentially decrease the risk of thrombophlebitis. Unfortunately, formulating parenteral nutrition solutions with lipids increases the cost of the solution and may increase the risk of complications.[946] Hyperlipidemia can occur in association with lipid administration to foals but does not appear to result in adverse effects.[719,946] Lipid emulsions are prone to contamination and promote bacterial growth. Because of these risks the IV lines through which lipid-containing solutions are administered should be changed daily, substantially increasing client costs. In a recent report the use of lipid-containing parenteral nutrition solutions allowed for the provision of 40 to 92 kcal/kg per day (mean = 63 kcal/kg/day) to foals, as opposed to only 25 to 66 kcal/kg per day (mean = 41 kcal/kg/day) with a dextrose-based solution.[719]

There are two basic approaches to the formulation of parenteral nutrition to foals. The first approach involves the exact determination of the anticipated metabolic needs of the patient, followed by the development of a formulation that will meet all of these needs in a fairly precise manner, using a mixture of dextrose, amino acids, and lipids. This approach is fairly complex and is best performed using a computerized spreadsheet to aid in performing the various calculations. The second approach is more practical and consists of using two basic parenteral nutrition formulas (Table 20.22). One of these solutions is intended for short-term use and consists only of 50% dextrose and 8.5% amino acid solutions (Solution I). The second solution incorporates a lipid energy source and is preferred for long-term administration or for administration to foals that are poorly tolerant of infused dextrose (Solution II). Solution I is formulated using 2000 mL of 50% dextrose (Dextrose 50%, Baxter Healthcare Corp., Clintec Nutrition Division, Deerfield, IL) and 2000 mL of 8.5% amino acids (Travasol 8.5%, Baxter Healthcare Corp., Clintec Nutrition Division, Deerfield, IL), whereas Solution II is formulated with 1500 mL of 50% dextrose, 500 mL of 20% lipids (Intralipid 20%, Baxter Healthcare Corp., Clintec Nutrition Division, Deerfield, IL), and 2000 mL of 8.5% amino acids.[719] The caloric density of these solutions is 1.02 kcal/mL for Solution I and 1.08 kcal/mL for Solution II. The ratio of nonprotein calories to nitrogen is 125 nonprotein calories per gram of nitrogen (NPC/gN) for Solution I and 131 NPC/gN for Solution II. An easy-to-use, shelf-stable multichamber bag preparation identical to Solution I is manufactured for human use, and it is cost-effective and practical for use in foals (Clinimix 4.25/25 sulfite-free [4.25% amino acid in 25% dextrose] injection, Baxter Healthcare Corp., Clintec Nutrition Division, Deerfield, IL).

TABLE **20.22 Formulation of Parenteral Nutrition Solutions**

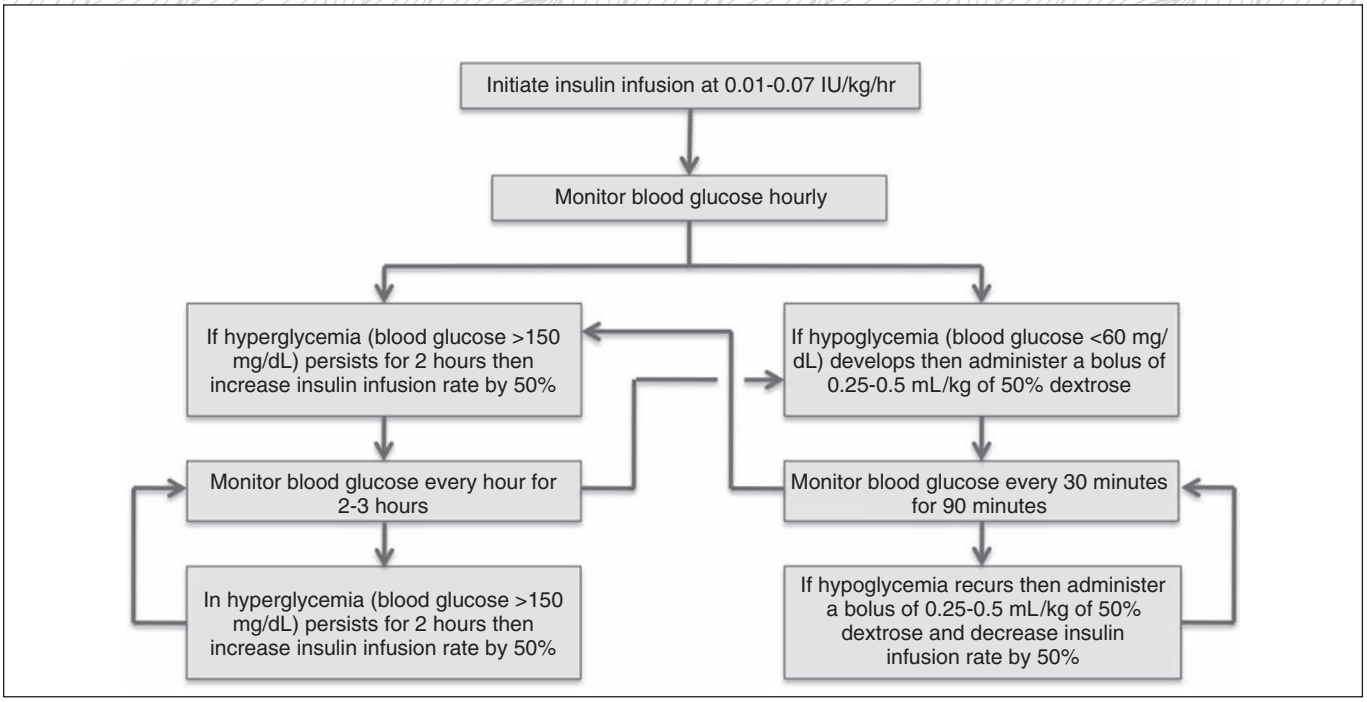
Formula	Composition	Caloric Density (kcal/mL)	Nonprotein Calories/gN
1	1500 mL 50% dextrose, 1500 mL 8.5% amino acids	1.02	125
2	1500 mL 50% dextrose, 500 mL 20% lipids, 2000 mL 8.5% amino acids	1.08	131

An electronic infusion pump should always be used when administering parenteral nutrition solutions, because the rate must be tightly controlled and adjustments to the infusion rate must be made easily and accurately. Excessive rates of administration can easily induce profound hyperglycemia, which has been shown in other species to be associated with severe complications and increased risk of death.[947] The solutions used for parenteral nutrition are all hypertonic and can cause injury to the vascular endothelium, increasing the risk of thrombophlebitis. For this reason it is recommended that parenteral nutrition solutions be administered through a 20-cm-long polyurethane long-term catheter placed in the jugular vein, because this provides a "central" line in most foals. The use of a multiple-lumen catheter allows for one lumen to be dedicated to infusion of the parenteral nutrition solution, minimizing the risks of contamination. Catheter management is extremely important when foals are receiving parenteral nutrition, and the catheter site and vein should be monitored at least twice daily for heat, swelling, or exudation. Increased resistance to fluid flow in the catheter may be an indication of thrombosis deeper within the vasculature and will often necessitate the placement of a catheter in an alternative site, such as the opposite jugular vein, a cephalic vein, or a lateral thoracic vein.

All components of parenteral nutrition solutions must be mixed in a sterile manner before administration. The bag containing the final parenteral nutrition composition should be covered with a brown plastic bag during administration to protect it from light, which can degrade the amino acids within the solution. The rate of infusion (in mL/h) is calculated based on the desired kcal/kg per day to be administered. A reasonable initial goal is 40 to 60 kcal/kg per day. The initial infusion rate of parenteral nutrition solutions should be 25% of the calculated final rate, and the rate should be gradually increased every 1 to 3 hours following monitoring of the blood glucose concentration to ensure that hyperglycemia (blood glucose >150 mg/dL) is not present. If the patient tolerates parenteral nutrition well and maintains blood glucose concentrations at or near normal levels, then consideration can be given to increasing the parenteral nutrition administration rate to a maximum of 50 to 60 kcal/kg per day.[948] When parenteral nutrition is to be discontinued it is recommended that the infusion rate gradually be reduced, decreasing the infusion rate in 25% to 50% increments every 4 to 6 hours while gradually introducing enteral feeding. It is important that blood glucose monitoring is continued during this weaning process to detect or prevent the development of hypoglycemia.

The foal must be frequently monitored, especially during the initial phase of parenteral nutrition therapy. This monitoring should include a general physical examination, with close

attention to neurologic status and respiratory function. Rectal temperature should also be closely monitored because fever is a common early manifestation of systemic infection. Blood glucose concentrations should be frequently monitored, initially on an hourly basis until the patient has stabilized with the appropriate rate of parenteral nutrition infusion, followed by monitoring every 3 to 6 hours for the first day of therapy. The frequency of blood glucose monitoring is dependent on the stability of the patient and may need to be more frequent in the critically ill, but it may not need to be monitored beyond every 12 hours in the stable patient. Monitoring of urine output and urine glucose concentration may aid in the detection of hyperglycemia. Although the actual renal threshold for glucose is not well described in foals, glucosuria and diuresis are typically seen when blood glucose levels exceed 180 mg/dL. Additional clinicopathologic monitoring should consist of daily complete blood counts and serum chemistry profiles in the critical case, whereas these can be performed every 48 to 72 hours in more stable patients. Serum electrolytes should be monitored at least twice daily. Particular attention should be paid to serum potassium concentrations because they can decrease rapidly, especially in foals receiving insulin therapy. Urine output should be monitored continuously, in combination with intermittent monitoring of urine glucose concentration, because of the risk of hyperglycemia-induced diuresis and glucosuria. Ideally body weight should be assessed on a daily basis to ensure that the foal is at least maintaining its body weight while on parenteral nutrition. Foals receiving parenteral nutrition solutions containing lipids should be monitored for the development of hypertriglyceridemia.[719,949]



Insulin Therapy

The critically ill foal will often demonstrate carbohydrate intolerance, and this can make it very difficult to achieve even a conservative rate of administration of IV nutrition. This situation can be addressed by the use of a lipid-containing parenteral nutrition solution, but if this is ineffective then the only alternative is administration of exogenous insulin. The administration of insulin to the neonatal foal is not to be undertaken lightly because this therapy places additional demands on both the clinician and nursing staff to ensure that profound hypoglycemia does not occur. Intermittent dosing of subcutaneous insulin may offer some advantages in terms of simplicity of administration, expense, and moderation of effects, but this route of administration does not allow for changes in dosage over the short term. One recommended dosage for subcutaneous insulin in foals is 0.1 to 0.5 IU of regular insulin every 12 hours.[950] A retrospective report of foal parenteral nutrition described subcutaneous insulin dosage rates 0.02 to 0.1 IU/kg given every 6 to 24 hours.[949] This approach is not recommended because the risks of hypoglycemia and hyperglycemia are greater than with CRIs, and it can be much more challenging to achieve homeostasis in terms of blood glucose concentrations when using intermittent bolus insulin therapy.

The use of CRI for the administration of insulin allows for a fairly rapid onset of action while providing a simple and timely means of adjustment of the dosage. Because of the gradual saturation of the cellular insulin receptors, the maximal effect of CRI insulin is not typically seen until roughly 90 minutes after initiation of the infusion. The response to the alteration of the rate of infusion occurs over a similar time frame, so one should take care to avoid altering the rate of infusion of parenteral nutrition solutions too soon after changing the rate of insulin infusion. An initial insulin infusion rate of 0.07 IU/kg per hour of regular insulin has been reported to be well tolerated and may represent a reasonable starting point in foals intolerant of parenteral nutrition.[720,951] This dosage was derived from a retrospective study of foals treated with parenteral nutrition, which reported initial insulin doses ranging from 0.014 to 0.2 IU/kg per hour, with a mean of 0.065 IU/kg per hour.[719] Interestingly, in that study the final insulin dose ranges remained very similar, from 0.015 to 0.2 IU/kg per hour, with a mean of 0.07 IU/kg per hour. Some advocate starting at lower dosages in foals, such as 0.01 IU/kg per hour.[952] This conservative approach is very safe, with less risk of hypoglycemia than the higher dosage rate, but may require a longer period of time before the dose is titrated to a high enough level to control hyperglycemia. Even lower dosage rates of insulin have been reported, with a recent retrospective report describing insulin infusions at dosages of 0.0016 to 0.018 IU/kg per hour.[949]

Therefore an initial insulin infusion rate of 0.01 to 0.07 IU/kg per hour represents a reasonable starting point. When "fine-tuning" insulin therapy it is best to avoid simultaneous alterations in both the insulin infusion rate and the parenteral nutrition infusion rate, because this can lead to a "roller-coaster ride" in which the blood glucose concentration rises and falls wildly because of the delay in the body's response to these changes[720] (Box 20.6). Blood glucose monitoring should be performed at least hourly for the first 2 to 3 hours after initiation of the insulin CRI, and if hyperglycemia (blood glucose >150 mg/dL) is persistent beyond the first 2 hours of insulin therapy, then the insulin infusion rate may be increased by 50%, followed by hourly blood glucose monitoring for a further 2 to 3 hours. This procedure for increasing the insulin infusion rate may be repeated if hyperglycemia persists. Conversely, if hypoglycemia (blood glucose <60 mg/dL) is noted then a bolus of 0.25 to 0.5 mL/kg of 50% dextrose solution should be administered intravenously over 3 to 5 minutes. The blood glucose level should then be reassessed every 30 minutes for at least 90 minutes ensure that hypoglycemia does not recur. If hypoglycemia does recur, then a second bolus of dextrose is administered and the insulin infusion rate is decreased by 50%. Close monitoring will then be required for a further 60 to 90 minutes to ensure that hypoglycemia does not recur and that hyperglycemia does not develop. Further changes to the insulin infusion rate are not usually necessary once a steady state has been achieved in which the blood glucose level is stable and the desired rate of parenteral nutrition administration has been achieved. Patient reassessment is indicated if one finds that the foal has become even more insulin resistant (requiring additional insulin administration to avoid hyperglycemia) as there may be an overall deterioration in the patient's condition accompanied by increasing systemic inflammation. When insulin therapy is to be discontinued the insulin administration rate should be gradually titrated downward in parallel with the parenteral nutrition rate, but there can be a substantial lag between changes in the insulin infusion rate and the patient's response to this change. Some time should be allowed to account for this lag. It is critical that foals being weaned from insulin infusions receive some form of enteral nutrition during this time period. It may be wise to wean them from parenteral nutrition and insulin over longer periods of time (24–36 hours) than would be required for a foal receiving parenteral nutrition alone to prevent glucose derangements.

BOX 20.6 Protocol for the Monitoring and Regulation of Insulin When Administered as a Continuous Rate Infusion to Foals

CHAPTER 21

Toxicologic Problems

Patricia Talcott

It is the dose that makes the toxin. In theory, almost anything that a horse could encounter in its daily regimen could act as a poison. In reality, that is not the case. There are a finite number of organic and inorganic substances that could pose a risk to horses given their typical environment, and these substances are what will be focused on in this chapter. Many toxins target specific organ systems, so the individual toxins are divided up by the major system affected. However, it should be recognized that many toxins target multiple organ systems; therefore clinical signs of illness can reflect changes occurring in more than one system. Very rarely will the clinical signs associated with toxicity be pathognomonic for a certain toxic substance. And the clinician needs to be aware that nontoxic differentials (e.g., infectious, inflammatory, nutrition, tumor) should be considered when presented with a patient where there is a concern that a toxicosis has occurred. Excellent history taking is essential in helping to confirm a poisoning, because many toxins, such as plant toxins, are not routinely tested for by veterinary diagnostic laboratories. Common toxicities seen in horses include plant toxins, cyanobacteria (i.e., blue-green algae), pesticides, and feed additives.

Toxicoses Related to the Gastrointestinal Tract

A wide range of toxic agents are capable of inducing signs of gastrointestinal disease, considering that the majority of toxicoses confirmed in horses is a result of oral exposures. Clinical signs of illness vary from mild to peracute and life threatening. Determination that a toxicosis is the cause of a problem such as diarrhea or colic sometimes is difficult, time consuming, and relatively costly.

PLANTS

Oak (*Quercus* spp.)

Clinical Signs

Oak blossoms, buds, leaves, stems, and acorns can be toxic to most animals. Most reports of toxicosis in livestock involve cattle, with a rare occurrence in the horse. Clinical signs attributed to acorn toxicosis in horses are acute onset of severe abdominal pain, rectal straining, hemorrhagic diarrhea, and pronounced intestinal borborygmi. Acorn parts may be apparent in feces. Occasionally, horses are found dead; other reported signs are hemoglobinuria and elevated heart and respiratory rates.

Pathophysiology

The toxicity of oak is attributed to a group of structurally similar compounds called *gallotannins* and their metabolites. Digallic acid is the major active metabolite produced by oak tannins. After bacterial fermentation digallic acid is converted to gallic acid and pyrogallol, both of which are considered toxic.[1] Pyrogallol and gallic acid are toxic to renal tubules and result in acute tubular necrosis, anuria, electrolyte abnormalities, and uremia.[1,2] Pyrogallol is also responsible for causing hemorrhagic gastroenteritis, subcutaneous hemorrhage, and hemolysis. Tannic acid itself is thought to result in increased vascular permeability, hemorrhage, and subsequent fluid loss into body spaces.[1]

Diagnosis

The diagnosis of oak toxicity is based on compatible clinical signs and a history of potential exposure to the tree. Under adequate forage conditions horses would seem to find large quantities of oak leaves and acorns distasteful; therefore most horses with oak trees in their environment do not develop toxicity. Toxicosis is more likely to result when abnormal conditions coupled with environmental factors (e.g., lack of access to normal forage or feed) result in large numbers of oak leaves, buds, and acorns becoming accessible to horses.

Laboratory findings compatible with oak toxicosis include dehydration or hemoconcentration to varying degrees, azotemia, hyperphosphatemia, hypocalcemia, and hypoproteinemia. Abnormal urine findings might include occult blood, proteinuria, and casts. An increase in gallic acid equivalent content in urine also has been used to support exposure to oak trees.[1] However, oak trees are not the only plant that can contain these tannins, and normal and toxic ranges of gallic acid in urine have not been established in livestock.

Necropsy findings suggestive of oak toxicosis include pericardial, thoracic, and peritoneal effusion; gastrointestinal and mesenteric edema; and pale and swollen kidneys that may bulge on cut surface. The intestinal tract may contain large quantities of oak and acorn parts, and colonic ulceration has been reported.[1]

Specific Treatment and Management

No specific antidote for oak toxicity is available. Animals should be allowed no further access to oak. Treatment of the acutely affected animal aims to maintain fluid and acid-base balance and to correct any electrolyte abnormalities. Fluids given intravenously to promote diuresis are the basic therapy. This therapy should be supplemented with calcium, bicarbonate, and other electrolytes, as necessary. The clinician should attempt evacuation of the intestinal tract using mineral oil or another suitable laxative.

The prognosis for affected horses is guarded. A paucity of information exists regarding mortality rates in affected horses, but death caused by ingestion of acorns has been reported.[1]

Castor Bean *(Ricinus communis)*

Clinical Signs

Castor beans contain ricin, a protein phytotoxin that acts as a potent proteolytic enzyme with significant antigenic qualities.[2] A latent period ranging from hours to several days usually occurs before the onset of clinical signs in affected horses. Poisonings with castor beans is rare in horses, and intoxication most likely occurs when the bean or plant material inadvertently is mixed into the feed source. To cause problems, the bean must be broken apart by chewing; beans swallowed intact are known to pass through the gastrointestinal tract uneventfully, at least in dogs.

The most commonly reported clinical signs of castor bean toxicosis described in the literature are varying degrees of abdominal pain, diarrhea, depression, incoordination, profuse sweating, and increased body temperature. Muscle twitching, convulsions, and prominent cardiac contractions occasionally are observed. If the horse absorbs enough ricin, signs of shock and anaphylaxis predominate.[2,3] Death may ensue as soon as 24 to 36 hours after ingestion.

Ricin is reported to be toxic to horses. One reference cites a ricin dosage of 0.1 µg/kg as a lethal dose,[2] and a second source indicates that 25 g of castor beans is lethal.[3] A published report in 1945 describes seven deaths attributed to castor bean toxicosis from a stable of 48 horses in London in 1931.[4] The exact number of affected horses was not reported. A review of the literature suggests that castor bean (ricin) toxicosis in human beings and dogs is not nearly as lethal as reported in the literature of the early twentieth century.[5,6] Whether this holds true for horses is unknown.

Pathophysiology

The oil extract of the bean contains ricinoleic acid. Within the small intestine, ricinoleate acts to reduce net absorption of fluid and electrolytes and stimulates peristalsis.[7] The fibrous residue of the seed contains the water-soluble toxalbumin ricin. Ricin is absorbed from the gastrointestinal tract and is a potent inhibitor of protein synthesis. Ricin contains two polypeptide chains. Chain B, a lectin, binds to the cell surface to facilitate toxin entry into the cell. Chain A disrupts protein synthesis by activating the 60S ribosomal subunit. The red blood cell agglutinating properties of ricin are independent of these toxic effects.[8]

Diagnosis

Diagnosis is made by a combination of history of exposure to the plant, clinical signs, and the identification of seeds in feed material, gastric contents, or feces. Analyses for ricin content in urine, as well as other samples, is not readily available and can only be performed at select laboratories.[8]

Treatment

Ricin has no specific antidote. Initial therapy aims to combat shock, alleviating abdominal pain and evacuating the bowel. Maintenance of fluid and electrolyte balance is important. Various sedatives and analgesics may be useful to control abdominal pain, if present. Oral administration of laxatives and protectants such as mineral oil and charcoal may be warranted. Antihistamines also have been recommended.[2]

Pokeweed *(Phytolacca americana)*

Clinical Signs

Pokeweed intoxication in horses is an uncommon occurrence. However, one text reports that horses show signs of gastrointestinal irritation and abdominal discomfort as the primary clinical signs, as is reported in other animal species. The plant also produces a burning sensation of the oral mucous membranes and may cause a hemolytic crisis. Fatalities caused by pokeweed ingestion are said to result from respiratory failure and convulsions.[2]

Pathophysiology

The plant contains phytolaccine, a powerful gastrointestinal irritant that in human beings causes symptoms ranging from a burning sensation of the alimentary tract to severe hemorrhagic gastritis. Five nonspecific mitogens that have hemagglutinating and mitotic activity have been isolated. These substances vary in concentration in the plant throughout the growing season. Noncardiac steroids and triterpenoid glycosides (saponins) also are present in significant quantities, but their role in pokeweed toxicity is unknown.[8] Saponins may potentiate gastrointestinal toxicity and produce vasodilation when given parenterally.

Diagnosis and Treatment

No specific diagnostic test is available. Horses suspected of having toxicosis must be treated symptomatically and supportively. The clinician should attempt to evacuate the gastrointestinal tract using laxatives. Adsorbents such as charcoal and protectants may be useful. If the horse develops a hemolytic crisis, ancillary therapy such as whole-blood transfusions may be lifesaving. Fluid and electrolyte balance must be maintained in these horses in an attempt to prevent or minimize hemoglobin- or hypoxic-induced nephrosis.[2]

Nightshade (*Solanum* spp.)

Clinical Signs

A number of *Solanum* spp. have been incriminated in causing toxicity in horses. However, these plants rarely are a source of natural intoxication to horses. Reported clinical signs are associated with the gastrointestinal and central nervous systems. The primary gastrointestinal signs observed are salivation, abdominal pain, increased borborygmi, and diarrhea. Signs of central nervous system (CNS) dysfunction include mydriasis, dullness, depression, weakness, and progressive paralysis, which can lead to prostration and death.[2,9,10]

Pathophysiology

Solanine is a toxic substance found in *Solanum* species; it is a water-soluble glycoalkaloid capable of producing local

irritation[2,3,8] and is absorbed poorly from the gastrointestinal tract. Intravenous doses have been shown to cause ventricular fibrillation in rabbits, and intraperitoneal doses have caused mild to moderate inhibition of specific and nonspecific cholinesterase activity.[8] It has been shown that exposure to *Solanum* plants can potentiate the effects of ivermectin in horses.[11] It has been hypothesized that the neuronal cytoskeletal alterations with subsequent interference of the axonal development in Purkinje cells may play a relevant role in the pathogenesis of the cerebellar lesions noted in *Solanum*-intoxicated cattle.[12]

Diagnosis and Treatment

No specific diagnostic test is available to confirm a diagnosis of *Solanum* toxicosis. Microscopic evaluation of brain tissue post mortem may reveal cerebellar cortical degeneration with perikaryal vacuolations, axonal swelling, and death primarily of Purkinje cells.[12] Animals suspected of having toxicosis should be treated symptomatically and supportively. Evacuation of the gastrointestinal tract using laxatives and protectants may be indicated. Charcoal also has been recommended for treatment of toxicosis in human beings.[8] The clinician should monitor the fluid, electrolyte, and acid-base status of affected animals and make corrections as needed.

Jimsonweed, Thornapple (*Datura* spp.)

Clinical Signs

Several species of *Datura* grow throughout North America, all of which can produce signs of toxicosis in livestock. However, these plants are rarely a source of natural intoxication in horses, probably because of the unpalatability of the fresh plant.[9,10] One report of equine acute toxicosis resulted when ingested feed was contaminated heavily with jimsonweed seeds. According to this report, one horse was affected acutely and died because of gastric rupture and gas-filled intestinal loops. A second horse was treated for several days before being euthanized. Clinical signs observed in the treated horse included abdominal distention with gas-filled intestinal loops, prolonged ileus, mydriasis, tachycardia, hyperpnea, and dry mucous membranes.[13]

Pathophysiology

The toxic substances found in *Datura* spp. are the tropane alkaloids atropine (a racemic mixture of D- and L-hyoscyamine) and scopolamine (L-hyoscine).[9,10,13] These substances exert an antimuscarinic effect by competitive inhibition with acetylcholine for receptor sites, resulting in attenuation of the physiologic response of neuroeffector junctions to parasympathetic nerve impulses. Blockade of the muscarinic receptors of different tissues accounts for the various clinical signs observed.

Diagnosis and Treatment

Toxicity is suspected when animals exhibit signs compatible with atropine overdose (e.g., dilated pupils, tachycardia, dry tacky mucous membranes, decreased gut sounds). Identification of seeds or plant material in ingesta, gastric lavage contents, or feedstuffs may support a diagnosis. Treatment is largely symptomatic and includes immediate removal of the offending feed or plants, evacuation of the gastrointestinal tract, and supportive care. The use of pilocarpine and physostigmine to counteract the atropine-like effects of these alkaloids has been recommended by some, but this treatment is considered controversial.[9,10]

MISCELLANEOUS AGENTS

Dioctyl Sodium Sulfosuccinate

Dioctyl sodium sulfosuccinate (DSS) is an anionic surface active agent that has been used to treat constipation and intestinal impaction in horses. A recommended dose of DSS is 17 to 66 mg/kg, with a maximum dose of 200 mg/kg.[2,14]

Clinical Signs

Signs of overdose commence within 60 to 120 minutes in affected horses. Initial signs are restlessness and increased intestinal sounds accompanied by steadily increasing heart and respiratory rates. Abdominal pain, watery diarrhea, and dehydration become apparent soon afterward, and horses gradually deteriorate to lateral recumbency and death in 14 to 72 hours.

Pathophysiology

Much information about the pharmacologic action of DSS remains uncertain.[7] The primary organ of involvement is the small intestine, where epithelial denudation, villous atrophy, and submucosal edema and congestion occur. DSS has been suggested possibly to cause epithelial detachment by lowering the surface tension on the basement membranes of intestinal epithelial cells.[15] Once detachment occurs, loss of fluid and electrolytes into the intestinal lumen is possible. The absorptive capacity of the epithelium is lost, and the osmotic effect of intestinal content causes further loss of fluid into the lumen. With extensive mucosal damage, the horse also becomes much more susceptible to endotoxemia. The rapid death in affected animals is caused by hypovolemic shock, endotoxemia, and circulatory collapse resulting from the loss of fluids and electrolytes into the intestinal lumen.

Diagnosis and Treatment

Diagnosis of DSS toxicity depends on observation of the aforementioned clinical signs along with a history of oral DSS administration. No specific antidote for DSS exists, and once clinical signs commence, treatment is aimed at supporting circulation and combating the effects of systemic endotoxin. Specific treatment for circulatory collapse and endotoxemia is covered elsewhere, but medications that might be useful include electrolyte solutions, electrolyte supplementation, corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDs), bicarbonate, and orally administered gastrointestinal protectants.

Inorganic Arsenic

Arsenic is found in a number of products, including insecticides, herbicides, defoliants, older rodenticides, livestock dips, medications, wood preservatives, paint pigments, detergents, and certain insulation materials.[14,16] Horses are most likely to be exposed to arsenic by eating contaminated or treated forage or being exposed accidentally to stored or improperly discarded pesticides.[16] Horses cannot receive a significant exposure through cribbing on arsenic-treated wood. However, if arsenic-treated lumber is burned, ingestion of the arsenic-laced ash could be problematic.

Clinical Signs

The clinical signs associated with arsenic toxicity are essentially those of a severe gastrointestinal irritant. Most toxicities result from inorganic forms of arsenic, and signs are similar in all animal species.

In peracute cases the animals may be found dead with no premonitory signs. Acute signs of toxicity include severe colic, staggering, weakness, salivation, diarrhea that may contain blood or shreds of mucosa, and signs of shock that indicate cardiovascular collapse. Death usually occurs in 1 to 3 days.[14,16,17] In subacute poisoning animals may live for several days, exhibiting signs of depression, anorexia, colic, diarrhea that may contain blood and mucus, polyuria followed by anuria, and subsequent shock before death. Horses that are poisoned by topical application of arsenic can show signs of blistering and edema of the skin.[14] Chronic arsenic poisoning rarely occurs in domestic animals.

Pathophysiology

Many factors play a role in the development of arsenic toxicosis in horses. In general, horses that are debilitated, weak, or dehydrated are more susceptible to toxicosis than normal animals. The formulation of the compound (trivalent arsenicals are more toxic than pentavalent forms), the solubility of the compound, the route of exposure, the rate of absorption from the gastrointestinal tract, and the rate of metabolism and excretion by the individual animal are factors that can influence the toxicity of the various arsenic formulations.[14] The most hazardous preparations are products in which the arsenical is in a highly soluble trivalent form, usually trioxide or arsenite. Sodium arsenite is 3 to 10 times more toxic than arsenic trioxide. The average total oral lethal doses of these compounds for the horse are 10 to 45 g of arsenic trioxide and 1 to 3 g of sodium arsenite.[14,16]

Soluble forms of arsenic are absorbed from all body surfaces. Less soluble arsenicals are absorbed poorly from the gastrointestinal tract and essentially are excreted unchanged in the feces. After absorption trivalent arsenic is excreted readily by way of the bile into the intestine, and pentavalent arsenic is excreted by the kidney. Regardless of whether an introduced arsenical is in the trivalent or pentavalent form, all the major actions can be attributed to the trivalent form.[14]

All arsenicals are thought to exert their effects by reacting with sulfhydryl groups in cells, very similar to lead. Trivalent arsenic acts primarily by combining with the two sulfhydryl groups of lipoic acid, thereby inactivating this essential cofactor necessary for the enzymatic decarboxylation of the keto acids pyruvate, ketoglutarate, and ketobutyrate. By inactivating lipoic acid, arsenic inhibits the formation of acetyl, succinyl, and propionyl coenzyme A. The net effect is the blocking of fat and carbohydrate metabolism and cellular respiration.[14,16] Trivalent arsenic may inactivate sulfhydryl groups of oxidative enzymes and the sulfhydryl group of glutathione and other essential monothiols and dithiols. Arsenic also causes a local corrosive action on the intestine.[16]

Arsenic seems to prefer tissues rich in oxidative enzymes such as the liver, kidney, and intestine. The capillary endothelial cells in these organs appear sensitive to arsenic because it relaxes capillaries and increases capillary permeability. Blood vessels with smooth muscle in their walls also dilate. In the intestinal tract the mucosa easily sloughs away because of the accumulation of fluid in the submucosa. In the kidney renal tubular degeneration occurs.[16]

Diagnosis

The clinical signs described previously should cause the practitioner to consider inorganic arsenic poisoning. Antemortem laboratory findings are consistent with gastrointestinal, hepatic, and renal damage. Feces may contain blood, mucus, and increased numbers of white blood cells. The liver enzymes sorbitol dehydrogenase, lactate dehydrogenase (LDH), aspartate aminotransferase (AST), and γ-glutamyltransferase (GGT) may be increased in serum, and urine might contain protein, red blood cells, and casts. Urine arsenic concentration in affected animals often exceeds 2 parts per million (ppm), but this is highly variable.[14]

Postmortem findings are characteristic of severe gastroenteritis and may include hepatic lipidosis and necrosis. In horses in which arsenic poisoning is suspected, the liver, kidneys, stomach, intestinal contents, milk, blood, and urine should be evaluated for arsenic concentrations.

Treatment

Specific therapy for arsenic toxicity is dimercaprol (or British Anti-Lewisite [BAL]). This chelating agent forms a nontoxic and easily excretable complex with arsenic. However, BAL may mobilize stored arsenic in tissues and cause an initial exacerbation of clinical signs by allowing more arsenic to circulate to the intestine and liver. BAL also can be toxic in sufficient doses. Signs of overdose include tremors, convulsions, coma, and death. In horses one recommended dose is 3 mg/kg intramuscularly as a 5% solution in a 10% solution of benzyl benzoate in peanut oil. This dose is administered every 4 hours for the first 2 days, every 6 hours on the third day, and twice daily for the next 10 days until recovery.[16]

Sodium thiosulfate also has been advocated for treatment of arsenic toxicosis, but its efficacy is questionable. The recommended dose for horses is 20 to 30 g orally in 300 mL of water, plus 8 to 10 g intravenously in a 10% to 20% solution.[16]

Symptomatic care of affected animals includes evacuation of the gastrointestinal tract with laxatives and oral demulcents to coat the intestinal tract. The clinician should evaluate fluid, acid-base, and electrolyte indices and provide support if necessary. Aggressive intravenous fluid diuresis is advocated by many to maintain adequate hydration and enhance urinary arsenic excretion. Because endotoxemia may develop as a result of the intestinal and liver lesions, prophylactic administration of flunixin meglumine at a dosage of 0.25 mg/kg every 8 hours may be beneficial. Other therapy to prevent shock and cardiovascular collapse also may be indicated.

Aluminum

One report describes an unexpectedly high incidence of horses on the same farm showing clinical signs compatible with granulomatous enteritis and the presence of abnormally high levels of aluminum in various body organs and tissues of the affected horses.[17] Clinical signs included weight loss with or without diarrhea, hyperkeratosis, ulcerative coronitis, and neurologic deficits compatible with cervical stenotic myelopathy. Laboratory abnormalities included hypoalbuminemia and elevated serum concentration of alkaline phosphatase in some horses. All horses had histologic evidence of granulomatous inflammation of the gastrointestinal tract in varying degrees of severity and distribution. Granulomas occurred in the mucosa, submucosa, and serosa of the small and large intestines and in the abdominal lymph nodes, portal areas of the liver, and pancreas. Aluminum was found within granulomas, and elevated aluminum levels were present in kidney and liver tissue.

Chronic environmental exposure to aluminum was postulated as a cause for the condition. Environmental factors

(e.g., soil pH, moisture content, plants) may have an effect on the bioavailability of aluminum, and it has been suggested that repeated exposure may induce hypersensitivity to aluminum in these horses. In human beings aluminum is known to induce nonimmunologic (foreign body) and immunologic granulomas after administration of aluminum-containing vaccines and hyposensitization products.[18,19] The association between high environmental concentrations of aluminum and increased incidence of generalized granulomatous inflammation in horses warrants further investigation. This is a very rare clinical condition.

Petroleum Distillates

Horses can be exposed to excessive amounts of crude oil or petroleum distillates through contamination of rangeland with byproducts of the oil industry or by iatrogenic application, because petroleum distillates are used as carrier agents for many insecticides.

Clinical Signs

The most frequently noted signs associated with ingestion of petroleum products are essentially those of gastrointestinal and respiratory dysfunction. Petroleum products are irritating to mucous membranes, and hence prominent signs of gastrointestinal dysfunction might include salivation and fluid feces. The feces actually may contain oil or oily substances. Chronically affected animals also may exhibit anorexia and weight loss over several days to weeks.

Signs of respiratory dysfunction are a common manifestation of excessive petroleum exposure. Aspiration of the oil or fumes is irritating to pulmonary tissue, and aspiration pneumonia is probably the most serious consequence of petroleum toxicity.[14] Signs of toxicity include increased respirations, anorexia, depression, weight loss, a variable degree of fever, and possibly increased nasal discharge.

Products that are applied inadvertently to the skin might cause some degree of respiratory impairment, but they are more likely to cause signs related to the absorption of excessive hydrocarbons.[16] Topically applied agents also may cause signs associated with a contact irritant.

Pathophysiology

The toxicity of crude oil is correlated with the gasoline, naphtha, and kerosene content in the oil. Crude oil rich in these low-temperature distillates is more toxic than petroleum containing a great deal of sulfur but less of the low-temperature distillates.[16] Petroleum products are irritating to mucous membranes, and their oiliness makes them difficult to remove from skin and mucous membranes and virtually impossible to remove from the respiratory epithelium. Once aspirated, they serve as a focus for foreign body pneumonia that may progress to abscessing pneumonia, pleuritis and pleural effusion, and death.

Diagnosis

History of possible exposure, clinical signs, and pathophysiologic signs are important in establishing a diagnosis. Suspected contents (i.e., gastrointestinal content or feces) may be mixed with water, and any oil that is present will float to the surface and be readily visible. Analytic chemistry methods sometimes can be used to establish the identity of an oil, but this is challenging and few laboratories offer these analyses on a routine basis.[14]

Treatment

Treatment is supportive. The clinician should evacuate and protect the gastrointestinal tract by using laxatives and demulcents. Products applied to the skin can be removed with warm soapy water followed by thorough rinsing. Products such as mechanics' hand degreasers can be tried first to remove fat-soluble compounds. Aspiration pneumonia may be frustrating to treat, and supportive care such as fluids and electrolytes, NSAIDs, and broad-spectrum antimicrobial therapy is potentially helpful.

Slaframine

Slaframine is an indole alkaloid produced by *Rhizoctonia leguminicola,* a mold that infects red clover, alfalfa, and other legumes.[15,16,20] *R. leguminicola* is a ubiquitous soil fungus that infects certain legumes during conditions of high rainfall or humidity.[20] The toxin can survive and persist in dried and baled hay.[14]

Clinical Signs

The most consistently reported clinical sign is excessive salivation characterized by profuse, viscous, clear saliva.[20] Salivation may begin 30 to 60 minutes after eating the affected feed, and response from one feeding may persist for up to 24 hours or more. Other, less commonly reported clinical signs include anorexia, polyuria, and sometimes watery diarrhea.[14] One case of abortion in an affected mare has been reported.[20] Clinical signs generally abate 48 to 96 hours after the infected feed is removed from the diet.[14]

Pathophysiology

Slaframine apparently is activated by liver microsomes after absorption. The active compound seems to have direct histaminergic effects or possibly a histamine-releasing effect, which is borne out in laboratory animal studies in which clinical signs responded better to antihistamines than to atropine.[16]

Diagnosis

The combination of acute clinical signs of excessive salivation coupled with digestive disturbances and recognition of clover/alfalfa in the diet (and a positive response to removing the offending feed) is adequate to establish a diagnosis. It is possible to analyze slaframine in feeds, but usually such tests are unnecessary.[14]

Treatment

No specific treatment usually is necessary. Animals generally recover uneventfully 48 to 96 hours after withdrawal of the contaminated forage.[14] Atropine and antihistaminic therapies have been suggested to help control clinical signs,[14,16] but their efficacy is questionable.

Pentachlorophenol

Documented instances of horses becoming intoxicated with pentachlorophenol are rare. However, because pentachlorophenol was historically used as a wood preservative and because other domestic animals, including cattle and swine, have been poisoned, some aspects of this toxin require description. Exposure potentially occurs as a result of the horse drinking from a container containing pentachlorophenol or lying on recently treated lumber or contaminated soil.

The chlorophenols (which include pentachlorophenol) generally are not water soluble but are soluble in oils and

organic solvents.[16,21] Pentachlorophenol is volatile and can give off toxic vapors.[16] The chlorophenols are absorbed readily from the gastrointestinal tract, by inhalation, and from intact skin and are excreted rapidly by the kidney.[16,21]

Several factors affect the toxicity of chlorophenols. High ambient temperature, physical activity, poor body condition, oily or organic solvent vehicles, prior exposure, and hyperthyroid states enhance the toxicity in human beings and other animal species. Cold temperatures, antithyroid drugs, and increased amounts of body fat help diminish the toxicity.[16]

The mechanism whereby the chlorophenols exert their toxicity involves the energy production sites of mitochondria, where they uncouple oxidative phosphorylation. The chlorophenols act at sites of adenosine triphosphate (ATP) production to decrease or block their production without blocking the electron transport chain. Free energy from the electron transport chain then is converted to body heat. As the body temperature is increased, the heat-dissipating mechanisms are overcome and metabolism is increased. The electron transport chain responds by using more oxygen in an effort to produce ATP, but much of the free energy is liberated as more body heat. Eventually, the oxygen demand overcomes the oxygen supply, and energy reserves become depleted.[16]

Clinical Signs

Clinical signs, if observed, may include fever, tachycardia, dyspnea, sweating, lethargy, incoordination, weakness, cyanosis, collapse, and death. Less severely affected animals may primarily manifest signs of hyperthermia and oxygen deficiency.[16] Pentachlorophenol in high doses to pregnant animals also is reported to cause embryonic and fetal deaths but is not teratogenic.[14]

Diagnosis and Treatment

Pentachlorophenol toxicity has been associated with the combination of clinical signs and blood pentachlorophenol levels greater than 40 ppm. No specific treatment is available, but saline diuresis has been suggested to be helpful in certain instances of human toxicosis.[14]

Chlorates

Chlorate salts (sodium chlorate or potassium chlorate) are used as herbicides and defoliants. Horses may become exposed by grazing in recently sprayed areas or by ingesting sodium chlorate when it is mistakenly substituted for sodium chloride as a feed additive. Chlorate toxicity in any animal species is rare.

Clinical Signs

Initial signs are those of gastrointestinal irritation and include colic and diarrhea. Hematuria and hemoglobinuria also are present early in the disease course. Within hours the horse may show dyspnea, cyanosis, and increased respiratory effort. Death can occur suddenly, without obvious signs.[14]

Pathophysiology

Chlorates are absorbed readily from the intestine, and once absorbed they continue to exert their damaging effects as long as they are present.[14,16] A dose of 250 g is reported to be lethal to horses.[14]

Chlorates cause toxic changes by three different mechanisms of action:

1. Direct irritation of the gastrointestinal tract
2. Oxidation of hemoglobin to methemoglobin
3. Inducement of hemolysis

The net effect of methemoglobinemia and hemolysis is a severe compromise in the oxygen-carrying capacity of blood, and animals may be so severely affected that they die as a result of anoxia.[16]

Diagnosis

The prolonged, extensive methemoglobinemia found in affected animals should alert the veterinarian to the possibility of chlorate poisoning. A history of exposure to chlorates also should accompany these clinical signs before a presumptive diagnosis is made. Analysis of blood, urine, or ocular fluid can help determine chlorate concentration, and because chlorates normally are not found in animals, their presence in a sample would confirm poisoning if clinical signs, history, lesions, and response to therapy also suggest this diagnosis.[16]

Treatment

After making the diagnosis, the clinician should immediately seek out the chlorate source and remove it from the horse's environment. Methemoglobinemia is treated with methylene blue at a dose of 4.4 mg/kg given as a 1% solution by intravenous drip. This dose may be repeated in 15 to 30 minutes if a clinical response is not obtained.[2,16] Other recommended therapeutic measures include gastric lavage with 1% sodium thiosulfate and the oral administration of intestinal protectants and demulcents.[2,14] Blood transfusion and oxygen supplementation may be beneficial in certain instances.[16]

Pyriminil (Vacor)

Pyriminil currently is not commercially available, but in previous years it was marketed as a rodenticide. Reports of toxicosis in horses are rare,[22] and no deaths caused by pyriminil ingestion have been reported.[22,23]

Clinical Signs

Reported signs in affected horses include severe muscular fasciculation, profuse sweating, dehydration, and mydriasis with a weak pupillary response. Hindlimb weakness, ataxia, persistent inappetence, and abdominal pain also have been reported.[22] Hyperglycemia is a fairly consistent laboratory finding.[14,22]

Pathophysiology

Pyriminil is absorbed from the gastrointestinal tract and excreted in the urine. Pyriminil acts as a nicotinamide antagonist, but its exact mechanism of action is unknown.[2,14,23] Pyriminil also has been shown to damage the pancreatic β-cells and to depress glucose uptake by erythrocytes.

Diagnosis

A presumptive diagnosis is based on compatible clinical signs and history of exposure to the rodenticide.

Treatment

Specific therapy for pyriminil toxicity is reported to be nicotinamide. However, the use of this drug in human beings appears to be effective only when given within 1 hour of ingestion of pyriminil. The reported dosage is 50 to 100 mg of nicotinamide intramuscularly every 4 hours for up to eight injections. This dosage is followed by 25 to 50 mg orally 3 to 5 times daily for 7 to 10 days.[14] Other therapies that may be beneficial include gastric lavage and the oral administration

of mineral oil and activated charcoal.[14,23] Apparently, affected horses recover because no deaths caused by pyriminil toxicosis have been recorded.

Tetrachlorodibenzodioxin

The polychlorinated dibenzodioxins include a large number of isomers that differ chemically only in the number and location of chlorine atoms on the dioxin nucleus but that vary greatly in their toxic potential to various animal species. Of the 75 possible isomers of polychlorinated dibenzodioxin, the specific isomer designated 2,3,7,8-tetrachlorodibenzodioxin (TCDD; dioxin) is most toxic and generally is considered the most toxic synthetic molecule known. TCDD was once a contaminant of certain herbicides and is a byproduct of certain chemical manufacturing and combustion processes.[14] It can also be found in soil as a naturally occurring compound or as a result of contamination by industrial waste. Dioxins have been found in ball clay that had been used as a binding agent for livestock feed. Currently, dioxins are more of a tissue residue issue for production animals than a toxicologic hazard for livestock. The chemical is a highly stable contaminant in the environment, with a half-life in soil of approximately 1 year.[24]

Clinical Signs

In one reported outbreak the initial signs began 4 days after exposure and included abdominal pain, polydipsia, anorexia, severe weight loss, alopecia, skin and oral ulcers, conjunctivitis, dependent edema, joint stiffness, and laminitis. A total of 85 horses were exposed, 58 became ill, and 43 subsequently died. The length of illness varied from 4 to 132 weeks in the terminally ill horses, with those having a heavier exposure exhibiting a shorter disease course (average of 32 weeks) than others (average of 74 weeks). In addition, abortions occurred in pregnant mares, and many foals that were exposed only in utero died at birth or shortly thereafter.[24] Other reported signs in animals included gastrointestinal hemorrhage with necrosis and ulceration of the gastrointestinal mucosa, cerebrovascular hemorrhage, hepatotoxicity, and thymic and peripheral lymph node atrophy.[14,24]

Pathophysiology

TCDD is absorbed readily by oral and dermal routes, and following absorption appears to be retained primarily by liver and adipose tissue. The mechanism of action of TCDD in various organs in not well defined. TCDD is known to induce microsomal mixed function oxidases in liver and kidney, and hepatic δ-aminolevulinic acid synthetase and aryl hydrocarbon hydroxylase, but the role of these processes in the induction of toxicity of TCDD remains to be elucidated.[14] TCDD also induces immunosuppression by causing thymic and peripheral lymph node atrophy.

Diagnosis

A combination of the described clinical signs and possible exposure to industrial waste oil products should alert the veterinarian to the possibility of TCDD toxicity. Dioxin content is confirmed in various tissues by means of gas-liquid chromatography and mass spectroscopy, but few laboratories offer this service, and the analysis is generally expensive.[14]

Liver lesions observed at necropsy in a number of horses included were microscopic evidence of bile stasis, hepatocyte necrosis, bile duct proliferation, and extensive fibrosis that was pronounced around the central veins but minimal in the peripheral liver lobules. Other microscopic changes noted were thickened vascular walls and endothelial proliferation in the smaller blood vessels of several different organs.[24]

Treatment

No known antidote exists for TCDD toxicity once clinical signs develop. After their onset, the clinician can offer only symptomatic and supportive care, and one should use every precaution to prevent laminitis. Activated charcoal appears to bind strongly to TCDD and inhibit its absorption, so if known ingestion has occurred, immediate oral administration of activated charcoal may have beneficial effects by reducing the amount absorbed.[14]

Cantharidin Toxicosis (Blister Beetle Toxicosis)

Cantharidin toxicosis results from ingestion of dead blister beetles that become entrapped in hay during harvesting. Essentially all reports are of horses being fed alfalfa hay or alfalfa products, but anecdotal reports exist of horses intoxicated by ingesting grass hay. More than 200 species of blister beetles inhabit the continental United States, but toxicity results primarily from beetles of the genus *Epicauta*.[25] Depending on the species of beetle, as few as a half dozen ingested beetles can be problematic. The liquid form of cantharidin is suspected in the malicious poisoning of horses.

Cantharidin is the sole toxic principle and is contained in the hemolymph, genitalia, and possibly other tissues of the beetle. Cantharidin is a highly irritating substance that causes acantholysis and vesicle formation when in contact with skin or mucous membranes, and the substance is absorbed from the gastrointestinal tract and rapidly excreted by the kidney. Storage of hay does not appear to reduce the toxicity of cantharidin.[25]

Clinical Signs

The signs associated with toxicosis are many, varied, and dose dependent. Horses affected with a minimal dose may show only signs of lethargy, anorexia, and occasionally polyuria, whereas horses ingesting a lethal dose may show signs of profound shock, gastrointestinal and urinary tract irritation, myocardial dysfunction, and hypocalcemia/hypomagnesemia.[25,26] The onset and duration of clinical signs vary from hours to days, but horses that succumb to cantharidin generally die within 48 hours of onset of signs. Horses that live longer than 48 hours have a better prognosis for recovery if no complications arise.

The most commonly observed clinical signs include varying degrees of abdominal pain, anorexia, lethargy, and repeatedly submerging the muzzle in water or frequently drinking small amounts of water. The respiratory and cardiac rates are elevated, and cardiac contractions are occasionally forceful enough to be observed through the thoracic wall. Mucous membranes are congested and cyanotic, and capillary refill time is prolonged. The feces may be watery in consistency but rarely contain blood or mucus. Profuse sweating is typical of more severely affected horses and may be a sign of severe abdominal pain. Affected horses often make frequent attempts to void urine. The urine is grossly normal early in the disease course but later may become tinged with blood or contain clots of blood. Gross hematuria, if it occurs, is usually in the later stages of the disease process. Less commonly observed signs include synchronous diaphragmatic flutter; erosions of

the gingival and oral mucous membranes; and occasionally a stiff, short-strided gait similar to that seen in acute myositis. Sudden death also has been reported.[25]

Pathophysiology

The mechanism of action of cantharidin at the cellular level has not been elucidated fully. Acantholysis and vesicle formation result from disrupted cell membranes. Cantharidin does not have a direct effect on membranes but is thought to interfere with oxidative enzymes bound to mitochondria. These enzyme systems are involved directly in active transport across the plasma membrane, and their failure results in cell death caused by significant permeability changes in the cell membrane.[25]

Hypovolemic shock and pain develop rapidly in more severely affected horses. The normal transfer of fluid, nutrients, and electrolytes across the intestinal mucosa is disrupted because of the morphologic changes induced by cantharidin. Although renal tubular damage is not severe enough to cause death, changes in the renal tubular epithelium also may be related to the development of fluid, acid-base, and electrolyte abnormalities.[25,26]

Hypoproteinemia develops later in the disease course, probably as a result of protein loss across the damaged intestinal mucosa. Protein also is lost into the peritoneal space, and a minor amount may be lost through the urine.[25]

The profound hypocalcemia and hypomagnesemia that may occur in many horses have not been explained fully. Calcium loss, derangement of calcium homeostasis, or a combination of both is the most likely explanation because the acute onset of the disease eliminates reduced intake as a possible cause. Calcium can be lost through urine and sweat and as protein-bound calcium through the damaged intestinal wall. An influx of intracellular calcium also may occur in certain tissues. Whether cantharidin has an effect on calcium-binding sites on proteins or in cells is unknown.[25]

The low urine specific gravity in most horses may be caused by decreased permeability of the collecting ducts to water. Other findings, however, point to a mild pathologic insult as a cause of the low urine specific gravity. These findings include the facts that a low specific gravity occurs suddenly within hours of toxin exposure; specific gravity returns to normal in 2 to 4 days in surviving horses; only mild to moderate changes are noted in other renal function tests; and the histologic renal lesions are mild, and neither acute nor chronic renal failure is associated with cantharidin toxicosis in horses.[25]

Myocardial necrosis can be observed post mortem in affected horses and may be caused by the direct effect of cantharidin on cardiac muscle. Dose-related intracellular changes involving the mitochondria, cristae, nuclear chromatin, sarcoplasmic reticulum, and myofibrils have been observed in the cardiac muscle of rabbits that were given cantharidin. A proposed mechanism for these changes suggests that an excessive transport of calcium into the myocardial cells occurs, leading to an intracellular calcium overload. This overload may result in a high-energy phosphate deficiency within the cell, leading to necrosis and cell death.[25]

Diagnosis

The clinician should consider cantharidin toxicosis when horses exhibit signs of abdominal pain, lethargy, or polyuria and their diet contains alfalfa hay or alfalfa products. The diagnosis can be made when horses have clinical signs and laboratory findings compatible with cantharidin toxicosis and beetles are found in the hay. Because the beetles can be difficult to identify in hay, it should be thoroughly searched. Cantharidin can be assayed using various techniques.[25,27] Samples to be tested are serum, urine, kidney, and stomach content from horses in which cantharidin toxicosis is suspected.

Laboratory findings are nonpathognomonic, but several abnormalities typically are noted. Packed cell volume (PCV) and serum protein concentrations are elevated early, but hypoproteinemia frequently develops after about 24 hours. Mild hypokalemia can occur but is not a striking feature of this disease. Blood urea nitrogen (BUN) concentration may be elevated moderately, and hyperglycemia is almost always present initially.[25]

Serum calcium and magnesium concentrations can be significantly decreased in some horses and remain low for longer than 48 hours if untreated. The urine generally contains red blood cells and has a low specific gravity, even in the face of clinical dehydration. Abnormal peritoneal fluid findings include increased protein concentration but relatively normal fibrinogen and white blood cell values. Feces are often positive for occult blood. Serum creatine kinase (CK) activity may be elevated in more severely affected horses and augurs a poor prognosis.[25] Although not diagnostic, laboratory findings of prolonged hypocalcemia and hypomagnesemia and elevated CK concentration may help differentiate cantharidin toxicosis from other causes of acute abdominal crisis.

Treatment

No specific antidote is available for cantharidin. Once the diagnosis is suspected, all suspect feed should be removed from the horse's environment and all hay carefully examined for the presence of beetles.

Horses suspected of having cantharidin toxicosis should be given mineral oil as soon as possible. The oil helps evacuate the bowel and also may help reduce the amount of cantharidin available for absorption because cantharidin is lipid soluble. Activated charcoal given through a nasogastric tube also may have beneficial effects.[25]

Fluids should be administered intravenously throughout the disease course to correct dehydration and promote diuresis. Diuretics also may be given once the horse is volume loaded. Analgesics usually are required because of the severity of the abdominal pain, and glucocorticoids may be necessary to aid in treating shock. Calcium gluconate should be administered to elevate the serum calcium concentration, and calculated deficits of magnesium should be replaced by slow intravenous infusion.[25]

Phosphorus

Elemental phosphorus can be available in red and white forms. Red phosphorus is used in manufacturing fertilizers and safety matches and is considered inert and relatively nontoxic. White phosphorus was used as a rodenticide and can be found in pastes containing from 1.5% to 5% phosphorus. The reported toxic dose for horses is 0.5 to 2.0 g.[14] This is a rare toxicosis in livestock.

Clinical Signs

The toxic manifestations of phosphorus poisoning are generally threefold: toxic signs commence within hours of ingestion; are followed by a latent period of 48 hours to several days, when the animal may appear to have recovered; and finally recur with greater severity.

The initial signs are characterized by severe abdominal pain and gastrointestinal irritation, with occasional episodes of diarrhea. Blood may be present in feces. Cardiac arrhythmias may occur during this phase, and if the dose is sufficiently large, cyanosis, shock, incoordination, and coma can develop, and the animal may die before the second and third stages develop.[14]

The latent period may occur from 48 to 96 hours after the onset of clinical signs, and during this time the animal may appear normal. The third stage is characterized as a recurrence of severe abdominal pain, and signs of liver dysfunction may become evident. Icterus and a tendency to bleed from the gingiva, stomach, intestine, or kidney may be evident.[14]

Pathophysiology

Phosphorus is absorbed from the gastrointestinal and respiratory tracts. Although dermal exposure may cause skin irritation or burning, absorption does not occur by this route. The mechanism of action of phosphorus is unknown but is noted for causing irritation and necrosis of affected tissue. Phosphorus is also known to cause peripheral vasodilation.[14]

Diagnosis and Treatment

Clinicopathologic abnormalities reflect hepatic and renal damage. Hypoglycemia may be pronounced, and liver enzymes such as AST, LDH, and sorbitol dehydrogenase are elevated. Renal damage is reflected by increased BUN and creatinine concentrations. Albumin, blood, and increased concentrations of amino acids may be present in the urine. The phosphorus concentration in blood is usually normal. Although elemental phosphorus in tissues can be assayed, in time a large portion may be oxidized to phosphates, thereby making confirmation of poisoning difficult by chemical means.[14]

No specific antidote is available for phosphorus intoxication. Therapy is essentially symptomatic and supportive.

Thallium

Thallium is toxic to all animals, including human beings, but clinical reports of toxicity are extremely rare. However, an oral dose of thallous acetate 27 mg/kg has been suggested as potentially lethal to horses.[16] Thallium has been used historically as a rodenticide, but its use now is limited and restricted only to government agencies.

Clinical Signs

Thallium ingestion can result in acute, subacute, or chronic syndromes. In the acute form clinical signs in animals usually begin within 1 to 4 days of ingestion. Initial signs are those of severe gastrointestinal insult and include vomiting or regurgitation, severe hemorrhagic diarrhea, abdominal pain, and anorexia. Labored breathing is apparent early in the disease course, and motor paralysis and trembling may occur. Signs suggesting renal dysfunction also may occur.[14]

The subacute form generally manifests signs in 3 to 7 days after ingestion. Signs of gastric distress and motor disturbances are less marked than in the acute form, but they persist for a longer time. In this form reddening of the skin and pustule formation occur. A pronounced reddening of the oral mucous membranes also seems to be unique to this particular toxicosis. Other clinical signs observed include conjunctivitis, hair loss, and crusty skin lesions. Secondary bacterial infections also may develop in affected animals.[14]

The chronic stage requires 7 to 10 days to appear. Signs of gastrointestinal and nervous system dysfunction are mild, but hair loss and dry, scaly skin become pronounced.[14]

Pathophysiology

Thallium is absorbed readily from the intestinal tract or through the skin; is distributed to all body tissues, although higher levels accumulate in the kidneys and liver; is excreted principally in feces and to a lesser extent in urine; and undergoes an enterohepatic cycle for resorption and excretion.[16]

Thallium is thought to combine with mitochondrial sulfhydryl enzymes at a specific yet unknown place in the scheme of sulfur metabolism. Thallium therefore interferes with oxidative phosphorylation within cells. Some evidence suggests that thallium exchanges for potassium in muscle and nerve cells primarily and also has a necrotizing effect on the intestinal tract, kidney, and occasionally the brain.[14,16]

Diagnosis

Thallium toxicosis is suspected on the basis of clinical signs, and urine can be assayed for thallium content. The finding of thallium in tissue in any amount is diagnostic, but liver and kidney levels tend to be higher than in other tissues.

Treatment

Chelation therapy using diphenylthiocarbazone (dithizon) at a dosage of 70 mg/kg administered orally thrice daily has been recommended for use in dogs.[14] However, cats react adversely to this agent. Its effect in horses is unknown.

Potassium chloride may aid in the elimination of thallium and can be given intravenously or orally, but the oral route is contraindicated in animals that also are being treated with an ion exchange agent.

One can attempt to trap thallium in the intestine with the ion exchange agent potassium ferric cyanoferrate–II (potassium–Prussian blue). Experimentally, potassium–Prussian blue is not absorbed from the intestinal tract and acts to immobilize the thallus ion by exchanging with the potassium of potassium–Prussian blue. Once trapped, thallium is not released readily from potassium–Prussian blue, and fecal excretion of thallium increases.[16]

Other forms of symptomatic therapy include intestinal protectants and demulcents, fluid and electrolyte support, analgesics, oral activated charcoal, and general nursing care.[16]

Toxicoses Causing Signs of Central Nervous System Stimulation

Dealing with horses showing signs of CNS stimulation can be one of the most difficult and challenging situations faced by the equine veterinarian. Signs can be hard to control, and clients' emotions often run high at the sight of a horse showing severe or uncontrollable signs such as hyperexcitability, exaggerated gait abnormalities, and seizures. The immediate clinical emphasis is usually on minimizing the risk or severity of self-induced trauma. Etiologic diagnosis may be difficult and protracted.

PLANTS

Locoweed

A nervous syndrome in horses, cattle, and sheep has long been associated with eating plants of the genera *Astragalus, Swainsona,* and *Oxytropis.* This group of plants is large. The *Astragalus* species that grow in North America number more than 300. Not all species of *Astragalus* and *Oxytropis* are toxic, however, and some species make nutritious forage for livestock.[28]

The toxic species of locoweed produce three different syndromes in livestock. Some species contain nitroglycosides, which cause methemoglobinemia and competitive inhibition of certain cellular enzymes; others accumulate toxic levels of selenium; and a third group contains alkaloids that cause locoism.[28,29] The first group of plants is of minor importance to the horse, and the selenium concentrators are discussed in the section on selenium toxicosis. A discussion of the clinical syndrome locoism follows.

The species of locoweed that have been associated with locoism include *Astragalus lentiginosus, Astragalus mollissimus, Astragalus wootonii, Astragalus thurberi, Astragalus nothoxys, Oxytropis sericea, Oxytropis lambertii,* and *Oxytropis saximontana.*[28] Additional *Astragalus* species incriminated in causing disease include *Astragalus argillophilus, Astragalus bisulcatus,* and *Astragalus earlei.*[28] Geographically, locoweeds are found from western Canada southward to include the western United States and northern Mexico.[28]

Clinical Signs

Locoweeds cause a number of problems in livestock, including neurologic and reproductive dysfunction, emaciation, and habituation.[28] Typical signs exhibited by affected horses include a slow, staggering gait; lethargy; an unthrifty appearance; emaciation; muscular incoordination; and nervousness, especially when the animal is under stress. The affected horse may become solitary and hard to manage and may have difficulty eating and drinking. In some animals sexual activity may become suppressed. Visual impairment also occurs in some horses, and mares ingesting locoweed during pregnancy have been known to abort or produce foals with various limb deformities.[29,30] Horses that are affected chronically are generally useless for riding or draft purposes because their behavior is so unpredictable.[28]

The onset of clinical signs varies from as short as 2 to 4 weeks to as long as 2 months after the horse starts to graze the plant. Some of these plants are considered unpalatable to horses, but once they start to ingest the plant, they seem to become addicted to it and will search it out.[28] The addiction can extend to subsequent growing seasons, so clinical signs can worsen progressively in successive years if animals continue to graze the plant.[29] Affected horses can recover if feeding or grazing is discontinued before they become too emaciated and if nutritious forage is provided.[28] However, the syndrome eventually may lead to death in chronically affected horses.[29]

Pathophysiology

The indolizidine alkaloids swainsonine and swainsonine *N*-oxide have been suggested as the toxic principles in locoweeds.[29] These alkaloids were first recovered from *Swainsona* species in Australia.[28,29] Evidence suggests that these alkaloids are actually mycotoxins, or toxins produced by endophytes located within the plant. Swainsonine inhibits α-mannosidase, a lysosomal enzyme essential in the cellular metabolism of oligosaccharides. As a result, mannose-rich oligosaccharides accumulate in lysosomes and disrupt cellular function. These accumulations are visible microscopically as intracytoplasmic vacuoles. Vacuolization of the renal cortical tubular cells can occur as early as 4 days after ingestion of locoweed begins, and neurons of the CNS, including Purkinje cells, may show vacuolization by 8 days. The vacuoles disappear shortly after consumption ceases in the early stages of disease, but if grazing is prolonged, permanent cellular damage occurs. Continuous feeding of the plant for 30 days or longer results in vacuolization of almost all tissues of the body except skeletal and cardiac muscle.[29]

Neurologic signs result from vacuolization of the axons, glial cells, and Purkinje cells of the cerebellum and cerebral cortex. The weight loss and emaciation result from impairment of the liver, pancreas, thyroid, and parathyroid glands. Vacuolization of cells of the retina and decreased lacrimation are responsible for impaired vision in some animals. Vacuoles also occur in lymph nodes, placenta, testicles, and lymphocytes.[28,29] The pathogenesis and lesions of locoism are similar to mannosidosis, a heritable lysosomal storage disease of Angus and Murray Grey cattle.[29]

Diagnosis and Treatment

A few laboratories test for swainsonine and mannosidase activity in a variety of biologic specimens. The diagnosis is suspected when horses show clinical signs compatible with locoism and have a history of exposure to the plant. Laboratory testing is nonspecific, and test results are expected to be consistent with multiple organ dysfunction. Microscopic lesions of intracytoplasmic vacuolization in various organs, including the CNS, are compatible with a diagnosis of locoism.[28,29] Peripheral lymphocytes that contain intracytoplasmic vacuoles also are considered indicative of locoism, if clinical signs are present.[29]

No effective cure exists for horses with chronic locoism that have had clinical signs for some time. Mild cases usually resolve in 1 to 2 weeks once ingestion ceases, so successful recovery from locoism depends on early recognition of the disease syndrome and prevention of further consumption. Reserpine has been suggested to be helpful in relieving some of the clinical signs of locoism in horses.[29]

Nervous Ergotism

Two forms of ergotism are observed in domestic animals, a nervous or convulsive form (rare) and a gangrenous form. Horses appear rarely to be affected with ergotism (in the United States, cattle and swine appear to be most commonly affected), but the nervous form is reported to occur much more frequently in horses than the gangrenous form.[31,32] Ergotism is caused by a number of alkaloids contained in *Claviceps purpurea,* a fungus infecting grains such as wheat, barley, rye, and oats and wild grasses such as quackgrass, smooth bromegrass, wheatgrass, bluegrasses, and wild rye. The fungal mass, or sclerotium, replaces the seed or kernel of the plant and may have the same general configuration as the seed but is usually larger, dark colored, and hard. Ergotism is rarely of concern in dry seasons, but abundant fungal growth can occur during wet periods.[4] Although well-documented cases of ergotism caused by *C. purpurea* in horses are absent in the literature, a nervous syndrome typical of *Claviceps paspali* poisoning has

been observed in horses in Australia. However, the cause of the clinical signs in these horses was suggested to have been the tremorogenic mycotoxins in *C. paspali* rather than the alkaloids found in ergot.[33]

Clinical Signs

The first sign of nervous ergotism in animals is reported to be dizziness or an unsteady gait. This phase may be interrupted by convulsions and temporary posterior paralysis and drowsiness.[31] Other behavioral effects that have been described include incoordination, lameness, difficulty in breathing, excessive salivation, and diarrhea.[32]

Pathophysiology

Approximately 40 different alkaloids have been isolated from *C. purpurea*. All of these alkaloids are derivatives of the tetracyclic compound 6-methylergoline, a lysergic acid base structurally similar to a number of biogenic amines such as dopamine, serotonin, and norepinephrine.[31,34] The most pharmacologically potent alkaloids in ergot are ergonovine, ergotamine, ergotsine, ergocristine, ergocryptine, and ergocornine.[31] Additionally, tyrosine, tryptophan, tyramine, histamine, histidine, choline, and acetylcholine have been isolated from ergot sclerotia, but their clinical significance is uncertain.[34]

The mechanism whereby ergot alkaloids induce CNS signs in horses has not been elucidated. Of the ergot alkaloids known to affect the CNS in human beings, bromocriptine is the prototype. Bromocriptine is a long-acting dopamine agonist that has central stimulating effects and may cause hypotension. Another ergot alkaloid, isoergine (lysergic acid amide), has one tenth the mind-altering potency of the structurally related compound lysergic acid diethylamide (LSD). LSD is thought to produce hallucinations by a series of complex agonist and antagonist actions on several central monoamine neurotransmitters, particularly serotonin.[34]

Diagnosis and Treatment

The diagnosis of nervous ergotism in horses is based primarily on clinical signs and eliminating other causes of CNS stimulation. One can assay the ergot alkaloid content of the suspect feed.[31]

No specific antidote exists for ergot alkaloid toxicity. Treatment of affected horses is largely symptomatic. Recommendations for control include using ergot-free feed, rotating crops, plowing deeply (because shallow cultivation and seeding leave the sclerotia near the soil surface, where they can germinate more readily), and mowing surrounding grasses to limit the spread of fungus into the cultivated crop.[32] Pasture grasses that may be infested with ergot should be mowed before the development of seed heads because *Claviceps* replaces the seed or kernel of the plant.

Blue-Green Algae (Cyanobacteria)

The occurrence of cyanobacterial poisoning in livestock is not uncommon in many areas. Most cases of toxicity involve other grazing animals, principally cattle and sheep, but horses are reported to be susceptible.[35] Toxicity may occur during times that favor algal growth in surface water. The most important factors that favor rapid algal growth are a nutrient source (e.g., nitrogen, phosphate, sulfate); quiet, calm weather conditions; and warmish water temperature. Therefore toxicosis is most likely to occur during periods of warm weather (i.e., late spring through fall), when surface water may be contaminated with fertilizer runoff or organic waste high in nitrogen, such as that from feedlots.[35,36] However, it is important to note that livestock toxicities caused by cyanobacteria have been reported in the winter months in the Northern Hemisphere. In more temperate areas cyanobacterial blooms can be a year-round occurrence.

Many genera of cyanobacteria are known to be toxic: *Anabaena, Aphanizomenon, Microcystis (Anacystis), Coelosphaerium, Cylindrospermopsis, Gloeotrichia, Lyngbya, Nodularia, Planktothrix (Oscillatoria), Nostoc, Raphidiopsis,* and *Umezakia;* however, the first three are of most concern in veterinary medicine. Toxins produced by cyanobacteria are either neurotoxic or hepatotoxic; therefore signs of poisoning are typically neurologic or hepatic, but rarely both are observed in an animal (even though some blooms are mixed). Most blooms are composed of one predominant cyanobacterial organism. *Microcystin (Anacystin)* organisms produce the hepatotoxin microcystin, and *Anabaena* and *Aphanizomenon* produce the neurotoxins anatoxin-a and anatoxin-a(s).

Clinical Signs

Common signs of cyanobacterial poisoning associated with microcystins may include rapid appearance of abdominal pain, diarrhea, muscle tremors, dyspnea and cyanosis, prostration, and death. Animals surviving several days may exhibit hemorrhagic diarrhea, muscle tremors, signs of liver damage, and secondary photosensitization.[35,36] Animals exposed to neurotoxic blooms frequently develop signs within a few minutes (less than 1 hour) of ingestion and may show rapid onset of CNS dysfunction with seizures, prostration, and death.

Pathophysiology

Anabaena and *Aphanizomenon* species may contain the low-molecular-weight alkaloid anatoxin-a. This toxin mimics the action of acetylcholine. Death results from respiratory arrest. Blooms of some *Aphanizomenon* species may produce small amounts of the neurotoxin (saxitoxin) and at least three related toxic compounds of unknown structure.[34,35] Saxitoxin blocks sodium conductance through excitable membranes, which subsequently stops nerve action potential. Death resulting from saxitoxin is caused by respiratory neuromuscular paralysis.[35] Anatoxin-a(s) can also be produced by these organisms, whose action is to inhibit acetylcholinesterase activity. *Microcystis* species of cyanobacteria can produce the cyclic hepatotoxin microcystin.[34,35] The immediate cause of death is hemorrhagic shock resulting from massive hepatocellular necrosis and collapse of the hepatic parenchyma.[37]

Diagnosis and Treatment

Analytic methods are now available that can isolate and identify the cyanobacteria organism and the toxins from affected animals (gastric contents, liver) or suspect water. Because the concentrations of cyanobacteria and toxins can vary tremendously over a short time, recovery of the organism or toxin from water may not be possible when clinical signs are noted in exposed animals. A diagnosis can be based on history of exposure to a water source when conditions favoring cyanobacterial overgrowth are present, coupled with onset of compatible clinical signs and analysis of tissues and water for the toxin. One can analyze water samples to identify specific blue-green algae, the presence of which may help support a diagnosis of algal toxicity if toxin testing is not feasible.[35]

No specific antidote is available, and animals often are found dead before treatment can be initiated.[35] Algal growth in surface water can be controlled by a variety of herbicides and copper sulfate. When water is treated with these compounds, it is important to ensure that the compounds are being used in a safe manner for all susceptible livestock.

PESTICIDES

Cholinesterase-Inhibiting Insecticides

The cholinesterase-inhibiting carbamate pesticides are composed of cyclic or aliphatic derivatives of carbamic acid, and numerous ones are commercially available.[35,38] A partial list of these compounds includes carbaryl, aldicarb, carbofuran, methiocarb, methomyl, and oxamyl. Carbamates are absorbed readily through the lungs, gastrointestinal tract, and skin. Carbamates do not accumulate in any particular tissue but do cross the rat placenta and depress fetal acetylcholinesterase; they are not metabolized readily in the fetus.[38] In human beings the carbamates generally penetrate the blood-brain barrier poorly and therefore may produce few CNS signs.[34] Carbamates do not require activation by liver enzymes to exert their effect. Toxicity data are not complete for several domestic animals, but lethal doses of the different compounds vary from less than 1 mg up to several hundred mg/kg of body weight. Carbamates are not stable in the environment and are fairly insoluble in water, but organic solvents and oils can carry the compounds across cell barriers.[38] It is important to note that not all so-called carbamate pesticides inhibit cholinesterase activity, so the clinician must determine exactly which carbamate compound the animal is exposed to and determine its mechanism of action.

Clinical Signs

Clinical signs can commence a few minutes to several hours after exposure, depending on the exposure scenario. The clinical episode frequently is less than 36 to 48 hours in duration, with the animal succumbing or recovering during this time.[35,38]

Signs of toxicity in horses reflect muscarinic and nicotinic cholinergic overstimulation. The signs suggestive of muscarinic cholinergic overstimulation include profuse salivation, severe gastrointestinal disturbances characterized by hypermotility, severe pain, abdominal cramps and diarrhea, excessive lacrimation, miosis, sweating, dyspnea, cyanosis, and urinary and fecal incontinence. Affected animals also may cough frequently as a sign of excessive accumulation of respiratory tract secretions. The signs reflected by nicotinic overstimulation include excessive stimulation of the skeletal muscles. The muscles of the face, eyelids, and tongue, in addition to the general musculature, may twitch. Some animals exhibit signs of generalized tetany that causes them to walk in a stiff-legged fashion. This hyperactivity may be followed by weakness and paralysis of the skeletal muscles.[35]

Signs of CNS involvement in domestic food-producing animals may include hyperactivity reflecting excessive stimulation of the CNS, but domestic animals rarely exhibit convulsive seizures (however, this can occur at high dose exposures). CNS depression is reported to be more common than CNS stimulation.[35]

Pathophysiology

Carbamates induce excessive stimulation of the parasympathetic nervous system by inhibiting acetylcholinesterase and pseudocholinesterase. The carbamate pesticides occupy the anionic and esteratic sites of acetylcholinesterase, with the esteratic site being carbamylated. Acetylcholinesterase can hydrolyze carbamate pesticides but at a slower rate than that for acetylcholine. Therefore carbamates are reversible inhibitors of acetylcholinesterase, but toxicosis occurs when the amount of pesticide is large enough that the rate of carbamylation of acetylcholinesterase exceeds the rate of hydrolysis of pesticide by the enzyme.[38] As a result, acetylcholine accumulates in neuroeffector and synaptic regions, resulting in the observed clinical signs of parasympathetic overstimulation.

The continuous stimulation of secretory glands leads to excessive salivation and accumulation of fluid within the respiratory tract and within the lumen of the bowel. Extensive pulmonary edema may occur and, along with bronchoconstriction, can lead to death in affected animals.[35]

Carbamates are removed from the circulation largely by spontaneous hydrolysis of the carbamate-cholinesterase complex. In addition, blood esterases can inactivate a portion of the circulating carbamate, and certain liver microsomal enzymes break down the compounds within hours of exposure.[34,38] The clinical signs associated with carbamate toxicity are generally rather short-lived, with recovery occurring in less than 36 to 48 hours in most animals.

Diagnosis and Treatment

The clinician is most likely to make a diagnosis on the basis of a history of possible exposure, clinical signs, and response to atropine treatment. Chemical analyses of biologic samples for carbamate residues can be rewarding; finding the pesticide in stomach contents, the liver, or feed samples may confirm the diagnosis.[35]

Cholinesterase activity in blood and brain tissue can also be used as a screening tool to determine exposure to this group of compounds (false inhibition can be observed if the patient is anemic). However, discretion must be used when interpreting these results because recommended therapeutic levels of carbamates applied to animals can result in some depression of blood cholinesterase activity. Because of the reversibility of the binding, one cannot rule out a carbamate exposure if the cholinesterase activity is determined to be normal. In one author's opinion, clinical signs of acute carbamate toxicity are associated with blood cholinesterase activity of less than 50% to 75% of normal values. Because the inactivation of cholinesterase by carbamates involves a much weaker and less stable binding than that by organophosphates, one should not dilute blood samples from suspect animals and should refrigerate them and analyze them as soon as possible.[35]

Affected animals should be treated as quickly as possible. Initial therapy should consist of atropine sulfate at 0.2 mg/kg of body weight. This initial dose should be divided, with approximately one fourth of the dose administered intravenously and the remainder given subcutaneously or intramuscularly. Repeated doses of atropine may be required but should be used only to counteract the parasympathetic signs. The skeletal muscle tremors may not respond to atropine therapy.[35]

Orally administered adsorbents such as activated charcoal may be useful in binding ingested pesticide, and aqueous cathartics may further aid in evacuation of the intestinal tract. Mineral oil probably should not be given orally in suspect

cases because organic solvents and oils may carry the compound across cell barriers. Dermally exposed animals should be washed with soap and water and rinsed thoroughly to prevent further exposure. Oximes such as pralidoxime are of questionable benefit in treating carbamate toxicosis, and their use may worsen the condition of the animals.[35,38] The cost of these drugs may be a prohibiting factor in their use in horses.

Organophosphates

The organophosphate pesticides are being used increasingly in a variety of ways. Some of the typical uses for these compounds include animal insecticides and parasiticides; plant insecticides, soil nematocides, fungicides, herbicides, and defoliants; insect repellents; and chemosterilants.[38] Horses can become intoxicated in several ways because these products are used so commonly in their environment.

A wide variety of organophosphorus compounds have been developed, and their toxicity varies greatly among compounds and among animal species. Osweiler et al.[35] have tabulated a good list of various organophosphorus compounds and their relative toxicities. In addition to variations in compound toxicity, a number of physicochemical factors also can affect the toxicity of organophosphorus compounds. The toxicity of these compounds decreases as they are degraded by sun, water, microbes, alkali, or metal ions such as iron or copper. An increase in toxicity may occur by storage activation, a process in which highly toxic isomers of certain pesticides are formed spontaneously in polar solvents or water. This reaction is speeded by heat. Parathion, malathion, fenthion, chlorpyrifos, diazinon, and coumaphos are some of the compounds that can undergo this type of storage activation.[38] The storage activation phenomena provide good reasons to use only freshly prepared preparations of organophosphate compounds on horses.

Other factors that can influence the toxicity of a particular organophosphorus compound are ambient temperature (higher temperatures may increase the toxicity of certain compounds); the vehicle in which the pesticide is dispersed; the age and sex of the animal; and the presence of other chemicals that may alter organophosphate toxicity. The combined effects of two organophosphates may be synergistic or antagonistic, and drugs that compete with organophosphates for target esterases, such as succinylcholine, phenothiazine, and procaine, may enhance organophosphate toxicity. In addition, drugs that have neuromuscular-blocking properties (e.g., inhalant anesthetics, magnesium ions, certain aminoglycoside antibiotics, and the depolarizing and nondepolarizing neuromuscular-blocking agents) also may enhance organophosphate toxicity. The organophosphates are poorly soluble in water but are soluble in organic solvents, fats, and oils. Oily vehicles or organic solvents also can facilitate passage of the organophosphates through the skin.[38]

Clinical Signs

Clinical signs of organophosphate toxicity are similar to those of carbamate toxicity and essentially are those of overstimulation of the parasympathetic nervous system, skeletal muscles, and CNS.

Overstimulation of muscarinic cholinergic sites results in profuse salivation and lacrimation; serous or seromucous nasal discharge; increased respiratory sounds and coughing resulting from bronchoconstriction and excessive bronchial secretions; profound gastrointestinal disturbances of increased motility, abdominal pain, and diarrhea; bradycardia; miosis; sweating; and frequent urination. Signs of nicotinic cholinergic overstimulation include muscle fasciculations, tremors, twitching, spasms, and a stiff or rigid gait. CNS signs frequently include anxiety, restlessness, and hyperactivity.[35,38] If the exposure is not severe enough to result in the death of the horse, the horse may require several days to recover completely; compounds that are more chlorinated can be stored in fat reserves and therefore have a longer half-life.[38]

Pathophysiology

Organophosphates can be absorbed from the gastrointestinal tract and lungs and through the skin. After absorption, they are distributed throughout the body, but most do not accumulate in any particular tissue. Many of the organophosphates must be activated by hepatic microsomal oxidative enzymes before they become potent esterase inhibitors. Phosphorothiolate and the phosphate class of organophosphates do not require activation and can inhibit esterases immediately after entering the bloodstream.[38]

Organophosphates act as irreversible inhibitors of true cholinesterase and pseudocholinesterase in mammals. They irreversibly phosphorylate the esteratic site of cholinesterases throughout the body. As a result, endogenous acetylcholine is not inactivated. Therefore acetylcholine accumulates in neuromuscular junctions; in parasympathetic postganglionic sites in smooth muscle, cardiac muscle, and glands; in all autonomic ganglia; and in cholinergic synapses within the CNS. The result is overstimulation of these sites, leading to clinical signs of toxicosis.[35,38]

Lethal amounts of organophosphates cause death by the combined effects of nicotinic, muscarinic, and central cholinergic overstimulation or receptor paralysis. These effects include hypotension, bradycardia, bronchoconstriction and excessive bronchial secretion, inability of the respiratory muscles to work properly, cyanosis, and central respiratory depression. The animal actually dies of asphyxia.[38]

Detoxification of organophosphates is accomplished mostly by serum and liver esterases. However, other enzymes in the liver and other tissues may attack the pesticides at rates dependent on the class of pesticide, the species, and the age of the animal. Water-soluble metabolites may be formed rapidly and the pesticide excreted quickly in the urine.[35,38]

Diagnosis and Treatment

The clinician should suspect organophosphate toxicosis when the horse has a history of possible exposure within the past 48 hours, along with characteristic signs of parasympathetic overstimulation. One can analytically test for organophosphate residues in body tissues or specimens and in other suspect materials.

A test for cholinesterase activity in blood or brain tissue is a rapid screening tool that can assist in determining if an animal has been exposed to excessive amounts of a cholinesterase inhibitor. Blood or brain cholinesterase activity values of less than 50% to 75% of normal can be compatible with exposure of the animal to excess organophosphates or other cholinesterase inhibitors (false inhibition can be observed if the patient is anemic). It should be noted that some depression of blood cholinesterase activity occurs when therapeutic levels of organophosphates or carbamates are used, so these results should be considered with discretion.[35,38]

Treatment to help control the muscarinic overstimulation should involve immediate use of atropine sulfate at 0.2 mg/kg of body weight. Approximately one fourth of this dose should be given intravenously, and the remainder should be given subcutaneously or intramuscularly. It may be necessary to repeat this dose at 3- to 6-hour intervals. Because atropine does not block the nicotinic cholinergic effects, the horse may continue to show signs of muscle fasciculation or tremors.[35,38] Atropine should be used with great discretion in the horse so as not to cause further complications, such as gut stasis with atropine overdosage.

The oximes, such as pralidoxime and pralidoxime chloride, act specifically on the organophosphorus-enzyme complex to free the enzyme and also react directly with the organophosphate to form a nontoxic complex that is excreted in urine. However, the use of these products in horses may not be economically feasible. The recommended dose varies between 20 mg/kg and 25 to 50 mg/kg given as a 20% solution intravenously, slowly, over several minutes. Oximes are reported to work best in the presence of atropine, so they should be given to the animal after atropine administration. Treatment with the oximes can be repeated if signs reappear.[38]

Other treatment measures include removal of the source, if possible; use of orally administered activated charcoal; laxatives to aid in evacuation of the bowel; washing with soap and water and thorough rinsing if dermal exposure has occurred; and supportive therapy such as fluids and electrolyte administration, if necessary. Drugs that should not be used when treating organophosphate toxicosis include phenothiazine tranquilizers, succinylcholine, and morphine.[35,38]

Chlorinated Hydrocarbons

The current use of chlorinated hydrocarbon pesticides is limited and severely restricted because of their persistence in the environment and their incorporation into the food chain. However, certain agents still are being used, primarily as contact insecticides and as ectoparasiticides.[35,38,39] A partial list of compounds includes lindane, aldrin, dieldrin, endosulfan, endrin, and methoxychlor.

The chlorinated hydrocarbon insecticides are poorly soluble in water but are soluble in organic solvents and oils. Oily vehicles or organic solvents can facilitate penetration of the insecticide through intact skin. Because this group of compounds also is characterized by volatility, exposure to the pesticide can occur through inhalation of the vaporized compound.[38] Because these compounds accumulate in body tissues, primarily adipose tissue, signs of toxicosis can result from repeated exposure to lesser amounts or after a single excessive dose.[39] Toxicity varies greatly among the different compounds, and Osweiler et al.[35] have tabulated the toxicity of a number of these compounds for various animal species.

Clinical Signs

The chlorinated hydrocarbons generally act as diffuse stimulants (less commonly as depressants) of the CNS, with the onset of signs ranging from several minutes to several days after exposure. The signs displayed may be progressively severe or explosive and fulminating.[35] Initially, the animal may be hypersensitive, apprehensive, or belligerent. These behavioral aberrations may progress to abnormal posturing or frenzied or maniacal behavior. Nervous signs can begin with hypersensitivity and muscle fasciculations beginning around the head and facial area and proceeding caudally eventually to include the hindquarters. These muscle spasms can occur intermittently or continuously. Clonic-tonic seizures often follow and may result in death or be followed by intermittent periods of CNS depression. Autonomic manifestations of profuse salivation, mydriasis, diarrhea, urination, and bradycardia or tachycardia with arrhythmias may occur. Some animals may lose coordination and stumble while walking, walk aimlessly, or move in circles. Other notable signs may include increased rate and depth of respiration and fluid sounds in the lungs. Death may occur within minutes, hours, or days or not at all.[35,38,39]

Pathophysiology

Chlorinated hydrocarbon pesticides gain entry into the body by way of the gastrointestinal and less commonly through the respiratory tracts and absorption through the skin. Once they enter the bloodstream, they are thought to bind to serum lipoproteins and are distributed throughout the body. Eventually, an equilibrium is reached in which the pesticide concentration varies among different body compartments. Most of the absorbed pesticide is stored in fat, but brain and fetus also can accumulate significant amounts.[35,38]

Adipose tissue is the main storage tissue for chlorinated hydrocarbons and as such can retain some of these compounds for an extended period. The pesticide is mobilized slowly from fat, which can account for its presence in blood and milk for weeks to months after a single exposure.[38]

The chlorinated hydrocarbons are broken down by liver microsomal enzymes, and the pesticide and its metabolites are excreted in urine, bile, milk, and feces. This first stage of elimination is fairly rapid and may account for 40% to 50% of the compound being eliminated during the first 3 to 4 days after exposure.[38]

The exact mechanism of action of all of the chlorinated hydrocarbons is unknown, but they act as nonspecific stimulants of the CNS. A suggested mechanism is that some of these compounds easily enter neural membranes and prolong the time during which some of the sodium channels in the membrane are open during depolarization. In addition, potassium efflux from the cell is hindered. The net effect of these ion imbalances is a decreased transmembrane resting potential that causes a decreased firing threshold and an increased neuronal excitability.[38]

An increase in whole-brain free ammonia concentration and brain glutamine also occurs, but whether these changes are a cause or an effect of the sodium-potassium flux defect is unknown. However, the onset and disappearance of convulsions in animals is correlated with an increase and decrease of brain ammonia concentration.[38]

The depression produced by some chlorinated hydrocarbons may result from rapid depolarizing blockade of neurons of the reticular activating system. Excessive depolarization of the medullary neurons may be responsible for respiratory failure, which is the usual cause of death in chlorinated hydrocarbon pesticide toxicosis. The muscle tremors in chlorinated hydrocarbon toxicosis are thought to be partly central in origin and partly caused by direct depolarizing effects on peripheral motor nerves.[38]

Diagnosis and Treatment

The clinician can make a tentative diagnosis when animals are known to have been exposed to an insecticide and are exhibiting compatible signs of toxicosis. Tissue samples

may be assayed for residues of the specific compound, but it is important to exercise caution when interpreting results because some of the compounds may be found in the fat of normal animals as a result of exposure to small concentrations in the environment. However, ppm concentrations may have diagnostic significance if history and clinical signs are consistent with chlorinated hydrocarbon poisoning. Brain and liver concentrations of this category of pesticides are reported to be better correlated with toxicosis than are concentrations in body fat.[38] Other suitable tissue specimens include blood, milk, kidney, and gastrointestinal contents.[35]

Because no specific antidote is available for the chlorinated hydrocarbons, treatment is symptomatic. For animals exhibiting convulsive seizures or neuromuscular hyperactivity, intravenous chloral hydrate or pentobarbital can be administered carefully to effect. Sedative doses of these two agents should control most of the behavioral, nervous, and locomotor signs. Sedation usually can be discontinued after 24 to 48 hours.

Oral exposure should be treated with saline cathartics and an adsorbent such as activated charcoal. If exposure was by the dermal route, the animal requires a thorough bathing with soap and water, followed by a thorough rinsing. As in all cases of pesticide toxicity, the source of contamination should be eliminated if possible.[35,38]

Strychnine

The present-day use of strychnine is primarily as a rodenticide. Although strychnine is available to the public through many retail outlets, instances of horses becoming intoxicated by strychnine are not common.[35,38,40] The approximate oral lethal dose for horses is 0.5 mg/kg.[35]

Clinical Signs

The clinical manifestation of strychnine toxicosis can appear as rapidly as 10 minutes to 2 hours after ingestion. Initial signs include apprehension, nervousness, and muscle stiffness. These signs are followed by stiffness and tetanic spasms that may appear spontaneously or may be initiated by stimuli such as sound, touch, or light. These tetanic spasms may vary from a few seconds to a minute or more and are characterized by extreme extensor muscle rigidity. Apnea frequently occurs during the spasms. Sometimes, intermittent periods of relaxation occur between seizures but become less frequent as the clinical episode progresses. In lethal cases the convulsive spasms become more frequent until death eventually occurs during a seizure or as a result of exhaustion and anoxia. The entire clinical episode typically lasts less than 2 hours.[35,38] Additional signs that are reported in horses include sweating, incoordination, prostration, convulsions, and death within approximately 2 hours of initial exposure.[38]

Pathophysiology

Strychnine is absorbed rapidly from the intestinal tract but not from the stomach. The alkaloid nature of the compound promotes its ionization within an acid medium; hence minimal absorption occurs from the stomach.[35] Once absorbed, strychnine is distributed readily throughout the body. Strychnine does not accumulate in any given tissue, but detectable concentrations can be found in the blood, urine, liver, and kidney.[35,38] Strychnine is metabolized in the liver by hepatic microsomal enzymes, and it and its metabolites are excreted in urine.[35] Excretion of strychnine is rapid, with most of a lethal dose being eliminated within 24 hours.[38]

Glycine is an inhibitory neurotransmitter in the spinal cord and medulla that serves to dampen or modulate efferent motor neuron activity. The purpose of this modulating effect is to provide smooth, coordinated muscle contraction and activity that are appropriate and consistent with the requirements for locomotion and respiration. Strychnine acts competitively to antagonize glycine by blocking its uptake at postsynaptic sites on receptors in the spinal cord and brainstem. The result of this blockade is hyperexcitation of muscle groups caused by lack of normal inhibition. Muscle reflex activity is allowed to proceed in basically an uncontrolled manner. All striated muscles are affected, but the more powerful extensor muscles tend to predominate and produce generalized rigidity and tonic seizures.[35,38]

Diagnosis and Treatment

A tentative diagnosis of strychnine poisoning can be made on the basis of a history of possible exposure, characteristic limb rigidity, and a rapid recovery (i.e., less than 24 hours in many cases) in animals aggressively treated in time. To confirm the diagnosis, the clinician may submit tissue samples for evaluation. Stomach content is the most suitable specimen for analysis.[35,38] Many commercial strychnine baits contain grain (e.g., wheat, oat, barley, sorghum) dyed red or green; seeing this in the stomach contents allows the clinician to pursue strychnine poisoning as a differential diagnosis.

Treatment of strychnine poisoning is symptomatic because no specific antidote is available. The horse should be kept in a quiet environment with minimal stimulation. Of primary importance is maintenance of relaxation and prevention of asphyxia. Pentobarbital or chloral hydrate solutions should be given intravenously to produce effective sedation. Complete anesthetization of the horse usually is not necessary or desired. Other medications have been recommended for use in dogs and should be effective in horses as well. These medications include the centrally acting muscle relaxants methocarbamol (150 mg/kg intravenously) and guaifenesin (110 mg/kg intravenously), repeated as needed; diazepam to control seizures; and inhalation anesthetics if necessary.[35] Oxygen therapy and assisted ventilation may be necessary in some animals.

Additional agents that are beneficial are activated charcoal given orally and followed by a laxative to evacuate the bowel. Acidification of urine with oral ammonium chloride at 132 mg/kg also may enhance excretion of strychnine, but the efficacy of this treatment is not well documented. Although toxic doses of strychnine may be depleted from the body in a short time, it may be necessary to maintain relaxation and sedation in the horse for 24 to 48 hours.[35]

Metaldehyde

Metaldehyde is used primarily as a molluscicide in snail and slug baits in coastal and low-lying areas. The baits are generally in the form of meal, pellets, and liquids and are placed around crops, gardens, or ornamental plants.[35,38] Horses can become poisoned through inadvertent exposure to bags or containers of bait. No specific toxicity studies could be found regarding horses, but reports indicate that horses may be more susceptible to toxicosis than dogs, in which the acute oral LD_{50} may be as little as 60 to 100 mg/kg.[38] In two separate reports, horses died after ingestion of as little as 60 mg/kg and 120 mg/kg.[41,42] Experimentally, a parasitized yearling colt died after exposure to 0.1 mg/kg.[42]

Clinical Signs

The clinical signs reported in horses include acute onset of signs within 1 hour after exposure; excessive sweating, profuse salivation, restlessness, hyperesthesia, incoordination, and tachycardia can be observed. One horse exhibited violent muscle spasms just before death.[41] Other signs include muscle fasciculations, clonic spasms, and rapid and deep respiratory movements.[42] Death occurs rapidly (3 to 5 hours) in horses exposed to a lethal amount of metaldehyde[41,42] and is thought to result from acute respiratory failure.[38] Dogs also are reported to exhibit signs of convulsions and elevated body temperature (often referred to as "shake and bake").[35,38]

Pathophysiology

Metaldehyde is absorbed readily from the gastrointestinal tract. Gastric hydrochloric acid enhances its decomposition to acetaldehyde, and metaldehyde and acetaldehyde are absorbed and readily cross the blood-brain barrier. The exact mechanism of action of metaldehyde is yet to be elucidated.[38]

Diagnosis and Treatment

A history of possible exposure to a molluscicide coupled with the appropriate clinical signs can lead to a tentative diagnosis of metaldehyde toxicity. Stomach contents can be analyzed to detect metaldehyde or acetaldehyde, and a formaldehyde-like odor may be present in the stomach contents.[35,38]

No antidote is available for metaldehyde. Treatment is symptomatic and aimed at sedation; removing the compound from the stomach; and supportive therapy such as maintaining proper fluid, electrolyte, and acid-base indexes. Sedatives such as xylazine, acepromazine, and diazepam may be useful to control convulsive behavior. Methocarbamol may help control muscle spasms and fasciculations, and mineral oil can be given orally to aid evacuation of the gastrointestinal tract.[35,38]

Methiocarb

This molluscicide has been reported to cause toxicity in two horses: one died, and the other fully recovered.[43,44] In each instance the amount ingested was estimated to be from 100 to 125 g of a 4% weight per volume preparation.

Clinical Signs

The onset of signs was rapid, beginning within a few minutes of ingestion. Muscle tremors, which became severe, and profuse sweating and salivation were noted. Both horses had increased heart and respiratory rates, and the surviving horse also exhibited signs of abdominal discomfort. Clinical signs gradually lessened until they became absent approximately 12 hours after onset in the surviving horse.[44] The horse that was fatally intoxicated died approximately 12 hours after initially showing signs. Postmortem findings included severe generalized pulmonary congestion with froth accumulation in the airways and a number of large hemorrhagic areas scattered throughout the intestinal tract.[43] Methiocarb is a cholinesterase-inhibiting carbamate compound; readers may wish to consult the section on carbamate and organophosphate pesticides for more information.

Treatment

The specific antidote for methiocarb is atropine sulfate.[43,44] Repeated dosing may be necessary. Other suggested remedies include supportive therapy consisting of sedatives, calcium solutions, and mineral oil.[44]

4-Aminopyridine

4-Aminopyridine is used commercially as a bird repellent and often is mixed with grain before its distribution. In the one reported instance of 4-aminopyridine toxicity, affected horses were exposed to corn that contained the substance.[45]

Clinical Signs

The two affected horses began showing signs of profuse sweating, severe convulsions, behavioral abnormalities, and rapid fluttering of the third eyelid. Both horses died within 2 hours of the onset of clinical signs and approximately 8 hours after ingesting the contaminated corn. No specific lesions were noted at necropsy. The estimated lethal dose of 4-aminopyridine for these two horses was 2 to 3 mg/kg of body weight.[45]

Pathophysiology

The mechanism whereby 4-aminopyridine causes death has not been elucidated. However, this substance readily crosses the blood-brain barrier and may enhance the release of acetylcholine and other neurotransmitters from prejunctional nerve endings.[38,46] The result is a stimulatory effect on the CNS.

Diagnosis and Treatment

A diagnosis of suspected toxicity is confirmed by testing the suspect material and stomach contents of affected horses.[45] No specific antidote for 4-aminopyridine toxicity is suggested, but the clinician can give affected horses supportive therapy and mineral oil orally to enhance evacuation of the intestinal tract. Given the known mechanism of action of this compound, CNS depressants such as phenobarbital would seem to have some value in treating the CNS signs of affected horses. However, the efficacy of this treatment in unknown.

Levamisole

Levamisole has not gained widespread use as an equine anthelmintic, principally because of its limited efficacy in destroying strongyles and because its toxic dose is close to its therapeutic dose. Levamisole is effective, however, in eliminating lungworms, ascarids, and adult pinworms from horses. The drug also has been used in human beings and other animal species in an attempt to enhance immune system function.

Clinical Signs

Clinical signs associated with levamisole toxicity occur within 1 hour of administration and include hyperexcitability, muscle tremors, hyperactivity, excessive sweating, and lacrimation. Recumbency may follow these signs, but animals that recover generally appear normal within 12 hours after exposure.[47-49] Adverse effects are more likely after subcutaneous injection than oral drenching.[49] The toxic dose of 20 mg/kg is close to the therapeutic dose of 15 mg/kg, and 20 mg/kg may cause death in some horses.[38]

Diagnosis and Treatment

The diagnosis is suspected when horses exhibit clinical signs suggesting levamisole toxicosis, and exposure is known to have occurred. No specific antidote is available, so therapy includes supportive care. Most animals recover uneventfully if a sublethal dose has been given.

Carbon Disulfide

Carbon disulfide is seldom used as an anthelmintic in present times but has enjoyed widespread use in the past for treatment

of infestation caused by *Parascaris equorum* and *Gastrophilus* species.[50] Carbon disulfide is a manufactured product used as a solvent for resins, pesticides, and waxes and as an agent to remove greases. The chemical is used widely as a fumigant to control insects in stored grain.[35] Carbon disulfide is an exceptional fat solvent and in the pure state is a clear, colorless volatile liquid with a sweet, aromatic odor resembling that of decaying cabbage. The chemical is well absorbed through the skin and lungs and after ingestion.[34,35]

Clinical Signs

Reported signs of acute toxicity in animals include dyspnea and cyanosis, spasmodic tremors, vascular collapse, prostration, convulsions, coma, and death.[35] Signs referable to local irritation following inhalation might include salivation and coughing. A combination product of piperazine–carbon disulfide and phenothiazine caused transitory signs of overtranquilization and unsteady gait when dosed at 8 oz per 45 kg of body weight.[50] Whether any of these effects were related directly to carbon disulfide was not determined. Chronic exposure causes neuropsychiatric changes, peripheral neuropathies, and cranial nerve dysfunction in human beings,[34] but chronic exposure in horses is unlikely.

Pathophysiology

Because carbon disulfide is a potent fat solvent, local skin contact results in erythema and pain, and prolonged contact produces chemical burns and vesiculation.[34] The chemical is irritating to mucous membranes when inhaled or ingested.[34]

At the cellular level carbon disulfide acts to block enzymatic processes by reacting with nucleophilic compounds, including pyridoxamine, monoamine oxidase in the cerebrum, and dopamine decarboxylase. Carbon disulfide binds to microsomal enzymes, thereby reducing their activity, and produces a centrilobular hepatic necrosis. In addition, carbon disulfide chelates copper and zinc and therefore can produce disturbances in trace mineral balance.[34]

Diagnosis and Treatment

No specific diagnostic test is available for use in animals suspected of suffering from carbon disulfide toxicosis. In one report affected animals had increased BUN and bilirubin concentrations, increased serum activities of AST and alanine aminotransferase, and increased serum cholesterol concentration. Affected horses also had depressed serum concentrations of protein-bound iodine and magnesium.[50]

In human beings the iodine-azide test is useful to identify carbon disulfide metabolites in urine,[34] but the efficacy of this procedure for diagnostic use in horses is unknown. Treatment of toxicosis primarily involves removal of the source and symptomatic care (Box 21.1).

BOX 21.1 General Rules Regarding Treatment of Suspected Toxicoses

1. Removal of the toxicant or animal from the environment
2. Removal of the toxin from the body of the animal, if possible
3. Cleaning of the skin or contact surface with suitable agents if the route of exposure is dermal
4. Evacuation of the gastrointestinal tract by appropriate means if contamination resulted from ingestion of the toxin
5. Maintenance of normal body functions and physiologic processes by means of basic supportive care measures, such as fluid administration and blood pH and electrolyte modification
6. Elimination of the toxin from the system of the animal as expeditiously as possible
7. Measures to prevent reexposure or recontamination of the animal by the toxic substance

MISCELLANEOUS AGENTS

Nicotine

Nicotine is an alkaloid contained in tobacco leaves. Although toxicosis might result from ingestion of excessive amounts of tobacco leaves or cured tobacco in cigarettes or cigars, this route of toxicosis probably is rare in horses. Horses are more likely to be intoxicated by ingestion or exposure to the salt nicotine sulfate.[35,38] A concentrated solution of nicotine sulfate (Blackleaf 40) has been used to control leaf-eating insects and occasionally as a premise spray to control certain ectoparasites.[35,39] Horses may ingest this substance from spills of the solution, from open containers, or from foliage that has been sprayed with the product.[38] Topical exposure may result when horses are housed in stables where this product has been used for mite control.[51] The lethal dose of nicotine in the horse is 100 to 300 mg.[35]

Clinical Signs

The signs of nicotine toxicity are rapid in onset, often occurring within a few minutes after exposure. Initially, the signs noted are those of cholinergic overstimulation (i.e., excitement, increased respiration, and salivation). Increased peristalsis and diarrhea also can occur.[35,39] These signs are transitory and are followed rapidly by lethargy, muscle weakness and ataxia, slow and shallow respiration, and an increased heart rate. Convulsions also can occur. In fatal cases these signs progress to collapse, coma, and death within minutes to hours after the onset of clinical signs.[35,38,39]

Pathophysiology

Nicotine is absorbed readily from the oral mucosa, respiratory tract, and gastrointestinal tract (excluding the stomach) and through intact skin.[34,35] If ingested, nicotine also can exert a direct, rapid caustic action on the mucosa of the mouth and throat, esophagus, and stomach.[35] The substance is metabolized primarily in the liver, and nicotine and its metabolites are excreted in urine. In human beings urinary acidification greatly enhances clearance of nicotine and its metabolites.[34]

Initially, and only for a short time, nicotine stimulates the autonomic nervous system ganglia, neuromuscular junctions, and some synapses in the CNS by depolarization of the postsynaptic membrane.[34,35] With toxicosis, however, the stimulation is followed rapidly by a depolarizing-type blockade of all these nicotinic cholinergic receptors.[34,35,38] Large doses result in a descending paralysis of the CNS, and death results from respiratory failure caused by paralysis of the diaphragm and chest muscles.[35,38] The effects of a sublethal dose should diminish in a few hours.[38]

Diagnosis and Treatment

No diagnostic lesions are present at necropsy. However, the distinct odor of nicotine may be present in stomach contents.[35,38] One can evaluate urine, blood, liver, kidney, and other tissues for nicotine content in suspect cases.[35]

Treatment often is ineffective because of the rapid course of the toxicosis. However, because no specific antidote exists for nicotine toxicity, affected horses should be treated symptomatically. If exposure has been through the skin, washing with soap and water, followed by thorough rinsing, is indicated.[35] After oral exposure, affected horses can be treated with oral laxatives in an attempt to reduce absorption of the toxin. Activated charcoal also may be beneficial in adsorbing residual nicotine in the intestinal tract.[35,39] Atropine sulfate is reported to be without value in affected horses because it does not protect vital nicotinic receptors in the respiratory muscles and the CNS from the effects of nicotine.[38] Artificial respiration becomes the only means of maintaining life once the respiratory depression reaches a critical level. This last-ditch effort usually fails.[38]

Ammonia

Ammonia toxicosis in the horse can occur in two ways: by primary exposure to ammonia gas or by secondary metabolism of urea to ammonia within the body (see the section on Urea and Nonprotein Nitrogen Substances).[34,35] Primary exposure to toxic concentrations of ammonia gas probably is rare in horses, even though ammonia is the air pollutant most frequently found in high concentrations in animal facilities. The concentrations of ammonia found in stables may be irritating to horses but probably will never reach lethal concentrations. Another source of ammonia toxicosis to horses might be compressed anhydrous ammonia, which is used as an agricultural fertilizer. An accidental spill or spray of anhydrous ammonia near a horse or livestock facility could have disastrous and possibly lethal results.[35] Human beings can detect the odor of ammonia at a concentration of 30 ppm, eye and nasal irritation occurs near 50 ppm, and severe pulmonary dysfunction results from concentrations greater than 1000 ppm. Immediate death occurs at concentrations nearing 1500 ppm.[34]

Clinical Signs

Signs associated with low concentrations of aerial ammonia are those of irritation to the eyes and respiratory tract. Excessive tearing, shallow breathing, coughing, and nasal discharge are common findings. Higher concentrations can induce laryngospasm and pulmonary edema.[34] Exposure to anhydrous ammonia can result in impairment of eyesight, permanent loss of eyesight, respiratory disease, and skin burns.[35]

Pathophysiology

Ammonia is a highly water-soluble, irritating alkaline gas that causes liquefactive necrosis at high concentrations.[34] Because ammonia is so highly water soluble, it readily reacts with the mucous membranes of the eye and the respiratory tract.[35]

Diagnosis and Treatment

A diagnosis of aerial ammonia toxicosis is based primarily on history and physical examination findings. Laboratory evaluation is of little value in establishing a diagnosis of inhalation exposure,[35] but laboratory evaluation can be useful to assess the degree of damage to the respiratory tract.

Treatment involves removing the horse from the source of exposure. If exposure has been severe enough to result in ophthalmic or respiratory tract disease, these conditions should be treated accordingly.

Urea and Nonprotein Nitrogen Substances

Urea and other nonprotein nitrogen substances, including various ammonium salts, are added to ruminant rations as a source of nonprotein nitrogen because ruminants can use these compounds to provide a large percentage of their protein nitrogen requirements. Urea has additional uses as a fertilizer and as a substitute for salt in melting snow and ice.[35,38] Horses are only mildly susceptible to urea toxicosis, and it is highly unlikely that horses would ingest urea or urea-containing feedstuffs in amounts sufficient to cause clinical signs.[35,39] However, horses are more susceptible to toxicosis caused by ingestion of ammonium salts,[35] which may occur after accidental exposure to these substances. In horses urea is lethal when ingested at a rate of 4 g/kg of body weight, and ammonium salts are lethal at a dose of 1.5 g/kg of body weight.[38] Urea and other nonprotein nitrogen formulations are toxic to animals simply because they are hydrolyzed to ammonia, which is responsible for causing the derangements associated with toxicosis.

Clinical Signs

The spectrum and intensity of signs in ruminants with urea toxicosis vary, and the same is probably true for horses. The clinical course is usually acute and rapid, often occurring from a few minutes to a few hours after consumption.[35] Occasionally, animals are found dead, or they may die quickly after exhibiting signs of weakness, dyspnea, colic, bloat, and terminal tonic convulsions. Other varied signs can be present. Behavioral abnormalities such as restlessness and dullness may be present. Excitement and even belligerency may follow these signs. Nervous signs such as hyperesthesia, tremors, and muscle twitching and spasms can occur. Autonomic nervous system derangements may include salivation, bradycardia, hypertension, and severe colic. More terminal signs may include increased and labored respirations, cardiac arrhythmias, frothing at the mouth, and cyanosis. Intermittent tonic-opisthotonic seizures also can be elicited near death. The onset of signs may range from 10 minutes to 4 hours, and death typically occurs within a few hours after exposure.[38]

Pathophysiology

Urea is hydrolyzed to ammonia by the action of the enzyme urease. This reaction is hastened by an alkaline pH, and in the horse these requirements are found in the cecum. In horses urea is absorbed from the small intestine and excreted in the urine. The only urea that might contribute to toxicity in the horse would be that excessive amount that reaches the cecum and is available for hydrolysis.[39]

In normal animals ammonia liberated from nonprotein nitrogen sources can be in the form of the ammonium ion. This ion is soluble, but its charge prevents it from being efficiently absorbed across membranes. Ammonia is also soluble; however, because it lacks an ionic charge, it can be absorbed readily across membranes to enter the bloodstream.[38] Ammonia is a normal byproduct of tissue metabolism, and in hepatocytes it is converted to urea by the urea cycle or is incorporated into glutamic acid in the synthesis of glutamine. Toxicosis occurs when the amount of ammonia absorbed into the bloodstream exceeds the ability of the horse to detoxify it.[38]

The primary mechanism of ammonia toxicosis is thought to be inhibition of the citric acid cycle, but the exact mechanism by which this occurs is not known.[38] Ammonia saturation of the glutamine-synthesizing system has been suggested to have an inhibitory effect on the citrate cycle, creating a decrease in its intermediates and a subsequent decrease in cellular energy production and respiration. As the citrate cycle fails, cells begin to malfunction. Cellular energy and respiration deficits may cause ultrastructural damage leading to degenerative changes and eventual cell death. The role of ammonia in causing signs of encephalopathy is controversial and not well understood.[51]

Laboratory abnormalities associated with ammonia toxicosis include elevated serum ammonia, potassium, phosphorus, lactic acid, glucose, and serum activity of the liver enzyme AST. Urine output decreases, and PCV increases as impending cardiac failure and shock ensue.[38]

The ultimate cause of death is inconsistent in urea toxicosis and poisoning by ammonium compounds. Cardiac failure may be induced by hyperkalemia, or ventricular fibrillation may result from the myocardial effects of ammonia itself. Convulsions may be prolonged and responsible for fatal anoxia. Pulmonary edema may be a complicating factor in some cases. Death also has been postulated to result from asphyxiation.[38]

Diagnosis and Treatment

Animals that die of ammonia toxicosis exhibit no characteristic lesions. Generalized venous stasis and congestion of organs may be present, along with pulmonary edema and scattered petechiation and ecchymoses. A strong odor of ammonia may be present, but this is probably much more characteristic of ruminants than of monogastric animals.[38]

Clinical signs and history can be helpful in establishing a diagnosis. Blood and ocular fluid ammonia can be evaluated in the laboratory, but the results must be interpreted with caution.[38] Storage of the sample, length of time between death and time of sampling, and length of time between sampling and analysis can influence the blood ammonia concentration. Tissue specimens must be frozen immediately if they are to be analyzed.[35] Suspect feeds can also be analyzed for urea or total nitrogen content.

Treatment is often unrewarding because of the rapidity of onset. No specific antidote is available for ammonia, so therapy is mostly symptomatic. Orally administered laxatives such as mineral oil may be beneficial. The clinician should correct any deficits in fluid volume or abnormalities in acid-base or electrolyte concentrations. Horses that are convulsing can be controlled with pentobarbital, and a patent airway should always be maintained. Assisted ventilation, if necessary, is usually futile because of the poor survival rate of severely affected animals.[38]

Toxicoses Causing Signs Relating to Central Nervous System Depression

As with toxic problems associated with other primary clinical signs, it can be difficult to determine the source of CNS depression. The principal task is to rule out the existence of primary cranial disease. Even with the availability of advanced imaging equipment, this can be difficult. Unless the clinical signs or history is definitive, the diagnosis of a toxic problem is often presumptive.

PLANTS

Black Locust *(Robinia pseudoacacia)*

The black locust tree has been described as toxic to horses.[52,53] The toxic principle is classified as a lectin, which is present in seeds, sap, roots, wood, leaves, and bark of the plant. Lectin has been used in cytologic research because of its ability to stimulate glycoprotein biosynthesis and cell proliferation in lymphocytes of various animal species.[54] Horses may become intoxicated by ingesting the bark. Only small amounts of lectin are reported to precipitate clinical disease.[53]

The clinical signs reported are mental depression, weakness, posterior paralysis, irregular heart rate, pale mucous membranes, and anorexia. Abdominal discomfort and diarrhea of varying degrees also may be evident.[52,53]

No definitive diagnostic test is available. Treatment of suspected toxicosis is mostly symptomatic and should include removal of the source; evacuation of the intestinal tract; and maintenance of normal fluid, electrolyte, and acid-base indexes. Honey locust *(Gleditsia triacanthos),* black locust's lookalike, is not thought to be toxic. However, the author is aware of a horse ingesting a large amount of honey locust seeds and suffering from acute colic and impaction.

Bracken Fern *(Pteridium aquilinum)*

Bracken fern is found most commonly in forested areas, burns, or abandoned fields in the northern and western United States.[53] Toxicity can occur at any time of year, but horses are more likely to consume the plant in late summer and fall, when other forage is scarce. However, horses also might acquire a taste for the plant in pastures or when it is incorporated in bedding. Horses also can become intoxicated from hay contaminated with large amounts of bracken fern. The entire plant is considered to be toxic.[52]

Clinical Signs

Signs of toxicosis occur after the horse has been consuming the plant for 30 to 60 days or longer. Horses also can exhibit signs even if they have not ingested bracken fern for 2 to 3 weeks.[52] The signs most frequently reported are incoordination, which may progress to severe ataxia; postural abnormalities, including arching of the back, crouching, and a base-wide stance; muscle fasciculations, which can progress to severe tremors; and bradycardia with cardiac arrhythmias early in the disease course, although tachycardia is most prevalent terminally. Terminal stages of the disease are characterized by signs of opisthotonus and clonic convulsions.[52,53] One report also describes an affected horse showing signs of colic and acute hemolytic anemia.[55]

Pathophysiology

The agent in bracken fern that is toxic to horses is thiaminase.[52,53] Bracken fern also is reported to contain ptaquiloside,[56] which is capable of inducing bone marrow suppression, hematuria, carcinomas, and a β-glucopyranoside that may enhance the release of endogenous histamine.[53] The significance of these last two compounds in the development of toxicity in horses is unknown. Thiamine plays an integral role in carbohydrate, fat, and protein metabolism and acts as a cofactor in enzymatic pathways responsible for energy production. Thiamine is an important cofactor in the decarboxylation of pyruvate to acetyl coenzyme A, which subsequently enters the tricarboxylic acid cycle.

Thiamine deficiency acts to interrupt these cellular energy processes and also limits certain metabolic pathways available for pyruvate metabolism, resulting in the systemic accumulation of a variety of metabolites, including pyruvate and lactate.

Diagnosis and Treatment

History and clinical signs are helpful in arriving at a diagnosis. No pathognomonic lesions or laboratory abnormalities occur, but some laboratory findings may include elevated blood pyruvate concentration and decreased plasma thiamine and red blood cell transketolase concentrations.[53]

Thiamine should be administered daily to affected horses at a dose of 0.25 to 0.5 mg/kg of body weight intravenously, subcutaneously, or intramuscularly for several days. Initially, thiamine can be given at a dose of 5 to 10 mg/kg intravenously, but this dose should be diluted in fluids and administered slowly because of the frequency of adverse reactions when thiamine is given intravenously. Thiamine deficiency usually can be prevented by dietary supplementation of yeast or cereal grains.[53]

Equisetum *(Equisetum arvense)*

Equisetum, commonly called *horsetail, marestail,* or *scouring rush,* has a geographic distribution similar to that of bracken fern. Like bracken fern, *Equisetum* is unpalatable to horses, and toxicosis usually results from hay contaminated with the plant.[52,53] Thiaminase is the toxic principle found in *Equisetum,* and the clinical signs, pathogenesis, and treatment are virtually identical to those of bracken fern.[52,53] Large amounts in the diet are necessary to induce clinical problems.

Milkweed (*Asclepias* spp.)

Several species of *Asclepias* have been reported to be toxic to large animals.[53,57] Clinical signs in affected animals are commonly associated with the nervous, respiratory, gastrointestinal, and cardiac systems. The fresh plants are reported to be distasteful to animals and not commonly grazed, but the plant may become incorporated into hay. Affected animals are reported to have a weak, rapid pulse; dyspnea; loss of muscular control; and muscular spasms. Salivation, bloating, and convulsions also may occur.[53,57] Most animals that reach the convulsive stage die.[57] Numerous compounds have been isolated from *Asclepias* species, including resinoids and cardioactive glycosides. One resinoid produces smooth muscle spasms of the gastrointestinal tract.[53] The mechanism of action of the other toxins has not been elucidated. No specific antidote is available,[53] but supportive care, including evacuation of the gastrointestinal tract, is indicated.

Yellow Starthistle *(Centaurea solstitialis)* and Russian Knapweed *(Acroptilon repens)*

Both yellow starthistle and Russian knapweed cause nigropallidal encephalomalacia in horses. *Centaurea melitensis* is suspected of causing this disease as well. These plants are found scattered over much of the western United States and are most abundant in nonirrigated pastures during the dry seasons of summer and fall. Both plants have a minimal moisture requirement and so may be the only green plants remaining in a dry season. Consequently, most poisonings occur during the summer or fall months.[53,58,59]

Horses apparently reject the plants when more suitable vegetation is available; the disease does not commonly occur in horses grazing improved pastures or grassland range.[59] However, some horses are reported to develop a craving for the plant and selectively seek it out.[53] Horses may eat the weeds, occasionally or frequently, without becoming ill, and continuous and protracted exposure to the plants is necessary for toxicosis to develop under experimental conditions. Feeding trials have shown that horses must consume an amount of weed equivalent to 59% to 200% of their body weight of yellow starthistle and 59% to 63% of their body weight of Russian knapweed for 3 to 11 weeks of continuous feeding before clinical signs develop. The plants retain their toxicity when dried and incorporated into hay. All ages may be affected, but younger horses generally seem more prone to the disease. One study reported a median age of about 2 years in affected horses.[59] Equids appear to be the only animals that develop nigropallidal encephalomalacia when exposed to these plants.

Clinical Signs

The onset of signs is always sudden, beginning with variable degrees of impairment of eating and drinking. Coordinated movements of prehension, mastication, and deglutition are often lacking. Affected horses are unable to chew adequately and propel the food to the back of the mouth. Some horses may show only faulty prehension, whereas others are unable to eat at all. Most horses, however, appear to be able to swallow if feed or water gains access to the posterior pharynx. More severely affected horses may attempt to drink by immersing their muzzles deeply into the water in an attempt to force water into the posterior pharynx.[53,59-61]

Hypertonicity of the facial muscles is a characteristic sign, particularly when feed is offered.[53] The horse often holds the mouth partially open with the lips retracted, resulting in a fixed facial expression. The tongue may protrude from the mouth, and many horses display constant chewing movements—hence the name "chewing disease."[53,61]

Other characteristic signs include weight loss, mild to moderate depression, and yawning. Most horses can be roused readily from somnolence by mild stimulation. Few animals may show aimless, slow walking or circling early in the disease course. The gait is usually normal, but occasional deficits are apparent, including stiffness, slowness, ataxia, tetraparesis, and conscious proprioceptive deficits.[53,61] In cases of prolonged exposure, a wobbly, shuffling gait may occur because of weakness. Sensation and reflexes appear normal, and the animals are afebrile.[61]

Horses less severely affected may adopt unusual means of eating by scooping feed into the mouth. These animals may survive for months, but complete recovery has not been observed in confirmed cases of the disease. In some instances, however, residual signs may become almost undetectable.[59] Death of affected horses is from starvation and dehydration.

Pathophysiology

The pathogenesis of the necrotic brain lesions is unknown, but these plants have been postulated possibly to contain a specifically toxic substance or to lack some nutritional component necessary for the health and well-being of the horse.[60,61] Several sesquiterpene lactones and polyacetylenes have been isolated from these plants, but their significance remains undetermined.[62] Dipyrone has been postulated to be the inciting agent.

Diagnosis and Treatment

The antemortem diagnosis of nigropallidal encephalomalacia is based largely on observation of clinical signs and prolonged exposure of the horse to the plants by grazing or by severely contaminated hay. If available, magnetic resonance imaging can identify characteristic lesions on T1-weighted, T2-weighted, and proton density images. These lesions do not contrast enhance after gadolinium-diethylenetriaminepentaacetic acid administration.[63] Characteristic necropsy findings include unilaterally or, more commonly, bilaterally symmetric softening and necrosis in areas of the globus pallidus and substantia nigra. These areas usually are sharply defined and may be cavitary.[53,61]

No known treatment exists for affected horses. Prevention requires keeping horses from the plant and providing adequate, suitable forage.

Milkvetch and Timber Milkvetch (*Astragalus* spp.)

Most of the variants of *Astragalus miser* are referred to as *timber milkvetch* or *milkvetch.* These plants are found primarily in the western United States from northern Mexico to Canada and are essentially a cause of toxicosis to ruminants. Horses are reported to be poisoned by this group of plants, but there are no reports of the lesions.[64]

The disease in ruminants is characterized primarily by general depression, mental dullness, incoordination, and eventual hindlimb paralysis. Respiratory distress, cyanosis, and acute collapse also may occur. Acute and chronic forms of the syndrome are reported.[64]

The toxic principle, referred to as *miserotoxin,* is a β-D-glucoside of 3-nitro-1-propanol, which is metabolized in the intestinal tract to the highly toxic compound 3-nitro-1-propanol. Miserotoxin is broken down into inorganic nitrite and a three-carbon side chain. The nitrite is responsible for producing methemoglobinemia in animals but is not the primary cause of death.[64]

No specific antidote is recommended. Poisoning is prevented by controlling the plants with herbicides and preventing livestock from grazing the plant.

MISCELLANEOUS AGENTS

Propylene Glycol

Propylene glycol is used commercially as a diluent for injectable drugs and as a glucose precursor in the treatment of hypoglycemia in ruminants. Horses may become intoxicated by the inadvertent use of propylene glycol if it is mistaken for a similar-appearing liquid paraffin preparation. Reports of toxicosis in horses are rare.[65,66]

Propylene glycol has a low oral toxicity in human beings. Approximately 45% of the absorbed dose is excreted unchanged by the kidney, and the remainder is metabolized by hepatic alcohol dehydrogenase to acetate, pyruvate, and lactate.[67]

Clinical Signs

Adverse signs occur within 10 to 30 minutes after a toxic dose of propylene glycol. Initial findings include salivation and profuse sweating, ataxia, depression, and tachypnea. Additional signs can include cyanosis, seizures, and coma.[65] Diarrhea also has been reported in one horse experimentally given a large dose of propylene glycol.[66] Death has occurred 1 to 3 days after ingestion of excessive amounts of the product.[65,66]

Pathophysiology

Propylene glycol is metabolized by hepatic alcohol dehydrogenase to form acetate, lactate, and pyruvate. After a large exposure, excessive amounts of these products accumulate, resulting in severe systemic lactic acidosis.[67] The clinical signs and toxicologic findings result from the effects of this severe acidemia on various body organs and tissues.

The acute oral LD_{50} for horses has not been established, but the doses for rats, rabbits, and dogs are 32, 18, and 9 mL/kg, respectively. One 450-kg horse died after intubation with 3.8 L (7.6 mL/kg) of propylene glycol,[65] but other horses have survived this dose. Toxic signs were reported in horses receiving 1.9 to 7.6 L of propylene glycol, but the only death occurred in the horse getting 7.6 L.[66]

Diagnosis and Treatment

Exposure to propylene glycol can be confirmed by chemical analysis of serum and urine (not commonly run by diagnostic laboratories). Necropsy findings associated with propylene glycol toxicosis may be minimal.[65] The horse given 7.6 L exhibited sloughing of the gastric mucosa, diffuse enterocolitis, renal congestion, and brain edema.[66] Histopathologic findings typically include hepatic necrosis, renal tubular necrosis and infarcts, myocardial perivascular edema, and pulmonary edema.[65,66]

Because no specific antidote is available, treatment of propylene glycol toxicosis aims at alleviating the severe acidemia that develops and providing supportive care for the other organs and tissues that may become compromised. Sodium bicarbonate solutions should be given to treat the acidosis. When possible, the clinician should monitor blood pH and adjust bicarbonate administration according to need. Intravenous fluids should be given to aid diuresis and maintain normal fluid volume. Pulmonary and renal function should be thoroughly evaluated in affected horses, and precautions should be taken to prevent the development of further pulmonary edema. Such precautions may require the use of diuretics and careful monitoring of the fluid administration rate.

Serum electrolyte concentrations should be maintained in normal ranges, and oxygen therapy may be beneficial in horses exhibiting tachypnea and cyanosis. Activated charcoal has been recommended in treating human toxicosis.[67]

Triclopyr

Triclopyr is an herbicide used to control hardwood species on road rights-of-way, industrial sites, and forest planting sites. Horses may become exposed to the herbicide by grazing areas that were inappropriately treated with the product in the past. This toxicosis is rare.

An experimental study was conducted to determine the toxic level of triclopyr to ponies. Ponies given 60 mg/kg per day for 4 days did not show any clinical sign of illness. Ponies given 300 mg/kg per day for 4 days did develop clinical signs. This study indicated that the toxic dosage in ponies was 5 times the estimated maximal intake for the highest recommended usage rate as an herbicide.[68] Therefore poisoning from the proper use of this herbicide is unlikely.

Clinical Signs

Initial signs of depression and decreased gastrointestinal motility were first noticed on the fourth day of the trial. Additional signs that developed were ataxia, weakness, muscle tremors, increased respiratory rate, cyanotic mucous membranes, and normal to slightly elevated body temperature. Some ponies became recumbent as clinical signs progressed. Two ponies died on the fifth and sixth days of the trial, and two other ponies were euthanized on the fifth day. The remaining two ponies were only mildly affected and recovered.

No significant changes were apparent in clinical chemistry values. Gross necropsy lesions consisted of pale livers and pale swollen kidneys, and a few horses had excessive intestinal fluid contents. Microscopic changes were mild and were those of nonspecific hepatosis and nephrosis.[68]

Pathophysiology

The mechanism whereby triclopyr produces clinical disease in horses has not been elucidated.

Diagnosis and Treatment

Toxicosis caused by triclopyr appears highly unlikely under natural circumstances.[68,69] Diagnosis of suspect cases is based on clinical signs and a history of exposure to the herbicide. No specific antidote is available. Affected individuals require supportive and symptomatic care.

Leukoencephalomalacia (Moldy Corn Disease)

Equine leukoencephalomalacia, a sporadically occurring disease of horses, ponies, donkeys, and mules, has a worldwide distribution. The disease usually is seasonal, with most cases occurring from late fall through early spring, and most outbreaks have been associated with a dry growing period followed by a wet period.[70,71]

This malady is caused by the mycotoxin fumonisin B_1, a metabolite of *Fusarium moniliforme*. Equidae become affected usually by ingesting *F. moniliforme*–infected corn or corn screenings, but the problem also has been associated with the consumption of commercially prepared diets.[70-73] Infected kernels often have a pink to reddish-brown discoloration, and damaged kernels and cob parts may have a much greater concentration of fumonisin than do undamaged kernels.[71,73] Feeds containing less than 10 ppm fumonisin B_1 have not been associated with disease, but concentrations of greater than 10 ppm can be lethal to horses.[74]

Clinical Signs

Two clinical syndromes are associated with fumonisin intoxication. The more common is the classic neurotoxic syndrome, but hepatotoxicosis also occurs in some horses. Older animals may be more susceptible than younger animals, and clinical signs become evident approximately 3 to 4 weeks after daily ingestion of contaminated feed. Onset of signs is typically abrupt, and death usually occurs in 2 to 3 days.[70,71] Occasionally, horses that showed few to no premonitory signs are found dead.[70]

The neurologic syndrome is characterized initially by incoordination, aimless walking, intermittent anorexia, lethargy, depression, blindness, and head pressing. These signs may be followed by hyperexcitability, belligerence, extreme agitation, profuse sweating, and delirium.[70,71] Recumbency and clonic-tetanic convulsions may occur before death. Recovery from acute episodes has been reported, but some horses retain neurologic deficits.[71]

Clinical signs associated with the hepatotoxic syndrome are swelling of the lips and nose, somnolence, severe icterus and petechiae of mucous membranes, abdominal breathing, and cyanosis. Affected horses also have acute onset of clinical signs with death occurring within a few hours to days.[70,71]

Pathophysiology

The gross lesions typical of equine leukoencephalomalacia include liquefactive necrosis and degeneration of the cerebral hemispheres, but degenerative changes also can occur in the brainstem, cerebellum, and spinal cord.[70-73] Necrotic areas can vary in size, and regions adjacent to the necrosis often are edematous and rarefied.[71,72] Lesions can be either unilateral or bilateral in appearance.

Gross hepatic lesions in affected horses generally are not pronounced. The liver may be slightly swollen, have a yellowish-brown discoloration, and contain irregular foci or nodules scattered throughout the parenchyma. Histologic abnormalities noted in the liver may include centrilobular necrosis and fibrosis, fatty infiltration of hepatocytes, portal fibrosis, biliary stasis, and bile duct proliferation.[70-72]

The mechanism whereby these changes occur has not been well elucidated but may be related to sphinganine and sphingasine metabolism. The brain lesions may be induced by ingesting smaller quantities of infected corn over a long period of time, whereby ingestion of higher quantities may produce fatal hepatotoxicosis over a shorter time interval.[71,75]

Several metabolites of *F. moniliforme* have been identified in feeds associated with outbreaks of equine leukoencephalomalacia. These include fusarin C, moniliformin, fusaric acid, 2-methoxy-4-ethylphenol, fumonisin B_1, and fumonisin B_2.[72,73] Toxicity information about fumonisin B_2 is unknown, but moniliformin, fusaric acid, and 2-methoxy-4-ethylphenol do not produce leukoencephalomalacia when injected intravenously into donkeys. Their role in the pathogenesis of the liver lesions in equine leukoencephalomalacia is likewise unknown. However, the neurologic and hepatotoxic syndromes can be produced by oral and intravenous administration of fumonisin B_1.[72]

Diagnosis and Treatment

The diagnosis of equine leukoencephalomalacia has been based mostly on observation of clinical signs coupled with a history of exposure to moldy corn. Typical postmortem lesions, when available, help confirm the diagnosis.

Clinicopathologic abnormalities are nonspecific and usually indicate some degree of liver dysfunction. Increased serum concentrations of bilirubin, AST, GGT, and LDH have been reported.[70,72,75] Cerebrospinal fluid abnormalities may include increased protein and total nucleated cell counts and an increased concentration of myelin basic protein.[71,75]

Analytic methods have been developed to assay fumonisin in feed material. Feed containing greater than 10 ppm fumonisin B_1 is not safe to feed to horses.[74] Because the disease requires a fairly prolonged exposure to infected corn, representative feed samples should be submitted for analysis. Feed currently being ingested may not be contaminated with the mold.

Treatment of equine leukoencephalomalacia is largely supportive. Horses that are hyperexcitable should be sedated to minimize injury to themselves and their handlers. Supportive therapy for hepatic dysfunction should be initiated if liver damage is evident, and some horses may require forced feeding and watering

if they become unable to eat and drink. Mannitol or DMSO may be administered to aid resolution of cerebral edema, and laxatives and activated charcoal may be given to eliminate toxins already in the digestive tract, although their usefulness is probably minimal because this disease is not an acute intoxication. Contaminated feed should be removed immediately from all exposed horses, and pastured horses should be moved to pastures without access to corn. Preventive measures include providing suitable feed material to horses and storing grains, particularly corn, under conditions that discourage mold growth.

Trichothecenes

The trichothecenes are a group of compounds elaborated primarily by *Fusarium tricinctum* and other *Fusarium* species. Only four of approximately 40 trichothecene derivatives have been found to occur naturally in feedstuffs. These four include T-2 toxin, deoxynivalenol, diacetoxyscirpenol, and nivalenol.[76,77] Of these, only one reported episode of T-2 intoxication in horses was found in the literature.[77] This group of mycotoxins more commonly causes gastrointestinal problems in other animals, mostly cattle.

In the reported outbreak horses showed clinical signs and laboratory abnormalities similar to those of equine leukoencephalomalacia caused by fumonisin B_1. Gross lesions in necropsied horses were also similar to those of equine leukoencephalomalacia. *F. tricinctum* was isolated from all suspect feed samples, and T-2 toxin was detected in varying concentrations in all examined feed samples. Other *Fusarium* metabolites detected in this outbreak included HT-2, verrucarin A and J, and roridin A. The toxicity of these metabolites in farm animals is not yet determined.[77]

Lead

Lead is reported to be one of the more common toxicants found in veterinary practice (mostly involving cattle), but it rarely is a cause of poisoning for horses. Materials that can serve as a source of lead toxicity to animals include lead-based paints, putty and caulking materials, greases, linoleum, leaded gasoline, solid lead solder, roofing materials, asphalt, discarded automobile batteries, and industrial effluents contaminating streams or forage. Water from lead plumbing also might serve as a source of toxicity.[53,76]

Acute and chronic forms of toxicosis can occur depending on the amount of lead ingested and the time frame in which ingestion occurs. Lead toxicosis in horses has historically been chronic and is associated with some type of forage contamination.[78,79] Foliage near lead smelters often contains excessive lead, and grasses located near busy highways have been reported to contain high lead concentrations.[53,79] Horses appear to be much more sensitive than cattle to prolonged, low-dose exposure to lead, yet they are much less sensitive than cattle to short-term exposure of large doses.[76,78] The acute oral lethal dose of lead acetate in horses is 500 to 750 g total dose, but chronic toxicosis can arise when 1 to 7 mg/kg per day is ingested over a period of days, weeks, or months.[76]

Numerous factors can influence the toxicity of lead in horses. Young animals and malnourished animals are reported to be more susceptible than older animals; solid lead is not as toxic as the more soluble salts, which are absorbed more readily; and concurrent exposure to lead and cadmium results in increased severity of clinical signs of lead poisoning. In addition, lead may interact with other minerals to affect toxicity. High levels of dietary calcium cause decreased gastrointestinal absorption of lead.[53,76,79]

Clinical Signs

The clinical signs of lead toxicity in horses are caused primarily by peripheral nerve dysfunction. The motor nerves are at greater risk, with minimal sensory perception loss in affected horses. Initially, affected horses may appear weak or have slight incoordination. Depression and weight loss become apparent and worsen over the disease course. Laryngeal and pharyngeal paralysis, dysphagia, dysphonia, and proprioceptive deficits occur. As the disease progresses, horses may exhibit flaccidity of the rectal sphincter; paresis of the lower lip; and difficulty in prehension, mastication, and deglutition. Aspiration pneumonia resulting from dysphagia and regurgitation of food is common, and fine muscle tremors may occur intermittently. Terminally, horses may show severe incoordination, anorexia, emaciation, and almost complete pharyngeal and esophageal paralysis with inability to swallow food or water. Seizures also may occur terminally. Colic and diarrhea may be apparent, but they are not common signs.[53,78,79] Progression of these disease signs may require weeks to develop.

Dietary lead crosses the placental barrier, and mares chronically exposed to lead in late pregnancy may deliver premature or small, weak foals. These foals are at greater risk of developing secondary disease complications.[78]

Pathophysiology

Lead enters the body primarily through ingestion. Inorganic lead cannot readily penetrate the skin, but organic forms such as tetraethyl lead and tetramethyl lead are absorbed through the skin. However, exposure of horses to organic lead compounds would seem to be a rare occurrence. Metallic lead shot or bullets lodged in tissues do not dissolve because tissue pH is too high.[76]

Metallic lead and lead sulfide are less absorbed than the acetate, carbonate, hydroxide, oxide, and phosphate salts. Less than 10% of ingested lead is absorbed across the gastrointestinal tract in adults, but if sufficient quantities of soluble salts are ingested, a significantly greater amount of lead can cross into blood. Even though intestinal absorption is inefficient, increases in blood lead concentrations can occur within 3 hours of dosing.[53,76]

Once absorbed, a large portion of lead is carried on erythrocyte membranes, where it is bound irreversibly to erythrocyte proteins. Much of the remaining lead becomes bound to albumin, and only a small proportion of the absorbed lead actually is free in serum. Unbound lead is in equilibrium with lead bound to erythrocytes and albumin, and distribution to various tissues takes place from the unbound fraction.

Much of the blood lead is removed in the liver. Within the liver, cellular trapping of lead is thought to occur by lead binding to cytoplasmic proteins called *metallothioneins*. Lead also accumulates within the renal cortex, where it becomes trapped as intranuclear lead proteinate inclusions in tubular epithelial cells. Unbound lead is excreted into milk, and it readily passes membrane barriers such as the placenta and the blood-brain barrier to become distributed in many body tissues.[76]

Unbound lead becomes immobilized and bound to bone substance, particularly in the physeal region, by an unknown mechanism. However, bone is considered to be the "sink" for lead and eventually may contain greater than 90% of the total body burden of lead. Deposition of lead into bone is a slow, gradual process, entailing redistribution of lead from other soft tissues. In this manner, bone serves as a detoxification mechanism under conditions of chronic exposure to

small concentrations. Bone cannot hold an infinite amount of lead, however, and when saturation occurs, signs of toxicosis may appear suddenly because of rising blood and soft tissue concentrations after continued exposure.[76]

Bile and feces are thought to be the primary pathways of lead excretion, and feces may contain unabsorbed lead and lead that has undergone enterohepatic circulation. Gastrointestinal secretions, including pancreatic secretions, also might be involved in elimination of lead from the body.[53,76]

The mechanism of action of lead at the cellular level is still under scrutiny. The known toxic effects of lead include inhibition of sulfhydryl groups of enzymes essential to cellular metabolism and inhibition of heme synthesis. Lead also is known to cause a decrease in local concentrations of the essential trace metals copper, iron, and zinc. These metals have important functions in mitochondrial enzymes, and interference by lead with these may adversely affect cellular respiration, oxidative phosphorylation, and the ATP synthetase complex.[76]

The peripheral neuropathy associated with lead toxicosis in horses is thought to be caused by peripheral nerve segmental demyelination, which impedes nerve impulse conduction and contributes to the clinical signs observed. The metabolic inhibitory effects of lead are speculated to cause the demyelination.[76,78]

Lead is known to damage the blood-brain barrier and capillary endothelial cells, resulting in cerebral edema and hemorrhage. Additionally, the damaged blood-brain barrier may allow cytotoxic solutes normally excluded from the brain to enter the brain substance.[76] Whether these mechanisms have any appreciable effect on the development of clinical signs observed in the horse is unknown.

Inhibition of heme synthesis is an important aspect of lead toxicosis in several animal species. This pathologic mechanism also occurs in the horse, but its significance to the overall disease course is limited. The result of heme metabolism interference and altered function of other erythrocyte proteins is a shortened erythrocyte half-life that can produce a normochromic, normocytic anemia, which is generally marginal in affected horses (PCV of 25%–30%).[78,79] The anemia also may be accompanied by nucleated red blood cells and Howell-Jolly bodies in peripheral blood.[79]

Two enzymes in the heme synthesis pathway that are particularly susceptible to lead are δ-aminolevulinic acid dehydratase (ALA dehydratase) and ferrochelatase. Inhibition of ALA dehydratase results in reduced levels of porphobilinogen in erythrocytes and an accumulation of ALA dehydratase, which is excreted in urine. Interference with ALA dehydratase also may be partly responsible for brain damage associated with lead toxicity in some species. Inhibition of ferrochelatase limits the formation of heme from protoporphyrin, resulting in an accumulation of unmetabolized porphyrins. These include protoporphyrin I, which is retained in the erythrocyte; uroporphyrins, which are excreted in urine; and coproporphyrins, which are excreted in feces. Lead also interferes with pyrimidine-specific 5′-nucleotidase activity, resulting in basophilic stippling of affected erythrocytes.[53]

Another important implication of lead toxicity is the suggestion that lead may be immunosuppressive by way of its interference with humoral and cell-mediated immune responses.[53,76]

Diagnosis and Treatment

Confirmation of suspected lead poisoning often is based on determination of blood or tissue lead concentrations. Blood levels of 0.30 ppm or greater are diagnostic if horses are showing clinical signs, but blood lead concentrations do not reflect the severity of poisoning.[78,79] Lead concentrations greater than 5 ppm in liver and kidney and 30 ppm in bone are considered diagnostic of lead intoxication in horses.[76]

In instances of chronic toxicity, however, blood lead values may be within the normal reference range. In such instances diagnosis of toxicity may be aided by administration of calcium disodium EDTA, which chelates lead in bone stores and increases the lead concentration in blood. The soluble lead complexes then are excreted in urine, with a resultant manyfold increase in urinary lead concentration within a few hours of EDTA administration.[53,76,77] The recommended dose of calcium disodium EDTA is 75 mg/kg intravenously.[53]

Clinicopathologic aberrations include increased concentrations of erythrocyte ALA and erythrocyte porphyrins and decreased activity of erythrocyte ALA dehydratase. Increased amounts of coproporphyrins, uroporphyrins, and aminolevulinic acid are found in urine, but measurement of erythrocytic ALA dehydratase is considered more diagnostic than measurement of urinary ALA dehydratase content.[53,76,78] Increased blood concentration of zinc protoporphyrin also has been documented in an affected horse.[80] These analyses generally are not routinely run by veterinary diagnostic laboratories.

Hematologic abnormalities in affected horses include a marginal anemia frequently accompanied by metarubricytes and Howell-Jolly bodies in peripheral blood.[53,79] Anisocytosis, poikilocytosis, hypochromasia, polychromasia, and basophilic stippling also can occur. These changes are suggestive but not pathognomonic of lead toxicity in horses.[53] One also can measure the concentration of lead in soil and in forages. Poisoning in horses has been reported when grazed forage contains lead levels in excess of 300 ppm.[53,78]

Treatment of affected horses should include immediate elimination of the lead source, if possible, and prompt initiation of chelation therapy. Calcium disodium EDTA is the chelator of choice; it chelates osseous lead but not tissue-bound lead. The chelated lead then becomes soluble and is excreted by the kidney. The unsaturated bone stores then reequilibrate with the lead in soft tissues. Calcium disodium EDTA can be administered by slow intravenous infusion at a dosage of 75 mg/kg of body weight daily for 3 to 5 days. A 2-day nontreatment period may follow to allow reequilibration of soft tissue and bone and then an additional 5-day treatment regimen if needed. An alternative dosage schedule is 110 mg/kg intravenously twice daily for 2 days. After a 2-day nontreatment period, this same regimen may be repeated. The clinician should base the decision to continue therapy with EDTA on posttreatment blood lead concentrations and renal function tests.[53]

Additional therapy should include fluid and nutritional support. Although thiamine administration has been advocated along with chelation therapy in small animal and ruminant lead toxicosis,[53] its efficacy in treating horses with lead poisoning has not been investigated. Dietary calcium supplementation or sodium-magnesium sulfate may have some beneficial effects by helping to reduce further gastrointestinal absorption of lead.

Methods aimed at reducing exposure to lead and preventing intoxication include appropriate cutting and disposal of contaminated forage, tilling or burning of the stubble, and addition of lime to the soil.[78] Use of alfalfa as a roughage also might be beneficial, possibly because of the high calcium

content in alfalfa, because intoxication is more difficult to produce experimentally in horses when alfalfa is being fed and because increased dietary calcium decreases the gastrointestinal absorption of lead.[53,78]

Toxicoses Causing Signs Relating to the Cardiovascular and Hemolymphatic Systems

Certain plants and ionophores are the most frequently encountered causes of cardiac problems in horses. Manifestations associated with hemolysis and anemia also are possible.

PLANTS

Oleander (*Nerium* spp.)

Clinical Signs

According to most research, sudden death is the most common sign attributed to oleander poisoning. Some reports suggest that affected horses exhibit lethargy, inappetence, and occasional signs of abdominal pain.[81,82] Profuse, watery, catarrhal, or bloody diarrhea also may occur within a few hours of ingestion.[83] Cardiac irregularities, including alternating bradycardia and tachycardia, may be accompanied by a variety of arrhythmias.[83,84] The extremities of the horse may feel cold to the touch, and mucous membranes may appear blanched. Profuse sweating and muscle twitching are followed by weakness and death. Death may occur less than 12 hours after ingestion. One could expect similar problems to occur when horses are exposed to foxglove (*Digitalis* spp.), another cardenolide glycoside–containing plant.

The green plant apparently is unpalatable to horses. Most toxicities occur when leaves have been incorporated into lawn clippings and offered to horses. Drying does not affect the toxicity of the leaves; therefore leaves incorporated into hay also may be toxic. According to reports, 0.005% of an animal's body weight of green oleander is lethal.[81]

Pathophysiology

Common oleander contains several cardiac glycosides that are found in all parts of the plant.[81,83,85] These glycosides (i.e., oleandrin, digitoxigenin, neriin, folinerin, rosagenin) inhibit the Na^+,K^+-ATPase (adenosine triphosphatase) system, resulting in hyperkalemia, conduction abnormalities, and ventricular arrhythmias. Which glycosides or metabolites cause specific abnormalities is unclear because of the undefined pharmacokinetics of the individual glycosides.[85]

Diagnosis and Treatment

Exposure to the plant along with the aforementioned clinical signs should alert the clinician to the possibility of oleander toxicity. The rapidity of onset of clinical signs or the finding of dead animals may preclude any effective treatment. Symptomatic therapy should be initiated in those animals in which toxicosis is suspected. Decontamination measures, such as evacuation of the intestinal tract by laxatives and enemas, may be useful. Atropine and propranolol have been advocated, but they must be used with extreme caution.[83,84] Fluids containing calcium should not be used because they may augment the effects of the glycoside on the myocardium.[81] Postmortem changes may include gastroenteritis, focal myocardial necrosis, and renal necrosis.

White Snakeroot (*Eupatorium rugosum*) and Rayless Goldenrod (*Isocoma wrightii*)

Cases of white snakeroot intoxication have been reported primarily in the eastern half of the United States, from Michigan south to Alabama and eastward.[86] The toxic principle is tremetol, which has been described as a fat-soluble, high-molecular-weight alcohol.[86,87] Tremetol poisoning is reported to be most prevalent in dry years or in circumstances in which animals are subjected to inadequate pasturage. The toxin is excreted slowly and therefore tends to accumulate in animals grazing the plant. Because of this cumulative effect, repeated small doses can result in toxicosis as well as a single, larger exposure to the plant. A total amount of green plant varying between 1% and 10% of body weight may be lethal to horses.[86] The toxic principle remains in the dried plant after freezing.[88] In the southwestern United States, rayless goldenrod is the source of tremetol, and ingestion of this plant produces the same clinical syndrome as that of white snakeroot intoxication.

Clinical Signs

Depression; a stiff gait with frequent crossing of the hindlimbs; and patchy, profuse sweating seem to be the most profound signs of tremetol toxicity. Other, less frequently noted findings include muscle tremors, particularly of the shoulders and limbs; labored or shallow respirations; normal to subnormal body temperature; pupillary dilation; cardiac arrhythmias; and darkly discolored urine.[86,88]

The time of onset of signs varies considerably, from less than 2 days to as long as 3 weeks after the last exposure to the plant. Most horses showing clinical signs die. Recovery is reported to be rare and usually is prolonged and often incomplete. However, a report describes two horses that apparently fully recovered from suspected tremetol toxicity.[86] Death often follows within 1 to 3 days of the appearance of clinical signs.[86]

Noted laboratory abnormalities include hematuria, hemoglobinuria and proteinuria, mild elevations in serum alkaline phosphatase activity, elevated AST concentration, and significant elevation of serum CK activity. Acidosis, hyperglycemia, and glucosuria also have been documented.[86,88]

Postmortem findings primarily consist of mild renal tubular degeneration and necrosis; nonsuppurative colitis; pulmonary congestion; increased amounts of pleural and peritoneal fluid; and moderate to severe centrilobular vacuolar changes in the liver. Other significant findings include pericarditis and extensive, patchy myocardial degeneration and necrosis. Extensive, minute epicardial hemorrhage also has been reported.[86,88] One reported case also described moderate, multifocal degeneration of skeletal muscle.[86]

Pathophysiology

The mechanism whereby tremetol causes the aforementioned lesions and signs remains unknown.

Diagnosis and Treatment

Diagnosis of tremetol toxicity is based on observation of the described clinical signs and concurrent clinicopathologic abnormalities. Additionally, evidence that the affected horses have been exposed to either plant should be present, and, when

available, necropsy findings should be compatible with those described for tremetol toxicity. Analysis for tremetol from suspect samples is not readily available but can be done.[86]

Treatment is symptomatic. The primary goal of therapy is promptly removing the horse from exposure to the plants and providing supportive care. The clinician should attempt to evacuate the horse's gastrointestinal tract with laxatives such as mineral oil. Activated charcoal also has been suggested as being beneficial in removing the toxin.[88] Based on observed histopathologic abnormalities, volume diuresis of affected animals seems appropriate, and the clinician should attempt to maintain normal acid-base and serum electrolyte concentrations. All affected horses should receive adequate and suitable forage and ample fresh water.

Maple (*Acer* spp.)

Several species of maple have been documented as causing hemolysis in horses; however, because of its widespread distribution, red maple is the most commonly identified species. All maples should be considered a potential risk to equids. Intoxication of the horse by leaves of the red maple tree is a seasonal disorder that occurs during the summer and fall months, primarily in the eastern United States.[89,90] Fresh leaves appear to present no problem to the horse, but wilted or dried leaves are toxic, and overnight freezing and storage of dried leaves for 30 days does not alter their toxicity.[91] Experimentally, dried leaves are toxic when administered at a dose of 1.5 mg/kg of body weight.[90,91] The toxins present in red maple leaves are thought to be gallotannins and gallic acid, which are converted in the horse's gut to pyrogallol. The clinical syndrome produced is one of acute hemolytic anemia with methemoglobinemia and Heinz body production.[89-92] Red maple toxicity has been recognized in horses[92] and Grevy's zebras,[93] and horses electively ingest the leaves when other suitable forage is available. Donkeys and mules should be considered potentially susceptible to maple's toxic effects.

Clinical Signs

Signs of toxicity generally commence within 48 hours of ingestion. Affected horses show acute onset of lethargy, anorexia, weakness, and depression. Increased heart and respiratory rates are typical, and the animals are afebrile. Two outstanding characteristics of most affected horses are the obvious presence of icteric, pale, or brown mucous membranes and a brownish discoloration of blood and urine. Many horses appear cyanotic, and petechiae on mucous membranes have been reported. Signs of secondary acute renal failure also have been documented.[92] Death, when it occurs, generally happens 3 to 7 days after ingestion.[89-92] The mortality rate in naturally occurring and experimental cases is approximately 60%.[94,94a]

The aforementioned signs are representative of naturally occurring instances of toxicity. In an experimental study, however, two patterns of toxicity were recognized. One group of ponies given dried leaves accumulated before September 15 exhibited signs of the typical hemolytic syndrome and died 3 to 5 days later. Ponies given leaves collected after September 15 died within 18 hours of dosing and exhibited clinical signs only of cyanosis and depression.[91] The reason for this disparity of signs was not offered.

Pathophysiology

The clinical syndrome is that of acute damage to the red blood cell that produces an acute hemolytic anemia with methemoglobinemia and Heinz body production in affected horses. The mechanism of erythrocyte damage has not been determined, but these hematologic abnormalities are characteristic of an oxidant.[90-92] Gallic acid and tannins have been implicated as possible toxic compounds in red maple leaves.[94b]

Heinz bodies are intracellular precipitates of oxidized hemoglobin that result from oxidant injury to erythrocytes. They damage the erythrocyte membrane and produce intravascular and extravascular hemolysis. Intravascular hemolysis results when erythrocyte membrane functions involving active and passive ion transport become impaired. The hyperpermeability changes that then occur alter the osmotic gradient of the erythrocyte and cause rupture of the affected red blood cell. Extravascular hemolysis occurs when the red blood cell remains intact, but the damaged erythrocyte is removed from circulation by cells of the reticuloendothelial system.[89,90,92]

Methemoglobin is formed when hemoglobin is oxidized from the ferrous to the ferric form of iron. A certain amount of direct oxidation of hemoglobin to methemoglobin occurs naturally, but erythrocytes are able to reduce methemoglobin back to hemoglobin. Excessive production of methemoglobin occurs under conditions of excessive oxidative stress or when methemoglobin reduction is impaired.[89,91] Although methemoglobin itself does not produce hemolysis, it is incapable of transporting oxygen and therefore contributes to hypoxia. When present in sufficient quantities, methemoglobin imparts a brown discoloration to peripheral blood and possibly to mucous membranes.

Diagnosis and Treatment

Maple leaf toxicosis occurs under rather specific conditions but is characterized by an acute onset of hemolytic anemia with methemoglobinemia and Heinz body production. The typical clinical signs and conditions supporting maple leaf intoxication should be in evidence before making a diagnosis.

Hematologic abnormalities noted in affected horses include moderate to severe anemia (PCV often less than 10% in severely affected horses), hemoglobinemia, methemoglobinemia, Heinz bodies, anisocytosis, hyperbilirubinemia, and increased erythrocyte fragility. Blood chemistry analysis may reveal depletion of erythrocyte-reduced glutathione and increased serum concentrations of LDH, creatine phosphokinase, AST, and sorbitol dehydrogenase.[89-92] Transient hypercalcemia has been recorded in some horses,[89] and increases in BUN and creatinine concentrations are expected in horses undergoing significant renal insult secondary to hemolysis.[92] Urinalysis may indicate varying degrees of hemoglobinuria, hematuria, bilirubinuria, and proteinuria.[89-91]

Treatment of affected horses is primarily symptomatic. Exposure to red maple leaves should be eliminated immediately, and affected horses should be kept in a quiet, calm environment. Oxygen therapy may be beneficial in selected cases, and blood transfusions can be administered to severely affected individuals.

Balanced fluid administration is important to maintain renal function and to aid in diuresis because affected horses may be at great risk of developing hemoglobin nephrosis and acute renal failure. Blood electrolyte and acid-base parameters should be monitored and abnormalities corrected as needed. Acute renal failure should be treated appropriately if it develops.

Other symptomatic therapies that have been suggested include nasogastric intubation with activated charcoal to aid in potentially binding to the toxin(s); dexamethasone to aid in stabilizing red blood cell membranes and decrease

phagocytosis of damaged red blood cells; and ascorbic acid (30 mg/kg) given in intravenous fluids twice daily, which may reduce oxidative damage to red blood cells. Whether dexamethasone increases the risk of laminitis in affected horses is unknown, and the efficacy of ascorbic acid is questionable.[94] Treatment with dexamethasone was associated with increased risk of death in one study.[94a]

Prevention of the disease is accomplished by preventing exposure of horses to dried maple leaves.

Onion (*Allium* spp.)

Onion toxicosis in horses is a rare event and occurs when horses are fed large amounts of culled onions (from commercial onion farms) or are forced to eat wild onions because of inadequate available forage. Horses appear to avoid these plants when suitable forage is available.[95,96] The toxic principles in onions, *n*-propyl disulfide and sulfoxide, affect only circulating erythrocytes and cause oxidant injury to the red blood cell, with resultant Heinz body formation and subsequent hemolytic anemia. Severely affected horses succumb to onion toxicosis because of severe anemia or secondary renal failure caused by hypoxic nephropathy.

The clinical signs, laboratory values and pathogenesis of the anemia are all similar to those of maple leaf toxicosis, with the exception that methemoglobin formation does not seem to be nearly as pronounced in onion toxicity as in the former. The carcasses of horses that die as a result of onion toxicosis may have an onion odor at necropsy.[95]

Affected horses may recover from onion toxicity if they are removed from the onion source soon enough and if anemia is not severe. Treatment is largely symptomatic and should include removal of the onion source and provision of adequate, suitable forage. Hematinics are of little value, but oxygen therapy and blood transfusions may be indicated in more severely affected animals.

Maintenance of renal function is of primary concern because affected horses are at risk of developing secondary hypoxic nephropathy. The clinician should give balanced fluids to promote diuresis and should correct electrolyte and acid-base abnormalities. Diuretics should be used with caution, but they may be of value in the volume-loaded horse.

Yew (*Taxus* spp.)

There are both native and ornamental yews distributed throughout the Northern Hemisphere; but by far the vast majority of poisonings in horses is due to accidental consumption of the ornamental shrubs. Yews are evergreen shrubs commonly used in landscaping around houses and property. Horses can be exposed by ingesting the plant directly through accidental access, ingesting plant trimmings thrown in brush piles, or intentionally being fed the plant by well-intentioned neighbors. These plants are popular as landscape shrubs because they stay green all year round and require little maintenance other than occasional trimming.

Pathophysiology

All parts of the plant are toxic (except for the red fleshy aril surrounding the seed), and toxicity is not lost in drying. The cardiotoxic taxines are thought to interfere with atrioventricular cardiac conduction leading to heart block, potentially due to inhibition of sodium and calcium currents in cardiac ells and/or possible potassium channel effects.[97] This inhibition leads to a decrease in the ventricular contraction rate, a variety of cardiac arrhythmias, and death due to cardiac arrest in diastole.[97]

Clinical Signs

Horses can abruptly collapse and die, while exhibiting few to no premonitory signs. Sometimes horses have died while plant material is still present in the oral cavity. Collapse and death can occur within a few minutes of ingesting a lethal dose (approximately 0.1%–0.5% of body weight). Sometimes weakness, tremors, ataxia, and difficulty breathing can be seen just before collapse and death. In many cases, horses are found dead.

Diagnosis and Treatment

Diagnosis relies heavily on identifying the plant material in the mouth or stomach contents, and several diagnostic laboratories can test for the taxine alkaloids. Microscopically one may see areas of multifocal necrosis of the heart tissue, particularly within the ventricles and the papillary muscles. Similar lesions have been reported in cattle exposed to Japanese yew.[98]

Treatment is rarely possible given the acute onset of clinical signs, collapse, and death. Evacuation and decontamination of the gastrointestinal contents with mineral oil and activated charcoal is appropriate, along with basic symptomatic and supportive care, if the patient survives the initial insult. It has been reported that calves who survived an initial nonlethal exposure to yew material died several days later exhibiting histologic changes of myocardial fibrosis.[99] This could conceivably happen in horses as well.

MISCELLANEOUS AGENTS

Coumarin Derivatives

Coumarin normally is present in some species of sweet clover and has no anticoagulant action. However, certain molds present within the plant can convert coumarin to dicoumarol; hence the term *moldy sweet clover poisoning*. Dicoumarol also has been detected in sweet vernal grass *(Anthoxanthum odoratum)*. Coumarin derivatives are used widely as anticoagulants, with bishydroxycoumarin (dicoumarol) and 3-(α-acetonylbenzyl)-4-hydroxycoumarin (warfarin sodium) being the first oral anticoagulants developed from coumarin.[87] These first-generation compounds are used therapeutically as anticoagulants and as rodenticides. There are several anticoagulants on the market, representing both first- and second-generation compounds. In horses warfarin has been used therapeutically to treat thrombotic disorders such as thrombophlebitis and to treat navicular disease.[100,101] Horses may exhibit signs of toxicity while being medicated with warfarin if a therapeutic concentration is exceeded. Rarely are horses exposed to anticoagulants used as rodenticides around buildings or feed storage areas, but it does occur. Second-generation anticoagulant rodenticides (e.g., brodifacoum and bromadiolone) have been developed because of acquired rodent resistance to the first-generation compounds. Because no indications exist for human or veterinary medicinal use of brodifacoum, toxicity associated with this compound is caused by accidental ingestion.[102] Exact toxic doses for horses have not been determined.

Clinical Signs

The clinical signs of toxicity noted with anticoagulants are largely those of a hemorrhagic diathesis. Onset of signs usually is acute and may include hematoma formation, epistaxis, anemia, weakness, pale mucous membranes, or ecchymoses

of mucous membranes. Hematuria and melena can occur, and hemorrhage into various body compartments may result in secondary signs caused by malfunction of the involved organ or tissue. Occasionally, affected animals are found dead.[103] Multiple fractional doses of first-generation compounds given over several days may be more toxic to horses than a single larger dose.[100] Brodifacoum, however, differs from warfarin in that a single oral dose has the potential of causing illness and may even be lethal (estimated LD_{50} of 1–2 kg per adult horse).[102,104]

The onset of clinical signs is delayed from the time of ingestion. In an experimental model the hypothrombogenic effect of warfarin anticoagulation was noticed 60 hours after an acute dose.[105] This effect persisted for approximately 30 hours. The effect of brodifacoum, however, is much longer and may persist for weeks, despite its half-life of 1.22 days.[102] In an experimental study horses given a single dose of brodifacoum (0.125 mg/kg body mass) showed increased partial thromboplastin time (PTT) at 24 hours and one-stage prothrombin time (PT) at 48 hours after exposure. These values returned to pretreatment levels by day 12. However, two horses required 23 days for clotting times to return to normal. In these horses peak plasma concentration of brodifacoum occurred 2 to 3 hours after oral administration. Additionally, four of the six experimental horses showed clinical signs of depression, anorexia, and weight loss.[104]

Pathophysiology

Warfarin is absorbed readily from the gastrointestinal tract but also may be administered intravenously for therapeutic purposes.[87,100] Once absorbed, warfarin is highly bound (greater than 90%) to plasma proteins, and some is stored in the liver.[87,100,105] The degree of anticoagulant protein binding in horses is not known but may be similar to other species.[102] Warfarin is hydroxylated by hepatic enzymes to inactive compounds that are eliminated by the kidney. The metabolites have no anticoagulant effect,[87] and the biologic half-life of warfarin in the horse is approximately 13 hours.[102] Coumarins also cross the placenta and are secreted in milk.[87]

Protein binding of warfarin is reversible, and the protein-bound, pharmacologically inactive warfarin serves as a reservoir. The unbound portion remains fairly constant in plasma.[87,100]

A number of factors can influence the amount of unbound free warfarin in serum. Protein-bound drugs such as phenylbutazone, chloral hydrate, and sulfonamides may enhance the toxicity of warfarin by displacing warfarin from protein-binding sites. This allows a greater proportion of the drug to be in the free form and thus able to exert its pharmacologic effect.[87,103] Corticosteroids and thyroxine may lower the therapeutic dose of warfarin by increasing clotting factor catabolism and receptor site affinity.[100]

Certain physiologic factors also may enhance the toxicity of warfarin. Hypoalbuminemia may result in fewer binding sites available, thereby increasing the amount of free drug. Hepatic dysfunction may impede metabolism of the anticoagulants, and reduced amounts of vitamin K in the diet may predispose to toxicity.[87]

Some drugs reduce the therapeutic response to a given dose of warfarin. Barbiturates, rifampin, and chloramphenicol induce hepatic microsomal enzyme activity, thereby accelerating the metabolism of warfarin. If these drugs are withdrawn during warfarin therapy, toxicosis may result.[87,100] Likewise, excessive dietary intake of vitamin K or vitamin K administration can reduce or inhibit the anticoagulant effects of warfarin.[100]

Warfarin acts as an anticoagulant by inhibiting production of the vitamin K–dependent clotting factors II, VII, IX, and X. Vitamin K is a cofactor in the synthesis of clotting factors II, VII, IX, and X and also acts on all clotting factor precursors to convert glutamyl residues to γ-carboxyglutamyl residues. During this carboxylation process vitamin K_1 is converted to vitamin K_1 2,3-epoxide, an inactive metabolite. This epoxide returns to active vitamin K_1 by the action of the microsomal enzyme vitamin K_1 epoxide reductase. The coumarin anticoagulants inhibit vitamin K_1 epoxide reductase, thereby creating a vitamin K_1 deficiency. The result is decreased production and subsequent deficiency of the vitamin K–dependent clotting factors.[85] The delayed onset of action of the coumarin derivative anticoagulants results from this impediment to clotting factor synthesis rather than from a direct effect on the clotting mechanism per se.

The various blood clotting factors have different plasma half-lives. Factor VII has a shorter half-life than the other clotting factors, so the earliest laboratory indication of anticoagulant toxicity is a prolonged PT. As the other clotting factors become depleted, activated PTT also increases as toxicity continues.[100] The clinician should monitor horses given warfarin therapeutically for clotting abnormalities. Prolongation of PT by 1.5 to 2 times the baseline value has been suggested as the effective range of anticoagulation. However, some horses maintained in this range may show signs of hemorrhage.[101] In fact, reports in horses suggest that factor IX may be depleted from circulation more rapidly than factor VII, indicating that the PTT would be the more sensitive clotting assay to assess in horses after exposure to anticoagulants.[102]

Diagnosis and Treatment

The diagnosis of warfarin or other coumarin-derivative anticoagulant intoxication is based on evidence of exposure to the compound, presence of a bleeding diathesis, and prolongation of PTT and PT. The platelet count, fibrinogen concentration, fibrin degradation product (FDP) concentration, and antithrombin III activity remain within their respective normal ranges of activity.[100,101] However, in dogs exposed to toxic doses of anticoagulant rodenticides, fibrinogen and FDPs have been found to be elevated 50% of the time.

Blood, liver, stomach and intestinal contents, and feces can be submitted for analytic testing for the anticoagulant residues. Specimens should be frozen for transportation to the laboratory.[103,105]

In horses intoxicated by warfarin, discontinuance of warfarin therapy or removal of the product from the environment is of primary importance. Mineral oil may be used to enhance fecal excretion of any orally ingested warfarin products. Vitamin K_1 should be given at a dosage of 300 to 500 mg subcutaneously every 4 to 6 hours until PTT and PT return to their baseline values (5–7 days is generally sufficient). PTT and PT should be monitored daily for 3 to 4 days thereafter to ensure stability. The subcutaneous route of vitamin K_1 administration is preferable because of the possibility of adverse reactions if the product is given intravenously or intramuscularly. Intravenous injection of vitamin K_1 may result in transient restlessness, tachypnea, tachycardia, sweating, and anaphylactic reactions.[106,107] Intramuscular administration of vitamin K_1 results in erratic response times and therefore may be

inappropriate for a hemorrhaging patient.[106] Alternative doses for vitamin K_1 administration are 0.3 to 0.5 mg/kg intravenously, and a dosage of greater than 0.5 mg/kg intravenously has been suggested to inhibit coumarin activity for several days.[100] If the intravenous route is chosen, vitamin K_1 should be diluted in 5% dextrose or saline and administered slowly.[103]

In horses intoxicated with long-acting anticoagulant rodenticides, treatment with vitamin K_1 may be required for 2 to 4 weeks or until coagulation status is normal 2 to 3 days after the last dose of vitamin K_1. Affected horses were given vitamin K_1 (2.5 mg/kg) subcutaneously every 12 hours for 36 hours and then orally twice daily for the duration of treatment.[102]

If bleeding is serious, fresh blood or fresh plasma given intravenously may be necessary to control hemorrhage and help correct hypovolemia. Other supportive measures such as bandaging and keeping the animal in a quiet environment may be helpful. Alfalfa hay added to the diet may provide a natural source of vitamin K_1.[102] Organ dysfunction induced by hemorrhage and hypoxia should be treated appropriately. The prognosis for horses intoxicated with anticoagulant compounds is good if the disorder is recognized early and appropriate therapy is instituted. For symptomatic patients the prognosis is highly dependent on the severity, site, and extent of blood loss.

To prevent warfarin toxicosis, the clinician should strive to minimize exposure to the product and carefully monitor the therapeutic use of the drug in the horse. Contraindications to its use include any clinical or laboratory suggestion of hepatic disease, hypoproteinemia, or other condition that might increase the risk of toxicity. The practitioner should evaluate the concurrent use of other medications, because they may affect the potential for toxicosis to develop, and reevaluate the dosage of warfarin administered if other concurrent medications are changed. Additionally, the potential for traumatic injury in horses undergoing warfarin therapy should be minimized.

Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO), a byproduct of the paper-making industry, is a colorless liquid originally used as an industrial solvent. The chemical is a polar compound that readily mixes with ethyl alcohol and many organic solvents; it is extremely hygroscopic and can absorb more than 70% of its weight of water from air. DMSO possesses some antimicrobial and antifungal activity, but its primary medical use has been as an antiinflammatory agent and a transdermal transport agent.[108] More recently, DMSO has been used as a diuretic and has shown promising results when used to treat acute cranial and spinal cord trauma.[108,109]

The systemic toxicity of DMSO is considered to be low, and its greatest toxic potential appears to result from its combination with other agents.[110] However, in an experimental study rapid infusion of DMSO in 20% and 40% concentrations caused hemolysis, hemoglobinuria, diarrhea, muscle tremors, and signs of colic in some horses.[111] The LD_{50} of DMSO has not been established for horses, but ranges between 2.5 and 9.0 g/kg as a single intravenous dose have been reported in a number of animal species.[110] A dose of 1 g/kg intravenously has been suggested for use in horses. This dose should be diluted to a 10% to 20% solution and administered slowly intravenously.[109,110]

DMSO produces hemolysis when given intravenously in concentrations of 20% to 50% or greater.[108-110] If hemolysis is severe, affected horses may be at increased risk of developing hypoxic nephrosis. Concentrations of 10% or less are considered suitable for intravenous injection in horses.[108,109,111] Additionally, increased white blood cell adherence and fibrinogen precipitation have been reported when concentrations greater than 50% were administered.[108]

DMSO is a mild cholinesterase inhibitor, and its concurrent use with organophosphates or other cholinesterase inhibitors is not recommended.[108,110] DMSO also is known to induce histamine release from mast cells, but the significance of this phenomenon is unclear.[110]

Skin reactions to topically applied DMSO sometimes occur. Varying degrees of erythema, pruritus, drying, hardening, and desquamation of normal skin may be evident. These reactions are usually self-limiting and typically diminish with repeated applications.[110]

The greatest risk of toxicity resulting from DMSO is probably a consequence of its concomitant use with other toxic or potentially toxic agents. DMSO may aid transport of a variety of toxic compounds across skin, thereby inducing toxicosis from the transported agent. For example, mercury toxicity has been reported in a horse that had a blister after DMSO and mercury were applied topically to a leg.[112] In such instances, the clinician should treat the specific toxic reaction (or reactions) appropriately. No specific antidote is recognized for DMSO toxicosis, and it should always be used judiciously and conscientiously. The practitioner should heed the aforementioned precautions when administering the drug.

Bicarbonate

Sodium bicarbonate is one of the most common alkalizing agents used in animals, including horses. Sodium bicarbonate is indicated specifically to treat acute, severe metabolic acidosis because of its rapid effect on blood pH when given intravenously.[113] Sodium bicarbonate also has been used in performance horses to treat exertional myopathies and in attempts to prevent rhabdomyolysis. More recently, sodium bicarbonate administration in performance horses has been investigated because of its suggested role in limiting or preventing systemic lactic acidosis, thereby enhancing performance level.[114,115] The adverse effects of bicarbonate administration occur when it is given too rapidly or in excessive quantities or when it is given in the presence of certain systemic abnormalities.

Clinical Signs

Animals, including horses, that suffer from an acute overdose of bicarbonate may exhibit signs of delirium, depression, and coma. Rapidly induced alkalosis also has been associated with cardiac dysrhythmias.[113]

Horses such as endurance horses or racehorses that are volume depleted and have sustained excessive electrolyte loss through sweat often have clinicopathologic changes of hypokalemia, hypochloremia, hypocalcemia, and metabolic alkalosis. When such horses are given bicarbonate, dramatic deleterious effects occur. These animals may exhibit signs of muscle fasciculation, synchronous diaphragmatic flutter, bruxism, and decreased respiratory rate. One also may note clinical evidence of further dehydration, such as increased capillary refill time, delayed jugular distensibility, diminished skin turgor, and decreased arterial pulse.[115]

Pathophysiology

The rapid administration or overdose of sodium bicarbonate has been associated with extracellular hyperosmolality, intracranial

hemorrhage, and cerebrospinal fluid (CSF) acidosis. Hyperosmolality results from hypernatremia because sodium bicarbonate dissociates into sodium ions and bicarbonate ions. An abrupt increase in serum osmolality can lead to intracranial hemorrhage as intracellular water moves into the extracellular space. This extracellular fluid accumulation may result in engorgement of perivascular spaces, with subsequent tearing of bridge veins and resultant hemorrhage. The CSF acidosis results from the rapid diffusion of generated carbon dioxide into the CSF. Carbon dioxide enters the CSF almost instantaneously, establishing new steady-state levels within minutes. Bicarbonate ion, however, is slow to enter the CSF and requires hours to days to achieve new steady-state levels. With sodium bicarbonate administration the increasing amount of carbon dioxide generated readily enters the CSF disproportionately more than does the bicarbonate ion. As a consequence, the CSF becomes acidic.[116] These mechanisms, individually or collectively, are thought to be responsible for development of the clinical signs observed with rapid or excessive administration of sodium bicarbonate solution.

Another effect of alkalosis is a shift to the left of the oxyhemoglobin dissociation curve. This left shift indicates an increased affinity of hemoglobin for oxygen, with a resultant decrease in the amount of oxygen available for cellular use. This change in hemoglobin affinity for oxygen has been associated with cardiac dysrhythmias following rapidly induced alkalosis.[113]

Horses undergoing extensive exercise or horses that are treated with furosemide (primarily as prerace medication for exercise-induced pulmonary hemorrhage) are at risk of developing hypochloremic, hypokalemic metabolic alkalosis. When sodium bicarbonate is given to these volume-depleted horses with electrolyte loss and concurrent metabolic alkalosis, another deleterious series of events can result. Further reduction of the circulating fluid volume may occur, along with development of serum hyperosmolality; electrolyte abnormalities of hypernatremia, hypokalemia, hypochloremia, and hypocalcemia; and further development of metabolic alkalosis.[115]

Excessive sodium bicarbonate produces hyperosmolality caused by hypernatremia because sodium bicarbonate dissociates into sodium and bicarbonate ions. The hypokalemia is explained partially by the intracellular shift of potassium in response to metabolic alkalosis, and the bicarbonate ion adds to the alkalosis already present. Furosemide administration causes urinary loss of potassium, chloride, and calcium, and sweating also can result in significant loss of chloride and calcium. Additionally, rapid intravenous infusion of 5% sodium bicarbonate in normal horses results in hypochloremia.[117]

The muscle fasciculations and diaphragmatic flutter noted in some horses likely result from hypocalcemia.[115] The total serum calcium concentration may be within a normal range, but alkalosis causes a reduction in the amount of circulating ionized calcium. Because ionized calcium is responsible for neuromuscular function, reduction in this fraction can cause clinical signs of hypocalcemia.

Diagnosis and Treatment. Horses being treated with sodium bicarbonate solutions should be monitored closely for clinical signs of alkalosis. Blood pH obviously is elevated, but rapid infusion of sodium bicarbonate or excessive use in horses already sustaining fluid and electrolyte loss can result in a number of clinicopathologic alterations. Affected horses typically exhibit increases in PCV, total serum protein, and serum bicarbonate and sodium concentrations. Additional findings of hypokalemia, hypochloremia, and hypocalcemia usually are present.

Treatment of affected horses involves cessation of bicarbonate administration and correction of the alkalosis and electrolyte abnormalities. Potassium chloride administration is indicated in horses with hypokalemic, hypochloremic metabolic alkalosis and is much more effective in correcting these electrolyte abnormalities than is sodium chloride. Potassium chloride also has been shown to cause a prompt, significant decline in venous blood pH in these horses.[115]

Apparently, hypertonic sodium bicarbonate solutions should not be used in dehydrated horses. The concurrent use of furosemide and sodium bicarbonate also appears to be contraindicated; if this is necessary, they must be used with extreme caution and close observation with laboratory assessment. Sodium bicarbonate should not be mixed with fluids containing calcium because insoluble complexes may form. The use of sodium bicarbonate orally in horses subjected to short-term intense exercise remains controversial.

Ionophore (Monensin)

Monensin is one of several biologically active compounds categorized as ionophore antibiotics (others include lasalocid, salinomycin, narasin, laidlomycin, maduramycin, and virginiamycin) because they can form lipid-soluble complexes with specific metal cations and transport them across biologic membranes. Monensin is produced by the fungus *Streptomyces cinnamonensis* and is selective in transporting sodium and potassium ions between intracellular and extracellular spaces.[103,118,119] Monensin is used routinely as a poultry coccidiostat and as a feed additive to improve feed efficiency in pasture and feedlot cattle. Horses are the domestic animals most sensitive to monensin toxicosis. The LD_{50} and possibly a single acute toxic dose of monensin for the horse is 1 to 2 mg/kg.[103]

Clinical Signs

Several syndromes of toxicity occur and seem to be dose related. Peracute toxicity may manifest as progressive, severe hemoconcentration; hypovolemic shock; and death within a few hours of ingestion. The acute form of the disorder is characterized by partial to complete feed aversion, abdominal pain, occasional watery diarrhea, intermittent profuse sweating, stiffness, progressive muscle weakness (especially in the hindquarters), progressive ataxia, tachycardia, hypotension, dyspnea, and polyuria. Affected horses may show clinical signs for 1 to 4 days before death.[119-121] Horses surviving sublethal doses of monensin exhibit signs of reduced athletic performance, unthriftiness, and cardiac failure. Cardiac arrhythmias, including atrial fibrillation and tachycardia, a prominent jugular pulse, and pleural and pericardial effusion, are apparent.[103] Intravascular hemolysis also may occur to a limited degree, but this is an uncommon finding.[118]

Pathophysiology

The primary action of monensin is the selective transport of sodium and potassium ions between the intracellular and extracellular spaces. Two mechanisms have been suggested to explain the toxic action.

According to one theory, monensin interacts with the mechanism regulating potassium entry into cell organelles, especially the mitochondria.[103] Low concentrations of monensin lead to a net accumulation of potassium within the cell, whereas higher

doses cause a net loss of potassium from the cell.[118] Because potassium is required for ATP hydrolysis by the mitochondria, the effect of monensin might be to inhibit ATP hydrolysis in mitochondria. As a result, cell energy production is decreased and can result in loss of cell function and death.[103,118]

The second hypothesis suggests that increased intracellular calcium concentration is the mechanism responsible for cell death. When the intracellular calcium concentration is increased, the mitochondria are forced to maintain calcium homeostasis by sequestering the excess calcium. This requires energy, which could take priority over ATP production. When the mitochondria become overloaded with calcium, oxidative phosphorylation is inhibited and less energy is produced to pump calcium out of the cell. When intracellular calcium levels reach a critical level, degradative enzymes are released, swelling of the mitochondria and sarcoplasmic reticulum occur, and cell necrosis and death follow.[103,118]

The heart is the primary target organ of monensin toxicosis, and electron microscopic studies of acute monensin toxicosis in ponies have shown structural changes in myocardial cells consistent with severe mitochondrial damage.[122] In horses ingesting a sublethal dose of monensin, the myocardial sarcolemma is damaged and is replaced by fibrous tissue in the healing process. Myocardial lesions are characterized microscopically by pale myofibers, loss of fiber striation, multifocal vacuolar degeneration, and scattered areas of necrosis. The result is a structurally weakened heart that can succumb to stress and cause acute collapse of the horse. Other lesions that may be present in affected horses include pericardial, pleural, and peritoneal effusions; hemopericardium; and epicardial hemorrhage. Chronically affected horses also may have hepatic congestion with centrilobular necrosis and hydropic degeneration of the renal tubules.[103,118]

Diagnosis

Monensin toxicosis is suspected when horses show clinical signs of feed refusal, abdominal discomfort, muscle weakness, and heart failure and when a possible exposure to contaminated feed has occurred. The practitioner can evaluate feeds, serum, liver, gastrointestinal content, and feces for the presence of monensin.

Clinicopathologic abnormalities are nonpathognomonic but include early signs of severe hemoconcentration and dehydration in horses affected peracutely. Serum potassium and calcium may be decreased moderately in the first 12 to 16 hours but then tend to come back to normal levels. BUN and creatinine concentrations are elevated in horses acutely affected but return to normal in surviving animals. Other enzymes that show elevated serum activity include CK, AST, and LDH isoenzyme fractions 1 (cardiac muscle) and 2 (red blood cell origin). Total serum bilirubin also may be elevated.[103,118] Troponin levels are often elevated, along with abnormal echocardiographic changes.

Abnormal findings in urine can include a progressive decrease in urine osmolality during the initial few hours of the disease course.[103] One also might expect elevations in urinary activity of renal tubular enzymes such as γ-glutamyl transferase and *N*-acetylglucosaminidase. Urinalysis abnormalities tend to correlate well with the degree of renal insult and are nonspecific indicators of renal damage.

Treatment

No specific antidote exists for monensin. Horses that have ingested a large amount should be treated early and aggressively with fluids to combat hemoconcentration and hypovolemic shock. Electrolyte and acid-base analysis should be performed, if possible, and any deficiencies corrected. The clinician should attempt to evacuate the bowel of the horse using orally administered laxatives such as mineral oil; activated charcoal may help decrease the absorption of monensin. Affected horses should be kept as quiet and nonstressed as possible for weeks after exposure to allow the damaged myocardium to heal.[103,118] Administration of selenium and vitamin E should be considered; these compounds have been shown to be somewhat protective against the toxic effects of monensin in swine.

Digitalis glycosides should never be used in acutely affected horses because they and monensin have been shown to be synergistic and immediately fatal to cardiac muscle cells. Digitalis glycosides should be used only with great caution in the weeks after recovery from the toxic episode. Likewise, calcium should not be given to acutely affected horses for two reasons. First, serum hypocalcemia is transitory, and serum calcium usually recovers to normal by 24 hours. Second, calcium can be dangerously irritating to an already injured myocardium.[118]

It is important to note that affected horses are susceptible to cardiac damage, which is often permanent. A critical evaluation of cardiac function and the integrity of any previously intoxicated horse that is destined to return to some form of athletic endeavor is judicious.

Ionophore (Lasalocid)

Lasalocid, another carboxylic ionophore antibiotic, is a fermentation product of the mold *Streptomyces lasaliensis* that is used commercially as a poultry coccidiostat and as a feed additive to improve feed efficiency and rate of weight gain in ruminants.

Clinical Signs

The signs observed in horses given toxic amounts of lasalocid are similar to those of monensin toxicosis. Affected horses exhibit lethargy, ataxia, paresis, and paralysis with partial to complete feed aversion. Once recumbent, some horses rise when given assistance. Most horses that survive appear normal 2 to 3 days after exposure. The lowest dose that has been reported to cause fatality was 15 mg/kg of body weight, but the LD_{50} for a single oral dose of lasalocid was estimated to be 21.5 mg/kg. Death occurred between 31 and 96 hours after oral dosing in the nonsurvivors.[123]

Results of a toxic feeding study indicated that poultry rations containing approved concentrations of lasalocid (75 to 125 g per metric ton) are not toxic or lethal to horses. This study revealed that horses voluntarily reduced their feed intake with increasing amounts of lasalocid in the ration and refused to eat the commercial premix when it was offered in place of their normal ration.[123]

Pathophysiology

The mechanism of action of lasalocid is thought to be similar to that of monensin. Lasalocid is the least toxic of the ionophores and differs from monensin in that it accepts divalent as well as monovalent cations.[87]

Diagnosis

No signs or laboratory findings are pathognomonic for lasalocid toxicity. In horses in which it is suspected, feedstuffs, stomach contents, serum, liver, and feces can be analyzed for lasalocid content.

Abnormal laboratory findings in affected horses may include hypocalcemia, hypophosphatemia, and hypokalemia early in the disease course (within 24 hours of exposure), but these values return to normal ranges by 120 hours after ingestion. Serum activity of AST frequently is increased, as are total serum bilirubin, glucose, and troponin concentrations. Occasionally, the BUN concentration is increased.[123] Echocardiographic and electrocardiographic changes can be observed.

Treatment

Initial treatment should include removal of all suspected feed sources and the oral administration of laxatives, along with activated charcoal, to enhance evacuation of the gastrointestinal tract and decrease absorption of the lasalocid. Other nonspecific supportive care may be helpful, but horses receiving a sublethal dose probably will recover with minimal assistance. If a lethal dose is forced into an animal inadvertently, oral laxatives and adsorbents such as activated charcoal may help bind lasalocid and reduce the amount absorbed. Administration of selenium and vitamin E before the onset of signs may help alleviate the severity of the clinical signs once they occur.

Ionophore (Salinomycin)

Salinomycin is an ionophore, also marketed as a coccidiostat, which is related more closely to monensin than is lasalocid. The ionic affinity of salinomycin is predominantly to sodium and potassium ions, and its mode of action and cellular effects are similar to those of monensin.[87]

In one report of affected horses, the clinical signs were similar to those of the other ionophore toxicoses. The range of clinical signs included partial to complete feed aversion, depression, occasional sweating, colic, dyspnea, weakness, ataxia, and recumbency. Occasionally, horses showed reduced performance for several weeks after exposure, but many horses that became recumbent were destroyed humanely. The clinicopathologic abnormalities exhibited by affected horses included elevated serum activities of CK, AST, and alkaline phosphatase.[124]

The diagnosis of salinomycin toxicity is hampered by the fact that none of the clinical signs are pathognomonic. However, one may assay suspect feed, gastrointestinal content, serum, liver, and feces for the presence and quantity of salinomycin.

Treatment of affected horses is mostly symptomatic because no specific antidote is available. Evacuation of the bowel by laxatives along with the use of activated charcoal may be helpful in reducing the amount of toxic material available for absorption. Fluid balance and electrolyte and acid-base indices should be maintained within normal ranges. Administration of selenium and vitamin E should be considered. Affected horses generally require an extended convalescence, and the clinician should consider the possibility of a persistent cardiomyopathy.[124] Affected horses should undergo a rigorous cardiac examination before returning to performance events.

Nitrates and Nitrites

Nitrates are an important component in the naturally occurring nitrogen cycle and as such are present in soils, groundwater, forages, row crops, weeds, animal tissues, and excreta. Nitrates also are used widely in fertilizers. Toxicity problems can arise when animals consume plants, feed, or water containing excessive amounts of nitrites. Nitrates naturally undergo microbial decomposition to nitrites, so nitrite toxicity can occur when animals ingest feed or water in which the nitrates have decomposed to yield large amounts of nitrites. This decomposition can occur in moist haystacks, water troughs, farm ponds, silages, and pig swills. Nitrite also is administered intravenously to treat cyanide poisoning, and overzealous use of this therapy can result in toxicity.[87] It is important to note that nitrate poisoning is common in ruminants but rare in horses and other monogastrics. As described, the risk is when horses are exposed to preformed nitrite.

The primary exposure to nitrite for most animals is the plants they consume. Many plants and forages are known to be nitrate accumulators, and a number of factors influence the uptake of nitrates in plants. Nitrate concentration by plants is enhanced by low soil pH; low soil molybdenum, sulfur, or phosphorus content; low soil temperature; drought; soil aeration; decreased light; and use of phenoxyacetic acid herbicides such as 2,4-dichlorophenoxyacetic acid. Nitrate and nitrite accumulation in ponds and groundwater is caused by water runoff from nitrate-rich soils or by direct contamination with nitrates and nitrites.[87,103] Nitrates and nitrites are water soluble and are carried easily from feedlots, pigpens, and fertilized areas into the soil and subsequently into plants, wells, and ponds.

The most important aspect of nitrates is their ease of microbial conversion to nitrites. Nitrite is responsible for the primary signs associated with toxicity in nitrate poisoning.

Clinical Signs

Although apparently rare, horses are reported to be susceptible to nitrate intoxication. Experimentally, an oral dose of 1 g/kg potassium nitrate caused illness but not death in horses. However, nitrites have been associated with death of horses under field conditions.

In monogastric animals, nitrate ingestion is reported to produce gastrointestinal irritation with resulting emesis/regurgitation or enteritis. Salivation, diarrhea, colic, and frequent urination may be evident if the nitrate is sufficiently concentrated.

Signs of acute poisoning with nitrites usually begin 30 minutes to 4 hours after ingestion of high-nitrite feed or water. The most characteristic signs are those referable to respiratory insufficiency and include dyspnea, cyanosis, rapid and weak pulse, and anxiety. Exertion may exacerbate these signs and induce muscle tremors and collapse. The horse may have terminal clonic convulsions. The blood of affected animals is usually brown or chocolate colored because of the formation of methemoglobin, and this imparts a cyanotic or pale appearance to mucous membranes. Death may occur in several hours or be delayed until 12 to 24 hours after ingestion.[87,103]

Pathophysiology

Nitrites are absorbed rapidly from the gastrointestinal tract into the bloodstream. The nitrite ion acts directly on vascular smooth muscle to cause relaxation and easily enters erythrocytes in exchange for chloride ion. Nitrite also can pass the placenta to enter fetal erythrocytes, which are especially sensitive to nitrite. The biologic half-life of blood nitrate in horses is 4.8 hours. Only small amounts of nitrate or nitrite are bound to plasma proteins.[87,125]

Nitrite causes acute poisoning by two mechanisms. The primary action of nitrite is to interact with hemoglobin to form methemoglobin. One molecule of nitrite interacts with two molecules of hemoglobin, causing the oxidation of normal

ferrous hemoglobin to ferric hemoglobin, which is called *methemoglobin*. Methemoglobin is incapable of transporting oxygen to tissues, and if sufficient quantities are formed, severe oxygen deficiency can occur. Clinical signs become evident when methemoglobin levels approach 30% to 40%, and death occurs when 80% to 90% of hemoglobin is oxidized to methemoglobin.[87,103] However, death can occur in active animals with only 50% to 60% methemoglobin.[87]

Normally, methemoglobin is converted back to ferrous hemoglobin by two reducing enzyme systems. This conversion occurs slowly, and in instances of nitrate toxicity, methemoglobin formation far exceeds the ability of these enzyme systems to regenerate hemoglobin.[87]

The second action of nitrite is to cause direct relaxation of smooth muscle, particularly vascular smooth muscle. The mechanism by which this occurs is unknown, but the physiologic changes brought about by the vasodilating action of nitrite include pulmonary arterial, central venous, and systemic arterial hypotension and decreased cardiac output. These changes may contribute to tissue anoxia and act to enhance tissue oxygen starvation already initiated by methemoglobin.[87]

Diagnosis and Treatment

The diagnosis of nitrate or nitrite toxicity is based on compatible clinical signs; presence of methemoglobinemia; history of exposure to potential nitrate- or nitrite-containing plants, water, or fertilizers; and nitrate quantitation in blood, plasma, or serum. One should perform blood methemoglobin determinations soon after collection because methemoglobin is not stable in refrigerated, heparinized blood for more than a few hours. However, blood mixed with a phosphate buffer preserves the methemoglobin and allows shipment to a diagnostic laboratory. Forage, hay, and water samples can be analyzed for nitrate or nitrite content, as well as other body fluids such as ocular fluid collected postmortem.[103]

Treatment aims to reduce methemoglobin back to hemoglobin. Mildly affected animals may recover spontaneously if the toxic source is removed and if they are given sufficient time for normal methemoglobin reduction processes to occur. Intravenous methylene blue may be used to treat more severely affected horses at a suggested dosage of 4.4 mg/kg, given slowly as a 1% solution in isotonic saline. The dose may be repeated in 30 minutes if clinical response is unsatisfactory. Caution is necessary, however, because excessive amounts of methylene blue may directly oxidize hemoglobin to methemoglobin. Methylene blue is converted to leukomethylene blue by an $NADPH_2$-dependent system. Leukomethylene then reduces methemoglobin to hemoglobin. In this reaction leukomethylene blue is oxidized back to methylene blue but can be reconverted to leukomethylene blue as long as sufficient $NADPH_2$ is available. If this $NADPH_2$ system becomes saturated with methylene blue, excessive methylene blue may oxidize hemoglobin directly to more methemoglobin.[87] Because methylene blue is difficult to obtain, ascorbic acid has been suggested as a less effective alternative.

Other nonspecific therapies include blood transfusion, oxygen therapy, and laxatives such as mineral oil to aid evacuation of the gastrointestinal tract.[87]

Cyanide

Hydrogen cyanide (HCN), cyanide, hydrocyanic acid, and *prussic acid* are terms that refer to the same toxic substance. Horses become exposed primarily through ingestion of certain plants that contain cyanogenic glycosides, but compounds containing cyanide also have been used as fumigants, rodenticides, and fertilizers.[87,103]

Numerous plants or plant parts may accumulate large quantities of cyanide or cyanogenic glycosides, and a more complete description of them can be found elsewhere.[126] When these cyanogenic glycosides undergo hydrolysis, free HCN is formed. Plant cells contain degradative enzymes that can hydrolyze these glycosides, but under natural conditions the enzymes are kept separated spatially from the glycosides in intact cells. Damage to the plant cells by wilting, freezing, or stunting allows enzymatic degradation of the glycoside.[103] Rapid hydrolysis and release of HCN occur only when the plant cell structure is disrupted. When the glycoside is exposed to an acid medium, or when maceration of the plant occurs within the intestinal tract, hydrolysis and subsequent formation of HCN also occur.

A number of factors can influence the toxic potential of cyanogenic plants. Because plant cyanogenic glycosides and degradative enzymes are controlled genetically by a dominant gene, selectively breeding plants with low cyanogenic potential is possible. Therefore different species and varieties of forage contain varying cyanogenic content. The ability to genetically remove plants with high cyanogenic potential is one reason that plant-related cyanide toxicity is an uncommon event. Sudan grass and Johnson grass historically have been problematic forages for livestock. High-nitrogen fertilization, nitrogen and phosphorus imbalance in soil, and drought conditions also can influence cyanide potential in plants.[103]

Most of the cyanogenic activity in the plant is located in the leaves and seeds, and immature and rapidly growing plants have the greatest potential for high glycoside levels. Conditions that damage the plant, such as drought, wilting, or freezing, may allow for more rapid combination of glycoside and enzyme, thereby enhancing plant toxicity. Other factors that may affect toxicity are the size of the animal, speed of ingestion, the type of food ingested along with the cyanogen, and the presence of active degradative enzymes in the plant and in the digestive tract of the horse.[103]

Clinical Signs

Because cyanide is such a potent, rapidly acting poison, affected animals commonly are found dead. On observation clinical signs may range from mild tachypnea and anxiousness to severe panting, gasping, and behavioral excitement. Salivation, lacrimation, muscle tremors, defecation, urination, and mydriasis may be evident. These signs are followed by prostration, clonic convulsions, and death. The mucous membranes may have a bright red appearance, and blood color may be bright cherry red, although this is not commonly reported in cases. Clinical signs may last from only a few minutes to a few hours, but horses that survive longer than 90 to 120 minutes after exposure usually survive.[84,87,103,126]

Pathophysiology

HCN is absorbed rapidly from the gastrointestinal tract or from the lungs. After absorption, endogenous thiosulfate combines with the cyanide ion to form thiocyanate, which is relatively harmless. This reaction occurs in the liver and other tissues, and the generated thiocyanate is excreted in urine. Another inherent detoxification mechanism involves inactivation of HCN in the bloodstream by combining with the ferric iron of methemoglobin. However, because a small amount of

methemoglobin normally is present in blood and endogenous stores of thiosulfate can be depleted rapidly, these two endogenous mechanisms of detoxification are overcome rapidly in cases of clinical toxicity.[103]

Excessive cyanide ion reacts readily with the trivalent (ferric) iron of cytochrome oxidase to form a stable cyanide-cytochrome oxidase complex. When iron is maintained in the ferric form, electron transport can no longer occur, and the chain of cellular respiration is brought to a halt. As a consequence, hemoglobin is unable to release its oxygen to the electron transport system, and cellular hypoxia results. This action occurs despite a large concentration of oxygen in the bloodstream. Cytochrome oxidase is most concentrated in tissues that have a high oxidative metabolic rate, such as the CNS and cardiac muscle. All tissues can be affected from this lack of usable oxygen, but death primarily is caused by anoxia in the brain.[87,103] The acute oral LD_{50} of HCN is 2 to 2.3 mg/kg, and rapid intake of plant material equivalent to about 4 mg/kg is thought to be a lethal amount.[87]

Diagnosis and Treatment

Cyanide poisoning should be considered when animals consuming cyanogenic plants are affected with acute signs of oxygen starvation and bright red blood (rarely present). The presence of cyanide is confirmed chemically, and samples of forage, blood, liver, muscle, brain, and heart may be submitted. All samples should be frozen as soon as possible and shipped.[87,103] Plant materials containing greater than 200 ppm HCN and concentrations in brain and ventricular myocardium greater than 100 mg/100 g wet weight are considered significant.[87]

Treatment aims at splitting the cyanide-cytochrome oxidase complex, with subsequent removal of the cyanide complex, and augmenting available thiosulfate in the bloodstream. Sodium nitrite displaces the cyanide molecule from the cytochrome enzyme and changes some of the hemoglobin to methemoglobin, which then competes with cytochrome oxidase for the cyanide ion. In this process methemoglobin and the cyanide ion form cyanomethemoglobin, and cytochrome oxidase subsequently is regenerated. Sodium nitrite should be used cautiously because of the possible danger of producing nitrite toxicosis, but it can be administered intravenously at dosages ranging from 6 mg/kg, given as a 20% solution,[87] to 15 to 25 mg/kg.[87]

Sodium thiosulfate reacts with the cyanide ion in the blood or liberated from cyanomethemoglobin and forms thiocyanate, which is essentially harmless and is excreted in urine. Sodium thiosulfate also can be given intravenously at dosages ranging from 60 to 660 mg/kg, as a 20% solution,[84] to 1.25 g/kg. Sodium nitrite and thiosulfate are not easy to obtain; thus these compounds rarely are used to treat clinically affected animals. In small animals a commercially available kit containing a vitamin B_{12} precursor, hydroxocobalamin, is currently recommended. An additional recommended therapy includes large doses of mineral oil. The cobalt in the vitamin B_{12} preparation may bind additional cyanide in the circulation, and mineral oil aids evacuation of the gastrointestinal tract. Animals that survive 24 hours usually do not require further treatment.[87]

Sodium Fluoroacetate (Compound 1080)

Sodium fluoroacetate and fluoroacetamide are highly toxic to many animal species. They have been used as rodenticides and in predator control, and because of their toxicity, their use in the United States is highly restricted. The compounds are odorless, tasteless, and water soluble and typically are incorporated into baits composed of carrot chunks, bread, bran, or meats. In the United States these compounds often are mixed with a dye before being placed in baits. Horses may become intoxicated by inadvertent exposure to these baits.[87,103]

Clinical Signs

Sodium fluoroacetate causes signs primarily related to cardiac dysfunction in herbivores. The onset of signs usually occurs from 30 minutes to 2 hours after ingestion. When signs begin, they usually have an acute onset and follow a rapid, usually violent course. Significant cardiac arrhythmias with rapid, weak pulse and eventual ventricular fibrillation are typical findings. Horses may exhibit staggering, trembling, restlessness, urination, and defecation. Moaning and bruxism may occur along with profuse sweating and signs of colic. Terminal convulsions also may occur. Ventricular fibrillation is the cause of death, and some horses may be found dead with no outward signs of struggle.[87,103]

Pathophysiology

Fluoroacetate is absorbed readily from the gastrointestinal tract, lungs, or open wounds but not through intact skin. After absorption, fluoroacetate is distributed throughout the body and does not accumulate in any specific tissue. The acute oral LD_{50} of fluoroacetate in horses is 0.35 to 0.55 mg/kg.[87]

After entry into cells, fluoroacetate can replace acetyl coenzyme A, combining with oxaloacetate to form fluorocitrate. Fluorocitrate then competes with citrate for the active site of aconitase, a Krebs cycle enzyme, and also inhibits succinate dehydrogenase, which catalyzes succinate metabolism. The inhibition of these two enzymes and the subsequent accumulation of citrate block the Krebs cycle, leading to decreased glucose metabolism, energy stores, and cellular respiration. These actions occur in all cells, but organs with high metabolic rates (e.g., brain, gastrointestinal tract, and heart) are affected most severely.[85,87,103]

The short latent period between ingestion and onset of signs occurs because fluoroacetate must be converted to the more toxic fluorocitrate. The accumulation of toxic levels of fluorocitrate therefore requires some time.[103]

Diagnosis and Treatment

Diagnosis of fluoroacetate toxicity must rely heavily on history of potential exposure, compatible clinical signs, and absence of other pathologic findings. Laboratory detection of these compounds can be difficult, but suspect baits, stomach contents, kidney, and urine are the best samples to submit for evaluation.[87,103] Significantly increased kidney citrate levels suggest compound 1080 toxicity.[87]

Laboratory abnormalities in affected animals might include hyperglycemia and lactic acidemia.[103] However, these findings are inconclusive and accompany many disease states in the horse.

Therapy is largely supportive and apparently unrewarding in horses already showing signs of toxicity. The practitioner may attempt intestinal decontamination using orally administered mineral oil and activated charcoal. If hypocalcemia develops, calcium gluconate or calcium chloride may be administered. Glycerol monoacetate at 0.1 to 0.5 mg/kg, administered intramuscularly with treatments repeated hourly, has been suggested but may not be effective after onset of clinical signs.[84,103]

Toxicoses Causing Signs Relating to the Epithelium, Skeletal System, and General Body Condition

Toxicoses causing these clinical signs can be among the most difficult to diagnose. Signs often are mild or moderate and quite nonspecific. In some cases the history is nonspecific, and the possibility of exposure to a toxin is difficult to evaluate.

PLANTS

Black Walnut *(Juglans nigra)*

Ingestion of shavings and aqueous extracts from black walnut trees is responsible for a toxic syndrome in horses characterized by acute onset of laminitis and variable degrees of limb edema.[127-130]

Clinical Signs

Horses begin showing signs of toxicity within 10 to 12 hours of being bedded with black walnut shavings. The primary signs are those of laminitis and include reluctance to move, shifting weight from limb to limb, increased digital pulse and temperature of the hoof, and positive response to hoof testers. The laminitis may vary from mild to severe.[127-129] Another characteristic finding is that of limb edema, which can become pronounced. Additional signs noted may include increased respiratory rate with flared nostrils, anorexia and lethargy, and abdominal pain.[128] Horses removed from the bedding after clinical signs have developed have a good prognosis for full recovery.[127,128] Ingestion of the plant hoary alyssum *(Berteroa incana)* by horses can elicit the exact same clinical syndrome.

Pathophysiology

The toxic principle involved in this toxicosis is unidentified. Juglone, a naphthoquinone found in roots, bark, and nuts of black walnut trees, was suggested in the past to be the causative agent.[127-129] Further work has shown, however, that an aqueous soluble toxin other than juglone that is found in the heartwood is more likely to be responsible for generation of clinical signs.[129] The mechanism of action of this soluble toxin has not been elucidated fully, but it has been shown to reversibly enhance vasoconstriction of isolated digital vessels in vitro induced by administration of epinephrine potentiated with hydrocortisone.[130]

Diagnosis and Treatment

Diagnosis of black walnut–induced laminitis is based primarily on known ingestion of shavings containing the plant and subsequent development of clinical signs. The treatment of laminitis is covered elsewhere in this text, but horses have a favorable prognosis for recovery if they are removed quickly from the offending bedding. Black walnut shavings should not be used as bedding for horses.

Wild Jasmine *(Cestrum diurnum)*

Cestrum diurnum (wild jasmine, day cestrum, day-blooming jessamine, king-of-the-day, Chinese inkberry) is a tropical to subtropical plant native to the West Indies that has been introduced and cultivated widely as an ornamental in warmer parts of the United States, including Florida, Texas, and southern California. The plant grows rapidly from seeds, and birds may contribute to its spread because of their appetite for ripe berries that contain seeds. The plant is naturalized in Hawaii and India. It also tends to multiply along fence rows, on roadsides, and in neglected pastures and fields. Horses show signs of disease after ingestion of the plant for several weeks to months.[131]

Clinical Signs

Affected horses show signs primarily of weight loss and lameness. Weight loss occurs over several weeks to months in spite of normal appetite. Lameness usually is of increasing severity and may begin with signs of generalized stiffness. Eventually, the fetlock joints may become overextended, and horses may exhibit kyphosis. The flexor tendons and particularly the suspensory ligament become sensitive to palpation. The lameness may grow so severe that euthanasia becomes necessary.[131] Signs of renal failure also may become evident in isolated cases.

Pathophysiology

C. diurnum and certain other members of the Solanaceae family contain a potent steroid glycoside with vitamin D–like activity. The toxic agent is a 1,25-dihydroxycholecalciferol ($1,25[OH]_2D_3$) glycoside found in the leaves of the plant.[132,133] Normally, vitamin D_3 is acquired from the diet or is produced in the skin by a reaction dependent on ultraviolet light. Vitamin D_3 is hydroxylated in the liver to yield 25-hydroxycholecalciferol, which subsequently is hydroxylated in the kidney to $1,25(OH)_2D_3$. This compound is the most active form of the vitamin and acts to increase calcium absorption and stimulate production of calcium-binding protein in the intestine.[132]

The normal rate of production of $1,25(OH)_2D_3$ is regulated by a negative feedback mechanism. Calcium or phosphorus deprivation stimulates the production of $1,25(OH)_2D_3$, and a decreased rate of production occurs when calcium or phosphorus is present in adequate amounts.[132]

This natural feedback mechanism is bypassed when $1,25(OH)_2D_3$ is supplied exogenously, as in the case of ingestion of *C. diurnum.* As a consequence, excessive calcium-binding protein is synthesized in the intestine, and excessive amounts of calcium and phosphorus are absorbed. If the calcium load exceeds the capacity of the kidney to excrete it, soft tissue mineralization (dystrophic calcification) and osteopetrosis occur.[132] In horses that have ingested toxic amounts of *C. diurnum,* calcification of the flexor tendons, suspensory ligament, and other elastic tissues appears to predominate over deposition of calcium into other soft tissues. Osteopetrosis is thought to result from sustained hypercalcemia and secondary elevation of calcitonin.[131]

Diagnosis and Treatment

A diagnosis of toxicosis is suspected when horses exhibit signs of weight loss and lameness and they are known to have had prolonged access to *C. diurnum.* This is a very uncommon problem. Affected horses typically are hypercalcemic, but serum phosphorus concentration usually is within a normal range. Renal dysfunction, if present, may be characterized by elevations in BUN and creatinine concentrations. Urine analysis may indicate an increased fractional excretion of sodium, potassium, and phosphorus, along with other laboratory findings associated with renal failure. Horses should be denied access to *C. diurnum* plants.

Hairy Vetch *(Vicia villosa)*

One report of toxicosis suspected to result from ingestion of hairy vetch is described.[134] The affected horse was a 1-year-old crossbred female that required euthanasia because of severe weight loss and bilateral corneal ulceration with perforation.

The clinical signs reported were weight loss despite good appetite, fluctuating body temperature, subcutaneous swelling that started around the lips and spread to involve the rest of the body, and bilateral corneal ulceration with eventual perforation.

The only recorded abnormal laboratory findings consisted of elevated serum concentrations of LDH and AST measured 2 weeks after onset of clinical signs. Histologic lesions consisted of multifocal to diffuse granulomatous inflammation of the heart, lungs, kidneys, skin, lymph nodes, ileum, colon, skeletal muscle, and choroid.

The toxic substance has not been identified, and no specific therapy has been recommended. A similar toxic condition occasionally occurs in other livestock grazing hairy vetch, with most cases of toxicosis occurring between April and July.

Photosensitizing Plants

Many plants can cause photosensitive reactions in horses. Some plants contain photodynamic substances that are absorbed from the gastrointestinal tract intact or in a form metabolically altered into an active compound (primary photosensitizing plants). Other plants may cause photodermatitis after liver dysfunction, in which the photodynamic toxin is a metabolite normally excreted in bile (secondary photosensitivity). Because of hepatic damage induced by the plant, these metabolites enter the circulation, and subsequent interaction with light results in clinical manifestation of disease. Box 21.2 lists plants[135-137] known to induce photosensitization in herbivores.

Clinical Signs

Signs of photosensitization are similar, regardless of the cause, and vary in degree of severity. Factors that influence the severity of signs include the amount of reactive pigment present in the skin at a given time; the degree of exposure to light of appropriate wavelength; and the severity of hepatic damage, if hepatogenous photosensitization is the cause.[137]

Restlessness and discomfort usually are the first evident signs. Erythema may be apparent, followed by edema of affected areas. Blister formation and subsequent serum exudation and scab formation occur as the condition progresses. Affected sites usually are painful when touched, and animals often attempt to protect themselves from direct sunlight.[135,137]

The light-colored or nonpigmented areas of skin are affected most severely, particularly the face, nose, back, escutcheon, and coronary band. Severely affected animals also may have involvement of pigmented areas of skin, and secondary self-trauma and bacterial infection may arise from attempts to rub the affected areas. Horses may lose patches of skin that slough in large, leathery plaques.[135,137]

Pathophysiology

Plants causing primary photosensitization contain a photodynamic agent that is absorbed from the gastrointestinal tract intact or that is later metabolically altered into an active compound. Secondary photosensitizing plants induce hepatic damage of sufficient magnitude to inhibit adequate clearance of photodynamic agents. Normally, these photodynamic toxins

BOX 21.2 Plants Inducing Photosensitization in Herbivores

PRIMARY PHOTOSENSITIZERS

Ammi majus (bishop's weed): contains furocoumarins
Astragalus cicer (chickpea milk vetch)
Avena fatua (oatgrass)
Brassica spp. (mustards)
Cooperia pedunculata
Cymopterus watsonii (spring parsley): contains furocoumarins
Erodium spp. (filaree)
Fagopyrum sagittatum (buckwheat): contains the naphthodianthrone derivative fagopyrin
Heracleum spp. (cow parsnip)
Hypericum perforatum (St. John's wort, Klamath weed): contains the naphthodianthrone derivative hypericin
Lotus spp. (trefoil)
Medicago (alfalfa)
Perennial ryegrass
Poaceae family (oats, sandbur, bermudagrass, barnyard grass, cupgrass, barley, rye, foxtail, sorghum, wheat, ryegrass)
Polygonum spp. (smartweed, lady's thumb, knotweed)
Ricinus communis (castor bean)
Rutaceae
Spenosciadium spp. (whiteheads)
Thamnosma spp. (blisterweed)
Trifolium spp. (clover)
Umbelliferae
Zephyranthes spp. (evening rain lily)

SECONDARY OR HEPATOGENOUS PHOTOSENSITIZERS

Agave lecheguilla (lecheguilla)
Blue-green algae
Brachiaria brizantha
Brassia hyssopifolia
Brassica napus (cultivated rape)
Holocalyx glaziovii
Lantana spp.
Lippia rehmanni
Myoporum laetum (ngaio)
Narthecium ossifragum (bog asphodel)
Nolina texana (sacahuiste)
Panicum spp. (panic grass, kleingrass)
Pithomyces chartarum and *Pithomyces minutissima*
Senecio spp. (ragwort, groundsel)
Tetradymia canescens (gray horsebrush)
Tetradymia glabrata (spineless horsebrush)
Tribulus terrestris (puncturevine)

OTHER PHOTOSENSITIZERS

Avena (oats)
Euphorbia maculata (milk purslane)
Kochia scoparia (summer cyprus, fireweed)
Medicago (alfalfa)
Polygonum spp. (smartweed)
Sorghum vulgare (Sudan grass)
Trifolium (clover)
Vicia spp. (vetches)

are metabolites excreted in bile. When the liver is damaged sufficiently or bile flow is hindered, these metabolites enter the circulation. Phylloerythrin, a normal chlorophyll breakdown product, is considered the only important photodynamic substance in instances of secondary photosensitization.[138] These photodynamic agents then are circulated throughout the body, eventually reaching the dermal capillaries.

Interaction of long-wave ultraviolet light with these photodynamic agents circulating in the skin capillaries results in chemical excitement of these substances. As a consequence, free radicals form that are highly inflammatory and cause degradation of cell phospholipid membranes, polypeptide proteins, and nucleic acids.[135,139] These processes disrupt the cells and ultimately result in the dermal lesions noted with this toxicity.

Diagnosis and Treatment

Clinical signs of photosensitivity are fairly typical and seldom are confused with other afflictions of skin. When clinical signs become evident, the horse should be evaluated thoroughly for evidence of hepatopathy because primary and secondary photosensitivity produce the same clinical signs. If hepatic disease is present, the clinician should ascertain the cause and institute appropriate therapy.

Primary photodynamic agents can be identified with several biologic assay systems, but this is rarely done. A mouse assay system and a microbial assay using *Candida albicans* are available for this purpose but, again, are rarely done.[135]

Specific therapy for photodermatitis is not available. Horses should be removed from direct sunlight until skin lesions are healed and the offending plant is removed from the environment. Various topical agents may be used to facilitate skin healing. Superficial bacterial dermatitis should be treated with appropriate antibiotics, and NSAID therapy may be beneficial during the initial stages of the disease process.

Tall Fescue *(Festuca arundinacea)*

The causative agent of the disorder associated with grazing tall fescue is *Neotyphodium coenophialum*[140] (formerly identified as *Acremonium coenophialum*), a fungal endophyte that you cannot visually see that grows within the stem, leaf sheaths, and seeds of tall fescue.[141,142] This endophyte is highly indigenous to many areas of the United States and may contaminate as much as 90% of fescue pastures in certain geographic areas.[141]

Clinical Signs

Horses grazing or being fed tall fescue hay preparations may develop a condition termed *summer slump* or *summer syndrome.*[135,143] The disorder is characterized by anorexia, weight loss, poor hair quality, pyrexia, and hypersalivation. Additionally, mares may sustain a variety of pregnancy- and reproduction-related disorders. Typical findings include the presence of a thick, tough placenta; prolonged gestation; abortion; birth of dead or weak dysmature foals; and high perinatal foal mortality.[144] Mares frequently are affected with agalactia, retained placenta, and rebreeding difficulties as well.[135,139,141]

Pathophysiology

The fungus produces multiple toxins, including peramines, lolines, and ergopeptine alkaloids. Peramines have no apparent effect on animal health, but the lolines (*N*-acetyl loline and *N*-formyl loline) present in *Neotyphodium* are pyrrolizidine alkaloids. However, the hepatotoxicity characteristic of pyrrolizidine alkaloids has not been observed with tall fescue toxicosis in any species.[142]

The ergopeptine alkaloids appear to be responsible for most of the abnormalities associated with fescue toxicosis. Ergotamine, ergosine, ergovaline, ergoine, ergocristine, ergocryptine, and ergocornine have been isolated, but ergovaline and ergosine are most prominent. Ergovaline is thought to account for 84% to 97% of the ergopeptine concentration of infected tall fescue. The concentration of ergot alkaloids in tall fescue tends to increase with nitrogen fertilization and drought stress, and toxicity varies from season to season and year to year depending on the percentage of endophyte present, drought stress, nitrogen fertilization, and probably other factors.[142]

Agalactia occurs for a variety of reasons. First, ergopeptines are dopamine D_2-receptor agonists, and dopamine is thought to be the major inhibitor of prolactin secretion in the body. Second, ergot alkaloids inhibit adrenocorticotropic hormone secretion, resulting in reduced fetal cortisol concentration that subsequently causes reduced progesterone secretion by the placenta. Third, these alkaloids decrease tissue binding of estradiol, which can lead to an elevated serum concentration of estradiol-17β[142] (normally, serum estradiol concentrations decline near parturition). The interaction of appropriate levels of prolactin, progesterone, and estradiol-17β plays a major role in preparing the mammary gland for lactation. The combination of reduced concentrations of prolactin and progesterone and elevated concentration of estradiol-17β likely is the major cause of the agalactia and impaired udder development in affected mares.

The gestation period may be prolonged because ergopeptines have been hypothesized to block corticotropin-releasing hormone activity in the foal, which results in a lack of fetal production of adrenocorticotropic hormone and cortisol. Because increased fetal cortisol concentration acts to signal the mare for parturition, lack of fetal production of corticotropin-releasing hormone, adrenocorticotropic hormone, and cortisol may contribute to extended gestation periods in affected mares.[142]

The placental abnormalities frequently noted have been suspected to be associated with vasoconstriction. Edema, fibrosis, and mucoid degeneration of arteries in placentae from affected mares have been observed.[143] These changes were thought to be consistent with anoxia, which was hypothesized to be associated with vasoconstriction. Ergovaline and *N*-acetylloline, which are present in infected fescue, have vasoconstrictive properties.[142]

Ergot alkaloids also may have a negative effect on fertilized ovum implantation in the endometrium, resulting in reduced reproductive efficiency of affected mares. In the mare the effects of ergopeptines on implantation are inconclusive, but ergocryptine, ergocornine, ergosine, and ergovaline are capable of interrupting early pregnancy in the rat.[142]

Foals born alive to affected mares may be hypothyroid (and dysmature), although the mechanism responsible for this is unknown.[144] High perinatal foal mortality probably also is influenced by agalactia and poor colostral antibody production by the mare, resulting in failure of passive transfer with associated septicemia and failure of the foal to thrive.[142]

Diagnosis and Treatment

Diagnosis often is empiric, based on clinical signs and access to fescue pasture or hay during late gestation. Affected mares

typically have reduced serum concentrations of prolactin and progesterone and elevated levels of estradiol-17β. Reduced serum concentrations of triiodothyronine, adrenocorticotropic hormone, cortisol, and total progestogens may be present in affected foals. Hay and pasture samples also may be evaluated for the presence of endophytes and ergovaline.[142]

Treatment of gravid mares past their foaling date should include removal from fescue as quickly as possible. Domperidone given orally once daily at 1.1 mg/kg during the last 15 days of gestation may be efficacious in helping establish udder development and lactation. Postfoaling mares may benefit from domperidone (1.1 mg/kg orally) administered once daily for several days in an attempt to stimulate milk production.

Prevention requires removing mares from fescue pasture or hay during late gestation. In one study fescue removed from the diet at 300 days of gestation was not associated with any problems in mares.[143] Thus the most critical time for exposure to infected fescue in pregnant mares seems to be during the last 30 days of pregnancy. Local or regional authorities can provide important information regarding current methods of managing infected pastures.

Hoary Alyssum *(Berteroa incana)*

Toxicosis in horses related to ingestion of hoary alyssum was first reported in 1992.[145,146] This plant is a member of the Cruciferae (mustard) family and can behave as an annual, biannual, or perennial. Hoary alyssum grows primarily in the northeastern and north-central United States and Canada but also is reported in the states of Oklahoma, Washington, Oregon, Idaho, and California and in Europe. The plant tends to flourish under conditions of drought, frost, and overgrazing and in areas of poor soil.[146,147] Toxicity has been reported in horses grazing contaminated pasture, eating plant-contaminated hay, and being fed oats containing hoary alyssum seed.[145-148] Reported cases are more prevalent during summer months after ingestion of recently cut hay, but toxicosis has resulted from feeding hay stored for 9 months.[146]

Clinical Signs

Not all horses exposed to hoary alyssum develop clinical signs of toxicosis. An estimated 45% of horses exposed to the plant under field conditions did not develop any signs of illness. However, the most common clinical signs observed under field and experimental conditions were varying degrees of fever, edema of one to four limbs, and laminitis. Horses affected with laminitis rarely are reported to develop rotation of the distal phalanges. These signs typically commence within 24 hours of ingestion (although this varies depending on the amount of plant material ingested) and in most cases subside within 2 to 4 days after removal of the source.[146] Other signs noted have been lethargy, short-term diarrhea, and abdominal discomfort.[148] Early parturition and abortion are rare occurrences in pregnant mares.[145,147] Rarely, individual horses are affected more severely and exhibit clinical signs of endotoxemia, hypovolemic shock, acute renal failure, and ventral rotation of the distal phalanges. Death can occur in these horses.[146,148]

Pregnant mares may be more susceptible to toxicity and develop more severe clinical signs, however. In one report 23 of 29 broodmares developed signs of fever, tachycardia, tachypnea, distal limb edema, and mild to severe laminitis.[147] Of these mares 15 subsequently developed moderate to profuse bloody diarrhea, dehydration, abdominal pain, hematuria, and oliguria. Four of these mares were euthanized, and two had necropsy findings of hemoperitoneum, hemothorax, and ventral rotation of distal phalanges. Three of the mares aborted spontaneously, but no abnormalities were noted in the placentae or fetuses.

Pathophysiology

The toxic agent in hoary alyssum remains unknown,[146] as does the mechanism of action of the toxic substance (or substances). However, red blood cell destruction appears to occur by way of hemolysis or some other mechanism.[146,147] No consistent laboratory abnormalities have been noted in an experimental feeding trial and in most field cases.[146] However, laboratory findings in more severely affected horses include significant red blood cell hemolysis; elevations in serum concentrations of creatinine, urea nitrogen, phosphorus, alkaline phosphatase, AST, CK, sorbitol dehydrogenase, and total bilirubin; neutropenia; proteinuria; hematuria; hemoglobinuria; and occult blood in feces and gastric fluid.[146-148] Which of these abnormalities are the direct result of the toxin and which result from physiologic deterioration of various organs is unknown.

Diagnosis and Treatment

A diagnosis is suspected on the basis of history of exposure to the plant and clinical signs. No specific therapy is indicated, but horses immediately should be denied access to the plant, and all contaminated hay and grain should be removed. One should initiate symptomatic treatment with fluids, NSAIDs, and gastrointestinal tract evacuation. Activated charcoal (1 to 3 g/kg administered through a nasogastric tube) has been suggested to help prevent absorption of the unknown toxin.[148] Intravenous DMSO should be used with caution because it has the potential to cause intravascular hemolysis, thereby compounding the red blood cell destruction caused by the toxin.[146,148] Most horses recover uneventfully in 2 to 4 days after removal of the plant and provision of supportive care.

MISCELLANEOUS AGENTS

Iodine

Iodine toxicosis or iodism is a rarely reported cause of toxicosis in horses. When iodism occurs, it most likely is caused by iatrogenic administration of iodine-containing substances. Many rations contain iodine in the form of various iodized salts, and sodium iodide and potassium iodide, along with the organic iodide compound ethylenediamine dihydroiodide, are used to treat various medical conditions.[135,149]

Clinical Signs

Nonpruritic generalized alopecia and diffuse scaliness of the skin were reported in a horse given 45 g of ethylenediamine dihydroiodide twice daily for 14 days.[150] Other reported clinical signs include goiter after excessive iodine intake, increased secretions of the respiratory tract, nasal discharge, intermittent nonproductive cough, and excessive lacrimation.[135,138,150] Pregnant mares receiving excessive amounts of iodine may produce weak foals with enlarged thyroid glands. Such foals have a high mortality rate.[135]

Pathophysiology

Organic and inorganic forms of iodine are absorbed rapidly and almost completely from the gastrointestinal tract in the ionic form and are distributed throughout the body. Iodine is

excreted primarily in the urine, but smaller amounts are present in feces, sweat, and milk.[138,149] The only known metabolic role of iodine is involvement in synthesis of the thyroid hormones thyroxine and triiodothyronine.[138]

Oral iodine salts, whether organic or inorganic, taken in higher doses stimulate nerve receptors in the stomach wall. Subsequently, the vagus nerve becomes stimulated and causes reflex secretion by cells in the upper respiratory tract.[138,151] Excessive iodine intake causes thyroidal organic iodine formation to increase to a maximal amount, and then a sharp decline in organic iodine formation occurs. Excessive iodine also inhibits release of organic iodine from the thyroid gland if the gland is stimulated by thyroid-stimulating hormone. The net results are clinical signs of increased amount and viscosity of respiratory tract secretions and occasional goiter development.[151] The mechanism underlying the development of the dermal lesions associated with iodism is unknown.[150]

Diagnosis and Treatment

Diagnosis of iodism is based on a history of exposure to high levels of iodine for a prolonged time coupled with compatible clinical signs of nasal discharge and excessive lacrimation, intermittent nonproductive cough, and nonpruritic generalized alopecia and scaling. Serum iodine concentrations, which are elevated in cases of iodism, can be measured, but blood levels decrease rapidly to near background levels within a few days if iodine exposure ceases.[138] Serum concentrations of thyroxine and triiodothyronine may be below normal reference values in affected horses.[150]

Treatment consists of removing the source of the iodine. Because iodine is mobilized rapidly and excreted from tissues, clinical signs usually subside rapidly when excessive iodine is removed.[138,149,150]

Snake Venom

The venomous snakes in North America belong to the families Crotalidae (pit vipers), Elapidae (cobra), and Viperidae (true vipers). Most poisonous snakebites reported in human beings are inflicted by members of the Crotalidae family, and the same is probably true for horses as well. Of this family *Crotalus* (rattlesnakes), *Agkistrodon* (copperhead, cottonmouth), and *Sistrurus* (pigmy rattlesnake, massasauga) are the three genera most commonly involved in snakebites of livestock. The eastern coral snake *(Micrurus fulvius)* and the Arizona coral snake *(Micruroides euryxanthus)* are two members of the Elapidae family indigenous to the United States, but they account for only about 3% of poisonous bites reported in human beings.[135,152]

Venom injected into prey is an aid to digestion and greatly reduces the time for complete digestion to occur in the snake. The amount of venom injected at a given time is under voluntary control, and larger amounts are injected into larger prey or when the snake strikes for defensive purposes. Not all bites result in envenomation, and rattlesnakes are estimated to fail to inject venom in up to 20% of bites (referred to as dry bites).[135,152]

Snake venom is a highly complex mixture of enzymes, lipids, biogenic amines, free amino acids, metal ions, proteins, and polypeptides. Most snake venoms contain up to 25 different fractions, yet many of them are not yet identified. Venom composition and toxic properties vary among *Crotalus* species and among individuals of the same species. Factors influencing venom composition include age, time from last feeding, and seasonal influences related to changes in feeding patterns or physiologic responses such as hibernation. The LD_{50} in mice exposed to venom of *Crotalus* species ranges from 0.23 mg/kg for the Mojave rattlesnake *(Crotalus scutulatus)* to 3.77 mg/kg for the red diamond rattlesnake *(Crotalus ruber ruber)*. The LD_{50} for mice for the copperhead *(Agkistrodon contortrix)* and cottonmouth *(Agkistrodon piscivorus)* is 10.92 mg/kg and 4.17 mg/kg, respectively.[152] This large variation in dose and chemical composition of venom accounts for the extreme amount of variation in the physiologic responses of animals to these substances.

Clinical Signs

Snakebites in horses are most common on or near the muzzle, but bites also may occur on the limbs or other parts of the body. The classic signs noted in most horses are acute onset of swelling and edema at the bite site. The muzzle and nasal passages may become swollen to the extent that respiration can become extremely labored, necessitating a tracheotomy. Epistaxis also may be apparent. Initially, fang marks may be evident, but they soon disappear with the onset of extensive swelling. Skin discoloration at the injection site is a common occurrence with many rattlesnakes but rarely occurs with copperhead and Mojave rattlesnake bites.[135] Varying degrees of necrosis of local tissue may occur, as well as secondary bacterial infections at the wound site. In the author's experience, bites involving the distal extremities of horses frequently have a prolonged convalescent period that may be accompanied by residual lameness.

Systemic manifestations of snake envenomation may be apparent when venom is injected intravascularly or perivascularly. In a retrospective study of rattlesnake venom poisoning in 32 horses, manifestations included fever, tachycardia, tachypnea, cardiac arrhythmia, hemolytic anemia, thrombocytopenia, hemorrhage, thrombosis of venipuncture sites, colic, diarrhea, and prehensile and masticatory dysfunction. Chronic problems included cardiac disease, pneumonia, laminitis, pharyngeal paralysis, and wound complications. The most common chronic problem observed in these horses was cardiac disease.[153] Labored respiration may result from pulmonary edema caused by passive congestion after vascular hypotension or precipitation of pulmonary emboli. Muscle fasciculation may be evident.[135] The venom of the Mojave rattlesnake produces respiratory paralysis that may result in death in human beings.[152] The overall mortality rate in 32 horses acutely affected with bites of prairie rattlesnake was 25%.[153]

The venom of coral snakes produces neurologic signs in affected human beings, with death occurring within 24 hours as a result of respiratory depression, hypotension, and cardiovascular collapse.[152] However, the coral snake requires prolonged contact (30 seconds or longer) to work the venom into the skin of its prey. Therefore it seems improbable that horses would become exposed to coral snake venom except under extremely unusual circumstances.

Pathophysiology

The venoms of Crotalidae are rich in enzymes. Proteases cause severe tissue damage by digesting tissue proteins and peptides, and hyaluronidase allows rapid spread of venom through tissue by hydrolyzing connective tissue hyaluronic acid. L-Amino acid oxidase, L-arginine ester hydrolases, and 5′-nucleotidase also may contribute to tissue destruction. Phospholipases A,

B, C, and D hydrolyze lipids and cause hemolysis by destroying lecithin in the red blood cell membranes. They also disrupt neurotransmission at the presynaptic and postsynaptic junctions. Other enzymes present in crotalid venom include ribonuclease, deoxyribonuclease, transaminase, phosphomonoesterase, phosphodiesterase, ATPase, DNAse, alkaline phosphatase, acid phosphatase, and endonuclease.[152]

Crotalid venom contains a number of polypeptides in addition to the enzymes. These polypeptides are low-molecular-weight proteins that are 5 to 20 times more lethal than crude venom in animal models, and they do not have enzymatic activity. They are present in higher concentrations in cobra venom than in rattlesnake venom and are mainly responsible for blood dyscrasias and coagulopathies. Small peptides are partly responsible for the generation of disseminated intravascular coagulation, and a venom fraction of the timber rattlesnake *(Crotalus horridus horridus)* causes platelet aggregation with resultant thrombocytopenia. Additionally, the venoms of the Mojave and Southern Pacific rattlesnakes contain a direct cardiotoxin.[152]

Rattlesnake venom contains substances with anticoagulant, procoagulant, and plasminogen-induced fibrinogenolytic properties. The coagulopathy that occurs in a given instance varies and depends on the content of the various venom components and on the dose of venom injected. The anticoagulant activity of crotalid venom appears to result from reversible binding of venom to prothrombin. Thrombin-like enzymes produce hypofibrinogenemia and increased concentration of FDPs. They also are capable of directly converting fibrinogen to fibrin, which may result in excessive fibrin formation and rapid disseminated intravascular coagulation. The fibrinolytic characteristics of crotalid venom occur directly or indirectly through the activation of endogenous plasminogen.[135,152]

Diagnosis and Treatment

Diagnosis of snakebite usually depends on clinical signs and accessibility to poisonous snakes. Laboratory abnormalities that may be present in affected horses include thrombocytopenia, hypofibrinogenemia, anemia, prolonged PT and PTT, hematuria, proteinuria, and myoglobinuria.[135,152]

Affected horses should be kept calm and quiet. Incision over the fang marks and suction are rarely indicated and probably of minimal value except in the immediate time frame of the bite, because the venom is absorbed almost immediately into the surrounding tissues. Tracheotomy is indicated in those horses that develop excessive edema and swelling of the head and external nares to the point that respiration becomes impaired. Topical cold therapy may have some beneficial effect if applied early and for short periods. Prolonged or excessive cold application, however, may enhance further tissue necrosis. Antivenom therapy commonly is used in instances of human snakebite but often is considered unnecessary in horses because of the low mortality rate, financial considerations, and availability of other therapies. An exception may be the horse or foal that is extremely valuable.

The clinician should initiate tetanus prophylaxis and systemic antibiotic therapy. Broad-spectrum antimicrobial drugs should be used because gram-positive and gram-negative organisms are found in the mouth of North American pit vipers. The most common organisms isolated include *Proteus vulgaris, Escherichia coli, Corynebacterium* spp., *Streptococcus* spp., and Enterobacteriaceae.[152]

NSAIDs should not be used during the early stages of the bite wound because they may enhance the defects in primary hemostasis frequently induced by snake venom. NSAIDs may be used in the later stages of the disease to help reduce pain, swelling, and inflammation. Corticosteroids should be used with caution because they may diminish the clearance of FDPs from the peripheral vasculature by the reticuloendothelial system, and they may increase susceptibility to wound infection at the site. Corticosteroids may be beneficial, however, in treating severe hypotensive shock in young animals or in patients with intravenous envenomation. Heparin therapy also has been suggested to be helpful in instances of thrombus formation.[135]

Animals affected with systemic hypotension and cardiac dysrhythmias should be treated appropriately. Treatment may include the administration of intravenous fluids and plasma and the use of specific antiarrhythmic medications.

Fluoride

Fluoride toxicosis in horses appears to be a rare event.[154] Although acute and chronic fluoride toxicosis have been described in various animals, chronic fluorosis appears more common. Common sources of fluoride in chronic fluorosis include forages subjected to airborne contamination from nearby industrial plants such as aluminum smelters, steel mills, or fertilizer plants that heat fluorine-containing materials and discharge fluorides; drinking water containing excessive fluoride; feed supplements and vitamin and mineral additives with high fluoride concentration; and vegetation grown on soils containing high fluoride levels.[138]

Animals normally ingest small amounts of fluoride throughout their lives, and it accumulates in the body as long as constant or increasing amounts are ingested. Chronic toxicosis can result from prolonged ingestion of sufficiently high levels. The long-term dietary tolerance for fluoride in the horse is reported to be 40 to 60 ppm dietary fluoride.

Fluoride is absorbed almost totally from the gastrointestinal tract. Once absorbed, approximately half is excreted rapidly in urine, with the remaining half being stored in bone and teeth. Fluoride accumulates in calcified tissues, but once exposure ceases, bone fluoride is depleted slowly over months to years.

Clinical Signs

Chronic fluorosis in the horse is a rare event. In one suspected case the affected horse exhibited chronic weight loss of months' duration; poor growth; difficulty in mastication; and deformed, discolored, and absent deciduous incisors. The horse also was missing some deciduous premolars and molars.[154] Classic dental abnormalities reported in other species include mottled, hypoplastic enamel and brown discoloration with uneven wear of teeth.[138] Additional signs associated with chronic fluorosis in other animals include hyperostosis, enlargement and roughening of involved bones, intermittent lameness and generalized stiffness, dry and roughened hair coat, and decreased weight and milk production.[154] Because of the insidious nature of chronic fluorosis, it is important to remember that a time lag may occur between ingestion of excessive fluoride and the appearance of clinical signs.

Pathophysiology

Excessive fluoride produces dental abnormalities by affecting the teeth during development. The primary effect of fluorine is thought to be a delaying and alteration of normal

mineralization of the preenamel, predentine, and precementum. High fluoride levels appear to cause specific ameloblastic and odontoblastic damage. The matrix laid down by these damaged cells fails to accept minerals normally, resulting in faulty mineralization of the tooth bud. Once the tooth is formed fully, the ameloblasts have lost their constructive ability and the enamel lesions cannot be repaired. However, odontoblasts can produce secondary dentine to compensate for deficiencies brought about by excessive fluoride.[138] The brown to black discoloration of affected teeth results from oxidation of organic material in the teeth.

The pathogenesis of bone lesions associated with fluoride toxicosis is still debated. One theory is that high fluoride levels lead to inadequate matrix and defective, irregular mineralization of bone. Another theory is that hydroxyl radicals in the hydroxyapatite crystal structure are replaced by fluoride ions, resulting in a decrease in crystal lattice dimensions. The pathologic results of skeletal fluorosis include dissociation of normal sequences of osteogenesis, production of abnormal bone, accelerated remodeling of bone, and occasional accelerated bone resorption.[138]

Diagnosis and Treatment

Diagnosis of chronic fluorosis is based primarily on clinical findings and history of possible exposure to fluorides. Fluorosis usually is confirmed by analysis of skeletal or dental tissues for fluoride content and evaluation of fluoride concentration in urine. Water and feed consumed by the animals also should be analyzed for fluoride content.

Treatment of chronic fluorosis aims mainly at dietary restriction of fluoride-containing substances. Aluminum sulfate, aluminum chloride, calcium aluminate, calcium carbonate, and defluorinated phosphate have been used to reduce the toxic effects of fluoride, but no substance completely prevents the toxic effects of ingesting excessive amounts of fluorides.

Zinc

Excessive exposure to dietary zinc can be a problem for young, growing horses. Sources of excessive zinc usually are soil and forage contamination from nearby smelters and pastures that were top dressed with zinc oxide.[155,156] Classic signs of copper deficiency associated with excessive zinc ingestion have been produced by experimental feeding of excessive zinc to young foals.[157,158] Skeletally mature horses do not appear to be susceptible to the effects of zinc-contaminated pastures.[158]

Clinical Signs

Signs associated with zinc-induced copper deficiency include swelling at the physeal region of long bones, gradual onset of lameness and stiffness that may become so severe that affected animals are reluctant to rise from lateral recumbency, swollen joints resulting from synovial effusion, unthriftiness, and weight loss despite normal appetite.[155-157] Anemia also may develop in more chronically affected individuals.[157] The joint swellings in affected horses are typical of those of osteochondrosis dissecans, and severe generalized osteochondrosis also develops in copper-deficient horses.[155,156,158]

Pathophysiology

In horses this disease actually appears to be a manifestation of copper deficiency and the subsequent development of hypocupremia-induced articular cartilage disease.[155,158] Copper is an essential cofactor for lysyl oxidase, an enzyme involved in the formation of collagen cross-links. Copper deficiency interferes with collagen metabolism and results in production of weak connective tissue. This allows articular cartilage fractures and growth physeal fractures to occur in the zone of hypertrophic cells, producing the clinical syndrome of osteochondritis dissecans.

The mechanism of zinc-induced copper deficiency is not totally understood but is most likely due to altered absorption from the gastrointestinal tract. Experimentally, affected foals at necropsy had high hepatic copper content despite low serum copper concentration, suggesting that the hepatic copper was not readily available for production of ceruloplasmin or could not be mobilized rapidly enough for use by other tissues.[158] Excessive zinc stimulates production of metallothionein, an intestinal cell protein that binds to excessive zinc, copper, and other divalent metal ions and facilitates their excretion in bile, feces, and saliva. Copper has a higher affinity for metallothionein than does zinc, and increased production of metallothionein, with subsequent binding to copper, may lead to copper deficiency through increased copper excretion.[159]

Diagnosis and Treatment

Once signs of osteochondritis develop, the condition should be appropriately treated. Diagnosis of excessive zinc intake may be difficult in that zinc is excreted rapidly after absorption, and blood and tissue zinc concentrations tend to decline quickly to normal levels with cessation of intake. Liver, kidney, and serum zinc concentrations can be measured, but fecal samples collected from affected horses may be more suitable. Feed and water supplies also can be evaluated for zinc content.[160]

Treatment of affected horses aims to restore proper copper concentration in the diet and remove the source of excessive zinc. Diets containing 7.7 mg of copper per kilogram and 250 mg of zinc per kilogram of dry weight were sufficient to maintain normal serum copper and zinc concentrations and did not induce disease in treated foals. Diets containing 1000 mg/kg or greater of zinc caused hypocupremia and subsequent osteochondrosis dissecans when fed to foals over a period of several weeks.[158] Osteochondrosis dissecans can be treated surgically.

Selenium

Selenium toxicity in horses usually results from prolonged ingestion of plants containing excessive amounts of selenium. Intoxication can result from horses foraging on soil with high levels of selenium and ingesting selenium-accumulating plants growing on soils with minimal amounts of selenium.[160-163] Acute toxicosis also can occur through inadvertent overdosing of selenium supplements added to rations or given by parenteral injection.[164] The acute single oral toxic dosage of selenium given as sodium selenite is between 3.3 and 6 mg/kg for the horse.[160,165]

Clinical Signs

Three different syndromes are attributed to selenium intoxication: acute toxicity and two chronic forms described as "blind staggers" and "alkali disease." Signs of acute toxicity develop within 6 hours of ingestion and include sweating, diarrhea, tachycardia, tachypnea, mild pyrexia, lethargy, and mild to severe colic. Clinical signs are attributable to selenium's effect on both the heart (myocardial necrosis) and lung (pulmonary necrosis and edema). Death may occur within 24 hours, and some horses exhibit a dumb attitude before death. Head pressing before death is suggested as a classic sign of acute selenosis.[160,165]

Chronic selenium intoxication described as blind staggers results from frequent ingestion of plants over weeks to months. Signs associated with this syndrome include aimless wandering or circling, muscle weakness, incoordination, respiratory difficulty, and decreased vision. In classic cases blindness eventually develops and is followed by paralysis and death.[166] Some have hypothesized that blind staggers is not due to selenium at all but is actually polioencephalomalacia associated with excess sulfur intake.

Alkali disease, the more common presentation of chronic selenosis in horses, results from ingestion of seleniferous plants, and signs may develop weeks to months after exposure. Initially, lameness and swelling of the coronary band regions are apparent, along with anorexia and mild depression. These signs progress to transverse cracking of the hoof wall distal to the coronary band with associated lameness. The hooves eventually may be sloughed. Loss of hair from the mane and tail occurs because the hairs become brittle and are broken easily, hence the term *bob-tailed disease.* Compromised reproductive and immune function also may develop in affected horses.[161-164]

Pathophysiology

Selenium is absorbed readily from the gastrointestinal tract, but organic forms of selenium generally are retained in greater amounts than are inorganic forms. Elimination occurs rapidly through urine, sweat, feces, and exhaled air. The clinician also must recognize hoof and hair as routes of excretion because excess selenium is deposited in these structures.[164] This latter fact has important diagnostic implications.

Selenium functions in a number of enzymatic and physiologic processes. The toxic effects of selenium have been associated with its affinity for reacting with sulfur-containing amino acid residues such as cysteine that are incorporated synthetically into biologically active glycoproteins and polypeptides. As a result, various selenosulfides are formed as a substitute for disulfide bonds.[167]

Diagnosis and Treatment

A presumptive diagnosis of selenium intoxication can be made on the basis of typical clinical signs and history of possible exposure to selenium iatrogenically in the form of selenium supplementation or through ingestion of appropriate plants. The clinician can attempt to make a definitive diagnosis by assaying blood, serum, hair, and hoof material for selenium content. In acute fatal selenosis blood selenium concentration may exceed 1 ppm.[160,165] A selenium concentration greater than 5 ppm in hair and hoof wall is considered diagnostic of selenosis.[160,161,163] It also is possible to measure selenium concentration in liver and kidney samples.

Treatment of affected horses involves removal of the selenium source, symptomatic treatment of lesions, and provision of good nursing care. Oral dosing of naphthalene at 4.5 g/day for 5 days, waiting 5 days, and then repeating the dose for an additional 5 days has been suggested for treatment of adult horses; however, this is not commonly done, and its efficacy is questionable.[160,161] Prevention of selenosis has been attempted by adding copper,[164] methionine,[168] or sodium arsenite[160,161] to the diet of at-risk animals.

Gangrenous Ergotism *(Claviceps purpurea)*

Claviceps purpurea is a fungal parasite that invades the developing ovary of the grass flower and cereal grains. This fungus commonly parasitizes rye, oats, wheat, and Kentucky bluegrass, which are associated most often with outbreaks of gangrenous ergotism. The fungus replaces the seed ovary with a dark brown to purple oblong body called a *sclerotium.* Sclerotia are slightly larger than the original whole grain seed, and their growth is promoted by warm, moist conditions. Horses rarely are affected by this condition, in part because of the distasteful nature of affected feedstuffs and because most fungal elements are removed during commercial grain processing procedures.

Clinical Signs

Signs of intoxication may become apparent if infected feeds are ingested over several days to weeks. An early sign observed in livestock following exposure to high levels of ergot include feed refusal. Dry gangrene of the extremities is the classic sign associated with *C. purpurea* toxicosis and can affect the limbs, nose, ears, and tail. Early signs of toxicosis are lameness and cool extremities. The hindlimbs often are affected first, with swelling and tenderness in the fetlock area. The involved tissues become dark and discolored, and a transverse line of demarcation may occur between normal skin and the distal parts of the limb. Eventually, the hoof and associated bones and tissue may slough. This same sequence may involve the nose, ears, and tail. Gangrenous signs may be preceded by colic and constipation or diarrhea. Possible subacute effects include depression, partial anorexia, general unthriftiness, and increased pulse and respiratory rates.[169] Abortions can also occur.

Pathophysiology

The major toxic alkaloids in ergot are a group of structurally similar ergopeptides. They are absorbed slowly and incompletely from the gastrointestinal tract, reaching peak plasma concentrations in approximately 2 hours. The liver is the primary site of metabolism, and approximately 90% of the metabolites are excreted in bile. Small amounts of unmetabolized alkaloids are excreted in urine. The total concentration and proportions of alkaloids present in ergot sclerotia may vary with species and environmental conditions.

Ergotamine, the most abundant of the alkaloids, is a polypeptide derivative of lysergic acid. The varied physiologic effects of ergot are caused primarily by mixtures of levoisomers of ergotamine, coupled with smaller amounts of acetylcholine, histamine, and tyramine.[169]

Ergotamine is a vasoactive substance that causes arterial and venous constriction. Ergotamine also may damage capillary endothelium. The combined effects of vasoconstriction and endothelial damage produce increased blood pressure, decreased blood flow through the extremities, vascular stasis, thrombosis, and eventually gangrene.[169]

The ergotoxine group of alkaloids produce α-adrenergic blockade and antagonize 5-hydroxytryptamine. This produces an increase in blood pressure as a result of peripheral vasoconstriction, particularly in postcapillary vessels.[169]

Diagnosis and Treatment

A tentative diagnosis of ergotism is based on clinical signs and exclusion of other disease processes. An experienced person can readily identify ergot sclerotia in grains. However, once grinding or pelleting of feed has occurred, ergot can be recognized only by microscopic examination or chemical analysis for ergot alkaloids. Ergot alkaloids can be identified and quantitated by chromatographic methods, and a sample of the

individual grain components should be obtained for analysis whenever possible.

No specific treatment exists for gangrenous ergotism. The offending grain should be removed, and affected animals should be kept warm to avoid cold-induced vasoconstriction in the extremities. Supportive therapy in the form of antibiotics and analgesics may be indicated. The use of anti–α-adrenergic pharmaceuticals to effect vasodilation also may be helpful. Such agents might include acepromazine, isoxsuprine, phenoxybenzamine, and similar products. [139]

Toxicoses Causing Signs Relating to Liver Disease or Dysfunction

PLANTS

Pyrrolizidine Alkaloids

Pyrrolizidine alkaloid toxicity results from consumption of plants that contain various pyrrolizidine alkaloids. Horses can become intoxicated after ingesting fresh plants and dried plants incorporated into hay. As with many toxic plants, however, these plants are frequently unpalatable to most horses, although certain conditions may render them more appetizing. This toxicity is characterized by a chronic, progressive disorder manifested by signs of liver failure. The more common plants that cause toxicosis in horses include *Senecio jacobaea* (tansy ragwort; also known as *Jacobaea vulgaris*), *Senecio vulgaris* (common groundsel), *Senecio longilobus* (groundsel), and *Cynoglossum officinale* (houndstongue).[169,170] Other plants that contain pyrrolizidine alkaloids but are not commonly associated with clinical disease in horses include *Amsinckia intermedia* (fiddleneck tarweed), *Crotalaria* spp. (rattlebox), *Echium plantagineum* (viper's bugloss), and *Heliotropium europaeum* (common heliotrope).

Clinical Signs

Signs of pyrrolizidine alkaloid intoxication in horses are essentially those of liver failure. The most frequently noted signs include weight loss of weeks to months in duration, icterus, and behavioral abnormalities. The behavioral changes indicate hepatoencephalopathy and may include aimless pacing or wandering, ataxia, licking inanimate objects, blindness, head pressing, and uncharacteristic aggression. Convulsions and coma may precede death. Clinical signs of abnormal behavior usually are a terminal event in the disease process and typically have an acute onset.[170,171] Other signs less frequently reported include diarrhea, photosensitization of nonpigmented areas of skin, hemoglobinuria, and inspiratory dyspnea.[170,172] Abortion and poor exercise tolerance (reduced athletic performance) also have been observed in horses after ingestion of sublethal amounts.[173] Because toxicity of these plants is related to liver dysfunction, clinical signs of disease may not become apparent for weeks to months after ingestion. A terminal hemolytic event is common in horses during end-stage liver failure.

Pathophysiology

A number of pyrrolizidine alkaloids are present in various plant species, and some plants may contain multiple alkaloids. These substances are absorbed from the gastrointestinal tract and carried to the liver, where they are metabolized by hepatic microsomal enzymes to pyrroles. These pyrroles then can cross-link double-stranded deoxyribonucleic acid (DNA) and bind to proteins and nucleic acid within hepatocytes.[169,170]

The cross-linking of DNA has an antimitotic effect on hepatocytes. The hepatocytes are unable to divide and subsequently become megalocytes. As these cells die, they are replaced by fibrous tissue rather than normal hepatocytes. Binding of protein and nucleic acid results in inhibition of cytoplasmic protein synthesis. These changes may lead to more rapid death of hepatocytes and cause centrilobular necrosis. Eventually, liver function begins to fail because of progressive hepatocellular death and subsequent fibrosis.[169,170] As the disease progresses, generalized fibrosis develops. Once connective tissue bridges form between portal areas, the disease is fatal.[169]

Variation in the dosage and frequency of administration of alkaloids results in a wide spectrum of hepatic lesions. Acute toxicosis resulting from massive doses is more likely to produce centrilobular necrosis with hemorrhage; however, this type of exposure is extremely rare. Chronic doses tend to produce hepatocellular death in the portal areas, along with megalocytosis, fibrosis, biliary hyperplasia, and occlusion of hepatic veins.[169,170] Liver failure is thought to be ultimately responsible for the clinical signs observed in pyrrolizidine alkaloid toxicosis.

The toxic dose of dried *Senecio* is estimated to be 5% of the body weight of the horse. This amount does not need to be ingested all at once, however, because the effects are cumulative. The total dose of alkaloids consumed determines the toxic effect, regardless of the amount of time in which the alkaloids were consumed.[169,170]

Diagnosis and Treatment

Most cases of pyrrolizidine alkaloid toxicosis are diagnosed on the basis of history, compatible clinical signs, serum liver enzyme activities, and liver biopsy findings. When active hepatocellular damage is occurring early in the disease process, sorbitol dehydrogenase and LDH usually are elevated, but they often decline to normal values by the time the horse is showing clinical signs. Serum GGT, alkaline phosphatase, and AST activities tend to be elevated throughout the disease course. Serum concentration of bile acids also is reported to be elevated in affected horses. Serum bilirubin concentration tends to be elevated in later stages of the disease, and hypoglycemia and hypoalbuminemia rarely are seen except in cases of severe hepatic disease.[169,170,172,173]

Other diagnostic aids that may be useful from a diagnostic and prognostic standpoint include measurement of the ratio of branched-chain amino acids to aromatic amino acids in serum. The branched-chain amino acids isoleucine, leucine, and valine are catabolized primarily in muscle, and the aromatic amino acids phenylalanine and tyrosine are catabolized mainly in the liver. The ratio of the sums of these amino acids (branched-chain to aromatic) decreases progressively from normal in horses affected with pyrrolizidine alkaloid toxicosis. If the ratio is below normal range and the horses are exposed continually to alkaloid-containing plants, they have a poor chance of survival. Some affected horses also showed a dramatic decrease in this ratio just before death.[174] Liver biopsy findings of a triad of fibrosis, bile duct proliferation, and megalocytosis are highly suggestive of pyrrolizidine alkaloid toxicosis. Liver biopsy samples also can help in establishing prognosis because the presence of advanced or generalized hepatic fibrosis warrants a grave prognosis.[169,170]

Feed samples may be analyzed for pyrrolizidine alkaloid content, but the process is often time consuming and unnecessary.[169] Pyrrole testing of liver tissue can be helpful in confirming exposure to the plant in the early stages of the disease; however, this analysis is offered by only a few laboratories.

No specific treatment for pyrrolizidine alkaloid toxicity exists. Affected horses may survive if they are denied further exposure to alkaloid-containing plants and are fed a suitable diet. However, some horses still may show signs of liver disease even though they have not had exposure to the plant for some time. Specific treatment of acute and chronic liver failure is discussed elsewhere.

Prevention entails keeping horses away from pasture or feed contaminated with pyrrolizidine alkaloid–containing plants.

Alsike and Red Clover *(Trifolium hybridum, Trifolium pratense)*

Both alsike and red clover are members of the Leguminosae family. Both are perennials that often are found in varying percentages in pastures and in seed pasture mixes, along with grasses. Both plants are very cold hardy, and tolerant of poorly drained wet, acidic, or clay soils, and often outcompete other grasses over time.

Liver disease associated with these two clovers has only been reported in the horse. Feed material that caused liver disease in horses has been fed safely to adult cattle. Toxicities can be the result of grazing pastures or ingesting contaminated hay. The toxic principle is unknown, but it has been hypothesized that it perhaps is a mycotoxin associated with the "black blotch" or "sooty blotch" fungus, *Cymodothea trifolii.* As little as 20% alsike clover in the diet has been associated with signs of poisoning, and depending on the percentage of clover in the diet, clinical signs of illness can be seen as early as 2 to 4 weeks after initial exposure.

Clinical Signs

Initial signs often recognized are lesions associated with a secondary photosensitivity. Sunburned lesions of the nonpigmented areas of the body, along with mucous membranes and cornea, are the sites most commonly affected. These lesions include vesicular swelling, erythema, edema, ulceration, and ultimately scab formation. This condition has been described in the literature as trifoliosis or dew poisoning and was thought to be the result of contact dermatitis. It is now recognized as a form of hepatogenous photosensitization.

As the disease progresses, nonspecific signs of hepatic disease start to develop. These may include decreased appetite, loss of body condition, weakness, sluggishness, weight loss, and poor hair coat. Acute onset of neurologic signs can occur in the more severe cases, which can include depression, aimless wandering and circling, head pressing, ataxia, yawning, teeth grinding, and colic. A rapid progression to recumbency, coma, and death has been reported.

Diagnosis and Treatment

Most cases of alsike and red clover poisoning are based on confirmation of exposure to the plant, clinical pathologic changes, and histologic lesions of either biopsy or necropsy tissue. Significant elevations in GGT, aspartate transaminase, sorbitol dehydrogenase, and alkaline phosphatase typically are seen. Serum bile acid and bilirubin concentrations will also be increased, although prominent icterus is not a consistent feature with this disease. Blood ammonia concentrations are also usually elevated, whereas hemograms are typically normal. Urinalyses may reveal bilirubinuria.

The liver often appears enlarged on ultrasound, along with irregular borders and texture. This feature had led to this disease once being referred to as "big liver disease." However, this change is not consistently observed, and small, shrunken, fibrotic livers have also been described.

Microscopic lesions reported include bile duct proliferation and perilobular, centrilobular, and periportal fibrosis. The severity of these findings is time dependent and can change depending on whether the exposure has been acute or chronic. There typically are mild inflammatory changes, mild hepatocellular swelling, and vacuolization, along with subtle and minimal necrosis. Mild megalocytosis has been reported in a few cases.

Specialists trained in plant identification can readily determine the presence of plants in a pasture or hay sample.

Mushroom (*Amanita* spp.)

One report describes fatal intoxication of a horse by ingestion of mushrooms (*Amanita* spp.).[175] Mushrooms apparently are unpalatable to livestock species, but the described horse also suffered from meningioangiomatosis, a rare benign tumor of the meninges and brain. The authors speculated that the presence of the tumor may have resulted in abnormal mentation and altered the normal eating behavior of the horse, resulting in mushroom consumption.

Clinical Signs

The described horse had acute onset of depression, head pressing, ataxia, and repeated recumbency with difficulty in rising. Before the onset of liver disease, many poisoned animals display signs of gastrointestinal distress. Clinical signs of shock, including hypothermia, poor capillary perfusion, and weak pulse, also were apparent. The horse was euthanized because of continued deterioration and lack of response to supportive therapy.

Pathophysiology

Some species of *Amanita* mushrooms contain a number of biologically active cyclic peptides such as amatoxins, phallotoxins, phallolysin, and antaminide. Some of these peptides affect actin polymerization and cause hepatocytes to lose their cytoskeletal organization and cellular attachments, resulting in hepatocellular dissociation and necrosis. Amanitins are peptides that inhibit ribonucleic acid (RNA) polymerase II within the nucleus, thereby preventing DNA transcription and subsequent protein synthesis. The result is acute submassive hepatic necrosis, which was present in the described horse.

Diagnosis and Treatment

Diagnosis in the described horse was based on histologic findings of submassive hepatic necrosis, acute onset of clinical signs, and presence of partially digested mushrooms in stomach contents. No specific therapy is recommended, although prompt evacuation of the gastrointestinal tract coupled with supportive care would seem prudent. The quantity of mushrooms ingested appears to be the primary prognostic indicator. If sufficient amounts of toxin are absorbed, the prognosis is grave. Hepatic coma often ensues in other species, and renal necrosis has been reported as well. Amatoxins can be tested for in various biologic samples (urine, kidney).

MISCELLANEOUS AGENTS

Iron

Iron toxicosis in horses is rare and can result from iatrogenic overdose of injected or oral products given to foals or from accidental consumption of iron-containing supplements. Supplemental iron is available in injectable and oral formulations, and more than 100 different iron preparations are on the market.[176] Iron dextran, iron polysaccharide, iron sorbitol, and ferric ammonium citrate are available injectable preparations. Oral formulations include iron salts such as ferrous sulfate, citrate, and ammonium citrate; ferrous sulfate, chloride, glutamate, lactate, fumarate, and carbonate; and ferric phosphate with sodium citrate. Chelated iron compounds are about one fourth as toxic as other compounds. Some forms of iron are more bioavailable than others.

The toxicity of iron is least by the oral route, with intramuscular and intravenous routes being increasingly more toxic. Because most animals do not have a mechanism for iron excretion, the toxicity of iron depends on the amount of iron already present in the body.

Clinical Signs

Two syndromes of iron toxicosis in animals are reported. A peracute syndrome is represented by sudden death a few minutes to hours after injection. This syndrome may resemble an anaphylactic reaction, but the triggering mechanism is unknown. A subacute reaction characterized by progressive depression, icterus, and disorientation leading to coma and death seems to be the more typical syndrome seen in horses.[176-178]

Pathophysiology

Experimentally, 5% to 10% of some forms of oral iron is absorbed in the small intestine, primarily from the duodenum and jejunum, by a rate-limited mucosal transfer system. The ferrous forms are absorbed to a greater extent than the ferric forms, but both can be absorbed if they are in the ionized state. Phosphates reduce the absorption of iron, and a high-sugar diet increases absorption. Once absorbed, iron is bound in serum by transferrin.[176]

Toxic doses of orally administered iron overwhelm the mechanism controlling absorption of iron from the intestine, resulting in massive iron absorption. Toxicity occurs when serum iron levels exceed the iron-binding capacity of transferrin. Free circulating iron then damages blood vessels, may cause erosion and ulceration of the stomach and intestine, causes hepatocellular necrosis and fatty degeneration of the myocardium, and can produce cerebral edema.[176,179] In horses hepatic failure appears to be the cause of death.[178]

At the cellular level, excessive iron causes extensive peroxidation of lipids in biologic membranes. A resulting decline in the ratio of unsaturated to saturated fatty acids leads to increased membrane rigidity, reduction of membrane potential, and increased permeability to various ions, leading to rupture of the membrane. The intracellular organelles adversely affected include the mitochondria and the lysosomal and sarcoplasmic membranes.[180] Elevated serum iron also inhibits the thrombin-induced conversion of fibrinogen to fibrin, thereby adversely affecting coagulation and enhancing any hemorrhagic process.[178] Histologically, affected livers are characterized by small size and have prominent bile duct proliferation, periportal fibrosis, and hepatocellular necrosis.[179]

Diagnosis

Measurement of serum iron concentration is the best method of confirming a diagnosis of iron toxicity.[176] In addition, a history of iron administration coupled with clinical signs and laboratory evidence of hepatocellular damage and cardiovascular collapse is highly suggestive of toxicity.

Abnormal laboratory findings include prolonged PTT and PT, high concentrations of aromatic amino acids (tyrosine, phenylalanine, tryptophan, methionine), elevated plasma ammonia concentration, and increased activities of the liver-derived enzymes alkaline phosphatase and GGT. In addition, a high ratio of aromatic to branched-chain amino acids and an elevated total serum bilirubin content can be found.[177]

Treatment

Treatment of peracute iron toxicosis usually is unrewarding. Once clinical signs become evident, major organ damage usually is present. No specific treatment for horses affected with iron toxicity is known. Treatment of affected dogs has included supportive therapy with glucose and norepinephrine and magnesium oxide given orally to help complex the ingested iron. Experimentally, a specific chelator of ferric iron, deferoxamine, has been used at 0.75 mg/kg/min intravenously to chelate the circulating iron in dogs. This drug should be administered slowly by intravenous drip because it can cause a sharp decline in blood pressure. Plasma extenders and intravenous fluids also have been used to counteract cardiovascular shock present in some dogs.[176]

In cases of human toxicosis, gastric lavage, chelating agents, and cathartics (sodium sulfate and magnesium sulfate) have been used. The use of oral bicarbonate solutions to decrease iron absorption is controversial, and activated charcoal is given orally to absorb the iron-deferoxamine complex, even though charcoal does not effectively bind free iron.[179]

The chelator of choice in human toxicosis is deferoxamine. Deferoxamine is administered intravenously for maximum effect; the drug has a plasma half-life of about 1 hour. Deferoxamine is detoxified by the liver, but the iron-deferoxamine complex is excreted by the kidneys.[179] There are other iron chelators used in humans (deferiprone and deferasirox), but their use has not been evaluated in horses.

Aflatoxin

Aflatoxicosis is a rarely documented disorder of horses, as demonstrated by the paucity of clinical cases reported in the literature.[181-183] In reported instances toxicosis developed in horses being fed contaminated feedstuffs, but horses also have been affected experimentally by forced feeding of aflatoxin-contaminated material.[184,185]

Aflatoxins are toxic metabolites primarily produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*. These molds are ubiquitous and normally can be found in stored feeds. The molds are not inherently toxigenic, but they can grow rapidly and produce large amounts of aflatoxin under environmental conditions of adequate temperature and humidity. Many feedstuffs can support the growth of these molds, but cereal grains, cottonseed meal and cake, and peanuts seem to be affected most commonly.[186]

These molds produce five major aflatoxins: B_1 and B_2, which fluoresce blue under long-wave ultraviolet light; G_1 and G_2, which fluoresce green; and M_1 aflatoxin, which is present in milk. B_1 is the most important of these because of its toxicity and it abundance under natural conditions.[186]

Aflatoxins are a group of polycyclic, unsaturated compounds that have a coumarin nucleus coupled to a reactive bifuran system and a pentenone or lactone. These toxins are insoluble in water and are heat resistant; they are absorbed rapidly from the gastrointestinal tract and bound to serum albumin. Most of the toxins are removed from the bloodstream in the liver, where aflatoxins bind to macromolecules such as DNA, endoplasmic steroid-binding sites, and certain enzymes within the hepatocytes. In the liver a variety of metabolites are produced at rates that vary among species. The metabolites may be lipid-soluble or water-soluble conjugates and are excreted in bile. At least some of the metabolites undergo an enterohepatic cycle of absorption and excretion. The aflatoxins and their metabolites are excreted in urine and feces, and complete elimination may take several days. The aflatoxins are not known to be stored in any particular tissue, other than perhaps liver and kidney.[186]

Acute and chronic aflatoxicoses are reported in a variety of animal species, including human beings. However, clinical reports of equine disease are concerned primarily with acute intoxication. The acute oral LD_{50} of aflatoxin B_1 in horses is reported to be 2 mg/kg or greater. One author reported signs of toxic hepatopathy and gastrointestinal upset in horses that consumed feed containing 2 to 50 ppb of aflatoxin B_1. Toxicity of aflatoxins also is reported to be enhanced by riboflavin; exposure to light; and a diet low in protein, choline, and vitamin B_{12}.[186]

Clinical Signs

Clinical signs associated with acute aflatoxicosis include anorexia, elevated temperature, increased heart and respiratory rates, ataxia, depression, lethargy, convulsions, icterus, colic and abdominal straining, bloody feces, and death. These signs were exhibited by horses experimentally intoxicated with aflatoxin at dosages of 2 to 5 mg/kg. Onset of signs began as early as 4 hours after dosing, and deaths occurred from 68 hours to 32 days after intoxication.[182,184,185] An additional sign observed in a naturally occurring instance of toxicosis was subcutaneous hemorrhages.[182]

The feed concentration of aflatoxin B_1 necessary to cause signs of chronic aflatoxicosis in horses has not been established, and reports of chronic aflatoxicosis were not found in the literature. Signs of chronic aflatoxicosis in other species have included reduced feed efficiency, rough hair coats, anemia, anorexia, depression, mild jaundice, and occasionally abortion.[186] It should be noted that experimental trials have indicated that some horses refuse mold-contaminated grain and well-fleshed animals may be at lesser risk of developing, aflatoxicosis than unthrifty animals.[182,184]

Pathophysiology

The hepatic cytotoxicity of aflatoxins is thought to be related to their binding to intracellular macromolecules. Aflatoxin B_1 binds to nuclear DNA to inhibit RNA synthesis, which subsequently inhibits synthesis of intracellular enzymes and other proteins. Aflatoxin also binds to endoplasmic steroidal ribosome-binding sites, resulting in ribosomal disaggregation. Metabolites of aflatoxin B_1 also can bind to cellular macromolecules, and most of the cytotoxicity of aflatoxin B_1 appears to result from binding of certain of these metabolites rather than from aflatoxin B_1 itself. This impairment of protein synthesis and the related ability to mobilize fats is thought to cause the early lesions of hepatic necrosis and fatty degeneration of the liver in aflatoxicosis.[176]

The possibility of other mechanisms being responsible for the other signs and lesions noted with aflatoxicosis has been suggested. Aflatoxins are known to be carcinogenic, they can be immunosuppressive, and they also can inhibit synthesis of clotting proteins. The mechanisms whereby these changes take place have not been well described.[186]

Diagnosis and Treatment

Definitive diagnosis of aflatoxicosis can be difficult because of the nonspecificity of many clinical signs and because the disease can mimic many other conditions. Experimentally intoxicated horses have elevations in serum concentrations of AST, alanine aminotransferase, GGT, iditol dehydrogenase, and arginase.[182,184,185] Other laboratory abnormalities include hypoglycemia, hyperlipidemia, lymphopenia, and elevated PT.[181,182,185]

Gross necropsy lesions typically consist of variable degrees of hepatic degeneration and necrosis, visceral petechial hemorrhages, and hemorrhagic enteritis.[181,182,185] Other lesions noted at necropsy include encephalomalacia of the cerebral hemispheres, myocardial degeneration, fatty infiltration of the kidney, and subcutaneous and intramuscular hemorrhage.[181,182] Histopathologic abnormalities may include fatty degeneration and necrosis of hepatocytes, bile duct hyperplasia, periportal fibrosis, and inflammatory cell infiltration into the liver. Renal lesions have included lipid accumulation in the tubular epithelial cells of the proximal tubules and protein precipitation in the tubular lumen.[181,185]

Although metabolites of *Aspergillus* species fluoresce under ultraviolet light, the presence of fluorescence in suspect feed samples is not pathognomonic for aflatoxin. Aflatoxin can be assayed definitively in feed samples by a variety of analytic methods.[182] It also is possible to quantitate aflatoxin in animal tissues, although this test is not routinely available through diagnostic laboratories.[181,185] Tissue residue testing can come up negative because of the long delay between time of exposure and demise of the patient. Mold culture is nondiagnostic.[186]

Treatment is largely symptomatic and must include removal of the offending feed material, if it still is being fed. An easily digested, low-fat diet containing appropriate protein has been recommended. Multiple vitamin supplementation might be beneficial, and treatment of specific organ dysfunction should be initiated. In acutely intoxicated horses orally administered charcoal has been recommended.[186] Prevention of the condition requires storing feeds in a suitable environment that discourages mold growth and the feeding of noncontaminated feedstuffs.

Toxicoses Causing Signs Relating to the Urinary System

Detection of renal disease can be difficult, regardless of cause. Whereas nephrotoxicity associated with equine administration of medications is well established and usually recognized, that linked to ingestion of plants is less commonly detected, which makes it more difficult to make a definitive diagnosis. Although heavy metals such as cadmium and mercury have long been known for their nephrotoxic effects, clinical signs are nonspecific, and the diagnosis will be made only if the clinician performs diagnostic tests to specifically rule these problems in or out.

PLANTS

Oxalate Toxicosis

The most common source of oxalates for livestock is plants, particularly those of the Chenopodiaceae family. These plants contain varied amounts of soluble oxalates, usually in the form of sodium or potassium salts. However, because plants containing oxalates (Box 21.3) are generally unpalatable to horses, plant-associated oxalate intoxication is rare.

Of the plants listed in Box 21.3, *Halogeton* and *Sarcobatus* seem to be the primary offenders in range animals in the western United States.[187]

Because oxalates accumulate in the plants throughout the growing season, the incidence of toxicosis may be highest in the fall and winter months.[188] The oxalate content is highest in the leaves, with a lesser amount in seeds and a minimal amount present in the stems. The nonfatal toxic dosage of sodium oxalate for adult horses is approximately 200 g/day for 8 days.[187]

Clinical Signs

Affected horses may begin to show signs of depression, mild to moderate colic, muscular weakness, and irregular gait 2 to 6 hours after ingestion. Weakness may proceed to lateral recumbency, unconsciousness, and death in 10 to 12 hours. Some animals may exhibit convulsions before succumbing to death.[187] The observed clinical signs of acute toxicity are typical of those of hypocalcemia.

Pathophysiology

Oxalates combine with serum calcium ions to form insoluble calcium oxalate. The result is a functional hypocalcemia in acute cases, with associated signs of altered behavior and neuromuscular abnormalities.

Acute and chronic ingestion of oxalates can result in renal failure. Insoluble calcium oxalate crystals can lodge in the renal tubules, producing tubular blockage and necrosis. Oxalates also may crystallize in the vasculature and infiltrate blood vessel walls, producing necrosis and hemorrhage.[187]

Diagnosis and Treatment

In instances of acute toxicosis, consistent clinicopathologic abnormalities include moderate to significant hypocalcemia and varied electrolyte alterations. Urinalysis may reveal the presence of characteristic calcium oxalate crystals on microscopic examination. Impending renal failure also is characterized by increases in BUN and creatinine concentrations.[187]

Treatment usually is of little value once clinical signs have appeared. Calcium gluconate can be administered intravenously, but usually it provides only temporary relief of signs. Balanced electrolyte solutions are indicated to aid diuresis, and diuretics also may have benefit in the volume-loaded patient. Prevention primarily entails keeping horses from the plants by providing adequate suitable sources of feed.[187]

Sorghum

Ingestion of *Sorghum* species and certain hybrid Sudan grasses has been associated with the development of an ataxia-cystitis syndrome.[189,190] This is, however, a very rare event. The toxicity occurs when horses graze the plants. More cases occur when the plant is young and rapidly growing, but mature and second-growth plants also have been incriminated. Horses being fed well-cured *Sorghum* species hay have not developed signs of toxicity. Occurrence of toxicity may increase during seasons of medium to high rainfall, but no cases have been recognized following the date of the first frost. Signs of toxicity may develop following a grazing period of 1 week to several months.[189]

BOX 21.3 Plants that Contain Large Amounts of Soluble Oxalates

Amaranthus spp.	Pigweed
Beta vulgaris	Beet, mangold
Chenopodium album	Lambsquarters
Halogeton glomeratus	Halogeton
Oxalis spp.	Wood sorrel, soursob
Portulaca oleracea	Purslane
Rheum rhaponticum	Rhubarb
Rumex spp.	Sorrel, dock
Salsola kali	Russian thistle
Sarcobatus vermiculatus	Black greasewood

Clinical Signs

The primary clinical signs are those of posterior ataxia and urinary incontinence or cystitis. The neurologic signs usually develop first and begin as posterior ataxia and incoordination. Affected horses may sway from side to side if forced to move, and signs tend to worsen on backing the animal. Occasionally, the rear quarters may drop almost to the ground, and flaccid paralysis of the tail and the rear legs may develop within 24 hours of the onset of neurologic signs. Affected horses remain alert and afebrile and have a normal appetite and pulse and respiratory rates. Mares frequently exhibit continual opening and closing of the vulva and relaxation of the perineal muscles. Males typically have a relaxed and extended penis.[189,190]

Urinary incontinence exhibited by continual urine dribbling is prominent in both sexes, and urine scalding on dependent skin becomes pronounced. The urinary bladder typically is distended and atonic, resulting in moderate to severe cystitis. Urethritis and ureteritis also may develop, and in horses that die because of the disease, ascending pyelonephritis usually is the cause of death. Other clinical signs include abortion and birth of foals with arthrogryposis.[189,190]

Pathophysiology

The clinical signs result from axonal degeneration and demyelination of nerve fibers in the spinal cord, particularly in the lumbar and sacral segments. The toxic substance in *Sorghum* species responsible for causing this change is not definitive. Most *Sorghum* species are cyanogenic plants and contain various amounts of HCN. Exposure to multiple sublethal doses of HCN has been suggested to induce axonal degeneration and demyelination.[189] Another hypothesis is that sorghum plants contain lathrogenic precursors and that this toxicosis may be caused by the ingestion of lathrogenic nitriles present in rapidly growing plants.[187,190]

Diagnosis and Treatment

Diagnosis of sorghum ataxia-cystitis is based primarily on appropriate clinical signs, history of grazing the plants, and exclusion of other known causes of posterior ataxia or paresis.

No specific diagnostic tests are available. Cystitis and pyelonephritis are diagnosed by standard laboratory methods.

No specific treatment is available. The offending feed should be removed immediately. Once the feed is removed, affected horses usually show gradual improvement over several weeks to months, but complete recovery may not occur. Supportive and symptomatic therapy should include appropriate antibiotic treatment of bacterial urinary tract infections and topical treatment of urine scald dermatitis. Periodic manual decompression of the urinary bladder may be helpful. Catheterization and frequent aspiration of bladder contents may be necessary to aid resolution of cystitis.

MISCELLANEOUS AGENTS

Vitamins D_2 and D_3

Horses are capable of meeting their requirement for vitamin D if they are exposed to sunlight or have access to sun-cured forages. Although dietary requirements for the horse have not been established, a maximum safe level of 44 IU/kg of body mass daily has been proposed for long-term feeding (more than 60 days).[191] Most cases of vitamin D intoxication are iatrogenic, resulting from overzealous use of vitamin supplements or improperly formulated vitamin D–supplemented feeds. Ingestion of *C. diurnum* (wild jasmine) also can result in vitamin D toxicosis because this plant contains a metabolically active glycoside of 1,25-dihydroxycholecalciferol (see the section on Wild Jasmine [*C. diurnum*] earlier in this chapter).

Vitamins D_2 (ergocalciferol) and D_3 (cholecalciferol) are potentially toxic, but vitamin D_3 is much more active and results in more severe lesions with wider tissue distribution than does an equivalent dose of vitamin D_2.[192,193] Other variables that may affect toxicosis include duration of treatment and route of administration. High concentrations of dietary calcium also might enhance the effects of excessive amounts of vitamin D. The effect of vitamin D supplementation is cumulative, and signs of toxicity may occur weeks after supplementation has begun.

Clinical Signs

The clinical signs associated with vitamin D toxicosis are associated with impairment of the renal, cardiovascular, and musculoskeletal systems. Signs may include depression, anorexia, weakness, polyuria and polydipsia, cardiac murmurs and tachycardia, limb stiffness with impaired mobility, and recumbency. Calcification of tendons, ligaments, and other soft tissue structures may be palpable on physical examination.[192] Ultrasonographic examination of these structures also may demonstrate abnormal mineralization within the tissues.

The toxicity of excessive amounts of vitamin D_3 results from extensive dystrophic mineralization rather than from any inherent toxicity of vitamin D itself. Soft tissue sites most frequently affected include the kidneys, the endocardium and walls of large blood vessels, and tendons and ligaments.[192,193]

Laboratory findings associated with toxicosis vary with the organ system affected but generally include persistent hypercalcemia and hyperphosphatemia, although the latter may not be especially pronounced. Serum calcium concentration may remain within a normal range in some horses. Other laboratory evidence of chronic renal failure may become evident with progression of toxicosis. A definitive diagnosis is made by measuring serum concentrations of vitamins D_2 and D_3 and 1,25-dihydroxycholecalciferol.[193]

Treatment

Treatment of vitamin D intoxication should include removal of all exogenous sources of vitamin D. A cation chelator such as sodium phytate may be helpful in reducing intestinal absorption of calcium, but the efficacy of this product has not been determined. If necessary, symptomatic therapy for renal insufficiency and failure should be instituted. Recovery may take months in less severely affected horses,[193] but treatment usually is unrewarding if excessive mineralization has occurred.

Menadione Sodium Bisulfite (Vitamin K_3)

Vitamin K_3 is a reported cause of acute renal failure in horses, but the product has been withdrawn from the U.S. market. When the product was given at the manufacturer's recommended dosage of 2.2 to 11 mg/kg intravenously or intramuscularly, signs of toxicity became evident 6 to 48 hours after injection in affected horses.[194] Clinical signs included depression, anorexia, colic, hematuria, and stranguria. Azotemia, electrolyte abnormalities, proteinuria, and isosthenuria also were apparent. Pathologic lesions noted at necropsy were those of acute tubular necrosis. Interstitial fibrosis and chronic renal failure also were present in one horse.[194] Treatment of affected horses is symptomatic for acute or chronic renal failure.

Cadmium

Intoxication with cadmium rarely is reported in horses but has been seen in animals raised near smelting operations.[195] Environmental contamination of soil and forage by cadmium and zinc was the cause of excessive intake.

Affected horses exhibited signs of unthriftiness, lameness, and swollen joints. Some of these signs were attributed to excess zinc in the diet, but the horses also had pronounced osteoporosis and nephrocalcinosis, which along with proteinuria are typical findings of cadmium toxicosis in human beings.[195]

Serum concentrations of zinc and potassium were elevated in these horses, and the serum magnesium concentration was low in one foal. Sodium, calcium, chloride, and bicarbonate concentrations also were decreased. Extensive nephrocalcinosis was characterized by multifocal loss of cortical tubules, which were replaced by dense deposits of calcium phosphate crystals.

Cadmium induces changes in proximal renal tubular cells by an unknown mechanism. However, increased numbers of lysosomes and mitochondrial swelling in the proximal tubular cells are early changes. Proteinuria usually is the first abnormality noted in human beings and laboratory animals. With continued chronic exposure, fibrosis and atrophy resulting from interstitial nephritis may ensue, leading to chronic renal failure.[196] Cadmium exposure can be confirmed by analyzing blood and various biologic tissues, including liver and kidney.

In human beings treatment essentially is supportive, with elimination of exposure to cadmium being imperative. Research data suggest a possible beneficial role of zinc, vitamin B complex, and nickel preparations, but their clinical efficacy is unproven.[196]

Mercury

Mercury exists in a variety of organic and inorganic forms. Both forms can be toxic to horses, but more recently reported cases involve acute toxicity resulting from inorganic mercury-containing blistering agents topically applied to skin.[197,198] Ingestion of feed or seed grain contaminated with organic mercurial seed preservatives has been a source of contamination in previous years.

Acute and chronic forms of toxicosis can occur in horses. The acute toxic dose of inorganic mercury in adults is 5 to 10 g.[187] Experimentally, chronic toxicity from inorganic mercury has been produced by ingestion of mercuric chloride, 0.8 mg/kg per day, over a 14-week period.[199] Chronic organic mercury toxicosis also has been produced experimentally by feeding methylmercury at 0.4 mg/kg per day for 10 weeks.[200]

Clinical Signs

Signs associated with toxicity of the various mercurial compounds differ, but they all include some degree of renal dysfunction. Acute toxicity resulting from inorganic mercury can cause signs of acute renal failure, including oliguria and depression, and signs of gastrointestinal irritation. Ulcerative stomatitis, excessive salivation, colic, and diarrhea are common findings associated with gastrointestinal tract disturbances.[197,198] Chronic intoxication with inorganic mercury can result in signs of oral ulceration, reduced appetite and weight loss, alopecia, progressive respiratory difficulty, gradually increasing urine production, and terminal azotemia.[199] Signs reported with chronic organic mercury toxicity include development of neurologic dysfunction characterized by proprioceptive deficits, exudative dermatitis, reluctance to move, reduced appetite and weight loss, dullness, and renal changes exhibited by a steadily increasing BUN concentration and glucosuria.[200]

Pathophysiology

Inorganic mercury compounds are absorbed from the lungs and gastrointestinal tract and absorbed poorly through the skin. After ingestion and absorption, accumulation in the liver and particularly the kidney occurs. Some forms of organic mercury are degraded in the body to inorganic forms, which then also accumulate in the kidney before excretion.[187]

Inorganic mercury is concentrated to high levels within the proximal renal tubular cells. Metallothionein, a low-molecular-weight metal-binding protein, is synthesized within 48 hours after exposure to heavy metals. This protein binds mercuric ions within the endoplasmic reticulum of the tubular epithelial cells and then slowly releases mercury. This slow release of sequestered mercury can cause continuing damage to tubular cells after the source of mercury is removed.[201] Hence the development of mercury nephropathy appears to be a function of the amount of protein-bound mercury concentrated in the renal tubules. Bound mercury can persist in the kidneys for several weeks after exposure.[188] Acute toxicity results in massive tubular necrosis and acute renal failure, and chronic exposure may cause renal interstitial fibrosis leading to chronic renal failure.

Methylmercury can be biotransformed in the body to inorganic mercury, but methylmercury also accumulates in the brain to a much greater extent than do other forms of mercury.[187] The exact mechanism whereby methylmercury and other alkylmercurials damage the nervous system is not well understood.[200]

At the cellular level mercury combines with sulfhydryl groups within cells. As a result, sulfhydryl enzyme systems essential to cellular metabolism and respiration are inhibited, resulting in cell death.

Diagnosis and Treatment

Mercury intoxication is suspected when horses show compatible clinical signs and have a history of exposure. Laboratory abnormalities are similar to those of other causes of acute or chronic renal failure and irritative gastrointestinal diseases. Definitive diagnosis usually is based on measurement of mercury concentrations in blood, kidney, and liver.[187] Stomach and intestine samples also may be submitted for analysis in acute cases.

Treatment of mercury intoxication initially involves removal of the source. In acute toxicity evacuation of the bowel with a mild laxative may be helpful. The oral administration of 500 g of activated charcoal might help block absorption of mercury, but its efficacy has not been demonstrated. Dimercaprol (used to inactivate circulating mercury) can be given at a dosage of 3 mg/kg intramuscularly every 4 hours for the first 2 days, 4 times on the third day, and twice daily for the next 10 days until recovery is complete.[197] The clinician also should follow other principles of therapy for acute or chronic renal failure. Treatment of chronic mercury intoxication usually is unrewarding.

APPENDIX I

Aspects of Clinical Relevance in Donkeys

Francisco J. Mendoza, Ramiro E. Toribio, and Alejandro Perez-Ecija

The donkey belongs to the order Perissodactyla, suborder Hippomorpha, family Equidae, and genus *Equus*. In this genus there is the horse and Przewalski's horse (*E. ferus caballus* and *E. ferus przewalskii*); the donkey or ass *(E. africanus asinus);* the onager or Asiatic wild ass *(E. hemionus onager);* the plains, common, or Burchell's zebra (*E. quagga,* formerly *E. burchellii*); the mountain and Hartmann's zebras (*E. zebra zebra* and *E. zebra hartmannae*); and the imperial or Grévy's zebra *(E. grevyi)*.[1] Donkeys and asses have 31 chromosomes (2n = 62), horses have 32 chromosomes (2n = 64), zebras have a variable number of chromosomes depending on the species (2n = 32 to 2n = 46), and mules have 63 chromosomes. Approximately 200 breeds of donkeys and asses are listed in the Food and Agricultural Organization Domestic Animal Diversity Information System (http://dad.fao.org/).

Donkeys and alike, including wild assess were domesticated before the horse and have contributed to social, economic, and cultural advances; religious customs; and human geographic expansion. Donkeys often live longer than horses, and their size, calm and stoic behavior, thriftiness, ability to perform hard work, and resistance to diseases made the donkey the preferred species for pack and draft work.[2,3]

In addition to physical work, donkeys are used for leisure and touristic activities; are a source of food (meat and milk) in some countries; their byproducts are used in the cosmetic industry; and more recently, donkey-assisted therapy is being used for people with mental and physical disabilities.[4] Because of its claimed hypoallergenic properties, excellent palatability, and nutritional value, donkey milk has been proposed to be a good breast milk substitute for infants with allergic disorders.[5]

Asinotherapy (onotherapy) is gaining popularity in treating and supporting people with mental and emotional disorders (Alzheimer's disease, autism, attention deficit hyperactivity disorder, and Down syndrome) and physical disabilities as well as in geriatric medicine as a therapeutic tool to improve physical and mental health and quality of life.[6] Behavioral tests to select donkeys for this purpose have been developed.[7]

Because interest in donkeys by the general public is increasing, it is important to generate donkey-specific information to provide better veterinary care. When facing the diagnosis and treatment of pathologic conditions of donkeys and asses, it should be considered that there are anatomic, physiologic, and metabolic differences from horses. From this perspective, extrapolating data for diagnostic and therapeutic purposes could be fine in most instances, but in others it may lead to misdiagnosis and unnecessary or inadequate treatment.

DISORDERS

Cardiovascular System

When their electrocardiogram is compared to horses', donkeys display shorter P waves (lead II), pronounced QRS complex–positive waves, and different QRS vectors, which could be related to cardiac size or cardiac location relative to the thorax.[8-10] Tricuspid and mitral peak flow velocities are lower in donkeys than horses.[11,12] These values must be taken with caution because they are likely influenced by breed, age, size, and fitness. Donkey gender and body weight affect cardiac dimensions on two-dimensional and M-mode echocardiography.[13] Standardized imaging protocols for M-mode and Doppler measurements described for horses also apply to donkeys.[11-13]

A low prevalence of cardiac diseases in donkeys was reported.[14] Third-degree atrioventricular block seems to be a common cardiac conduction disorder in donkeys, particularly in small breeds.[15] It has been reported that 2% of donkeys have an audible murmur,[14] which is lower than horses (50%–80%).[16]

Respiratory Tract

Respiratory disorders documented in horses also affect donkeys, although the presentation and severity of signs varies. Because of their stoic nature, signs of respiratory disease in donkeys tend to be less evident, and when present, the disease process is often advanced. Lower respiratory tract cytologic distribution is similar between donkeys and horses.[17,18]

Pulmonary fibrosis and tracheal collapse are common in geriatric donkeys.[19,20] An association between tracheal collapse and pulmonary fibrosis has been proposed.[21] Asinine herpesvirus 4 (AHV-4) and AHV-5 have been isolated and proposed as potential causative agents.[22] One can speculate that this condition is equivalent to equine multinodular pulmonary fibrosis, which has been linked to equine herpesvirus 5 (EHV-5) in horses.

Donkeys and mules can be reservoirs for infectious and parasitic diseases that affect horses (e.g., herpesviruses, lungworms). Therefore, their cohabitation can be problematic, particularly in farms with poor sanitary management or frequent animal movements.[23] Influenza is the most common respiratory infectious disease in donkeys[24] and they are apparently more susceptible than horses to the influenzavirus.[25]

Donkeys can be infected by EHV-1 and EHV-4,[26] as well as specific asinine herpesviruses (AHV-1, AHV-2, AHV-3, AHV-4, AHV-5, and AHV-6). Not every asinine variant causes clinical respiratory disease in donkeys. Mules can be infected but rarely show signs.[27] There are no vaccines for AHVs, and vaccination protocols are based on the use of vaccines for horses.

Based on serologic surveys, donkeys and mules develop antibodies against equine arteritis virus (EAV).[28] However, naturally occurring EAV has not been reported in donkeys or mules. There are donkey-specific EAV strains (asinine-94) with limited transmission to horses,[29] but reports of clinical disease in donkeys are lacking. Fever, mild depression, nasal and ocular discharge, conjunctivitis, and dependent edema were reported in donkeys experimentally infected with the KY-84 strain.[29]

Donkeys and mules appear to be more prone to glanders *(Burkholderia mallei)* than horses.[30,31] African horse sickness is less severe and rarely fatal in donkeys,[32] which may have epidemiologic implications, because donkeys and mules can act as carriers.[33]

Donkeys can host high numbers of adult lungworms *(Dictyocaulus arnfieldi)* with minimal to no clinical signs compared with horses, thus, acting as carriers. Prevalences of 68% to 87.5% for donkeys and 29% for mules were reported.[34,35] Therefore having horses and donkeys grazing together should be avoided, particularly when a parasite control program is not established. Diagnosis is achieved via fecal examination (Baermann method), and bronchoalveolar cytology may show eosinophilic inflammation and larval stages. Macrocyclic lactones and benzimidazoles are effective against *D. arnfieldi.*[36]

Alimentary Tract

A recent report based on postmortem examination of aged donkeys at a sanctuary described a 40% prevalence of gastric ulcers.[37] A gastric ulcer scoring system for donkeys has not been developed, but the one for horses seems valid. *Draschia megastoma* is considered the most pathogenic gastric parasite in donkeys.[37]

For equivalent intestinal lesions, donkeys exhibit less pain than horses, which is a factor that should be taken into consideration when deciding management, including exploratory laparotomy. In a large population of donkeys, among all types of colic, the prevalence of large colon impaction was 55% and the mortality risk was 51%.[38] The prevalence of enteroliths is geographic and is more frequent in areas with hard water and access to alfalfa (e.g., Mediterranean basin, California).[39]

Donkey-specific information on drugs that influence gastrointestinal function, including gastric secretion, is scarce. Management of colitis relies on the same principles as for other equids.

Endocrine and Metabolic Disorders

Nutritional Requirements

Donkeys can handle water deprivation longer than horses,[40] and their tolerance to dehydration has been equated to that of camels and Zebu cattle.[41] Dehydrated donkeys when allowed free access to water are very effective at restoring their hydration status, with minimal risk for overhydration.

Donkeys are thrifty animals, with low energy requirements and a natural ability to digest poor quality forages.[42-45] Concentrates and caloric-rich diets are unnecessary and should be avoided unless the animal is performing heavy work.

Metabolic Disorders

Hyperlipemia. The prevalence of dyslipidemias is higher in donkeys (10%–20%) than horses and ponies, with higher mortality rates (up to 80%).[42,46] Liver disease (19.4%) followed by colic (13.8%) was the most common condition in 449 dyslipidemic donkeys.[47] Transport can be stressful for some donkeys, which may explain their susceptibility to hyperlipemia after transportation.[48] For details on the pathogenesis of hyperlipemia, see Chapter 13.

Baseline triglyceride concentrations (range: 53–248 mg/dL; 0.6–2.8 mmol/L) in healthy donkeys are higher than values reported for healthy horses and ponies.[49] Serum leptin concentrations in healthy donkeys (2.7 ± 0.3 ng/mL) are similar to values reported for horses.[50] Therapeutic principles of hyperlipemia in small equids apply to donkeys.

Endocrine Disorders

Pathophysiologic principles of obesity, insulin resistance, metabolic syndrome, endocrinopathic laminitis, and pituitary pars intermedia dysfunction (PPID) apply to donkeys[50,51]; however, donkey-specific information for these conditions is minimal.

Donkey or Asinine Metabolic Syndrome. Obesity is common in donkeys in developed countries. When high-quality or calorie-rich feed is provided, donkeys easily accumulate adipose tissue. From the equine perspective, they can be considered "easy keepers."

A donkey-specific Body Condition Scoring (BCS) system ranging from 1 to 9 points (<3 = underweight; 4–6 = optimal condition; >7 = overweight) has been developed.[51] The Donkey Sanctuary, a charitable organization in England, developed a formula to estimate body weight in donkeys. For adult donkeys, weight (kg) = 0.000252 × height 0.24 × heart girth 2.575.[52] In donkeys younger than 2 years of age, the formula is weight (kg) = 0.000283 × heart girth 2.778.[52] A neck scoring system for donkeys has also been developed.[51] This score ranges from 0 (thin neck without palpable crest) to 4 (thick neck, rounded, cresty).

A link between obesity, insulin resistance, and laminitis has been documented in donkeys.[53] However, detailed information on asinine metabolic syndrome (AMS) and insulin resistance is limited. Other signs of equine metabolic syndrome reported in horses, such as hypertension or reproductive disturbances, have not been documented in donkeys. Insulin concentrations are often high in obese donkeys, suggesting insulin resistance. Unlike horses, hyperinsulinemia as a direct cause of laminitis has not been demonstrated in donkeys.[54] Similar to horses, geriatric donkeys have lower insulin concentrations that could result in reduced β-cell mass or less β-cell sensitivity to glucose.[51]

The diagnosis of insulin resistance relies on the same principles for horses. Few studies have evaluated glucose and insulin dynamics in donkeys.[53,55-57] In one study, insulin concentrations >20 μIU/mL were associated with laminitis.[58] The clinical relevance of this or higher insulin cutoff values to diagnose insulin resistance and evaluate their risk for endocrinopathic laminitis remains unclear. Reference values for glucose ratios and surrogates have been described in healthy donkeys.[57]

When dynamic diagnostic testing is performed in donkeys, validated protocols should be used.[56,57,59,60] Donkeys have an inherently delayed insulin-mediated glucose uptake compared with horses and ponies.[57] Their glucose curve is right-shifted

in the combined glucose insulin test (CGIT), intravenous glucose tolerance test (IVGTT), and oral glucose tolerance test compared with horses.[59,61-63] These differences support delaying glucose sampling for 60 or 75 minutes in donkeys versus 45 minutes for horses in the CGIT and for 150 minutes in the IVGTT.[64]

Serum leptin concentrations are higher in donkeys with high BCS and neck scores,[51] as well as in old donkeys compared with young donkeys.[51] The association between blood adiponectin, glucagon, ghrelin, and insulin growth factor–1 concentrations with age, gender, and obesity was recently reported in healthy donkeys.[51]

Specific treatments for AMS are not described, but principles for horses seem to apply. Grazing should be reduced when pastures may be rich in carbohydrates. A grazing muzzle could be useful in some animals. A weight-loss program should be oriented toward reducing body weight by 2% monthly until an optimal weight and BCS are achieved. Pharmacologic treatments used in horses to promote weight loss and increase insulin sensitivity have not been critically evaluated in donkeys.

Pituitary Pars Intermedia Dysfunction. Epidemiologic information for PPID in donkeys is lacking. PPID is more prevalent in donkeys older than 15 years of age.[65] No gender or breed predisposition has been demonstrated.

Clinical signs are similar to horses, with hypertrichosis (hirsutism) being the most frequent sign, considering that the hair-coat is longer and the hair is thicker in donkeys than horses. Laminitis, insulin resistance, abnormal fat distribution, and muscle wasting (sarcopenia, potbelly) are also signs of PPID in donkeys. Polyuria is rarely seen. Other signs described for horses (reproductive disturbances, blindness, seizures, secondary infections, and lethargy) have not been reported in donkeys.[65]

The diagnosis of PPID in donkeys is based on protocols described for horses.[65] Basal plasma cortisol concentrations in healthy donkeys and horses are similar[66]; however, adrenocorticotropic hormone (ACTH) concentrations are higher in donkeys than in horses.[66] This indicates that using equine-specific ACTH cutoff values for a healthy donkey could potentially cause misdiagnosis of PPID. Seasonal ACTH reference values for donkeys have not been generated. Dynamic diagnostic testing protocols for PPID in horses (the thyrotropin releasing hormone stimulation test) also appear to be valid for PPID donkeys.[67]

Based on clinical results, pergolide dosing for horses also works in donkeys with PPID.

Thyroid Gland Diseases. Information on thyroid gland disorders in donkeys is minimal. Thyroxine (T4) and triiodothyronine (T3) concentrations are occasionally measured, but result interpretation can be misleading. Healthy donkeys have higher plasma free T3, total T3, free T4, total T4, and reverse T3 concentrations than horses.[68] This is a good example in which values from horses should not be extrapolated to donkeys because it could lead to misdiagnoses. Sexual dimorphism for thyroid hormones has not been demonstrated in donkeys or horses.[69,70] Similar to horses,[71] age affects thyroid hormones, with younger animals having higher thyroid hormone concentrations.[68]

Drugs known to reduce thyroid hormone concentrations, such as phenylbutazone and glucocorticoids, should be taken into consideration for data interpretation,[72-74] particularly if these drugs have been administered within a month of testing.

Neurology

The neurologic examination of donkeys with mild spinal ataxia can be challenging for multiple reasons, including differences in gait, type of lesion, and spinal cord response to disease. Cervical stenotic myelopathy is uncommon in donkeys and mules but may develop from developmental, traumatic, or inflammatory processes. Information on viral (Borna; EHV-1; rabies; coronavirus; West Nile virus; Japanese viral encephalitis; and Eastern, Western, and Venezuelan equine encephalitis),[75-81] bacterial (e.g., neuroborreliosis or Lyme disease),[82] and parasitic (e.g., *Neospora* spp., *Strongylus vulgaris*)[83,84] disorders of donkeys is lacking. Clinical signs of Venezuelan equine encephalitis are usually mild in donkeys and mules,[85] but they could act as amplifying vectors, propagating the virus to horses and people. There are no published cases of equine protozoal myeloencephalitis *(Sarcocystis neurona)* in donkeys, and they are considered to be relatively resistant to the disease.[86]

Nutritional and metabolic imbalances leading to neurologic disorders have been reported in donkeys and mules. Signs similar to equine degenerative myelopathy from vitamin E deficiency were reported in donkeys.[87,88]

Urinary System

Urinary tract diseases are uncommon in donkeys, with urolithiasis being the most common.[89-92] In one postmortem survey of renal lesions in 100 donkeys, tubulointerstitial nephritis (50%), cystitis (19%), and renal fibrosis and cysts (13%) were the most common lesions found in the urinary tract.[89] Dysuria, stranguria, pollakiuria, hyperkalemia and hyponatremia, and urinary tract infections were common signs of urinary tract disease in donkeys.[89,90]

Most drugs used in horses and ponies to treat renal disease have not been investigated in donkeys, and dosing protocols are derived from horses.

Ophthalmology

Corneal ulceration is the most frequent ocular pathology in donkeys.[93,94] Equine recurrent uveitis prevalence seems to be lower in donkeys than horses, which could be explained by a lower predisposition to this condition or reflect infrequent ocular examinations in donkeys.[95] Old donkeys are prone to lens pathologies such as cataracts and luxation[96] or even colobomas.[97] Nonulcerative eosinophilic keratitis was reported in mules and donkeys.[98]

Ocular parasites described in donkeys include *Onchocerca* spp.[99] and *Setaria equina*.[100] Habronemiasis mainly affects the conjunctiva and occurs sporadically.[93]

Blindness can go unnoticed in donkeys, which likely reflects their ability to memorize their surroundings better than horses.

Dermatology

Congenital dermatoses such as junctional epidermolysis bullosa,[101] epitheliogenesis imperfecta, or an Ehlers-Danlos–like syndrome[102] have been documented in donkeys. Immune-mediated dermatopathies are rare in donkeys. Pemphigus foliaceus was reported in a pregnant jennie.[101] Atopic dermatitis, characterized by pruritus and urticaria on the face, trunk, and legs, was

reported in a Miniature donkey.[103] Traumatic skin lesions are a frequent problem in working donkeys.

Sarcoids are frequent cutaneous tumors in donkeys. Invasive and fibroblastic types are the most reported in donkeys, whereas the occult and verrucose forms are rare.[102] Other skin tumors of donkeys include squamous cell carcinomas, fibromas, fibrosarcomas, melanomas, and epitheliotropic lymphomas.[104] Melanomas are usually located in periocular areas and rarely related to haircoat color. Squamous cell carcinomas tend to be ocular and are less frequently located in the oral and nasal cavities, prepuce, vulva, or proximal gastrointestinal tract.

Musculoskeletal

There are foot anatomic and radiologic differences between donkeys and horses.[105] For a more detailed description of the donkey hoof, see Thiemann and Rickards.[106]

Foot lesions are the main cause of lameness (65% of the cases), and endocrinopathic laminitis is the main one.[107] Pedal abscesses are the second cause of lameness in donkeys. Long hooves are a frequent cause of coffin bone remodeling. White line disease, interphalangeal joint contracture, luxations, and keratomas are infrequent problems.[106,108,109] Hip fractures and coxofemoral luxations in small- to medium-sized donkeys (<250 kg) may be seen sporadically.[110,111]

Deep and superficial digital flexor tendinitis (23%–47%), suspensory desmitis (16%–31%), and digital flexor tendon sheath swelling (62%–77%) are the main soft tissue problems associated with lameness. Exertional rhabdomyolysis, polysaccharide storage myopathy, grass sickness, and atypical myopathy have been described in donkeys.[112-116]

CLINICAL PATHOLOGY

Interpretation of hematologic and biochemical information using equine reference values can be misleading because of the lack of donkey-specific information in most veterinary laboratories.

Hematology

Hematologic variables from donkeys are listed in Table A.1. The donkey red blood cell (RBC) count tends to be lower, but erythrocytes are larger than in horses. RBC count, hematocrit (HCT), and hemoglobin (Hb) values are closer to ponies than horses.[129] Reticulocytes are not found in peripheral circulation. Large- and medium-sized lymphocytes are more frequent in blood smears from donkeys than horses. Eosinophils and basophils are slightly larger in donkeys.

No effect of gender on hematologic variables has been documented. RBC, HCT, and Hb concentrations are higher in newborn donkey foals and then decrease in the first week postpartum.[130] Erythrocyte volume, corpuscular Hb concentration, and red cell distribution width remain unchanged in the first week of life. White blood cell count is lower in the immediate postpartum period, ranging from 4 to 12,000/μL (birth to day 3) to 6 to 15,000/μL (days 3–7).[130] The neutrophil:lymphocyte ratio can be as high as 2.8 at birth in donkey foals, but it declines to 1 by 12 months of age. Eosinophils and basophils change minimally in the first weeks of life, although their numbers tend to be higher than those for equine foals. Platelet parameters do not change in the first week of life, and the platelet number is higher than in adults.

Neonatal isoerythrolysis is a frequent problem in mule foals.[131] The presence of a donkey-specific erythrocyte antigen (donkey factor) is suspected to be responsible for this disorder. Considering that horses do not have alloantibodies against the donkey factor, mule foals with isoerythrolysis could receive blood transfusion from a horse with no history of breeding to donkeys. Washed erythrocytes from the dam can also be used. Neonatal alloimmune thrombocytopenia is an occasional finding in sick newborn mules. This condition usually develops within 24 to 48 hours after colostrum ingestion.[132] Immune-mediated thrombocytopenia can be a serious complication in donkey foals receiving plasma transfusion of equine origin.

Biochemistry

Biochemical variables from a number of studies are listed in Table A.2. Hepatic enzyme activities and bilirubin concentrations are lower in donkeys compared with horses, whereas creatine kinase, γ-glutamyl transpeptidase, and plasma triglyceride concentrations are higher in donkeys.[130] In one study, jennies had higher aspartate aminotransferase activity, total protein, total calcium, and indirect bilirubin concentrations, whereas male donkeys had greater alkaline phosphatase activity, albumin, phosphorus, glucose, creatinine, cholesterol, magnesium, and ionized calcium concentrations.[135] Pregnancy, foaling, and lactation can influence biochemical variables.[136] There are age-related differences for a number of biochemical variables.[130] Coagulation profiles vary between donkeys and horses.[137] Fibrinolytic subproducts (fibrin/fibrinogen degradation products [D-dimers]) were higher in healthy donkeys compared with horses.[137]

PHARMACOLOGY

Drugs commonly used in horses do not necessarily have similar pharmacokinetic and pharmacodynamic properties in donkeys and mules, and donkey-specific information is lacking (Tables A.3 and A.4). Depending on the drug, caution must be used when extrapolating doses and frequency from horses to avoid inadequate dosing and toxicity.

Antiinflammatory Drugs

There are differences in nonsteroidal antiinflammatory drug metabolism between donkeys and horses (Table A.3).[163] Phenylbutazone has a shorter half-life in Miniature donkeys, requiring shorter treatment intervals compared with regular-sized donkeys and horses.[164] Flunixin meglumine showed an earlier entrance of the drug into the exudate in donkeys compared with horses, although its maximal concentration and durability was shorter.[165,166] Information on steroid pharmacology in donkeys is lacking.

Antibiotics

There are pharmacologic data for a number of antimicrobial drugs in donkeys (Table A.4). Donkeys show a higher metabolism for most antibiotics, with faster clearance rates and shorter half-lives for many of them compared with horses (Table A.4).

Antiparasitic Drugs

Pharmacologic data for antiparasitic drugs used in donkeys are compiled in Table A.5. It is important to note that most of these drugs are not approved by regulatory agencies for the specific use in donkeys. Close monitoring is indicated for drugs lacking species-specific literature. Donkeys are more

Doramectin	Roundworms *Dictyocaulus arnfieldi*	0.2 mg/kg, PO	167
Eprinomectin	*D. arnfieldi* Lice	0.5 mg/kg, pour on	168,169
Fenbendazole	Roundworms	30–60 mg/kg, PO	170
Imidocarb	*Babesia caballi, Theileria equi*	<2.2 mg/kg, IM q 24 h (*B. caballi*) and 48 h (*T. equi*)	171
Ivermectin	Roundworms *D. arnfieldi* Arthropods	0.2 mg/kg, PO	167
Mebendazole	Roundworms	10 mg/kg, PO	172
Moxidectin	Roundworms	0.2 mg/kg, IM	173
Oxfendazole	Roundworms *D. arnfieldi*	10 mg/kg, PO	170
Praziquantel	Cestodes	1 mg/kg, PO	174
Pyrantel pamoate	Roundworms Cestodes	19 mg/kg, PO	175
Secnidazole	*Balantidium coli*	10 mg/kg, PO	176
Triclabendazole	*Fasciola hepatica*	12 mg/kg, PO	177
		38 mg/kg, PO	170

IM, Intramuscularly; *PO,* orally.

sensitive to imidocarb toxicity than horses, so lower doses are recommended. Caution must be taken with macrocyclic lactones, particularly in animals in poor body condition, because of the risk of neurologic toxicity.

Anal sphincter paralysis, 652
Analgesia, nonsteroidal antiinflammatory drugs for, 121
Analgesics
critically ill horse and, 185
for duodenitis-proximal jejunitis, 740
Anal/tail clamp reflex, of neonatal foals, 1382t
Anaphylatoxins, 719
Anaphylaxis, systemic, 43–45
Anaplasma phagocytophila, 996, 1011–1012
Anatomic dead space, 177
Ancillary diagnostic aids
for body temperature, 236–237
for collapse, 268
for dysphagia, 272
for polyuria and polydipsia, 288–289
Ancillary diagnostic tests
for colic, 276–277
for cough, 249–250
for edema, 263
for hypothermia, 238
for respiratory distress, 258
for weight gain, 241
for weight loss, 244
Androstane, 1076
Androstanediol, 1076
Anemia
aplastic, 1017
equine infectious, 1008
in hepatitis, 869
in Fell pony syndrome, 53
hemolytic, 1010–1011
immune-mediated hemolytic, 1007–1008

Anemia *(Continued)*
of inflammation/chronic disease, 1017
iron deficiency, 1016
neonatal isoerythrolysis and, 1415
nonregenerative/hypoproliferative, 1016–1018
paraneoplastic disease and, 372
secondary to other deficiencies, 1016–1017
secondary to recombinant human erythropoietin administration, 1017
Anesthesia
halothane, interaction with aminoglycosides, 108–109
local, for pain management, 144t–145t
for traumatic brain injury, 617
Anestrus
lactational, 1225
winter, 1221
Angiocardiography, 398b, 418, 419f
Angiostrongylus cantonensis, verminous encephalomyelitis and, 682
Angiotensin II, in acute renal failure, 925
Angiotensin-converting enzyme, in chronic kidney disease, 943–946
Angiotensin-converting enzyme (ACE) inhibitors, 457t–461t
Anhidrosis, 233, 1110, 1211
clinical signs of, 1112
diagnosis of, 1112
epidemiology of, 1110
pathophysiology of, 1111–1112
physiology of, 1110–1111
prevention of, 1112–1113
prognosis of, 1112–1113
systemic manifestations of, 1165t–1167t
treatment of, 1112–1113
Anisocytosis, 993
Anoplocephala perfoliata infections, 14
Anorexia, weight loss associated with, 241
Anovulatory season, 1221
Antacids, for gastroduodenal ulceration, 807–808
Antiarrhythmics, 457t–461t, 513–514
Antibacterial shampoo, for dermatophilosis, 1174
Antibiotics
beta-lactam, 99–100
for corneal disorders, 1146
critically ill horse and, 186
for dermatophilosis, 1174
for diarrhea, 755–756
for endometritis, 1252–1253
for equine herpesvirus-1 myeloencephalopathy, 650
for infective endocarditis, 484
for pleuropneumonia, 350, 350t
for spinal cord injury, 621
for tetanus, 671
for toxic injury, 490
Antibodies
in adaptive immunity, 23–24
in immune response, in foals, 40
Antibody-mediated hypersensitivity diseases, 44–46
Antibody-mediated immunity
in foals, 40–41
tests for, 48–49, 49f–50f
Anticholinergic (vagolytic) agents, 457t–461t
Anticoagulant rodenticide toxicity, 1014
Anticoagulants, for hemostatic dysfunction, 1005
Anticoagulation, hemostasis and, 1001
Anticollagenases, for corneal disorders, 1146–1147
Anticomplement factor, bacterial spread and, 7
damage and diseased tissues and, 6t
Anticonvulsants, 606
for pain management, 148
Antidiuretic hormone challenge test, 919–921, 921f
Antiendotoxin therapy, for duodenitis proximal jejunitis, 740
Antifibrinolysis, hemostasis and, 1001
Antifungals, for corneal disorders, 1146
Antigenic determinants, in adaptive immunity, 23
Antigenic shifts, 14
Antigens
in adaptive immunity, 23
major histocompatibility, 28, 29f
Antigen-specific immunomodulation, 62–63
Antigen-specific receptors
of B lymphocytes, 24–27
signaling through, 30–31, 32f
of T cells, 27
Antihistamines, for allergic skin disease, 1193
Antiinflammatory drugs
for cervical vertebral compressive myelopathy, 636
for duodenitis-proximal jejunitis, 740
for equine herpesvirus-1 myeloencephalopathy, 650
for equine protozoal myeloencephalitis, 644
for gastrointestinal ileus, 776
for hepatic insufficiency, 864
for pain management, 143–145
for placentitis, 1366–1367
for temporohyoid osteoarthropathy, 626
for traumatic brain injury, 617
for verminous encephalomyelitis, 684–685
Antimicrobial therapy, 94
aminoglycosides in, 105–109, 107t, 108f
aminopenicillins in, 101–102
amphenicols in, 109–110
Antimicrobial therapy *(Continued)*
antipseudomonal penicillins in, 102
benzylpenicillin in, 100–101
beta-lactam antibiotics in, 99–100
beta-lactamase inhibitors in, 99–100
carbapenems in, 105
cephalosporins in, 99–100, 102–105
chloramphenicol (CPHC) in, 109
concurrent use of additional antimicrobials in, 99
designing of dosage regimens of, 95, 97–98
for duodenitis-proximal jejunitis, 740
for endotoxemia, 733
florfenicol (FLF) in, 109
fluoroquinolones in, 116–118
for foals, 1420–1424, 1422t
aerosol administration in, 1424
aminoglycosides as, 1423
cephalosporins as, 1421–1423
chloramphenicol as, 1424
fluoroquinolones as, 1424
β-lactams as, 1421
macrolides as, 1423–1424
metronidazole as, 1424
potentiated sulfonamides as, 1423
rifamycins as, 1424
tetracyclines as, 1423
therapeutic targets of, 1420–1421
for gastrointestinal ileus, 777–778
for infective endocarditis, 484
macrolides and azalides in, 114–116
metronidazole in, 119–120
prophylactic use of, 99
rational use of, 94–97
bactericidal *versus* bacteriostatic antimicrobials, 96–97, 97b
infection documentation and, 95
minimum inhibitory concentration interpretation in, 95–96, 96f
pharmacokinetic-pharmacodynamic relationships in, 97, 98f, 98b
postantibiotic effect of, 97, 97t
rifampin in, 118–119
sulfonamides in, 110–112, 111t
for tetanus, 671
tetracyclines in, 112–114
Antioxidants, for endotoxemia, 736
Antiprotozoal medication, 644
Antipseudomonal penicillins, 102
Antithrombin III, hepatic insufficiency and, 856
Anus, neurologic examination of, 584, 588
Aorta, 441b–443b, 464
Aortic valve
auscultation of, 402f, 403
echocardiographic and Doppler studies of, 441b–443b
infective endocarditis, 481–484, 482f–483f
regurgitation of, 476–479, 476f, 478f–479f
causes of, 401t–402t
Aortocardiac fistula, 493f, 496–497
Aortoiliac thrombosis, as cardiovascular disorder, 493f–494f, 495–496
Aphthovirus, 344–345
Aplastic anemia, 1017
Apoptosis

for foals, 1424
Flow cytometry, in cellular immunity assessment, 51f
Fluconazole
for endometritis, 1258, 1259t
for foals, 1422t
for fungal pneumonia, 356t
for guttural pouch mycosis, 326
Fluid therapy, 163–165, 166t
for acute renal failure, 1409–1410
for endotoxemia, 737–738
for foals, 1424–1429
dosage of, 1427–1429
patient requirement for, 1425
routes of administration for, 1426–1427
types of fluids for, 1425–1426, 1426t
for gastrointestinal ileus, 776
for neonatal sepsis, 1379
orally administered, 165–167, 166t
planning, 163–165
for shock, 175
for traumatic brain injury, 617
vascular access and administration of, 161–163, 162t
Flumazenil, for hepatic insufficiency, 864
Flunixin meglumine
for acute rhabdomyolysis, 549
for equine herpesvirus-1 myeloencephalopathy, 650
for hepatic insufficiency, 864
for infective endocarditis, 484
for pain management, 144t–145t
for periparturient hemorrhage, 1305
for peritonitis, 765
pharmacology of, 124
for placentitis, 1366–1367
for pleuropneumonia, 350t
in retained fetal membranes, 1307
for spinal cord injury, 621
for thrombophlebitis, 495
for verminous encephalomyelitis, 684–685
Fluorescent antibody testing, in rabies, 664
Fluoride toxicity, 1499–1500
Fluoroquinolones, 116–118
adverse effects and drug interactions of, 118
clinical use of, 118
for foals, 1424
formulations of, 118
mechanism of action of, 116–117
mechanism of resistance of, 117
pharmacokinetics of, 117–118
Fluphenazine
for recurrent exertional rhabdomyolysis, 553
toxicity, 686
Flutter, atrial, 500f, 502–503
Foal heat diarrhea, 1401–1402
Foals
aminoglycosides in, 107
antiinflammatory and analgesic therapy for, 1431–1432, 1432t
antimicrobial therapy for, 1420–1424, 1422t
botulism in, 673–674
cerebellar abiotrophy in, 630
disorders of, 1365–1459
dysmaturity of, 1369–1370
endocrine disorders of, 1410–1414
dysfunction of somatotropic axis and energy regulation as, 1412–1414
hypothalamic-pituitary-adrenal axis function and dysfunction as, 1410–1412
hypothalamic-pituitary-thyroid axis function and dysfunction as, 1412
endotoxemia in, 737
examination of, 1367–1369
failure of transfer of passive immunity in, 55–57
Fell pony syndrome in, 53
fetal assessment, monitoring, and management of, 1365–1367
fluid therapy in, 1424–1429
dosage of, 1427–1429
patient requirement for, 1425
routes of administration for, 1426–1427
types of fluids for, 1425–1426, 1426t
gastric ulceration in, 805
gastrointestinal disorders of, 1400–1406
diarrhea as, 1401–1404
gastric ulceration as, 1404–1406, 1405t

  radial and suprascapular nerve, 596, 597f
  spinal cord and vertebral, 618–622, 618t

Injuries *(Continued)*
thermal, 1197–1198
traumatic brain. *see* Traumatic brain injury
Innate immunity, acute inflammatory response and, 20–23
acute phase proteins, proinflammatory cytokines, and complement in, 20–23, 20t, 21f
chemotaxis and leukocyte trafficking in, 22–23
in foals, 38–39
lipid mediators in, 21–22
tests of, 52
Innate responses, 20
Inotropes
in critical care, 174
for heart disease, 457t–461t
Insect allergies, 1195
Insect bite hypersensitivity, 45, 1190–1191, 1190f–1191f
Insecticides, 1188
cholinesterase-inhibiting, 1471–1472
Insemination
artificial
with cooled shipped semen, 1266
with fresh semen, 1266
of frozen semen, 1266–1267
deep intrauterine, 1312–1313
hysteroscopic, 1313
in oocyte transfer, 1311–1312
Insertional activity, 592–593, 593f
decreased, 593
prolonged, 593
Insulin, 1080
administration of, in critically ill foals, 210
for foals, 1437, 1438f, 1438b
in hyperkalemia, 517
Insulin degrading enzyme (IDE), 1094–1095
Insulin dysregulation, 1085
clinical pathology of, 1090
clinical signs of, 1089–1090, 1089f–1090f
definition of, 1088
diagnostic testing in, 1090–1100
differential diagnoses of, 1089–1090, 1089f–1090f
etiology of, 1088–1089
genetics in, 1089
management of, 1098–1099
treatment of, 1100
Insulin resistance syndrome, 1085–1086
Integrins, in neutrophil adherences, 22
Intensive care units, 158–161
emergency drugs in, 159, 160t
equipment in, 159, 159b
Interferon-α, for immunostimulation, 60
Interferon-γ, in pathophysiology of colitis, 722t
Interleukin-1
in endotoxemia, 727t–728t
in pathophysiology of colitis, 722t
Interleukin-1 receptor antagonist protein, for pain management, 149
Interleukin-6, as inflammatory mediators, 727t–728t
Interleukin-8 (IL-8), 717–718
as inflammatory mediators, 727t–728t
Intermediate lipoproteins, 847
Internal abscessation, in *S. equi* infection, 335–336
Internal genitalia, of stallions, 1314–1316
evaluation of, 1322–1323
Internal medicine, clinical nutrition and, 191–217
Internist's tumor, 969
Interstitial fluid, 258–259
ionic composition of, 900t
Interstitial pattern, radiographic, 320–322, 321f
Interstitial pulmonary disease, 352–354
clinical findings of, 353
diagnosis of, 353, 353f
etiology of, 352–353
prognosis of, 354
treatment of, 353
Interval-extension method, 93–94, 93f–94f
Intestinal anaphylaxis, 758–759
Intestinal blood loss, 1006
Intestinal microbiota, 723
Intestinal tract, ischemic disorders of, 778
strangulating obstruction, 778, 779f
Intestine
barrier function of, 767
ischemia/ reperfusion injury, 768–770, 769f–770f, 769t
parathyroid hormone effects on, 1037
strangulation, 172
Intracellular adhesion molecules (ICAMs), 717–718
Intracellular calcium, 1029
Intracellular fluid, 900, 900t
Intracytoplasmic sperm injection, 1310
Intrarenal vasoconstriction, in acute renal failure, 925
Intrauterine antibiotics, for endometritis, 1253, 1254t
Intrauterine growth retardation, of foals, 1369–1370
Intravenous catheters, central venous pressure measurement and, 169
Intraventricular conduction blocks, 516f
Intubation, nasogastric, in critical care, 170–171
Intussusceptions, 781, 781f–782f
postpartum, 1306
Iodine, toxic effects of, 1497–1498
Iodine toxicity, 1187
Iodine-azide test, 1476
Iodism, 1165t–1167t
Ionization, drug, 84, 84b
Ionophore toxicity, 1489–1491
rhabdomyolysis and, 568
in toxic injury, 490–491
Ipratropium, for interstitial pulmonary disease, 352–353
Ipratropium bromide, as bronchodilator, 1396–1397, 1397t
Iris prolapse, 1148, 1149f
Iris stromal hypoplasia, 1151
Iron
metabolism, 994–995, 996t
toxic effects of, 1504
in foals, 1418
hepatic, 870–871
Iron deficiency anemia, 1016
Irreversible adrenal insufficiency, 1072
Ischemia
CNS dysfunction and, 687
intestinal, 778
epithelial injury, 768–769
nonstrangulating, 783–784
rectal prolapse, 783f, 783t
reperfusion injury in, 768–770, 769f–770f, 769t
strangulating obstruction, 769–770, 778, 779f
Ischemic coagulative necrosis, 850
Isocoma wrightii, 1484–1485
rhabdomyolysis from, 568
Isoerythrolysis, neonatal, 45–46, 46f
as hepatic disorder, 1418
as immunologic disorder, 1414–1416
Isosthenuria, 1409
Isotonic crystalloids, 166
Isotonic electrolyte-containing fluids, for fluid therapy, 1425
Isotonic fluids, for traumatic brain injury, 617–618
Isotonic replacement fluid, 1428
Isotonic saline, 164
Isotypes, of antibody, 24–25
Isovolumic period, 392–395
Isovolumic relaxation, 392–395
ITAM. *see* Immunoreceptor tyrosine based activation motif
Itraconazole
for dermatophytosis, 1178
for endometritis, 1258, 1259t
for fungal pneumonia, 356t
Ivermectin
for cutaneous habronemiasis, 1186
for demodicosis, 1184
for lice, 1181–1182
for onchocerciasis, 1185
for parasitic pneumonitis, 357
for scabies, 1182
for verminous encephalomyelitis, 684
Ixodid ticks, 1184

J

Japanese encephalitis, 659
Jasmine, wild, 1494
Jaundice, hepatic, 854
Jaundiced foal agglutination (JFA) test, for neonatal isoerythrolysis, 1415
Jejunitis, duodenitis-proximal, 738
clinical and clinicopathologic signs of, 739–740
pathophysiology of, 738–739
prognosis for, 741
treatment of, 740–741, 740f
Jejunojejunal intussusception, 781, 781f
Jimsonweed toxicity, 1462
Journal reputation, in evidence-based medicine, 221–222
Juglans nigra, 1494
Jugular pulsations, 410–411
Jugular pulse, 392
Jugular veins
compression of, CSF pressure and, 589
examination of, 176
pulse of, 392
abnormalities of, 410–411
thrombophlebitis of, 491, 492f, 493–494
Junctional arrhythmias, 511
Junctional epidermolysis bullosa type 1 (JEB-1), 1173
Junctional epidermolysis bullosa type 2 (JEB-2), 1173
Juvenile idiopathic epilepsy, in neonatal foals, 1385

K

Kallikrein-bradykinin system, 719

idiopathic nonulcerative, 1150
Keratomalacia, 1145f
Keratosis
cannon, 1171
linear, 1171
Kernicterus, 1385
Kerosene, for endometritis, 1255, 1255t
Ketamine
for pain management, 144t–145t, 147–148
for seizures, 607
for traumatic brain injury, 617
Ketoconazole
for endometritis, 1258, 1259t
for guttural pouch mycosis, 326
Ketoprofen
for acute rhabdomyolysis, 549
for pain management, 144t–145t
pharmacology of, 124–125
Kidneys
acute renal failure. *see* Acute renal failure
anatomy of, 888
chronic kidney disease. *see* Chronic kidney disease

Kidneys *(Continued)*
developmental malformations of, 891–898
agenesis, hypoplasia, and dysplasia in, 891–893, 893f
cysts in, 893
polycystic kidney disease, glomerulocystic disease, and other hereditary nephropathies in, 893–894, 894f
vascular anomalies in, 894, 895f
pendulant, 894
physiology of, 898
nitrogenous and organic wastes, production and elimination of, 898–900, 898b
polycystic kidney disease in, 893–894, 894f
ultrasonography in, 917–918, 918f
Kinetics
of drug metabolism, 88–89
fetal, during parturition, 1297–1298
flip-flop, 86, 87f
Klebsiella spp., 1234
Klossiella equi, in urinary tract infections, 949
Klotho, 1040
Kupffer cells, 843–845, 849, 856

L

Laboratory studies
in cardiovascular disorders, 398b, 411–454
in atrial fibrillation, 504
in infective endocarditis, 482–483
in myocardial disease, 489
in pericardial disease, 485
failure of passive transfer and, 56
Fell pony syndrome, 54
severe combined immunodeficiency and, 52–53
Lacerations
eyelid, 1141
perineal, postpartum, 1309
uterine, 1243–1244
vaginal, 1309
β-Lactams, for foals, 1421
Lactate dehydrogenase (LDH), 545
in cerebrospinal fluid, 591t
in liver disease, 861
Lactate dehydrogenase-5, hepatic insufficiency and, 857t
Lactated Ringer's solution, 166–167
for endometritis, 1255t
for hyperkalemia, 517
Lactation
induction of, in barren mare, 1264
tetany, 1310
Lactic acid
in cerebrospinal fluid, 591, 591t
recurrent exertional rhabdomyolysis and, 551
Lactose tolerance testing, 714
Lactulose, for hepatic insufficiency, 863–864
Lameness, in poor performance, 289
Laminitis, 1088
Laparocystotomy, for cystic calculi, 954–955
Laparoscopy, gastrointestinal, 715
Large colon impaction, 786–787
Large colon volvulus, 781–783
Large intestine, displacement of, 710
Large-vessel thrombosis, in plasma-based coagulation system, 1015–1016
Larval cyathostomiasis, 15
Laryngeal hemiplegia, in *S. equi* infection, 336
Laryngeal tie-forward procedure, for dorsal displacement of soft palate, 328–329
Larynx
hemiplegia, 596–597
innervation to, neurologic examination of, 584
recurrent neuropathy of, 329–330, 329t
Lasalocid
in toxic injury, 490
toxicity, 1490–1491
Latency, defined, 10
Lateral thoracic vein catheterization, 161–162
Lavage
pericardial, 485–486
uterine, for endometritis, 1255–1256, 1255t
Lawsonia intracellularis
equine proliferative enteropathy due to, 1404
weight loss and, 242–243
Lead toxicity, 1482–1484
Leads, electrocardiographic, 415, 415b
Lectin pathway, 21
Lectins, 6–7
Lens, disorders of, 1153–1154, 1153f–1154f
Leptocyte, 993
Leptospirosis
in abortion, 1282
in hemolysis, 1009
in neonatal foals, 1417–1418
Leucinosis, systemic manifestations of, 1165t–1167t
Leukemia, 1019
Leukocyte trafficking, in acute inflammatory response, 22–23
Leukocytes, 995–998
fecal, in diarrhea assessment, 282
Leukocytoclastic vasculitis, 1201–1202, 1202f
Leukoderma, 1168
Leukoencephalomalacia, 686, 1481–1482
Leukopenia
in endotoxemia, 732
in neonatal foals, 1370
Leukoproliferative disease-associated immunodeficiency, 58
Leukotrichia, 1168–1169, 1168f–1169f
Leukotrienes, in inflammatory response, 21–22
Levamisole
for immunostimulation, 62
toxic effects of, 1475
Levator veli palatini, 328t
Level of consciousness, in traumatic brain injury, 613–614
Levofloxacin, 116
Levothyroxine sodium, 1099
Leydig cells, 1314
Libido, in breeding stallions
frequency of service, 1331
low, 1331
Lice infestations, 1165t–1167t, 1181–1182
Lidocaine
for endotoxemia, 736
for gastrointestinal ileus, 778
for heart disease, 457t–461t
for pain management, 144t–145t, 147
for ventricular tachycardia, 513–514
Light breeds, polysaccharide storage myopathy in, 555
Limb strength, of neonatal foals, 1382t
Lime sulfur dip
for dermatophytosis, 1178
for lice, 1182
Linear keratosis, 1171
Lip, 790
Lipid A-proximal, of lipopolysaccharides, 724, 724f
Lipid mediators, inflammatory response and, 21–22
Lipid metabolism, 846–848, 846f–847f
in hepatic insufficiency, 859–860
Lipid solubility, of drugs, 84, 84b
Lipidosis, hepatic, 871–874, 873f
in foals, 1418
Lipoma, strangulation by, 780
Lipophilic antimicrobials, for equine proliferative enteropathy, 1404
Lipopolysaccharide (LPS)
capsule and, 7
in endotoxemia, 724, 724f
Escherichia coli, 724–725, 725f
in gastrointestinal inflammation, 715
inhibition of, 735
scavenging of, 733
Lipoteichoic acid, 6t
Lipoxygenase products, in pathophysiology of colitis, 722t
Lithocholate, 848
Live cover breedings, 1328, 1328f–1329f
Liver
anatomy of, 843
histology of, 843–845, 844f
physiology of, 845–849
protein metabolism in, 845–846, 846f–847f
Liver disorders, 843–887
in plasma-based coagulation system, 1014–1015
toxicoses and, 1502–1503
Liver enzymes, in hepatic insufficiency, 860–861
Liver lobe torsion, 881
L-lactate, in critical patients, monitoring of, 176
Llewellyn procedure, for dorsal displacement of soft palate, 328
Loading dose, 91
Local anesthetics
for gastrointestinal ileus, 778
for pain management, 144t–145t, 147
Locomotor disorders, in poor performance, 290–291
Locoweed toxicity, 1469
Loop diuretics, in acute renal failure, 929
Low-density lipoproteins, 847
Lower airway disease, 178, 179b
Lower respiratory tract
bronchoalveolar lavage in, 318–319, 319t
diagnostic sampling of, 318–323
examination of, 316–318
endoscopy for, 316–317, 317f
radiography for, 317–318, 318f
lung biopsy in, 322–323
pulmonary function testing in, 322
thoracic radiography for, 320–322, 321f
thoracocentesis in, 319–320, 319f
thoracoscopy in, 323
tracheobronchial aspiration in, 318
Low-level laser therapy, for pain management, 151
Low-molecular-weight heparin (LMWH), for hemostatic dysfunction, 1005
Lufenuron, for endometritis, 1258, 1259t
Lung biopsy, 322–323
Lung fields
auscultation of, 316
ultrasonographic examination of, 320
Lung movement, measurements of, 322
Lupus erythematosus, systemic, 1165t–1167t, 1196

Melanoma, 1208–1209, 1208f–1209f
in eyelid, 1141
Melanosomes, 1161–1167
Meloxicam, 125
for pain management, 144t–145t
for pleuropneumonia, 350t
Menace response, in neonatal foals, 1381
Menadione sodium bisulfite, 1507
Meningitis, bacterial, 1383–1384
Meperidine, for pain management, 144t–145t
Mepivacaine, for pain management, 144t–145t
Mercury toxicity, 1188, 1507–1508
systemic manifestations of, 1165t–1167t
Mesenteric portography, operative, 862
Mesothelioma, 484–485
Messenger ribonucleic acid (mRNA), 9
Metabolic acidosis, 180–181, 711
bicarbonate, supplemental, 164–165
endotoxemia and, 737
Metabolic alkalosis, 180–181
Metabolic disorders, CNS dysfunction and, 686–687
hepatoencephalopathy, 686–687
hypoglycemia, hypoxemia, and ischemia, 687
Metabolic encephalopathies, in foals, 1384–1385
Metabolic syndrome
equine, 1086–1088
human, 1085–1086
Metabolism
of carbohydrate
liver's role in, 846, 846f
testing of, in hepatic insufficiency, 859
of creatinine, 899
foal, nutrient requirements and, 207
hepatic, of drugs, 88, 88f
sulfonamides, 111
induction and inhibition of, 88, 88b
of lipid
in hepatic insufficiency, 859–860

Metabolism *(Continued)*
liver's role in, 846–848, 846f–847f
liver's role in, 845, 846f–847f
of nitrogenous and organic compounds, 900
of protein, 845–846, 846f–847f
of urea, 898–899
Metaldehyde, 1474–1475
Metformin, 1099–1100
Methadone, for pain management, 144t–145t
Methemoglobin
maple toxicity and, 1485
nitrite toxicity and, 1491–1492
Methiocarb, 1475
Methocarbamol
for acute rhabdomyolysis, 549–550
for pain management, 144t–145t, 148
Methylmercurial poisoning, 632
Methylprednisolone sodium succinate (MPSS)
critically ill horse and, 185
for spinal cord injury, 621
Methylprednisolone succinate, for acute rhabdomyolysis, 549–550
Metoclopramide
for gastrointestinal ileus, 777
for reflux esophagitis, 801
Metritis
contagious equine, 1340
toxic, postpartum, 1306–1308
Metronidazole
for *C. perfringens* enterocolitis, 1403
for foals, 1422t, 1424
pharmacology of, 119–120
for pleuropneumonia, 350, 350t
for tetanus, 671
for thrombophlebitis, 495
Metyrapone, 1076
MHC. *see* Major histocompatibility complex
MIC. *see* Minimum inhibitory concentration
Michaelis-Menten kinetics, 88
Miconazole
for endometritis, 1258, 1259t
for fungal pneumonia, 356t
Microbial surface components recognizing adhesive matrix molecules, 6
Microbiologic testing, for stallions, 1326
Microbiome, 3–5
fungal, 5
intestinal, 4
nosocomial infections, 5
oral, 3–4
pharyngeal and respiratory, 4
skin, 3
urogenital, 4–5
Microfold, 36
Microfold (M) cells, of respiratory tract, 314
Microscopic hematuria, 957–958
Microsomes, in biotransformation, 849
Micturition, control of, 973
Midbrain, traumatic injury to, 615t
Middle gluteal muscle, electromyography of, 593f
Middle molecules, 938
Migrating motility complexes, 774
Mild ventral edema, with chronic kidney disease, 939
Milk aspiration, 1392
Milkvetch toxicity, 1480
Milkweed toxicity, 1479
Milrinone, 457t–461t
Mineral oil
for cantharidin toxicosis, 1467
for hepatic insufficiency, 863
Minimum bactericidal concentration (MBC)
of antimicrobials, 95
bactericidal *versus* bacteriostatic, 96–97, 97b
Minimum inhibitory concentration (MIC)
of antimicrobials, 95
bactericidal *versus* bacteriostatic, 96–97, 97b
interpretation of, in antimicrobial therapy, 95–96, 96f
Minocycline
for foals, 1423
pharmacology of, 112
for pleuropneumonia, 350t
Minute volume, measurement of, 322
Miserotoxin, 1480
Misoprostol, for gastric ulceration in foals, 1405–1406, 1405t
Missouri University model artificial vagina, 1323
Mite infestations, 1182–1184, 1182f
Mitochondrial myopathy, 560
Mitomycin-C, for sarcoid, 1205
Mitral valve, 390, 391f
echocardiographic and Doppler studies of, 441b–443b
infective endocarditis, 481–484, 482f–483f
regurgitation of, 472–476, 473f
causes of, 401t–402t
Mixed hamartoma, 880
M-mode echocardiogram, 394f, 420, 444f, 447f, 449f
in aortic regurgitation, 477
in mitral regurgitation, 474f
Mobile crash carts, 159
Models, in pharmacokinetics, 79–80
Modified water deprivation test, 919–921
Moisture
dermatophilosis and, 1173
dermatophytosis and, 1177
Moldy corn disease, 1481–1482
Monensin toxicity, 1489–1490
Monensin toxicosis, myocardial, 490
Monitoring
arterial blood pressure, 168–169, 168f–169f, 168t
cardiovascular, 175–176
central venous pressure, 169
in intensive care units, 159
therapeutic drug, 91, 92b
Monitoring, pregnant mares, 1286–1288
Mononuclear cells, in cerebrospinal fluid, 590
Mononuclear phagocyte system, hepatic, 849
Morbillivirus, 345
Morphine
gastrointestinal ileus and, 775
for pain management, 144t–145t, 145
Mosquitoes, hypersensitivity to, 1191
Mossy fibers, 629
Motility
abnormal, diarrhea and, 278–279
esophageal, disorders of, 801
gastrointestinal, in diarrhea, 723
Motor neuron disease, equine, as neurologic disorder, 665–668, 665f
Motor unit, disease affecting, 595–597
Motor unit action potentials, 592, 593f
polyphasic, 593–594, 594f
Mouldy sweet clover toxicity, 1014
Mouth. *see* Oral cavity
Moxidectin, for parasitic pneumonitis, 357
Moxifloxacin, 116
MPSS. *see* Methylprednisolone sodium succinate
MRT. *see* Mean residence time

in foals, 1374
Multisystem neuropathy, 676
Multisystemic eosinophilic epitheliotropic disease (MEED), 743t–744t, 745, 1213
Muramyl dipeptide, for immunostimulation, 61
Murmur, cardiac
of aortic regurgitation, 476
auscultation of, 399–400, 400t, 402f, 404f
causes of, 401t–402t
functional systolic ejection, 392–395, 393f, 408
of infective endocarditis, 482
Murmur, cardiac *(Continued)*
of mitral regurgitation, 472f, 474
phonocardiograms of, 472f
poor performance and, 399b
of tricuspid regurgitation, 479
of ventricular septal defects, 466–467
Murray Valley virus, 659
Musca, hypersensitivity to, 1190
Muscle
atrophy, 596
cramping, 573–574
form and function of, 542–548, 543f
skeletal, 542
Muscular dystrophy, nutritional, 561
Musculoskeletal system
associated with poor performance, 290
disorders of, 542–579
atrophy and, pathophysiology of, 545, 545f
bacterial-associated myositis as, 564
classification of, 544–545, 544b
diagnostic approach to, 542–543
diagnostic tools for, 545–548
electrolytes as, 546
electromyography as, 547
genetic testing as, 546–547
muscle biopsy as, 547, 547f
renal parameters as, 546
selenium and vitamin E as, 546
serum CK exercise response test as, 546
serum creatine kinase and aspartate transaminase activities as, 545–546
urinalysis as, 546
exertional myopathies as, 543
chronic, 550–553
idiopathic chronic, 560
fasciculations and, pathophysiology of, 545
glycogen branching enzyme deficiency as, 560–561
history of, 542
hyperkalemic periodic paralysis as, 572–573
hypocalcemic tetany as, 573–574
idiopathic immune-mediated/inflammatory myopathies, 568
imaging for, 548
nuclear scintigraphy as, 548
ultrasonography as, 548, 548f
immune-mediated myopathies as, 566–568
immune-mediated myositis in Quarter horse-related breeds as, 566–567
infarctive purpura hemorrhagica as, 566
inflammatory myopathies as, 563–568
inspection of, 542–543, 544f

Musculoskeletal system *(Continued)*
locomotor and neurologic examination of, 543
malignant hyperthermia as, 553–554, 570
masseter muscle myodegeneration, 562
muscle fasciculations in, 571b
muscle form and function in, 542–548, 543f
myopathy as
focal, 569–570
generalized postanesthetic, 570
hypoglycin A, 568–569
mitochondrial, 560
myofibrillar, 559–560
polysaccharide storage, 554–559
postanesthetic, 569–570
Streptococcus Equi subsp.*Equi*-associated myopathy as, 564–565
vitamin E-deficient, 562–563
myotonia as, 570–571
ear tick-associated, 571–572, 571f
myotonic, 570–572
nonexertional myopathies as, 560–563, 560b
nutritional myodegeneration as, 561–562
physical examination of, 543
rhabdomyolysis and
acute, treatment of, 549–550
anaplasma-associated, 564
pathophysiology of, 544–545, 545f
recurrent exertional, 550–553
severe, 550
sporadic exertional, 548–550
toxic causes of, 568–569
sarcocystosis as, 563–564
synchronous diaphragmatic flutter as, 574
systemic calcinosis as, 567–568
tetracyclines and, 114
Mushroom toxicity, 1503
Mutant prevention concentration (MPC), of antimicrobials, 95
Mutation, obstetric, 1301
Mycetomata, 1179, 1180t
Mycobacterial products, for immunostimulation, 61
Mycotoxins, 871
Myeloencephalitis, equine protozoal, 640–645

Season, thyroid gland function and testing and, 1062
Seborrhea, 1170–1171
  in hepatic insufficiency, 856
Second heart sound, 392–395, 403–404
  auscultation of, 403, 403f
Secondary adrenal insufficiency, 1073
Secondary erythrocytosis, 1018
Secondary hemostasis, 999
Secondary immunodeficiency, 55–59
Secondary thrombocytosis, 1018
Second-degree AV block, 514, 515f
Second-degree burns, 1198
Secreted aspartyl proteinase (SAP), 8
Secretion, mucus, 313
Sedation
  α_2-adrenoreceptor agonists and, 146
  critically ill horse and, 185
  in tetanus, 671
Sediment examination, 913, 914f
Seizures, 264–267, 603–607
  clinical signs and diagnosis of, 605–606
  etiology/pathogenesis of, 604–605, 604t–605t
  in foals, 1383, 1386t
  hypocalcemic, 1041
  in traumatic brain injury, 617
  treatment of, 606–607
Selectins, in neutrophil adherences, 22
Selective IgM deficiency, 54–55
Selenium
  concentrations, sporadic exertional rhabdomyolysis and, 549
  deficiency of
    in dilated cardiomyopathy, 491
    nutritional myodegeneration and, 561
  for masseter muscle myodegeneration, 562
  for musculoskeletal system disorders, 546
  for nutritional myodegeneration, 1420, 1419–1420
  toxic effects of, 1500–1501
  toxicosis, 1187, 1188f
Selenosis, 1010–1011, 1165t–1167t
Self-cure, parasitic, 17
Self-mutilation, in breeding stallions, 1332
SeM protein, of *Streptococcus equi*, 334
Semen
  abnormalities of, 1339–1340
  collection of, 1323–1326
    miscellaneous methods of, 1324
    using live mare, 1328
  cooled shipped, 1266
  evaluation of, 1324–1326
  fresh, 1266
  frozen, 1266–1267, 1325
Seminal vesicles, 1316
  evaluation of, 1322–1323
Senecio species, 874, 874t
Sensitization
  central, 138
  peripheral, 138
Sensory afferents, in neuromuscular physiology of ventilation, 251
Sepsis, 724. *see also* Endotoxemia
  hypocalcemia and, 1043
  neonatal, 1373–1380
    clinical presentation of, 1377–1379
    identification of, 1377–1379
    management of, 1379
    pathophysiology of, 1374–1377, 1374t, 1375f, 1375b

Sepsis *(Continued)*

nutritional and toxic, 1187–1189
physical examination of, 1161
with systemic manifestations, 1165t–1167t
Skull fracture, 615f
Slaframine toxicity, 1464
Sleep, 607–608
definition of, 265
deprivation, 608, 609t
Sleep disorders, 265–267, 608–610
Sling, for recumbent horses, 187
Slow-adapting receptors, 245
Small intestine
palpation of, 710
simple obstruction, 784–786
strangulation, 778–781
Smooth lipopolysaccharide, 724
Snake bites, 43–44, 1189, 1189f
Snake venom toxicity, 1498–1499
Snakes, envenomation by, in hemolysis, 1010
SNAP test, 56–57
Snowshoe hare virus, 662
Soapy water enemas, for meconium impaction, 1400–1401
Sodium
in cardiac cell electrical activity, 413
in cerebrospinal fluid, 591t
Sodium bicarbonate
for chronic kidney disease, 945
in hyperkalemia, 517
Sodium channel blocker, 457t–461t
Sodium chloride (NaCl), for chronic kidney disease, 945
Sodium fluoroacetate toxicity, 1493
Sodium iodide, for fungal pneumonia, 356t
Sodium iodine, for dermatophytosis, 1178
Sodium penicillin G, for pleuropneumonia, 350t
Sodium phosphate enemas, for meconium impaction, 1400–1401
Sodium thiosulfate, for cyanide toxicity, 1493
Soft palate
dorsal displacement of, 328–329, 328t
muscles controlling, 328t
Soft tissue mass, radiographic imaging of, 318f
Solanine, 1461–1462
Solanum toxicity, 1461–1462
Solute, excretion of, 908–909
Somatostatin (SST), 1081
Somatotropic axis, dysfunction of, energy regulation and, 1412–1414
Sorbitol dehydrogenase (SDH), hepatic insufficiency and, 857t, 860
Sorghum, toxic effects of, 1506–1507
Space of Disse, 843–845
Spasmolytic peptide, 773
Spasms, muscle, in tetanus, 671
Spastic bladder, 973
Spasticity, 585, 637
Specific gravity, urine, 159
Speculum examination, vaginal, 1232–1233
Spermatic cord, 1315
abnormalities of, 1338
Spermatocytogenesis, 1317–1318
Spermatogenesis, 1317–1318
Spermatozoa, abnormalities of, 1339–1340
Spermiation, 1317–1318
Spherocyte, 993
Sphygmomanometry, oscillometric, 169, 169f
Spider bites, 1189
Spinal cord
cervical, localization of lesion in, 586
compression of
in cervical vertebral compressive myelopathy, 635
magnetic resonance imaging in, 602, 603f
injury, 618–622, 618t
Spinal nerve root, in electromyography, 592t
Spinal reflexes, of neonatal foals, 1381
Spinous layer, epidermal, 1159

Sporadic exertional rhabdomyolysis, 548–550
dietary imbalances and, 549
electrolyte imbalances and, 549
exhaustion and, 549
focal or generalized trauma and, 549
overexertion in, 549
signalment, history, and diagnosis in, 548–549
vitamin E and selenium concentrations and, 549
Sporotrichosis, 1178, 1179f, 1180t
SPORTDiscus, 220
Squamous cell carcinoma
of conjunctiva and third eyelid, 1143, 1143f
of cornea, 1150–1151, 1150f
cutaneous, 1206–1208, 1207f
of eyelid, 1141–1142, 1141f
St. Louis encephalitis virus, 659
ST segment, in electrocardiography, 418
Stable flies, hypersensitivity to, 1190
Stabling, for insect control, 1163b–1164b
Stachybotryotoxicosis, 1181
Stallion reproductive evaluations (SREs), 1318
Stallions, 1313
anatomy of, 1314–1316
assisted reproductive techniques for, 1312–1313
breeding, 1327–1330
exercise for, 1327
herd health management for, 1327–1328
measuring reproductive performance of, 1330
methods for, 1328–1330
novice or maiden, 1330
nutrition of, 1327
records of, 1318–1319
clinical evaluation of, 1319f–1322f
physiology of, 1316–1318
Staphylococcal pseudomycetoma. *see* Botryomycosis
Staphylococcal pyoderma, 1174
Staphylococcus aureus, toxins of, 7
Starch, 194b, 198
Starling equation, 259–260
Starling forces, 259–260, 260f–261f, 261b
alterations in, 261–262
Starvation
feeding thin and starved horses, 213
metabolic consequences of, 202
Status epilepticus, 603
Steatorrhea, in hepatic insufficiency, 855
Stenosis, pyloric, 808
Stercobilin, 849
Stereoisomers, nonsteroidal anti-inflammatory drugs as, 121
Steroidogenesis, 1071–1072, 1071f–1072f
Stethoscope examination, 400–403, 401t–402t, 402f–403f
Stimulation, central nervous system, toxicoses and, 1468
Stings, venomous, 1189
Stomach
diseases of, 803–808
dilation and rupture, 808
gastroduodenal ulceration, 803–806
in adults, 805–806
diagnosis of, 806, 806t
neonatal, 805
pathophysiology of, 803–804, 804f
prevalence of, 803
risk factors of, 804–805
in sucklings and early weanling foals, 805, 805f–806f
treatment of, 806–808
impaction, 808
pyloric obstruction and delayed gastric emptying, 808
mucosal barrier of, 766
Stomatitis
equine exfoliative eosinophilic dermatitis and, 1165t–1167t
oral, 795
vesicular, 1176–1177, 1176f
Stomoxys calcitrans, hypersensitivity to, 1190
Strabismus
in traumatic brain injury, 614–615
in vestibular disease, 624
Strangles, 331–338, 1165t–1167t
Strangulating obstruction, 769–770
Strangulating umbilical hernias, 780
Stratified squamous, barrier function of, 766
Streptococcus equi
in central vestibular disease, 627–628
in cerebellar abscess, 632
guttural pouch empyema from, 327
hyaluronic acid capsules of, 333
purpura hemorrhagica and, 46
virulence factors of, 334
Streptococcus equi subsp. *equi* infection, 331–338
associated myopathy in, 337
clinical management of, 335
clinical pathology of, 334
clinical signs of, 334
diagnosis of, 334–335
disease prevention in, 337–338
epidemiology of, 331–332, 332f–333f
general control measures in, 338
internal abscessation in, 335–336
other complications of, 336
outbreak management of, 337
pathogenesis of, 332–334
transmission of, 332
treatment of, 335
Streptococcus equi subsp. *zooepidemicus*, 331
in bacterial pneumonia, 346–347
bacterial pneumonia due to, 1394
Streptococcus-associated myopathy, 337
Streptokinase, 1005–1006
Streptolysin-like toxin, 334
Streptomycin, 627
Stricture, esophageal, 801–802
Stride length
evaluation in poor performance, 293–294
during exercise, 295
Stringhalt, abnormal gaits associated with, 586–587
Stroke, heat, 233
Stroke volume, 173
in cardiac cycle, 392–395, 394f
Stromal abscess, corneal, 1148–1149, 1149f
Stromal cells, in adaptive immunity, 23–24
Strongyloides westeri
acquired resistance to, 17
in foal diarrhea, 1404
Strongylosis
acute diarrhea and, 753–754
acute diarrhea associated with, 748t
therapies for, 762
Strongylus equinus, in verminous encephalomyelitis, 682
Strongylus vulgaris
in aortoiliac thrombosis, 493f, 495
colic and, 14
in parasitic vascular lesions, 494f, 496
resistance to, 17
in verminous encephalomyelitis, 682
Strontium-90, for squamous cell carcinoma, 1208
Strychnine, 1474
ST-T wave, in electrocardiography, 414
Styloglossus muscles, in DDSP, 328
Stylopharyngeus muscle, 328
Subepiglottic cyst, 314f
Subpalpebral lavage catheters, for corneal disorders, 1147–1148
Suck reflex, in sick, recumbent foals, 208–209
Suckle reflex, of neonatal foals, 1380, 1382t
Suckling, gastroduodenal ulcer disease in, 805, 805f–806f
Sucralfate, 807
for gastric ulceration in foals, 1405–1406, 1405t
Sudden cardiovascular death, 399b
Sugars, simple, 197
Sulfadiazine
for endometritis, 1254t
for equine protozoal myeloencephalitis, 644
Sulfadiazine-trimethoprim, for foals, 1422t
Sulfonamides, 110–112
adverse effects and drug interactions of, 111–112
clinical use of, 112
critically ill horse and, 186
for equine herpesvirus-1 myeloencephalopathy, 650
Sulfonamides *(Continued)*
for equine protozoal myeloencephalitis, 644
formulations of, 112
mechanism of action of, 110
mechanism of resistance of, 110

T_H17 CD_4+ effector T cells, 35
Thalamus, traumatic injury to, 615t
Thallium toxicity, 1468
Theileria equi, 1249
Theiler's disease, 865–866, 866f
Theiler's disease-associated virus, 867
Therapeutic drug monitoring (TDM), 91–92, 92t
of aminoglycosides, 108
Thermal injuries, 1197–1198
Thermoregulation, 233
in neonatal foals, 1369
Thiabendazole, 1186
for parasitic pneumonitis, 357
Thiamine
for bracken fern toxicity, 1479
deficiency, refeeding syndrome and, 214
in traumatic brain injury, 618
Thin and starved horses, feeding for, 213–214
Third eyelid, disorders of, 1142–1143
Third heart sound, 395
auscultation of, 403f
Third-degree burns, 1197
Third-degree or complete AV block, 514, 515f
Thirst, contributes to water balance, 286
Thoracic percussion, 316
Thoracic radiography, 418–419, 419f
in cardiovascular disorders, 398b
in congestive heart failure, 456–457
Thoracic ultrasonographic examination, 320
Thoracocentesis, 170, 319–320, 319f
in pleuropneumonia, 348
Thoracoscopy, 323
Thoracotomy, for pleuropneumonia, 351
Thorax, auscultation of, 402f
Thornapple toxicity, 1462
Thrombin activatable fibrinolysis inhibitor (TAFI), 1001
Thrombocytopenia, 1012
alloimmune, 45–46
differential diagnoses for, 998b
immune-mediated, 1012
neonatal alloimmune, 1012–1013, 1416
secondary to systemic disease, 1012
Thrombocytosis, 997–998, 1018–1019
Thrombophlebitis, 482, 492f, 493–495
Thrombosis
aortoiliac, as cardiovascular disorder, 493f–494f, 495–496
in plasma-based coagulation system, 1015–1016
vascular, hyperlipemia and, 872
Thromboxane
as inflammatory mediators, 727t–728t
in pathophysiology of colitis, 722t
Through-the-needle catheters, 162t
Thymus, development of, 38
Thyroid gland, 1058–1069
diagnostic tests in, 1060t–1061t, 1064–1065
factors that affect, 1060–1064, 1060t
hyperthyroidism in, 1068
hypothyroidism in, 1061t, 1065
imaging of, 1065
tumors in, 1068–1069
Thyroid hormones
function of, 1058–1059
metabolism of, 1059
molecular actions of, 1059
Thyroid suppression test, 1065
Thyroid-stimulating hormone stimulation test, 1064
Thyrotropin-releasing hormone stimulation test, 1064–1065
Thyroxine, recurrent exertional rhabdomyolysis and, 553
Tiamulin, 114
Ticarcillin, 102
for foals, 1421, 1422t
Ticarcillin + clavulanic acid, for endometritis, 1253, 1254t
Tick infestations, 1184
Ticks, in Lyme disease, 678
Tidal volume, measurement of, 322
Tilmicosin, 114
Timber milkvetch toxicity, 1480
Tissue injury, during inflammation, 719–720
Togaviral encephalitis, 655–659, 656t, 658t
Toll-like receptors (TLRs), 20–21, 726
Tongue, 790
Torsion
ovarian, 1245
umbilical cord torsion, 1284
uterine, 1291–1292
Total bilirubin, in hepatic insufficiency, 857, 857t
Total fluid replacement, for rhabdomyolysis, 550
Total nonstarch polysaccharides (NSPs), 197–198
Total protein, in cerebrospinal fluid, 590, 591t
Total red cell volume analysis, during exercise testing, 293–294
Total run time, in poor performance, 295
Toxic disorders, 686
Toxic hepatopathy, 869–871
Toxic injury, to heart, 399b, 490–491
Toxic metritis, postpartum, 1306–1308
Toxicity
fescue, during pregnancy, 1293–1294
oxalate, 1032t
in urinary system, 958
Toxicoinfectious botulism, 673
Toxicologic problems, 1460–1512
Toxicoses
blister beetle, 1466–1467
cantharidin, 1466–1467
cardiovascular and hemolymphatic systems and, 1484
central nervous system depression and, 1478
stimulation and, 1468
epithelium and skeletal system and, 1494
gastrointestinal tract and, 1460
hairy vetch, 1165t–1167t
liver disease or dysfunction and, 1502–1503
oxalate, 1506, 1506b
selenium, 1187, 1188f
suspected, rules regarding treatment of, 1476b
urinary system and, 1505

Toxins
aflatoxin, 1504–1505
alsike, 1503
aluminum, 1463–1464
4-aminopyridine, 1475
ammonia, 1477
arsenic
acute diarrhea associated with, 748t, 758
gastrointestinal effects of, 1462–1463
bicarbonates, 1488–1489
black locust, 1478
black walnut, 1494
blue-green algae, 1470–1471
in botulism, 672–674
bracken fern, 1478–1479
cadmium, 1507
cantharidin, 1466–1467
acute diarrhea associated with, 748t, 757–758
carbamates, 1471
carbon disulfide, 1475–1476
castor beans, 1461
chlorates, 1465
chlorinated hydrocarbons, 1473–1474
coumarin derivatives, 1486–1488
cyanide, 1492–1493
damage to host tissue by
in bacterial infection, 7
in fungal infection, 8
dimethyl sulfoxide, 1488
dioctyl sodium sulfosuccinate, 1462
Equisetum, 1479
ergotism due to
gangrenous, 1501–1502
nervous, 1469–1470
fluoride, 1499–1500
hairy vetch, 1495
hepatotoxins, 870
hoary alyssum, 1497
increased body temperature and disorders of, 233–234
iodine, 1497–1498
iron, 1504
hepatic, 870–871
jimsonweed, 1462
lasalocid, 1490–1491
lead, 1482–1484
leukoencephalomalacia, 1481–1482
levamisole, 1475
locoweed, 1469
maple, 1485–1486
menadione sodium bisulfite, 1507
mercury, 1507–1508
metaldehyde, 1474–1475
methiocarb, 1475
milkvetch, 1480
milkweed, 1479
monensin, 1489–1490
mushroom, 1503
mycotoxins, 871
nicotine, 1476–1477
nightshade, 1461–1462
nitrates and nitrites, 1491–1492
nonprotein nitrogen substances, 1477–1478
oak, 1460–1461
Toxins *(Continued)*
oleander, 1484
onion, 1486
organophosphates, 1472–1473
oxalates, 1506, 1506b
pentachlorophenol, 1464–1465
pesticides, 1471–1476
petroleum distillates, 1464
phosphorus, 1467–1468
photosensitizing plants, 1495–1496, 1495b
pokeweed, 1461
propylene glycol, 1480
pyriminil, 1465–1466
from pyrrolizidine alkaloid-containing plants, 874–875, 874f, 874t
pyrrolizidine alkaloids, 1502–1503
rayless goldenrod, 1484–1485
red clover, 1503
Russian knapweed, 1479–1480
salinomycin, 1491
selenium, 1500–1501
slaframine, 1464
snake venom, 1498–1499
sodium fluoroacetate, 1493
sorghum, 1506–1507
strychnine, 1474
tall fescue, 1496–1497
in tetanus, 668–669
tetrachlorodibenzodioxin, 1466
thallium, 1468
timber milkvetch, 1480
trichothecenes, 1482
triclopyr, 1480–1481
urea, 1477–1478
vitamins D_2 and D_3, 1507
white snakeroot, 1484–1485
wild jasmine, 1494
yellow starthistle, 1479–1480
yew, 1486
zinc, 1500
Tracheobronchial aspiration, 318
Tracheostomy, 169–170, 170b
Tramadol
for hemostatic dysfunction, 1004–1005
for pain management, 148
Tranexamic acid, for hemostatic dysfunction, 1004–1005
Tranquilizers, for recurrent exertional rhabdomyolysis, 553
Transabdominal ballottement, 709
Transcutaneous (abdominal) ultrasound-guided fetal puncture, 1278
Transfer
of equine embryo, 1267–1268
gamete intrafallopian, 1313
oocyte, 1310–1312
success of, 1312
Transforming growth factor-β (TGF-β), 773
Transfusion
medicine, for hematopoietic disorders, 1002–1004
reactions, 1165t–1167t
whole blood, 167
Transient hypogammaglobulinemia, 55
Transient tachypnea, 1392
Transition state, 1089
Translocation, of endotoxins, 725
Transport, in poor performance, 289–290
Transrectal palpation, 710
in mare breeding soundness examination, 1227–1228, 1228t
in uterine torsion, 1291
Transtracheal wash (TTW), 316–318
Transvaginal ultrasound-guided twin reduction, 1277
Transverse presentation, 1303
TRAP. *see* Tartrate-resistant acid phosphatase
Trauma
cardiac, sudden cardiovascular death and, 399b
cervical, 1241
in foals, 1384
focal or generalized, sporadic exertional rhabdomyolysis and, 549
vaginal, during breeding, 1240
Traumatic brain injury, 611–618
neurologic evaluation of, 613–616, 614f–615f, 615t
pathophysiology of, 611–613, 612f
spinal cord and vertebral injury, 618–622, 618t
treatment and prognosis in, 616–618, 616f
verminous encephalomyelitis, 682–685, 684t
vestibular disease and, 622–628
Traumatic optic neuropathy, 1155
Trefoil peptides, 766–767, 773
Tremetone, rhabdomyolysis from, 568
Tremors
in cerebellar disease, 630
neurologic examination of, 583
Triangular ligaments, of liver, 843
Trichlorfon, for cutaneous habronemiasis, 1186
Trichophyton species, 1177
Trichorrhexis nodosa, 1169
Trichothecenes, 1482
Tricide, for endometritis, 1255t
Triclopyr, 1480–1481
Tricuspid atresia, 471
Tricuspid valve, 390
auscultation of, 402f, 403
echocardiographic and Doppler studies of, 441b–443b
infective endocarditis, 481–484, 482f–483f
regurgitation, 479–480, 480f
causes of, 401t–402t
Trifolium hybridum, 1503
Trifolium pratense, 1503
Trigeminal nerve
neurologic examination of, 584
paralysis, 624
Trigeminal-mediated headshaking, 680–682, 680t–681t
Triglyceride, hepatic insufficiency and, 857t
Triheptanoin, polysaccharide storage myopathy and, 559
Trilostane, 1078
Trimethoprim, for endometritis, 1254t
Trimethoprim sulfa, for dermatophilosis, 1174
Trimethoprim (TMP), 110, 111t
Trimethoprim-sulfamethoxazole
critically ill horse and, 186
for equine herpesvirus-1 myeloencephalopathy, 650
Trimethoprim-sulfonamide, for pleuropneumonia, 350t
Trocarization, 172, 172b, 173f
Trochlear nerve, 622
Trombiculiasis, 1183
Trot
gait evaluation during, 585
normal, 586
Truncus arteriosus, 470–471
Trypanosoma equiperdum, 1340
Tubuloglomerular feedback, in acute renal failure, 925
Tumor necrosis factor
antibodies directed against, 737
in endotoxemia, 726–727, 727t–728t
Tumor necrosis factor alpha (TNF-α), in fever, 235
Turbid CSF, 590
Twins
abortion of, 1284
management of, 1275–1278
Two-dimensional (2D) echocardiography, 420–440, 444f, 448f
in aortic regurgitation, 477
in atrial fibrillation, 507, 508f
cardiac output and, 453
in infective endocarditis, 483f
in pericardial disease, 484f
in tricuspid regurgitation, 480f
in ventricular function, 396
in ventricular septal defects, 467
TXA_2, in inflammatory response, 22
Tylosin, 114
Tympany, guttural pouch, 325
Tyrosine, 1161–1167
Tyzzer's disease, 868, 1417

U

Ulceration
corneal, 1144
antibiotics for, 1146
anticollagenases for, 1146–1147
antifungals for, 1146
complicated, 1144–1146
descemetocele and, 1144f
fungal keratitis and, 1145f–1146f
laceration and, 1144f–1145f
melting, 1145f
nonhealing, 1144
subpalpebral lavage catheters for, 1147–1148
systemic NSAIDs for, 1147
uncomplicated, 1144
decubital, 1197

Ulceration *(Continued)*
gastroduodenal, 803–806
diagnosis of, 806, 806t
neonatal, 805
pathophysiology of, 803–804, 804f
prevalence of, 803
risk factors of, 804–805
treatment of, 806–808
Ulcerative lymphangitis, 1174
Ultrapurified polymerized bovine hemoglobin, 1426
Ultrasonography
for aortoiliac thrombosis, 494f, 496
body temperature and, 237
for cardiovascular disorders, 420
for cholelithiasis, 877, 877f
for disorders of the gastrointestinal system, 713
for gastrointestinal disorders, 1401

  for foals, 1422t
Vallate papillae, 790
Valvular heart disease, 390–391, 391f, 471–484, 472f
  aortic regurgitation, 476–479, 476f, 478f–479f
  infective endocarditis, 481–484, 482f–483f
  mitral regurgitation, 472–476, 473f
  pulmonary regurgitation, 481, 481f
  tricuspid regurgitation, 479–480, 480f
Valvular regurgitation, 450–451
  aortic, 476–479, 476f, 478f–479f
    auscultation of, 402f
  causes of, 401t–402t
  mitral, 472–476, 473f
  pulmonary, 481, 481f
  tricuspid, 479–480, 480f
VAMP. *see* Vesicle-associated membrane protein
Vancomycin, auditory system and, 627
Varicose veins, vaginal, 1240
Vascular cell adhesion molecules, 717–718
Vascular endothelium, 260
Vascular pattern, radiographic, 320–322
Vascular permeability, changes in, 262
Vascular system
  disorders of
    anatomic correlates of, 387–392, 388b–389b, 390f–391f
    aortocardiac and aortopulmonary fistula, 493f, 496–497
    aortoiliac thrombosis, 493f–494f, 495–496
    arteriovenous fistulas, 496
    parasitic vascular lesions, 494f, 496
    poor performance and, 399b
    pulmonary artery rupture, 497
    thrombophlebitis, 482, 492f, 493–495
  peripheral, examination of, 409–411
Vascular tumors, 1019–1020
Vasculitis, 1011
  cutaneous, systemic manifestations of, 1165t–1167t
  edema and, 262
  equine herpesvirus-1 myeloencephalopathy and, 650
  immune-mediated, 1196–1197, 1196f
  leukocytoclastic, 1201–1202, 1202f
Vasoactive drugs, in critical care, 174
Vasoactive intestinal peptide, colitis and, 722t
Vasodilators
  for congestive heart failure, 462
  for heart disease, 457t–461t
Vasopressin
  for acute renal failure, 925
  in critical care, 175
  for diabetes insipidus, 965
  for foals, 1430
Vasopressors, in critical care, 174–175
V(D)J recombination, 52
Vedaprofen, 126
VEE. *see* Venezuelan equine encephalomyelitis
Vegetable oils, 201, 204
Veins
  cutaneous, examination of, 410
  echocardiographic and Doppler studies of, 441b–443b
  varicose, vaginal, 1240
Venezuelan equine encephalomyelitis (VEE), 655, 656t
Venom, snake, 1498–1499
Venomous bites and stings, 1189
Venous blood gas, monitoring of, in critical care, 177
Ventilation
  control of, 251–253, 252f
  effectors of, 253
Ventilation-perfusion (V-Q) mismatch, 254–255
Ventilator-induced lung injury (VILI), in foals, 1399–1400
Ventipulmin, for interstitial pulmonary disease, 352–353
Ventral body wall hernias, 1290–1291
Ventral edema
  in infective endocarditis, 483f
  in lymphoma, 370
Ventral sacculation, uterine, 1232
Ventricles, 390f
  arrhythmias of, 510f–511f, 512
    premature complexes, 512–513
    tachycardia, 512f, 513–514
  cardiac cycle and, 392–395
  echocardiographic and Doppler studies of, 441b–443b
  function of, 395–397, 395b
Ventricular hypertrophy, 469–470
Ventricular septal defects, 463f, 465–468, 465f–467f
  echocardiography in, 466f, 467
  paramembranous, 402f
  pathophysiology of, 466
  pulmonary atresia with, 470–471, 470f
  thoracic radiography in, 419f
Ventricular septum, 463
  echocardiographic and Doppler studies of, 441b–443b
Ventricular synergy, 396
Verapamil, 457t–461t
Verminous encephalomyelitis, 682–685, 684t
Vermis, 628
Vernal transition, 1222
  hormonal manipulation of, 1258–1259
Verrucous sarcoids, 1202, 1204f
Vertebral injury, 618–622, 618t
Very-low-density lipoproteins, 847
Vesicle-associated membrane protein (VAMP), 668–669
Vesicoureteral reflux, 947–948
Vesicovaginal reflux. *see* Urovagina
Vesicular sounds, in respiratory tract examination, 316
Vesicular stomatitis, 1176–1177, 1176f
Vestibular system, 622–623
  disease of, 622–628
    brainstem auditory evoked response in, 628
    caloric testing in, 628
    central vestibular disease, 627–628
    clinical signs of, 623–625, 623f–624f
    peripheral vestibular disease, 625–627
  neurologic examination of, 580–582
Vestibule, 1219, 1220f–1221f
Vestibulocochlear nerve
  neurologic examination of, 583
  temporohyoid osteoarthropathy and, 625
VetMed Resource, 220
VetSRev, 221
Vicia villosa, 1495
Videoendoscopic examination, of upper respiratory tract, 317
Vincristine, 627
Vinegar, for endometritis, 1255, 1255t
Viral agents, of rhinitis, 323
Viral encephalitis, 654–659, 655t
Viral hepatitis, 869
Viral infections
  abortion and, 1282–1283
  cutaneous, 1175–1177
  immunologic avoidance, 14
  in neonatal foals, 1393
  papillomatosis, 1175–1176
  pathogenesis of, 8–14, 10f–12f
  pathology of, 12
  spread of, 10–11
  virulence of, 10–11
  virus life cycle and, 9, 12f
Viral products, for immunostimulation, 61–62
Viral-associated myopathies, 563
Virologic latency, 10
Virulence
  bacterial infection and, 5–6
  fungal infection and, 7–8
  viral infection and, 10–11
Visceral pain, 138
Vital HN, 204
Vitamin D
  actions of, 1037f, 1039
  in calcium and phosphate homeostasis, 1037–1038
  metabolism of, 1038–1039
Vitamin D_2 toxicity, 1507
Vitamin D_3 toxicity, 1507
Vitamin E
  deficiency of
    in dilated cardiomyopathy, 491
    in equine degenerative myeloencephalopathy, 637–638
    nutritional myodegeneration and, 561
  deficient myopathy, 562–563
    clinical signs of, 563, 563f, 563b
    diagnosis of, 563
    pathogenesis of, 562–563
    treatment of, 563
  in musculoskeletal system disorders, 546
  for nutritional myodegeneration, 1420, 1419–1420
  for pregnant mare, 1367
  sporadic exertional rhabdomyolysis and, 549
  supplementation of
    in equine degenerative myeloencephalopathy, 639–640
    in equine motor neuron disease, 667
Vitamin K, 1000
  deficiency, 1000
    bleeding, in neonatal foals, 1014
Vitamin K_3 toxicity, 1507
Vitiligo, of Arabian horses, 1168, 1168f

Volatile fatty acids (VFAs), 278
Volume of distribution (Vd)
  clinical use of different values, 83, 83b
  conditions that affect, 83–84
  of drug, 82, 82f–83f
Volutrauma, in foals, 1399–1400
Volvulus
  large colon, 781–783
  small intestinal, 780
Von Willebrand's disease, 1013–1014
Voriconazole, for fungal pneumonia, 356t
Vulva, 1219, 1222f
  hematomas of, postpartum, 1310
  pathology of, 1238–1239
Vulvoplasty, Caslick, 1239

Zona fasciculata, 1071
Zona glomerulosa, 1071

See detailed videos of diseases and procedures you read about!

More than 130 video clips on the **companion website** bring to life the symptoms and treatment of diseases covered in the text. These clips demonstrate problems and procedures related to the cardiovascular and neurologic systems for greater comprehension.

The Companion Website includes:

- **Video clips of different procedures** relating what you read to real-life examples of diseases and their treatment.
- **Audio-visual demonstrations** that familiarize you with all aspects of carrying out procedures.

Start using the website now!
