BoNT intoxication results in diffuse, symmetric, flaccid paralysis and loss of muscle strength. Although there are some suggestions that there may be subtle differences in clinical signs depending on the BoNT involved, this remains unconfirmed in the horse, and the clinical signs of botulism in horses are similar, regardless of the type or source of BoNT.[758,761] The speed of progression of disease is variable, resulting in peracute, acute, and chronic forms of botulism. Some cases may present as sudden deaths. Depending on the amount of ingested toxin, initial signs may be subtle or overt. Generally, the clinical signs appear from 24 hours up to 17 days after exposure.[755] The incubation period may be associated with inoculum size, which suggests that the shorter the incubation, the more severe the disease. The disease usually affects motor nerves with high efferent traffic, resulting in weakness, dysphagia, and poor muscle tone. Usually generalized weakness, dysphagia, or both are the first clinical signs detected by observant horse owners. Early in some cases the owners will note prolongation of the time the horse takes to eat its grain, or they will note abdominal discomfort and colic. Some horses may have decreased salivation and occasionally urinary retention resulting from involvement of the cholinergic autonomic nervous system. Over time affected horses demonstrate muscle fasciculations, often first in the triceps region, that eventually progress to the entire body and result in recumbency. At first the horse appears to gain strength after lying down for a short time and may return to standing spontaneously or with coaxing. Eventually the horse is unable to rise. Death often results from respiratory failure. In foals, clinical signs are similar, although frequently foals are presented for excessive recumbency ad muscle fasciculations. Foals are typically bright and alert when they are lying down, but when they stand will develop fine muscle fasciculations that progress to severe muscle trembling, hence the term "shaker foal syndrome," before the foal stumbles and falls down. Foals are too weak to lie down in a normal fashion, yet they fall down. Similar to adult horses, foals regain strength after lying down until they are too weak and unable to rise anymore.

Clinical evaluation should include careful examination of cranial nerve and spinal cord function. Special attention should be paid to the palpebral and pupillary light responses, tongue tone, ability to prehend, and evidence of dysphagia, tail tone, gait and posture, and assessment of vital parameters and respiratory pattern. Vital signs are typically normal in the early stages, but heart rate and respiratory rate increase once the horse is recumbent, depending on the amount of struggling that occurs. Affected horses appear to maintain coordination and therefore appear weak but not ataxic. A low head and neck carriage and inability to lift the head can be seen and initially were thought to be more prevalent in BoNT/C botulism[770] but recently have been shown to occur in cases with BoNT/A botulism as well.[771,772] Occasionally these horses develop severe edema of the head and airways and then inspiratory stridor.

Mydriasis and ptosis are observed early in the disease process, as well as a sluggish pupillary light response. Reduced tongue tone and slow tongue retraction are characteristic early signs of botulism that typically occur before the onset of obvious muscle weakness. However, there are some cases of botulism that do not demonstrate clear dysphagia. Tail tone is frequently decreased in horses with botulism, but this can be difficult to assess given the wide variation in normal tail tone among horses. Profound tail tone reduction is frequently reported in advanced botulism.

The time to ingest a small quantity (usually a cup) of grain can be useful as a predictor of whether the horse has botulism. A botulism grain test has been described in which the suspect horse is offered 8 ounces of sweet feed in a large flat feeding tub on the floor, and the horse's ability to consume the feed is timed.[757] Most normal horses will consume an 8-ounce cup of sweet feed in less than 2 minutes and many horses faster than that. As the ability to retract the tongue diminishes, the time for the horse to eat the grain becomes longer. Also, grain mixed with saliva often falls out of the mouth through the horse's lips while eating. This is highly characteristic of botulism and is one of the earliest clinical signs.

Differential Diagnosis

The differential diagnosis for horses affected with botulism can be any cause of weakness and dysphagia in horses and should include EPM; EMND; EHV-1 myeloencephalopathy; WNV; rabies; several toxins such as lead, ionophore drugs, yew, and yellow star thistle; low blood calcium; and hyperkalemic periodic paralysis.[757] One also should consider less common clinical diseases such as tick paralysis, vascular accident, or even unusual examples of exercise intolerance.

Diagnosis

The diagnosis of botulism is difficult and frequently is based on compatible clinical signs of acute onset of flaccid paralysis, weak or poor eyelid tone, poor tail tone, slow or difficult eating, and dysphagia, as well as a compatible history of possible exposure to toxin. Clinical pathology results are mostly within normal limits. Some of the abnormalities seen may be reflective of dehydration, there may be elevated muscle enzymes detected in recumbent horses, and in the case of wound botulism there may be results consistent with infection. CSF evaluation is normal. Electrodiagnostic testing, specifically performing repetitive nerve stimulation, can demonstrate facilitation characterized by incremental

responses in both amplitude and area under the curve at a high stimulus rate.[37]

Laboratory support for a diagnosis of botulism requires at least one of the following: (1) detection of BoNT in serum, gastrointestinal contents, or from a wound; (2) detection of BoNT and/or BoNT-producing clostridial spores in the feed and/or gastrointestinal contents in addition to compatible clinical signs; or (3) detection of an antibody response in a convalescent patient.[757] BoNT is stable in frozen tissues or plasma and can be stored at −20°C for several weeks. The current gold standard test for botulism is the mouse bioassay.[755,759] This test involves the inoculation of mice with a sample from the suspect horse and subsequent observation of the mice for development of clinical signs of botulism. Because the horse is extremely susceptible to BoNT the circulating concentration in an affected horse is often below the threshold for detection by the mouse bioassay.[757] The mouse bioassay was recently reviewed and shown to have low sensitivity in adult horses (32%) and foals (53%) but high specificity (97% in adults and 100% in foals).[759] These results indicate that a positive result is highly suggestive of botulism but that negative results do not exclude the diagnosis. A higher sensitivity can be obtained by culture enrichment of the sample, which takes advantage of the presence of BoNT-producing clostridial spores that are not present in unaffected humans or animals.[758,759] The low sensitivity of the mouse bioassay is consistent with previous reports in horses that show that preformed BoNT is only found in approximately 20% of cases using this test.[757,760]

Quantitative real-time PCR assays for BoNT genes have been developed and validated and shown to have higher sensitivity with similar specificity as the mouse bioassay.[773,774] Other advantages of the qPCR test are that results are available much quicker (4 days vs. 2–3 weeks for culture-enriched mouse bioassay) and reduction of the live-animal use. The mouse bioassay would still be required to confirm gene expression by detection of BoNT in qPCR-positive samples.[773,774] Although ELISA tests have been developed these have not been shown to be superior to the mouse bioassay and have not been validated in the horse.[757] It is also possible to determine antibody titers in unvaccinated horses that have survived botulism. Despite the relatively low probability of confirming botulism through laboratory tests, testing remains an important component in managing botulism cases, first to identify the BoNT type, which may have important implications for treatment and prevention strategies and will provide information on epidemiologic characteristics, and second, if new botulism syndromes or toxin types were discovered, their full description would require as much testing data as we can provide.

Treatment and Prevention

Treatment of horses with botulism is expensive, time consuming, and often unrewarding. The first therapeutic objective is prompt administration of specific or multivalent antitoxin to bind circulating BoNT. A single dose of antitoxin is considered to be sufficient (30,000 IU for a foal and 70,000 IU for an adult horse) because that should provide passive protection for more than 60 days.[757,758] Antitoxin is not effective after BoNT has translocated into the cells; the earlier in the course of the disease the antitoxin is administered, the better. The horse should be confined to a stall, and physical activity should be kept to a minimum, if necessary with the use of sedatives. Antimicrobial therapy may be used to treat botulism or specific secondary complications. However, antimicrobials can potentiate neuromuscular blockage (aminoglycosides, tetracyclines, and procaine penicillin) and should be avoided. Mineral oil or other cathartics may be indicated to reduce impaction colic. Additional therapy includes appropriate nursing and supportive care. Of particular importance are maintaining the horse's hydration status and providing nutrient support through tube feeding in dysphagic animals. In severely affected foals or adults with respiratory failure, mechanical ventilation is indicated.

Prognosis for horses with untreated botulism is poor. In outbreak situations survival is typically reported at only 10% to 30%.[760,761,765,770] A recent review of 92 cases of botulism in adult horses showed that overall survival was 48%. Survival was significantly better for horses that arrived standing (67%) and even higher (95%) for horses that remained able to stand throughout hospitalization.[760] Treatment with antitoxin increased the odds of survival significantly, with treated patients being four times more likely to survive. Horses with abnormal respiratory effort or inability to stand had decreased odds of survival. Horses that lose the ability to stand have a poor chance of survival. Unfortunately there are horses that despite receiving antitoxin deteriorate over up to 5 days, likely due to the fact that the antitoxin binds only unbound BoNT and not the toxins already bound to the motor end plates. Horses in which treatment is initiated after they are recumbent only have a 13% chance of survival. Early diagnosis and treatment are critical for horses with botulism. Development of complications such as decubital ulcers, corneal ulcerations, muscle disease, pneumonia, and gastrointestinal disease during hospitalization for botulism is common but does not affect overall survival.[760] In horses that do survive, recovery is complete, but it can take months for the horse to regain full strength.

In foals, survival can be high with appropriate treatment. A review of 30 foals that were less than 6 months of age showed a survival of treated cases of greater than 96%. All foals, except one mildly affected one, received botulism antitoxin. Approximately 50% of the cases required oxygen therapy, and 30% required mechanical ventilation. Mean duration of hospitalization was 14 days.[767] It is possible that foals affected with BoNT/A may require longer term care and have slower recoveries than foals affected with other BoNTs.[772] Mechanical ventilation is an important aspect of treatment of botulism in human infants and, although this is not commonly performed in adult horses with botulism, it is a strategy that can be successfully used to reduce death from respiratory failure in foals. A study of nine foals with toxicoinfectious botulism employed mechanical ventilation early on in the course of hospitalization in foals that were progressively acidemic and had increased $Paco_2$ tensions. Arterial blood gas abnormalities were ameliorated with mechanical ventilation, and survival in treated foals was 87.5%.[775]

Type B botulism is preventable by vaccination using type B toxoid, which was initially developed to prevent disease in newborn foals. The current USDA-approved available product is a killed (toxoid) vaccine directed against *C. botulinum* type B. The AAEP recommends a vaccination schedule that includes an initial three-dose series at 1-month intervals followed by an annual booster. For brood mares they recommend administering the annual booster 4 to 6 weeks before foaling. Interestingly, a recent large study evaluating 92 cases of botulism showed that two horses with botulism were reportedly fully vaccinated. Both

of these horses had mild clinical signs and both survived. These were the first two horses reported in the literature to develop botulism despite an adequate vaccination history, of which one was confirmed positive for BoNT/B spores on mouse bioassay, representing a true vaccine failure.[760]

Additional preventive measures involve (1) providing safe and high-quality feed; (2) properly storing animal feed; (3) inspecting water sources for dying of dead small animals and birds; (4) avoiding spreading poultry litter that contains birds or dead animals on pastures; and (5) avoiding use of poultry litter as bedding material. Whenever more than one horse on a premise demonstrates clinical signs compatible with botulism, quick analysis of the entire ration and the feeding methodology to determine whether contamination has occurred is recommended. This aggressive approach may prevent additional horses or other animals on the farm from becoming infected. Beginning the investigation with the feed is always best, because this is the most common source of toxin. Conditions may be optimal for proliferation of botulism spores and toxin production in improperly prepared hay or hay stored in plastic bags.

EQUINE GRASS SICKNESS (EQUINE DYSAUTONOMIA)

Yvette S. Nout-Lomas

Equine grass sickness (EGS) is an acquired degenerative polyneuropathy that predominantly affects the neurons of the autonomic and enteric nervous system. As the name implies there is a strong association between EGS and grazing. The disease was recognized first in Scotland in 1909.[776] Since then it has been reported in other parts of England, continental Europe, the Falkland Islands, and Australia. Although there had been an earlier credible, but unpublished, report of EGS from the United States (Missouri),[777] the disease was not confirmed until 2010, when it was diagnosed based on clinical and pathologic findings in a mule in Kansas.[778] A clinically and histopathologically similar disease, mal seco, has been described in South America, predominantly in Chile. Britain has remained the country most affected by EGS, and a nationwide surveillance scheme has been instituted.[779]

The disease predominantly affects the prevertebral and paravertebral ganglia of the autonomic nervous system and enteric neurons (myenteric and submucosal plexuses) and is therefore characterized as a dysautonomia; however, given the fact that neuronal degeneration has also been identified in the brain and spinal cord of horses with EGS, the disease is likely better termed a *multisystem neuropathy.*[780] Clinical signs vary, and the severity is likely related to the extent of degenerative neuronal damage. The disease occurs sporadically and is often fatal. Although EGS has been studied extensively, the cause of the disease remains unknown.

Epidemiology

EGS has been reported in other equids such as the Przewalski's Horse, zebra, donkey, mule, and pony, but it occurs primarily in young, mature horses that have access to pasture. Horses with EGS are generally young adults between 2 and 7 years of age.[780] No gender predilection is apparent, but a study in Scotland found that there may be an increased susceptibility to EGS in native Scottish breeds.[781]

There is a strong association between EGS and grazing. Numerous epidemiologic studies have been performed over the years, and besides grazing, other consistently reported risk factors for development of the disease are age, recent movement to new pasture or premises, and time of year, with most cases occurring in spring and early summer.[780,782,783] Other factors that appear to increase the risk for disease, or recurrence thereof, include previous occurrence of cases on the premises, recent prior movement to a new premises (within the previous 2 weeks), increased stock density, and cooler drier weather and irregular ground frosts. Also, loam and sandy soils are associated with an increased risk of EGS, and abundance of *Ranunculus* species and higher herbage iron, lead, arsenic, and chromium concentrations, as well as increased soil nitrogen and high titatium/low zinc and high titanium/low chromium concentrations have been found in EGS pastures.[780,784] Although a previous occurrence of EGS on the premises is associated with an increased risk of diagnosing EGS on that premises again, previous contact and/or cograzing with a previous case of EGS appears to decrease the risk of EGS in horses. Also, chalk soil reduced recurrence of EGS. Interestingly, an increased risk of EGS is seen in horses with low serum antibody titers to BoNT/C and to surface antigens of BoNT/C-producing clostridia and *C. novyi* Type A,[785] and horses with higher titers to BoNT/C and BoNT/C-producing clostridia had reduced risk of developing EGS.[786]

Clinical Signs

Acute, subacute, and chronic forms of EGS are recognized, of which clinical signs are correlated with extent of neuronal damage and overlap from one form to the other.[780,787,788] Clinical signs are reflective of dysfunction of the autonomic nervous system, including the enteric nervous system, together with somatic dysfunction. Most horses are depressed, anorexic, dysphagic, and tachycardic. The dysphagia is likely caused by cranial nerve dysfunction and possibly esophageal dysfunction and is recognized by drooling of saliva, feed material in the nares, impacted feed material in the buccal pouches, and difficulty drinking. The drooling of saliva seen in EGS may also be caused by excessive salivation, which has been reported in some forms of human dysautonomia. Contributors to the tachycardia include increased adrenaline and noradrenaline and removal of vagal inhibitory input. Ptosis, sweating, and muscle fasciculations can also be present in all forms of EGS.

Acute Form

Clinical signs are related to acute onset of gastrointestinal ileus. The course of disease is generally less than 48 hours. Signs of abdominal pain are mild to moderate and are caused by gastric and small intestinal distention. Typically these cases produce large quantities of nasogastric reflux. Affected horses are hypovolemic, and the reduced circulating volume may cause death from cardiac failure. Considering the degree of gastrointestinal distention, the severity of abdominal pain is usually less than would be expected. Examination per rectum reveals small intestinal distention and often a mild secondary impaction of the large colon.

Subacute Form

The course of disease is 3 to 7 days, and clinical signs are similar but less severe than in acute EGS. Horses with subacute EGS do not develop gastric or small intestinal distention, and

nasogastric reflux is usually absent. Horses with subacute EGS often have large colon or cecal impactions.

Chronic Form

The course of the disease is weeks to months. Cachexia, with the development of a "tucked up" appearance, is the most prominent clinical abnormality in horses with chronic EGS. In addition, horses will develop evidence of progressive myasthenia, demonstrated by a base-narrow stance, leaning back against walls and weight shifting of the limbs. Unlike in botulism and equine lower motor neuron disease where horses spend more time recumbent, this is not the case in horses with EGS. Furthermore, in EGS muscle fasciculations are also present when animals are lying down, which is typically not the case in botulism or equine lower motor neuron disease. Development of rhinitis sicca is characteristic of chronic EGS and is thought to be caused by loss of innervation of the nasal mucosa. The entire gastrointestinal tract is empty in these horses, and they usually have dry mucus-covered feces in the rectum; the latter is a finding commonly seen in all three forms of EGS. Other clinical signs in animals with chronic EGS are gait abnormalities (short strided), snoring, pica, and penile prolapse. In a later stage, one may observe coat abnormalities such as areas of piloerection, growth of a long coat, and pallor of the coat.

Pathologic Findings

Gross necropsy findings are usually reflective of gastrointestinal dysfunction that was present antemortem.[789] Gross necropsy findings in acute EGS are consistent with gastrointestinal ileus. A large fluid-filled stomach and distended small intestine are present. Secondary impacted ingesta is often present in the large colon and cecum. Splenomegaly and erosions of the esophageal mucosa are other findings in acute EGS. Gross necropsy findings in subacute EGS are less severe and include colonic impaction. One may find inspissated mucus in the lumen of the small colon and rectum and evidence of intraluminal hemorrhage such as inspissated blood or black feces. In horses with subacute and chronic EGS, one may find rhinitis sicca.

Neuronal lesions are most severe in the autonomic ganglia (cranial cervical, stellate, celiacomesenteric) and enteric nerves. Lesions are also found in brainstem nuclei and the somatic efferent lower motor neurons of the spinal cord.[787-789] Specific histopathologic findings characteristic of neuronal degeneration include chromatolysis, loss of Nissl's substance, eccentricity or pyknosis of the nuclei, neuronal swelling and vacuolization, accumulation of intracytoplasmic eosinophilic spheroids, and axonal dystrophy. Although the locations of neuropathologic lesions found in EGS are very similar to those found in dysautonomias of other species, including finding lesions in brainstem nuclei and spinal cord, this latter fact gives rise to the question of whether EGS is a true dysautonomia or a multifocal neurologic disease.[780] This similarity in anatomic distribution of neuropathologic changes in EGS supports the hypothesis of a common factor sensitizing the neurons to specific insults. The insult in EGS appears to be specific and repeatable, consistent with findings in primary dysautonomias in other species.

The extent of lesions of the enteric nervous system largely determines the severity of disease, with most severe lesions seen in acute EGS. Specific lesions include neuronal loss in both the submucosal and myenteric plexuses throughout the gastrointestinal tract and reduction of interstitial cells of Cajal in the myenteric plexus regions of the gastrointestinal tract. Neuropathologic lesions within the autonomic nervous system have been reported at the ciliary ganglion, cranial cervical ganglion, caudal cervical ganglion, stellate ganglion, thoracic and abdominal sympathetic trunk, celiac/cranial mesenteric ganglion, caudal mesenteric ganglion, and parasympathetic terminal cardiac ganglion. Furthermore, CNS lesions have been identified in brainstem nuclei, spinal cord lower motor neurons, and spinal cord intermediolateral horn neurons.[780] The association between central neuronal pathologic findings and severity of clinical disease is unclear. In one study, increased neuronal pathologic findings were observed in milder clinical cases (chronic EGS), which contrasts to another study that demonstrated increased neuronal pathologic findings in acute cases of EGS.[790]

Pathogenesis

Clinical signs are related predominantly to dysfunction of the autonomic nervous system. The most severe lesions are found in the myenteric and submucosal plexuses of the ileum, and less severe changes occur in the celiacomesenteric ganglion. The altered autonomic activity results in cessation or decrease of intestinal peristalsis and subsequently leads to the development of ileus and colonic impaction. The dysphagia in most cases of EGS is caused by cranial nerve or brainstem involvement. Based on epidemiologic and pathologic findings in horses with EGS, an unidentified neurotoxin is implicated as the causative agent of the disease. Epidemiology supports the role of an ingested soil-borne agent capable, under certain conditions, of producing or liberating a putative neurotoxin. Some of the pathologic findings support retrograde axonal transport of the toxin from the gastrointestinal tract to the ganglia, whereas there are other studies that suggest that the widespread nature of the neuropathology in EGS is also consistent with more extensive distribution of the toxin, for example, via hematogenous dissemination.[780]

Multiple experimental studies over the past decades have failed to identify the causative agent or agents of EGS. Agents studied include alsike clover, *C. perfringens* enterotoxicity, insect vectors, and fungi. Toxicoinfection with BoNT/C-producing clostridia was proposed as an etiology for EGS in the 1920s,[776] and it has dominated recent research efforts as well.[780,786,791-795] The hypothesis is that a dietary trigger induces intestinal bacterial overgrowth and in vivo production of BoNT/C and/or BoNT/D. Despite the overwhelming evidence to support an association between BoNT-producing clostridia and EGS, there are a number of significant differences between the clinical and pathologic findings of botulism and EGS. Vaccine trials are under way in Britain and perhaps the results of those will provide answers about the involvement of BoNTs in the pathogenesis of EGS.[795,796] Given the differences between EGS and botulism, investigators are currently focusing investigative efforts on potential roles of other etiologic agents, for example, *Fusarium* spp. that are known to produce mycotoxins.[792,795]

Diagnosis

No noninvasive definitive test exists to obtain an antemortem diagnosis of EGS. A presumptive diagnosis is made based on the history, epidemiologic information, nature and progression of clinical signs, and elimination of other possible

diagnoses. Serum biochemical and hematologic examinations do not reveal specific changes in horses with EGS. Acute phase proteins and fibrinogen concentrations are significantly higher in horses with EGS compared to those with intestinal tract obstructions.[797] Other ancillary diagnostic tests that may be helpful include evaluation of esophageal motility by endoscopy or contrast imaging, electrodiagnostic testing, and the use of 0.5% phenylephrine applied to the cornea to confirm the presence of smooth muscle paralysis underlying the ptosis (ptosis should temporarily disappear).[798-800] A definite antemortem diagnosis can only be made following histopathologic examination of enteric ganglia.[787,801]

Because antemortem diagnosis requires collection of biopsies via exploratory laparotomy, often taken at the ileum, investigators have been evaluating alternative biopsy sites. Histopathologic examination of rectal biopsies was investigated as a less invasive and cost-prohibitive diagnostic tool; however, the sensitivity of this approach was disappointing.[802] Recently histopathologic examination of gustatory papillae via a lingual biopsy technique was evaluated in postmortem specimens of horses with EGS and was shown to have a sensitivity of 100% and a specificity of 98.2%.[803] This approach has the potential to offer a valuable and cost-effective means of antemortem disease confirmation but requires further prospective validation.

The most important differential diagnoses for acute EGS are a small intestinal strangulating lesion and duodenitis-proximal jejunitis. Clinical signs and neuronal lesions in chronic EMND and chronic EGS may be similar, and these similarities have led to the speculation that these two diseases are related. Further examination, however, reveals important differences such as the fact that EMND occurs in older horses that have not had access to pasture, and EGS occurs in young horses with access to pasture. EGS sometimes occurs along with EMND.[804]

Prognosis, Treatment, and Prevention

The case fatality rates for acute and subacute EGS are 100%. No effective cure exists. Horses with acute EGS may respond initially to gastric decompression, analgesic administration, and intravenous fluid therapy, and this supportive treatment can be provided until a more definitive diagnosis is achieved, at which point euthanasia should be recommended. The clinical signs that are generally associated with a grave prognosis include persistent gastric reflux or the presence of firm colonic impactions, both reflective of severe intestinal dysmotility resulting from extensive neuronal degeneration within the ENS and generally accepted as supporting a diagnosis of acute and subacute EGS, respectively.

Horses with chronic EGS often are euthanized because of weakness, inability to stand, and emaciation; however, when given appropriate care at a referral hospital, approximately 40% to 50% of horses may survive long term.[787,805] Nonsurvival is associated with severe rhinitis sicca and high subjective clinical scores based on the severity of dysphagia, anorexia, colic, and reduction in intestinal sounds.[806] More recently it was shown that rapidity and magnitude of body-weight loss were predictive of outcome, with nonsurvivors losing more weight than survivors.[807] The greatest obstacle for treatment of horses with chronic EGS is the profound anorexia that is often present. Providing palatable high-quality food is the cornerstone for treatment of chronic EGS. In addition, use of analgesics, antimicrobials, and providing light exercise may be indicated for selected cases. Unfortunately there has not been a clear benefit of using ancillary treatments such as appetite stimulants and prokinetics in the management of horses with chronic EGS.[780]

LYME DISEASE IN HORSES

Stephen M. Reed

Lyme disease is the most common vector-borne infectious disease in human beings in the United States. Initially recognized in the mid-1970s in Lyme, Connecticut, as the cause of unexplained rheumatoid arthritis in children, the causative agent of Lyme disease was discovered to be a spirochete, *Borrelia burgdorferi (sensu lato).* In addition to human beings, Lyme disease affects domestic animals such as dogs, cats, cattle, and horses.[808-814]

Human beings and animals acquire Lyme disease by transmission of *B. burgdorferi* through the bite of infected hard ticks (*Ixodes* spp.). In the Eastern and Midwestern United States the vector is the blacklegged tick or deer tick, *Ixodes scapularis* (formerly *I. dammini*), whereas in the Western United States the vector is the western blacklegged tick, *I. pacificus.* In Europe the sheep tick, *I. ricinus,* is the vector of Lyme borreliosis.

Not all ticks are infected with the spirochete, and infection varies by tick species and geographic region. These ticks have a 2-year, three-stage life cycle and feed once during each stage.[815,816] The larvae hatch in the spring and summer and are usually noninfective because transovarial transmission is rare.[817] The tick may become infected at any stage of the life cycle by feeding on small mammalian hosts, typically the white-footed mouse *(Peromyscus leucopus),* which is a natural host for the spirochete. The nymphal stage emerges the next spring and is most likely to transmit the disease because it is small, difficult to see, and engorges faster; engorgement is necessary to transmit *B. burgdorferi.* The white-tailed deer *(Odocoileus virginianus)* is the host for adult ticks. The life cycle of *I. ricinus* in Europe involves birds and mammals because immature stages feed on birds and reptiles. Nymphal *I. scapularis* are the main vectors of *B. burgdorferi* in human beings. These ticks are more active from May to July. Once the tick has engorged, *B. burgdorferi* is transmitted to the host via lymphatics or blood. Although larval and nymph stages are responsible for *B. burgdorferi* transmission to other mammals, the stage responsible for transmitting Lyme disease in horses is unknown.

Epidemiology

In endemic areas of the northeastern and midwestern United States, approximately 20% of nymphal stages and 30% to 40% of adult stages of *Ixodes scapularis* are infected with *Borrelia burgdorferi.* In contrast, *I. pacificus* often feeds on lizards that are poor reservoirs for *B. burgdorferi,* and only 1% to 3% of these ticks, including the nymphal stages, are infected with the spirochete.[817] This difference in the number of infected ticks might explain the difference in the prevalence of Lyme borreliosis between the eastern and western United States. Equine seroprevalence is high in the northeastern United States, but limited information is available for other parts of the country.[809,813] In Europe, clinical cases and equine serorologic surveys have documented Lyme borreliosis as a cause of equine disease in Poland, Germany, Scandinavia, and England.[812,818,819]

The apparent increasing incidence of disease in human beings and animals might result from an increased deer population, increased number of ixodid ticks, expansion of human and horse populations into previously rural woodland areas, or increased recognition of the disease manifestations.

The disease has a seasonal prevalence and is most common in spring, summer, and fall, with a peak incidence in June and July. In some climates such as California, ticks might be active throughout the year. The organism is maintained in a complex life cycle of small wild mammals and immature stages of the blacklegged tick. Larval and nymphal stages of the tick acquire the infection when they feed on infected mice. The white-tailed deer *(Odocoileus virginianus)* is not a reservoir for Lyme disease but rather the host for the adult stages of the tick. This is relevant to tick and Lyme disease control programs, because regional reductions in the number of *I. scapularis* has only been possible when the deer population has been decreased.[815]

Clinical Signs

Clinical signs associated with *Borrelia burgdorferi* in horses, as in human beings, are often nonspecific and involve multiple body systems. In human beings, clinical signs frequently include annular rash, erythema migrans, myalgia, aseptic meningitis, arthritis, and seventh cranial nerve palsy.[817] The disease usually begins as a skin rash and often progresses to involve joints and the nervous and cardiac systems but may involve other body systems as well. In human beings the skin rash may be slowly progressive and sometimes may take up to 1 month before becoming apparent.

In horses, reported clinical signs of Lyme borreliosis include chronic weight loss, sporadic lameness, laminitis, low-grade fever, swollen joints, muscle tenderness, anterior uveitis, encephalitis, and abortion.[810,811,820] Some horses might demonstrate clinical illness and obtundation and might go off feed in a short time. The bacteria might enter the CNS within a short time after exposure. Chronic arthritis might develop as a result of autoimmune mechanisms, although this is not fully understood. *Ixodid* spp. ticks are often coinfected with *Borrelia burgdorferi* and *Anaplasma phagocytophila;* however, dual infections remain to be documented in the horse. An important consideration is that limb swelling and response to tetracycline treatment, indicating Lyme borreliosis could be the result of *A. phagocytophila* infection. Infection with *Borrelia burgdorferi* is common but rarely results in neuroborreliosis. Neurologic signs could be variable. These signs might include behavioral changes, hyperesthesia, hyperreactivity, gait abnormalities, cranial nerve deficits, neck stiffness, muscle atrophy and muscle tremors or fasciculations.[821]

Diagnosis

The diagnosis of Lyme disease is often difficult. History of tick exposure or living in a Lyme disease–endemic area is helpful; when combined with the identification of clinical signs and the elimination of other diseases, this information allows the clinician to make a presumptive diagnosis. Examination of blood work for other diseases is important. In human beings an early increase in serum IgM often occurs. Response to therapy might help to support a presumptive diagnosis of Lyme disease, but it is not definitive. Diagnosis of Lyme disease in horses is difficult,[822] and in many cases one bases a presumptive diagnosis on history, clinical signs, and response to antibiotic therapy in an animal with probable cause to be infected (i.e., possible exposure). In human beings the skin lesions are obvious. Blood tests are of limited value; however, ELISA, kinetic ELISA, Western blot testing, and PCR on blood samples and synovial fluid from suspect animals have been evaluated.[809,812-814,822,823] One may test samples of joint fluid, CSF, and tissues from affected patients for the presence of organisms. Several pathologic conditions should be considered in the differential diagnosis of equine borreliosis, including *Anaplasma phagocytophila* infection, chronic diseases, vasculitis, and immune-mediated arthritis if limb or periarticular swelling is present, as well as causes of neurologic disease.

Neuroborreliosis is rarely diagnosed. CSF reveals neutrophilic or lymphocytic pleocytosis and increased total protein. Other tests include culture of the organism, immunohistochemistry, PCR of tissue samples and CSF, and others previously described. More recently a fluorescent bead–based multiplex assay (Multiplex) in serum and CSF has been developed for the diagnosis of borreliosis and neuroborreliosis.[824] Multiplex assay tests serum at a dilution of 1:400 whereas CSF is generally run undiluted. In serologic assays, a positive result indicates past or present infection (exposure) and not necessarily cause of clinical disease, and vaccination can also cause a positive result. Horses living in endemic areas are often seropositive. Development of an antibody ratio test to compare antibody concentration in blood to the concentration in CSF is being evaluated and may prove to be useful in the future (Amy Johnson, personal communication).

Pathogenesis

Borrelia burgdorferi organisms are capable of nonspecifically activating monocytes, macrophages, and synovial lining cells, as well as natural killer cells, B cells, and complement, leading to production of host proinflammatory mediators. These proinflammatory mediators seem to localize in joints, leading to chronic arthritis and lameness. *B. burgdorferi* has developed strategies to interact with the mammalian host, including adhesion to host cells and components of the extracellular matrix such as fibronectin, β_3 integrins, and glycosaminoglycans. The current thinking in the development of arthritis is that outer-surface proteins (Osps) of *B. burgdorferi* trigger an autoimmune reaction because antibodies to OspA and OspB have been detected in 50% to 80% of human patients with arthritis.[825,826] Natural killer cells also play a central role in joint inflammation by producing excessive amounts of TNF-α and IL-8.[825]

Treatment and Prevention

Recommended treatment includes oxytetracycline (6.6 mg/kg IV every 24 hours) or doxycycline (10 mg/kg PO every 12 hours).[827] Treatment can be started with tetracycline for 1 week followed with doxycycline for 3 to 4 weeks. Ceftiofur (2.2–4.4 mg/kg IV every 12 hours) has also been evaluated.[827] In animals infected with *B. burgdorferi,* a rapid clinical response (2–4 days) is expected with tetracyclines. In some horses the clinical signs might show an initial worsening as a response to toxins released after death of the organisms. Currently, no licensed vaccine is available to prevent Lyme disease in horses, although vaccines are available for dogs and human beings. A recombinant OspA vaccine was evaluated in horses with promising results.[828]

Aids to prevention include daily grooming with removal of ticks, along with the use of tick repellents that contain permethrin. One should apply tick repellents to the head, neck, legs, abdomen, and under the tail. Keeping pastures mowed and removing brush and woodpiles makes the environment

less hospitable for rodents, which in turn decreases the tick population. Regional programs to control Lyme disease are based on reducing the deer population.

TRIGEMINAL-MEDIATED HEADSHAKING

Monica Aleman

Idiopathic headshaking has been recognized for over 100 years.[829] The disorder is characterized by spontaneously occurring uncontrolled violent head shakes. One study showed that the maxillary branch of the trigeminal nerve, has a low threshold for firing, therefore even innocuous stimuli could trigger sensory activation and firing of this nerve, causing facial pain.[46] Therefore the authors of the study proposed calling this condition *trigeminal-mediated headshaking* to reflect more accurately the source of pain despite an uncertain etiology.[830] It is important to rule out other causes of headshaking (Table 11.18). Headshaking is a widely recognized disorder characterized by persistent or intermittent, spontaneous, and frequently repetitive vertical (most common), horizontal, or rotary movements of the head and neck.[831] The affected horse shakes, jerks, or flicks its head uncontrollably in the absence of obvious physical stimuli or apparently innocuous stimuli (i.e., light, wind, exercise), and the condition can be severe enough to render the horse unusable and dangerous.[832-836] Headshaking often is accompanied by snorting and sneezing, and many horses rub their noses on stationary objects or on the ground while moving. In addition to shaking the head up and down, flipping the upper lip, or shaking the head side to side, horses also might act as if a bee has flown up the nostril or might strike at the face with the thoracic limbs.[832,836,837] Headshaking horses also might exhibit avoidance behavior, with low head carriage, corner seeking, and nostril clamping.[831,838] To characterize the severity of clinical signs, a grading system of 1 to 5 has been described, with grade 1 being a rideable horse with intermittent and mild signs (facial muscle twitching) and grade 5 being an unrideable, uncontrollable, dangerous horse with bizarre behavior patterns.[831] Clinical signs are usually worse during exercise; however, headshaking can affect horses at rest.[831-835,837] Severely affected horses might inflict self-trauma and compromise welfare.[830] Mean age of onset is typically 7 to 9 years, and Thoroughbreds and geldings appear to be overrepresented in some studies.[832,833,836] Headshaking can be seasonal or nonseasonal. Early literature suggested an increased incidence of headshaking during the warmer months of the year,[834] and a later study indicated that the peak periods of onset were spring and early summer.[833] Studies have found that 64%[833] and 59%[832] of headshaking horses are affected seasonally, with the majority developing signs in the spring or early summer.

Pathogenesis

It is important to rule out other causes of headshaking before considering trigeminal-mediated headshaking (see Table 11.18).[839] Reported and suggested causes include behavioral resentment to rider-induced head and neck flexion, exercise-induced hypoxia, ear mites, cranial nerve dysfunction, otitis media or otitis interna, cervical injury, ocular disease, guttural pouch mycosis, dental periapical osteitis, vasomotor rhinitis, allergic rhinitis, *Trombicula autumnalis* (harvest mite) larval infestation, maxillary osteoma, and EPM.[833,835,839-844] A study of 100 headshaking horses revealed a potential specific cause in only 11 horses, and elimination of the abnormality resulted in resolution of the headshaking in only 2 of them.[833] Idiopathic headshaking has been used to describe the majority of cases in which no specific underlying cause is found, and necropsy results in these horses reveal no lesions.[845] Further, a study evaluated the possibility of herpesvirus infection as a potential cause of this disorder but found no association.[845] However, immune-mediated reaction or inflammation of the trigeminal ganglia can cause headshaking.

The clinical signs exhibited by most headshaking horses now generally are thought to result from sharp, electric-like, burning pain involving the trigeminal nerve.[831,832] Trigeminal nerve involvement is supported by the observations that some horses

Excessive head and neck flexion

improve after blocking the infraorbital nerve (part of the maxillary branch)[846,847] and that most horses improve after blocking the caudal nasal nerve, a branch of the maxillary nerve commonly referred to as the posterior ethmoidal nerve (branch of ophthalmic nerve). Horses that headshake in response to light stimulation have been described as *photic headshakers*.[838] Most of these horses are affected seasonally (spring and summer), improve at night or when brought indoors, and improve when blindfolded or when gray lenses are placed over their eyes. Photic headshaking is hypothesized to be caused by optic-trigeminal summation (stimulation of the optic nerve that results in referred sensation to parts of the nose innervated by the trigeminal nerve), a mechanism similar to that proposed for photic sneezing in human beings.[832,838] Many features of headshaking in the horse are similar to trigeminal neuralgia in human beings—a severe chronic pain syndrome characterized by dramatic, brief stabbing or electric shock–like pain paroxysms felt in one or more divisions of the trigeminal distribution, spontaneously or on gentle tactile stimulation of a trigger point on the face or oral cavity. The disease is associated with microvascular compression and pathologic changes in the trigeminal root and trigeminal ganglion.[848] The trigeminal nerve was postulated to be hypersensitive and to fire in response to a variety of trigger factors, including wind, airway turbulence, increased blood flow, pollen, dust, warmth, cold, insects, allergies, or other irritations. These trigger factors appear to act intranasally in many horses but could act in any trigeminal sensory region.[831] As previously mentioned, there is evidence that the trigeminal nerve has a low threshold for firing.[849]

Diagnosis and Treatment

One should perform a complete physical examination, including neurologic, dental, ophthalmic, and otoscopic examinations, to rule out potential underlying causes (see Table 11.18). Other diagnostics could include endoscopy of the nasal passages, pharynx, and guttural pouches; radiography of the skull and cervical spine; CBC; and serum biochemistry profile. For photic headshaking horses, clinical signs should improve after blindfolding or after placement of a mask shielding the eyes from the sun.

Treatment of trigeminal-mediated headshaking could be challenging as shown in a recent owner survey (Table 11.19).[830] Because the etiology of headshaking is unknown, current treatments are neither specific nor curative; therefore the majority of horses with headshaking are managed, rather than cured. Cyproheptadine, an antihistamine and serotonin antagonist with anticholinergic effects, has been used (0.3 mg/kg PO twice daily) to treat headshaking horses, resulting in improvement in 5 of 7 horses in one study[838] and 43 of 61 horses in another.[832] Horses that respond do so within 1 week, and some might respond within 24 hours. Cyproheptadine also works as a calcium channel blocker in addition to blocking serotonin-mediated pain as a proposed mechanism of action.[838] Cyproheptadine has also been used with carbamazepine (4–8 mg/kg PO q 6–8 h), resulting in 80% to 100% improvement in seven of nine cases, with horses responding within 3 to 4 days.[831] Carbamazepine is a sodium channel–blocking antiepileptic drug and is the drug of choice for treating trigeminal neuralgia in human beings.[850] Carbamazepine alone was reported to be effective in headshaking horses, but results were unpredictable.[831] The elimination half-life of carbamazepine in the horse is less than 2 hours, making sustaining therapeutic concentrations difficult; the drug is therefore of more benefit diagnostically than therapeutically in headshaking horses (D. C. Knottenbelt, personal communication). Other medications and therapies, including NSAIDs, corticosteroids, antihistamines, acupuncture, chiropractic manipulation, homeopathy, and feed supplements, are generally ineffective in most horses.[832,851] Pulse therapy with corticosteroids has not been effective to manage trigeminal-mediated headshaking.[852]

Because the disorder affects more geldings than females and intact males, a study investigated the role of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by using a gonadotropin-releasing hormone vaccine.[853] This vaccine significantly decreased FSH and LH levels but did not affect headshaking in horses.

Diagnostic blockade of trigeminal nerve branches can be useful for identifying trigger points in headshaking horses. Blockade of the infraorbital nerve might improve some horses and might identify candidates for infraorbital neurectomy.[846,847] However, results of infraorbital blockade and infraorbital neurectomy do not correlate, and infraorbital neurectomy is not a recommended procedure because of neuroma formation, self-trauma, risk of infection, low success rate, and recurrence of pain that might require a second surgery.[846] A high percentage of horses improve after blockade of branches of the maxillary nerve, and sclerosis of this nerve results in temporary improvement in some horses.[831] More recently, a study investigated the neuromodulation of the trigeminal nerve by using percutaneous electrical nerve stimulation under sedation. Horses tolerated well the procedure, which proved to be safe and

TABLE **11.19 Drugs Used for the Treatment of Trigeminal-Mediated Headshaking**

Drug	Dosage (mg/kg)	Route	Frequency
Carbamazepine	2–8	PO	q 6–12 hours
Clonidine	0.0025	PO	q 12 hours
Cyproheptadine	0.3	PO	q 12 hours
Fluphenazine	0.1	IM	q 1–4 months
Gabapentin	5	PO	q 8–12 hours
Hydroxyzine	0.6–0.8	PO	q 12 hours
Magnesium	20–40	PO	q 24 hours
Melatonin	0.03–0.04	PO	q 24 hours at 5 pm
Phenobarbital	3	PO	q 12 hours
Sodium chromoglycolate	1 drop	Ophthalmic	q 6 hours

minimally invasive and provided pain relief in the short to medium term (months).[854]

Therapies aimed at decreasing the response to trigger factors can be effective and include tinted contact lenses; face masks or hoods that block sunlight, wind, insects, and dust, with mesh or dark eye cups; and nose nets.[831,832,838,851,855,856] An owner survey found that nose nets that cover the nostrils with mesh and include a drawstring or elastic band that applies pressure to the upper lip resulted in some improvement in 70% of head-shaking horses and that 70% or more improvement occurred in about 30% of the horses.[855]

VERMINOUS ENCEPHALOMYELITIS

Aberrant migration of helminth and fly larvae through the CNS of horses and donkeys is a rare but important cause of severe neurologic disease. Parasites that have been reported to affect the brain and spinal cord of equids include rhabditid nematodes *(Halicephalobus gingivalis),* strongyloid nematodes *(Strongylus vulgaris, S. equinus,* and *Angiostrongylus cantonensis),* protostrongyloid nematodes *(Parelaphostrongylus tenuis),* spiruroid nematodes *(Draschia megastoma),* filarid nematodes (*Setaria digitata* and other *Setaria* spp.), and warble fly larvae (*Hypoderma* spp.).

Antemortem diagnosis is often impossible; however, a high index of suspicion might be warranted for certain clinical signs (acute onset or rapidly progressive asymmetric, focal, or multifocal brain or spinal cord signs) and changes in CSF analysis, in which case the treatment regimen should include specific antiparasitic drugs (e.g., fenbendazole) in addition to the more routinely used symptomatic and antiinflammatory treatments (e.g., NSAIDs, DMSO, corticosteroids, antiprotozoal drugs).

Causes

Halicephalobus gingivalis

Halicephalobus gingivalis was previously known as *Micronema deletrix,* then *Halicephalobus deletrix.*[857] The parasite was referred to as *Micronema deletrix* until the 1970s and 1980s, with use of the new nomenclature beginning in 1990.[857] The life cycle of *Halicephalobus* spp. nematodes is unknown. This small roundworm generally is considered a saprophytic organism that occasionally acts as a facultative parasite in horses and human beings. The likely route of entry is through nasal and oral mucosa, followed by possible hematogenous spread to organs with high vascularization such as the brain, spinal cord, and kidneys.[858] *H. gingivalis* recently has been shown to be transmitted from a mare to her foal because of mammary infestation.[859] CSF is abnormal, showing mixed pleocytosis with elevated protein concentration. In one study, *H. gingivalis* was observed on cytologic examination of CSF.[860]

Organs affected by migration of *Halicephalobus* spp. include the brain, spinal cord, nasal and oral cavities, pituitary gland, and kidneys and less commonly the lymph nodes, heart, lungs, stomach, liver, and bones.[248,861] Organisms affecting the CNS have been reported to have a predilection for the basilar, pituitary region of the brainstem.[862] Characteristic histopathologic lesions in the CNS include malacia, granulomatous, and lymphohistiocytic inflammatory infiltration, meningitis, and vasculitis in addition to identification of the nematodes. Other clinical signs include oral and nasal granulomata, renal involvement (*H. gingivalis* is visible in the urine), granulomatous osteomyelitis,[863] and granulomatous chorioretinitis.[864]

Most of the cases of *Halicephalobus* encephalomyelitis in adult horses reported in the literature during the past 40 years describe simultaneous renal granulomatous lesions encapsulating the nematodes.[248,859,861-874] Granulomata within or adjacent to the renal parenchyma were observed on postmortem examination in 13 of 16 horses with neurologic disease; of the other 3 horses, in one case lesions were confined to the sacral spinal cord and cauda equine, and in another case only the skull and brain were examined at postmortem examination. In contrast, all three cases reported to date in foals showed no renal involvement but did show pulmonary granulomata.[859,862]

Strongylus vulgaris, Strongylus equinus, and Angiostrongylus cantonensis

Aberrant strongyle larval migration is a much less common cause of neurologic signs because of routine broad-spectrum antiparasitic treatment with ivermectin and moxidectin. The pathogenic mechanisms described for strongyle encephalomyelitis include aberrantly migrating fourth- and fifth-stage larvae in the intima of the aorta or left ventricle, which causes endothelial damage, stimulates the clotting cascade, and results in formation of a thrombus that often contains the parasitic larva.[875] Lesions are generally asymmetric because of random migration in the brain, although migration along the spinal cord has been reported in a donkey.[500,875]

Adult parasites of *Angiostrongylus cantonensis* are found in the right ventricle and pulmonary artery of rats. The pulmonary circulation carries eggs released by adult worms to the alveoli, where the first larval stage develops and migrates up the trachea, is swallowed, and passes in feces. Snails and slugs are intermediate hosts, and ingestion of the snail results in ingestion of the infective larvae that migrate through the CNS, and finally the larvae reach the heart via the circulation. Aberrant CNS migration of *A. cantonensis* larvae has been reported in two foals with tetraparesis in Australia,[876] and aberrant migration is a recognized cause of eosinophilic meningoencephalitis in human beings and dogs.[877]

Parelaphostrongylus tenuis

The meningeal worm *Parelaphostrongylus tenuis* causes neurologic disease in cervids, ovids, bovids, and camelids. There have been multiple reports of similar disease in horses ranging in age from 6 months to 9 years.[5,878,879] Affected horses have a history of sudden onset of scoliosis with no history or evidence of trauma.

Draschia megastoma

Adult *Draschia megastoma* worms are found in the stomach of equids where they cause mucosal granulomatous masses and mild chronic gastritis. The life cycle of *Draschia* is indirect because the organism uses flies as the intermediate host. Eggs and larvae are released into the gastric lumen, and the first larval stage passes in the feces and is ingested by fly larvae of the genus *Musca* in which *Draschia* spp. organisms develop to infective larvae. Finally, horses become infected when the third larval stage is deposited on the host by adult flies. Infective larvae that are ingested and reach the stomach develop into adults and complete the life cycle. Larvae deposited in damaged skin result in local inflammation and development of extensive granulation tissue, which is the typical lesion of cutaneous habronemiasis.

Stray *D. megastoma* larvae may be found anywhere throughout the body, and a case has been reported of *D. megastoma* migration in the brainstem of a horse in the southern United States, resulting in asymmetric brainstem disease.[880]

Setaria Species

Infestation with the filarial nematode *Setaria* is common in the abdominal cavity of ungulates where the organism does not cause significant clinical effects. *S. labiatopapillosa* is found in cattle, and *S. equina* is found in horses. Microfilariae gain access to peripheral circulation and then are transmitted to other potential hosts via mosquitoes. In a postmortem examination study of 305 horses in Japan, *S. equina* was recovered from 66 of those horses (approximately 22%).[881]

The cattle parasite *S. digitata* occurs only in Asia, and infestation in unnatural hosts (horses, sheep, goats, camels, and human beings) has been associated with cerebrospinal nematodiasis. This condition can be enzootic in India, Burma, and Sri Lanka, is called *Kumri* (weak back), and has a seasonal occurrence, usually during the fly season (late summer and fall).[882]

Two cases of aberrant *S. digitata* CNS migration have been reported in Japanese racehorses, and one case of *Setaria* spp. larval migration in the brainstem and cervical spinal cord has been reported in a 12-year-old Quarter Horse mare in the midwestern United States.[881,883]

Hypoderma Species

Cattle are normal hosts of *Hypoderma* spp., but horses are accidental hosts of warble fly larvae. In cattle, *Hypoderma* larvae penetrate the skin after hatching from eggs attached to hair in the rump and lower legs. These larvae migrate through connective tissues to reach the esophagus, in the case of *H. lineatum,* or to the vertebral canal around epidural fat, in the case of *H. bovis.* Finally, the larvae migrate back to the skin over the back where they create a breathing hole. Cutaneous myiasis is uncommon in horses, and warble fly larvae occasionally might migrate aberrantly into the brain. Tissue damage causing necrosis and hemorrhage is extensive because of the big size of the instars.[884-886] Instars can enter through large natural foramina such as the foramen magnum, optic foramen, and occasionally intervertebral foramina.

Clinical Signs

Severity and duration of clinical signs vary from mild, transient, and insidious to severe and fatal. In some cases, clinical signs progress over 2 to 4 months, with periods of improvement or stabilization.[861,865,880] Variability of clinical signs depends on the number of parasites (thromboembolic shower of *S. vulgaris*), on the size of the migrating organism (*Hypoderma* spp. larvae are large and cause severe necrosis and hemorrhage as they migrate in the CNS parenchyma), and neuroanatomic localization of the lesions. Horses suffering from larval migrations in the brain (*S. vulgaris, Halicephalobus deletrix, Draschia megastoma,* and *Hypoderma* spp.) might display head tilt, circling, recumbency, blindness, hyperesthesia, stiff neck, ataxia, head pressing, recumbency, seizures, and coma. In those cases in which larvae cause lesions in the spinal cord (*S. vulgaris, H. gingivalis, Setaria* spp., *Angiostrongylus cantonensis*), clinical signs might include focal or multifocal asymmetric ataxia, weakness, dog-sitting posture caused by paraparesis, increased patellar reflexes, atonic bladder, poor tail tone, and poor rectal tone with impaction of feces. A case of cauda equine neuritis was reported to be caused by *H. gingivalis* migration in the sacral spinal cord and cauda equina nerves.[871]

Clinical signs of *Parelaphostrongylus tenuis* infection are quite characteristic and include acute onset of scoliosis (observed in 90% of reported cases), with progressive gait deficits. Scoliosis is most common in the cervical area.[5,878,879] The affected area of the vertebral column is usually C shaped, with flaccid muscles and decreased cutaneous sensation on the convex side of the curve. Tetraparesis and ataxia is mild to moderate and predominantly ipsilateral to the convex side of the curve. If bilateral gait deficits are observed, they are worse on the convex side. The proposed pathogenesis for clinical signs involves unilateral weakness of the paraspinal epaxial muscles on the convex side of the curve.[879] A linear lesion that extends for several segments, most likely in the dorsal gray column, is most likely to cause the observed signs.

Differential Diagnosis

One should consider verminous encephalomyelitis in all cases of acute or progressive asymmetric disease of the spinal cord, cerebrum, cerebellum, or brainstem. If brain involvement is evident without other localizing signs, the differential diagnosis list might include equine togaviral encephalomyelitis, rabies, equine protozoal myelitis (EPM), trauma, cerebral abscess or basilar epidural empyema, bacterial meningitis, hepatic encephalopathy, neoplasia, and leukoencephalomalacia. If the neurologic signs are limited to spinal cord involvement, other diseases to include in the differential diagnosis list might be cervical stenotic myelopathy, EPM, EHV-1 myeloencephalopathy, trauma, WNV meningoencephalitis, EDM, trauma, spinal osteomyelitis or discospondylitis, vertebral fracture, and neoplasia. If the only signs present are related to cauda equina syndrome, other conditions to consider are polyneuritis equi, sacral or coccygeal fracture, EPM, EHV-1 myeloencephalopathy, sorghum or Sudan grass toxicity, epidural abscess from tail blocking, and neoplasia.

Initial diagnostics should include CBC, serum chemistry profile, urinalysis, and CSF collection for cytologic evaluation. Radiographs of the cervical or lumbosacral spine and myelography might be required to rule out more common causes of spinal cord disease (cervical stenotic myelopathy, trauma, fractures). Although only routinely available at referral hospitals, advanced imaging techniques (e.g., CT, MRI) might be useful in diagnosing parasitic encephalomyelitis or other conditions with similar clinical signs.

CSF analysis in cases of parasitic encephalomyelitis can be normal; however, CSF changes are common and include xanthochromia, increased protein, and neutrophilic and mononuclear pleocytosis, but eosinophils rarely occur (Table 11.20). Only in a case of *Angiostrongylus cantonensis* were eosinophils the predominant cell type on CSF cytologic examination. In addition, *Halicephalobus gingivalis* might be observed in CSF subjected to cytocentrifugation.[860,862] Similarly, *H. gingivalis* larvae might be visible on microscopic examination of urine sediment or semen in cases of renal and testicular involvement.[861] Analysis of CSF obtained from horses with *Parelaphostrongylus tenuis* neurologic disease has been within normal limits.[879] PCR is a highly sensitive diagnostic modality that can aid in the definitive diagnosis of disease as reported in one case of a horse with verminous encephalitis due to *P. tenuis.*[878]

B, Basophils; *CSF,* cerebrospinal fluid; *E,* eosinophils; *L,* small lymphocytes; *M,* large mononuclear cells; *N,* neutrophils; *PMN,* polymorphonuclear neutrophil leukocytes.

Antemortem diagnosis might be possible in those cases in which renal or bony involvement is detected and nematodes are identified in biopsies of the affected tissues.[863] As described previously, renal involvement with granulomatous lesions encapsulating *Halicephalobus gingivalis* worms is observed in most cases of *H. gingivalis* encephalomyelitis. Therefore transabdominal renal ultrasound examination and ultrasound-guided biopsy (in those cases with renal lesions present), as well as microscopic examination of urine sediment, might prove useful in cases of acute-onset progressive asymmetric neurologic disease, especially if one suspects cerebrospinal nematodiasis caused by *H. gingivalis.*

Additionally, a PCR-based diagnostic test has been developed for confirmation of *Setaria* encephalomyelitis in goats, sheep, and horses.[887] This test is based on specific amplification of *Setaria* spp. filarial DNA from a blood sample from the host.

Pathologic Findings

The gross and histopathologic lesions depend on the parasite involved. Thorough postmortem examination with sectioning and histopathologic examination of all areas of the CNS relevant to the antemortem clinical signs are important to identify migrating parasites. *Strongylus vulgaris* and *Hypoderma* spp. larvae are easy to see, but other nematodes are only visible on microscopic examination. Some reports describe how one may recover and examine whole, fixed nematodes for distinctive morphologic features by centrifugation of formalin solution in which the brain had been fixed.[866,873] Gross examination of other tissues for evidence of *S. vulgaris* thrombi or presence of *Halicephalobus gingivalis* granulomatous lesions might help establish a postmortem diagnosis.

On histopathologic examination, one generally sees extensive tissue necrosis with mixed inflammatory response. *H. gingivalis* migration in the CNS typically results in histiolymphocytic infiltrates, malacia, glial proliferation, and perivascular lymphocytic cuffing. Migrations of warble fly and *S. vulgaris* larvae result in severe hemorrhage, large malacic tracts, and edema caused by their relatively larger size.

Treatment

Treatment of verminous encephalomyelitis in horses is often unrewarding. None of the cases reported in the literature has responded favorably to antiinflammatory drugs and anthelmintics. In one horse with a *Halicephalobus gingivalis* granuloma limited to the prepuce, therapy with ivermectin and diethylcarbamazine was successful.[888]

Therapeutic recommendations depend on the severity, progression, and localization of neurologic signs, as well as on consideration of possible contraindications (e.g., if one suspects a bacterial or viral cause, one should avoid using corticosteroids). In cases of acute neurologic disease use of the following antiinflammatory drugs might be warranted: NSAIDs such as phenylbutazone (2.2 mg/kg twice a day), flunixin meglumine (1 mg/kg twice a day), or ketoprofen (2 mg/kg twice a day); intravenously administered DMSO (1 g/kg as a 10% solution once daily for 3–5 days); and corticosteroids (dexamethasone at 0.1–0.25 mg/kg once daily or prednisolone

at 0.2–4.4 mg/kg once daily). If cerebral and/or brainstem signs are observed, one might administer mannitol (0.25–2 g/kg as a 20% solution once daily), or hypertonic saline might be warranted in an attempt to minimize cerebral edema. In countries in which EPM is known to occur, antiprotozoal treatment is recommended.

Specific antiparasitics suggested for treating verminous encephalomyelitis include benzimidazole compounds (oxfendazole, thiabendazole, fenbendazole, and mebendazole), diethylcarbamazine and ivermectin for the treatment of nematodes, and organophosphates with caution (trichlorfon and dichlorvos) for the treatment of warble fly larvae. Although ivermectin is effective against most equine parasites, it might not be the best choice because of its delayed method of killing, which might take as long as 10 to 14 days. Some authors have suggested administration of fenbendazole at 50 mg/kg by mouth once daily for 3 days[4,501]; however, specific data on the efficacy of anthelmintics in treating nematode or warble fly larvae migration through the CNS are not available.

MISCELLANEOUS NEUROLOGIC DISORDERS

Debra C. Sellon

In addition to the numerous neurologic problems discussed in detail earlier in this chapter, horses can develop a wide variety of acute or chronic neurologic disorders with clinical signs related to brain, spinal cord, or nerve dysfunction. Clinical signs can occur because of primary disease or dysfunction of the CNS or secondary to a variety of metabolic disorders or disorders of other body systems. This section will mention the most important of the miscellaneous CNS disorders and refer the reader to relevant chapters for more detailed information.

Neurologic Neoplasia

Many types of neoplastic lesions have been identified in the brain and spinal cord of horses. A comprehensive review of the clinical and pathologic aspects of equine CNS neoplasia, however, is lacking in the peer-reviewed veterinary literature. Available case reports and summaries of pathologic studies suggest that CNS neoplasia is quite uncommon in horses. In one Australian survey of 450 horses, with neurologic disease, the prevalence of neurologic disease secondary to neoplasia was less than 2%.[141] This percentage is likely to be much lower in horses in the United States because of the much higher incidence of encephalitic disorders and EPM.

Tumors of the nervous system can be classified on the basis of their cellular origin as tumors of nerve cells, neuroepithelium, glia, nerves and nerve sheaths, mesodermal structures, and endocrine organs. Neoplasms of nerve cell origin appear to be extremely uncommon in horses, with only a few reports of ganglioneuromas, complex tumors arising in peripheral ganglia and composed of well-differentiated neurons, nerve processes, Schwann cells, and glial cells.[889,890] These tumors might cause intestinal obstruction and signs of colic in affected horses.

Tumors of neuroepithelial origin in horses include ependymoma, choroid plexus papilloma, neuroepithelial tumor of the optic nerve, malignant medulloepithelioma, ocular medulloepithelioma, and pineoblastoma.[891-906] Glial cell tumors include glioblastoma multiforme, optic disc astrocytoma, retinoblastoma, and microglioma.[900,906-908] Neoplasms of nerves and nerve sheaths appear to be more common than CNS neoplasia and include neurofibromas and neurofibrosarcomas.[909-914] The most common sites for neurofibromas are in the cutaneous tissues, of the pectoral region, abdomen, neck, and face, but gastrointestinal tract lesions have also been described.[909] There are also reports of intracranial and mediastinal schwannomas in horses.[915,916]

The most common mesodermal neoplasm in horses appears to be meningioma.[892,905,917] Neoplastic reticulosis, lipoma in the mesencephalic aqueduct, angioma in the cervical spinal cord, primary meningeal lymphoma, and melanoblastoma of the cerebellar meninges have also been described.[918-920]

Older texts may refer to pituitary pars intermedia dysfunction (PPID) of older horses as a neoplastic lesion. This disorder is most likely a manifestation of oxidative damage to dopamine-producing neurons in the CNS with subsequent dysregulation of hormone production within the pars intermedia of the pituitary gland. PPID is discussed in detail in the Endocrinology chapter (Chapter 16).

Cholesterol granulomas (cholesteatomas, cholesterinic granulomas) are likewise not neoplastic lesions.[921-929] These lesions are found in the choroid plexus of up to 20% of older horses.[930] Although more common in the choroid plexus of the fourth ventricle, lesions in the lateral ventricles may be more likely to result in clinical signs. Lesions might represent a chronic granulomatous reaction to deposition of cholesterol crystals associated with chronic choroid plexus leakage. Grossly the granulomas are circumscribed, firm, granular, and yellow-brown with a glistening cut surface. They are most often recognized as incidental findings at necropsy of horses without noticeable clinical signs. If they are large enough, however, they might cause CNS signs as a result of direct pressure on cerebral tissues or obstructive hydrocephalus. In affected horses, reported clinical signs have included altered behavior, obtundation, somnolence, seizures, ataxia, weakness, and coma. CSF from affected horses might have an elevated protein and appear xanthochromic.[921-923]

Secondary neoplastic conditions affecting the CNS might penetrate the cranial vault or vertebrae, extend through osseous foramina, or metastasize via the vascular system. Clinical signs vary depending on the type, site, and extent of the lesion. Lymphoma is probably the most common secondary neoplasm of the CNS in horses.[920,931-936] Lesions might cause forebrain signs if present in the cranial vault or ataxia and paresis if causing compression of the spinal cord.

Melanoma of the spinal cord, meninges, and brain may occur with metastasis of primary cutaneous lesions.[937-939] Alternatively, clinical signs may represent spread from affected sublumbar lymph nodes.[920,940] Melanoma of the CNS is most common in gray horses.

Hemangiosarcoma and undifferentiated sarcoma have been reported to affect the CNS of horses.[920,941-943] There are numerous descriptions of adenocarcinomas and carcinomas (including squamous cell carcinoma) affecting the CNS of horses by direct spread from a primary site in the head or by metastasis from a distant site.[920,944-950] Tumors of the bone or bone marrow might involve the skull or vertebrae, resulting in compression of the brain or spinal cord, respectively.[920,951-953]

Malformation tumors, including epidermoids, dermoids, teratomas, and teratoids, might also affect the CNS.[920] They are often incidental findings at necropsy but might occasionally be clinically significant.

Supportive evidence for the presence of CNS neoplasia can be obtained with advanced imaging (i.e., CT, MRI) of the brain or spinal cord in select equine patients. Definitive diagnosis of primary CNS neoplasia in horses requires cytologic or histopathologic identification of neoplastic cells or tissues. This diagnosis necessitates biopsy, cytologic evaluation of an aspirate from a suspect lesion, or identification of neoplastic cells in CSF. Analysis of CSF is rarely diagnostic of neoplasia in horses because of the rarity of the presence of neoplastic cells in the fluid. Given the practical difficulties inherent in obtaining biopsy samples from the brain or spinal cord, definitive diagnosis of primary CNS neoplasia in horses rarely occurs antemortem. Definitive diagnosis is more likely in horses with secondary CNS neoplasia in which a diagnosis is made by biopsy or cytologic evaluation of primary lesions identified external to the CNS.

Toxic Disorders

A wide variety of toxic substances can affect the CNS of horses. Most of these are discussed in detail in the Toxicology chapter (Chapter 21). Three toxic neurologic conditions merit mention in this chapter because of their common occurrence in some geographic areas and their distinctive clinical appearance as demonstrated in the referenced video segments on the DVD accompanying this text.

Leukoencephalomalacia

Equine leukoencephalomalacia is a seasonal disorder of horses, ponies, donkeys, and mules, occurring most commonly in late fall through early spring. Most outbreaks are associated with a dry growing period followed by a wet period. The disorder is caused by ingestion of the mycotoxin fumonisin B1, a metabolite of *Fusarium moniliforme*.[954-976] Two clinical syndromes are associated with fumonisin B1 intoxication. The more common is a neurologic syndrome characterized initially by incoordination, aimless walking, intermittent anorexia, lethargy, obtundation, blindness, and head pressing. These signs might be followed by hyperexcitablity, belligerence, extreme agitation, profuse sweating, and delirium. Recumbency and clonic-tetanic seizures might occur before death. Less commonly, horses develop a hepatotoxic syndrome with swelling of the lips and nose, somnolence, severe icterus and petechiation of mucous membranes, abdominal breathing, and cyanosis. Gross lesions include liquefactive necrosis and degeneration of the cerebral hemispheres; changes might also occur in the brainstem, cerebellum, and spinal cord.

Nigropallidal Encephalomalacia

Yellow star thistle and Russian knapweed grow over much of the western United States in nonirrigated pastures during dry seasons of summer and fall. Ingestion of these plants can result in unilateral or more commonly bilateral softening and necrosis in areas of the globus pallidus and substantia nigra.[977-986] Lesions are often sharply defined and may be cavitary. Although the plants are generally considered unpalatable by most horses, some horses may develop a craving for the plants and selectively seek them out. The exact toxic principle in these plants has not been determined. Affected horses demonstrate variable degrees of impairment of eating and drinking with lack of coordination of movements of prehension, mastication, and deglutition. Most horses appear to be able to swallow if food or water is placed in the posterior pharynx. Severely affected horses might attempt to drink by immersing their muzzle deeply into the water in an apparent attempt to force water into the posterior pharynx. Hypertonicity of facial muscles is common, with the horse often holding the mouth partially open with the lips retracted. The tongue may protrude from the mouth, and many horses display constant chewing movements.

Fluphenazine Toxicity

Fluphenazine administration to horses may result in characteristic clinical signs of toxicity.[987-991] Fluphenazine is a highly potent phenothiazine neuroleptic that is widely used in human medicine for a variety of psychological disturbances. In horses, fluphenazine decanoate has been used to provide a persistent sedative effect. It binds avidly to dopamine D_2 receptors in the brain. The very slow dissociation of fluphenazine from these receptors is associated with a greater risk of adverse extrapyramidal signs than is observed with newer atypical antipsychotic medications.[987] Its administration to some horses can result in severe extrapyramidal effects and parkinsonism with clinical signs including agitation, profuse sweating, hypermetria, aimless circling, intense pawing and striking with the thoracic limbs, and rhythmic swinging of the head and neck alternating with periods of severe stupor. A study using liquid chromatography showed that fluphenazine decanoate administered intramuscularly can be detected in serum up to 14 days after administration, with the highest concentration detected in serum at 1.4 ng/mL.[992] The lower limit of detection was determined to be 0.05 ng/mL.[992] A long-acting depot formulation for intramuscular administration is available and appears to be most commonly used. One published report suggests a dosage of 0.05 to 0.08 mg/kg IM every 2 weeks with a warning to beware of idiosyncratic reactions.[993] Horses have exhibited signs of extrapyramidal effects of fluphenazine decanoate after receiving doses as low as 40 mg IM.[987] Given that recommended doses for adult humans range from 25 to 50 mg, it is reasonable to assume that at least some horses are much more susceptible than humans to the adverse effects of fluphenazine decanoate. The severity of clinical signs observed in some affected horses is sufficient to pose considerable safety risks for veterinarians and handlers treating these horses. This author is aware of at least one horse that was euthanized because of the extreme danger of clinical signs after administration of fluphenazine; other authors have indicated similar adverse outcomes.[987] Treatment consists of discontinuation of drug administration and enhancing cholinergic function by administering anticholinergic medications. Diphenhydramine chloride results in significant improvement in some, but not all, affected horses.[987,989] Benztropine mesylate (0.018 mg/kg IV every 8 hours) has also been helpful for treatment of some affected horses.[987] Other horses apparently benefited from sodium pentobarbital (2 mg/kg IV followed by a constant rate infusion at 2.5 mg/kg/h) in an attempt to control maniacal behavior without inducing recumbency or anesthesia.[987]

Metabolic Disorders

A wide variety of metabolic disorders can cause clinical signs indicative of central nervous system dysfunction. These signs include hepatic dysfunction, hypoglycemia, hypoxemia and ischemia, and severe abnormalities in plasma electrolyte concentrations.

Hepatoencephalopathy

An excellent review of the etiology, pathogenesis, clinical signs, diagnosis, and treatment of liver disease is included

elsewhere in this text. A normally functioning liver is necessary to maintain normal brain neuron and astrocyte function. With acute liver disease hepatoencephalopathy is most often a result of astrocyte swelling, acute cytotoxic cerebral edema, and intracranial hypertension. In chronic hepatic disease astrocytes are swollen but also show evidence of Alzheimer type II changes. Horses with hepatoencephalopathy show signs of cerebral cortex dysfunction. The earliest recognizable clinical signs in horses are often obtundation, lethargy, mild ataxia, and various forms of inappropriate behavior. These signs can progress to head pressing, circling, somnolence, and diminished responsiveness to external stimuli. Eventually affected horses become recumbent and comatose. Seizures might occasionally be observed, but they are not common (not clinically manifested). The type and severity of clinical signs do not correlate with type or reversibility of the underlying hepatic disease.

Hypoglycemia, Hypoxemia, and Ischemia

Severe hypoglycemia is not common in adult horses but is common in neonates, often as a complication of sepsis, prematurity, hypoxic ischemic encephalopathy, or hypothermia. When hypoglycemia does occur it might result in weakness, obtundation, ataxia, and eventually loss of consciousness. Seizure activity is not common in adult horses but might occasionally be observed in affected foals. Iatrogenic hypoglycemia can occur in horses treated with insulin or with abrupt cessation of intravenous glucose therapy. Clinical signs are rapidly reversed with intravenous administration of glucose-containing solutions. Guidelines for intravenous glucose therapy are included in Chapter 20.

Because of the brain's high and continuous demand for oxygen, the CNS is extremely susceptible to hypoxic or ischemic damage. This is most apparent in the neonate with hypoxic ischemic encephalopathy, as discussed in detail in Chapter 20. As nervous tissue switches to anaerobic glycolysis to meet its energy needs, brain glucose is depleted, and localized lactic acidosis occurs. Neurons swell, and cytotoxic edema exacerbates ischemia. The end result is irreversible cell damage and neuronal death. Clinical signs depend on what areas of the brain are affected. Localized hypoxia may occur with thromboembolic disorders or intracarotid injections. Deprivation of oxygen to the entire CNS results in more dramatic clinical signs of impaired cerebral function ultimately leading to seizures, coma, and death. This type of generalized severe tissue hypoxia may result from decreased inspired oxygen, ventilation/perfusion abnormalities, right-to-left shunting of blood, impairment of gas diffusion within the lungs, hypoventilation, severe anemia, impaired oxygen utilization by tissues, or profound hypotension secondary to sepsis, hemorrhage, anaphylaxis, or cardiac failure. These disorders are discussed in detail in the appropriate chapters elsewhere in this text.

Electrolyte Abnormalities

Severe hyponatremia or hypernatremia can result in CNS dysfunction. Hyponatremia most often results from water intoxication because of excessive IV or oral administration or consumption of hypotonic solutions. A common clinical scenario resulting in hyponatremia is oral consumption of large quantities of water by a patient with a disorder that results in significant concurrent electrolyte loss (e.g., diarrhea, excessive sweating, polyuric renal failure). Clinical signs are most common in horses with a serum sodium concentration of less than 110 mEq/L. Profound hypernatremia might result in clinical signs of spasticity, myoclonus, and obtundation. Severe hyponatremia was identified in 4% of foals (69 of 1718) presented to an intensive care unit.[994] Of those affected foals, 16% displayed neurologic signs attributed to hyponatremic encephalopathy.[994] Signs included seizures, obtundation, ataxia, and blindness. Severe hyponatremia was associated with renal disease, enterocolitis, and uroperitoneum. Survival rate to discharge was 72.5% (50 of 69 foals).[994] Long-term survival in a 12-month follow-up was 76%.[994] A different study in 4 foals with hyponatremic encephalopathy reported resolution of neurologic signs in 3 of 4 foals.[995] Signs were attributed to increased intracranial pressure as the result of severe hyponatremia. Azotemia due to acute renal failure in these foals was slow to resolve with intensive therapy. Therapy of foals affected with profound hyponatremia or hypernatremia is discussed in Chapter 20.

CHAPTER 12

Disorders of the Gastrointestinal System

L. Chris Sanchez*

Physical Examination

Examination of patients with disease of the gastrointestinal tract must include evaluation of the metabolic and cardiovascular status of the patient because acute conditions of the proximal or distal intestinal tract can lead to endotoxemia and sepsis. Examination of the cardiovascular system (heart, peripheral pulse, and mucous membranes), lungs, and abdomen is essential to detect clinical signs of systemic inflammation from endotoxemia, coagulation disorders, dehydration, ileus, shock, and other abnormalities resulting from injury to the small or large intestine. Clinical signs of systemic inflammation from endotoxemia and sepsis are described later in this chapter.

The physical examination of the abdomen should include auscultation, transabdominal ballottement, and transrectal palpation. Abdominal distention often indicates distention of the large intestine; small intestinal distention also can cause visible abdominal distention if a large proportion of the small intestine is involved. Abdominal palpation can be performed in neonatal foals. After several weeks of age the abdominal wall is too rigid to allow effective palpation of intraabdominal structures.

Abdominal auscultation is particularly useful for assessing the motility of the large intestine. Progressive motility of the small intestine, conversely, is difficult to distinguish by auscultation from nonprogressive motility. The distinct character of the borborygmi produced during propulsive contractions of the cecum and ascending colon allows evaluation of the frequency and strength of retropulsion and propulsion. Propulsive contractions of the cecum and ventral colon occur every 3 to 4 minutes and give rise to prolonged rushing sounds heard over long segments of intestine. Retropulsive sounds presumably are similar to propulsive sounds, but they occur less frequently. Distinguishing between propulsion and retropulsion is not important clinically because both types of contractions signify normal motility. Interhaustral and intrahaustral mixing contractions produce nonspecific sounds of fluid and ingesta movement that are difficult to distinguish from other borborygmi, such as small intestinal contractions or spasmodic contractions.[1]

Auscultation over the right flank and proceeding along the caudal edge of the costal margin toward the xiphoid allows evaluation of the cecal borborygmi. Auscultation over a similar area on the left side allows evaluation of the pelvic flexure and ascending colon. Typical progressive borborygmi heard every 3 to 4 minutes on both sides of the abdomen indicate normal motility of the cecum and ascending colon. Less frequent progressive sounds may indicate a pathologic condition of the large intestine or may result from anorexia, nervousness (sympathetic tone), or pharmacologic inhibition of motility (i.e., α_2-adrenergic agonists such as xylazine).[2-5] Absolute absence of any auscultable borborygmi suggests abnormal motility and indicates ileus resulting from a serious pathologic condition but is not specific to any segment of the intestine.[3,6] If borborygmi are audible but progressive sounds are not detectable, determining whether a significant abnormality exists is difficult, and such findings should not be overinterpreted.[6] Borborygmi heard more frequently than normal may result from increased motility following feeding; from excessive stimulation from irritation, distention, or inflammation; or after administration of parasympathomimetic drugs such as neostigmine. Large intestinal motility increases in the early stages of intestinal distention regardless of the site.[7] Mild inflammation or irritation of the large intestinal mucosa also can stimulate motility.[3] Parasympathomimetic drugs stimulate contractions and auscultable borborygmi in the large intestine; an increase in parasympathetic tone may result in segmental contractions, which actually inhibit progressive motility.[2]

Percussion of the abdomen during auscultation can reveal gas in the large intestine. The characteristic *ping* produced by simultaneous digital percussion and auscultation over a gas-filled viscus often is associated with abnormal accumulation of gas under pressure. This technique is particularly useful in foals, ponies, and Miniature Horses because of the limitations of rectal palpation.

Transabdominal ballottement can be used to detect large, firm masses or an abnormal volume of peritoneal fluid (PF). The usefulness of this technique is usually limited to animals too small to palpate rectally. Soft tissue masses or fetuses can be detected by bumping the structures with a hand or fist. If excessive PF is present, a fluid wave can be generated by ballottement; however, this technique is not as useful in horses older than 4 weeks because the abdominal wall is rigid.

*The editors and authors acknowledge and appreciate the contributions of Samuel L. Jones, Katharina I. Lohmann, Michelle Henry Barton, Laura Javsicas, Anthony T. Blikslager, and Dana N. Zimmel as previous contributors to this chapter. Some of their original work has been incorporated into this edition.

Transrectal palpation is the most specific physical examination technique for investigation of intestinal disease and is particularly valuable when evaluating obstructive diseases.[8] The primary objectives of transrectal palpation are to assess the size, consistency, and position of the segments of the large intestine; to determine the presence of any distention of the small intestine; and to detect intraabdominal masses. Evaluation of the wall thickness and texture and the mesenteric structures (blood and lymphatic vessels and lymph nodes) also may aid in diagnosis of large intestinal disease. The interpretation of transrectal palpation findings in light of clinical signs and laboratory results is an important diagnostic aid for developing appropriate treatment strategies for intestinal diseases manifested by abdominal pain. Enlargement of one or more segments of large intestine detected by transrectal palpation provides evidence of obstruction at or distal to the enlarged segment. By systematically evaluating each segment, the site of obstruction may be determined. Obstruction of the pelvic flexure, for instance, results in enlargement of the pelvic flexure and ventral colon, but the dorsal and descending colons are of normal size. Enlargement of a segment of the large intestine usually is accompanied by abnormal consistency of the contents. It is possible to distinguish among gas, fluid, and ingesta and to detect foreign bodies in palpable segments. Accumulation of gas and fluid suggests complete and acute obstruction, whereas accumulation of ingesta suggests chronic and incomplete obstruction. Accumulation of fluid usually indicates ileus. The practitioner must evaluate the consistency of the contents in light of the size of the segment; ingesta in the ventral colon of a dehydrated patient may be firm, but the size of the ventral colon will be normal. Conversely, if the ingesta is firm because of a distal obstruction, the ventral colon will be enlarged.

Displacement of a segment of the large intestine may create an obstruction detectable by enlargement of the segment and accumulation of gas and fluid, even if the site of obstruction is not palpable. Torsion of the ascending colon at the sternal and diaphragmatic flexures results in acute accumulation of gas and fluid proximal to the torsion, causing distention of the left dorsal and ventral colons. Depending on the degree of torsion, the position of the ventral and dorsal colons may not be significantly abnormal. Displacement of a segment of large intestine often results in incomplete obstruction, and the diagnosis is either confirmed on detection of the displaced segment in an abnormal position or suspected when the segment is not palpable in a normal position. A determination should be made as to whether the segment that appears to be displaced is in a normal position but of smaller than normal size because of a decreased volume of ingesta. The cecum, right dorsal and ventral colons, pelvic flexure, and descending colon are palpable in most horses. The nephrosplenic space should be palpated to detect the presence of intestine, usually pelvic flexure, entrapped within the ligament.

Small intestine is not normally palpable in the horse. Distention indicates ileus with gas or fluid retention, usually following a strangulating or nonstrangulating obstruction. Strangulating obstructions often are accompanied by severe pain, dehydration, PF changes, and a varying degree of gastric fluid accumulation. The small intestine in these cases is turgid and firm on palpation. The mesentery and wall thickness should be assessed in the same manner as for large intestinal disorders. Careful palpation of the inguinal rings in stallions with small intestinal distention is crucial for determining inguinal herniation.

Evaluation of the wall thickness and mesenteric vessels can reveal venous congestion (mural edema and enlarged blood and lymphatic vessels) or inflammation (mural edema with normal vessels). Disruption of arterial blood flow does not cause venous congestion, but the arterial pulse is not detectable. Mesenteric tears may not be palpable, but the entrapped ischemic intestinal segment may be thickened. Enlargement of mesenteric lymph nodes also may be noted. Abnormalities in the wall or vessels should be interpreted in light of the size, consistency, and position of the segment of intestine and the clinical signs. Several conditions involving small intestinal strangulating lesions do not necessarily cause abnormal rectal examination findings until the disease has been present for an extended time. These conditions include diaphragmatic hernias and epiploic foramen entrapments (EFEs). PF analysis can be normal in these cases as well because the fluid is trapped in the thorax or cranial abdomen.

Nonstrangulating causes of small intestinal distention can be divided further into intraluminal and extraluminal obstructions. Ileal impactions are the most common cause of intraluminal obstruction, and on rare occasions the impaction can be palpated in the upper right quadrant, near the ileocecal opening. Intraluminal masses caused by lymphoma, eosinophilic enteritis, foreign bodies, or ascarid impactions often lead to small intestinal distention and are usually indistinguishable from one another on the basis of palpation alone. Small intestine in these cases can be moderately to severely distended, depending on the degree of obstruction. Extraluminal obstructions include abdominal masses and large colon displacement. The rest of the abdomen should be carefully palpated to help rule out these causes. Some cases of small intestinal distention result from physiologic ileus rather than mechanical obstruction. The bowel is usually mildly to moderately distended and almost always is accompanied by significant gastric fluid.

The small colon is easily distinguishable by the presence of normal fecal balls and an antimesenteric band. In horses with impaction of the small colon, a long, hard, tubelike structure is present in the caudal abdomen, and the band is palpable along the length. Fluid stool is often present in the rectum in these horses, as is tenesmus, and the rectal mucosa is often edematous and occasionally roughened. Rectal tears can be detected and evaluated with careful rectal palpation. Also detectable are mural masses in palpable segments of intestine or mesentery; if a mass causes obstruction, then it is possible to detect the result of the obstruction in proximal segments of intestine even if the mass is unreachable. Palpation of the mesenteric vessels may reveal thickening and thrombosis, which can lead to ischemia or infarction.

Visual inspection of the mucosa of the rectum and descending colon can be performed with the aid of a speculum or flexible endoscope. A flexible endoscope is also useful for evaluation of rectal tears or perforations, mural masses, strictures, or mucosal inflammation and obtaining biopsy specimens of the mucosa or masses. The obvious limitations are the amount of fecal material, which can interfere with the examination, and the distance of the lesion of interest from the anus. These techniques offer little advantage over palpation in many cases, unless the patient is too small to palpate.

Examination of the oral cavity in horses with dysphagia or weight loss is an important extension of the physical examination. The horse should be adequately sedated and a full-mouth speculum used to allow palpation and visual examination of all parts of the oral cavity and detection of abnormal dentition, foreign bodies, fractures, abscesses, or mucosal ulceration.

The presence of fluid accumulation in the stomach indicates a functional or mechanical obstruction of gastric

outflow. Fluid accumulation in the stomach is assessed by siphoning of the gastric contents with a nasogastric tube and examining the fluid for amount, color, and odor. Normal fluid is green and may contain foamy saliva. The net volume obtained by gastric lavage is usually less than 4 L. Large volumes (≥8–10 L) of foul-smelling fluid may indicate proximal enteritis. Horses with strangulating obstructions or luminal obstructions often accumulate moderate amounts of gastric fluid, but the amount is generally less than in horses with proximal enteritis or postoperative ileus (POI). Distinction between these conditions should not be made based on the volume and character of gastric fluid alone. Hemorrhage in the gastric fluid usually indicates devitalized small intestine, stomach wall, or severe gastric ulceration. Endoscopy or contrast radiography may aid in the diagnosis of gastric outflow obstruction.

DIAGNOSTIC EVALUATION

Clinical Pathology

Hematologic alterations associated with diseases of the gastrointestinal tract are often nonspecific, reflecting systemic response to inflammation, endotoxemia, or sepsis. Neutrophilic leukocytosis and normochromic, normocytic anemia with or without hyperfibrinogenemia commonly are associated with chronic inflammatory conditions of the intestine. Anemia from chronic blood loss occurs infrequently in adult horses because of the large iron stores and high concentrations of iron in their diet; anemia usually follows chronic inflammation, as do alterations in the leukon and plasma fibrinogen concentrations. Plasma protein concentrations vary depending on gastrointestinal losses of albumin and globulin and elevation of globulin concentration from antigenic stimulation. Protein-losing enteropathy may manifest as a hypoalbuminemia or panhypoproteinemia.

Significant alterations of the hemogram do not accompany acute disease of the intestine unless severe dehydration, endotoxemia, or systemic inflammatory response syndrome (SIRS) is present. During the early stages of SIRS, elevations in circulating concentrations of inflammatory mediators, epinephrine, and cortisol produce characteristic changes in the hemogram. Leukopenia, with neutropenia and a left shift, toxic changes in the neutrophil cytoplasm, and lymphopenia commonly occur early in the disease, but neutrophilic leukocytosis is more common during the later stages of SIRS. Hemoconcentration and hyperfibrinogenemia are also common. Thrombocytopenia and other coagulopathies are also features of SIRS.

Electrolyte imbalances and increased blood lactate are common biochemical abnormalities in horses with acute gastrointestinal disease. Decreased serum calcium concentrations are common and nonspecific.[9] Mucosal inflammation can disrupt electrolyte fluxes; diarrhea or gastric reflux greatly exacerbates sodium, potassium, calcium, magnesium, and bicarbonate loss. Large colon ischemia causes increased lactate and potassium concentrations and metabolic acidosis in the colonic vasculature and inflammation in the colonic and systemic vasculature.[10] Reduced perfusion of peripheral tissues from hypotensive shock and intestinal ischemia can cause increased blood lactate; intestinal obstruction during ischemia may also result in absorption of lactate from the lumen. Increased blood lactate can result from a variety of causes, including hypovolemia, and blood lactate alone should not be used for diagnostic or prognostic purposes in horses with colic.[11] Increases in blood lactate over time are greater in nonsurvivors, relative to survivors, in adult equine emergencies (many of which had gastrointestinal disease).[12] Portable lactate analyzers have demonstrated variable intraanalyzer reliability in equine blood so that caution should be exercised in interpretation and comparison of results reported from various searches.[13,14] Metabolic acidosis may accompany lactic acidemia, but an inconsistent association exists between the two, especially when mixed acid-base imbalances are present.[15,16] Increases in hepatic enzymes, specifically γ-glutamyl transferase (GGT), may occur with large colon displacements, duodenal strictures, or proximal enteritis. Increased GTT is more suggestive of right, rather than left, dorsal displacement.[17]

Relative polycythemia from hemoconcentration or splenic contraction and changes in red blood cell deformability from hypoxia or hypocalcemia may increase blood viscosity. Blood viscosity increases in patients with acute obstructive disease. Hyperviscosity reduces perfusion of capillary beds, exacerbating ischemia and tissue hypoxia.[18]

Peritoneal Fluid

Abdominocentesis and analysis of PF are performed on many patients with gastrointestinal disease and are especially helpful in differentiating strangulating from nonstrangulating disorders of the small intestine. Important quantifications include white and red blood cell counts and protein, lactate, and glucose concentrations. Cytologic evaluation can reveal cellular abnormalities, especially in horses with intestinal neoplasia. Results of PF analysis may help establish a specific diagnosis and, more important, may reflect inflammatory, vascular, or ischemic injury to the intestine, requiring surgical intervention.

Alteration of PF reflects a sequence of events during acute intestinal vascular injury. The PF protein concentration increases first, followed by increases in red blood cell count and fibrinogen concentration. A transudative process resulting from vascular congestion and increased endothelial permeability allows small macromolecules (albumin) to escape into the PF, followed by larger macromolecules (globulin and fibrinogen), and finally diapedesis of cells (red then white blood cells). Severe ischemic intestinal inflammation or visceral peritonitis result in an exudative process, with large quantities of protein and white blood cells (WBCs), primarily neutrophils, to escape into the PF.[19,20] Eventually, bacteria begin to translocate across the intestinal wall and appear in the PF as the mucosal barrier breaks down. If perforation occurs, bacteria and particles of ingesta appear in the PF, and the neutrophils become degenerate (i.e., pyknotic), with karyorrhexis, karyolysis, and smudge cells.

Increased PF protein concentration is an indicator of early inflammation, whereas increased red blood cell counts in the presence of normal WBC counts suggest vascular damage without significant tissue ischemia.[20] Of note, the anticoagulant potassium ethylenediamine tetraacetic acid, but not lithium heparin, can cause an increase in total protein as measured by a refractometer, relative to the value obtained from the same sample without anticoagulant.[21] The gross color of the PF can be helpful in detecting injury and necrosis of the intestine. A serosanguineous appearance indicates vascular injury, whereas orange or brown-red indicates necrosis with the release of pigments such as hemosiderin.

Tissue hypoxia and ischemia cause rapid increases in PF lactate dehydrogenase, creatine kinase, and alkaline phosphatase (AP) activity and lactate concentration.[22,23] Phosphate

concentration increases when cellular disruption occurs.[24] PF enzyme activities, phosphate, and lactate concentration increase faster and higher than serum activities.[16,22-24] PF pH and glucose concentration tend to decrease during intestinal ischemia but not as dramatically as in septic peritonitis.[25] Lactate concentrations in PF are commonly evaluated and are better predictors of strangulating small intestinal obstruction than blood lactate,[22] although increases in both lactate (the term by which L-lactate is commonly referred) and D-lactate are likely more accurate for predicting strangulating lesions as opposed to ruling them out.[26] Serial sampling of blood and PF lactate may be useful in cases in which clinical and diagnostic findings at initial presentation were not conclusive for either strangulating or nonstrangulating lesions and/or a horse's clinical condition deteriorates.[27]

Cytologic examination of PF may reflect chronic inflammatory intestinal conditions or neoplastic diseases.[28] Although culturing PF is recommended to distinguish bacterial infections from noninfectious inflammation unless bacteria are visible on cytologic examination, culturing PF is often unrewarding. Decreases in PF glucose concentrations (<30 mg/dL) and pH (<7.3) are early indicators of septic peritonitis. Glucose concentration and pH in PF should approximately equal blood values in normal horses.

Practically, the gross appearance and the total solids of PF in conjunction with a comparison of PF to serum lactate are most useful when distinguishing between strangulating and nonstrangulating small intestinal disorders in a horse presenting for acute colic. Potential risks associated with performing an abdominocentesis should be considered, and this procedure is performed only if results are likely to alter the treatment plan. For example, if other examination findings indicate that an exploratory laparotomy is clearly indicated or not in the case of a horse with acute colic, abdominocentesis is likely not indicated.

Fecal Examination

Gross examination of the feces can provide information about digestion and transit time in the large intestine. Large fiber particles in the feces represent poor mastication or poor digestion in the large intestine. Small, mucus-covered, hard fecal balls indicate prolonged transit through the descending colon, whereas increased fluidity implies decreased transit time. Feces containing sand or gravel are not necessarily abnormal. However, a significant amount of sand implies that large quantities are present in the colon. Alternatively, absence of sand in feces does not confirm an absence of sand in the colon. Frank blood indicates substantial bleeding into the distal colon (right dorsal colon, small colon, or both) resulting from mucosal damage.

Laboratory analysis of the feces can be performed for horses with diarrhea. Fecal cytologic examination and tests for occult blood detect mucosal inflammation, erosion, or ulceration. Increased fecal leukocyte counts have been documented in horses with diarrhea and salmonellosis, but specificity of this test is low.[29]

Fecal occult blood tests detect blood in the feces, presumably from erosion or ulceration of the mucosa, but do not distinguish the source of the blood. Large volumes of blood (1–2 L) given by nasogastric tube were required to produce a positive test for occult blood in the feces, but the amount of blood originating from the large intestine required to produce a positive test is unknown. Despite initial reports to the contrary,[30] there does not appear to be any correlation between endoscopic evidence of glandular or nonglandular gastric ulceration and detection of fecal albumin or hemoglobin.[31]

Bacteriologic examination of the fecal flora has been used in horses with diarrhea. Quantitation of clostridial species may be beneficial in diagnosing clostridial infection of the large intestine, although tests to detect clostridial toxins in intestinal contents or feces are important for determining whether clostridia cultured from the feces are causing disease. The most common bacterial pathogens isolated from the feces of horses are *Salmonella* spp. and *Clostridium* spp. The number of *Salmonella* organisms isolated from the feces of horses with clinical salmonellosis is usually higher than from horses with asymptomatic infections. However, the volume of feces in many cases of acute diarrhea is high, and the concentration of *Salmonella* organisms may be lower than would be expected, accounting for many false-negative fecal cultures. The sensitivity of fecal cultures for detecting *Salmonella* infection may be as low as 20%. Culture of five consecutive daily fecal samples is recommended to increase the sensitivity of the test. Real-time polymerase chain reaction (PCR) assays used on fecal samples can detect DNA from *Salmonella* spp. and have performed well in recent validation studies; accuracy of point-of-care tests remains elusive.[32-35] Currently, PCR assays can be used for detection of viral (rotavirus and coronavirus), bacterial (*Cryptosporidium* spp., *Salmonella* spp., *Neorickettsia risticii, Lawsonia intracellularis*), or bacterial toxin (*Clostridium difficile* toxins A and B, *Clostridium perfringens* enterotoxin A) DNA in feces or blood (*N. risticii*).

Qualitative fecal examination can detect nematode and cestode ova, protozoan oocysts, parasitic larvae, and protozoan trophozoites. A direct smear of fecal material can rapidly detect parasite larvae and trophozoites and motility of ciliates and parasite larvae. Fecal flotation with zinc sulfate or sucrose solutions is often used to concentrate less dense ova and oocysts. Zinc sulfate produces less distortion of trophozoites and larvae than sucrose solutions. Fecal sedimentation is particularly appropriate for ciliates, *Giardia* organisms, and trichomonads. Quantitative techniques such as the Cornell–McMaster method allow estimation of the number of eggs per gram of feces and are most appropriate in monitoring parasite control programs.

RADIOGRAPHY

Survey radiography of the normal esophagus is usually unrewarding. It is possible to detect foreign bodies or soft tissue masses and, in cases of esophageal rupture, free air and ingesta in the tissues surrounding the esophagus and pneumomediastinum. Thoracic radiographs may be necessary to detect megaesophagus or cranial mediastinal masses causing extraluminal obstruction. Barium swallows or double-contrast esophagrams may be used after resolution of an esophageal obstruction to determine whether a stricture, diverticulum, or other underlying disorder is present, although endoscopy can provide similar information. Barium sulfate is the usual contrast medium and can be administered orally by way of a dose syringe or nasogastric tube (50–100 mL of a 40% barium sulfate suspension or barium paste). Oral administration is preferred for evaluation of swallowing and lesions in the proximal esophagus. Administration of contrast using a nasogastric tube (preferably cuffed) allows for delivery of larger volumes of barium (up to 500 mL) but should be performed

without sedation if possible. Administration of contrast material can be followed with air insufflation to create a double-contrast effect. If rupture of the esophagus is suspected or if the contrast material is likely to be aspirated, barium should be avoided, and iodinated organic compounds in an aqueous solution should be used as contrast material to decrease the potential for adverse effects. When interpreting esophageal radiographs, the veterinarian should take particular care if the horse is sedated. Acepromazine or detomidine administration causes esophageal dilation in normal horses, especially after passage of a nasogastric tube.[36]

Radiography of the adult equine abdomen is an effective technique in detecting radiodense material in the large intestine, such as enteroliths, sand, and metallic objects.[37-40] One survey demonstrated that radiography has 76.9% sensitivity and 94.4% specificity for diagnosing enterolithiasis.[40] Recently, an objective scoring system demonstrated greater efficacy and less interobserver variability than a subjective assessment of radiographic sand accumulation in horses with or without a clinical diagnosis of sand colic.[38] The large size and density of the adult abdomen preclude evaluation of soft tissue structures because the detail and contrast of the radiographs are usually poor, and ultrasonography is a much more useful imaging modality in the equine abdomen.

Administration of contrast (barium sulfate 30% at 5 mL/kg) through a nasogastric tube or retrograde (20 mL/kg) through a 24-Fr Foley catheter inserted into the rectum may be helpful for the diagnosis of gastric outflow obstruction or disorders of the rectum, small colon, or transverse colon, respectively, in foals.[41-44]

ULTRASONOGRAPHY

Transcutaneous ultrasonographic evaluation of the abdomen is quick and noninvasive and can add valuable information in cases of acute or chronic gastrointestinal disease. Ultrasound has become a virtually indispensable tool for horses with acute or chronic gastrointestinal conditions. This section provides a brief summary. Examination of the adult horse requires a 2.5- to 5.0-MHz transducer, depending on size of the horse; a curvilinear transducer is preferred. A functional examination is often performed with isopropyl alcohol saturation alone, although clipping, with or without coupling gel, can be used to enhance evaluation, especially in large or overweight patients.

A protocol for fast localized abdominal sonography (FLASH) has been described and demonstrates good predictive value of the requirement for surgical intervention in the acute abdomen, even with relatively inexperienced examiners.[45] This examination evaluates seven locations (ventral abdomen, gastric window, splenorenal window, left middle third of the abdomen, duodenal window, right middle third of the abdomen, and thoracic window) and can be performed in less than 15 minutes. A complete examination requires a methodical approach to the evaluation of the entire abdomen; details of the examination can be variable based on equipment and experience of the examiner. A complete review of abdominal ultrasound is beyond the scope of this chapter; a thorough, detailed examination is reviewed elsewhere.[46]

In general terms, a quick examination of the acute abdomen should include estimation of gastric size and assessment of small intestinal diameter, wall thickness, motility, and location. Specific abnormalities, such as ascarid impaction or intussusception, may also be visible. Evaluation of the large colon and cecum should include estimation of mural thickening or increased fluidity of contents, and whether or not the colon obscures viewing of the left kidney in the left paralumbar fossa. It is important to remember that other causes of colonic distention can have the same result; thus, it is always important to combine physical, rectal, and ultrasonographic examination findings for any given case. Sand impactions may appear as hyperechoic bands on the ventral abdominal wall,[47] but according to the author and others,[46] ultrasound does not allow for consistent diagnosis of sand accumulation. Evaluation of the abdomen always should include assessment of the peritoneal space for any evidence of an increased amount or echogenicity of PF. Ultrasonography also can be useful in determining the ideal location for abdominocentesis.

NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy has several proposed uses for evaluation of the gastrointestinal tract, although most have been replaced with cross-sectional imaging (dental disease[48,49]), ultrasonography (right dorsal colitis[50]), or other modalities (gastric emptying[51]).

CROSS-SECTIONAL IMAGING

Computed tomography (CT) and, less commonly, magnetic resonance imaging are extremely useful for evaluating dental disease as well as tumors and masses of the head, larynx, pharynx, and proximal esophagus in adult horses[52-55] and some abdominal disorders in foals.[56] Availability, gantry size, and table weight limits provide the biggest limitations for widespread use.

ENDOSCOPY

Endoscopic examination of the gastrointestinal tract begins with evaluation of the pharynx for signs of collapse, dysfunction, or dysphagia. The oral cavity should only be examined endoscopically with the use of heavy sedation or anesthesia and a full-mouth speculum. Indications include examination of the teeth, palate, and tongue for completeness, ulceration, masses, or foreign bodies. The most common gastrointestinal indication is evaluation of the stomach, proximal esophagus, and duodenum, typically with a 3-m flexible endoscope.

The esophagus should be examined aborad to orad because of its collapsible nature. The esophageal mucosa is normally smooth and light pink. Erosion or ulceration can occur secondary to obstruction, reflux esophagitis, or an indwelling nasogastric tube, among other causes. Erosions may be punctate, linear, or circumferential, and their extent (depth, length, etc.) should be evaluated carefully. Distinguishing normal peristaltic contractions from areas of stricture requires observation of the area and its motility over time. Diverticula also may be noted as outpouchings of the mucosa, sometimes associated with a stricture distally. Megaesophagus, although rare, appears as generalized dilation. Reevaluation after resolution of an obstruction is especially important for detecting the presence of complications (ulceration and rupture) or initiating causes (strictures, diverticula, masses).

Gastroscopy is best performed after a minimum 12-hour fast. Complete examination of the stomach, including the antrum and pylorus, and preferably proximal duodenum, is critical to avoid missing lesions in the more aborad regions. The

squamous mucosa should resemble the esophageal mucosa. The glandular mucosa should be glistening red and may have a reticulated pattern. The veterinarian should carefully examine it for evidence of ulceration or masses. Transendoscopic biopsy material can be easily obtained from esophageal, pharyngeal, or gastric masses, and because the biopsy size will be small, several samples should be taken for histopathologic examination. A complete description of gastroscopy and evaluation of gastric and gastroduodenal ulceration are available in Gastroduodenal Ulcer Disease.

TESTS OF ABSORPTION AND DIGESTION

Oral Glucose Tolerance Test

D-Glucose or D-xylose absorption tests are useful in determining malabsorption of carbohydrates from the small intestine in horses. For either test, the horse should be fasted for 14 to 18 hours before testing. Prolonged fasting (≥24 hours) results in a delayed and slightly lower peak plasma glucose concentration.[57] A dosage of 1 g/kg of D-glucose is administered as a 20% solution via nasogastric tube. Xylazine sedation does not appear to significantly alter D-xylose results.[58] Blood glucose or xylose concentrations are then measured 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes after administration. Additional samples can be taken up to 6 hours after dosing if the results are questionable. Sodium fluoride and heparin are the preferred anticoagulants for glucose and xylose, respectively.

A normal D-glucose absorption test, also known as an *oral glucose tolerance test (OGTT),* should peak between 90 and 120 minutes at a glucose concentration >85% above the resting glucose concentration.[59] *Complete malabsorption* is defined as a peak less than 15% above the resting concentration, and *partial malabsorption* is defined as a peak between 15% and 85% above the resting concentration. Gastric emptying, gastrointestinal transit time, length of fasting, glucose and insulin metabolism, age, diet, and endocrine function can influence glucose absorption curves.[59,60] Higher glucose peaks are recorded from healthy animals eating grass or hay than from those eating concentrates[60] and from horses fed a pasture (clover and kikuyu) versus stable (oat hay, complete feed, and alfalfa/oat chaff) diet.[61] Results from the OGTT can also be affected by the content of nonstructural carbohydrate and fat in the diet[62] and other disorders, such as polysaccharide storage myopathy.[63]

Oral Xylose Tolerance Test

The xylose absorption test is performed as per the OGTT, except 0.5 g D-xylose per kilogram body weight is administered as a 10% solution via nasogastric tube. The pretest period of fasting and timing of sample collection are identical. The laboratory to which samples will be sent should be contacted before collection to ensure that heparinized plasma is acceptable for their laboratory. Plasma D-xylose should peak between 20 and 25 mg/dL between 60 and 90 minutes following administration, with occasional peaks as late as 120 minutes.[64,65] D-Xylose absorption testing is not confounded by hormonal effects or mucosal metabolism as is glucose, but it is altered by diet, length of fasting (which could also be influenced by recent appetite or degree of cachexia), and age. Horses fed a high-energy (oat chaff, oats, and corn) diet had a lower mean peak plasma D-xylose concentration (14.1 mg/dL versus 24.9 mg/dL) than those consuming a low-energy (alfalfa chaff) diet.[61] Healthy mares fasted for up to 96 hours had flatter curves and a slower decrease in plasma xylose than when fasted for 12 to 36 hours.[64] Kinetic analysis indicates that prolonged food deprivation does not alter renal or nonrenal excretion of D-xylose; thus, the effect of fasting on the curve is likely related to either intestinal transit, small intestinal absorption, or both.[66,67] Ponies may have lower peak D-xylose concentrations than horses, although the range is wide, and diagnostic discriminatory cutoff points for peak plasma xylose concentrations have not been determined. Foals normally have a higher mean peak xylose concentration at 1 and 2 months of age, but mean peak falls to a level similar to that seen in adults by 3 months of age.[68] Gastric emptying rate, intestinal motility, intraluminal bacterial overgrowth, and renal clearance can affect curve shape.[69]

Lactose Tolerance Testing

Milk intolerance is well documented in children and can result from primary or secondary lactase (neutral β-galactosidase) deficiency. Secondary lactase deficiency can occur when a small intestinal disorder, typically rotavirus, damages the epithelial cells, resulting in decreased brush border disaccharidase activity. Such an association has been reported secondary to clostridial enteritis in the foal.[40] In horses, lactase activity peaks at birth and declines slowly, such that activity is approximately 50% at 2 years of age and rapidly decelerates after 3 years of age, and it is barely detectable by 4 years of age.[41] The oral lactose tolerance test is performed in foals after a 4-hour fast, with a standard dose of 1 g/kg lactose monohydrate given via nasogastric tube as a 20% solution. Blood sampling is as per the OGTT. Plasma glucose typically peaks 60 minutes following lactose administration, with a range from 30 to 90 minutes, with a mean increase of 77 mg/dL, with a 35-mg/dL increase covering 2 standard deviations.[42] Of note, older foals (12 weeks) had a more significant increase in plasma glucose relative to 1-week-old foals.

Evaluation of Gastric Emptying

Assessment of gastric emptying may be useful in cases of gastric and esophageal ulceration or suspected gastric outflow obstruction, although accurate assessment can be challenging.

Contrast radiography can be used in foals. In the normal foal, a significant amount of liquid barium should empty within 2 hours.[41] Nuclear scintigraphy can be used for measurement of liquid[51] or solid phase emptying[70] by use of orally administered ^{99m}Tc pentetate (10 mCi) or a ^{99m}Tc-labeled pelleted ration, respectively.

Alternatively, absorption testing of glucose or xylose (discussed previously) or acetaminophen can be used as an indirect determination of liquid gastric emptying. Acetaminophen absorption is performed by administering 20 mg/kg of acetaminophen orally, sampling blood, then calculating the time to reach maximum serum concentrations and the absorption constant.[71,72] In humans the proximal small intestine absorbs almost all of the acetaminophen.[73] The median time to reach peak plasma levels using acetaminophen absorption in horses is 47.7 minutes.[72]

The ^{13}C-octane acid breath test offers an easy, noninvasive method of determining gastric emptying of solids.[70,74] This test is performed by feeding a standard ^{13}C-labeled test meal and then collecting breath samples using a modified mask. The breath is then analyzed for the ratio of the novel isotope, $13{:}CO_2$, to the normally produced $12{:}CO_2$.

HISTOPATHOLOGIC EXAMINATION

It is often necessary to perform a histopathologic examination of tissues from the intestine to diagnose chronic inflammatory, infiltrative, or neoplastic conditions, and such an examination can be useful in evaluating the extent of injury after obstruction or ischemia. Rectal mucosal biopsies are easy to collect, with few complications. Full-thickness biopsy often provides more thorough analysis and can be directed based on serosal appearance via a flank, ventral midline, or laparoscopic approach. When taking gastric or duodenal biopsies endoscopically for the putative diagnosis of inflammatory bowel disorders, multiple samples are recommended. The likelihood of establishing an accurate diagnosis varies with tissue quality, number of samples, skill of the endoscopist, and submission technique.[75]

Laparoscopy

Laparoscopic evaluation of the equine abdomen requires specialized equipment and training. The laparoscopic procedure can be done with the horse standing or recumbent. Advantages of this technique over a flank or ventral midline celiotomy include smaller incisions, shorter healing time, and shorter procedure time. Disadvantages include equipment and personnel needs, limited therapeutic potential, and limited visual field, especially relative to midline celiotomy. Potential gastrointestinal applications of abdominal laparoscopy include the correction of rectal tears; percutaneous abscess drainage, assessment of adhesions, displacements, and integrity of the serosa of various bowel segments; biopsy of abdominal masses; and closure of the nephrosplenic space.[76-80]

Pathophysiology of Gastrointestinal Inflammation

The inflammatory response of the gastrointestinal tract is a mechanism ultimately aimed at eliminating pathogens, initiating tissue repair, and restoring the gastrointestinal barrier. Blood flow is altered, endothelial permeability increases, cells are rapidly recruited into the tissue, plasma protein cascades are activated, and myriad soluble products are released that coordinate the response, trigger innate and adaptive immunity, and mobilize reparative elements. Although the cellular and vascular response and the secreted mediators of inflammation are important for killing pathogens and limiting invasion of injured tissues by commensal organisms, they can be quite damaging to host cells and proteins if not tightly regulated. If the inciting stimulus is not eliminated quickly, then the inflammatory response itself will cause significant tissue injury. The mechanism regulating inflammation has been the focus of a great deal of research to identify therapeutic targets to modulate the damage to host tissues that occurs in many gastrointestinal diseases. Recent work has provided some of the molecular and cellular details of this complex physiology and has led to novel therapeutic strategies for treating inflammation.

INITIATION OF THE INFLAMMATORY RESPONSE

Epithelium

The gastrointestinal epithelium interfaces with a luminal environment that is inhabited by potentially hostile microbial organisms. The epithelium presents a physical barrier to invasion by the flora of the gastrointestinal tract, consisting of the apical cellular membrane, intercellular tight junctions (the permeability of which is highly regulated), and a secreted layer of mucus. When invading pathogens breach the mucosal barrier, potent soluble and neural signals are generated that initiate an inflammatory response.[81] The epithelium can be conceptualized as a sensory organ that detects pathogen invasion to trigger an appropriate host defense and reparative response.

Noninfectious mucosal injury or invasion of epithelial cells by pathogenic organisms such as *Salmonella* activates the synthesis of proinflammatory chemokines (chemoattractants) by epithelial cells that triggers a robust influx of neutrophils into the tissue within hours of the damage.[81] Of the chemoattractants produced by epithelium, interleukin-8 (IL-8) has a particularly important role in initiating inflammation by recruiting neutrophils from blood[82] and regulating neutrophil migration through tissue matrix adjacent to epithelium.[83,84] Complement fragments such as C5a and bacteria-derived formylated chemotactic peptides also act as potent "end target" chemoattractants that are fully capable of stimulating a robust inflammatory response in the intestine if the epithelial barrier permits invasion of bacteria or the diffusion of bacterial peptides across the mucosa.

Epithelial cells activated during infection produce cytokines such as tumor necrosis factor–α (TNF-α), arachidonic acid metabolites, and other proinflammatory mediators that activate recruited leukocytes.[85] Microbial products, particularly lipopolysaccharide (LPS) and other bacterial cell wall components and microbial nucleic acids, are potent activators of leukocytes recruited into the tissue.[86] Mast cells are key sentinel leukocytes that sense microbial invasion, releasing TNF-α, which appears to be a critical initiator and regulator of the cellular phase of inflammation.[87] Once the inflammatory response has been initiated, TNF-α; IL-1β; and other proinflammatory products of neutrophils, monocytes, mast cells, and epithelial cells amplify the inflammatory response.

The enteric nervous system (ENS) has a key role in sensing and regulating inflammatory responses in the intestine. For example, *C. difficile* toxin A activates a neural pathway that triggers mast cell degranulation and neutrophil influx into the tissue.[88,89] Blockade of this neural pathway is sufficient to abolish the profound inflammatory response induced by toxin A as well as many of the effects of toxin A on enterocyte secretion. Other pathogens and immune-mediated hypersensitivity reactions similarly stimulate inflammation by mechanisms that involve the ENS. Thus the epithelium interacts in a highly complex manner with the intestinal milieu, the ENS, and inflammatory cells to regulate the tissue response to injury and infection.

Macrophages

Resident macrophages located in the lamina propria, submucosa, and intestinal lymphoid organs are among the first cells beyond the epithelium to respond to infection or injury.

Macrophages are activated by microbial products by way of pattern recognition receptors and begin to produce proinflammatory molecules important for recruiting and activating neutrophils and monocytes. Pattern recognition receptors recognize microbial molecules such as LPS, lipoproteins, flagellin, peptidoglycan, and nucleic acids to signal the invasion by pathogens.[86] Of the pattern recognition receptors, the LPS receptor complex is perhaps the best defined. LPS activates macrophages by way of the CD14 Toll-like receptor 4 (TLR-4) complex to initiate transcription of the inflammatory cytokines TNF-α and IL-1β, which synergize with LPS to amplify the macrophage response.[86] LPS, particularly in concert with inflammatory cytokines, stimulates macrophages to produce copious amounts of nitric oxide, which is both microbicidal and vasoactive.[90] Nitric oxide and other nitrogen radicals react with reactive oxygen intermediates (ROIs) generated by the activated oxidase complex to produce some of the most toxic molecules of the host defense system: the peroxynitrites.[90] IL-8 is produced as well to recruit neutrophils. As the response progresses, other inflammatory mediators, particularly the arachidonic acid–derived lipids dependent on inflammation-induced cyclooxygenase (COX)-2 and 5-lipoxygenase activity, are produced that have potent vasoactive and proinflammatory effects through the activation of endothelial cells, neutrophils, and platelets.[91]

VASCULAR RESPONSE DURING INFLAMMATION

Four important changes occur in the intestinal vasculature during inflammation: (1) alteration of blood flow; (2) increased vascular permeability; (3) increased adhesiveness of endothelial cells, leukocytes, and platelets; and (4) exposure of the basement membrane and activation of the complement, contact, and coagulation cascades.

A wide range of mediators alter blood flow during inflammation in the intestinal tract, ranging from gases such as nitric oxide (a major vasodilator of the intestinal vasculature) to lipids (prostaglandins, leukotrienes, thromboxanes, and platelet-activating factor [PAF]), cytokines, bradykinin, histamine, and others. The major sources for these mediators include activated leukocytes, endothelial cells, epithelial cells, and fibroblasts. The primary determinant of blood flow early in inflammation is vascular caliber, which initially decreases in arterioles but then quickly changes to vasodilation coincident with the opening of new capillary beds, increasing net blood flow. The increase in blood flow is relatively short-lived, because the viscosity of the blood increases from fluid loss and tissue edema resulting from leaky capillaries. Leukocyte margination, platelet adhesion to endothelial cells and exposed matrix, and areas of coagulation protein accumulation further decrease local circulation.

Increased vascular permeability is initially caused by inflammatory mediator actions on the endothelial cells. Histamine, leukotrienes, PAF, prostaglandins, bradykinin, and other mediators stimulate endothelial cell contraction, and interendothelial gaps form.[92,93] This stage of increased vascular permeability is readily reversible. Concurrently, mediators such as the cytokines TNF-α and IL-1β induce a structural reorganization of the interendothelial junctions, resulting in frank discontinuities in the endothelial monolayer.[94] Cytokines also stimulate endothelial cells to express adhesion molecules that support adhesion of leukocytes and platelets,[95] leading to the next and perhaps most devastating event. Leukocytes (primarily neutrophils) and platelets adhere to exposed basement membranes and activated endothelial cells. Adherent neutrophils and platelets are then exposed to the mediators of inflammation present in the surrounding milieu, which activates the cells to release oxidants and proteases (particularly elastase) that injure the endothelium and have the potential to cause irreparable harm to the microvasculature.[96-98] Marginated neutrophils begin to transmigrate between endothelial cells (as described in later sections), which, if in sufficiently large numbers, disrupts the integrity of the interendothelial junctions, worsening the vascular leakage.[97]

These stages of enhanced vascular permeability can be conceptualized as a mechanism to allow plasma proteins to enter the tissues and to potentiate the critical influx of leukocytes into tissues. However, if they are not regulated precisely, alterations in both hydrostatic and oncotic forces and irreversible damage to the vascular bed may have devastating consequences. Moreover, inappropriate activation of plasma protein cascades and leukocytes by activated endothelium and exposed matrix proteins can contribute to SIRS (see the later section Gastrointestinal Ileus for more information) characterized by hypotension, generalized vascular leak syndrome, and multiorgan dysfunction, which may be fatal. Phosphodiesterase inhibitors reduce endothelial permeability in ischemia–reperfusion injury and other models of inflammation-induced vascular leakage[99,100] by increasing endothelial tight junction integrity; thus, it may be a viable therapeutic strategy to prevent or reduce the permeability alterations associated with inflammation.

CELLULAR EFFECTORS OF INFLAMMATION

Endothelial Cells

Endothelial cells respond to products of activated epithelial cells and macrophages in the intestinal tissue to recruit cells and humoral mediators of inflammation into the tissue. Activated endothelial cells display a range of molecules critical for neutrophil and platelet adhesion. The role of endothelial cells in mediating neutrophil recruitment is discussed in more detail later in this chapter. Intercellular permeability is increased to expose basement membrane proteins that trigger humoral defense systems (complement, coagulation, and contact system cascades) and to provide access for these macromolecules to the tissue. Endothelial cells are an important source of inflammatory mediators that amplify the response and vasoactive substances (particularly nitric oxide) altering blood flow.

Neutrophils

Recruitment

Infection or injury to the gastrointestinal mucosa causes an influx of leukocytes from the blood that lay the foundation of the inflammatory response. Neutrophils, the first to arrive during inflammation, have a dominant role in the acute response. Within minutes neutrophils are recruited into the tissue, in which they are activated to release products that not only are lethal to pathogens and proinflammatory but also may damage host cells and tissues.[101] Not surprisingly, a great

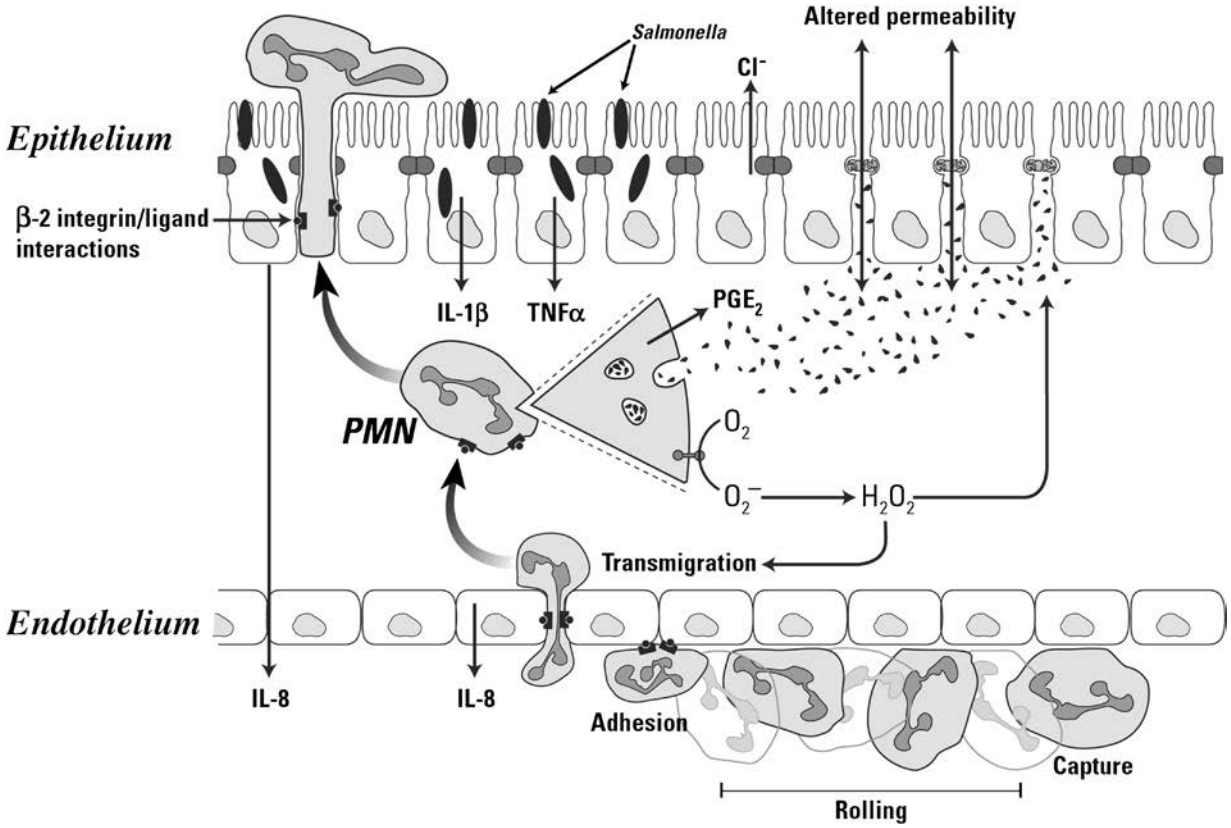

FIG. **12.1** Depiction of neutrophil responses during intestinal inflammation in response to *Salmonella* infection. Salmonellae infect epithelial cells, stimulating the production of chemokines (interleukin-8 [IL-8]), cytokines (IL-1β and tumor necrosis factor-α [TNF-α]), and other proinflammatory mediators. Endothelial cells stimulated by inflammatory mediators produce chemoattractants (such as IL-8) and display adhesion molecules that promote neutrophil emigration. The three steps of neutrophil (polymorphonuclear [PMN]) emigration capture/rolling (mediated by selectins), adhesion (mediated by β_2 integrins), and transendothelial migration (mediated by integrins and platelet/endothelial cellular adhesion molecule) occur on activated endothelium. Chemoattractant molecules such as IL-8 trigger neutrophil emigration. In inflamed tissues cytokines (IL-1β and TNF-α) and a variety of other proinflammatory mediators stimulate the neutrophil oxidase complex to produce reactive oxygen intermediates (ROIs; O_2^- and H_2O_2 and their derivatives). Activated neutrophils degranulate to release proteases and other hydrolases, cationic peptides (defensins), myeloperoxidase, and other products into the tissue. Activated neutrophils synthesize a variety of inflammatory mediators, including prostaglandins (PGE_2) that modulate the inflammatory response. The products of activated neutrophils (ROIs, proteases, and mediators) stimulate epithelial secretion and alter tight junction permeability, promoting diarrhea. Neutrophils eventually migrate across the infected epithelium by a mechanism that involves integrins, disrupting tight junction integrity and increasing permeability to bacterial products, thus exacerbating the inflammatory response.

deal of attention has been paid to the role of neutrophils in the pathophysiology of many inflammatory conditions.[102] Neutrophil depletion is protective in many models of gastrointestinal inflammatory disease. Of interest to clinicians, blockade of neutrophil migration into inflamed tissues prevents many of the pathophysiologic events associated with infectious enteritis, ischemia–reperfusion injury, and other gastrointestinal diseases.[98,103-106]

Neutrophil transendothelial migration is a multistep process that is temporally and spatially regulated and has a degree of cell type specificity (Fig. 12.1). The predominant sites of neutrophil transendothelial migration are in the postcapillary venules and, in some tissues, capillaries. Endothelial cells in these vessels respond to cytokines and other soluble signals by expressing molecules that promote neutrophil adhesion and transmigration, including selectins and counterreceptors for integrins. As neutrophils flow through these vessels, they are first tethered to activated endothelium. Tethering is mediated by selectin molecules expressed on neutrophils (L-selectin) and on activated endothelial cells (P- and E-selectins), which bind to PSGL-1, ESL-1, and other mucin counterreceptors.[107,108] The function of tethering is to increase the exposure of the neutrophil to activating chemokines presented on the surface of the endothelial cells.

Stimulation of neutrophils by IL-8 and other chemokines activate the second step of transendothelial migration. Chemokine binding to their receptors on the neutrophil generates signals that activate the binding of integrin adhesion receptors to their ligands, called *intracellular adhesion molecules* (ICAMs) or *vascular cell adhesion molecules*, expressed on endothelial

cells in inflamed mucosa. Integrin ligation to ICAMs arrests the tethered neutrophils, resulting in firm adhesion to the endothelium. Of the integrins expressed on neutrophils, the β_2-integrins have a particularly important role in transendothelial migration. Calves and people with the disorder leukocyte adhesion deficiency (LAD) illustrate the requirement for β_2-integrin–mediated adhesion in neutrophil function. LAD is a result of an autosomal recessive trait resulting in the lack of the β_2-integrin expression. The neutrophils from affected individuals cannot migrate into most tissues and do not function normally, resulting in poor tissue healing and profound susceptibility to infection, especially at epithelial barriers.[109,110] Other integrins also have a role in transendothelial migration. β_1-Integrins mediate transendothelial migration in some cells and seem to be particularly important for mediating emigration of monocytes into many tissues.[111]

Following this firm adhesion step, neutrophils migrate through the endothelium along a chemotactic gradient of IL-8 and other chemoattractants, such as C5a and leukotriene B_4 (LTB4).[82,97,112] Neutrophils migrate across the endothelial monolayer at intercellular junctions by way of a mechanism involving a series of integrin-ligand interactions mediated by both β_2- and β_1-integrins and other adhesion molecules,[108] which is generally capable of maintaining the integrity of the endothelial barrier.[113] However, a massive flux of neutrophils through the endothelium alters endothelial tight junctions and injures the basement membrane, resulting in increased endothelial permeability to molecules as large as plasma proteins and even endothelial cell detachment from the basement membrane.[96,97] Nonintegrin molecules such as platelet–endothelial cell adhesion molecules (PECAMs) also are involved in transendothelial migration of neutrophils.[108] Homotypic binding of PECAMs on adjacent endothelial cells form part of the intercellular junction. Neutrophils express an integrin of the β_3-family that can bind PECAMs, and through sequential binding of β_3-integrins to PECAMs, the neutrophil can "unzip" the intercellular junction and migrate through, closing it behind itself.

Activation

A key feature of neutrophils and other leukocytes is the requirement for integrin-mediated adhesion to extracellular matrix (ECM) proteins or other cells to achieve an optimal effector phenotype.[114] Critical components of the ECM in inflamed tissues include fibronectin, fibrinogen, and vitronectin, deposited in tissues as a result of plasma leakage and by synthesis of new proteins by stromal cells and resident macrophages in response to inflammatory mediator activation. The changing composition of the matrix proteins deposited in tissues during inflammation serves as a clue as to the nature of the tissue environment for recruited inflammatory cells as they become activated. Individual gene expression studies have demonstrated that adhesion to matrix proteins induces the expression of cytokines and chemokines and their receptors, arachidonic acid–derived lipid mediator synthases, metalloproteinases, growth factors, transcription factors, and other genes that influence the differentiation and activation of inflammatory cells.[115] ROI production, phagocytosis, degranulation, and other effector functions stimulated by inflammatory mediators and bacterial products are optimal only when neutrophils are adherent to the ECM.[114] Adhesion to distinct ECM proteins selectively activates signaling pathways and gene expression of neutrophils, monocytes, and other leukocytes with differing abilities to promote certain functions such that the composition of ECM in many ways controls the development of the ultimate effector phenotype. Thus integrin-mediated adhesion provides a mechanism in which neutrophils and other leukocytes can sense the complex tissue environment and respond appropriately.

Of the activators of neutrophils at sites of inflammation, complement (C3-opsonized particles), cytokines (TNF-α and IL-1β), PAF, immune complexes, and bacterial products are among the most potent stimuli. Other mediators produced during inflammation may modify neutrophil activity, particularly formylated bacterial peptides, chemokines, complement fragments (C5a), LTB_4, and prostaglandins. Activated neutrophils are highly phagocytic; produce large amounts of ROI; degranulate to release myeloperoxidase, cationic antimicrobial peptides (defensins), serine proteases (mainly elastase), and metalloproteinases; and secrete inflammatory mediators (TNF-α, IL-1β, prostaglandins, leukotrienes, and others) (see Fig. 12.1).

Mast Cells

Mast cells strategically reside in mucosal tissues, including the submucosa and lamina propria of the gastrointestinal tract, and constitute a crucial first line of defense at epithelial barriers. However, they are also important effector cells of the pathophysiology of inflammatory gastrointestinal diseases.[116] Experimental depletion of mast cells, genetic deficiency in the development of mast cells, or pharmacologic stabilization of mast cells to prevent degranulation all have a protective effect in a variety of models of gastrointestinal inflammatory disease, including dextran sulfate sodium–induced or trinitrobenzenesulfonic acid–induced colitis,[117,118] ischemia–reperfusion injury,[119,120] and immediate hypersensitivity responses.[121]

Mast cells are activated by a wide variety of microbial products and host-derived mediators.[122] Among the activators of mast cells, the so-called anaphylatoxins (complement fragments C3a, C5a, and C4a) are extremely potent stimuli causing release of mediators of inflammation. In addition, mast cells are the primary effector cells of IgE-mediated anaphylaxis (type I hypersensitivity reactions) by virtue of their high-affinity receptors for IgE. The cross-linking of a receptor-bound IgE on the mast cell surface by antigens (i.e., food antigens) causes rapid degranulation, which results in the explosive release of granule contents.[123] Neural pathways in the intestine also regulate mast cells, which respond to enteric pathogen invasion via neural reflexes that stimulate the release of inflammatory mediators.

Activated mast cells release preformed histamine, 5-hydroxytryptamine (5-HT), proteases, heparin, and cytokines from granules. Activation also stimulates de novo synthesis of a range of inflammatory mediators, including prostaglandins, PAF, and leukotrienes. Transcription of a number of peptide mediators, such as the cytokines TNF-α and IL-1β among many others, also increases stimulation of mast cells. Mast cell products have profound effects on the vasculature, increasing endothelial permeability and causing vasodilation.[124] Moreover, mast cell–derived mediators markedly enhance epithelial secretion by a mechanism that involves the activation of neural pathways and direct stimulation of epithelial cells.[123] In particular, the mast cell granule protease tryptase operating via the protease-activated receptor-2 is a key regulator of gastrointestinal physiologic responses during inflammation, including epithelial secretion and intercellular

junction integrity, motility, and pain responses.[125,126] Mast cell products significantly alter intestinal motility, generally increasing transit and expulsion of intestinal contents. Mast cell–derived leukotrienes and TNF-α also have crucial roles in host defense against bacterial pathogens, acting to recruit and activate neutrophils,[127,128] and are crucial players in the mechanism regulating dendritic cell function and adaptive immune responses.[129]

Mast cells have a role in host defense and inflammatory responses to bacterial pathogens, partly because of the release of proinflammatory mediators during bacterial infection, which is critical for recruiting and activating other innate host defense cells such as neutrophils.[87] Mast cells are also phagocytic, have microbicidal properties, and can act as antigen-presenting cells to the adaptive immune system.[87] The role for mast cells in host protective responses appears to be as a sensor of bacterial invasion. Unlike IgE-mediated responses, bacterial products seem to elicit a highly regulated and selective response from mast cells.

Humoral Mediators of Inflammation

Complement

The complement cascade is a fundamental part of the inflammatory response. Activation of the complement cascade, either by immune complexes (classical pathway) or by bacteria or bacterial products, polysaccharides, viruses, fungi, or host cells (alternative pathway), results in the deposition of complement proteins on the activating surface and the release of soluble proteolytic fragments of several complement components.[130] In particular, activation of either pathway results in the deposition of various fragments of the complement protein C3, which are potent activators of neutrophils and monocytes.[130] Opsonization of particles with C3 fragments constitutes a major mechanism of target recognition and phagocyte activation.[131] During the activation of the complement cascade culminating in deposition of C3, soluble fragments of C3 (C3a), C5 (C5a), and C4 (C4a) are liberated. These fragments, termed *anaphylatoxins,* have potent effects on tissues and cells during inflammation. Perhaps most notably, they are chemotactic for neutrophils (particularly C5a), activate neutrophil and mast cell degranulation, and stimulate reactive oxygen metabolite release from neutrophils.[130] The termination of the complement cascade results in the formation of a membrane attack complex in membranes at the site of complement activation. If this occurs on host cells such as endothelium, the cell may be irreversibly injured. Although the primary source of complement is plasma, epithelial cells of the gastrointestinal tract also produce C3, suggesting that local production and activation of the complement cascade during inflammation occurs in intestinal tissues.

It is clear that if the regulatory mechanisms of the complement cascade fail, then the inflammatory response may be inappropriate and tissue injury can occur. The role of complement in gastrointestinal inflammation has been most extensively studied in models of ischemia–reperfusion injury. Activation of the complement cascades has a major role in altered endothelial and epithelial permeability in these models. Several lines of evidence support the importance of complement in intestinal injury. Mice deficient in C3 or C4 are protected against ischemia–reperfusion injury.[132] Moreover, administration of monoclonal antibodies against C5 reduced local and remote injury and inflammation during intestinal reperfusion injury in a rat model.[133] Administration of a soluble form of complement receptor 1, a regulatory protein that halts the complement cascade by dissociating C3 and C5 on host cell membranes, reduced mucosal permeability, neutrophil influx, and LTB4 production during ischemia–reperfusion injury in rats and mice.[132,134] Although neutrophils and mast cells mediate many of the pathophysiologic effects of the complement cascade, the membrane attack complex may have a primary role in altered vascular permeability during ischemia–reperfusion injury.[135]

Contact System

The contact system of plasma is initiated by four components: Hageman factor (HF), prekallikrein, factor XI, and high-molecular-weight kininogen. HF is a large plasma glycoprotein that binds avidly to negatively charged surfaces.[136] Bacterial cell walls, vascular basement membranes, heparin, glycosaminoglycans, and other negatively charged surfaces in the intestine capture HF and the other three important initiators of the contact system in a large multimolecular complex. Of the surfaces that bind HF, the ECM is an extremely potent activator of the contact system. Once bound, HF is converted to HF-α, which cleaves prekallikrein to kallikrein and factor XI to factor XIa. The ultimate result is further cleavage of HF by kallikrein and triggering of the contact system cascade, activation of intrinsic coagulation by factor XIa, activation of the alternative pathway by HF, and proteolytic cleavage of high-molecular-weight kininogen by kallikrein, releasing biologically active kinins.

The products of the contact system, particularly bradykinin, have several important biologic properties that drive many of the vascular and leukocyte responses during inflammation.[136] Bradykinin induces endothelial cell contracture and intracellular tight junction alterations that increase vascular permeability to fluid and macromolecules. Bradykinin also affects vascular smooth muscle contracture, resulting in either vasoconstriction or vasodilation, depending on the location. Bradykinin also increases intestinal motility, enhances chloride secretion by the intestinal mucosa, and intensifies gastrointestinal pain. In neutrophils kinins stimulate the release of many inflammatory mediators, including cytokines, prostaglandins, leukotrienes, and ROIs.[137] Kallikrein cleaves C5 to release C5a, a potent chemotactic factor for neutrophils, and thus has a role in recruiting and activating inflammatory leukocytes.

The plasma kallikrein–bradykinin system is activated in a variety of acute and chronic inflammatory diseases of the gastrointestinal tract.[138,139] Blockade of the pathophysiologic effects of bradykinin has clinical applications. Oral or intravenous (IV) administration of the bradykinin receptor antagonist icatibant reduces the clinical signs, onset of diarrhea, and many of the histopathologic changes in experimental models of colitis in mice.[140] Inhibition of kallikrein by oral administration of P8720 attenuated the intestinal inflammation, clinical score, and systemic manifestations in a model of chronic granulomatous enterocolitis.[138] Thus the contact system is a potential therapeutic target for inflammatory diseases of the intestine.

TISSUE INJURY DURING INFLAMMATION

Changes in blood flow to the mucosa and other regions of the intestine that reduce perfusion of the tissues can potentiate the initial damage caused by infection or injury. For example,

reperfusion of ischemic tissues is associated with platelet and neutrophil clumping in the small vessels of the mucosa, which can impede blood flow.[141] Platelets are activated and adhere to exposed basement membrane and activated endothelial cells and provide a surface for leukocyte adhesion. The accumulation of platelets and leukocytes can significantly reduce vessel diameter and blood flow while potentiating local coagulation and thrombus formation.

Soluble mediators released by activated leukocytes and endothelial cells also affect blood flow. Histamine and the vasoactive lipids derived from arachidonic acid (leukotrienes, prostaglandins, thromboxane, prostacyclin, and PAF) have a prominent role in regulating local perfusion during inflammation and may have systemic effects on blood flow as well. Procoagulant mediators released by inflammatory cells in response to the inflammatory process (i.e., tissue factor produced by macrophages or endothelial cells), exposed basement membrane proteins, and bacterial components can trigger the contact system and the coagulation and complement cascades, the products of which affect blood flow. Nitric oxide, whether produced by endothelial cells or leukocytes (macrophages), is a potent regulator of blood flow and has a significant role in the control of perfusion during inflammation.[142] Many of the mediators that affect perfusion also affect endothelial permeability, altering osmotic and hydrostatic balance and tissue edema. In extreme cases local and systemic coagulopathies initiated by vascular injury and absorption of microbial products and inflammatory mediators induce a hypercoagulable state, leading to microthrombus formation, which can reduce blood flow or macrothrombus formation, causing tissue infarction.

The cellular mediators of inflammation have the potential to inflict severe injury to intestinal tissues. Neutrophils have an important role in the pathophysiology of many intestinal diseases, including ischemia–reperfusion injury,[98] infectious enterocolitis,[105,143] nonsteroidal antiinflammatory drug–induced mucosal ulceration,[106] and others. Depletion of neutrophils, blockade of their emigration into tissues, or inhibition of neutrophil activation reduces the severity of these and other inflammatory diseases.[144] Many antiinflammatory therapies are emerging that specifically target neutrophil adhesion, migration, and activation.

Migration of neutrophils through endothelium during emigration into inflamed tissues is remarkable in that the permeability of the endothelial monolayer is preserved under most circumstances. However, there is a limit above which neutrophil migration alters the permeability characteristics of the endothelium. The effect is in part physical in that the mere movement of large numbers of neutrophils through the endothelium is sufficient to mechanically disrupt the tight junctions and in part because of toxic products of neutrophils that damage endothelial cells and basement membranes.[141,145] Serine proteases (particularly elastase) and metalloproteinases released by degranulating neutrophils liquefy tissue matrix proteins and cleave cell-surface proteins that make up endothelial intercellular junctions to ease neutrophil migration to the site of infection.[101] These degradative enzymes are particularly damaging to basement membranes and the cellular barriers of the endothelium, thus contributing to vascular permeability (and local tissue edema) and thrombosis. The permeability may be affected to the extent that not only water but also macromolecules (e.g., albumin, matrix proteins, complement) leak into the interstitium. Blockade of neutrophil adhesion to endothelium with anti–β_2-integrin antibodies has a sparing effect on the microvasculature in experimental intestinal ischemia–reperfusion injury, reducing the alterations in vascular permeability and histopathologic evidence of microvascular damage.[141]

Similar to the endothelium of inflamed tissues, massive neutrophil transmigration occurs across the epithelium in response to infection or injury. Neutrophil transepithelial migration increases epithelial permeability by disrupting tight junctions.[145] Like the endothelium, neutrophils disrupt the epithelial barrier mechanically as they migrate through (see Fig. 12.1). Proteases, particularly elastase, degrade basement membrane components and tight junction proteins. Protease activated receptor-2 activated by neutrophil granule serine proteases alter epithelial and endothelial tight junction integrity. Proinflammatory products of activated neutrophils (TNF-α and IFN-γ) increase tight junction permeability by direct effects on enterocytes. Prostaglandins released by activated neutrophils stimulate epithelial secretion, thus contributing to diarrhea. Subepithelial accumulation of neutrophils can lead to deadhesion of the epithelial cells from the basement membrane and mild to severe ulceration. The physiologic result of the effects of neutrophils and their products on the epithelial barrier includes protein-losing enteropathy and absorption of bacterial cell wall constituents, which potentiates the local and systemic inflammatory responses.

Neutrophils in inflamed tissues stimulated by potent host-derived activators (such as IL-1β and TNF-α) and bacterial products (LPS) release copious amounts of ROIs (see Fig. 12.1). Although these oxygen and oxyhalide radicals are important for killing pathogens, they are also potentially toxic to epithelial and endothelial cells and matrix proteins. Reactive nitrogen intermediates, produced primarily by macrophages during inflammation, combine with ROIs to form peroxynitrites, which are particularly toxic.[90] In addition to injury to mucosal tissues, ROIs also have an as yet ill-defined role in recruiting and activating neutrophils, potentiating the inflammatory response.[146] In support of the role of ROIs in inflammatory diseases of the gastrointestinal tract, administration of inhibitors of ROI production or pharmacologic ROI scavengers can be protective in many models of reperfusion injury or enterocolitis. Many therapies are aimed at inhibiting neutrophil activation, and effector functions in tissues have been evaluated for use in intestinal diseases. Phosphodiesterase inhibitors, by causing cyclic adenosine monophosphate (cAMP) accumulation in neutrophils, are antiinflammatory by virtue of their ability to suppress neutrophil activation and ROI production. New phosphodiesterase inhibitors selective for the predominant neutrophil isoform of phosphodiesterase hold promise for use in many inflammatory diseases.

Subepithelial mast cells also have an important role in altering epithelial permeability in inflamed intestine. During the intestinal hypersensitivity response subepithelial mast cell release of mast cell protease tryptase by degranulation increases epithelial permeability via an effect on tight junctions.[147,148] This alteration in tight junction permeability results in enhanced transepithelial flux of macromolecules, including proteins and bacterial products. Cytokines released by mast cells and phagocytes also regulate tight junction permeability. IL-4, a product of mast cells and macrophages, has been demonstrated to increase epithelial permeability.[149] Moreover, TNF-α and IFN-γ, products of many inflammatory cells, synergistically increase tight junction permeability.[150]

PATHOPHYSIOLOGY OF DIARRHEA

Acute equine colitis causes rapid, severe debilitation and, often, death in horses. Diarrhea associated with acute equine colitis occurs sporadically and is characterized by intraluminal sequestration of fluid, moderate to severe colic (abdominal pain), and profuse watery diarrhea with resultant endotoxemia, leukopenia, and hypovolemia.[151,152] Causes of acute colitis and therapeutic options are discussed later in this section.

Although all mechanisms responsible for fluid losses are not known, inflammatory cells likely play an integral role; colitis is characterized by granulocyte infiltration of the large intestinal mucosa.[153-157] Equine cecal and colonic tissues collected during the acute stages of experimentally induced acute equine colitis (Potomac horse fever, lincomycin with and without *Clostridium* spp. inoculation, nonsteroidal antiinflammatory drug administration) reveal the presence of numerous neutrophils and eosinophils in the lamina propria and submucosa.[153,156,158,159] Granulocyte-derived ROIs are crucial to antimicrobial defenses in the gut and stimulate chloride and water secretion by interactions with enterocytes.[160,161] Normal equine intestinal tissue is unique compared with that in most other mammalian species for a preponderance of eosinophils located in the intestinal mucosa and submucosa.[162,163] Production of ROIs by stimulated phagocytic granulocytes following mucosal barrier disruption may be responsible for the massive fluid secretory response that occurs during the early stages of acute equine colitis.

Colitis refers to inflammation and mucosal injury of the colon and cecum (typhlocolitis) that may occur in response to a number of causes.[164] The cause of the colonic injury may be well defined such as in naturally occurring infectious or experimentally induced colitis. However, many cases of human and animal diarrhea have a speculative or unknown diagnosis or no diagnosis. Irrespective of the underlying or initiating cause of colonic injury, the colon apparently has a limited repertoire of responses to damage because most forms of colitis demonstrate similarities in histopathologic appearance and clinical presentation. Various degrees of mucosal erosion and ulceration, submucosal/mucosal edema, goblet cell depletion, and the presence of an inflammatory cellular infiltrate within the mucosa and submucosa are common to many types of human and animal colitis.[163,164] Characteristic clinical manifestations include intraluminal fluid sequestration; abdominal discomfort; hypovolemia; and most often profuse, watery diarrhea.

PATHOPHYSIOLOGY OF COLITIS

Large bowel diarrhea results from abnormal fluid and ion transport by cecal and colonic mucosa. Loss of fluid by the large intestine can result from malabsorptive or hypersecretory processes and is often a combination of the two.[165] Colonic secretory processes are a function of the crypt epithelium, whereas absorptive processes are limited to surface epithelial cells.[166,167] Under normal baseline conditions, an underlying secretion by crypt epithelium is masked by a greater rate of surface epithelial cell absorption. Abnormal forces influencing the rates of secretion and absorption can result in massive, uncontrolled secretion and malabsorption by large intestinal mucosal epithelial cells, leading to rapid dehydration and death.[165-167]

Two intracellular processes control colonic secretion: the cyclic nucleotide (cAMP and cyclic guanosine monophosphate [cGMP]) and the calcium systems.[168,169] Agents may activate adenyl cyclase (vasoactive intestinal peptide, prostaglandin E2 [PGE_2]) or guanylyl cyclase (bacterial enterotoxins) and induce increases in cAMP or cGMP, respectively. This reaction causes phosphorylation of specific protein kinases that induce the actual apical and basolateral membrane transport events. Increases in intracellular free calcium may arise from cyclic nucleotide–dependent release of stored calcium within the cell or from increased calcium entry across the cell membrane.[165-167] Calcium may act through calmodulin, which then can activate membrane-phosphorylating protein kinases.

At least four central systems control intestinal secretion: (1) the hormonal system, (2) the ENS, (3) bacterial enterotoxins, and (4) the immune system.[169,170] Hormonal control of colonic electrolyte transport is exerted primarily through the renin–angiotensin–aldosterone axis.[171] The ENS controls transport through three separate components: (1) extrinsic nerves of the parasympathetic and sympathetic pathways; (2) intrinsic ganglia and nerves, secreting a variety of neurotransmitters including peptides; and (3) neuroendocrine cells (intraepithelial lymphocytes) that reside in the epithelium and release messengers onto the epithelial cells in a paracrine manner.[165,169-171] Many bacterial enterotoxins can induce intestinal secretion by cAMP or cGMP signal transduction.[172] Bacterial enterotoxins can stimulate release of mediators (such as substance P) from primary afferent neurons, which then affect enteric neurons, often propagating neurogenic inflammation.[173]

Preformed inflammatory mediators such as histamine, serotonin, or adenosine and newly synthesized mediators such as prostaglandins, leukotrienes, PAF, various cytokines, the inducible form of nitric oxide, and reactive oxygen metabolites can initiate intestinal secretion by directly stimulating the enterocyte and by acting on enteric nerves indirectly to induce neurotransmitter-mediator intestinal secretion.[170] Prostaglandins of the E and F series can cause an increase in chloride secretion in intact tissue and isolated colonic cells.[174,175] Leukotrienes, PAF, and a number of cytokines have been shown to have no effect on T84 cell secretion but have a significant effect on electrolyte transport in intact tissue, suggesting that intermediate cell types may be involved in these secretory responses.[176-178]

The epithelial cell chloride secretory response occurs via prostaglandin-mediated and adenosine-mediated increases in cellular cAMP, whereas histamine acts by H_1 receptor induction of phosphatidylinositol turnover, production of inositol triphosphate, and mobilization of intracellular calcium stores.[170] Lipoxygenase products (leukotrienes) are capable of activating a colonic secretory response and do not appear to involve the cyclic nucleotides or calcium ions.[176] Phagocyte-derived reactive oxygen mediators (ROMs) can induce colonic electrolyte secretion in vitro, suggesting that oxidants may contribute directly to the diarrhea associated with colitis.[179] Reactive oxygen species initiate the secretory response by increasing cellular cAMP or stimulating mesenchymal release of PGE_2 or prostacyclin, which in turn stimulates the epithelial cell or enteric neuron, respectively.[179-182] Sodium nitroprusside, an exogenous source of nitric oxide, stimulated an increase in chloride secretion in rat colon that was mediated by COX products and enteric neurons.[183] Table 12.1 summarizes inflammatory mediator–induced epithelial cell chloride secretion.

TABLE **12.1 Inflammatory Mediators That Stimulate Epithelial Cell Chloride Secretion**

Mediator	Action
Prostaglandin E_2	Increases Cl secretion
	Decreases neutral NaCl absorption
Vasoactive intestinal peptide	Increases cAMP-mediated NaCl secretion
	Activates cholinergic nerves
Endotoxin	Increases Na absorption
	Increases cell membrane permeability
Serotonin	Increases fluid and electrolyte secretion
Interferon-γ	Decreases tight junctions and causes increase in cell membrane permeability
Interleukin-1 and interleukin-1β	Increase prostaglandins E_2 and $F_1\alpha$ and thromboxane B_2
Histamine (H_1)	Increases Cl secretion via Ca-mediated pathways
Bradykinin	Increases Cl secretion through prostaglandin-mediated pathways
Reactive oxygen mediators	Increase Cl secretion
Thromboxanes	Increase Cl secretion
	Decrease neutral NaCl absorption
Lipoxygenase products	Increase Cl secretion via prostaglandin-mediated pathways
Platelet-activating factor	Increases Isc (Cl secretion)
Adenosine	Increases Cl secretion

cAMP, Cyclic adenosine monophosphate.

ROLE OF INFLAMMATORY CELLS

Acute colitis rarely develops by a simple cause or effect phenomenon but is influenced by many extrinsic and intrinsic host and microorganism factors. Inflammatory mediators released from mast cells and monocytic or granulocytic phagocytes cause intestinal chloride and water secretion and inhibit neutral sodium and chloride absorption.[169,170,184] Inflammatory cells, particularly the phagocytic granulocytes, play an important role in mucosal pathophysiology in cases of colitis.[161,185] Large numbers of these cells are observed on histopathologic examination of tissues from human and animal cases of colitis. Products of cell activation stimulate direct and indirect secretory responses in intestinal cells and tissues.[169,170] Products of phagocyte secretion may amplify the inflammatory signal or have effects on other target cells in intestine such as enterocytes and smooth muscle cells.

ROLE OF PHAGOCYTE-DERIVED REACTIVE OXYGEN METABOLITES

The nicotinamide adenine dinucleotide phosphate (NADPH)-NADPH oxidase system of phagocytes (neutrophils, eosinophils, and monocytes/macrophages) is a potent inducer of superoxide radicals used as a host defense mechanism to kill invading microorganisms.[161] During inappropriate stimulation such as inflammation, trauma, or ischemia followed by reperfusion, increased levels of toxic oxygen species are produced, causing damage to host tissues. Engagement of any of several receptor and nonreceptor types including phagocytosis mediators, chemotactic agents, various cytokines, and microbial products can stimulate phagocytes.[161] Resident phagocytes or those recruited to colonic mucosa early in the disease process are considered to augment mechanisms causing fluid and electrolyte secretory processes, a so-called amplification process.[104,186]

Activation of the respiratory burst results in the production and release of large amounts of superoxide anion (O_2^-) and H_2O_2.[187] In addition to these ROMs, activated phagocytes secrete peroxidase enzyme (myeloperoxidase from neutrophils and eosinophil peroxidase from eosinophils) into the extracellular space. The peroxidases catalyze the oxidation of Cl^- by H_2O_2 to yield HOCl, the active ingredient in household bleach products. The peroxidase–H_2O_2–halide system is the most cytotoxic system of the phagocytes; HOCl is 100 to 1000 times more toxic than O_2^- or H_2O_2. HOCl is a nonspecific oxidizing and chlorinating agent that reacts rapidly with a variety of biologic compounds including DNA, sulfhydryls, nucleotides, amino acids, and other nitrogen-containing compounds. It reacts rapidly with primary amines to produce the cytotoxic *N*-chloramines. The mechanisms by which these substances damage cells and tissue remain speculative, but possibilities include direct sulfhydryl oxidation, hemoprotein inactivation, protein and amino acid degradation, and inactivation of metabolic cofactors of DNA.[188] Luminal perfusion of specific ROMs increased mucosal permeability, and serosal application caused increases in Cl^- secretion in vitro.[189] Tissue myeloperoxidase activity, an index of tissue granulocyte infiltration, is used experimentally to assess intestinal inflammation.[190] Myeloperoxidase activity is elevated in acute flare-ups of human inflammatory bowel disease and various animal models of acute colitis.[190-192] The acute inflammatory response in these conditions is characterized predominantly by neutrophils, although this assay measures total hemoprotein peroxidase, which includes monocyte and eosinophil peroxidase in addition to neutrophils.[193] Moreover, levels of peroxidase activity in equine circulating eosinophils are greater than in circulating neutrophils,[194] and this may apply to resident tissue eosinophils as well.

Arachidonic acid metabolites are thought to play a role in intestinal inflammation in diarrheal disease.[170] Elevated levels of these intermediate metabolites have been demonstrated in natural disease and experimental models of colitis and appear to parallel increases in ROMs in inflamed intestine.[195] The addition of H_2O_2 or HOCl to rat colonic tissue in Ussing chambers induces PGE_2 release and active Cl^- secretion.[182,196] Prostaglandins can stimulate increases in Cl^- secretion in intact intestinal tissue[181,196,197] and in isolated colonic T84 cells.[180,182] Interactions between ROMs and mesenchymal release of PGE_2/PGI_2 may be relevant to the mechanisms producing the diarrheic condition. Fibroblasts cocultured or juxtaposed to colonic T84 cells greatly increased the Cl^- secretory response to H_2O_2 in vitro through the release of PGE_2.[180] In addition, equine colonic mucosa has an increased sensitivity to endogenously released prostaglandin by exhibiting a significant secretory response under in vitro conditions.[198]

ROLE OF OTHER FACTORS

Endotoxin

Endotoxin, the LPS component of the outer cell wall of gram-negative bacteria, is present in large quantities in the large intestine of healthy horses.[194,198] The intact bowel forms an effective barrier to the transport of significant amounts of these highly antigenic toxins, but the diseased gut absorbs these macromolecules in large amounts, causing the subsequent adverse systemic effects that are often life-threatening.[199] A complete review of endotoxemia is presented later in this chapter.

Endotoxins trigger mucosal immune cells and subsequent release of inflammatory mediators in cases of colitis. In vitro studies on the effects of endotoxin on intestinal water and electrolyte transport in adult male rats showed a significant decrease in net colonic sodium absorption and increased colonic permeability.[200] In horses, endotoxin negatively affects gastrointestinal motility, including in the cecum and right ventral colon, and perfusion.[201]

Immunodeficiency

The importance of a normal immune system to the defense of the mucosal surface of the gastrointestinal tract is evident in the immunosuppressed state. Primary immunodeficiencies affecting the gastrointestinal tract are well documented. Common agammaglobulinemia is the most frequently reported gastrointestinal immunodeficiency and causes B-cell deficiency–associated giardiasis in other species.[202] In horses, severe combined immunodeficiency can result in diarrhea secondary to adenovirus, coronavirus, and/or *Cryptosporidium* infection.[203,204] Interestingly, selective immunoglobulin A (IgA) deficiency rarely results in intestinal disease because of a speculated increase in mucosal IgM response. However, combined IgA and IgM deficiencies with a higher incidence of intestinal disease occur. A selective deficiency of secretory IgA has been associated with intestinal candidiasis in other species. Certain mucosal pathogens may enhance their pathogenicity by producing IgA proteases.[202] Acquired immunodeficiency or immunosuppression in adults can result from infectious diseases (particularly viral), nutritional deficiencies, aging phenomena, and drugs (corticosteroids, azathioprine, and cyclophosphamide). Chronic salmonellosis was documented secondary to adult-onset B-cell deficiency in a Quarter Horse.[205]

Nutritional Deficiencies

Nutrition is a critical determinant of immunocompetence and risk of illness in many species.[206] Impaired systemic and mucosal immunity contributes to an increased frequency and severity of intestinal infections observed in patients with undernourishment. Abnormalities occur in cell-mediated immunity, complement system, phagocytic function, mucosal secretory antibody response, and antibody affinity. Morbidity caused by diarrheal disease is increased, particularly among individuals with stunted growth rate because of malnourishment.[207] The interaction between nutritional deficiency and intestinal health in the horse requires further investigation.

Intestinal Microbiota

Recently knowledge regarding the equine intestinal microbiota has expended dramatically. The intestinal microbiome is complex, and additional discussion is provided in Chapter 1 of this text. Briefly, fecal microbiota varies widely between healthy horses and those with colitis,[208] and changes can precede episodes of colic in postpartum mares.[209] The intestinal microbiota is affected by antimicrobial administration,[210] transport, fasting and anesthesia,[211] and dietary starch,[212] among other factors; many of these have been associated with the development of colitis.

Factors Affecting Motility

Disturbances in motility patterns occur during inflammatory diseases of the colon, but the role of motility alterations in the pathogenesis of diarrhea remains unclear. Invasive bacteria cause characteristic motor patterns in the colon consisting of rapid bursts of motor activity that appear to decrease transit time through the large intestine. The result is reduced clearance of bacteria from the large intestine, which may contribute to the virulence of the organism.[213] Absorption of endotoxin and the release of inflammatory mediators such as prostaglandins disrupts the motility patterns of the large intestine, resulting in less coordinated contractions, and may contribute to the alterations in motility seen with invasive bacteria. Although the effect of endotoxin and prostaglandins on transit time is not profound, the disruption of coordinated activity may play a role in causing diarrhea.[214] Thorough mixing and prolonged retention time of ingesta are important not only in microbial digestion of nutrients but also in absorption of microbial byproducts and fluid.[171] The ingesta is viscous and therefore must be mixed to bring luminal ingesta in contact with the mucosa for absorption. In addition, poor mixing increases the thickness of the unstirred layer, decreasing contact of ingesta with the mucosa and decreasing absorption.[171]

Progressive motility must be present, however, if a diarrheal state is to occur.[171] Ileus may be accompanied by increased fluid in the lumen of the large intestine, but without progressive motility the fluid is not passed. Acute colitis is often associated with a period of ileus characterized by scant stool, which may be the reason for signs of colic in the early stages of colitis. Diarrhea is apparent only when motility returns. Increased progressive motility has been suggested to contribute to diarrhea by decreasing transit time; this is thought to play a role in irritant catharsis and in the mechanism of action of some laxatives.[3]

Endotoxemia

Endotoxemia is literally defined as the presence of endotoxin in the bloodstream. Most often, however, the term is used to refer to the associated clinical manifestations caused by an excessive and unbalanced inflammatory reaction. Endotoxemia is not a disease in its own right; rather, it is a complication of many septic and nonseptic disease processes affecting horses and other animals. Its diagnosis and management must therefore be discussed in the context of underlying primary pathologic conditions.

In its pathophysiologic consequences the innate immune response to endotoxin (LPS) is similar to the response to other stimuli (e.g., bacterial infection, viral infection, severe trauma). Moreover, the clinical presentation and clinical pathologic abnormalities of patients suffering from severe systemic inflammation are consistent regardless of the etiologic cause, and outcome may be predicted more accurately by the severity of the inflammatory response than the nature of the

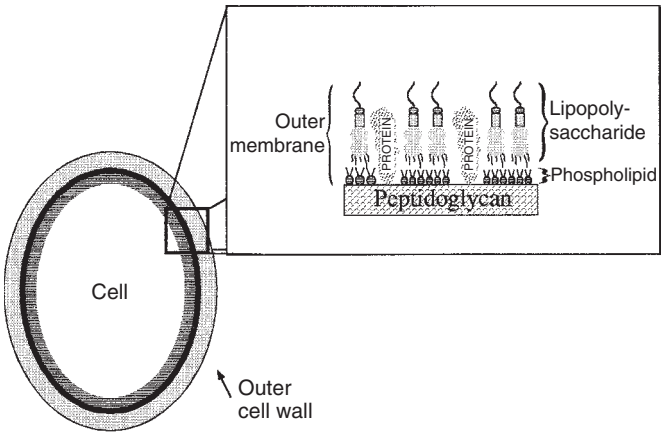

FIG. **12.2** Lipopolysaccharide.

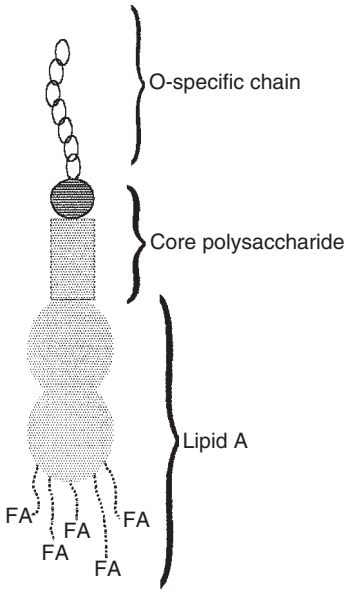

FIG. **12.3** Three domains of the lipopolysaccharide molecule. *FA*, fatty acid.

inciting insult.[215] In 1992, therefore, the term *systemic inflammatory response syndrome* (SIRS) was introduced in a consensus statement of chest physicians and critical care physicians to account for these similarities and provide a case definition for clinical and research purposes. Fairly soon thereafter, however, the 1992 SIRS definition was criticized as being too sensitive while providing little specificity,[216] and its usefulness for clinical practice was challenged because it failed to predict outcome and to discriminate patients at a high risk of morbidity and mortality.[217] The definition of *SIRS* may therefore be valuable from a conceptual standpoint, but it has little value in daily clinical practice.

Sepsis was defined as the systemic inflammatory response to infection, and *septic shock* as "sepsis-induced hypotension, persisting despite adequate fluid resuscitation, along with the presence of hypoperfusion abnormalities or organ dysfunction."[215] According to these definitions the diagnosis of sepsis requires documentation of infection by culture in addition to two or more of the following findings: hypothermia or hyperthermia; tachycardia; tachypnea or hypocapnia; and leukocytosis, leukopenia, or an increased proportion of immature leukocyte forms.

Organ failure is a common sequela of endotoxic or septic shock, and the term *multiple organ dysfunction syndrome* describes insufficiency of two or more organ systems, as evident by clinical or clinicopathologic changes. In horses the laminae of the feet should be included in the list of organs susceptible to failure.

German scientist Richard Pfeiffer (1858–1945), in working with *Vibrio cholerae,* first described endotoxin as a toxin "closely attached to, and probably integral of, the bacterial body."[218] He observed this toxin to be distinct from the actively secreted, heat-labile, and proteinaceous bacterial exotoxins. Endotoxin later was found to be a heat-stable LPS structure, and the terms *endotoxin* and *LPS* now are often used interchangeably.

LPS is a major structural cell wall component of all gram-negative bacteria, including noninfectious species (Fig. 12.2). With 3 to 4 × 10^6 molecules per cell, LPS makes up about 75% of the outer layer of the outer cell membrane and is a key functional molecule for the bacterial outer membrane, serving as a permeability barrier against external noxious agents. The LPS molecule consists of four domains that are essential for the virulence of gram-negative bacteria.[219] Three of the domains (inner core, outer core, and O-specific chain) represent the hydrophilic polysaccharide portion of the molecule, whereas the lipid A portion represents the hydrophobic lipid portion (Fig. 12.3). Combined, these domains confer the overall amphiphilic properties of the molecule that lead to the formation of micellar aggregates in aqueous solutions.

O-specific chains (also called O-antigen polysaccharides or O-chains) are characteristic of any given type of LPS and show enormous structural variability among bacterial serotypes.[220] O-chains are synthesized by the addition of preformed oligosaccharide blocks to a growing polymer chain and therefore have a repetitive structure. O-specific chains determine part of the immunospecificity of bacterial cells[221] and, on interaction with the host immune system, serve as antigens for the production of species-specific antibodies.[222] O-specific chains are further responsible for the smooth appearance of gram-negative bacterial colonies on culture plates,[219] and LPS molecules containing an O-chain are termed *smooth lipopolysaccharide.*

The inner (lipid A-proximal) and outer (O-chain-proximal) core oligosaccharide portion is more conserved among different strains of gram-negative bacteria than the O-specific chain.[220] The core of all LPS molecules contains the unusual sugar 3-deoxy-D-manno-oct-2-ulopyranosonic acid (KDO), which links the core region to the lipid A molecule. Synthesis of a minimal core is essential for the survival of bacteria,[223] and the smallest naturally occurring LPS structure consists of lipid A and KDO.[224] In contrast to the S-form colonies, colonies of gram-negative bacteria with LPS molecules that lack the O-specific chain but contain a core region show a rough appearance on culture plates. Rough LPS molecules are denoted further as Ra, Rb, and so on to indicate the length of the core region. In Re-LPS (also called *deep rough LPS*), the core region is reduced to a KDO residue. Re-mutants often are used to raise antibodies against the core region in an attempt to provide cross-protection against a variety of bacterial species. The lipid A portion, which serves to anchor the LPS molecule in the bacterial outer membrane, has been identified as the toxic principle of LPS,[225] and its structure is highly conserved among gram-negative bacteria. The common structure

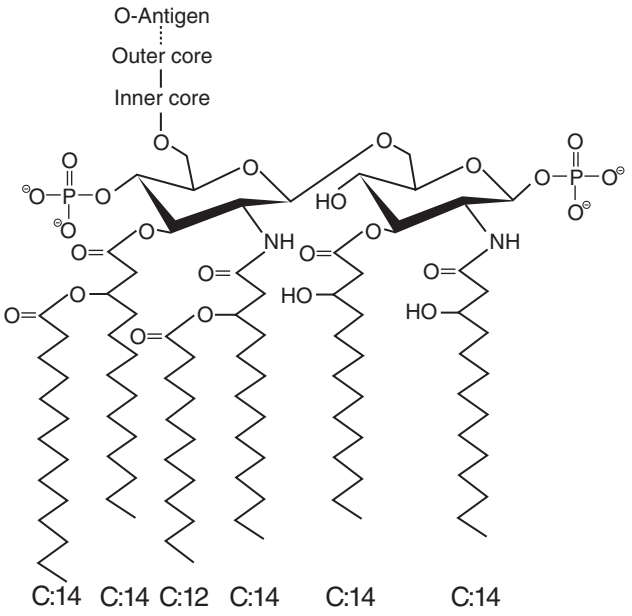

FIG. **12.4** Acylation pattern for *Escherichia coli* lipopolysaccharide.

shared by lipid A molecules is a 1,4′-bisphosphorylated β1,6-linked D-glucosamine disaccharide backbone (lipid A backbone), which is acylated by up to six fatty acids.[220] Fig. 12.4 shows the acylation pattern for *Escherichia coli* LPS. Variation in the lipid A structure between gram-negative bacteria affects the number, length, and position of fatty acids and the backbone structure and the substitution of phosphate by other polar groups.[222]

CAUSES OF ENDOTOXEMIA IN HORSES

According to its nature as a structural cell wall component, the presence of endotoxin implies the presence of gram-negative bacteria as a source. Depending on the nature of the underlying disease, these bacteria may circulate in the bloodstream in their intact form (i.e., bacteremia), may be confined to a localized infectious process, or may be part of the endogenous bacterial florae colonizing the gastrointestinal tract. In any of these scenarios endotoxin molecules are released as a byproduct of bacterial growth and in large numbers on bacterial cell death.[226] Common infectious conditions associated with endotoxemia in horses include neonatal gram-negative sepsis, bacterial pneumonia and pleuropneumonia, endometritis, peritonitis, and infectious colitis with bacteria such as *Salmonella* spp. that are not part of the normal intestinal florae. In one study, for example, endotoxin was detectable in plasma of 50% of foals evaluated for presumed sepsis.[227]

The term *translocation* describes entry of endogenous bacteria and bacterial products from the gastrointestinal tract into tissues and the systemic circulation.[228] The natural intestinal flora of horses consists mainly of gram-negative, anaerobic bacteria; thus, large amounts of endotoxin normally exist in the lumen of the equine intestinal tract.[229] Even in healthy horse small amounts of endotoxin probably cross the intact mucosal barrier and reach the portal circulation and the liver.[230] These molecules are cleared, however, by the mononuclear phagocytic system in the liver and lead only to a localized and restricted activation of the host immune system. For endotoxin translocation to become detrimental, excessive amounts have to cross the intestinal barrier and overwhelm the mononuclear phagocytic system, or the capacity of the liver to detoxify LPS must be compromised. The latter may be a concern in conditions such as hepatitis, cholangiohepatitis, or portosystemic shunting of blood.

Permeability of the intestinal mucosal barrier frequently increases in cases of acute gastrointestinal disease. Colic patients are prime candidates for developing endotoxemia, and plasma endotoxin was detectable in 10% to 40% of colic patients on admission.[231,232] The studies differed in their inclusion criteria, and the higher percentage of horses testing positive for plasma endotoxin was observed when only patients presenting for surgical intervention were evaluated.[232] Aside from gastrointestinal rupture, increased permeability to intact bacteria or free endotoxin molecules is thought to be associated most commonly with ischemic insults such as strangulating obstruction and bowel infarction; severe inflammation, as in proximal enteritis and colitis; bacterial overgrowth; and intraluminal acidosis, which occurs with grain overload.[233,234] One study, however, found no difference in plasma endotoxin detection among disease groups, emphasizing the fact that any disease of the abdominal cavity can induce endotoxemia in horses. In the same study endotoxin was approximately three times more likely to be detected in PF as opposed to plasma samples. Similarly, higher cytokine concentrations have been measured in PF than in plasma. The likely explanation for these findings is a local inflammatory response in the peritoneal cavity elicited by translocated bacteria or LPS molecules before their absorption into the systemic circulation.[231]

Although gastrointestinal disease is likely the most important cause of endotoxin translocation in horses, other conditions may also result in translocation of endotoxin and bacteria. In experimental studies using laboratory animals, entry of gut-associated bacteria into the lymphatic system was demonstrated after hypovolemic shock, burn injuries, trauma, malnutrition, and starvation.[235-237] Furthermore, endotoxin itself caused bacterial translocation into mesenteric lymph nodes after intraperitoneal administration to mice.[238] These findings have received much attention in the literature concerning human patients because they serve to explain cases of endotoxic shock in the absence of demonstrable bacterial infection. The veterinarian should keep in mind the possibility of translocation when evaluating cases of presumed SIRS in horses, in which bacterial infection or gastrointestinal disease cannot be demonstrated. Endotoxin translocation also may be associated with strenuous exercise, which results in reduced splanchnic blood flow, hypoxemia, and a higher body temperature. In fit racehorses a significantly increased mean plasma LPS concentration was found after racing, whereas anti-LPS IgG levels were decreased. Fit horses showed significantly higher anti-LPS IgG concentrations at rest than sedentary controls, suggesting leakage of small amounts of endotoxin from the intestinal lumen during training and racing.[239] A study in endurance horses demonstrated detectable LPS concentration in approximately 50% of horses, and correlation between plasma endotoxin and lactate concentration suggested that plasma endotoxin concentration may be reflective of the vigor of exercise.[240] Surprisingly, the latter study failed to show a correlation between plasma endotoxin concentration and levels of inflammatory mediators such as TNF-α and IL-6,[240] such that the clinical significance of endotoxin translocation during exercise requires further investigation. At least

experimentally, however, alterations in innate immune function during and after strenuous exercise in horses have been demonstrated.[241]

Mechanisms of Cellular Activation by Lipopolysaccharide

The initiating event in the pathophysiology of endotoxemia is the activation of LPS-responsive cells by endotoxin, resulting in altered cellular functions and increased expression of inflammatory mediators. Immune cells such as macrophages respond to minute amounts of LPS, which usually allows them to eliminate gram-negative bacteria and free LPS molecules efficiently. An important factor in the exquisite sensitivity to LPS is the presence of LPS-binding protein (LBP).[220] LBP is an approximately 60-kDa plasma glycoprotein[242] synthesized primarily by hepatocytes[243] and belongs to the family of lipid transfer/LBPs. LBP is an acute phase protein, and inflammatory agents and cytokines such as IL-1 increase LBP plasma concentration 10- to 100-fold within 24 to 48 hours of an inflammatory stimulus.[244,245] The main function of LBP is to transfer LPS to endotoxin-responsive cells, which include mononuclear phagocytes, neutrophils, lymphocytes, and endothelial cells. The importance of a highly sensitive response to LPS for protection against gram-negative bacterial infection is demonstrated in experiments using LBP knockout mice—that is, mice that lack the LBP gene and are therefore unable to synthesize LBP. Although these animals are resistant to the effects of purified LPS, they are unable to control infection with viable bacteria and rapidly succumb.[246] Despite its crucial importance for an effective host defense, LBP is not essential for LPS-receptor interaction per se, because high concentrations of LPS can activate cells in the absence of LBP.[247]

Aside from its role as a catalyst of cellular activation by LPS, LBP has opsonizing activity[248] and participates in the phagocytosis of LPS by macrophages and neutrophils.[249,250] Although phagocytosis of LPS is receptor dependent, it appears to be uncoupled from intracellular signaling events and occurs in the absence of cell activation.[251] LBP further catalyzes transfer of LPS to lipoproteins, such as high-density lipoprotein, which neutralizes LPS activity.[252] This detoxifying effect may become important when large amounts of LPS are present. A protective effect of LBP against LPS challenge and infection has been demonstrated in a murine model of septic shock,[253] and further studies investigating potential therapeutic uses of LBP are under way. More recently, LBP has also been investigated as a diagnostic and prognostic indicator in human patients, in which it may differentiate between SIRS and sepsis and predict outcome of septic patients.[245] One study investigating serum amyloid A (SAA) and LBP in horses with colic[254] found no correlation between serum concentration of LBP with outcome, type of disease process, or affected portion of the gastrointestinal tract.

The most important LPS receptors are cluster differentiation antigen 14 (CD14)[247] and TLR-4.[255] Both are classified as pattern-recognition receptors,[256] which means that they recognize LPS as a structural motif common to all gram-negative bacteria. CD14 is a 53-kDa protein that in its membrane-bound form (mCD14) is inserted into the cell membrane via a glycosyl–phosphatidyl–inositol anchor.[257] CD14 is expressed primarily on monocytes and tissue macrophages and to a lesser extent on neutrophils.[258] It also is found in a soluble form (sCD14)[259] that can bind to cell types lacking CD14, such as endothelial cells, and make them LPS responsive. In addition to this proinflammatory effect, high concentrations of sCD14 can sequester and neutralize LPS.[260] The amount of circulating sCD14 greatly increases during inflammation, which makes it a useful marker of acute and chronic inflammation.[258]

Although CD14 is known to be crucial for cellular activation, it cannot transmit signals to the inside of the cell because it lacks a transmembrane domain. The missing link between CD14 and the cytosolic environment is a Toll-like receptor in association with the molecule MD-2.[261] The name *Toll-like receptor* stems from the homology of the mammalian receptor with a receptor type in *Drosophila* (Toll) that is important for dorsoventral orientation and immune responses in the fly. A number of Toll-like receptors have been identified in mammalian species thus far, but TLR4 appears to be the receptor subtype most important for LPS signaling.[255] The importance of CD14 and TLR4 in the cellular response to LPS has been demonstrated in a number of experiments. Mice deficient in CD14 are incapable of mounting a normal inflammatory response to LPS,[260] whereas mutation or deletion of the gene encoding for TLR4 causes LPS hyporesponsiveness.[262-264]

After binding of LPS to cellular receptors, TLR4 undergoes oligomerization and recruits downstream adaptor proteins to activate intracellular signaling pathways.[265] Signaling pathways are characterized by sequential phosphorylation and activation of enzymatic activities and ultimately result in the alterations of cellular metabolism known as *cell activation*. A typical result of intracellular signaling is the activation of transcription factors—that is, proteins that bind to DNA and promote gene transcription. Translational mechanisms are activated in a similar manner.

TLR4-dependent cell signaling pathways can be differentiated according to the use of adaptor proteins that bind to the intracellular domain of TLR4.[265] The myeloid differentiation primary response gene 88 (MyD88)-dependent pathway results in activation of IKK (Iκβ kinase) and mitogen-activated protein kinase (MAPK) pathways and ultimately in the expression of proinflammatory cytokine genes. IKK activates the well-described transcription factor NF-κβ by phosphorylating an inhibitor protein complex (IκB) that sequesters and inactivates NF-κβ in the cytoplasm. On phosphorylation IκB is ubiquitinated and degraded, and NF-κβ is translocated to the nucleus, in which it unfolds its activity.[266] The MyD88-independent pathway, on the other hand, is activated by interaction of TLR4 with the adaptor protein Toll-IL-1 receptor domain-containing adaptor inducing interferon-β (TRIF). Although the MyD88-independent pathway also activates MAPK and NF-κβ (in addition to a transcription factor called *IRF3*), this pathway primarily results in activation of type I interferons, which are important for antiviral and antibacterial responses.[265] Despite the characterization of seemingly separate and "ordered" pathways, one should recognize that interaction and synergy between pathways are likely to occur. Similarly, inhibitory pathways are required for regulation of the cell response and can target multiple levels of TLR4 signaling.[265] The potential manipulation of signaling pathways for therapeutic use in septic patients is under investigation.

Inflammatory Mediators

Although endotoxin can exert some direct effects, cytokines are a primary mediator of LPS effects. Cytokines are glycoprotein molecules that regulate inflammatory and immune responses by acting as a signal between cells.[267] Cytokines of major interest

in the pathogenesis of endotoxemia include TNF-α, the interleukins, chemokines, and growth factors such as granulocyte-monocyte colony-stimulating factor. TNF-α is thought of as the most "proximal" cytokine released in response to LPS. Studies corroborate this by showing that administration of recombinant TNF-α mimics the effects of LPS[268] and that antibodies directed against TNF-α protect against the lethal effects of endotoxin.[269] Increased plasma activity of TNF is associated with increased mortality in equine patients with acute gastrointestinal disease and in septic neonates.[231] Despite being a structurally diverse group of proteins, cytokines share several characteristics that allow them to execute their complex functions in the inflammatory response.[267] Any individual cytokine generally is produced by several different cell types, can act on different cell types, and has multiple effects on any given cell. Furthermore, cytokine effects are redundant, meaning that different cytokines can share the same effect. In endotoxemia this is particularly true for the effects of IL-1 and TNF-α.[270] Many of the biologic activities of cytokines in vivo result from synergistic or antagonistic actions involving two or more cytokines.[271] Within itself the cytokine response is highly regulated: cytokines induce or suppress synthesis of other cytokines, including their own (feedback regulation); regulate expression of cytokine receptors; and regulate cytokine activities. Additional regulatory mechanisms include the release of specific cytokine inhibitors such as soluble IL-1 and TNF-α receptors; cytokine receptor antagonists such as the IL-1 receptor antagonist; and antiinflammatory cytokines, including IL-10, IL-4, IL-13, and transforming growth factor-β (TGF-β). Glucocorticoids, which are produced increasingly in response to endotoxin, also inhibit the production of cytokines.[272] During a "controlled" inflammatory response, therefore, cytokine secretion is a self-limited event, whereas excessive stimulation of cytokine production can lead to the perpetuation of the inflammatory response even after the initial stimulus has been removed. Aberrations from the controlled, self-regulated inflammatory response have been described as predominantly proinflammatory (SIRS), antiinflammatory or hypoinflammatory (compensatory antiinflammatory response syndrome [CARS]), or combined (mixed antagonist response syndrome) responses.[273] That these responses may not represent a continuum in response to infection was demonstrated in a recent study investigating cytokine profiles in an experimental model of sepsis.[274] Here, increased plasma concentration of antiinflammatory mediators such as IL-1 receptor antagonist and IL-10 in the early phase of sepsis predicted early mortality almost as accurately as the typical proinflammatory cytokines such as IL-6. Cytokine profiles failed to predict mortality in the later stages of sepsis, thereby suggesting that late outcome is not "preprogrammed" early on in the disease. A progression from proinflammatory (SIRS) to antiinflammatory (CARS), as previously proposed, could not be demonstrated.[274] The authors concluded that use of biomarkers may be helpful in determining the inflammatory status of clinical patients suffering from sepsis and that the success of treatments aimed at suppressing or stimulating immune responses may depend on the individual patient's inflammatory profile.

Interestingly, tolerance to endotoxin develops after repeated exposure to LPS.[275] Tolerance can be demonstrated in vitro and in vivo and encompasses decreased production of cytokines and a diminished clinical response.[275,276] Tolerance may be a protective mechanism and was shown to reduce mortality in some experimental models; however, impaired resistance to infectious processes was demonstrated by other investigators.[277] Mechanisms that likely are responsible for the development of endotoxin tolerance include receptor downregulation,[278] downregulation of intracellular signaling pathways,[277,279] and mediators such as glucocorticoids and IL-10.[277] The development of endotoxin tolerance in horses has been reported.[280,281] More recently, the term *cellular reprogramming* has been introduced to describe altered inflammatory cell functions in septic and SIRS patients. This term better accounts for the observation that cellular LPS-sensing ability appears to be maintained, whereas intracellular signaling and cytokine production are modified toward an antiinflammatory rather than a proinflammatory response.[277]

Aside from cytokines, a number of other molecules function as inflammatory mediators in the pathogenesis of endotoxemia, the synthesis and release of which are stimulated by endotoxin and by cytokines. These mediators include the arachidonic acid metabolites or prostanoids, PAF, oxygen-derived free radicals, nitric oxide, histamine, kinins, and complement components. Table 12.2 summarizes the origins, targets, and effects of the most important inflammatory mediators involved in the pathogenesis of endotoxemia. Fig. 12.5 shows the pathways of arachidonic acid metabolism by COX and lipoxygenase. COX products are the prostaglandins, prostacyclin (PGI_2) and thromboxanes, and the lipoxygenase produces the leukotrienes.

TABLE **12.2** **Important Mediators of the Systemic Inflammatory Response to Endotoxin**

Mediator	Origin	Effects
TNF	Macrophages	Induces synthesis of TNF, IL-1, IL-6, and GM-CSF
	Monocytes	Activates neutrophils
	Neutrophils	Activates fibrinolysis and coagulation
	CD4+ T cells	Activates contact and complement system
	Natural killer cells	Induces a catabolic state
		Induces insulin resistance
		Is a pyrogen (direct action and via IL-1 induction)
		Induces synthesis of TNF, IL-1, IL-6, PGI_2, PAF, and GM-CSF
IL-1	Activated macrophages	Activates pyrogen
	Endothelial cells	Induces malaise
	Fibroblasts	Activates neutrophils and chemotaxis

Continued

TABLE **12.2 Important Mediators of the Systemic Inflammatory Response to Endotoxin—cont'd**

Mediator	Origin	Effects
	Dendritic cells	Activates fibrinolysis and coagulation
	Lymphocytes	Activates contact and complement system
	Keratinocytes	Induces acute phase response
		Increases activity of lipoprotein lipase
		Mobilizes amino acids
		Induces muscle proteolysis
IL-6	Activated macrophages	Induces acute phase response
	Fibroblasts	Induces stress response
	Keratinocytes	Is a weak pyrogen
	T lymphocytes	
IL-8	Macrophages	Activates neutrophils and chemotaxis
	Endothelial cells	
Thromboxane A_2	Platelets	Induces vasoconstriction
		Activates platelet aggregation
PGE_2	Most nucleated cells	Induces vasodilation
		Activates platelet aggregation
		Induces fever
PGI_2	Vascular endothelial cells	Induces vasodilation
		Inhibits platelet aggregation
PAF	Macrophages	Activates platelet aggregation
	Platelets	Activates macrophages and neutrophils
	Neutrophils	Induces hypotension
	Mast cells	Increases vascular permeability
	Eosinophils	Aids recruitment of leukocytes
		Induces visceral smooth muscle contraction
		Is a negative inotrope and arrhythmogenic
		Induces ileus
$PGF_2\alpha$	Most nucleated cells	Induces vasoconstriction
		Activates luteolysis
Leukotriene B_4	Most nucleated cells	Is a chemoattractant
		Promotes neutrophil interaction with endothelial cells
Leukotrienes C_4, D_4, E_4	Most nucleated cells	Increase vascular permeability
		Induce bronchoconstriction
		Induce vasoconstriction
Kinins	Produced from serum precursors	Increase vascular permeability
		Induce smooth muscle contraction cause pain
Complement components (C3a, C5a)		Activate neutrophils and chemotaxis
		Induce smooth muscle constriction
		Induce mast cell degranulation
		Induce release of histamine and serotonin
		Increase vascular permeability
Oxygen-derived free radicals	Macrophages	Damage cell membranes
	Neutrophils	Inactivate enzymes
		Damage tissues
GM-CSF		Induces rebound neutrophilia

GM-CSF, Granulocyte-monocyte colony-stimulating factor; *IL,* interleukin; *PAF,* platelet-activating factor; *PG,* prostaglandin; *TNF,* tumor necrosis factor.

Pathogenesis

The innate immune response to LPS is an efficient defense mechanism that provides maintenance of homeostasis and therefore health in the face of an almost continuous exposure to microorganisms and their products.[282] Detrimental consequences of this immune response occur only if excessive and uncontrolled mediator output results in endothelial damage, neutrophil-mediated tissue damage, and uncontrolled activation of the coagulation and fibrinolytic cascades and the complement system. Ultimately, the combination of these events culminates in cardiovascular instability, impaired hemostasis, organ failure, shock, and death. The following discussion addresses the various pathophysiologic events in the development of endotoxemia and shock and the role of inflammatory mediators.

Endothelial Dysfunction and Damage

Normal endothelium plays an important role in regulating blood pressure and regional tissue perfusion and provides an anticoagulant surface. Endothelial dysfunction and damage result in a decreased responsiveness to vasoactive agents (vasoplegia), increased vascular permeability, and a tendency for clot formation in the microvasculature. If the basement membrane and underlying matrix are compromised, microvascular hemorrhage can occur. Endothelial cell damage is primarily neutrophil mediated. More specifically, damage is caused by oxygen-derived free radicals, which are produced within endothelial cells through reactions involving neutrophil-derived elastase and hydrogen peroxide molecules, endothelial cell enzymes such as xanthine oxidase, and endothelial cytosolic iron. The hypochloric anion radical ($HO^{\cdot}$) is thought to be responsible most directly for endothelial cell cytotoxicity. Nitric oxide, which is produced by constitutively expressed nitric oxide synthase in endothelial cells and scavenges superoxide radicals in a reaction to form peroxynitrite, may afford protection from oxygen radical–induced endothelial cell damage. Variations in the ability to produce nitric oxide may explain why vascular beds in different organs vary in their susceptibility to neutrophil-mediated damage.[283] Excessive production of nitric oxide by an inducible form of nitric oxide synthase (iNOS), however, contributes to tissue damage, and increased peroxynitrite concentrations may be responsible in part for PAF-induced increases in vascular permeability.[284] In addition to oxygen-derived free radicals, activated neutrophils release matrix metalloproteinases, which contribute to tissue damage.[272] Vascular endothelial cells are further susceptible to direct effects of various cytokines, most prominently TNF-α and IL-1. These cytokines are thought to cause damage via the induction of COX activity and production of prostanoids and through generation of free radicals. Endothelial cell damage in response to endotoxin infusion and the association with leukocyte attachment have been demonstrated in horses.[285]

Neutrophil Activation, Margination, and Transmigration

Neutrophil activation by LPS and cytokines results in stimulation of phagocytosis and the respiratory burst, release of lysosomal enzymes and inflammatory mediators, and expression of adhesion molecules. Perhaps the single most specific clinicopathologic indicator of endotoxemia is pronounced neutropenia,[286] which temporally correlates with peak plasma concentrations of TNF.[287] Neutropenia is caused primarily by margination of neutrophils in the vasculature, especially of the lungs,[288] whereas significant loss through active migration into peripheral tissues likely is limited to the presence of a localized source of infection. In fact, neutrophils exposed to endotoxin or inflammatory mediators exhibit reduced capacity to respond to chemotactic stimuli and extravasate.[288] Margination is made possible by adhesion molecules on endothelial cells and leukocytes that interact and allow sticking of leukocytes to the endothelial lining of blood vessels. The details of neutrophil margination and transmigration are reviewed in several excellent texts.[289,290] Recent evidence demonstrates a role for TLR-4 in neutrophil margination in the lung microvasculature during endotoxemia, and suggests that activation and TLR-4 expression of endothelial cells may be more important than that of circulating neutrophils.[288] Although neutrophil activation during infections provides the body with an effective defense system against microbial invaders, margination and reduced migratory ability of neutrophils during endotoxemia results in the accumulation of activated cells at the endothelial surface. These cells are then positioned to effect endothelial injury, increase vascular permeability, and in some cases cause parenchymal cell death and organ dysfunction.[291] In addition, inhibition of transmigration deprives the body of phagocytic cells at sites of infection, resulting in reduced ability to fight bacterial infection. This latter complication of endotoxemia may have significant clinical impact, because defective neutrophil recruitment has been demonstrated at low endotoxin doses that do not yet result in tissue damage.[291,292] In human patients endotoxemia and impaired neutrophil migration have been associated with infectious complications of surgical procedures.[291] Decreased phagocytic function and oxidative burst activity have also been suggested in sick and septic hospitalized foals,[293,294] in which a beneficial effect of plasma transfusion on neutrophil function could be demonstrated. The mechanisms of migration inhibition during endotoxemia are incompletely understood but may include occupation of neutrophil chemotactic receptors by cytokines and complement components, resulting in an inability of activated cells to respond to a chemotactic gradient.[291] Rebound neutrophilia, which is observed frequently following episodes of endotoxemia, is caused by neutrophil release from the bone marrow reserve pool and by stimulation of myeloid cell proliferation via granulocyte-macrophage colony-stimulating factor and is mediated primarily by TNF and IL-1.[270]

Coagulopathy and Disseminated Intravascular Coagulation

In health coagulation and fibrinolysis underlie stringent control mechanisms that allow appropriate clot formation and their resolution. Coagulopathies frequently are observed in horses with colic[233,295,296] and foals with sepsis[227] and are likely attributable to endotoxemia. In human medicine virtually all septic patients are considered to have some degree of coagulopathy, which may range from subclinical abnormalities of the clotting profile to fulminant disseminated intravascular coagulation (DIC).[297,298] DIC results from a widespread activation of the coagulation and fibrinolytic systems and failure of their control mechanisms. Ultimately, this leads to disseminated fibrin deposition in the microvasculature, consumption of platelets and clotting factors, and accumulation of fibrin degradation products (FDPs). Depending on the underlying disease process and the relative impairment of the coagulation and fibrinolytic systems, DIC can manifest as a diffuse thrombotic syndrome leading to ischemic organ failure, a fibrinolytic syndrome with uncontrolled hemorrhage, or a combination of both.[299] A procoagulant state characterized by clinicopathologic abnormalities of the clotting profile precedes DIC.

The intrinsic and extrinsic arms of the coagulation cascade are activated in endotoxemia. The intrinsic pathway is initiated by activation of coagulation factor XII (HF), prekallikrein, and high-molecular-weight kininogen, which compose the contact system.[300] Although direct activation of coagulation factor XII by endotoxin has been demonstrated,[301] the extrinsic pathway likely is more important for the development of coagulopathy in endotoxemia and sepsis.[300] Activation of the extrinsic pathway depends on the interaction of coagulation factor VII with tissue factor, which is the only coagulation factor not constitutively present in blood. Tissue factor is present in subendothelial tissues and is exposed on vascular injury but also is expressed on endothelial cells and mononuclear phagocytes in response to LPS.[302,303] Increased expression of monocyte tissue factor (also described as increased procoagulant activity) was significantly associated with coagulopathy and poor prognosis in horses with colic.[304] Furthermore, LPS-induced tissue factor expression by equine peritoneal macrophages may be associated with the development of intraabdominal adhesions.[280]

Regulatory mechanisms of the coagulation cascade include tissue factor pathway inhibitor, antithrombin III (AT III) and the protein C system.[300] Protein C acts as an anticoagulant by inactivating clotting factors V and VIII and promotes fibrinolysis by inactivating plasminogen activator inhibitor (PAI).[305] Protein C activation by thrombin-thrombomodulin complexes is important for the anticoagulative properties of normal endothelium,[300] and downregulation of endothelial thrombomodulin expression by TNF and IL-1 along with decreased expression of AT III and tissue factor pathway inhibitor by damaged endothelial cells contribute to the procoagulant state in endotoxemia and sepsis.[306-308] In addition, activation of vascular endothelial cells leads to a loss of prostacyclin and nitric oxide production and an increased release of thromboxane A_2 (TXA_2). As a result, platelets are stimulated to aggregate and release TXA_2 and PAF, further promoting clot formation.[234]

The crucial step in the fibrinolytic cascade is the conversion of plasminogen to plasmin, a fibrin-degrading enzyme.[300] Tissue-type (tPA) and urokinase-type (uPA) plasminogen activator are the major initiators of fibrinolysis, whereas PAI and α_2-antiplasmin are the main regulatory components.[309,310] TNF and IL-1 have been shown to induce the release of uPA and tPA and the synthesis of PAI.[300] Activation of fibrinolysis leads to consumption of α_2-antiplasmin and accumulation of FDPs, which if present in high concentrations can interfere with platelet aggregation, fibrin polymerization, and thrombin formation and can promote bleeding. Additionally, FDPs mediate an increase in vascular permeability. LPS infusion in rabbits[311] and humans[312] resulted in an early increase in plasma

tPA activity, followed by a later profound rise in PAI activity and fall in tPA activity. Increased plasma PAI concentrations also were found in horses with colic compared with controls.[313,314] Although fibrinolysis may compensate initially for accelerated coagulation, its subsequent inhibition contributes to clot formation.

Cross-activation between the inflammatory and coagulation cascades plays an important role in endotoxemia and sepsis, and the presence of coagulopathies has been associated with an increased risk of organ failure and poor outcome in septic human patients.[297,298] Activated protein C reduces mortality in septic human patients.[315] Activated protein C reduces inflammation by inhibiting leukocyte activation and cytokine production and was shown to lower plasma concentration of IL-6.[315] Although bleeding complications were increased in treated patients, incidence of severe bleeding was not increased significantly.

Complement Activation

Activation of the complement system in endotoxemia occurs via the alternative pathway through interaction with LPS. Increased concentrations of plasmin and kallikrein (caused by activation of the fibrinolytic and contact system) further promote this pathway by directly activating complement factors C3a and C5a. Aside from being key molecules in the complement cascade, C3a and C5a are anaphylatoxins and cause an increase in vascular permeability via mast cell degranulation. C5a further activates the lipoxygenase pathway in neutrophils and monocytes, acts as a chemotaxin for leukocytes and monocytes, and promotes neutrophil adhesion to endothelial cells.

Acute Phase Response

In response to acute inflammation, synthesis and secretion of a number of proteins called the *acute phase proteins* increase in hepatocytes, whereas synthesis of albumin decreases. The primary function of this acute phase response may be to suppress and contain inflammatory processes.[272] IL-6 and IL-1 are the most important cytokines that induce the acute phase response,[316] which typically begins within a few hours of the insult and subsides within 24 to 48 hours,[317] unless the initiating cause persists. In horses fibrinogen (the most commonly evaluated acute phase protein), haptoglobin, transferrin, ferritin, ceruloplasmin, coagulation factor VIII:C, SAA, C-reactive protein, α_1-acid glycoprotein, and phospholipase A_2 are considered part of the acute phase response.[318] SAA is a sensitive indicator of experimentally induced inflammation[319] and may be helpful in the diagnosis of inflammatory gastrointestinal disease,[254] neonatal weakness and diarrhea,[320] and various infectious diseases. A commercially available turbidimetric immunoassay for human SAA is reliable for measuring equine SAA.[321]

The effect of acute inflammation on the serum concentration of several coagulation factors must be considered when evaluating coagulation profiles. Serum fibrinogen concentration is determined primarily by the acute phase response, although fibrinogen is consumed increasingly on activation of the clotting cascade.

Hemodynamic Changes, Development of Shock, and Organ Failure

Shock is characterized by a loss of homeostasis attributable to the breakdown of hemodynamic control mechanisms, decreases in cardiac output and the effective circulating volume, and inadequate perfusion of vital organs. Shock caused by endotoxemia is classified as distributive shock[322] and is largely initiated by vascular dysfunction in the periphery. Peripheral vascular beds are of major importance for the regulation of local tissue perfusion and affect systemic blood pressure by regulating total peripheral resistance. Normally, vascular smooth muscle tone is regulated by endothelin-1 (vasoconstriction), nitric oxide, and prostacyclin (vasodilation) released from vascular endothelial cells.[323] Detrimental effects of nitric oxide are attributable to overproduction of nitric oxide by iNOS in macrophages and other cell types, rather than endothelial-derived nitric oxide. Peripheral vasomotor effects of endotoxin manifest as vasodilation and vasoplegia and are mediated by PGI_2, nitric oxide, and mediators such as bradykinin. Widespread vasodilation leads to vascular blood pooling, decentralization of blood flow, decreased venous return, and in effect decreased effective circulating volume and cardiac output.[322] Compensatory responses in the form of an initial hyperdynamic phase include tachycardia, increased cardiac output and central venous pressure, pulmonary hypertension, peripheral vasoconstriction, and increased peripheral vascular resistance.[322,324,325]

The early vasoconstrictive phase corresponds to an increased serum concentration of TXA_2,[234] but additional vasoconstrictors such as arginine vasopressin, angiotensin II, serotonin, endothelin, and norepinephrine likely are implicated in the pathogenesis of shock and organ failure.[272] With progression of disease the animal enters a stage of decompensated shock and progressive systemic hypotension, which corresponds to increased plasma concentrations of prostacyclin, PGE_2, and bradykinin.[234,272] Inadequate blood flow and oxygen delivery to tissues caused by hypotension are confounded by direct myocardial suppression via nitric oxide,[322] increased vascular permeability,[234] intravascular microthrombosis, and impaired tissue oxygen extraction[322] and results in progressive metabolic acidosis and inhibition of normal cellular metabolism.

CLINICAL SIGNS AND DIAGNOSIS

Quantification of endotoxin in plasma samples is possible. The Limulus amebocyte lysate assay is an activity assay based on the endotoxin-sensitive hemolymph coagulation cascade in the horseshoe crab *Limulus polyphemus.* In *Limulus,* this reaction is thought to be a defense mechanism against gram-negative infection.[326] Although frequently used as a research tool, the assay is not convenient enough to become a routine clinical test. The clinician therefore must appreciate the primary disease processes associated with a high risk of endotoxemia and rely on clinical signs and clinicopathologic data to achieve a diagnosis. In a survey of board-certified internal medicine specialists and surgeons, colitis/enteritis, small intestinal strangulation and obstruction, retained fetal membranes/metritis, grain overload, and pleuropneumonia were among the most frequently cited conditions associated with endotoxemia.[327] In some cases, endotoxemia may be the first indication of disease or may be the most overt of otherwise subtle clinical manifestations. With colitis or proximal enteritis, for example, one may detect signs of endotoxemia before the development of colic, diarrhea, or gastric reflux, which more specifically indicate the nature of the primary illness. The presence of neutropenia should always prompt the clinician to investigate causes of endotoxemia.

In vivo LPS challenge experiments in horses clearly show that many of the clinical signs associated with acute gastrointestinal disease and sepsis are attributable to endotoxemia. On administration of sublethal doses of LPS, the clinical response can be divided into the early hyperdynamic and the later hypodynamic or shock phases. Clinical signs during the first phase, which begins within 15 to 45 minutes after LPS administration, include anorexia, yawning, sweating, depression, evidence of abdominal discomfort, muscle fasciculations, and recumbency. Heart and respiratory rates increase, and decreased borborygmi suggest ileus. Hyperemia of the mucous membranes and an accelerated capillary refill time indicate the hyperdynamic state.[286] If large amounts of LPS are administered or if exposure is ongoing, depression worsens progressively, anorexia persists, and feces develop a diarrheic character. Signs of colic typically abate after the initial stage. Fever develops as a result of direct action of TNF on the thermoregulatory center and IL-1–induced local production of PGE_2 in or near the hypothalamus.[328,329] Because of compromised peripheral perfusion, mucous membrane color changes to brick red or purple, a dark "toxic" line appears, and capillary refill time is prolonged.[286] Inadequate peripheral perfusion and compromised organ function finally characterize the hypodynamic shock phase. Body temperature may become subnormal, and the skin, especially on extremities, is cool to the touch. The arterial pulse weakens, and venous fill is decreased. Vascular endothelial damage and increased capillary permeability result in a muddy mucous membrane color and diffuse scleral reddening. Similar changes are evident in horses suffering from endotoxemia associated with natural disease. In the previously mentioned survey,[327] tachycardia, fever, abnormal mucous membrane color, and increased capillary refill time were named by most specialists as indicating endotoxemia.

Hemostatic abnormalities can manifest in the form of thrombosis or increased bleeding tendency with mucosal petechiation or ecchymoses and prolonged bleeding from venipuncture sites.[299] Bleeding also may occur in the form of spontaneous epistaxis or prolonged hemorrhage after nasogastric intubation.[234] Additional clinical signs typically reflect the development of organ failure. Renal failure and laminitis[327] appear to be common complications of endotoxemia in horses, and endotoxemia was identified as the only clinical condition significantly associated with the development of acute laminitis in one retrospective case-control study of horses admitted to a referral center.[330] Other potential complications include liver failure,[299] respiratory failure, colic and ischemia-induced gastrointestinal ulceration,[234] cardiac failure, and abortion in pregnant mares.[331,332] Renal failure results from ischemic cortical necrosis and acute tubular necrosis caused by coagulopathy-induced afferent arteriolar obstruction. Clinical signs may include oliguria, anuria, or hematuria caused by renal infarction. Laminitis may lead to lameness, increased digital arterial pulsation, increased warmth of the hoof wall, and sensitivity to hoof tester pressure. The exact nature of the association between endotoxemia and laminitis is not understood, and, interestingly, experimental endotoxin infusion does not reliably induce laminitis. Studies have shown, however, that endotoxin administration decreases digital blood flow and laminar perfusion[333] coincident with increased plasma concentrations of 5-HT and thromboxane B_2 (TXB_2).[334] In addition, in vitro vascular reactivity of digital vessels is altered following sublethal endotoxin administration to horses.[335] In addition to the response to circulating mediators, LPS exposure also alters the production of vasoactive mediators by digital vascular endothelial cells.[336] Alterations in vascular reactivity are, therefore, likely responsible for development of laminitis in endotoxemia; however, other mechanisms may apply depending on the underlying clinical disease.

CLINICAL PATHOLOGIC TESTING

Leukopenia caused by neutropenia may be the most specific indicator of acute bacterial sepsis or endotoxemia.[286] In prolonged cases an increased proportion of immature neutrophil forms (bands) and toxic changes are observed. Toxic changes resulting from neutrophil activation include vacuolation, cytoplasmic granulation, basophilic cytoplasm, and Döhle bodies. Because neutropenia occurs early in the development of endotoxemia, it also may be a useful parameter for monitoring horses at risk.[286] On recovery neutropenia typically is followed by a pronounced rebound neutrophilia. Other alterations in the hemogram and serum biochemical profile mainly reflect the underlying disease process and the occurrence of organ failure.

An elevated hematocrit and total serum protein concentration are frequently interpreted as evidence of dehydration; however, splenic contraction caused by increased sympathetic stimulation, increased production of acute phase proteins, or protein losses also influence these parameters. Hyperproteinemia may be observed as a result of increases in the fibrinogen or globulin concentration, and determination of protein fractions, including protein electrophoresis, is indicated in hyperproteinemic patients. Hypoproteinemia and hypoalbuminemia can occur because of loss via the gastrointestinal or urinary tract or with pleural or peritoneal cavity effusion. Increased vascular permeability and edema formation contribute to hypoproteinemia.

Serum electrolyte abnormalities primarily depend on the nature and duration of underlying disease processes and need to be evaluated individually. In human patients, gram-negative sepsis frequently is associated with hypocalcemia, more specifically a decrease in serum ionized calcium concentration. Endotoxin is thought to be a causative factor, and proposed mechanisms include acquired parathyroid gland insufficiency, dietary vitamin D deficiency, impaired calcium mobilization, and renal 1-hydroxylase insufficiency, leading to decreased 1,25-hydroxylation of vitamin D. Hypocalcemia in septic human patients was associated with hypotension and poor outcome.[337] In horses with surgically managed gastrointestinal disease, decreased serum ionized calcium concentration was a common finding and was most severe in patients with strangulating or nonstrangulating infarctions. In some horses, ionized calcium concentration decreased further throughout surgery. Treatment with calcium gluconate resulted in normalization of serum ionized calcium concentrations in all cases.[338]

Septic neonatal patients are frequently hypoglycemic, which may be attributable to decreased oral intake, generally increased metabolism, glucose use by the infecting bacteria, inhibition of gluconeogenesis by endotoxin, and insulin-like activity produced by macrophages.[234] Interestingly, experimental endotoxin administration results in transient hyperglycemia in adult horses,[324] whereas profound hypoglycemia occurs in foals.[339] Because of the high incidence of coagulopathies in endotoxemic and septic patients, clinicians should consider monitoring coagulation parameters. The most

significant changes can be expected with severe inflammatory disease such as colitis,[295,296] devitalized intestine as with strangulating obstruction,[296,340] and with increased duration of disease. In 30 horses with acute gastrointestinal disease, coagulation profiles were considered normal in only two horses.[295] Although coagulation times may be shortened during the procoagulant state, commonly observed abnormalities with developing DIC include an increased concentration of FDPs and soluble fibrin monomer, prolonged prothrombin time indicative of factor VII consumption, prolonged activated partial thromboplastin time indicative of factor VIII:C and IX consumption, prolonged thrombin time, decreased AT III activity, thrombocytopenia, and decreased protein C and plasminogen activities. Fibrinogen concentration appears to reflect the acute phase response rather than coagulation abnormalities in horses and is frequently increased.[304] Some clinicians make a diagnosis of DIC if three or more coagulation parameters (specifically AT III, FDPs, platelet count, prothrombin time, and activated partial thromboplastin time) are abnormal,[340] whereas others require overt clinical signs of hemorrhage and concomitant thrombosis in addition to classic laboratory findings.[296] The prognostic value of coagulation parameters has been evaluated.[233,296,314] Overall, persistence or worsening of abnormalities in the face of treatment appears to be more indicative of poor outcome than alterations in any specific parameter. In one study decreased serum AT III concentration was the parameter most commonly associated with fatal outcome in mature horses with colic.[295]

Hypoxemia observed in response to endotoxin infusion is thought to be caused by an increase in ventilation-perfusion mismatch rather than pulmonary edema, as occurs in human patients with acute respiratory distress syndrome. Pulmonary edema may occur in patients with associated sepsis or complications such as DIC.[341]

MANAGEMENT

The ideal treatment for endotoxemia is prevention. Recognition and close monitoring of patients at risk are crucial because doing so allows institution of timely, possibly proactive treatment, which may reverse the effects of endotoxin before the inflammatory response has developed a dynamic of its own. Unfortunately, endotoxemia can develop rapidly, and horses are exquisitely sensitive to the effects of endotoxin; therefore, many equine patients are not presented for evaluation until they have reached more severe stages of endotoxemia or shock. Prognosis and patient outcome then frequently depend on the severity of complications associated with endotoxemia.[234]

Treatment of endotoxemia involves multiple aspects, and the following strategies have been proposed[342]:

- Inhibition of endotoxin release into the circulation
- Scavenging of LPS molecules to prevent direct effects and interaction with inflammatory cells
- Inhibition of cellular activation by LPS
- Inhibition of mediator synthesis
- Interference with the effects of inflammatory mediators
- General supportive care

In addition, treatment must also address the primary disease process as well as any complications.

When evaluating reports concerning the efficacy of any one treatment, the clinician should keep in mind differences in underlying disease processes and the complexity of the inflammatory cascade. A "one for all" treatment most likely will not be found; similarly, any one treatment can address only a few pathophysiologic aspects of endotoxemia at most.

Inhibition of Endotoxin Release into the Circulation

Inhibition of endotoxin release requires identification and removal of its source. Identification of responsible microorganisms and their antimicrobial sensitivity spectrum are crucial steps toward effective therapy; however, one should not necessarily delay treatment to obtain culture results. Specimen containers with antimicrobial removal devices may be useful in cases for which initiation of treatment precedes specimen collection. Once a diagnosis is reached, correction of the primary disease process is critical. Examples are removal of devitalized sections of bowel or infected umbilical remnants, drainage of infected pleural or PF, and gastric lavage followed by administration of intestinal adsorbents in cases of grain overload. Di-tri-octahedral smectite (DTO; Bio-Sponge, Platinum Performance Inc., Buellton, CA) was shown to remove endotoxin in an in vitro assay[343] and may be useful in preventing endotoxemia of intestinal origin. Septic processes must be addressed with appropriate antimicrobial therapy, and principles of antimicrobial therapy should be followed. Regarding endotoxemia specifically, antimicrobial therapy has been suggested to increase the amount of circulating endotoxin by inducing endotoxin release on cell death of gram-negative bacteria. An in vitro study comparing endotoxin release and inflammatory mediator activity among antimicrobials commonly used to treat *E. coli* bacteremia in foals evaluated amikacin, ampicillin, amikacin plus ampicillin, ceftiofur, and imipenem. Although these antimicrobials showed no difference in the ability to kill bacteria, amikacin and the amikacin–ampicillin combination resulted in the lowest, and ceftiofur in the greatest, release of endotoxin. Endotoxin release appeared to be dose dependent in that lesser amounts were released at higher antimicrobial concentrations.[344] On the basis of these results and clinical experience, combining antimicrobial therapy with endotoxin-binding agents such as polymyxin B may be beneficial, especially when using β-lactam antimicrobials.

Scavenging of Lipopolysaccharide Molecules

Endotoxin typically has a short plasma half-life and is removed rapidly by mononuclear phagocytes or neutralized by binding to serum proteins and lipoproteins. Many conditions responsible for the development of endotoxemia in horses, however, may be associated with an ongoing release of endotoxin. Examples include severe gastrointestinal inflammation as in proximal enteritis or colitis, grain overload, or uncontrolled sepsis. Therapy directed against endotoxin itself may be able to interrupt the continuous activation of the inflammatory cascade in these cases. Further benefits of antiendotoxin treatment may be derived if large amounts of endotoxin have been released before the inciting cause can be addressed.

Immunotherapy

An important consideration regarding the efficacy of immunotherapy is the region of the LPS molecule against which antibodies are raised. The O-chain of LPS acts as a potent antigen[222]; however, antibodies directed against the O-chain are serotype specific and cannot afford significant cross-protection against heterologous gram-negative bacterial strains. The core and lipid A region, both of which show a much

higher degree of homology between LPS derived from different bacterial strains, offer a more promising target for immunotherapy. Active immunization against endotoxins has been reported for horses. Vaccination with a bacterin-toxoid vaccine prepared from rough mutants of *Salmonella typhimurium* or *S. enteritidis* protected horses against homologous and heterologous endotoxin challenge[345,346] and carbohydrate overload.[346] Despite these encouraging results and the availability of a vaccine for use in horses (Endovac-Equi, Immvac Inc., Columbia, MO), active immunization against endotoxin does not appear to be a common practice. In comparison, passive immunization with anti-LPS antibodies is used widely. Rough bacterial mutants, most commonly J5 of *E. coli* O111:B4 and *S. minnesota* Re595, are used to immunize donor horses and subsequently prepare serum or plasma products. Proposed mechanisms of action after binding of the antibodies to LPS include steric blockade of lipid A interaction with cellular receptors and enhanced bacterial clearance by opsonization.[347-349] Studies concerning the efficacy of antibody administration in equine patients vary in their results. Beneficial effects have been described in experimental models of endotoxemia, acute gastrointestinal disease, and neonates with sepsis,[346,350-353] whereas in other studies antibodies failed to protect foals and horses against endotoxin effects.[354-356] Administration of an *S. typhimurium* antiserum to foals was associated with an increased respiratory rate and higher serum activities of IL-6 and TNF.[354]

Various equine serum and plasma products are commercially available. An antiserum raised against the LPS core of *S. typhimurium* (Endoserum, Immvac Inc., Columbia, MO) is available for administration to endotoxemic horses at a recommended dosage of 1.5 mL/kg body mass. Diluting the serum 10- to 20-fold in crystalloid IV solutions, administering it slowly over 1 to 2 hours, and monitoring the patient for adverse reactions is advisable. Although the product is marketed for use in foals with failure of passive transfer, adverse effects have been reported,[354] and one should use caution when administering it to neonates. Plasma from donors inoculated with J5 *(E. coli)* and *S. typhimurium* (Re-mutant) is available under a California license (Equiplas J, Plasvacc USA Inc., Templeton, CA). The manufacturer recommends administration of at least 1 to 2 L in cases of endotoxemia. Hyperimmune plasma, which has a guaranteed minimum IgG content but does not contain specific antiendotoxin antibodies (HiGamm Equi, Lake Immunogenics, Inc., Ontario, NY; Equiplas and Equiplas Plus, Plasvacc USA Inc.,), is marketed for treatment of failure of passive transfer, and many clinicians use it to treat endotoxemia and sepsis. In addition to antibodies and protein, plasma contains active constituents such as complement components, fibronectin, clotting factors, and AT III[351] and therefore may be particularly useful in patients with endotoxemia-induced coagulopathy. Volumes of 2 to 10 mL/kg body mass of hyperimmune plasma have been recommended for use in endotoxemic patients.[272,357]

Polymyxin B

Polymyxin B is a cationic polypeptide antibiotic that binds to the anionic lipid A portion of LPS and neutralizes its endotoxin capacity.[358] At dosages required for antimicrobial activity, polymyxin B carries the risk of respiratory paralysis and ototoxic, nephrotoxic, and neurotoxic side effects; however, a much lower dose is required for endotoxin-binding activity. The effects of polymyxin B in horses have been evaluated in different experimental models.[354,358,359] In an in vivo study in foals, treatment with polymyxin B at a dosage of 6000 U/kg body mass before infusion with *S. typhimurium* LPS resulted in significantly less severe elevations of body temperature, respiratory rate, and serum activities of TNF and IL-6 compared with untreated controls.[354] Similarly, polymyxin B treatment of adult horses given endotoxin ameliorated clinical signs and decreased plasma TNF activity.[360] In the latter study benefits of treatment were also evident at lower dosages of polymyxin B (1000 and 5000 U/kg body mass) and administration of polymyxin B 1 hour after the start of endotoxin infusion. Conversely, polymyxin B failed to ameliorate clinical signs of endotoxemia or prevent the development of coagulopathy, acidosis, lameness, and shock in experimental carbohydrate overload.[361] Adverse effects suggestive of neurotoxicity appeared after repeated administration of 5 mg/kg body mass (36,000 U/kg) and in a milder form after administration of 2.5 mg/kg body mass (18,000 U/kg). Nephrotoxicity was not observed. Currently, use of polymyxin B in equine patients is recommended at dosages of 1000 to 6000 U/kg body mass every 8 to 12 hours administered as a slow bolus.[362,363] Treatment should be initiated as early in the disease process as possible because the beneficial effects of LPS scavenging may be limited to the first 24 to 48 hours after the onset of endotoxemia, before endotoxin tolerance develops. Adverse effects in the form of neuromuscular blockade and apnea, which necessitate slow infusion of the drug in human patients, have not been observed in horses. If treating horses with hypovolemia, dehydration, or azotemia, the clinician should attempt to improve peripheral tissue perfusion, minimize the polymyxin B dose, and closely monitor patients for nephrotoxicity. Close monitoring is also important if medications such as aminoglycoside antibiotics, which share a similar spectrum of potential side effects, are administered concurrently. Azotemic neonates are more susceptible to the nephrotoxic effects of polymyxin B than adult horses.[360]

In an attempt to decrease the risk for adverse effects while preserving the LPS-neutralizing ability, a conjugate of polymyxin B with dextran has been developed.[364] In conjugated form, polymyxin B is prevented from extravasation into tissues, in which it exerts toxic effects by interaction with cell membranes. In addition, conjugation increases the residence time of polymyxin B in the circulation; therefore, it should prolong the antiendotoxic effect. The polymyxin B–dextran combination was evaluated at a total dose of 5 mg/kg body mass of polymyxin B in 6.6 g/kg body mass dextran, given 15 minutes before administration of endotoxin in horses.[365] Treatment blocked the development of tachycardia, tachypnea, fever, and neutropenia completely and prevented increases in serum concentrations of TNF, IL-6, TXB_2 (a TXA_2 metabolite), and the prostacyclin metabolite 6-keto-$PGF_1\alpha$. Although mild adverse effects in the form of tachypnea, sweating, and increased systolic blood pressure were observed, these were transient and could be prevented by pretreatment with ketoprofen. To the author's knowledge, the polymyxin B–dextran combination is not commercially available at this time.

Natural Endotoxin-Binding Substances

Natural endotoxin-binding proteins such as LBP, lipoproteins, and sCD14 have been evaluated experimentally. Results of these studies are somewhat contradictory, and detrimental effects occurred in some cases.[366] A protein receiving a great deal of attention regarding potential therapeutic efficacy is

the bactericidal permeability-increasing (BPI) protein. This protein is structurally similar to LBP but is expressed exclusively in myeloid precursors of polymorphonuclear (PMN) leukocytes.[367] BPI is stored in primary granules of mature neutrophils and during inflammation is expressed on their cell membranes and secreted into the extracellular environment.[368] BPI has an even higher affinity for LPS than LBP[369] and shows antibacterial activity specific for gram-negative bacteria.[219] Binding of BPI to the gram-negative bacterial membrane results in growth arrest and is an important factor in the antibacterial activity of intact neutrophils. Furthermore, BPI binding disrupts normal membrane organization and makes bacteria more susceptible to hydrophobic substances, including antimicrobials.[370] Experimentally, recombinant BPI protects against the toxic and lethal effects of isolated LPS and intact gram-negative bacteria, and clinical trials in human patients show promising results regarding its therapeutic use.[371] The biology and potential use of BPI in horses has not been evaluated.

Phospholipid emulsions have recently been evaluated for treatment of experimentally induced endotoxemia in horses. Phospholipid infusion improved clinical parameters, ameliorated neutropenia, and reduced inflammatory mediator production in response to an endotoxin challenge.[372,373] Because hemolysis was a complication of phospholipid infusion in some horses in these studies, optimization of dose and time of administration will be necessary before evaluating this treatment for potential clinical use.

Inhibition of Cellular Activation by Lipopolysaccharides

Treatments aimed at inhibiting LPS interaction with cells or turning off intracellular signaling pathways are under investigation. Nontoxic LPS or lipid A structures can act as endotoxin antagonists, if they competitively inhibit binding to LBP or cellular receptors or inhibit cellular activation by other mechanisms. Of the potential antagonists that have been evaluated experimentally, LPS and lipid A of the phototrophic bacterium *Rhodobacter sphaeroides* and the synthetic compounds E5531 and E5564 have been most promising.[373-379] Unfortunately, species differences exist regarding cellular response to these structures, and *R. sphaeroides* LPS as well as E5531 have been found to have agonist activity in equine cells.[380,381] In cell transfection experiments, TLR-4 was shown to be responsible for this phenotypic variation regarding *R. sphaeroides* LPS.[382] Given these results, any future potential LPS antagonists must be evaluated in equine systems.

Inhibition of Mediator Synthesis

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are probably the most commonly used drugs to treat endotoxemia in horses. The rationale for their use is inhibition of COX, which inhibits prostanoid production (see Fig. 12.5). Additional beneficial effects may include scavenging of oxygen-derived free radicals and iron chelation; however, side effects may occur at dosages required to achieve these effects.[374] Prostanoids have been identified as important mediators in the inflammatory response in a number of studies, and inhibition of their synthesis is associated with beneficial effects. Generally speaking, two COX isoforms are recognized: constitutively expressed COX-1 and inducible COX-2. Upregulation of COX-2 expression results from various proinflammatory stimuli, including LPS, TNF-α, and IL-1.[383] Constitutively expressed COX products are likely important for maintenance of homeostasis, whereas increased production of prostanoids by COX-2 is thought to be responsible for detrimental effects during inflammation and shock.

In horses, the most commonly used NSAID to treat endotoxemia is flunixin meglumine. Beneficial effects of flunixin meglumine have been described in experimental models of endotoxemia[384-386] and in clinical cases. In equine colic patients treatment with flunixin meglumine before exploratory surgery resulted in reduced plasma concentrations of TXB_2 and PGE_2 and had a favorable effect on cardiovascular parameters.[387] Flunixin meglumine was shown further to maintain cardiac output and systemic arterial blood pressure, improve blood flow to vital organs, reduce pulmonary endothelial damage, and improve survival on endotoxin challenge.[285,388-390] Conversely, in vitro studies have suggested that flunixin meglumine impairs recovery of intestinal barrier function in intestinal segments subjected to ischemia–reperfusion injury and may increase mucosal permeability to LPS.[391,392] This effect may be reduced or eliminated by concurrent administration of continuous rate infusion of lidocaine.

NSAID use in horses carries the risk of adverse effects, the most significant of which are development of gastrointestinal ulceration and renal papillary necrosis (renal crest necrosis). Differences may exist among NSAIDs in their propensity to induce adverse effects,[393] but all NSAIDs must be used cautiously. Because of the potential concerns for masking of cardiovascular effects of endotoxin in horses with colic, a reduced dose of flunixin meglumine (0.25 mg/kg body mass thrice daily) has been suggested and is used widely in horses.[327] At this dosage flunixin meglumine inhibits eicosanoid synthesis efficiently in an in vivo model of endotoxemia.[394] Reduction of clinical signs, however, was dose dependent, and lower doses provide minimal, if any, analgesia (see Chapter 2 for further discussion of NSAID therapy in horses).

Some researchers have suggested that ketoprofen offers superior effects because of a proposed dual inhibitory effect on COX and lipoxygenase and may carry a decreased risk of adverse effects compared with flunixin meglumine and phenylbutazone. A comparison of cytokine and eicosanoid production by LPS-stimulated isolated monocytes in vitro, however, showed no significant difference between horses pretreated with flunixin meglumine (1.1 mg/kg body mass) or ketoprofen (2.2 mg/kg body mass), respectively.[395]

Given 15 minutes before LPS infusion, eltenac at a dosage of 0.5 mg/kg protected against changes in clinical, hemodynamic, and hematologic parameters and blunted the LPS-induced rise in plasma cytokine concentrations compared with controls in an experimental model of endotoxemia.[396] Some parameters, however, including heart rate, leukocyte count, lactate concentration, and plasma TNF activity, were not improved. Ibuprofen may have beneficial effects superior to those of the other NSAIDs because it may be possible to achieve tissue concentrations safely that allow iron chelation to occur. According to a study in healthy foals, dosages of ibuprofen up to 25 mg/kg every 8 hours can be given safely for up to 6 days.[397] To the author's knowledge, the COX-2 inhibitor firocoxib has not yet been evaluated critically for treatment of endotoxemia.

Corticosteroids

The use of corticosteroids for antiinflammatory therapy in sepsis and endotoxemia has been controversial in human and equine patients, and beneficial effects superior to the ones achieved by NSAIDs have not been demonstrated consistently. Corticosteroids inhibit the activity of phospholipase A_2 and the release of arachidonic acid from cell membrane phospholipids, as well as the production of TNF, IL-1, and IL-6 in response to an LPS stimulus. Experimentally, beneficial effects of dexamethasone in equine endotoxemia have been demonstrated.[398,399] To inhibit TNF production by equine peritoneal macrophages, however, the required concentration of dexamethasone was high and corresponded to an in vivo dosage (approximately 3 mg/kg body mass) greatly exceeding current recommendations.[398] Although single doses of corticosteroids are unlikely to carry a disproportionate risk of adverse effects, the clinician should consider the suggested association of laminitis with corticosteroid use in horses. In cases of sepsis immunosuppressive effects could also be detrimental.

In human patients with certain types of septic shock, dysfunction of the hypothalamic–pituitary–adrenal axis has been recognized and successfully treated with hydrocortisone replacement therapy.[400] Hypothalamic–pituitary–adrenal axis dysfunction has been suggested to occur in septic foals[401]; however, the use of low-dose corticosteroids for this indication remains to be investigated in horses.

Pentoxifylline

Pentoxifylline, a methylxanthine derivative and phosphodiesterase inhibitor, has been suggested for use in endotoxemia because of its effects on neutrophil function and its ability to inhibit the production of various cytokines, interferons, and thromboplastin. Decreased production of TNF, IL-6, TXB_2, and thromboplastin in response to endotoxin was shown in an equine ex vivo model.[402] In horses given endotoxin followed by treatment with pentoxifylline (7.5 mg/kg body mass followed by continuous infusion of 3 mg/kg/h for 3 hours), however, only minimal beneficial effects were observed.[403] Treatment significantly improved body temperature, respiratory rate, and whole blood recalcification time, but no effect was observed regarding heart rate, blood pressure, leukocyte count, plasma fibrinogen concentration, and serum cytokine concentrations. The conclusion was that benefits of treatment with pentoxifylline might be restricted to administration of high bolus doses or continuous infusion early in the pathophysiologic process. In an in vivo endotoxemia model in horses, the combination of pentoxifylline (8 mg/kg body mass) and flunixin meglumine (1.1 mg/kg body mass) had greater benefit than each treatment on its own.[404] Because of its rheologic properties (i.e., the ability to increase erythrocyte deformability and microvascular blood flow), pentoxifylline has been suggested for use in endotoxemic patients showing evidence of laminitis; however, no effect on blood flow to the hoof was demonstrated after administration to healthy horses.[405] An IV preparation of pentoxifylline is not commercially available.

Antioxidants

Dimethyl sulfoxide (DMSO) is used by some clinicians in an attempt to scavenge oxygen-derived radicals. However, DMSO failed to show beneficial effects in an experimental model of intestinal ischemia when administered on reperfusion of the ischemic intestine.[406] DMSO at a dosage of 1 g/kg body mass increased mucosal loss after ischemia and reperfusion of the large colon,[407] and a reduced dosage of 0.1 g/kg body mass has been proposed for horses with intestinal ischemia. DMSO failed to show significant benefit in an experimental model of endotoxemia in horses, although it ameliorated the effect on fever, and many clinicians do not advocate its use.[408] The xanthine oxidase inhibitor allopurinol has been suggested as a treatment to prevent oxygen radical–induced tissue damage. During periods of ischemia tissue xanthine dehydrogenase is converted to xanthine oxidase, which on reperfusion catalyzes the generation of superoxide radicals.[409,410] Evaluation in horses showed beneficial effects of allopurinol 5 mg/kg body mass administered 12 hours before endotoxin challenge.[411] In another study mucosal damage attributable to oxygen-derived free radicals was not attenuated by allopurinol in an experimental ischemia–reperfusion model.[407]

Lidocaine

Lidocaine given IV has been suggested as an antiinflammatory, analgesic, and prokinetic agent. In an experimental endotoxemia model in rabbits, lidocaine inhibited hemodynamic and cytokine responses to endotoxin profoundly if given immediately after LPS infusion.[412] Lidocaine further ameliorated the inhibitory effects of flunixin on recovery of mucosal barrier function following ischemic injury in equine small intestine.[413] Use of lidocaine therefore may have merit in endotoxemic patients. A common regimen for lidocaine use in horses is the administration of an initial bolus (1.3 mg/kg body mass) followed by continuous infusion at a rate of 0.05 mg/kg/min.

ω-3 Fatty Acids

High concentrations of ω-3 fatty acids can alter the phospholipid composition of cellular membranes toward a decreased ratio of ω-6 to ω-3, affecting membrane functions such as phagocytosis, receptor binding, and activities of membrane-bound enzymes.[286] Most important for the treatment of endotoxemia, ω-3 fatty acid incorporation into cell membranes decreases the availability of arachidonic acid (an ω-6 fatty acid) for eicosanoid synthesis[414] and provides alternative substrates. Metabolism of ω-3 fatty acids via the COX and lipoxygenase pathway leads to the production of 3-series prostaglandins and 5-series leukotrienes, which have less biologic activity than their 2-series and 4-series counterparts derived from arachidonic acid. Aside from these mechanisms, ω-3 fatty acids prevent LPS-induced upregulation of CD14 in monocytic cells; therefore, they may be able to block transmembrane signaling of LPS.[415] Cells from horses given linseed oil (high in ω-3 fatty acids) for 8 weeks before blood collection showed significantly decreased expression of procoagulant activity, TXB_2, and TNF in response to LPS stimulation.[416,417] In an in vivo experimental model of endotoxemia in horses, treatment resulted in prolonged activated partial thromboplastin time and whole blood recalcification time, suggesting an anticoagulant effect; however, a significant beneficial effect on clinical response and serum eicosanoid concentrations was not observed.[418] Because dietary addition of ω-3 fatty acids requires several weeks of treatment, IV infusion was evaluated and shown to alter the composition of cell membrane phospholipids rapidly.[419] Further evaluation of this treatment for use in horses is necessary before specific dosage recommendations can be made.

Interference with the Effects of Specific Inflammatory Mediators

Antibodies Directed Against Tumor Necrosis Factor

Monoclonal and polyclonal antibodies against equine TNF have been evaluated in horses.[420-422] Administration of a monoclonal antibody preparation before LPS infusion resulted in significantly reduced plasma TNF activity, improved clinical abnormality scores, lower heart rate, and higher leukocyte count compared with controls.[421] Plasma concentrations of lactate and 6-keto-PGF1α were reduced significantly, whereas TXA_2 production was not affected.[420] In another study[422] administration of a rabbit polyclonal antibody against recombinant human TNF did not improve clinical and hematologic parameters when given shortly (15 minutes) after LPS infusion, although inhibition of TNF activity was present in vitro.[422,423] Findings in horses are in agreement with studies in other species and suggest that beneficial effects of TNF inhibition may be limited to administration before LPS exposure. Widespread clinical use therefore is unlikely to become feasible. Clinical trials in septic human patients have not shown significant benefits of TNF antibody treatment.[424,425]

Platelet-Activating Factor Receptor Antagonists

The effects of selective PAF receptor antagonists have been evaluated. PAF is implicated in the development of systemic hypotension,[426] LPS-induced platelet aggregation,[427] ileus,[428] and increased vascular permeability[429] and may mediate recruitment of leukocytes to inflamed tissues.[430,431] A study in horses using the PAF receptor antagonist SRI 63-441 before LPS infusion showed significant decreases in heart rate and shorter elevation of lactate concentrations in response to the treatment. Although not statistically significant, additional beneficial effects included delayed onset of fever, a shortened period of neutropenia, and reduced maximal platelet aggregation.[432]

Supportive Care

Fluid Therapy and Cardiovascular Support

Fluid therapy is a mainstay of therapy of most endotoxemic patients suffering from the cardiovascular effects of systemic inflammation. Many endotoxemic equine patients require fluid therapy for treatment of the underlying disease process and correction of dehydration and electrolyte and acid-base abnormalities. Principles of fluid therapy are discussed in Chapter 4 of this text.

Patients with severe hypovolemia and shock present management challenges, especially because increased vascular permeability in endotoxemic patients requires careful consideration of fluid therapy plans. A rapid increase in total body fluid volume may be detrimental in patients with compromised cardiac and peripheral vasomotor function and may increase the severity of vascular pooling in peripheral organs. In these patients hypertonic solutions or colloids may be more appropriate means of stabilization than large volumes of crystalloid solutions. Hypertonic saline solution (7.5% sodium chloride) is the most commonly used hypertonic solution in horses and has beneficial effects in endotoxemic patients.[433] A dosage of 4 mL/kg is recommended, which should be given as a bolus infusion over 10 to 15 minutes, followed by administration of an isotonic solution to restore total body fluid volume. The clinician should use hypertonic saline with caution in patients with sodium or chloride derangements and should monitor serum electrolyte concentrations in the case of repeated administration. Failure of urination despite appropriate fluid resuscitation should result in critical evaluation of renal function. In one recent study small-volume resuscitation with hypertonic saline plus hydroxyethyl starch failed to alleviate hemodynamic responses in experimental endotoxin infusion in horses.[434]

Plasma is an ideal colloid and should be administered to maintain a serum total protein concentration above 4.2 g/dL.[357] To raise plasma protein concentration and colloid osmotic pressure significantly, however, horses often require large volumes of plasma (7–10 L or more in a 450-kg horse), and alternative colloids should be considered. High-molecular-weight polymers are thought to provide superior oncotic effects in cases of sepsis and endotoxemia, when vascular permeability is increased. Hetastarch, or hydroxyethyl starch (Hespan), is commercially available as a 6% solution in 0.9% sodium chloride. Hetastarch molecules have a very high molecular weight, and degradation must occur before renal excretion.[435] These properties result in a longer plasma half-life and prolonged oncotic effects compared with other colloids; persistence of the oncotic effect for 24 hours was observed in hypoproteinemic horses.[436] A dosage of 5 to 15 mL/kg given by slow IV infusion along with an equal or greater volume of crystalloid fluids has been recommended.[435,437] In human patients prolonged activated partial thromboplastin time, decreased factor VIII activity, and decreased serum fibrinogen concentration have been described in association with hetastarch use.[438] In the limited number of equine studies, bleeding times were not affected[439,440]; however, patients treated with hetastarch should be monitored for coagulopathy.

Metabolic acidosis in endotoxic shock is attributable to lactic acidemia and inadequate tissue perfusion.[441] Acid-base balance often improves considerably after fluid resuscitation alone; however, additional sodium bicarbonate may be required in cases in which serum bicarbonate concentration remains below 15 mEq/L.

Foals with sepsis are frequently hypoglycemic, and 5% dextrose solutions are useful as initial resuscitation fluids. The clinician should reduce the glucose concentration of IV solutions according to the blood glucose concentration to avoid prolonged hyperglycemia. Administration of hyperimmune plasma (20–40 mL/kg body mass) is highly recommended in foals with evidence of partial or complete failure of passive transfer.

One should consider positive inotropic and vasomotor agents in patients with persistently inadequate tissue perfusion. Lower dosages of dopamine (0.5–2 μg/kg/min) result in vasodilation of the renal, mesenteric, coronary, and intracerebral vasculature via dopaminergic effects, whereas higher dosages (up to 10 μg/kg/min) also exert stimulation of α_1-adrenergic receptors, resulting in increased myocardial contractility and heart rate.[442] Dobutamine is a direct α_1-adrenergic agonist and does not appear to have significant vasodilator properties. Dosages for dobutamine of 1 to 5 μg/kg/min as a continuous IV infusion have been recommended for use in horses. Norepinephrine was evaluated in hypotensive critically ill foals that were refractory to the effects of dopamine and dobutamine.[443] At dosages up to 1.5 μg/kg/min administered concurrently with dobutamine, six of seven foals showed an increase

in mean arterial pressure, and all foals had increased urine output. Because of the risk of cardiac side effects, close monitoring of heart rate and rhythm should accompany infusion of inotropes. Indirect blood pressure measurements using a tail cuff may be used to monitor the effects of treatment.

Management of Coagulopathy

More frequently than overt thrombosis or bleeding attributable to DIC, hemostatic abnormalities occur in the form of alterations in the coagulation profile. A procoagulant state with shortened bleeding times or prolonged bleeding times caused by consumption of clotting factors may be evident. One should address abnormalities in the coagulation profile as early as possible but especially if they persist more than 24 hours after initiation of therapy. Because of the complex interactions of coagulation and fibrinolysis during endotoxemia, it might be necessary to combine anticoagulant therapy with the administration of fresh frozen plasma to replace clotting and fibrinolytic factors. Heparin acts as an anticoagulant by activation of AT III and subsequent inhibition of thrombin, release of tissue factor pathway inhibitor from endothelial cells, and inhibition of platelet aggregation.[444] Because endogenous AT III levels frequently are decreased in patients with coagulopathy, the addition of heparin to fresh frozen plasma may be the most effective route of administration. An initial dosage of 100 IU/kg body mass followed by 40 to 80 IU/kg body mass thrice daily has been recommended.[357] Anemia caused by erythrocyte agglutination occurs in some patients during therapy with unfractionated heparin[445,446] but typically resolves within 96 hours if therapy is discontinued.[357] Because of the risk of microthrombosis associated with erythrocyte agglutination, use of low-molecular-weight heparin (50 IU/kg body mass subcutaneously [SC] every 24 hours) has been recommended[447] but may be cost prohibitive. Aspirin can be given orally (10–20 mg/kg body mass every 48 hours), which irreversibly inhibits platelet COX activity, to inhibit platelet aggregation and microthrombosis. Platelet hyperaggregability has been implicated in the pathogenesis of carbohydrate-induced laminitis,[448] and heparin and aspirin have been recommended to prevent the development of laminitis. In an in vitro study, however, aspirin did not inhibit endotoxin-induced platelet aggregation.[449]

Other Considerations

Luteolysis caused by increased concentrations of $PGF_2\alpha$ may lead to pregnancy loss in endotoxemic mares before day 55 of pregnancy (see Chapter 19).[450] Daily administration of altrenogest (Regu-Mate, Hoechst-Roussel Agri-Vet, Somerville, NJ) at a dosage of 44 mg orally consistently prevented fetal loss in mares if administered until day 70 of pregnancy.[331] Treatment with flunixin meglumine, by blockade of $PGF_2\alpha$ release,[332] also may contribute to the maintenance of pregnancy in endotoxemic mares. The pathogenesis of fetal loss and abortion caused by endotoxemia, surgery, or systemic disease later in gestation is not understood completely. Proposed mechanisms include direct effects on the fetus, placental function, or placental progesterone production.[451]

Decreased nitric oxide production by vascular endothelial cells in response to endotoxin has been suggested as a mechanism for vasoconstriction and decreased blood flow leading to laminitis)[452]; however, use of nitric oxide donors remains controversial. Maintenance of adequate peripheral perfusion and anticoagulant and antiinflammatory therapy may be helpful in preventing and treating laminitis caused by endotoxemia.

CRYOTHERAPY

Digital cryotherapy is a critical component of supportive care in the equine patient with suspected endotoxemia, including those suffering from many of the inflammatory diseases discussed in this chapter. Cryotherapy has been shown to reduce the severity of laminitis lesions in the oligofructose model,[453-455] including when initiated after the onset of lameness.[456] It has also been shown to decrease the incidence of laminitis in horses diagnosed with colitis.[457] When initiated, digital cryotherapy should include immersion of the hoof and pastern, at a minimum.[458]

Inflammatory Diseases of the Small Intestine

DUODENTITIS-PROXIMAL JEJUNITIS

Duodenitis-proximal jejunitis (DPJ) is an inflammatory condition affecting the upper small intestine and resulting in distention, abdominal pain, gastric reflux caused by excessive fluid and electrolyte secretion, and increased PF protein concentration without a significant elevated nucleated cell count. Other terms for this condition are *anterior enteritis* and *proximal enteritis.* Clinical signs of DPJ mimic those of a small intestinal obstruction. The clinical syndrome of DPJ was well described in the 1980s,[19,459-461] but the severity of clinical signs, especially duration of disease, is variable. Although not typical, DPJ can occur in conjunction with gastritis, ileitis, typhlitis, and colitis.

PATHOPHYSIOLOGY

Typical pathologic findings in horses with DPJ include involvement of the duodenum and usually the proximal jejunum.[19] The ileum and large colon usually are grossly normal. Gastric distention is common because of hypersecretion in the proximal small intestine combined with functional ileus. Small intestinal diameter often measures 5 to 7 cm, filled with malodorous, red to brown-red fluid. Duodenal and jejunal serosal surfaces may have varying degrees and distribution of bright red to dark red petechial and ecchymotic hemorrhages and yellow to white streaks. The enteric mucosal surfaces are usually hyperemic with varying degrees of petechiation and ulceration.

Microscopically, the most severe lesions are located in the duodenum and proximal jejunum but may extend proximally to the gastric mucosa and aborally to the large intestinal mucosa and submucosa.[19] Microscopic lesions include varying degrees of mucosal and submucosal hyperemia and edema, villous degeneration with necrosis and, more severely, sloughing of villous epithelium. The lamina propria, mucosa, and submucosa may have varying degrees of granulocyte infiltration (predominantly neutrophils), and the muscular layers and serosa may contain small hemorrhages. Proximal small intestinal serosal fibrinopurulent exudate is a common finding in the more severe cases; therefore the term *hemorrhagic fibrinonecrotic duodenitis-proximal jejunitis* has been suggested as a more descriptive name for this syndrome.[461]

Horses with DPJ can have hepatic changes including hepatocellular vacuolization, cholestasis, inflammatory infiltrate (either in association with centrilobular necrosis or periportal), and biliary hyperplasia.[462] Hepatic disease is thought to result from ascending infection via the common bile duct, local absorption of endotoxin via the portal circulation, systemic consequences of endotoxin absorption, metabolic imbalances, and hypoperfusion or hypovolemia.

In most cases, an underlying etiology cannot be determined. In some cases, *Salmonella* spp. or *Clostridium* spp. can be isolated from culture of gastric reflux. Salmonellosis has never been consistently identified in a majority of cases, and many horses with documented infections by these organisms do not develop DPJ. Alternatively, toxigenic strains of *C. difficile* were isolated from the reflux of five of five horses with DPJ and none of six control horses with other causes of nasogastric reflux.[463] To the author's knowledge, such an association has not been identified in other geographic locations. Another suspected infectious agent is *Fusarium* spp.[464] Alteration of the gastrointestinal microflora caused by recent dietary change has been suggested as a predisposing cause for DPJ; in one report, horses with DPJ were fed significantly more grain and were more likely to have grazed pasture, relative to horses with other forms of colic, but these associations were not deemed strong enough to allow clinical differentiation.[465]

Two intracellular processes control intestinal secretion: the cyclic nucleotide (cAMP and cGMP) and calcium systems.[169] Inflammatory mediators, microorganisms, and toxins can activate adenyl cyclase (vasoactive intestinal peptide and PGE_2) or guanylyl cyclase (bacterial enterotoxins) and induce increases in cAMP and cGMP, respectively. This reaction causes phosphorylation of specific protein kinases, which induce the actual mucosal membrane transport events. Increases in intracellular free calcium may arise from cyclic nucleotide–dependent release of stored calcium within the cell or from increased calcium entry across the cell membrane. Calcium may act through calmodulin, which then can activate membrane-phosphorylating protein kinases. The net effect is increased movement of sodium and chloride into the mucosal cell from the interstitium, with secretion of sodium and chloride into the intestinal lumen. Water follows the directional flux of sodium and chloride through highly permeable intercellular spaces. Several bacterial toxins and endogenous mediators can cause active secretion and contribute to a synergistic mucosal secretory response. Passive secretion of protein-rich fluid into the lumen occurs after damage to the mucosal epithelium, capillary endothelium, and submucosal inflammation in the proximal small intestine. The clinically relevant events that result from active and passive fluid secretion are proximal small intestinal distention and nasogastric reflux, dehydration, and circulatory shock.[466]

The concentration of protein in the PF from horses with DPJ is usually higher than in horses with small intestinal obstruction. A disproportionate increase in total protein concentration relative to nucleated cell count occurs, probably by leakage of blood or plasma into the peritoneal cavity without a significant stimulus for leukocyte chemotaxis. Suggested mechanisms for increased abdominal fluid protein concentration include serositis associated with inflamed intestine and small intestinal distention causing passive congestion and increased capillary hydrostatic pressure of visceral peritoneal vessels.[467] Small intestinal ileus is another hallmark sign of DPJ, and the pathophysiology is complicated, involving primary and secondary dysfunction of the central, autonomic, and ENSs and their purported roles in governing intestinal motility. Further detail regarding the effect of inflammation on small intestinal motility is provided in Inflammatory Disease of the Small Intestine later in this chapter.

CLINICAL AND CLINICOPATHOLOGIC SIGNS

Differentiating horses with DPJ from horses with small intestinal obstructive lesions can be challenging because there is no single distinguishing feature, and all information must be considered collectively. Horses with obstructive lesions of the small intestine usually show consistent signs of abdominal pain until the affected viscus is repaired surgically or ruptures. In contrast, signs of acute abdominal pain typically subside after gastric decompression and volume replacement in horses with DPJ. They are replaced by signs of lethargy and general malaise. On rectal examination the degree of small intestinal distention may be subjectively less with DPJ than with obstructive lesions, particularly following gastric decompression. Although the color and odor of gastric reflux can be similar, horses with DPJ tend to have a larger volume (≥4–20 L with each decompressive effort) of reflux than horses with obstructive lesions. Horses with DPJ often have a mild fever of 38.6°C to 39.1°C (101.5°F–102.5°F), whereas horses with obstructive lesions are typically normothermic or hypothermic.

Abnormalities in the leukogram are more common in horses with DPJ than with an acute obstructive lesion.[19,460] In addition, hyponatremia, hypochloremia, hypokalemia, prerenal azotemia, and elevated hepatic enzymes (GGT, alanine transaminase, and AP) are often evident.[462] Hyperlactemia from poor tissue perfusion and hypovolemia is common with both conditions.

PF analysis may be helpful in distinguishing DPJ from an obstructive lesion. The typical findings with DPJ include an increased PF protein concentration (often ≥3.5 g/dL) and a mild to moderate elevation of the peritoneal WBC count, although the count usually is less than 10,000 cells/μL; PF lactate concentration typically mirrors peripheral blood concentrations. The disproportionate increase in PF total protein compared with peritoneal nucleated cell count may be caused by leakage of blood or plasma without a marked leukotactic response.[19] The PF is usually yellow and turbid, but in severe cases, diapedesis can occur, resulting in a serosanguineous color. Strangulating lesions typically result in more severe changes in the PF. Serosanguineous PF with increased protein, lactate, and white and red blood cells is typical. Horses with intraluminal obstructions such as ileal impactions typically have grossly normal PF with a mildly elevated protein resulting from intestinal distention.[419,460,466]

Ultrasonographic findings in horses with DPJ typically include gastric and duodenal distention and segments of small intestine containing hypoechoic to anechoic fluid. The wall of the small intestine can be normal or thickened with time. Peristalsis can be decreased, normal, or increased. Differentiation from a small intestinal obstructive lesion remains difficult. More long-standing obstructions typically result in increased wall thickness, sedimentation of ingesta within the small intestinal lumen, and distended small intestine proximal to the lesion with collapsed intestine distally.

FIG. **12.6** Endoscopic image from a 15-year-old Quarter Horse gelding. The horse was diagnosed with duodenitis-proximal jejunitis (DPJ) and developed mild respiratory stridor and gagging and retching behavior after an indwelling nasogastric tube had been in place for 48 hours to allow for intermittent drainage of gastric reflux. The horse responded well to medical therapy for DPJ and pharyngitis-esophagitis.

In most cases, the diagnosis is suspected on the basis of clinical and clinicopathologic signs and response to therapy; a definitive diagnosis of DPJ requires gross examination of the duodenum and proximal jejunum at surgery or at necropsy

TREATMENT

Horses with DPJ appear to share a common characteristic clinical presentation. Treatment is supportive and should include volume replacement, analgesic and antiinflammatory therapy, gastric decompression, antiendotoxin therapy, antimicrobial therapy if indicated, nutritional support, and nursing care.

Gastric Decompression

Although the signs of abdominal pain usually resolve after gastric decompression, most horses remain lethargic. Horses with DPJ often require gastric decompression at 2-hour intervals, with 2 to 10 L of fluid recovered each time. Nasogastric tubes left in place for long periods cause varying degrees of pharyngitis (Fig. 12.6), laryngitis, and esophagitis, and maintenance of an indwelling nasogastric tube may further delay gastric emptying.[466,468,469] Thus one should use the smallest, softest nasogastric tube needed for gastric decompression and remove the tube as soon as possible.

Supportive Care

Much of the supportive care for horses with DPJ mirrors that described for other cases of endotoxemia and is discussed in detail in Endotoxemia earlier in this chapter. Specific fluid replacement should take ongoing losses through reflux into consideration. Horses should not receive food or water until they remain comfortable and reflux ceases. Occasional sips of water or rinsing of the mouth may decrease halitosis. The refeeding plan should be conservative, because horses refed quickly may relapse.

Antiinflammatory and Analgesic

NSAIDs are the most frequently used group of drugs for treatment of abdominal pain in horses (flunixin meglumine 0.25–1.1 mg/kg IV every 8–12 hours, with the higher dose given only at the least frequent interval). These agents also have beneficial antiinflammatory and antiendotoxic effects. The clinician must weigh the benefit of these drugs against their negative effects on gastrointestinal mucosa and renal function. Another popular analgesic option is butorphanol, an opioid agonist-antagonist, given at 0.02 to 0.1 mg/kg intramuscularly every 6 to 8 hours or as a constant rate infusion at 13 μg/kg/h.[470] This route appears to have minimal effects on gastrointestinal motility.

Antimicrobial

Because *Clostridium* spp. are suspected as a causative agent of DPJ, penicillin, metronidazole, or both may be administered to affected horses in geographic locations in which said organisms appear prevalent. Broad-spectrum antimicrobial therapy may be considered for horses with DPJ and significant leukopenia.

Nutritional Support

The veterinarian should consider the nutritional needs of horses with DPJ. Most horses have a total body protein loss because of cachexia and a protein-losing enteropathy. Total or partial parenteral nutrition may be indicated in horses that remain anorectic for more than 3 to 4 days. Parenterally administered solutions containing glucose, balanced amino acid solutions, lipid emulsions, balanced electrolyte and trace minerals, and vitamins have been administered to adult horses with small intestinal ileus or enterocolitis. Based on a small number of horses, this therapy has proved promising in terms of minimizing protein losses and decreasing the duration of illness. Postoperative parenteral nutrition ameliorates clinicopathologic evidence of starvation following small intestinal resection and anastomosis in adult horses.[471,472] Providing for part of the nutritional requirements of the horse (8000–12,000 kcal/day) is possible with glucose–amino acid solutions, which are of moderate cost. It is reasonable to suppose that providing nutritional support to an anorectic, severely ill horse will facilitate healing and even shorten the duration of illness. Thus the overall cost of providing parenteral nutritional supplementation to horses with DPJ may be offset by quicker recovery and diminished requirements for other, expensive treatments, but further data are necessary to accurately assess this point.

Prokinetics

Normal (healthy) intestine is necessary for optimal performance of most prokinetic agents in horses. Many motility-modifying agents likely are ineffective in cases of DPJ. Inflamed jejunal tissue has been shown to have downregulation and decreased production of motilin receptors, which may alter the prokinetic response to erythromycin.[473] However, some benefit may come of the judicious use of prokinetic agents in inflammatory conditions of the equine intestine, particularly if the agent provides additional effects. Lidocaine has shown particular promise for this use. Although the exact mechanism of action is unknown, the beneficial effects in horses with ileus are likely caused by antiinflammatory effects because a direct prokinetic effect has not been demonstrated.[474] In horses with nasogastric reflux attributable to POI or enteritis, a constant rate infusion of lidocaine was shown to reduce the hourly

volume of reflux and shorten the time to cessation of reflux compared with saline.[475] Prokinetic therapy with erythromycin lactobionate, metoclopramide, or bethanechol can also be considered.[476,477] Motility-modifying agents and the influence of inflammation on their effects are discussed in Gastrointestinal Ileus later in this chapter.

Surgical Therapy

Medical therapy is successful in most cases of DPJ. For horses with DPJ that continue to produce copious enterogastric reflux despite aggressive medical treatment, or when a mechanical obstruction cannot be satisfactorily ruled out, surgery may be considered. Refractory cases have improved with surgical intervention; however, some horses with refractory DPJ have been observed to recover after prolonged (up to 20 days) supportive care and gastric decompression. The latter is not recommended in the author's experience. For a horse exhibiting abdominal discomfort with small intestinal distention palpable per rectum and more than 2 L of gastric reflux, the veterinarian should recommend referral to an appropriate surgical facility. Typically, the main determinants for surgical intervention are degree and duration of abdominal pain, PF analysis, and results of (often repeated) rectal palpation and ultrasonography.

Short-term mortality rates have been reported to be 37% for horses in which manual evacuation of the small intestine into the cecum was performed surgically, compared with 40% for horses that received medical treatment.[478] A 95% recovery rate was reported in horses with DPJ that underwent laparotomy and manual evacuation of the small intestine into the cecum, combined with treatment for *C. perfringens* consisting of IV metronidazole and intramuscular procaine penicillin.[479] Drawbacks of surgery include the expense, risks of anesthesia, prolonged return to training, and risk of incisional complications. However, when an obstruction cannot be ruled out, these concerns are of minor consequence.[466]

PROGNOSIS

Survival rates for DPJ range between 25%[460] and 94%.[19,460] At present the survival of horses with DPJ that undergo surgery is much greater than previously described, and certainly greater than that of horses with small intestinal obstruction that do not have surgery.[478,479] Horses with DPJ that receive appropriate therapy have a reasonably good chance of making a full recovery, and recurrence is rare. Horses that continue to have frequent episodes of voluminous nasogastric reflux and systemic signs of endotoxemia and sepsis have a poorer prognosis for recovery. Frequent complications of DPJ include laminitis, thrombophlebitis, and weight loss. There appears to be geographic variation in the severity and prognosis for DPJ, with horses in the southeastern United States most severely affected.

EQUINE CORONAVIRUS

Equine coronavirus (ECoV) is classified as a betacoronavirus and is associated with fever, lethargy, anorexia, and enteric disease (colic and/or alteration in fecal consistency) in some horses.[480-482] A definitive association between ECoV and diarrhea in foals was not recognized before the year 2000[483,484] or in adult horses before 2011.[480,481] Diagnosis is confirmed via fecal PCR.[480,482] Mortality is typically low (7%),[480,482] with death caused by suspected[482] or confirmed[485] hyperammonemia and neurologic disease or severe endotoxemia and sepsis.[482,485] In some outbreaks, the fatality rate has been higher (27%), with fecal viral load higher in nonsurvivors.[486] Histologically, ECoV is associated with necrotizing enteritis, particularly in the jejunum and ileum, with hemorrhage in the ventral colon in nonsurviving horses in one report.[485]

INFLAMMATORY SMALL INTESTINAL DISEASES ASSOCIATED WITH MALABSORPTION AND MALDIGESTION

Malabsorption and maldigestion are commonly recognized clinical problems in humans and small animals and documented clinical entities in the horse. The term *malabsorption* implies impairment of digestive and absorptive processes arising from functional or structural disorders of the small intestine and related organs, the pancreas, liver, and biliary tract. The condition can affect absorption of carbohydrates, proteins, fats, vitamins, minerals, and to a lesser extent, water and electrolytes. In horses, the resulting pathophysiologic changes may influence large intestinal function adversely through alterations in the substrate presented for fermentation or through direct infiltration of the large colon.

Differentiation between carbohydrate, protein, or fat malabsorption is not possible in the horse because of the herbivorous diet and the contribution of large intestinal functions. The rarity of pancreatic problems, such as exocrine pancreatic insufficiency, in horses along with their herbivorous diet makes maldigestion less problematic, but maldigestion can contribute to chronic weight loss in horses with severe infiltrative small intestinal disease and exacerbate diarrhea in the suckling foal through reduced intestinal bile salt concentrations from hepatic or ileal dysfunction.

Malabsorption is not synonymous with diarrhea, although diarrhea may be a feature. Adult horses rarely exhibit diarrhea with small intestinal problems unless large intestinal involvement is concomitant. Chronic diarrhea is predominantly a large intestinal disorder that reflects an overload of water and electrolytes and thus may be considered a state of impaired absorption. Primary small intestinal disease is more likely to occur in neonates and young foals. For example, acquired small intestinal brush border lactase deficiency may result in increased lactose fermentation in the large intestine and induction of osmotic diarrhea.[487]

The clinical signs of chronic wasting and poor body condition, although nonspecific for a diagnosis of malabsorption antemortem, can typically be attributed to proliferative or inflammatory intestinal disorders, often collectively referred to as *chronic inflammatory bowel diseases* (CIBD).[488]

Clinical Assessment

The primary clinical sign associated with diseases of malabsorption and maldigestion is weight loss with or without diarrhea. Physical, ultrasonographic, and laboratory assessment is as described for other gastrointestinal diseases and detailed in Diagnostic Evaluation earlier in this chapter.

Rectal biopsy is easy to perform and may provide an indication of cellular infiltration that could be present at more proximal locations, but interpretation is often difficult. In one retrospective study, inflammatory bowel disease was

diagnosed from rectal biopsy specimens in approximately 50% of cases.[489] In that report, simple proctitis (neutrophils in the crypt or surface epithelium) was associated with inflammatory disorders, whereas only mild scattered neutrophil infiltration was seen in controls. Rectal biopsy aided diagnosis for 3 of 7 horses with lymphocytic-plasmacytic enterocolitis[490] and 1 of 2 horses with eosinophilic enterocolitis.[491] Tables 12.3 and 12.4 present the clinicopathologic and pathologic features of the diseases most commonly associated with malabsorption. In the same animal the extent and severity of pathologic changes differ in different regions of the small and large intestines, influencing the severity of clinical signs and abnormalities in tests of intestinal function. Early diagnosis remains a challenge, and even multiple intestinal biopsies taken at exploratory laparotomy may prove unhelpful.

Biopsies of skin, liver, lymph node, or lung may reveal evidence of multisystemic disease and can be easily obtained in the standing horse, with organ biopsies typically obtained with ultrasonographic guidance. Duodenal mucosal biopsies can be obtained endoscopically. Exploratory laparotomy facilitates rigorous inspection of the gastrointestinal tract and associated organs to obtain multiple biopsies from intestinal sites and lymph nodes. Cost and potential postoperative complications may limit surgical procedures for diagnosis. Laparoscopy may provide an alternative means to facilitate biopsy of certain tissues but is typically more helpful from a diagnostic rather than therapeutic standpoint. From this perspective, surgical exploration should be considered as an option early in the process rather than as a last resort.

Carbohydrate absorption tests, described in Diagnostic Evaluation earlier in this chapter, can provide a practical and inexpensive means to assess the absorptive capability of the small intestine. Pathologic changes in the mucosa and submucosa must be extensive and widely distributed to greatly affect the peak plasma concentration and shape of the curve. In one report of 42 mature horses with chronic weight loss, a normal OGTT (peak glucose concentration at 120 minutes >85% baseline) was not associated with abnormal small intestinal morphology in any of the 5 horses in which it was documented. When peak glucose concentration was between 15% and 85% of baseline at 120 minutes (considered partial malabsorption), approximately 72% had small intestinal infiltrative disease, and when peak concentration at 120 minutes was less than 15% above baseline (total malabsorption), all had severe small intestinal infiltrative disease.[59] Other reports have documented horses with flat OGTT curves that subsequently showed more normal OGTT responses and resolved clinical condition.[492] Carbohydrate absorption tests probably have poor diagnostic sensitivity to detect small intestinal involvement in horses with chronic diarrhea and predominantly large intestinal problems.[493] An abnormal absorption test and weight loss can occur in the horse as a transient event and without significant morphologic changes in the small intestine.

The intestinal sugar active transport system has a low affinity for D-xylose in the equine jejunum in vitro, hence D-xylose absorption likely occurs primarily by convection or diffusion.[494] An abnormal D-xylose absorption test likely indicates abnormal mucosal surface area or permeability and has been observed in horses with CIBD, parasitism, and idiopathic villous atrophy.[488,495] Abnormal absorption curves have been detected in the absence of small intestinal histologic changes,[496] and interpretation is clouded further by findings from small intestinal resection studies in healthy ponies. One study demonstrated a progressive decline in mean peak xylose concentration after 70% distal small intestinal resection in ponies despite their normal clinical appearance and absence of diarrhea.[497] In another study, a similar decline in peak xylose concentration following extensive (≥60%) small intestinal resection was accompanied by weight loss, diarrhea, and ill thrift.[498] Peak xylose concentrations were much lower in horses with granulomatous enteritis than those with eosinophilic granulomatosis (EG), whereas in EG the absorption curve shifted to the right, with the peak occurring at 240 minutes.[499] This is not surprising given the typical lesion distribution with these disorders. As with the OGTT, results of the xylose absorption test can improve following therapy.[500]

Alimentary Lymphosarcoma

Alimentary lymphosarcoma of the horse may represent a primary neoplasia of the gut-associated lymphoid tissue with significant cellular infiltration of the small intestine and associated lymph nodes with minimal large intestinal or systemic involvement. Case series and pathology reports indicate that young horses 2 to 4 years of age primarily are affected, although the age range can be broad.[501-503] No breed or sex predilection has been documented, and disease prevalence is unknown. Despite the progressive nature of lymphomata, onset of clinical signs can be rapid, and the animal may become acutely ill. As with all adult cases of CIBD, antemortem diagnosis is by a process of exclusion and usually is confirmed postmortem. Frequent abnormalities include anemia, thrombocytopenia, neutrophilia or neutropenia, and hypoalbuminemia with hyperglobulinemia, resulting in either a normal elevated serum protein. Lymphocytosis is rare. Intraabdominal masses such as enlarged mesenteric lymph nodes may be palpated per rectum. Abdominocentesis and rectal biopsy can provide a diagnosis but are not sensitive indicators of disease. Carbohydrate absorption tests usually reveal partial to total malabsorption indicative of the severely reduced surface area resulting from significant villous atrophy and the extensive mucosal or transmural infiltration. Confirmation of a diagnosis requires exploratory laparotomy to obtain multiple intestinal and lymph node biopsies if rectal biopsy and/or abdominocentesis are normal. Prognosis is poor, especially because most horses are presented in an advanced state of disease. Immunosuppressive drugs or chemotherapy may afford temporary improvement, but long-term outcome is unaffected.

Granulomatous Enteritis

Granulomatous enteritis was first described as a chronic wasting condition in 1974[504]; 9 of 10 horses were young Standardbreds. Most affected horses are 2 to 3 years of age. Case reports from many countries revealed a predominance of Standardbred over Thoroughbred horses by three to one.[499,505] Some of the Standardbreds were related, implicating a genetic predisposition, but this has not been proven. Prevalence of this disease is low. The condition is sporadic and has an insidious onset, and the course can be protracted. Significant diagnostic features include anemia, slight increases or decreases in WBC counts, hypoalbuminemia, normal serum protein or hypoproteinemia, occasional increases in serum AP activity, normal serum GGT activity, and enlarged mesenteric lymph nodes on rectal palpation. Partial or complete malabsorption is typically documented via carbohydrate absorption testing. One can attribute the low proportion of horses exhibiting diarrhea

TABLE **12.3** **Predominant Clinical and Clinicopathologic Features of Horses with Proliferative and Infl ammatory Bowel Diseases**

Condition	Breed	Age Range	Clinical Signs	Dermatitis/Coronitis	Hematology	Chemistry	Absorption Tests
Alimentary lymphosarcoma	None	2 yr to aged; Majority ≤4 yr	Weight loss, poor appetite, edema, depression, occadional fever, occasional diarrhea or colic	+/– Scurfy skin	Anemia, neutrophilia; lymphocytosis rare	Decreased albumin; TP normal to increased; increased globulin	Reduced absorption; partial to complete malabsorption
Granulomatous enteritis	Standardbred	1-6 yr; Majority ≤3 yr	Severe wasting, edema, variable appetite, depression, infrequent diarrhea, occasional slight fever	+/– Scurfy skin; severe lesions rare	Anemia; Leukocytes normal to slightly increased or decreased	Decreased albumin; TP normal to decreased; GGT normal, ALP normal to increased	Reduced absorption; partial to complete malabsorption
Multisystemic eosinophilic epitheliotropic disease	Standardbred, Thoroughbred	1 yr to aged; Majority ≤4 yr	Severe wasting, edema, appetite poor to ravenous, slight fever, diarrhea or soft feces common, rare colic, depression, oral ulcers	++++ Severe skin lesions and ulcerative coronitis prominent	Anemia rare to slight; neutrophilia and eosinophilia rare	Decreased albumin; TP normal to decreased; GGT and ALP normal to increased	Delayed absorption (peak shifted to right); reduced or normal peak concentration
Lymphocytic plasmacytic enterocolitis	None	3 yr to aged	Inappetence, depression, colic, edema		Normal	Decreased albumin and TP; increased fibrinogen	Inadequate absorption
Proliferative enteropathy	None	3-8 months; sporadic reports older	Depression, colic, diarrhea, edema, appetite often normal, concurrent infection	+/– Scurfy skin	Anemia, leukocytosis	Decreased albumin and TP; increased CK	Often normal

TABLE **12.4 Pathologic Features of Proliferative and Inflammatory Bowel Diseases of Horses**

Condition		Small Intestine	Large Intestine	Other Organs/Systems
Alimentary lymphosarcoma	G	*Constant;* extensive thickening, thickened mucosa, fissures, serosal plaques, nodules, congestion	*Infrequent;* unremarkable to thickened segments	MLNs massively enlarged; occasional enlargement of other LNs
	H	Villous atrophy (partial to total); crypts disappear with hyperplasia; infiltrate of pleomorphic lymphoid cells, plasma cells; transmural	Nothing evident to diffuse mucosal infiltration	Extensive infiltration of MLNs; moderate in other LNs (liver, spleen, stomach rare)
Granulomatous enteritis	G	*Constant;* thickened wall and mucosa, fissures, widespread ulceration (tiny ulcers)	*Common,* generally discrete	MLNs enlarged, edematous; stomach commonly affected (generally discrete); liver/pancreas rare
	H	Villous atrophy (partial to total), crypt hyperplasia and abscesses, diffuse granulomatous inflammation; mononuclear cells (lymphoid), giant cells, epithelioid foci; lymphangiectasia	Similar infiltrate usually discrete; mucosa, submucosa	Similar infiltrate; stomach discrete; MLNs discrete to florid macrophage infiltration; diffuse cortical hyperplasia
Multisystemic eosinophilic epitheliotropic disease	G	*Common;* diffusely thickened, especially proximal duodenum and distal ileum; serosal nodules or granularity; ulceration	*Constant;* severe; segmental or multifocal granuloma; mucosal (predominantly) and transmural thickening; extensive ulcers	MLNs and other LNs enlarged; stomach and esophagus commonly affected; liver/pancreas commonly affected; may be hyperkeratotic Skin: exudative dermatitis, ulcerative coronitis
	H	Villous atrophy rare; lymphocytic and eosinophilic infiltration most severe in cranial duodenum, ileum, ileocecal junction; infiltrate more widespread than gross lesions	Segmental/multifocal lesions, severe infiltration, reactive fibrosis, tissue eosinophilia, walled-off granulomata, central necrotic core of eosinophilic material	Similar infiltration with fibrosis of MLNs, liver, pancreas Skin: acanthosis, hyperkeratosis, diffuse infiltrate of eosinophils, lymphocytes in dermis; focal eosinophilic accumulations
Lymphocytic-plasmacytic enterocolitis	G	*Constant;* mucosal/submucosal edema; prominent folds	*Common;* edema, congestion, areas of mucosal ulceration	MLNs enlarged
	H	Villous blunting to atrophy; moderate to severe infiltration of lymphocytes, plasma cells; edema, dilated lymphatics	Similar infiltrate, less remarkable	Minimal evidence
Proliferative enteropathy	G	*Constant;* significant mucosal thickening, corrugated appearance from proximal jejunum to distal ileum	*Uncommon;* submucosal edema	MLNs unremarkable
	H	Villous shortening, severe hyperplasia of crypt epithelium, small curved bacteria in apical cytoplasm, mononuclear infiltrate	No evidence	No evidence

to the preferential distribution of inflammatory infiltration in the small intestine.[506] Rectal biopsy can be a useful aid to diagnosis.[489]

The cause of granulomatous enteritis is unknown. Several infectious agents have been implicated, including *Mycobacterium avium.*[507] The condition may represent a granulomatous hypersensitivity reaction. Immunomediated responses to dietary, parasitic, or bacterial antigens may be important initiating factors.[488] Six horses purported to have granulomatous enteritis were linked to environmental contamination with aluminum,[508] although problems existed regarding the case definition, data, and interpretation.[509]

Treatment of horses with granulomatous enteritis with a variety of drugs, particularly corticosteroids, has not affected the long-term outcome in the majority of cases.[510] Prolonged (5 months) corticosteroid administration produced clinical

remission and a favorable athletic outcome in a 6-year-old Standardbred gelding based on improvement in clinical signs and in D-xylose absorption.[500] Surgery may be indicated with localized disease. Two young horses underwent resection of the thickened terminal small intestine; one horse died 4 months after surgery, and the other remained clinically normal for at least 10 years.[505]

Multisystemic Eosinophilic Epitheliotropic Disease

Multisystemic eosinophilic epitheliotropic disease (MEED) encompasses disorders characterized by a predominant eosinophilic infiltrate in the gastrointestinal tract, associated lymph nodes, liver, pancreas, skin, and other structures accompanied by some degree of malabsorption and enteric protein loss. The disorders include chronic eosinophilic gastroenteritis,[511] EG,[499] chronic eosinophilic dermatitis,[512] and probably basophilic enterocolitis.[513]

Although prevalence is low, MEED appears to be more common than granulomatous enteritis. Most affected horses are 2 to 4 years of age, and Standardbreds and Thoroughbreds are reported to predominate. The condition is sporadic, has an insidious onset, and often a protracted course (duration of 1–10 months). Diarrhea is common. Severe skin lesions with exudative dermatitis and ulcerative coronitis are prominent and frequently are the principal presenting complaint. Despite extensive tissue eosinophilia, systemic eosinophilia is rare, and hematologic values are usually unremarkable. Notable features include hypoalbuminemia and elevations in serum GGT and AP activities. Most reports of carbohydrate absorption test findings indicate a reduced or normal peak concentration delayed for at least 180 minutes. Morphologic changes are less pronounced in the small intestine than in the large intestine,[514] and small intestinal lesions predominate segmentally in the proximal duodenum and distal ileum. Significant hyperkeratosis of the fundic region may contribute to gastric muscle contractile disruption. Diarrhea can be a consequence of the severe segmental or multifocal granulomatous lesions in the large intestine with mucosal and transmural thickening and extensive ulceration. Abundant fibrosis is a feature of all affected tissues.

The cause of MEED is unknown, and the disease may represent a chronic ongoing immediate hypersensitivity reaction against undefined antigens ingested or excreted into the lumen from parasitic, bacterial, or dietary sources. Infectious agents have not been identified.[511,512] Eosinophilia is a feature of parasitism in the equine intestinal tract, although nematodes rarely have been identified in any lesions of MEED.[511,515] Failure to detect larval structures in these lesions, however, may be attributable to chronicity of the disease and destruction of the parasites in tissue.[505] Biopsies of the rectal mucosa[489] or of the skin, liver, intestinal tract, and lymph nodes may assist in diagnosis. Unlike the other conditions associated with malabsorption/maldigestion in horses, MEED has definitive liver and pancreatic involvement; thus, maldigestion may contribute to the wasting disease.

Treatment has been attempted with a variety of drugs, including antibiotics, corticosteroids, and anthelmintics with larvicidal activity. Although some horses can improve briefly, the long-term prognosis is poor.

Eosinophilic Enterocolitis

Idiopathic eosinophilic enterocolitis affects segmental lesions in the small or large intestine, inducing signs of colic, often requiring surgical intervention.[505,516,517] This problem may not involve evidence of malabsorption and does not have multisystem involvement. Because the problem is often associated with signs of colic and not signs of malabsorption, eosinophilic enterocolitis differs from the other conditions discussed in this section and is often diagnosed at the time of surgery. It carries a much better prognosis than the other inflammatory bowel diseases.

Lymphocytic-Plasmacytic Enterocolitis

The morphologic findings in lymphocytic-plasmacytic enterocolitis reflect the predominant infiltrative cellular elements of this rarely encountered condition. No specific clinical or clinicopathologic features differentiate this condition antemortem from other inflammatory diseases of adult horses. In a retrospective study of 14 horses, carbohydrate absorption was abnormal or delayed in 9 of 12 horses, consistent with the predominance of small intestinal pathologic changes.[490] Rectal biopsies were abnormal in 3 of 7 horses, two of which were reported as having lymphocytic-plasmacytic proctitis. Prognosis is typically reported as poor, likely caused by the advanced nature of the condition at the beginning of treatment. In the author's experience, some horses with small intestinal mural thickening, lymphocytic-plasmacytic infiltrate evident on duodenal biopsy, and signs of abdominal pain and/or weight loss may improve with dietary modification and/or corticosteroid therapy.

Proliferative Enteropathy

Proliferative enteropathy (PE) typically affects weanling foals from 3 to 8 months of age and has been reported in North America, Europe, and Australia, causing disease in individuals or outbreaks of multiple affected animals on the same premise.[518-522] PE is uncommon in yearlings and adult horses.[518,523] The disease affects many other species, namely swine, and is caused by *L. intracellularis,* an obligate intracellular bacterium found in the cytoplasm of proliferative crypt epithelial cells of the jejunum and ileum.[518,524,525]

Like pigs, horses are affected as weanlings. The incubation period is 2 to 3 weeks in nonequine species and is presumed to be similar in horses. In some epidemiologic investigations, close proximity to swine operations was apparent, but in most instances such an association was not evident.[518,523] Comparisons of epidemiologic findings from the swine disease indicated that overcrowding, feed changes, antibiotic usage, and mixing and transportation were potential risk factors at two of the farms in one study, and recent weaning appears to be a common risk factor.[518] The window for exposure appears narrow,[526] and multiple cases on a given farm are common. Affected animals shedding the organism in the feces serve as a source of infection for herdmates. It is possible that nonequine species serve as reservoirs contributing to outbreaks on horse farms.

Profound hyperplasia of the mucosa associated with proliferation of crypt epithelium and crypt hyperplasia is induced locally in infected islands of tissue that eventually extend to the entire distal jejunum and ileum. *L. intracellularis* preferentially infects proliferating cells; thus, it is the tropism for the crypt epithelium. Infected cells proliferate far more rapidly than uninfected cells, suggesting that *L. intracellularis* directly

induces the proliferative response, but the molecular basis for enhanced proliferation is not known. *L. intracellularis* penetrates epithelial cells in a membrane-bound vesicle but eventually escapes the vacuole and is found free in the cytoplasm, concentrated at the apical pole of the cell. The gross pathologic lesions of equine PE are quite characteristic.[518] Lesions may be segmental and are most commonly found in the ileum and terminal jejunum in horses, but the duodenum may also be affected. Severe mucosal hypertrophy is often observed but may wane during the chronic stages of the disease. The mucosa may become corrugated with focal erosions or ulcers. Submucosal edema is often readily identified on cut sections of affected segments. Moderate to severe crypt hyperplasia with atrophy of intestinal villi is a consistent feature. Hyperplastic crypts are branched and may herniate into the submucosa. Necrosis, edema of the submucosal and lamina propria, hemorrhage, mononuclear inflammation, and muscular hypertrophy have been reported in affected intestinal segments but are not consistent. Special stains such as silver stain are required to detect intracellular organisms. The organisms are curved or comma-shaped rods found clustered in the apical cytoplasm of hyperplastic crypt epithelium. The proliferative response of the intestinal mucosa alters absorption of nutrients and fluid secretion by disrupting the architecture of the villi and by altering the maturation of epithelial cells into absorptive cells, accounting for the secretory diarrhea and often severe weight loss. The combined effects of the inflammatory response and malabsorption may account for the clinically observed protein-losing enteropathy.

Clinical signs include depression, rapid and significant weight loss, edema, diarrhea, and colic.[518] Poor body condition, a rough hair coat, and potbelly appearance are also reported. Not all clinical signs are present in all cases, and diarrhea has only been observed in approximately half of reported cases. Other problems often were concurrent, including respiratory tract infection, dermatitis, intestinal parasitism, and gastric ulceration. The most significant laboratory finding is profound hypoproteinemia, predominantly characterized by hypoalbuminemia; panhypoproteinemia can also occur.[518,521,527] Leukocytosis and hyperfibrinogenemia are also common, with occasional alterations in electrolytes (hyponatremia, hypokalemia, and hypochloremia) and elevated serum creatine kinase concentrations. Abdominal ultrasound commonly reveals increased small intestinal mural thickness.[521,527] Although small intestinal mural thickness >3 mm, in conjunction with clinical and clinicopathologic signs, is highly suggestive, PE should not be ruled out in the absence of this finding. Colloid oncotic pressure, if measured, is typically low.[527]

PE should be considered in a weanling foal with compatible clinical signs and severe hypoalbuminemia with exclusion of common enteric infections. Fecal PCR has very high specificity but variable sensitivity for confirmation of diagnosis.[528] Serum immunoperoxidase monolayer assay or indirect enzyme-linked immunosorbent assay (ELISA) are highly specific for exposure; submission of fecal PCR and serologic testing is recommended, although both tests are quite specific, because they can lack sensitivity, especially early in the course of disease (serology) or with prior antimicrobial therapy (fecal PCR).[518,527,529] Of note, fecal PCR can become negative in affected foals within 4 days of antimicrobial therapy.[530] PE is not typically associated with abnormal carbohydrate absorption test results.[518,530] In horses with diarrhea, other infectious causes should be ruled out. A definitive postmortem diagnosis can be confirmed by identifying characteristic mural thickening and intracellular bacteria within the apical cytoplasm of proliferating crypt epithelial cells using silver stains, PCR, and/or immunohistochemical testing.[518]

Antimicrobial therapy with erythromycin, alone or with rifampin, azithromycin, clarithromycin, oxytetracycline, doxycycline, metronidazole, or chloramphenicol has been reported.[518,519,527] Macrolides should not be used in adults or older foals because of an increased risk of colitis.[529] Recent reports favor the use of IV oxytetracycline, followed by oral doxycycline or minocycline, with apparent success.[519,527] Duration of therapy is typically 2 to 3 weeks. Affected foals often need supportive therapy including crystalloid fluid and electrolyte replacement and, potentially, colloid support. Nonsteroidal antiinflammatory therapy can be used as needed for significant pyrexia. Corticosteroid therapy is not indicated, because inflammation is not a significant pathologic finding. Response to therapy has been good, with reported survival rates between 82% and 93%.[518,519,527] Rapid improvement in clinical signs, even within 24 hours, precedes the rise in plasma protein concentration.

Foals with PE should be isolated from unaffected animals for at least 1 week after institution of antimicrobial therapy to avoid shedding of organisms into the environment. Intrarectal vaccination with an avirulent live vaccine marketed for use in pigs has demonstrated a protective effect in foals experimentally challenged with *L. intracellularis*.[531]

Miscellaneous Conditions

Abnormal D-xylose absorption has also been noted in association with AA amyloid-associated gastroenteropathy in an 18-year-old Morgan stallion[532] and a horse with a gastric mass and secondary small intestinal villous atrophy.[533]

Management, Therapy, and Outcome

The chronic wasting horse with suspected malabsorption and probable enteric protein loss generally has a guarded to poor prognosis. Diseases with a good prognosis include eosinophilic enteritis and PE. Prognosis may be improved through early and aggressive investigation to achieve a diagnosis. The owner must be cognizant from the start that the outcome may not be altered, even after protracted therapy; only a few case reports of successful responses with long-term follow-up have been documented.

Nutrition

Some level of digestive and absorptive capability remains in the diseased small intestine. Interval feeding of small quantities of easily digestible food may be beneficial. Diet may include feeds with a high fiber, but potentially low bulk. Some commercially available complete pelleted feeds offer high-fiber rations based on beet pulp and soybean hulls. Some affected horses may tolerate increased dietary fat. Consultation with an equine nutritionist may provide additional options for a given horse and, in the author's experience, can prove beneficial. The objective for an affected horse is to sustain, and preferably increase, dietary intake, value, and efficiency. The owner of an affected horse must be prepared to experiment with feeds slowly and deliberately, must be patient, and must keep records. Exposure to a feed component may contribute to the problem as an allergen eliciting a hypersensitivity reaction. Identifying the potential allergen through immunologic testing or by stepwise removal and outcome assessment over a longer period may be difficult.

Pharmacologic Therapy

Immunosuppressive agents have produced the most promising responses to ameliorate the effects of conditions associated with malabsorption, particularly CIBD. Short-duration, and in some cases more prolonged and sustained, improvements in body condition, weight gain, demeanor, energy, and activity levels have occurred following corticosteroid administration. Treatment should be initiated as early as possible in the course of disease. Initial parenteral (intramuscular or IV) loading doses of dexamethasone (sodium phosphate) should be followed with a series of depot injections, or orally administered prednisolone, on a tapered dose protocol over a period of months. Interval low-dose therapy may be necessary if clinical signs return after treatment ends. The lowest dose necessary to control the clinical signs with alternate-day therapy should be used. Clinical benefits far outweigh concerns over potential adverse effects. Chemotherapeutic agents such as vincristine, cytosine, cyclophosphamide, and hydroxyurea have been tried in a few cases of CIBD or lymphosarcoma with no apparent success, probably related to the advanced stage of the disease when treatment was initiated and the dose selected.

SURGERY

Resection of a segment of intestine that is edematous, hemorrhagic, or constricted is an option in localized forms of CIBD,[505,517] particularly if gross changes are not discernible in adjacent or distant parts of the intestinal tract—that is, malabsorption is not a feature. Long-term outcome has been favorable. Removal of a substantial proportion of the diseased small intestine may be indicated in a horse with malabsorption, considering that resection of 70% distal small intestine was performed in healthy animals without inducing adverse effects.[497] Because pathologic changes may exist in normal-appearing small or large intestine that is not resected or biopsied, the prognosis remains guarded. Two young horses with granulomatous enteritis had the thickened terminal small intestine resected with positive outcomes; one survived 4 months, the other has a follow-up extending more than 10 years.[505]

Inflammatory Diseases of the Large Intestine

Acute diarrhea caused by colitis in adult or young horses is a potentially life-threatening disorder with a variety of possible etiologies (Table 12.5) characterized by hypersecretion of fluid, motility disturbances, and an impaired mucosal barrier resulting from direct injury or inflammation. Many of the clinical and clinicopathologic features are similar regardless of the underlying cause. Severe dehydration with profound electrolyte abnormalities is common, as is systemic inflammation secondary to absorption of endotoxin or other bacterial products through compromised gastrointestinal mucosa. Severe cases may be complicated by serosal inflammation and mural ischemia and infarction as a direct extension of mucosal inflammation or secondary to coagulopathies. The diagnostic approach for horses with acute diarrhea is aimed at determining the underlying etiology but must be accompanied by clinical and laboratory assessment of hydration, electrolyte and acid-base balance, organ function, and evaluation of the degree of systemic inflammation and the integrity of the intestinal wall. The therapeutic approach for horses with colitis, regardless of cause, consists primarily of controlling local and systemic inflammation, maintaining fluid and electrolyte balance, and promoting mucosal repair. In addition, some horses with acute colitis require specific therapy aimed at the underlying etiology.

INFECTIOUS DISEASES

Salmonellosis

Pathogenesis

S. enterica is a species of gram-negative facultatively anaerobic bacteria that is a common gastrointestinal pathogen in horses. Many serovars of *S. enterica* have been reported to infect horses, but those classified in group B appear to be more commonly associated with disease than those in other groups. Group B includes *S. enterica* var. Typhimurium and *S. enterica* var. Agona, two of the species most frequently isolated from horses.[534-536] *S. enterica* var. Typhimurium is the most pathogenic serotype in horses and is associated with a higher case fatality rate than other serovars of *S. enterica*.[534] The number of horses that are inapparently infected with and actively shed *S. enterica* in their feces has been reported to be as high as 10% to 20%, but actual prevalence of *S. enterica* shedding in the general horse population is likely to be much lower, less than 2%.[537] Horses shedding *S. enterica* are a potential source of infection to susceptible horses,[534,538] as are environmental reservoirs.[539-541] For these reasons salmonellosis is one of the most common nosocomial diseases in horses. Nosocomial salmonellosis significantly affects morbidity and mortality in hospitalized horses.[542] The emergence of multidrug resistance in equine *S. enterica* isolates has been a cause of concern because of the importance of salmonellosis as a nosocomial disease and because a number of serovars of *S. enterica* are significant zoonotic pathogens.[540,543-546]

The virulence of the bacteria varies tremendously with serotype and even among strains of the same serotype. This is because of the important role of host susceptibility in the pathogenicity of particular organisms. The infective dose is generally on the order of millions of organisms inoculated orally, but various environmental and host factors can reduce the infective dose to a few thousand or even hundreds of organisms.[547-549] Environmental factors or stresses that increase susceptibility to *S. enterica* infection are not well defined, but it is known that high ambient temperature, for example, can greatly increase the prevalence of salmonellosis in horses.[539,548,549] Indeed, the peak incidence of salmonellosis in horses occurs in late summer and fall.[539,548,549] Other environmental and host factors that are associated with salmonellosis or shedding of *S. enterica* organisms in feces include transportation, antibiotic administration before or during hospitalization, gastrointestinal or abdominal surgery, general anesthesia, preexisting gastrointestinal disease (e.g., colic, diarrhea), the presence of leukopenia or laminitis during hospitalization, prolonged hospital stay, change in diet, and immunosuppression.[534,541,549-551] Interestingly, foals with gastrointestinal disease are more likely to shed *S. enterica* organisms than are adult horses with gastrointestinal disease.[548]

Host factors that restrict gastrointestinal colonization and invasion by pathogens include gastric pH, commensal

TABLE **12.5 Differentials and Diagnosis of Some Causes of Acute Diarrhea in Adult Horses**

Category	Differentials	Diagnosis
Infectious	Salmonellosis	Fecal culture (five consecutive) Fecal PCR
	Clostridium perfringens	Quantitative fecal culture Fecal toxin immunoassay or PCR
	C. difficile	Fecal culture Fecal toxin immunoassay or PCR
	Neorickettsia risticii	Fecal or blood PCR Serology
	Coronavirus	Fecal PCR
Parasitic	Strongylosis	Fecal egg counts Cranial mesenteric artery palpation Serum IgG(T)
	Cyathostominosis	Fecal egg count Rectal biopsy Cecal or colonic biopsy
Toxic	NSAID	History and clinical signs Right dorsal colon ultrasonography Laparoscopy or laparotomy
	Cantharidin	History of exposure Fecal or urine cantharidin concentrations
	Arsenic	History of exposure Fecal, blood, urine, or tissue arsenic concentrations
Miscellaneous	Carbohydrate overload	History of inappropriate ingestion of carbohydrate Blood lactate concentration
	Sand enteropathy	Auscultation of ventral colon Fecal sand content Abdominal radiography

Ig, Immunoglobulin; *NSAID,* nonsteroidal antiinflammatory drugs; *PCR,* polymerase chain reaction.

gastrointestinal flora, gastrointestinal motility, the mucosal barrier, and mucosal immunity.[534,552] Gastric acidity is an important defense mechanism for preventing live organisms from reaching the intestine.[552] Altering the gastric pH, with histamine H_2 receptor antagonists, for example, may increase susceptibility to infection. Gastrointestinal flora inhibit the proliferation and colonization of *S. enterica* by secreting bacteriocins, short-chain fatty acids (SCFAs), and other substances that are toxic to *S. enterica.*[552] Elements of the normal flora compete for nutrients and space, especially on the mucosa.[552] Being predominantly anaerobic, the normal flora maintain a low oxidation-reduction potential in the environment of the large intestine, which inhibits the growth of many bacterial pathogens.[553] The importance of normal host gastrointestinal ecology is illustrated by the fact that disturbances of the colonic flora with antibiotics, changes in feed, ileus, or other underlying gastrointestinal disease markedly increases the susceptibility of the host to infection by *S. enterica,* often resulting in serious disease.

The immune status of the host may be one of the most important factors determining not only the susceptibility to *S. enterica* infections but also the degree of invasion and subsequent outcome of the infection. Local immunity, such as mucosal antibody secretion and enterocyte-derived cationic peptides, prevents colonization of the mucosa.[552,554,555] Opsonizing antibodies and activation of the complement cascade are important in fighting systemic invasion by *S. enterica* by increasing the efficiency of phagocytosis and by direct bactericidal activity. Humoral immunity, however, is often ineffective in preventing disease and dissemination once invasion occurs and *S. enterica* is established in its intracellular niche. Following invasion, *S. enterica* is capable of surviving and multiplying within macrophages, rendering the humoral (noncellular) immune systems ineffective.[556,557] Specific cellular immunity may be the most effective defense mechanism in the host arsenal against dissemination and systemic infection by *S. enterica.*[557,558] Protective immunity in horses and calves may be induced by oral inoculation with small numbers of virulent organisms, but the duration of the immunity is not known.[559,560] Oral and parenteral vaccines using killed or attenuated organisms and bacterial products have been promising but are effective only against homologous organisms and are usually not cross-protective among different serogroups.[559-561]

In adult horses *S. enterica* primarily infects the cecum and proximal colon, causing enterocolitis, with limited likelihood of dissemination beyond the intestine. In foals, however, salmonellosis is often associated with septicemia. The ability of *S. enterica* to cause enterocolitis depends on the ability of the bacteria to invade the gastrointestinal mucosa.[552,556] Invasion of the gastrointestinal mucosa occurs preferentially through specialized enterocytes called *M cells* that overlie intestinal lymphoid tissues such as Peyer's patches in nonequine species. M cells are exploited by a variety of enteric pathogens

during infection of intestinal tissue.[562] Invasion of the epithelium occurs by self-induced uptake via the apical membrane of the M cell, often killing the cell in the process.[556] *S. enterica* then invades neighboring cells via the basolateral membrane, eventually spreading the destruction of the epithelium beyond the principal area of attack. Virulent *S. enterica* have a well-developed invasion mechanism that involves the generation of an apparatus called a type III secretory system that enables virulence gene products to be injected directly into enterocytes.[563] Virulence proteins injected by *S. enterica* into enterocytes engage the cellular machinery and induce the cell to engulf the bacteria by macropinocytosis. *S. enterica* virulence gene products also induce enterocyte chloride and fluid secretion and upregulate enterocyte transcription of inflammatory cytokines (TNF-α and IL-1β) and chemokines that trigger a mucosal inflammatory response.[81,556,563]

Once *S. enterica* has invaded the mucosa, organisms are quickly phagocytosed by macrophages and dendritic cells in the lamina propria and in lymphoid tissues. The ability of *S. enterica* to disseminate systemically and cause enteric fever is associated with the ability to survive and proliferate in macrophages. Indeed, phagocytes have an important role in dissemination to blood, lymph nodes, liver, and spleen.[564] The majority of *S. enterica* in the blood and tissues of animals infected with a strain of *S. enterica* that is competent to cause enteric fever are within phagocytic cells.[564] In adult horses with salmonellosis, dissemination appears to be limited to the intestine and mesenteric lymph nodes, and *S. enterica* is rarely cultured from blood. However, in foals and in some adults, *S. enterica* causes an enteric fever–like disease with dissemination to mesenteric lymph nodes, liver, spleen, and blood.

Specific virulence gene clusters called *pathogenicity islands* encoded on the chromosome or on plasmids confer the main virulence traits of *S. enterica:* invasion, enteropathogenesis, intracellular survival, and proliferation.[556] Some of the genes encoded within these islands or virulence factors are sensors that signal to the bacteria that it has entered an intracellular environment and to turn on other genes required for intracellular survival. Others, such as invasion genes, are transported from the bacteria and injected into macrophage cytosol by a type III secretory system apparatus to prevent phagosome-lysosome fusion and subvert other essential macrophage-killing mechanisms. Virulent *S. enterica* may also possess multiple genes that enable adhesion to target cells or confer resistance to reactive oxygen and nitrogen metabolites, which is, perhaps, the most lethal antimicrobial mechanisms of macrophages.[565]

Diarrhea associated with salmonellosis has multiple causes. An *S. enterica* cytotoxin inhibits protein synthesis in mucosal cells, causing morphologic damage and altered permeability.[566] Virulent *S. enterica* also produce an enterotoxin that is similar to the heat-labile (LT) toxin produced by *E. coli*.[567,568] This enterotoxin contributes to, but is not required, in the pathogenesis of diarrhea.[569,570] *S. enterica* enterotoxin increases secretion of chloride and water by colonic mucosal cells in many species, including horses, by increasing intracellular cAMP concentrations.[567,568,571]

The ability of virulent *S. enterica* to cause diarrhea appears to be most closely associated with the ability to invade enterocytes and to trigger an inflammatory reaction in the intestinal tissue.[103,556] Gene products injected into enterocyte cytosol by the type III secretory system of invading *S. enterica* stimulate chloride and fluid secretion.[563] *S. enterica* invasion of enterocytes is also a potent activator of inflammatory chemokine and cytokine production, resulting in the recruitment of leukocytes, particularly neutrophils, and activation of resident macrophages and mast cells. Products of these activated leukocytes, including prostaglandins, leukotrienes, reactive oxygen metabolites, and histamine, are potent stimulators of chloride secretion in the colon of many species.[213,552,572,573] The ENS integrates the diverse processes of pathogen recognition, triggering of the inflammatory response, and induction of enterocyte fluid secretion.[213]

Many of the inflammatory mediators studied stimulate colonic secretion by prostaglandin-dependent mechanisms, resulting in either increased intracellular cAMP or calcium concentrations, or both, in mucosal cells.[213] These mediators and the ENS may also stimulate secretion by prostaglandin-independent mechanisms, inhibit sodium and water absorption, cause motility disturbances, and potentiate tissue injury, all of which enhance the pathogenicity and dissemination of *S. enterica* and contribute to the pathogenesis of diarrhea.[213,573] Neutrophils recruited to the mucosa by signals generated by the infected enterocytes physically contribute to mucosal injury by producing a variety of products that are lethal to pathogens but are also toxic to host cells.[84,574] Neutrophils attracted to infected epithelial cells accumulate beneath the monolayer, lifting it off the basement membrane in sheets. Neutrophils also migrate across the epithelial monolayer in potentially massive numbers—enough to be detectable in feces as a marker of inflammatory diarrhea. Although the transepithelial migration of neutrophils has a benefit, positioning the host defense cell at the apical membrane to ward off attacks by invading bacteria, the mechanical disruption to the epithelial barrier may be significant enough to increase the permeability to macromolecules, bacterial products, and even bacteria.[574] Potentially massive losses of electrolytes, water, and protein can occur, depending on bacterial and host factors. Perhaps most devastatingly, mucosal injury and altered permeability allow systemic absorption of bacterial products and dissemination of bacteria, resulting in life-threatening sepsis.

Clinical Signs and Diagnosis

Four clinical syndromes of *S. enterica* infection have been documented clinically and reproduced experimentally in horses: (1) inapparent infections with latent or active carrier states; (2) depression, fever, anorexia, and neutropenia without diarrhea or colic; (3) fulminant or peracute enterocolitis with diarrhea; and (4) septicemia (enteric fever) with or without diarrhea.[575] Inapparent infections can be activated to clinical disease in compromised horses, such as horses with colic or horses being treated with antibiotics, causing mild to severe enterocolitis. Latent infections (nonshedding) can become active infections (shedding) under certain conditions, such as transportation stress and antibiotic treatment. Horses with depression, anorexia, fever, and neutropenia without diarrhea generally have a good prognosis and recover in several days without specific treatment.[575] The septicemic form is mostly restricted to neonatal foals and is uncommon in adult horses. The focus of this discussion is acute enterocolitis.

Acute enterocolitis is characterized by severe fibrinonecrotic typhlocolitis, with interstitial edema and variable degrees of intramural vascular thrombosis that may progress to infarction.[534] Severe ulceration of the large intestinal mucosa may occur, with serosal ecchymoses and congestion. The earliest signs of enterocolitis are usually fever and anorexia.[534,549] Signs of colic may be seen early in the course of the disease,

especially if ileus is present. Clinical signs of endotoxemia are common and range from fever, elevated heart and respiratory rates, poor peripheral perfusion, and ileus to fulminant and rapidly progressive signs of endotoxemic shock. Oral mucous membranes are often pale with perigingival hyperemia (a toxic rim) but may be brick red or cyanotic, with prolonged capillary refill time. Weakness, muscle fasciculations, cold extremities, and other signs suggestive of hypotensive shock; synchronous diaphragmatic flutter; abdominal pain; and marked metabolic and electrolyte abnormalities may be noted in severe cases of enterocolitis. Signs of mild dehydration may be observed before diarrhea is seen. Once diarrhea is evident, dehydration may rapidly become severe. Occasionally, horses die peracutely, without developing diarrhea.

Diarrhea may not occur for several days but usually is evident by 24 to 48 hours after the onset of fever.[534,549] The duration of diarrhea may be days to weeks. The character of the first diarrheal feces is usually watery, with particles of roughage, but may rapidly become fluid without solid material. Finding frank blood and fibrin in the feces is unusual. The volume of feces is often large, with frequent defecation. Straining or signs of colic may be observed when the patient is defecating, and rectal prolapse may occasionally occur. Persistent straining and rectal prolapse may be signs of colonic infarction. Abdominal borborygmi are often absent early in the course of the disease because of ileus but become evident later, usually when diarrhea begins. Fluid and gas sounds are commonly auscultated, but normal progressive motility is less frequently heard. Transrectal palpation may reveal edematous rectal and colonic mucosa and fluid-filled colon and cecum. Gastric reflux may be obtained, especially early in the course, when ileus is evident.

Hematologic abnormalities early in the course of the disease include moderate to severe neutropenia, lymphopenia, and leukopenia; a mild to moderate left shift; and toxic changes in the neutrophils.[534,549] Thrombocytopenia, moderate to severe hemoconcentration, and hyperfibrinogenemia are also common. Neutropenia is an early but nonspecific indicator of salmonellosis, often occurring concurrently with the onset of fever.[534] Later in the course of disease, neutrophilic leukocytosis may be seen, indicating recovery. A degenerating left shift, with metamyelocytes and myelocytes seen in the peripheral blood, is a poor prognostic sign.

Serum biochemical analysis may reveal azotemia, increases in serum sorbitol dehydrogenase and γ-glutamine aminotransferase activity, and increased blood lactic acid concentration. Azotemia is often prerenal, but acute hemodynamic renal failure may be seen in severely dehydrated, endotoxemic, or septic patients. Indeed, elevation of creatinine concentration is a poor prognostic indicator in horses with acute colitis.[576] Hemodynamic renal disease may be complicated by toxic injury caused by the administration of nephrotoxic drugs. Hyponatremia may also contribute to prerenal azotemia. Elevations in hepatocellular enzymes are usually mild and reflect damage to the hepatocytes from absorbed toxins, such as endotoxin, and from poor perfusion resulting from hypotensive shock, dehydration, or both. Lactic acidemia may be present, reflecting poor tissue perfusion. Plasma protein drops rapidly as protein is lost in the gastrointestinal tract, resulting in moderate to severe hypoalbuminemia and hypoglobulinemia. Peripheral or organ edema (vascular leak syndrome) may occur if hypoproteinemia is severe, coupled with systemic inflammation-induced increases in endothelial permeability.

Hypokalemia, hyponatremia, hypochloremia, and hypocalcemia are common electrolyte abnormalities in patients with enterocolitis. Metabolic acidosis may also be present, and DIC is common. Urinalysis may reveal isosthenuria, proteinuria, hematuria, cylindruria, or glucosuria if hemodynamic or toxic renal injury is present. The number of leukocytes in the feces is usually increased, and occult blood may be detected. PF is usually normal except when severe mural inflammation or colonic infarction occurs.

S. enterica in feces is routinely detected by analyzing five daily cultures of large samples (10–30 g) of feces using enrichment techniques.[534,577,578] The sensitivity of fecal culture can be as low as 30% to 50%, even if several fecal samples collected daily are cultured.[578] Concurrent culture of rectal biopsy specimens and feces increases the sensitivity of culture techniques to 60% to 75%.[578] Currently, the PCR test is the most sensitive and rapid way to detect *S. enterica* in feces. A single PCR test applied early in the course of disease is a more sensitive test for the presence of *S. enterica* than repeated fecal cultures,[579,580] with as high as 100% sensitivity and 98% specificity for detection of organisms in some reports.[581] Although detection of *S. enterica* organisms in feces does not prove a diagnosis of salmonellosis, the positive predictive value of either a positive PCR or culture result is high in horses with compatible clinical signs. Culture of peripheral blood may allow isolation of the organism if bacteremia or septicemia is present, but blood cultures are not a sensitive test for salmonellosis in adult horses. Foals are more likely than adults to become septicemic, and so blood culture is recommended in all foals with signs of sepsis. Increased numbers of fecal leukocytes suggest an invasive process in the colon but are not specific for salmonellosis.

Early in the course of the disease, dehydration, electrolyte and acid-base imbalances, endotoxemia, and sepsis may be life-threatening. Aggressive treatment during the acute stages to replace fluids lost in the diarrhea and to control sepsis and endotoxemia is often effective in controlling the primary disease. Weight loss and hypoproteinemia are often severe. Possible complications include multiorgan dysfunction, vascular leak syndrome with peripheral and organ edema, laminitis, acute renal failure, venous thrombosis and septic phlebitis, irreversible protein-losing enteropathy or chronic malabsorption, pulmonary aspergillosis, and gastrointestinal infarction. The reader is referred to the section Endotoxemia in this chapter for additional information regarding treatment of horses with severe endotoxemia and SIRS.

In many instances horses recover from acute salmonellosis with aggressive treatment, only to succumb to complications of the disease, which partially explains the high fatality rate of equine salmonellosis compared with that of human salmonellosis. Chronic mild to moderate diarrhea is occasionally seen in horses after a bout of severe salmonellosis, usually with protein-losing enteropathy. If the chronic diarrhea persists beyond 4 to 5 weeks after the onset of signs, the prognosis for recovery is poor.[549]

Potomac Horse Fever

Pathogenesis

Potomac horse fever is caused by the obligate intracellular rickettsial organism *N. risticii* (formerly called *Ehrlichia risticii*).[582-586] The disease is most common from late summer to early fall, with a peak incidence in July and August.[583,584] Potomac horse fever was first described in the northeastern

United States but has since been described now in most areas of the continental United States, with a particularly high prevalence in the Northeast and Midwest. The geographic distribution is characterized by a significantly higher percentage of cases found along waterways and rivers.[583,584] The disease occurs sporadically, both temporally and geographically, and can affect any age group of horses. The case fatality rate ranges from 5% to 30%.[583]

Transmission of *N. risticii* has been reproduced experimentally by oral, intramuscular, intradermal, SC, and IV routes.[583,587] Attempts to transmit the disease experimentally with ticks *(Dermacentor variabilis)* or biting flies *(Stomoxys calcitrans)* were unsuccessful.[588,589] *N. risticii* infects virgulate cercariae, larval stages of trematodes that use operculate freshwater snails of the family Pleuroceridae (*Juga* spp. in California and *Elimia* spp. in Ohio and Pennsylvania), as intermediate hosts in their life cycle.[590-593] Infected virgulate cercariae have been identified in aquatic snails collected in other parts of the world as well.[594] Although the trematode species infected with *N. risticii* remain to be definitively identified, at least two species have been identified as potential vectors,[595] and at least two potential definitive hosts were identified when *N. risticii* DNA was detected in the blood, liver, or spleen of 23 of 53 little and big brown bats harboring gravid trematodes in their intestinal tracts.[596]

Aquatic snails release large numbers of infected cercariae into water, in which they seek their next intermediate host, which is any of a variety of aquatic insects.[593,597] Successful transmission of *N. risticii* to horses was accomplished experimentally using trematode stages collected from *Juga yrekaensis* snails.[598] The number of PCR-positive snails in endemic regions corresponds to the seasonal incidence of Potomac horse fever and may be as high as 26%.[599] Preliminary studies suggest that *N. risticii* may in fact be naturally transmitted to horses through the ingestion of caddisflies and mayflies.[593,600]

The pathogenesis of *N. risticii* is not completely understood. The organism infects and survives in monocytes and monocyte-derived leukocytes and can be found in blood monocytes during natural infections, but the sequence of events resulting in enterocolitis remains open to speculation. The organism appears first to infect blood monocytes in experimentally infected horses, which may be the vehicle of organ infection.[585,601] It is unclear whether leukocytes of the monocytic lineage or epithelial cells are infected first in naturally infected horses. The target organ is the gastrointestinal mucosa, with the most severe lesions found in the large intestine.[156,601] Infection of human colonic cells in vitro does not cause major cytopathologic effects for several days.[602] Disruption of the microvilli in the region of the plasma membrane in which sodium chloride channels are located has been observed in human colonic cell cultures.[602] Infection in horses is associated with variable degrees of morphologic damage.[156,601] Mild morphologic damage and mononuclear cell infiltration of the lamina propria occur early during the infection, but fibrinous, necrotizing typhlocolitis with severe mucosal ulceration and inflammation of the lamina propria may occur later in the disease. Vasculitis and intravascular coagulation are consistent features in the large intestine, with perivascular edema.[156] *N. risticii* can be observed in mucosal cells and macrophages and mast cells of the lamina propria.[156,601] *N. risticii* can survive and multiply in macrophages by inhibiting the production of ROIs and avoiding lysosomal digestion by blocking phagosome–lysosome fusion.[603-605]

Some researchers have suggested that impaired sodium chloride absorption in the colon contributes to diarrhea in infected horses and may be related to destruction of the enterocyte membrane structure in the region of sodium chloride channels.[602,606] Direct injury to the mucosa by *N. risticii* and colonic inflammation are likely to be prominent features leading to diarrhea, especially later in the disease.[156] Loss of fluid, protein, and electrolyte is likely caused by mucosal injury and effects on enterocyte fluid secretion caused by the inflammatory response. Like other inflammatory conditions of the colon, systemic inflammation caused by absorption of bacteria and bacterial products is a potential complication of *N. risticii* infections if mucosal injury is severe, which contributes to the clinical signs seen during the disease.

Clinical Signs and Diagnosis

N. risticii infection is clinically similar to other forms of enterocolitis and is characterized by anorexia, depression, and fever.[156,583,607] Experimental infections produce a biphasic fever in which the second febrile phase occurs 6 to 7 days after the first.[607,608] Decreased gastrointestinal motility, manifested as reduced borborygmi, occurs during the early stages, before the onset of diarrhea. Diarrhea is seen in 75% of cases and occurs 2 days after the second fever episode during experimental infections.[607,608] The diarrhea can be moderate to severe and dehydrating. Ileus can develop at any stage of the disease and can cause signs of moderate to severe colic. Systemic signs of endotoxemia, shock, and peripheral edema may occur and are similar to those described for salmonellosis. Experimental and natural infection with *N. risticii* can cause abortion of infected fetuses in pregnant mares.[609,610] Laminitis is a complication in 20% to 30% of naturally occurring cases and is often severe.[584] Other complications include protein-losing enteropathy, thrombosis, and renal failure, as described for salmonellosis.

Hematologic abnormalities reflect endotoxemia, dehydration, and sepsis and are essentially identical to those described for salmonellosis. Neutropenia with a left shift is a consistent feature and occurs concurrently with or soon after the onset of diarrhea.[608] Thrombocytopenia is common and often severe.[608] Neutrophilic leukocytosis occurs later in the course of the disease. Hyperfibrinogenemia is usually more pronounced than that seen with salmonellosis. Serum electrolyte, acid-base, and biochemical abnormalities are also similar to those described for salmonellosis. Coagulopathies are commonly seen during *N. risticii* infection and reflect activation of coagulation pathways. DIC is not uncommon and may be the cause of the high frequency of laminitis associated with *N. risticii* infection.[611]

Diagnosis of *N. risticii* infection cannot be based solely on clinical signs because the disease is clinically similar to other forms of enterocolitis. In endemic areas, acute colitis is likely to be caused by *N. risticii;* thus, the clinical signs of acute inflammatory colitis may in fact have a high predictive value in these areas. Serologic evidence of infection, such as rising antibody titers to *N. risticii* detected by indirect immunofluorescence (IFA) or ELISA in paired serum samples, may be helpful in establishing a diagnosis.[584,612] Care should be taken when interpreting the IFA serologic test for *N. risticii* because the test appears to have a high false-positive rate.[613] Culture of the organism from blood is possible but difficult and is generally useful only in the research laboratory. Recently developed PCR tests for *N. risticii* DNA are rapid, highly sensitive (as

sensitive as culture), and there are specific tests for *N. risticii* infection that can be applied to blood or feces.[614-616]

Prevention

Prevention of the disease by reducing exposure to the etiologic organism is difficult because the mode of transmission is not known. A killed vaccine has been developed that is relatively effective in preventing clinical illness other than fever in 80% of experimentally challenged horses using the vaccine strain. Field studies, however, suggest the vaccine has limited benefit for preventing natural infection or decreasing its severity.[617,618] Vaccine failures have been attributed to strain differences in antigenicity or to poor antibody responses to the vaccine.[617,618]

Equine Intestinal Clostridiosis

Pathogenesis

Clostridiosis is an important cause of acute enterocolitis in foals and adult horses. *C. perfringens* and *C. difficile* are most commonly associated with intestinal clostridiosis in horses, but other clostridial species, including *C. septicum, C. cadaveris,* and *C. sordellii* have also been isolated from horses with enterocolitis.[619-624] In horses of all ages, clostridial enterocolitis appears to be a common antibiotic-associated and nosocomial cause of enterocolitis.[623,625,626] Hemorrhagic enterocolitis caused by *C. perfringens* in neonatal foals is a distinct clinical entity and will be discussed in more detail in Chapter 20. This discussion focuses on adult intestinal clostridiosis.

Clostridium organisms are obligate anaerobic to aerotolerant spore-forming gram-positive rods that are ubiquitous in the environment in the spore form.[624] They are elements of the normal flora of horses of all ages and are among the first bacteria acquired after birth. *Clostridium* organisms inhabiting the gastrointestinal tract are normally found in very low numbers and do not produce enterotoxins. Clostridiosis is associated with an increase in the number of a particular species of *Clostridia* in the gastrointestinal tract and, perhaps most important, exotoxin production. Although the conditions resulting in exotoxin production are not fully understood, several factors increase clostridial numbers in the gastrointestinal tract. Dietary factors affect the numbers of *Clostridium* species shed in horse feces.[619] Experimental induction of colic increases fecal shedding of *Clostridium* species in the absence of diarrhea.[627] Antibiotics, particularly those administered orally or recycled via the enterohepatic system, increase the recovery of *Clostridia* colony-forming units (CFUs) in equine feces and clinical clostridiosis.[620,622,628-630] Clostridiosis associated with *C. difficile* is likely to be the most important cause of antibiotic-induced enterocolitis in the horse.

Clostridium perfringens. *C. perfringens* includes many genetically distinct strains of variable virulence that produce one or more of a large group of exotoxins. The pattern of exotoxin production is used to classify *C. perfringens* into five types: A, B, C, D, and E. *C. perfringens* type A is the most common clostridial isolate from healthy and diarrheic horses of all ages. *C. perfringens* types A, B, C, and D have all been associated with hemorrhagic enteritis in foals younger than 10 days of age, with type C being the most common cause in North America.

The primary toxin produced by *C. perfringens* type A is α-toxin (phospholipase C), which interferes with glucose uptake and energy production and activates arachidonic acid metabolism and signaling pathways in enterocytes.[624] Oral administration of α-toxin does not cause tissue necrosis but causes increased secretion by small intestinal mucosal cells.[631,632] The β-toxin of types B and C is a cytotoxin that causes enterocyte necrosis, ulceration, and ultimately severe intestinal inflammation and hemorrhage.[624,632] A novel toxin designated β_2 may also have a role in *C. perfringens* enterocolitis.[633] The biologic activity of the β_2-toxin is similar to that of β-toxin, but β_2-toxin is not related to β-toxin in its genetic sequence. The β_2-toxin was prevalent in two groups of horses with acute enterocolitis but not in healthy horses.[634] It is predominantly associated with *C. perfringens* that would have otherwise been classified as type A but that may in fact represent a previously undescribed type.

Virulent strains of *C. perfringens* type A and, to a lesser extent, type C may produce enterotoxin. Enterotoxin is a cytotoxin that inserts into cell membranes to form pores, which alter permeability to water and macromolecules and ultimately lead to cellular necrosis.[635] Massive desquamation of the intestinal mucosa that is a result of enterotoxin cytotoxicity triggers an inflammatory response, intestinal edema, mural hemorrhage, and systemic inflammation.[158] Enterotoxin also alters tight junction integrity, resulting in increased paracellular permeability by a noncytotoxic mechanism.[636]

Clostridium difficile. *C. difficile* produces several toxins, only two of which, toxin A and toxin B, have been studied in detail. Toxin B is a potent cytotoxin in vitro, but its role in enterocolitis is less clear than that of toxin A. It does not induce fluid secretion, inflammation, or characteristic alterations in intestinal morphology. *C. difficile* toxin A is an enterotoxin that induces an inflammatory response with hypersecretory diarrhea.[637] Toxin A induces neutrophil influx into intestinal tissue, mast cell degranulation, and secretion of prostaglandins, histamine, cytokines, and 5-HT by these activated leukocytes.[142,637,638] The products of neutrophils and mast cells have a significant role in the vasodilatory and secretory responses in the intestine during *C. difficile* infection.

The ENS is central to the induction of intestinal inflammation and mucosal secretion by toxin A. A model for toxin A–induced secretory diarrhea has emerged in which toxin A stimulates substance P–containing afferent sensory nerve fibers, which in turn stimulate mast cell degranulation, recruitment and activation of PMNs, and vasodilation.[88,89,639] Toxin A–induced stimulation of enterocyte secretion can occur via secretomotor neuronal stimulation by substance P–containing sensory neurons or products of mast cells and PMNs. Mast cell degranulation, PMN influx, and enterocyte secretion are all abolished by neural blockade or depletion of substance P. How toxin A triggers the sensory component of the ENS remains unknown, but it is likely that toxin A–induced necrosis of enterocytes exposes afferent neurons to the noxious milieu of the intestinal contents.

Clinical Signs and Diagnosis

Equine intestinal clostridiosis is clinically similar to other forms of acute enterocolitis in horses.[619,624] Although the clinical course is usually acute, peracute colitis with rapid death may occur. Occasionally, a milder, more prolonged clinical course is seen. Fever, anorexia, and depression may be observed before the onset of gastrointestinal signs, but the absence of prodromal signs is more common. Signs of endotoxemia and shock may accompany acute signs of colic and severe, dehydrating diarrhea. Diarrhea may not be profuse but is usually dark and foul. Like the clinical signs, hematologic and

serum biochemical abnormalities are similar to those associated with other forms of enterocolitis and reflect fluid, protein, and electrolyte loss and systemic inflammation resulting from endotoxemia. Neutropenia, leukopenia, and hemoconcentration are common. Hypoproteinemia may be profound. Hyponatremia, hypokalemia, hypochloremia, hypocalcemia, and a mixed prerenal–renal azotemia are often noted, as well as metabolic acidosis and coagulopathies. Serum concentrations of hepatocellular enzymes, such as sorbitol dehydrogenase, may be elevated, and liver function may be reduced.

Preliminary diagnosis of equine intestinal clostridiosis caused by *C. perfringens* is based on the isolation of greater than 100 CFUs of *C. perfringens* type A per gram of feces from patients with diarrhea and signs suggestive of toxemia.[619,640] Similar criteria are used to screen human patients for *C. perfringens* type A infection. Normal horses shed less than 100 CFU/g of feces, and usually horses with intestinal clostridiosis shed greater than 10^6 CFU/g.[619,640] Identification of high numbers of *Clostridium* organisms in the feces does not prove infection as the cause of the observed clinical signs. Detection of *C. perfringens* toxins in feces or intestinal contents in horses with high numbers of fecal CFUs and clinical signs of enterocolitis is more conclusive evidence of an enterotoxigenic infection than that based on culture alone.[624] Immunoassays are available to detect *C. perfringens* enterotoxin,[624] but the reliability (specificity) of some immunoassays has come into question. PCR multiplex and gene probe assays are now available for detection of the major lethal toxins in bacterial isolates or fecal samples to determine the pattern of toxin production and are currently the preferred methods of detection.[641-643]

Like *C. perfringens,* diagnosis of *C. difficile* infection depends on the culture of the organism from feces and identification of toxins in the feces. Bacterial culture of *C. difficile* may be difficult; therefore, it is an insensitive diagnostic test in horses.[644,645] Enrichment techniques and culture of multiple fecal samples may be required.[645,646] Detection of toxin A or B (or both) in feces by cell cytotoxicity assay or immunoassay is the preferred test for diagnosis of *C. difficile* infection in humans.[624] These tests are more sensitive than bacterial culture for identifying *C. difficile* infection in adult horses.[644,645] Sensitive PCR methods may also be used to identify genes for toxins A and B in fecal samples from diarrheic horses.[624]

Strongylosis

Pathogenesis

Strongyle infections in horses are caused by two groups of nematodes: large and small strongyles (see later section Cyathostomiasis). Large strongyles that are pathogenic in horses include *Strongylus vulgaris, S. edentatus,* and *S. equinus.* Of these species *S. vulgaris* is by far the most important cause of disease in the large intestine and is the most pathogenic parasitic infection in horses.[647] *S. vulgaris* infection in horses is manifested as acute or chronic disease.[647] The age and resistance of the host, the infective dose, and the size and function of the affected arteries influence the type and degree of disease that occurs. Sudden ingestion of large numbers of infective larvae by a naive host causes acute strongylosis, whereas ingestion of fewer infective larvae over a long period of time by an older, more resistant host causes chronic strongylosis. Acute strongylosis is more likely to cause colic than diarrhea and may be rapidly fatal. Chronic strongylosis tends to cause debilitation and signs of colic but may also cause diarrhea.

Diarrhea associated with acute strongylosis occurs within several days of infection and is likely to be caused by migration of the larvae through the intestinal wall. Fourth-stage larvae migrate through the mucosa and submucosa into the arterioles of the intestine, causing mural edema, hemorrhage, and infiltration of inflammatory cells.[647,648] Increased secretion and decreased absorption of fluid and electrolytes, stimulated by inflammatory mediators such as prostaglandins and histamine, may play a role in the diarrhea induced by *S. vulgaris.* Interstitial edema and damage to the interstitial matrix and mucosa may occur as a result of inflammation and migration of the parasites, causing increased secretion of fluid and albumin loss. Abnormal gastrointestinal motility may also play a role in the development of diarrhea. Migration of larvae through the intestinal wall early in the course of infection affects myoelectrical activity and motility in the large intestine and may affect retention of ingesta and absorption of fluid.[649,650] The cause of death in acute strongylosis has not been addressed, but it may be related to massive migration through the vasculature, causing thrombosis with ischemia and infarction of the intestine.

Chronic strongylosis causes typical verminous arteritis and is more commonly associated with natural infections in horses than acute strongylosis.[647] Lesions of the large intestinal vasculature caused by migration of larvae through the intima are characterized by thrombus formation, narrowing of the arterial lumen, fibrosis, and thickening of the arterial wall.[647,648] Embolization may occur, causing acute segmental infarction of the large intestine, but more commonly, reduced blood flow without embolization causes ischemia and occasionally infarction.[648,651] Postmortem examination of horses with colonic infarction failed to reveal embolization as the cause in the majority of cases.[651] Reduced blood flow in the tissues of the intestine usually results from narrowing of the arterial lumen by the thrombus and formation of microthrombi at sites independent of the parasites. Release of vasoconstrictive inflammatory mediators, such as leukotrienes, from platelets, neutrophils, and eosinophils, as well as elaboration of parasitic antigens or toxins, may cause vasoconstriction and ischemia.[652] Horses with experimental strongylosis had a 50% reduction of blood flow in the colonic vasculature.[653]

Clearly, reduced blood flow is an important effect of chronic strongylosis, but the relationship between blood flow and diarrhea is unclear. Disrupted motility resulting from ischemia may lead to diarrhea by reducing the retention of ingesta and absorption of fluid. Acute infarction and mucosal ulceration cause severe, chronic diarrhea in naturally infected horses.[654] Release of inflammatory mediators, such as prostaglandins, histamine, and kinins, from inflammatory cells associated with thrombi and inflamed intestine may also affect secretion, absorption, and motility, leading to diarrhea.

Clinical Signs and Diagnosis

The clinical signs of acute strongylosis caused by *S. vulgaris* infection include depression, moderate to severe colic, and fever.[655] Diarrhea is less often a feature of acute strongylosis than colic.[647] Most cases of acute strongylosis occur in young naive horses introduced to an infested environment or inoculated experimentally with infective larvae. This form of strongylosis is not often recognized naturally. Chronic strongylosis is most commonly observed as a natural syndrome. Weight loss or poor weight gain; chronic, intermittent colic; fever; poor appetite; and diarrhea are frequently observed.[647,648] Diarrhea may be profuse and watery, or the feces may be soft

but of normal volume. Transrectal palpation may reveal thickening and fremitus in the cranial mesenteric artery. Young horses are most commonly affected, but older horses may also be too. Horses with acute infarction or large intestinal ulceration secondary to chronic strongylosis may have signs of severe abdominal pain, sepsis, and endotoxemia, and profuse, watery diarrhea is common.

Hematologic abnormalities associated with strongylosis include neutrophilic leukocytosis and eosinophilia.[655-657] Neutrophilia appears to be an early event during the course of the disease, and eosinophilia tends to appear later.[655,657] Hyperfibrinogenemia may also occur, especially later in the course of the disease. Serum α-globulin and β-globulin and IgG(T) concentrations are characteristically elevated.[656,658] Horses with chronic ulcerative colitis secondary to strongylosis may develop severe hypoalbuminemia.[654] PF analysis may reveal an elevated protein concentration and eosinophilia.[656,657] Tentative diagnosis is based on clinical signs, hematologic abnormalities, and PF analysis. Elevated serum α-globulin and β-globulin concentrations and IgG(T) concentration support the diagnosis.[658] Fecal analysis may reveal strongyle eggs, but fecal egg counts are often unreliable because nonpatent larvae cause the disease.

Prevention

Appropriate preventive measures are important in controlling this disease, including such management procedures as preventing overcrowding, reducing exposure of susceptible individuals, and instituting proper deworming schedules. Ivermectin is the preferred anthelmintic used to control strongylosis in horses. Monitoring fecal egg counts as a means of evaluating the efficacy of parasite control measures is recommended.

Cyathostomiasis

Pathogenesis

Infection with small strongyles (cyathostomiasis) is well recognized as a cause of diarrhea and large intestinal disease in horses of all ages.[659-664] Clinical disease is caused by intramural larval stages of more than 50 species of small strongyles (cyathostomes). The cyathostome life cycle requires migration by fourth-stage larvae through the mucosa of the large intestine and may include a period of hypobiosis, during which the larvae remain encysted within the mucosal layer of the large intestine.[659] After a period of hypobiosis, the larvae emerge in response to a largely unknown stimulus. Most cases occur when larval emergence takes place, classically in the late winter and spring in the northern temperate zones and in the late fall or winter months in the southeastern United States and subtropical regions.[659] Sudden emergence of encysted larvae causes mucosal injury, ulceration, and an inflammatory reaction, which are largely responsible for the clinical disease.[659,665] Migration of the larvae as they penetrate the mucosa affects motility patterns and can cause inflammation that may contribute to diarrhea.[659] Chronic, eosinophilic, granulomatous colitis and diarrhea with histopathologic evidence of hypobiotic cyathostome larvae in the large intestine have been reported in two horses during a period in which the emergence of larvae would not be expected to occur (early winter).[659]

Natural emergence of cyathostome larvae causes fibrinous inflammation of the large intestine, focal necrosis, mural hemorrhage, and ulceration of the large intestinal mucosa, which may even result in bleeding into the lumen.[648,665] Mild to moderate eosinophilic and mononuclear inflammation of the lamina propria is seen.[648,665] Moderate to severe interstitial edema is frequently observed.[648,665] Colonic inflammation and interstitial edema may contribute to diarrhea, in conjunction with the loss of the mucosal barrier, by causing increased active and passive secretion of fluid, electrolytes, and protein. Protein loss is often significant, resulting in profound hypoalbuminemia and interstitial edema of skin and other organs. Chronic granulomatous colitis has been reported to occur in response to encysted larvae and may cause diarrhea by increased secretion secondary to granulomatous inflammation or disruption of the interstitium by granulomatous infiltration. Administration of an anthelmintic to horses with a heavy load of encysted larvae may also cause rapid larval death and acute and often severe inflammation similar to natural emergence.

Clinical Signs and Diagnosis

Cyathostomiasis may be the most commonly identified cause of chronic diarrhea in the horse.[493,666,667] However, an acute syndrome has also been associated with cyathostomiasis.[664] Clinical signs of cyathostomiasis are characterized by moderate to severe weight loss or poor weight gain, ill thrift, ventral edema, intermittent fever, and intermittent mild colic.[659-664,667] Acute onset of diarrhea is typically profuse and progresses to chronic diarrhea that is often mild, the consistency of bovine feces, and may be intermittent.[659-664,667] Appetite is usually normal, but some affected horses have a ravenous appetite. Transrectal palpation usually does not reveal any abnormalities. Horses of any age may be affected, and clinical signs are more common during periods of emergence of larvae, corresponding to late winter and spring in northern temperate zones. The deworming history may appear to be adequate.

Neutrophilic leukocytosis is typically evident, but the WBC count may be normal.[659-664] Profound hypoalbuminemia is a characteristic feature of cyathostomiasis, manifested clinically by ventral edema. Plasma α-globulin and β-globulin concentrations may be elevated, which can result in a normal total plasma protein concentration in spite of hypoalbuminemia.[658-660] The serum IgG(T) concentration, however, has been reported to be normal, which may help distinguish cyathostomiasis from *S. vulgaris* infection.[659,661,662] PF analysis does not usually reveal any abnormalities, in contrast to horses with *S. vulgaris* infection. Fecal analysis may be unrewarding because the infection is often not patent when clinical signs are apparent. Measurement of plasma fructosamine may provide a measure of protein catabolism or protein loss in the absence of hypoalbuminemia.[667,668] Plasma fructosamine concentrations are significantly lower in horses with experimental cyathostomiasis than in normal controls,[667,668] suggesting that this test may be a useful diagnostic tool. However, the test has not yet been validated in naturally occurring cases, and neither the specificity nor the sensitivity is known. Rectal scrapings or rectal mucosal biopsies may reveal evidence of cyathostome larvae.[659,662] Definitive diagnosis usually requires microscopic examination of biopsy specimens of the cecum and ascending colon, collected by laparotomy. Examination of biopsy specimens collected from the small intestine is recommended to rule out other causes of weight loss and diarrhea. Appropriate diagnostic tests, such as culture of feces for pathogenic bacteria, should be included in the workup to further rule out other causes.

Prevention

Preventive measures are appropriate for other horses on the premises known to have a problem with cyathostomiasis. These include frequent deworming (every 6 weeks) during times of high infectivity (spring and summer in the north and fall, winter, and early spring in the south) to eliminate parasites before they become patent.[659] Because of high levels of resistance to benzimidazoles, avermectins (ivermectin or moxidectin) are often the drugs of choice for cyathostome control.[669-671] Resistance to ivermectin has been demonstrated, but the prevalence of ivermectin resistance appears to remain low.[669] Although daily pyrantel pamoate administration has also been reported to effectively reduce worm burdens and pasture infectivity in young and mature horses,[672] cyathostome resistance has been reported and is a concern for the use of this drug as a routine preventive anthelmintic.[670,673,674] Because of the rapid emergence of resistant strains to even ivermectin, targeted treatment, based on fecal egg counts and careful monitoring for the development of resistance to any anthelmintics used for cyathostome control, is warranted.[674]

TOXICOLOGIC DISEASES

Antibiotic-Associated Diarrhea

Pathogenesis

Antibiotic-associated diarrhea has been reported in many species, including horses.[675] Certain antibiotics, such as trimethoprim-sulfonamide combinations, erythromycin, penicillins, tetracyclines, clindamycin, and lincomycin, are associated with naturally occurring and experimental enterocolitis syndromes in horses.[620,675-678] In some cases, such as those seen with trimethoprim-sulfonamide combinations, the geographic incidence of antibiotic-associated diarrhea appears to differ markedly.

C. perfringens, C. difficile, and serovars of *S. enterica* are apparently the most common causes of antibiotic-associated diarrhea in horses. Outbreaks of *C. difficile* have been reported in hospitalized horses being treated with antibiotics.[622,626] In Sweden accidental erythromycin ingestion has been associated with *C. difficile* enterocolitis in mares in which their foals were being treated for *R. equi*.[629,677,679] Tetracycline administration has been associated with an increase in the numbers of gram-negative enteric bacteria and *C. perfringens* in the feces of horses as well as reactivation of salmonellosis and prolongation of fecal shedding of serovars of *S. enterica*.[619,680]

The most common mechanism by which antibiotics cause diarrhea is disruption of the gastrointestinal flora. The normal large intestinal flora, composed of mainly obligate anaerobes and streptococci, protects the host from pathogenic bacteria by colonization resistance.[553] Ecologic factors play an important role in colonization resistance. For example, surface bacteria in the large intestine interact with receptors on the mucosal cells, facilitating adherence to the mucosa.[545,681] In doing so, the normal organisms compete more successfully for this important niche. Competition for space and nutrients is an important means of preventing colonization and proliferation of pathogenic bacteria.[552,553,681] Anaerobic bacteria produce SCFAs and other metabolites that are toxic to facultative anaerobic bacteria, especially in the conditions of the large intestine.[552,553,681] Organisms of the normal flora produce bacteriocins that inhibit growth of potential pathogens.[552]

Antibiotics that deplete the population of obligate anaerobes and streptococci efficiently decrease colonization resistance.[552] Production of fatty acids is diminished, and competition for space and nutrients is reduced. As a result, gram-negative enteric bacteria, such as *S. enterica* var. Typhimurium, are able to proliferate. Pathogenic anaerobes normally found in low numbers can also proliferate. Antibiotic-resistant strains of bacteria, especially gram-negative enteric bacteria and possibly clostridia, may be selected by antibiotic administration, allowing proliferation of pathogenic bacteria resistant to many antibiotics.[682] Obligate anaerobic commensal organisms, perhaps the most critical group of microbes for maintaining colonization resistance, are usually susceptible to macrolides, tetracyclines, β-lactams, and lincosamides, which may explain the high incidence of diarrhea associated with the administration of these antibiotics.[624]

In addition to reduction of colonization resistance, depletion of the normal anaerobic microbial population in the intestine decreases carbohydrate fermentation and production of SCFAs, which contributes to the pathogenesis of antibiotic-associated diarrhea by decreasing absorption of sodium and water by the colonic mucosa.[171] Ampicillin decreases colonic fermentation of carbohydrates in humans.[683] Human patients with antibiotic-associated diarrhea have markedly impaired colonic fermentation and very low production of SCFAs.[684] Erythromycin, ampicillin, or metronidazole treatment is associated with decreased production of SCFAs in patients with and without diarrhea.[684] Absorption of sodium and water is stimulated by absorption of SCFAs in the equine colon, suggesting that reduction of colonic SCFA content by antibiotic-induced depletion of anaerobic flora has similar effects in horses as in humans.[171]

Broad-spectrum antibiotics exert a more profound effect on the gastrointestinal flora than narrow-spectrum antibiotics.[685] Antibiotics administered orally, especially those that are poorly absorbed, are more likely to cause diarrhea than parenterally administered antibiotics.[685] For instance, clindamycin is less likely to cause diarrhea in humans when administered IV than when administered orally.[685] Antibiotics with extensive enterohepatic circulation, such as tetracyclines and erythromycin, are excreted in high concentrations in the bile and are more commonly associated with diarrhea than antibiotics that do not undergo enterohepatic circulation.[685]

Antibiotics may cause diarrhea by other means than by disrupting the normal flora. Direct toxic effects may play a role in producing irritation, increasing secretion, and disrupting motility patterns. Tetracyclines are irritating to the gastrointestinal mucosa and may cause inflammation and increase secretion.[685] Erythromycin interacts with smooth muscle cells, stimulating gastrointestinal motility.[685,686] Normal peristalsis plays an important role in suppressing the population size of potentially pathogenic bacteria. Normally, bacteria that are prevented from adhering to the mucosa by colonization resistance are swept aborally by peristalsis and excreted in the feces. Disruption of normal motility patterns may prevent clearance of pathogenic bacteria, contributing to the colonization of mucosal surfaces.

Clinical Signs and Diagnosis

Diarrhea induced by antibiotics usually occurs within 7 days of initiation of antibiotic administration but may occur several days after cessation of antibiotic treatment. The clinical syndrome of antibiotic-associated diarrhea varies from mild

diarrhea to fulminant enterocolitis with severe diarrhea. Mild diarrhea is common, especially in foals receiving erythromycin, trimethoprim-sulfa combinations, or rifampin[677,687] and are usually not clinically significant. Acute, severe enterocolitis can occur in horses of all ages receiving antibiotics and can be life-threatening. Clinical signs are identical to those resulting from other causes of acute enterocolitis. Severe, dehydrating diarrhea; endotoxemia; sepsis; and shock may occur. Hemoconcentration, neutropenia, hypoproteinemia, and electrolyte and acid-base imbalances are common. Severe hyponatremia may occur in foals with antibiotic-associated diarrhea, especially if trimethoprim-sulfa and rifampin combinations are the cause.[687] More detailed descriptions of the clinical and laboratory findings were given earlier. Diagnosis is presumptive because definitive diagnosis of antibiotic-associated diarrhea is impossible. Fecal culture or PCR testing may reveal *S. enterica* or *Clostridium* spp. infection.

Nonsteroidal Antiinflammatory Drug Toxicity

Pathogenesis

Toxicity resulting from NSAID administration has been well documented in several species, including horses, and is discussed in Chapter 2.[688-694] In horses and humans NSAID toxicity is manifested by renal and gastrointestinal disease. Foals are considered to be more susceptible than adult horses to gastrointestinal disease secondary to NSAID administration, and ponies may be more susceptible than horses. NSAID toxicity varies primarily as a result of properties that influence distribution to sensitive tissues and relative selectivity for COX-1 or COX-2. All nonselective NSAIDs are capable of inducing gastrointestinal and renal damage at toxic concentrations. Aspirin has been suggested to be more toxic than other NSAIDs because it irreversibly inactivates COX by acetylation, whereas other NSAIDs reversibly inhibit COX.[688] Phenylbutazone is the drug most commonly reported to cause gastrointestinal toxicity in horses, perhaps because of its widespread usage by veterinarians and horse owners or perhaps because of bona fide differences in toxicity in horses compared with other nonselective NSAIDs. Acute phenylbutazone toxicity in horses resulting from overdose is characterized by mucosal ulceration throughout the gastrointestinal tract, oral ulceration, renal papillary necrosis, vasculopathy, thrombosis, and protein-losing enteropathy with hypoalbuminemia.[690-692] COX-2–selective NSAIDs appear to be much less toxic in the equine gastrointestinal tract.[392,695] The focus of this discussion is on the toxic effects of NSAIDs on the large intestine, but this necessarily includes elements of upper gastrointestinal and renal disease.

Horses with large intestinal disease resulting from NSAID toxicity generally are receiving inappropriately large doses or have underlying disorders that predispose the large intestine to the toxic effects of NSAIDs, even at appropriate dosages. The dosage regimen recommended for phenylbutazone (4.4 mg/kg every 12 hours for 1 day, then 2.2 mg/kg every 12 hours) is considered safe. Experimental studies in horses, however, have shown toxicity to occur when amounts exceeding the recommended dosage (6.6 mg/kg/day) are administered for several days.[688,689] Most reported cases of phenylbutazone toxicosis occurred in horses receiving higher than recommended dosages.[692,694,696] Regardless, administration of phenylbutazone at the recommended dosage has been reported to cause a significant decrease in plasma protein concentration and gastrointestinal disease.[691,697] Moreover, signs of NSAID toxicity have been reported in normovolemic horses treated with appropriate doses of phenylbutazone.[697,698] Dehydration, sepsis, endotoxemia, and other conditions that alter hemodynamic homeostasis exacerbate renal and gastrointestinal toxicity of NSAIDs.[688] Underlying inflammation of the intestinal tissues may increase the likelihood of gastrointestinal ulceration resulting from NSAIDs.

Gastrointestinal disease induced by NSAIDs is manifested by mucosal ulceration, inflammation, bleeding, and protein-losing enteropathy.[690,691,694,697] In addition to direct effects on the mucosal barrier, NSAID administration causes an acute relapse of preexisting colonic inflammatory disease and worsens colonic inflammation in humans with inflammatory bowel disease.[688,699,700]

It is not clear whether the previously mentioned NSAID effects occur in horses. The mechanism by which NSAIDs induce mucosal damage is probably multifactorial. Direct irritation may play a role in oral and gastric irritation and ulceration; however, parenteral administration of NSAIDs produces oral and gastric ulceration as well. Inhibition of prostaglandin synthesis by inhibition of both COX-1 and COX-2 appears to be the most important mechanism of mucosal injury. Prostaglandins, particularly PGE_2 and PGI_2, are critical for mucosal health and repair after injury.[701,702] PGE_2 increases mucosal blood flow; increases secretion of mucus, water, and bicarbonate; increases mucosal cell turnover rate and migration; stimulates adenyl cyclase activity; and exerts other protective effects in the gastric mucosa of several species.[688,701,702] Perhaps most important, PGE_2 and PGI_2 have roles in maintaining epithelial tight junction integrity, which is indispensable for mucosal barrier function and repair after mucosal injury.[701]

In spite of the overwhelming amount of information about the role of prostaglandins in maintaining the mucosal barrier in other species and clear clinical and experimental evidence that NSAIDs injure the equine colonic mucosa, the role of prostaglandins in mucosal protection in the equine colon is not yet well defined. Inhibition of COX-1 and COX-2 in equine colonic mucosa with flunixin meglumine results in reduced electrical resistance of the mucosa and increased permeability to macromolecules in vitro,[703] suggesting that flunixin treatment disrupts the epithelial tight junctions in the equine colon. This was correlated with a profound inhibition of PGE_2 and PGI_2 concentrations in the treated tissues. Administration of a PGE_2 analog prevents the gastrointestinal manifestations of phenylbutazone toxicosis in ponies.[691]

The recent development of NSAIDs that specifically inhibit COX-2 has markedly reduced the frequency and severity of gastrointestinal side effects in humans taking NSAIDs for chronic musculoskeletal conditions.[704] COX-2–specific NSAIDs such as firocoxib hold promise for use in horses to treat arthritis[705] and other conditions, with reduced incidence of toxicity. For example, the relatively COX-2–specific inhibitors meloxicam and firocoxib are less harmful to equine intestinal mucosa than flunixin meglumine in vitro.[392,695] Moreover, COX-2–selective inhibitors are significantly more permissive than flunixin for recovery of the mucosa in equine ischemic-injured intestinal tissues; recovery is no different from that for control tissues.[392,695]

NSAID-induced mucosal injury is associated with a marked inflammatory response to microbial products exposed to the lamina propria.[706] This inflammation exacerbates mucosal dysfunction and injury associated with NSAID toxicity. For

example, depletion of neutrophils or blockade of neutrophil influx into gastrointestinal tissues or inhibition of neutrophil activation and release of toxic products prevents many of the pathophysiologic effects of NSAID toxicity in the gastrointestinal tract.[106,707-709] The inflammatory response alone may result in moderate to severe gastrointestinal ulceration, mural vascular thrombosis and edema, fluid secretion, protein-losing enteropathy, and mucosal hemorrhage.

Clinical Signs and Diagnosis

NSAID colitis manifests as two clinical syndromes: right dorsal ulcerative colitis (RDUC) and generalized NSAID toxicity. As its name implies, RDUC is a disorder isolated to the right dorsal segment of the large intestine.[693,694,698] The most prominent clinical signs of RDUC are anorexia, lethargy, and colic. Anorexia, depression, diarrhea, fever, and signs of endotoxemia may also be features. If RDUC is chronic, weight loss, intermittent colic, lethargy, anorexia, and ventral edema are common clinical signs with soft and unformed feces. Ulceration of the right dorsal colonic mucosa results in protein-losing enteropathy and significant hypoproteinemia attributable mainly to hypoalbuminemia. Hypoproteinemia may be one of the earliest clinical manifestations of RDUC and can be sufficiently severe to cause peripheral (usually ventral) edema. In some horses, dehydration, electrolyte abnormalities, neutropenia or anemia, azotemia, and biochemical abnormalities may be noted if the ulceration and diarrhea are severe or if systemic inflammation is present.

Clinical signs of generalized NSAID toxicity vary from mild diarrhea with no systemic signs to severe dehydrating diarrhea with anorexia, fever, depression, peripheral edema, oral ulceration, and colic.[691,692,696]

Clinical signs of systemic inflammation caused by endotoxemia may occur, manifested as poor peripheral perfusion, tachycardia and tachypnea, weakness, trembling, and cyanotic or hyperemic oral mucous membranes. Hematuria or oliguria may be present with renal involvement. Complications associated with other forms of severe enterocolitis, such as laminitis, thrombophlebitis, and severe weight loss, may occur.

Although phenylbutazone has been associated specifically with bone marrow depression resulting in abnormalities in one or more blood cell lines,[710] hematologic abnormalities of generalized NSAID toxicity are usually nonspecific and include neutropenia with a left shift or leukocytosis and hemoconcentration. Serum biochemical analysis is characterized by profound hypoproteinemia, hyponatremia, and metabolic acidosis.[696,697] Hypocalcemia, hypokalemia, hypochloremia, and elevated hepatocellular enzyme activities may also be seen. Hypoproteinemia may occur without signs of diarrhea. Azotemia may be prerenal as a result of dehydration, but it is frequently caused by renal failure that results from a combination of hemodynamic effects of NSAIDs and direct toxic renal injury. Urinalysis frequently reveals hematuria, proteinuria, cylindruria, and isosthenuria. Fecal occult blood is frequently detected.

Diagnosis of either form of NSAID colitis is often presumptive, with a history of overdose of NSAIDs being strong evidence of NSAID toxicity. As discussed earlier, toxicity may occur with dosage regimens that are not considered inappropriate, particularly if the horse experiences a concurrent period of dehydration. Ultrasonographic examination of the right dorsal colon can be used to confirm a diagnosis of RDUC, but the sensitivity of this method appears to be low.[711] Ultrasonography (3.5- to 5-MHz transducer at the right twelfth through fifteenth intercostal spaces below the margin of the lung axial to the liver) may reveal a thickened right dorsal colon (>0.5 cm) and evidence of colonic edema in horses with RDUC.[711,712] Nuclear scintigraphy of horses after infusion with technetium-99–labeled WBCs can be used to document inflammation of the right dorsal colon.[50] Laparotomy or laparoscopic examination of the right dorsal colon may be required for definitive diagnosis of RDUC. Other causes of enterocolitis, such as salmonellosis, Potomac horse fever, clostridiosis, and antibiotic-associated diarrhea, must be ruled out.

Cantharidin Toxicity

Pathogenesis

Cantharidin is the toxic substance found in beetles of the genus *Epicauta,* commonly known as *blister beetles.*[713-715] Ingestion of the beetles causes release of the toxin and absorption through the gastrointestinal tract. Transcutaneous absorption may occur but appears to be rare in horses. Blister beetles feed on the flowers of alfalfa and may be incorporated into processed alfalfa hay if the hay is cut and processed simultaneously, as by crimping.[713-715] The beetles often swarm, and large numbers of beetles may be found in relatively small portions of hay. The lethal dose of cantharidin is less than 1 mg/kg, but the concentration of cantharidin varies among species of blister beetles and between sexes.[713,714] As many as 100 to as few as 6 beetles may be lethal. Usually, only one or a few horses fed contaminated hay will ingest beetles because they are concentrated in a small portion of the hay. However, outbreaks involving many horses on a farm have occurred. Most cases have occurred in Texas and Oklahoma, but horses in other states may be affected as well, especially if hay is imported from states in which blister beetles are common. Peak incidence is in late summer and fall.[716] The fatality rate may be 50% or greater,[713,717] but if the patient survives several days, recovery is probable.

Cantharidin is absorbed from the gastrointestinal tract and excreted by the kidneys. It is a potent irritant, causing acantholysis and vesicle formation when applied topically.[713,715,717] The chemical is thought to disrupt the oxidative metabolism in the mitochondria, causing mitochondrial swelling, plasma membrane damage, and changes in membrane permeability.[713] The mucosa of the gastrointestinal tract is most commonly affected in horses because they ingest the toxin. Cell swelling and necrosis occur, resulting in mucosal ulceration. Oral, esophageal, gastric, and small and large intestinal ulceration have been observed in natural and experimental cantharidiasis.[713,715,717] Severe fibrinous to pseudomembranous inflammation and submucosal edema of the intestine have also been reported. Diarrhea probably results from the severe ulceration and inflammation of the large intestine, causing increased secretion of water, electrolytes, and protein and decreased absorption of fluid. Large volumes of fluid and protein are lost in the gastrointestinal tract, causing hemoconcentration and profound hypoalbuminemia in some affected horses.[713,715,717]

Cystitis and myocarditis occur in natural and experimentally induced cases of cantharidin toxicity.[713,715,717] The toxin is excreted by the kidneys, and high concentrations of cantharidin in the urine induce cystitis. Occasionally, hemorrhagic cystitis may occur, resulting in hematuria or frank hemorrhage into the bladder.[713] The cause of myocarditis and myocardial necrosis is unknown but may be a direct effect of toxin on the myocardium. Increased plasma creatine kinase activity

is often observed and has been postulated to arise from the damaged myocardium.[713,714] Affected horses have a characteristically stiff gait, but histopathologic evidence of skeletal muscle injury that explains the elevated plasma creatine kinase activity has not been observed.[714] The kidneys are often pale, swollen, and moist, with occasional infarcts.[715]

Hypocalcemia and hypomagnesemia are biochemical features of cantharidin toxicity in horses that have not been explained.[713,714,717] Hypocalcemia may result from hypoalbuminemia, but the ionized calcium concentration is often decreased, indicating that hypoalbuminemia is not responsible for the hypocalcemia.[714]

Clinical Signs and Diagnosis

Cantharidin toxicity can cause a range of clinical signs, from mild depression and abdominal discomfort to fulminant signs of toxemia and rapid death, depending on the ingested dose of toxin.[713,714,717] Most commonly, clinical signs include depression, sweating, irritability, abdominal pain, elevated heart and respiratory rates, fever, polyuria, polydipsia, and profuse diarrhea.[713,714,717] Blood is rarely seen in the feces. Stranguria and pollakiuria are common.[713] Signs of hypocalcemia include synchronous diaphragmatic flutter and tremors. A stiff and stilted gait may be evident. Neurologic signs such as head pressing, swaying, and disorientation may be noted.[717] Signs of systemic inflammation resulting from endotoxemia may be seen in severe cases. Some horses develop severe depression and toxemia and may die within hours of ingesting cantharidin without developing diarrhea.[713,717]

Hematologic abnormalities include hemoconcentration and neutrophilic leukocytosis.[713,714] Occasionally, neutropenia and leukopenia may accompany endotoxemia. Serum biochemical analysis usually reveals increased creatine kinase activity, hypocalcemia, and hypoalbuminemia.[713,714] Biochemical abnormalities include hypocalcemia (both ionized and total calcium concentrations), hypomagnesemia, and azotemia.[713,714,717] Urine specific gravity is characteristically in the hyposthenuric range.[713,714] Microscopic hematuria and mild proteinuria may be evident. Fecal occult blood is often present, but hematochezia is unusual.

A tentative diagnosis can be made on the basis of clinical signs and identification of blister beetles in the hay. Determining the species of the insects may be necessary to estimate the amount of cantharidin ingested. All species of *Epicauta* contain cantharidin, but some have small amounts. Definitive diagnosis requires the measurement of the cantharidin concentration in gastric or intestinal contents and urine.[713,716]

Arsenic Toxicosis

Pathogenesis

Arsenic toxicosis is an unusual cause of diarrhea in horses, resulting from ingestion of arsenic-containing herbicides, insecticides, and other pest-control products contaminating water or roughage used as a food source.[718] The toxicity of arsenic depends on the valence of the element.[718,719] Arsenate may be reduced to arsenite in mammalian systems.[719] It is thought to be more toxic than arsenate and less rapidly excreted in urine.[719] Arsenate and arsenite uncouple oxidative phosphorylation, leading to the breakdown of energy metabolism in the cells of many tissues.[719] Widespread cellular injury and death occur rapidly during acute arsenic toxicosis. Multiorgan failure is usually the result. Cardiomyopathy and pulmonary disease are common causes of death in humans.[720] Damage to the large intestine is probably caused in part by direct cellular toxicity and corrosion by the compound. However, vasculitis is a hallmark of the disease in humans and horses and is thought to be the most important mechanism of large intestinal disease in humans.[718,721] Acute hemorrhagic colitis is a feature of arsenic toxicosis, with severe mural edema and mucosal ulceration.[718] Profuse hemorrhagic diarrhea and abdominal pain result. Chronic arsenic toxicity can occur but appears to be rare in horses.

Clinical Signs and Diagnosis

Depression, weakness, abdominal pain, hemorrhagic diarrhea, and shock are characteristic of acute arsenic toxicosis in horses.[718] Death may occur before diarrhea is evident. Initial clinical signs may be difficult to distinguish from other peracute forms of colitis and are related to endotoxic shock, metabolic disturbances, and dehydration. Later, cardiac arrhythmias, pulmonary edema, acute renal failure, and neurologic deficits (ataxia and stupor) may develop.[718] Anuria or polyuria may be observed. Hemolytic anemia caused by preferential binding of arsenic compounds to red blood cells is a feature of arsenic poisoning in humans.[720] Hematologic abnormalities resulting from injury to bone marrow cells and ongoing hemolysis may be seen after the peracute stage. Leukopenia and thrombocytopenia have been described in human patients.[720] Serum biochemical analysis may reveal azotemia, hepatocellular enzyme activities higher than generally attributed to endotoxemia, and increased creatine kinase activity.[718] Urine specific gravity may be in the isosthenuric range, with hematuria, cylindruria, and proteinuria evident by urinalysis.

Diagnosis may be possible by measuring blood and urine arsenic concentration, but these tests may not be diagnostic. Postmortem diagnosis is confirmed by measuring arsenic concentrations in liver and kidney samples.[718] History of exposure and clinical signs remain the primary means of diagnosis.

MISCELLANEOUS INFLAMMATORY DISORDERS OF THE LARGE INTESTINE

Intestinal Anaphylaxis

Pathogenesis

Severe intestinal anaphylaxis is a syndrome in horses characterized by peracute, rapidly fatal colitis.[722] The severe syndrome is clinically and pathologically similar to other known causes of peracute colitis. Some cases are less severe and manifest as mild to moderate diarrhea or colic (or both). The syndrome of intestinal anaphylaxis can be produced by either an IgE-mediated type I hypersensitivity or an IgE-independent anaphylactoid reaction.[723,724] Intestinal anaphylaxis is usually induced by local gastrointestinal exposure to a food, environmental, drug, or other allergen[723,725] but may also occur with systemic exposure to an allergen.[726-728] Massive mast cell degranulation, secretion of inflammatory mediators, and activation of enteric neural reflexes in the intestine cause profound alterations in blood flow, increased vascular permeability and interstitial edema, recruitment of neutrophils, altered motility, mucosal injury, absorption of microbial products, and mucosal hypersecretion.[729-733] Systemic signs may be caused by the anaphylactic reaction or may be associated with SIRS.

The peracute form is characterized by severe intramural edema and hemorrhagic inflammation of the large intestine, often producing submucosal thickening on the order of many centimeters.[162,722] Vascular thrombosis may be widespread, with mucosal and serosal petechiae and ecchymoses. Less severe forms of intestinal anaphylaxis may manifest as patchy areas of intestinal edema and congestion.[726] Diarrhea results from intestinal inflammation initiated by the type I hypersensitivity response. Many of the mediators of type I hypersensitivity, such as histamine and 5-HT, have well-documented stimulatory effects on mucosal secretory activity, vascular and epithelial permeability, and motility[729-731] in the intestine. Systemic inflammation resulting from endotoxemia may be overwhelming once the mucosal barrier breaks down. Infarction of intestinal segments and other organs may result from intravascular coagulation. Ileus, abdominal distention, and moderate to severe abdominal pain may result from motility disturbances and infarction of the large intestine.

Clinical Signs and Diagnosis

The clinical signs are similar to those described for other forms of peracute colitis. Severe diarrhea is possible, but death may occur before diarrhea is evident. Multiorgan failure resulting from DIC is not unusual. The rapid onset of weakness, staggering, and trembling commonly precedes death. The syndrome may cause death in 4 to 24 hours.

Diagnosis is based on clinical signs, postmortem findings, and exclusion of other causes. Most diagnostic tests are inconclusive. If an antigen is suspected to be the trigger of the anaphylaxis, a Prausnitz-Kustner passive cutaneous anaphylaxis sensitization test can confirm the presence of antigen-specific IgE in the patient's serum.[726]

Carbohydrate Overload

Pathogenesis

Overeating of soluble carbohydrates, especially so-called hot grains such as corn, overwhelms the digestive capability of the small intestine, resulting in a high percentage of soluble carbohydrates entering the large intestine. The amount of soluble carbohydrates that will produce diarrhea varies according to the previous dietary history of the individual. Horses fed diets higher in soluble carbohydrates are more resistant to the deleterious effects of carbohydrate overload. Gradual accommodation to a diet high in carbohydrates can be accomplished over several weeks. Horses fed an unusually large amount of grains or other form of soluble carbohydrates often develop diarrhea and may, depending on the amount ingested, develop severe colitis, systemic inflammation resulting from endotoxemia, metabolic acidosis, and laminitis.[229,734-736]

The pathogenesis of colitis from carbohydrate overload is primarily caused by the toxic effects on the microbial flora in the large intestine.[735] A sudden delivery of soluble carbohydrates to the large intestine causes rapid fermentation by gram-positive lactic acid–producing bacteria and a sudden increase in organic acid production.[229] The cecal pH level rapidly decreases, and the lactic acid concentration rapidly increases.[229] Rapid organic acid production overwhelms the buffering capacity of the large intestine, not only by directly depleting the buffers found in the contents but also by reducing the efficiency of buffer secretion. Bicarbonate secretion is linked to absorption of volatile fatty acids, which are produced in low amounts by fermentation of soluble carbohydrates. The contents of the large intestine become profoundly acidic, resulting in unfavorable conditions for the microbial flora. Lactic acid–producing bacteria flourish, whereas the gram-negative bacteria, especially the Enterobacteriaceae, are killed in large numbers by the acids. Large quantities of endotoxin are released from the dying bacteria.[229]

The osmotic load from lactic acid produced in the large intestine is an important factor in the development of diarrhea because organic acids such as lactic acid are poorly absorbed. Mild cases of carbohydrate overload may result purely from osmotic diarrhea. In more severe cases the acidic contents of the large intestine are toxic to the mucosa, causing necrosis of the mucosal tissues similar to that seen in ruminal acidosis. Mucosal ulceration allows absorption of large quantities of endotoxin and lactic acid produced by the massive die-off of acid-intolerant microbes and fermentation of soluble carbohydrates, normally poorly absorbed by intact mucosa.[736] Systemic inflammation resulting from endotoxemia may be overwhelming; clinical and laboratory findings are consistent with that described for endotoxemia. Laminitis is a frequent complication; carbohydrate overload is used to induce laminitis as an experimental model because of the consistency of laminitis produced.[229,735,736]

Clinical Signs and Diagnosis

Clinical signs of colitis from carbohydrate overload can vary according to the amount of carbohydrate ingested and accommodation of the flora to a high-carbohydrate diet. Mild cases may result in a transient osmotic diarrhea, with no systemic effects. Severe cases are characterized by signs similar to those described for other forms of colitis, including abdominal pain, moderate to severe diarrhea, and dehydration. Signs of endotoxemia and sepsis are frequently present in severe cases. Nasogastric intubation may yield significant acidic gastric reflux. Particles of grain may be noted in the gastric reflux and the feces if grain overload is the source of the carbohydrate overload. Laminitis is a common complication.

Sand Enteropathy

Sand enteropathy is often associated with acute intestinal obstruction due to abnormally large amounts of sand in the large intestine.[737] However, chronic sand-induced diarrhea is a distinct syndrome that can occur at any age as a result of the abnormal accumulation of sand in the large intestine.[738,739] Chronic diarrhea and signs of colic may be seen without obstruction. Diagnosis is usually based on the presence of abnormal amounts of sand in the feces, although some horses with sand enteropathy may not be passing sand in the feces at any given moment. Occasionally, radiography may be required to detect sand in the colon.[738]

PRINCIPLES OF THERAPY FOR ACUTE DIARRHEA

The principles of therapy for acute diarrhea resulting from colitis are similar regardless of the cause and include replacement of fluid and electrolyte losses, control of colonic inflammation, reduction of fluid secretion, promotion of mucosal repair, control of endotoxemia and sepsis, and reestablishment of normal flora. The reader is referred elsewhere in this chapter for a discussion of general treatment of endotoxemia, for which many of the principles of therapy overlap.

Fluid Replacement and Circulatory Support

Replacement of fluid and electrolyte losses is of primary concern in treating horses with salmonellosis. Depending on the severity of the disease, fluid losses may be minimal or massive. Fluid and electrolytes can be administered orally or IV. Some horses with mild to moderate diarrhea may maintain hydration and electrolyte balance by consuming water and electrolytes voluntarily. Fresh water and water containing electrolytes should be available in all cases. In many instances, periodic nasogastric intubation and administration of water and electrolytes through the tube may be sufficient to maintain hydration.[740] IV administration of fluids is preferred in cases requiring significant quantities of fluid to replace and maintain hydration and electrolyte balance.[357] It is not unusual for patients with severe diarrhea to require large volumes (50–100 L/day) of IV fluids to maintain hydration. Monitoring of packed cell volume, serum electrolyte concentration, venous blood gases, blood urea nitrogen and creatinine, urine protein and cytology, and body weight is important to evaluate hydration, electrolyte and acid-base balance, and renal function.

Isotonic sodium chloride or lactated Ringer's solution is frequently used to restore and maintain fluid and electrolyte balance. Potassium chloride can be added to the fluids and administered at a rate up to 0.5 to 1.0 mEq/kg/h. Generally, a rate of less than 0.5 mEq/kg/h is used. Hypertonic NaCl solutions (1–2 L of 5% or 7.5% NaCl) have been used in horses with acute, severe hyponatremia (<120 mEq/dL) and those with hemodynamic shock resulting from sepsis. The beneficial effects of hypertonic NaCl are short-lived (30–60 minutes). Isotonic solutions should be administered concurrently or immediately after administration of hypertonic NaCl solutions. Isotonic (1.3%) or hypertonic (5.0%) sodium bicarbonate solutions are used to correct metabolic acidosis. Prolonged administration of sodium-containing fluids may promote diuresis and renal water loss or accumulation of peripheral edema and should be used conservatively when a relative free water loss is noted. Administration of isotonic dextrose (5%) or 2.5% dextrose/0.45% NaCl solutions may be beneficial when free water loss (relative sodium excess) is evident.

Many horses with acute colitis are concurrently hypoproteinemic because of gastrointestinal losses and are absorbing bacterial products that induce a systemic inflammatory response. Plasma oncotic pressures are abnormally low in the face of increased vascular permeability. Interstitial edema formation is a clinical problem in these patients, which contributes to organ dysfunction. Crystalloid fluids, although critical for replacing water and electrolyte losses resulting from diarrhea, may actually contribute to a decline in plasma oncotic pressure as a result of hemodilution.[436,439] Administration of colloid solutions is helpful for volume expansion and maintenance of plasma oncotic pressures. Discussion of colloid replacement is included in the section Endotoxemia.

Antiinflammatory Therapy

Control of colonic inflammation and secretion is a difficult and poorly studied aspect of equine acute colitis. The role of inflammation and mediators such as prostaglandins as a cause of fluid loss is well known during *S. enterica* and clostridial infection.[103,142,198,552,571,637,638,741] COX inhibitors (NSAIDs) have antisecretory effects on the inflamed intestinal tract,[91,169] including in the equine colon.[742,743] NSAIDs are commonly administered to horses with colitis to reduce inflammation-associated fluid secretion. However, prostaglandins such as PGE_2 and PGI_2 also have cytoprotective effects on gastrointestinal mucosa and are critical for mucosal repair.[91,701] NSAIDs used pharmacologically to inhibit colonic inflammation and secretion may be detrimental to mucosal integrity and healing if not used judiciously. NSAIDs exacerbate colonic inflammation in humans with inflammatory colitis, impede mucosal healing in several models of mucosal injury, and have well-documented detrimental effects on colonic mucosa in horses.[91,690,698,701] In addition to toxicity to the colonic mucosa, gastric ulceration is not unusual in horses with enterocolitis and may be related to treatment with NSAIDs. Although the use of COX-2–selective NSAIDs should, in theory, be less likely to harm or impede repair of the colonic mucosal in patients with colonic inflammation causing diarrhea, the safety and efficacy of these medications has not been evaluated in this application. The prothrombotic adverse effects of COX-2–selective drugs[744] suggest that very cautious use of highly COX-2–selective medications is warranted in patients with systemic inflammation at risk for thrombosis (e.g., endotoxemia and sepsis).

In addition to NSAIDs, other drugs are occasionally used as antiinflammatory and antisecretory therapy. Bismuth subsalicylate is commonly used in adults and foals with diarrhea. The volume required for any effect in adults with colitis is quite high (1–4 L by nasogastric tube every 4–8 hours), which often precludes its use. Metronidazole has beneficial effects in experimental models of gastrointestinal inflammation, including NSAID toxicity,[706] and may be useful for treating horses with colitis; however, evidence supporting its use is lacking.

Mucosal Repair and Protection

Sucralfate (20 mg/kg by mouth every 6 hours) has been advocated to aid in healing of the colonic mucosa in patients with NSAID toxicity. There is evidence in experimental phenylbutazone toxicosis in foals suggesting that sucralfate administration lessens ulceration and other histopathologic lesions throughout the alimentary tract and lessens protein loss.[745] There is no evidence supporting the use of sucralfate to treat colonic ulceration in adult horses.

Misoprostol (5 μg/kg by mouth every 12 hours or 2 μg/kg by mouth every 6–8 hours) and other synthetic PGE analogs enhance mucosal healing in the intestine and promote recovery in experimental models of colitis.[746] Misoprostol may be particularly useful for treating NSAID toxicity, either the generalized form or RDUC. However, the efficacy of misoprostol in hastening mucosal healing is clinically unproven in equine colitis. The primary drawbacks of prostaglandin analogs such as misoprostol are the adverse effects of the drug, including abdominal cramping, diarrhea, sweating, and abortion in pregnant mares.

Psyllium mucilloid can be added to the diet (5 tablespoons every 12–24 hours) to increase the production of SCFAs in the colon. Amylase-resistant fermentable fiber such as psyllium is hydrolyzed by colonic bacteria to SCFAs such as butyrate, which represent a major energy source for colonocytes. Butyrate and other SCFAs hasten epithelial maturation and stimulate salt (and thus fluid) absorption in the colon, improve the clinical course of ulcerative colitis, and hasten colon healing.[747] Psyllium is itself a source of butyrate in the colon and also promotes the movement of amylase-sensitive carbohydrates into the distal colon, which are then fermented to SCFAs. Psyllium is thought to be clinically useful for promoting mucosal healing in colitis.

Pain Control

Many horses with colitis have mild to severe signs of abdominal pain. Analgesia can be accomplished with NSAIDs such as flunixin, but the potential for worsening mucosal injury or nephrotoxicity may prevent the use of analgesic doses, especially in horses with suspected NSAID toxicity. Relative COX-2–selective inhibitors may spare the gastrointestinal mucosa. For example, meloxicam and firocoxib have analgesic properties in horses in experimental models of ischemic colic and spare the intestinal mucosa from the detrimental effects associated with nonselective COX inhibitor treatment.[695,748]

Xylazine, detomidine, or butorphanol (bolus dosing) may provide temporary analgesia. Constant rate infusions of butorphanol, lidocaine, and/or ketamine (alone or in combination) may provide more profound analgesia and can be useful if one is certain that an obstructive or infarctive process is not present. Pain management is discussed in Chapter 3 of this text.

Antimicrobial Therapy

Broad-spectrum antibiotic treatment is often recommended in neutropenic horses or horses with signs of sepsis. Broad-spectrum antibiotics lessen septic complications in human patients. Evidence supporting this principle in horses with colitis is lacking.

Treatment with antibiotics is not thought to alter the course of the enterocolitis, but it may lessen dissemination and severity of disease. Treatment with antibiotics directly targeted at *S. enterica* is often reserved for patients with sepsis. Lipid-soluble antibiotics are ideally suited for *S. enterica* infections because the bacteria persist intracellularly. Enrofloxacin is often preferred, but antimicrobial sensitivity of the isolate should dictate directed therapy.

In patients in which the likelihood of *N. risticii* infection is high, treatment with directed antimicrobial therapy is often indicated before a definitive diagnosis. Lipid-soluble drugs are preferred because the organism can live within cells. Oxytetracycline (6.6 mg/kg/day IV), often followed by doxycycline (10 mg/kg PO every 12 hours), appear to be the most effective antibiotics for treatment of Potomac horse fever and are considered the treatment of choice. Treatment is most successful if initiated before the onset of diarrhea.[584,749]

If antibiotics are being administered at the onset of enterocolitis, they should be discontinued if possible. Specific treatment with metronidazole is effective for treating clostridiosis in humans and appears to be effective in horses.[624,750] Metronidazole resistance in clinical isolates of *C. difficile* has been reported in one outbreak but appears to be rare in most human and equine cases.[751] Metronidazole-resistant isolates were sensitive to vancomycin, which may be effective for treating clinical cases if metronidazole resistance is suspected. Vancomycin use is not recommended in horses because of concerns for antimicrobial stewardship. *C. perfringens* type C antitoxin has been recommended for treatment of neonatal clostridiosis, but there is no evidence of its efficacy.[752] Antitoxin preparations are not advocated for use in adult horses with clostridiosis.

Anticoagulation

Hypercoagulability is a common complication of enterocolitis, associated with systemic inflammation resulting from endotoxemia. Administration of heparin (20–80 IU/kg SC or IV every 6–12 hours) may prevent thrombosis in these patients, provided antithrombin III concentrations are adequate in the plasma. Concentrated sources of antithrombin III are not available for use in horses, but whole plasma may provide an important source. Treatment with heparin is thought to decrease thrombosis, especially of the jugular vein, which is a serious complication of salmonellosis. Low-dose aspirin treatment (10 mg/kg PO every 24–48 hours) in conjunction with heparin treatment may provide added benefit by irreversibly inhibiting platelet function.[753] Heparin and aspirin may have protective effects on the digital lamina.[753,754] Heparin may enhance the phagocytic activity of the reticuloendothelial system by enhancing the efficiency of opsonins, such as fibronectin and immunoglobulin, stimulating phagocytosis of products of coagulation and possibly other particles, including bacteria.[755,756]

Probiotics

Maintenance of the bacterial flora in the gastrointestinal tract is an important defense mechanisms preventing colonization by pathogenic bacteria. Little work has been done to investigate the efficacy of these products in horses. Preparations of *Saccharomyces boulardii* were shown to decrease the duration and severity of disease in horses with colitis.[757] In foals, probiotic use was associated with increased risk of diarrhea and, especially, diarrhea requiring clinical intervention. In humans, fecal transplantation (known to most veterinarians as transfaunation) has been proven effective for intestinal clostridiosis. As the intestinal microbiota are extremely diverse,[756] restoration of the overall flora is more likely to be effective than restoration of single bacterial species.

Absorbent Powders and Mineral Oil

Absorbent powders are often used to reduce the bioactivity and absorption of bacterial toxins produced by bacterial or toxic metabolites produced by bacteria and other microorganisms (e.g., lactic acid in grain overload). In a rat model of cantharidin toxicosis, mineral oil, which is often used in equine cantharidin toxicosis, increased cantharidin absorption and also increased morbidity and mortality.[758] In that study, rats treated with charcoal or DTO smectite had improved survival. DTO smectite powder (Bio-Sponge, Platinum Performance, Buellton, California) binds *C. difficile* and *C. perfringens* exotoxins in vitro[343,759] and may be useful for treating intestinal clostridiosis, or unspecified colitis, in horses. DTO smectite is available as a powder or paste and should be administered according to the manufacturer's instructions for 3 to 5 days.

Nutrition

Good nursing care and adequate nutrition are vital to the treatment of horses with colitis. Normal intake of roughage to provide energy may be inadequate; however, feeding of grains should be avoided to prevent delivery of highly fermentable carbohydrate to the colon. Dietary management usually consists of restricting or eliminating long-stem roughage (hay) from the diet and feeding exclusively a complete pelleted diet (at least 30% dietary fiber). The rationale behind this recommendation is to reduce the mechanical and physiologic load on the colon. Frequent meals (4–6 times a day) are recommended. Corn oil (1 cup every 12–24 hours) can be added to the pellets to increase the caloric intake without adding roughage or grain. It is important to note that if a horse with colitis refuses to eat pelleted feed, then high-quality grass hay should be fed. In anorectic or severely catabolic patients, enteral and parenteral nutrition (total and partial) has been used successfully to provide calories and nutritional support.

Specific Therapies

Strongylosis

Treatment of *S. vulgaris* infection requires treatment of the migrating parasite larvae and the lesions produced by the parasite. Fenbendazole (10 mg/kg PO every 24 hours for 3 days or 10 mg/kg PO every 24 hours for 5 days) and ivermectin (200 mg/kg, PO) are effective in killing fourth-stage larvae.[647] Other anthelmintics may also be effective when given at higher doses than those required to kill adult worms. The efficacy of these anthelmintics against larvae within thrombi is not known.

Thrombolytic and antithrombotic therapy has been advocated in horses with suspected strongylosis.[647,654] Heparin (20–80 IU IV or SC every 6–12 hours) may be administered as an anticoagulant. High-molecular-weight heparin causes anemia by inducing aggregation of red blood cells, which is an undesirable effect in sepsis. Low-molecular-weight heparins appear to be less likely to have this effect in horses. Aspirin (10–30 mg/kg PO every 12–48 hours) is usually combined with heparin to inhibit platelet adhesion. Aspirin may also inhibit release of platelet products, such as thromboxane, which affect the motility of the large intestine. Low-molecular-weight dextrans have been advocated as antithrombotics that act by inhibiting platelet function and coagulation.[654] The clinical efficacy of dextran administration appears to be good, but no controlled studies have been performed.

Cyathostomiasis

Anthelmintic administration is usually the only treatment necessary for mild to moderate cases of cyathostomiasis treated early in the course of the disease (within 1–3 weeks of onset). Fenbendazole is effective against many larval stages, but resistance is high in some populations. Although the reported efficacy of ivermectin is variable against certain stages,[760] one study reported an overall efficacy of 75%.[761] Currently, fenbendazole (7.5–10 mg/kg PO every 24 hours for 5 days) followed on day 6 by ivermectin (200 mg/kg PO) is the most commonly advocated treatment regimen.[659,762] Moxidectin (400 µg/kg PO every 24 hours) may also be effective against adult organisms and L_3 and L_4 larval stages[763] and may be useful for treating cyathostomiasis. Antiinflammatory therapy may be beneficial, especially in severe or refractory cases or before treatment with larvicidal medications. Pretreatment with dexamethasone or prednisolone is indicated before anthelmintic administration if heavy larval loads are suspected to prevent an acute exacerbation of the disease by rapid death of encysted larvae. Larvicidal treatment with moxidectin appears to be less likely than fenbendazole to result in tissue inflammation resulting from larval death.[764] NSAID administration may have limited value, but dexamethasone appears to be efficacious in refractory cases when used in conjunction with larvicidal anthelmintics.[659,662] Bismuth subsalicylate is often administered orally as an antisecretory agent in young animals. Supportive care may be necessary in severe cases, particularly if hypoproteinemia is severe. Administration of IV crystalloid fluids and plasma or other colloids is occasionally required. Proper nutritional support is also important.

Arsenic Toxicity

Reduction of arsenic absorption by administration of cathartics such as activated charcoal should be initiated immediately.[718] Chelation therapy with sodium thiosulfate (20–30 g in 300 mL of water, administered orally) and dimercaprol (British anti-Lewisite; 3 mg/kg PO every 4 hours) is indicated.[718] Dimercaprol is a specific antidote for trivalent arsenicals, but its efficacy in horses is questionable.

Intestinal Anaphylaxis

Treatment of intestinal anaphylaxis is in principle similar to treatment of other forms of colitis, but it is often unsuccessful because of the rapidly progressive nature of the syndrome.[162,722,727] Early treatment with prednisolone sodium succinate (10–20 mg/kg IV) or dexamethasone (0.1–0.2 mg/kg IV) may be essential for successful treatment.[722]

Peritonitis

STRUCTURE AND FUNCTION

The peritoneum consists of a single layer of mesothelial cells. The mesothelial lining of the diaphragm, abdominal walls, and pelvic cavity is termed the *parietal peritoneum*. The visceral peritoneum forms the serosal surfaces of the intraabdominal organs. Caudally, the peritoneum reflects over the surfaces of the pelvic organs (portions of the urogenital tract and rectum), excluding them from the peritoneal space, and defining the retroperitoneal space. The peritoneal space communicates with the lumen of the uterus (and thus the external environment) via the fallopian tubes in females. In males the peritoneum forms a true blind sac. The vascular supply and nervous innervation of the visceral peritoneum are supplied by the splanchnic vessels and visceral autonomic nerves, respectively. Branches of the intercostal, lumbar, and iliac arteries supply the parietal peritoneum, and the phrenic and intercostal nerves provide nervous innervation. Inflammation of the parietal peritoneum is perceived as somatic pain, resulting in a splinted abdominal wall, pain on external palpation, and reluctance to move.

The peritoneal lining functions as a semipermeable barrier to the diffusion of water and low-molecular-weight solutes between the blood and the abdominal cavity.[765] The peritoneum secretes a serous fluid that lubricates the abdominal cavity, inhibits adhesion formation, and has minor antibacterial properties.[765,766] Macrophages, mast cells, mesothelial cells, and lymphocytes provide immune function within the peritoneum.[767] The peritoneal surface maintains a high level of fibrinolytic activity through the production of plasminogen activators by mesothelial cells. This function, together with the lubricant properties of the PF, helps to maintain gliding surfaces within the peritoneum and prevent adhesion formation. PF produced by the mesothelium tends to move ventrally and cranially, aided largely by diaphragmatic movement. PF, waste products, and foreign material exit the peritoneal cavity to enter the lymphatic system through diffusely distributed subendothelial pores or via the large diaphragmatic stomata, depending on particle size. Large molecules and particles greater than approximately 40,000 MW (such as bacteria) exit through the diaphragmatic stomata and ultimately enter the thoracic duct. The term *peritonitis* refers to inflammation of the mesothelial lining of the peritoneal cavity.

ETIOPATHOGENESIS

Peritonitis can occur in association with any insult—mechanical, chemical, or infectious—that results in disruption or irritation of the peritoneal lining, inflammation or infection of abdominal organs, or compromise of the intestinal wall.[765] Common mechanical injuries include blunt or perforating trauma to the abdominal wall, breeding and foaling accidents, and abdominal surgery. A variety of iatrogenic insults can cause peritonitis, such as abdominocentesis, enterocentesis, splenic puncture, bowel trocarization, liver biopsy, uterine biopsy, castration, and rectal tear. Chemical insults of endogenous origin include blood, urine, pancreatic enzymes, bile, gastric juice, chyme, and chyle. Talc, contrast agents, antibiotics, and lavage solutions are additional examples of chemical insults. Traumatic events often involve bacterial contamination at the time of injury, and mechanical and chemical injuries can become infected secondarily.

The most common manifestation of peritonitis is acute, diffuse, septic peritonitis following inflammation, vascular insult, perforation, or surgical manipulation (enterotomy, resection, and anastomosis) of the gastrointestinal tract. The septic process in such cases involves mixed bacteria of gastrointestinal origin. Penetrating abdominal wounds also result in mixed infections. Less commonly, singular bacterial forms gain access to the peritoneum through hematogenous spread, extension from a contiguous organ, or through the female genital tract. Primary monomicrobial infections have been reported involving *Streptococcus equi* subsp. *equi,*[768] *S. equi* subsp. *zooepidemicus,*[769] *Rhodococcus equi,*[770] and *Corynebacterium pseudotuberculosis.*[771] Several case series involving peritonitis associated with *Actinobacillus equuli* have been reported.[772-775] Sepsis, septic omphalitis, ascending urinary tract infections, and uterine infections are additional causes of monomicrobial infection.

Most cases of trauma or intestinal perforation result in contamination of the peritoneum with large numbers of many types of bacteria. The intestinal tract contains a mixed population of bacteria, and the quantity of bacteria and prevalence of anaerobic species increase in the distal segments. Not surprisingly, mortality associated with contamination from the lower bowel is high. Hirsch and Jang[776] reported isolation of an infective agent from exudative equine PF in approximately 25% of attempts. Obligate anaerobic bacteria were cultured most frequently, followed by members of the Enterobacteriaceae family (predominantly *E. coli*). Penicillin-resistant *Bacteroides fragilis* was isolated from 10% to 20% of cases. In another study in which bacteria were identified in equine abdominal fluid by cytologic examination or culture, *E. coli* was the organism most commonly isolated.[777] In human beings and laboratory animals, despite the variety of organisms initially introduced by polymicrobial contamination, established infections are characterized by only a few types of bacteria, which are often gram-negative aerobes and anaerobic bacteria. This selectivity occurs through the processes of selective reduction of bacterial populations and bacterial synergism. An example of synergism in human beings and laboratory animals is peritonitis involving *E. coli* and *B. fragilis.* The presence of each organism is beneficial to the survival of the other, and each is important in the overall pathogenesis of the disease. *E. coli* is associated with septicemia and early mortality, whereas *B. fragilis* infection tends to result in chronic abscessation with delayed morbidity and mortality.[766]

Other causes of equine peritonitis include parasites, viral disorders (influenza, equine viral arteritis, equine infectious anemia, African horse sickness), and neoplasia. Verminous arteritis caused by strongylosis can lead to vascular damage (thromboembolism and infarction) to the intestine. The activities of strongyles, ascarids, and tapeworms can result in perforation of the bowel and damage to other abdominal organs. There has been one report of septic peritonitis caused by colonic perforation associated with aberrant migration of *Gasterophilus intestinalis* larva.[778]

Biologic events resulting from contamination of the abdomen or injury to the mesothelial cells include release of catecholamines, histamine, and serotonin from peritoneal mast cells; vasodilation and hyperemia; an increase in peritoneal vascular permeability; secretion of protein-rich fluid into the peritoneum; transformation of mesothelial cells into macrophages; and influx of PMN cells, humoral opsonins, natural antibodies, and serum complement into the peritoneal cavity.[765] Other possible events include depression of the peritoneal fibrinolytic activity, fibrin deposits on the peritoneal surface, and inflammatory-mediated and sympathetic-mediated ileus. These processes serve to confine contamination and infection and, with clean, minimally invasive procedures such as enterocentesis or trocarization, are effective. However, with greater severity of peritoneal contamination or irritation, these processes are magnified and become deleterious. Consequences include hypovolemia, hypoproteinemia, gastrointestinal ileus, ischemia of the bowel wall with subsequent absorption of bacteria and toxins, and ultimately adhesion and abscess formation. Equine peritoneal macrophages release a multitude of inflammatory mediators when exposed to bacterial LPS, and endotoxemia contributes the clinical picture. A complete review of endotoxemia is presented in Endotoxemia.

A complete pathologic description of peritonitis includes origin (primary or secondary), onset (peracute, acute, and chronic), distribution (localized versus diffuse), and presence of bacteria (septic versus nonseptic). Clinically, viewing the pathogenesis of peritonitis as a series of stages is useful. The contamination stage, lasting 3 to 6 hours, involves introduction of bacteria into the peritoneum and initiation of the acute inflammatory response previously described. If the organisms are not eliminated, the process evolves to the stage of acute diffuse peritonitis as, regardless of the location of the initial contamination, bacteria spread throughout the peritoneum within several hours. The stage of acute diffuse peritonitis lasts up to 5 days. The inflammatory response persists and escalates with continued exudation of proteinaceous fluid and influx of inflammatory cells. Offending organisms are delivered to the lymphatic system and may be eliminated by the immune system. Alternatively, organisms can gain access to the systemic circulation in sufficient numbers to result in clinically relevant bacteremia. This stage of the disease process has the highest mortality because of the effects of severe peritoneal inflammation, endotoxemia, and sepsis. If the animal survives this stage but fails to eliminate infection from the peritoneal cavity, the disease enters a transitional phase referred to as the acute adhesive (or localizing) stage, typically occurring 4 to 10 days after the initial insult. Neutrophils are still active, macrophages are increasing in numbers, and fibrin aggregates are being organized or lysed. If infection persists beyond this point, organization of fibrin proceeds and organisms become isolated from host

defenses. At this point, the disease process enters the stage of chronic abscessation. This stage can begin as early as 8 days after inoculation and persist indefinitely.

Clinical Signs

Clinical signs of peritonitis depend on the primary disease process, the duration of the problem, and the extent of peritoneal inflammation. Localized peritonitis may have few or no systemic manifestations, whereas severe localized or generalized peritonitis often is accompanied by severe toxemia, sepsis, or both. Septic peritonitis usually causes more severe clinical signs because of the systemic inflammatory response and endotoxemia. Most clinical signs are nonspecific and include fever, lethargy, inappetence, decreased borborygmi, and dehydration. Additional signs include colic, ileus, weight loss, and diarrhea.[768]

Horses with peracute peritonitis, as occurs with rupture of the bowel or rectal tear, have clinical signs associated with severe endotoxemia, weakness, lethargy, colic, and/or circulatory failure. Fever may not be present depending on the degree of shock. Parietal pain, characterized by reluctance to move, splinting of the abdominal wall, and sensitivity to external abdominal pressure occur in some acute cases. With extensive abdominal fecal contamination, rectal examination may reveal a gritty feeling of the serosal and parietal surface of the peritoneum because of fibrin deposition.

In horses with more chronic peritonitis, clinical signs include intermittent colic, lethargy, anorexia, weight loss, intermittent fever, ventral edema, exercise intolerance, decreased or absent intestinal sounds, and mild dehydration. Heart and respiratory rates may be normal. Fecal output may be normal; however, horses with chronic diarrhea and weight loss have been reported. Rectal examination findings can include pain on palpation of fibrinous or fibrous adhesions, intestinal distention, an abdominal mass, or an impression of bowel floating in fluid. In many cases, rectal examination does not reveal significant abnormalities.[768]

In cases of *A. equuli* peritonitis, clinical signs in most horses included lethargy, inappetence, and mild to moderate abdominal pain if acute or weight loss if chronic.[773,774] Postpartum mares with peritonitis secondary to a uterine perforation typically present with fever and depression, with or without abdominal pain. Septic tenosynovitis of the tarsal sheath secondary to bacterial peritonitis from gastrointestinal perforation has been reported.[779] Foals with peritonitis usually exhibit signs of colic (acute or chronic) and are febrile, depressed, and inappetent. In young foals, peritonitis can cause rapid metabolic deterioration, and determination and correction of the primary problem require immediate attention. In older foals, peritonitis may occur insidiously in association with *S. equi* subsp. *equi* or *R. equi* infections.

Clinicopathologic Findings

Clinicopathologic abnormalities vary depending on the time of onset and severity. In the acute stage, leukopenia, hemoconcentration, metabolic acidosis, and azotemia predominate. After several days, leukocytosis and hyperfibrinogenemia are more typical. In chronic peritonitis, hyperproteinemia with hyperglobulinemia may be present. SAA is also increased.[254] Neonates with uroperitoneum tend to develop azotemia, hyponatremia, hypochloremia, hyperkalemia, and acidemia.

PF analysis is principal to the diagnosis of peritonitis. Detailed description of PF analysis is provided in the Examination section of this chapter. PF WBC counts in acute peritonitis are reportedly higher than those in chronic peritonitis,[768] but this is not always the case, and the WBC count does not always correlate with disease severity or prognosis. The PF WBC count can be greater than 100,000/μL following enterocentesis, with no clinical signs or problems.[780] Conversely, peritoneal WBC counts of fewer than 100,000/μL may be found in foals or horses with intraabdominal abscesses.[781] The peritoneal WBC count can increase to greater than 150,000/μL following celiotomy[782] and can be higher if an enterotomy is done. Postoperatively, the WBC count normally continues to decline and returns to near normal by 5 to 7 days. Failure of the WBC count to decrease suggests peritonitis resulting from a postoperative complication. Finally, PF WBC counts greater than 500,000/μL indicate severe focal or generalized peritoneal sepsis. With acute peritonitis, PMN cells typically increase to a greater degree than mononuclear cells, but this depends on the cause. In horses with gastrointestinal disease and endotoxemia, the number of peritoneal mononuclear cells increases, as does transformation of mesothelial cells to macrophages. In chronic cases, one easily may mistake transforming mesothelial cells for neoplastic cells, which can make diagnosis difficult.

The presence of free and phagocytosed bacteria in PF indicates generalized suppuration, abscessation, or compromised bowel. If one observes numerous microorganisms of mixed types free in the PF, especially in conjunction with plant material, bowel rupture likely has occurred. The presence of toxic or degenerate neutrophils and bacteria within PMN cells helps to distinguish PF from intestinal contents in such horses. Fluid obtained from enterocentesis is largely devoid of WBCs but is discolored and contains mixed microorganisms and plant material. Bacterial contamination of a sample can occur during collection of the sample, and iatrogenic contamination of a sample can result in free and intracellular bacteria, particularly if processing is delayed. In such cases the bacterial numbers are few and the neutrophils appear healthy. In some cases of gastrointestinal perforation the luminal material, inflammatory cells, and protein may be sequestered by the omentum and further contained by fibrinous adhesions. Abdominal fluid obtained via standard ventral paracentesis may have low cellularity and protein content but large numbers of mixed bacteria, indicating bowel rupture.[768] Examples include gastric rupture along the greater curvature of the stomach between the omental layers (omental bursa) and perforated gastric or duodenal ulcers in foals. Correlating all cytologic findings with clinical and clinicopathologic findings is important for interpreting the results of PF cytologic examination.

Biochemical analysis of PF may be useful in detecting sepsis when cytologic examination and culture are negative or otherwise unavailable. PF pH and glucose concentrations from horses with septic peritonitis were significantly lower than in horses with nonseptic peritonitis and healthy horses.[783] PF pH less than 7.3, glucose less than 30 mg/dL, and fibrinogen concentration greater than 200 mg/dL were considered highly predictive of septic peritonitis. Serum to peritoneal glucose concentration differences of greater than 50 mg/dL were considered the most diagnostically useful test for septic peritonitis in the study. PF lactate concentration is also increased because of septic peritonitis, and a blood-to-peritoneal lactate concentration difference may have diagnostic significance. In a small study in dogs, a blood-to-fluid lactate difference of ≤2.0 mmol/L was shown to be 100% sensitive and specific for a diagnosis of septic peritonitis.[784]

PF samples should be submitted for aerobic and anaerobic cultures in appropriate media (i.e., BBL Port-A-Cul tubes, Becton, Dickinson & Co., Franklin Lakes, NJ, in an attempt to identify the pathogenic organism(s). To enhance recovery of bacteria, PF may be inoculated into blood culture medium (i.e., Septi-Chek Columbia, Hoffmann-LaRoche Inc., Nutley, NJ). If the horse has received prior antimicrobial treatment, the fluid sample should be passed through an antimicrobial removal device before culture (i.e., A.R.D., Becton Dickinson & Co., Franklin Lakes, NJ).

Treatment

Early and aggressive therapy is important for a successful outcome. Treatment goals are to resolve the primary problem, minimize inflammation, and prevent long-term complications. In the acute phase, analgesia and therapy as described for endotoxemia are important. Flunixin meglumine is advocated for its local and systemic antiinflammatory effects and may be effective in retarding adhesion formation.[785]

Initial antimicrobial selection should be broad spectrum based on the presumption that mixed infection is present. IV administration is preferred over oral or intramuscular routes in acute, diffuse, septic peritonitis because more reliable concentrations of drugs are achieved in the tissues and PF.[786] The combination of a β-lactam antibiotic with an aminoglycoside, such as potassium penicillin (22,000–44,000 IU/kg IV every 6 hours) combined with gentamicin (6.6 mg/kg every 24 hours), is appropriate in most circumstances. Metronidazole (25 mg/kg orally every 12 hours) can be added to the regimen given the strong possibility of infection involving penicillin-resistant *B. fragilis*. This regimen can be modified when culture and antimicrobial sensitivity results become available. Peritonitis caused by *A. equuli* generally responds well to therapy with penicillin either alone or in combination with gentamicin. Aminoglycosides and NSAIDs have the potential to induce acute renal tubular damage, particularly with concurrent dehydration and decreased renal perfusion. Therefore adequate restoration and maintenance of hydration and monitoring of renal function are important. Monitoring of the WBC count, plasma fibrinogen, SAA, and abdominal fluid analysis often guide duration of therapy. Horses with abdominal abscessation resulting from monomicrobial infections typically require weeks to months of therapy, whereas polymicrobial infection may require many months of antibiotic treatment. Further details regarding principles of antimicrobial therapy are provided elsewhere in this text (Chapter 2).

Abdominal drainage and lavage can help remove excess fluid, foreign materials, fibrin, and bacterial products from horses with peritonitis. Postoperative lavage decreases the incidence of experimentally induced abdominal adhesions.[787] Open surgical exploration provides the most effective and thorough examination of all peritoneal surfaces and is recommended if gastrointestinal perforation or ischemia is suspected or in any other case in which correction of a primary lesion is indicated. A ventral abdominal drain can either be placed at the time of surgery or in the standing horse with sedation and local anesthesia. Techniques have been described in detail elsewhere.[788,789]

Peritoneal lavage is typically performed with 10 to 20 L of a balanced isotonic electrolyte solution twice a day for 3 to 5 days, until the lavage solution becomes clear or until the catheter becomes clogged with fibrin or omentum. Hypertonic solutions should be avoided because they can result in fluid shifts into the peritoneum. The addition of povidone iodine to a balanced solution should be avoided because concentrations as low as 3% can induce peritoneal inflammation.[790] Other agents such as antibiotics or heparin have also been suggested as components of the lavage solution, but data demonstrating their benefit are not currently available. Active (or closed suction) abdominal drains have also been advocated, with similar benefits and potential complications to other methods.[789] Lavage with a plain isotonic solution did not alter the pharmacokinetics of gentamicin administered systemically.[791] Thus alteration of antimicrobial dosing does not appear necessary if lavage with plain solutions is part of the therapeutic regimen. Complications associated with the use of abdominal drains or repeated peritoneal drainage include retrograde infection, local irritation, pneumoperitoneum, and SC seepage around the drain and resultant cellulitis. If the patient is hypovolemic or hypoproteinemic, volume replacement and administration of plasma or synthetic colloids should be considered before removing large quantities of fluid from the abdomen.

In horses with suspected parasitic involvement, one should give larvicidal doses of an anthelmintic once the condition of the horse is stabilized. Ivermectin, fenbendazole, and thiabendazole have been recommended as larvicidal therapies.

The decision to perform surgical versus medical treatment is controversial in horses with peritonitis and needs to be made on a case-by-case basis. Although surgical exploration may allow diagnosis and resolution of the inciting cause and more thorough lavage of the abdomen, the risks of anesthesia, possible additional cost of surgery, and potential for a prolonged return to performance may be significant. In a recent study of horses and foals with peritonitis, survival to discharge without surgery was associated with lack of signs of abdominal pain, normal or improved rectal temperature, normal or improved borborygmi, normal fecal production, no abnormal findings on palpation per rectum, no nasogastric reflux, and yellow/orange PF.[792] A retrospective comparison of medical and surgical treatment of postpartum mares with peritonitis secondary to a uterine tear found no significant difference between admission variables, survival rate, hospital bill, duration of hospital stay, and likelihood to foal following discharge.[793] A limitation of this study is the ability to definitively diagnose a uterine tear in those mares treated medically; if a tear was not palpable, the diagnosis was based on the exclusion of other causes.

Prognosis

The prognosis is grave for peritonitis associated with gastrointestinal rupture. Reported survival rates for horses with peritonitis vary but can be as high as 78%.[792,794] In one study with a 78% overall survival rate, 68% of horses treated medically survived[792]; in another, 93% of those treated medically survived.[795] Some of the variability in reported survival percentages can be related to inclusion criteria, mainly whether or not horses with gastrointestinal rupture were included. Septic peritonitis following abdominal surgery was associated with high mortality (56%) in some reports,[777] although no difference in short-term survival was seen in another study.[796] Peritonitis associated with *A. equuli* carries a very favorable prognosis, and all horses in these reports responded to medical therapy if attempted.[773,774]

Pathophysiology of Mucosal Injury and Repair

MUCOSAL BARRIER FUNCTION

To gain an appreciation of the mechanisms in which the mucosa is injured and subsequently repaired, it is important to understand how the integrity of the mucosa is physiologically regulated. Regulation of mucosal integrity is referred to as mucosal barrier function, which is vital because it prevents bacteria and associated toxins from gaining access to subepithelial tissues and the circulation. However, the mucosa has two conflicting functions: it must serve as a protective barrier while continuing to absorb solutes necessary to maintain the well-being of the host. This conflict is most notable at the intercellular (paracellular) space, which allows passage of select solutes and water[797-800] but does not admit large molecules, including bacterial toxins.[801] The paracellular space is almost exclusively regulated by the tight junction,[574] which is the interepithelial junction at the apical-most aspect of the paracellular space. Although these tight junctions were originally viewed as inert cellular adhesion sites, it has become clear in recent years that tight junction permeability is dependent on tissue-specific molecular structure and regulated by a complex array of intracellular proteins and the cytoskeleton. Tight junctions consist of a group of transmembrane proteins that interdigitate from adjacent cells. Although occludin was originally thought to be the predominant tight junction transmembrane protein, a group of proteins termed *claudins* appear to fine-tune the function of the tight junction. For example, select claudins are responsible for the relative porosity of the barrier to select electrolytes based on their charge within the paracellular space.[802] These transmembrane proteins interact with the cytoskeleton via a series of intracellular proteins, including zonula occludens (ZO)-1, ZO-2, ZO-3, cingulin, and others.[803] In addition, local regulatory proteins such as the small GTPase Rho are critical to tight junction function. Generally, the relative contractile state of the actin cytoskeleton determines the degree to which tight junctions are open or closed, but the complexities of regulation of this process are poorly understood.[804,805]

The most sensitive measure of mucosal barrier function is transepithelial electrical resistance, which is measured by mounting mucosa in an in vitro system called an Ussing chamber, because this measurement is largely a reflection of the permeability of mucosa to ions.[806,807] There are two routes ions it may follow when traversing the epithelium: transcellular and paracellular.[801] Because cell membranes have a resistance to the passive flow of ions 1.5 to 3 log units greater than that of the epithelium as a whole, measurements of transepithelial resistance largely reflect the resistance of the paracellular space, particularly the tight junctions that regulate the paracellular flow of ions.[807] Because tight junctions differ in structure from different portions of the mucosa,[808] measurements of transepithelial resistance reflect the net resistance of the epithelium of variable permeability within a given tissue. For example, tight junctions in the intestinal glandular structures called crypts are leakier than those in the surface epithelium because of fewer and less organized tight junction strands.[806,809] Conversely, surface epithelium has a greater number of well-organized tight junction strands that result in epithelium with a relatively high resistance.[806] This correlates well with the absorptive function of epithelium located on the mucosal surface and the secretory function of crypt epithelium. The structure of tight junctions also varies with the segment of intestine. For example, tight junctions have more strands in the ileum than the jejunum, which is reflected by a higher transepithelial resistance in the ileum.[810] In addition, cells are more closely apposed at the level of the tight junction within the colon. This is in keeping with the largely absorptive role of the colon and is advantageous given the hostile microbial environment of the colon.

Gastric Mucosal Barrier Function

There are four regions of the stomach based on the type of mucosal lining (in an orad to aborad order): nonglandular stratified squamous epithelium, cardiac epithelium, proper gastric mucosa, and pyloric mucosa.[811] Stratified squamous epithelium has distinct differences in terms of barrier function compared with the remainder of the gastrointestinal tract. This epithelium has baseline transepithelial resistance measurements of approximately 2 to 3000 $\Omega \cdot cm^2$, which is an order of magnitude higher than the adjacent cardiac mucosa.[812,813] Thus the stratified squamous mucosa is exceptionally impermeable. This is the only mechanism this mucosa has to defend itself against injury. The stratified squamous epithelium consists of four layers: the outer *stratum corneum, stratum transitionale, stratum spinosum,* and the basal *stratum germinativum.* However, not all layers contribute equally to barrier function, which is largely composed of interepithelial tight junctions in the *stratum corneum* and mucosubstances secreted by the *stratum spinosum.*[812,814] The relative impermeability of stratified squamous mucosa can be demonstrated by the effects of HCl on this type of epithelium in vitro, which has very little effect until it reaches a pH of 2.5 or below.[813] Although the majority of the literature on equine ulceration pertains to the effects of HCl and inhibitors of HCl secretion,[815-818] other factors may be critical to the development of gastric ulcer disease.

The site of HCl secretion (proper gastric mucosa) is protected from so-called back diffusion of H^+ ions by a relatively high transepithelial electrical resistance (compared with cardiac mucosa), but there are also a number of other critical mechanisms to prevent acid injury. The gastric mucosa secretes both mucus and bicarbonate, which together form an HCO_3^- containing gel that titrates acid before it reaches the lumen.[819,820] The mucous layer is principally formed by glycoproteins (mucins) secreted by goblet cells but also includes other gastric secretions and sloughed epithelial cells. Mucins consist of core peptides with a series of densely packed *O*-linked polysaccharide side chains that, once secreted, become hydrated and form a viscoelastic gel. The mucous layer, however, does not form an absolute barrier to back diffusion of acid. For acid that does back diffuse into the gastric mucosa, epithelial Na^+/H^+ exchangers are capable of expelling H^+ once the cell reaches a critical pH.[820]

Recent studies have renewed interest in the protective mechanisms of mucus because of the discovery of a group of compounds secreted by goblet cells called the trefoil peptides. The name of these peptides is derived from a highly conserved cloverleaf structural motif, which confers substantial resistance to degradation by proteases including pepsin. There are three known members of this group, pS2, SP, and intestinal trefoil factor (ITF), the latter of which is solely secreted by

goblet cells in the small and large intestine. Both pS2 and SP are secreted by goblet cells within the stomach and are believed to intercalate with mucous glycoproteins, possibly contributing to the barrier properties of mucus.[821] These peptides also play a critical role in repair of injured mucosa.

An additional mucosal function that serves to reduce the level of injury is adaptive cytoprotection, in which application of topical irritants to gastric mucosa results in subsequent protection of mucosa in response to repeated exposure to damaging agents. For example, pretreatment with 10% ethanol protected against mucosal damage in response to subsequent application of absolute ethanol, and this effect was abolished by treatment with the COX inhibitor indomethacin.[822] The cytoprotective effects of prostaglandins have been demonstrated directly in studies in which preadministration of prostaglandins protected gastric mucosa from damage by agents such as concentrated hydrochloric acid and hypertonic saline.[823] Prostaglandins appear to be cytoprotective in the stomach at doses less than those used to inhibit gastric acid secretion, ruling out a simple antacid mechanism.[824] Although not fully characterized, cytoprotection has been attributed in part to prostaglandin-stimulated mucous production.[825] An associated beneficial effect of prostaglandins is the increased production of bicarbonate, which is trapped within mucus on the surface of the mucosa.[826,827] Interestingly, PGE_2 appears to lose its cytoprotective activity in the presence of the mucolytic agent *N*-acetylcysteine. Attention has also been directed at enhanced mucosal blood flow as a potential mechanism for prostaglandin-mediated cytoprotection—for example, pretreatment with PGI_2 protected against ethanol-induced mucosal damage as a result of increased mucosal blood flow.[828] In addition PGE_2, which is also cytoprotective despite the fact that it does not increase blood flow,[829] prevents vascular stasis associated with irritant-induced vascular damage by inhibiting neutrophil adherence to damaged endothelium.[830]

Sensory nerves distributed throughout gastrointestinal mucosa have also been implicated in cytoprotective mechanisms. As an example of their importance in mucosal cytoprotection, pretreatment of newborn rats with capsaicin (which dose dependently destroys sensory nerves) renders the mature rats more susceptible to gastric injury.[831] Alternatively, the use of a low dose of capsaicin, which stimulates rather than destroys sensory nerves, protects gastric mucosa against injurious agents.[832,833] Sensory nerves contain neuropeptides such as calcitonin-gene–related peptide (CGRP) and substance P, which may play a protective role via vascular mechanisms. For instance, CGRP stimulates increased gastric blood flow, which is theorized to reduce injury similarly to prostaglandins. Recent studies suggest that the roles of prostaglandins and CGRP in gastric cytoprotection are intimately intertwined. In particular, PGI_2 is believed to sensitize sensory nerves following treatment with a mild irritant, with resultant increases in CGRP release and mucosal flow. Similar studies have shown that antagonists of CGRP inhibit the cytoprotective action of PGE_2.[834] Another neural mediator, nitric oxide, has also been implicated in adaptive cytoprotection. Interestingly, nitric oxide has a number of actions that are similar to those of prostaglandins, including maintenance of mucosal blood flow.[835]

Intestinal Barrier Function

Regulation of barrier function in the intestine is not as well characterized as that of the stomach, although mechanisms of barrier function, including secretion of mucus and regulation of mucosal blood flow, are presumed to be similar. The proximal duodenum also has to protect itself from acid damage as it receives gastric contents, and this involves secretion of mucus and bicarbonate similarly to the stomach. One other mechanism that helps both the stomach and the intestine to maintain mucosal barrier function is the speed with which the mucosa repairs. For a defect to develop in the mucosal barrier, injurious factors have to outpace mucosal recovery. Such recovery initially involves epithelial migration across denuded regions of basement membrane (restitution).[821] This process is so rapid that epithelial defects may be resurfaced within minutes. For example, in bile salt–injured equine colon, denuded surface mucosa was completely covered by restituting epithelium within 180 minutes.[207] In the small intestine, intestinal villi greatly amplify the surface area of the mucosal luminal surface, which in turn takes far longer to resurface with restituting epithelium once it has become denuded.[836] Intestinal villi, however, are able to dramatically reduce the denuded surface area by contracting.[837]

MECHANISMS OF GASTRIC INJURY

Although the stratified squamous epithelium is relatively impermeable to HCl, there are a number of factors that can dramatically enhance the damaging effects of HCl in this epithelium. In particular, bile salts and SCFAs are capable of breaking down the squamous epithelial barrier at an acid pH, exposing deep layers to HCl, with subsequent development of ulceration.[813,838] Relatively high concentrations of SCFA normally exist within the equine stomach as a result of microbial fermentation.[812] These weak acids penetrate squamous mucosa and appear to damage Na^+ transport activity principally located in the stratum germinativum. Bile salts may also be present in the proximal stomach as a result of reflux from the duodenum. Although such reflux has a relatively high pH, it appears that bile salts adhere to stratified squamous epithelium, becoming lipid soluble and triggering damage once the pH falls below 4.[839] Diet and management (e.g., periods of fasting) also play crucial roles in the development of conditions conducive to gastric ulceration. Typically, there is a pH gradation in horses from proximal to distal compartments of the stomach, with the lowest pH values in the distal stomach.[840] During periods of fasting, this stratification is disrupted such that low pH values may be recorded in the proximal stomach.[841] Fasting conditions also increase the concentration of duodenal contents within the proximal stomach, particularly bile.[839]

Proper gastric mucosa is exposed to injurious agents, including pepsin, bile, and acid. The latter is constantly secreted by parietal cells in the horse as an adaptation to near-continuous intake of roughage,[811] but it is tightly regulated by enterochromaffin (ECL)-like cells within the proper gastric mucosa and G and D cells, which are present within the pyloric mucosa. Acid secretion is amplified by ECL-released histamine, which interacts with H_2 receptors on parietal cells, and G cells, which release the prosecretory hormone gastrin. A combination of histamine and gastrin can have a synergistic effect on parietal cell gastric secretion, because these mediators have distinct receptors and second messengers. On the other hand, D cells are sensitive to an acidic environment and release somatostatin, which inhibits acid secretion.[842] Nonetheless, gastric mucosa may be exposed to acid for prolonged periods of time, particularly in horses that are extensively meal

fed and do not have the benefit of roughage, which tends to buffer stomach contents.[839,842]

Aside from peptic ulceration, induced by combinations of acid and pepsin, research in the human field has revealed the tremendous importance of *Helicobacter pylori* in inducing ulceration. Infection with this organism has the effect of raising gastric pH because of disruption of gastric glands but also induces an inflammatory reaction that causes damage.[843] However, there is very little evidence that this organism is involved in gastric ulcers in horses. In the absence of a known role for infectious agents in gastric ulceration in animals, ulceration likely develops from injurious factors similar to those found in the proximal stomach, including gastric acid and bile. Some factors that are important to the induction of squamous epithelial ulceration may not be important in the development of proper gastric mucosal ulceration. For example, feed deprivation and intensive training reproducibly induce squamous epithelial ulceration in horses but have little effect on proper gastric mucosa in horses.[844] Gastric acid likely plays a key role, whereas other factors such as NSAIDs serve to reduce gastric defense mechanisms. In particular, inhibition of prostaglandin production would reduce mucous and bicarbonate secretion while reducing gastric mucosal blood flow.[845] Some of the NSAIDs also have a topical irritant effect, although this appears to be of minor significance, because the route of administration (oral or parenteral) seems to have little influence on the development of ulceration.[846]

The source of prostaglandins responsible for gastric protection was originally assumed to be COX-1, because this COX isoform is constitutively expressed in gastric mucosa, whereas COX-2 is not expressed in the stomach unless it is induced by inflammatory mediators. However, mice in which the COX-1 gene has been knocked out fail to develop spontaneous gastric lesions,[847] possibly because of compensatory increases in prostaglandin production by COX-2.[848] This concept agrees with recent data indicating that inhibition of both COX isoforms is required to induce gastric ulceration.[849] From a clinical perspective, these data indicate that drugs selective for either COX-1 or COX-2 may be less ulcerogenic in the horse because they allow the uninhibited COX isoforms to continue to produce protective prostanoids. Because COX-2 elaborates prostaglandins induced by inflammatory stimuli, preferential or selective inhibitors of COX-2 may be particularly useful because of their ability to serve as antiinflammatory agents that are less ulcerogenic.[392]

INTESTINAL ISCHEMIA/ REPERFUSION INJURY

The most notable cause of intestinal mucosal injury in horses, particularly those suffering from colic, is ischemia. Initially, it seems intuitive that by reducing gastrointestinal blood supply, the mucosa becomes injured. The anatomy of the gastrointestinal tract, and the differing structure of the intestinal mucosa at various anatomic locations, has a significant influence on the extent of mucosal injury. Ischemic injury may be induced by several different mechanisms, including occlusion of arterial supply by a thrombus, strangulation of intestinal vasculature, and generalized reduction in blood flow associated with various shock states. A number of seemingly distinct mechanisms of intestinal injury, such as intestinal distention, also trigger mucosal injury via an ischemic mechanism. Reperfusion injury may also influence the extent of mucosal injury following an ischemic episode and has been proposed as a potential site of therapeutic intervention.[850,851] It is critical that the mechanisms of ischemia/reperfusion injury be understood to develop an understanding of the severity of various clinical conditions, and begin to formulate a therapeutic approach to diseases characterized by this devastating form of injury.

Regulation of Intestinal Blood Flow

The intestinal circulation is capable of closely regulating blood flow during periods of low systemic perfusion pressure.[852,853] In particular, local regulation of resistance vessels within the microvasculature is particularly prominent; metabolic end products of ATP result in continued dilatation of resistance vessels despite reductions in systemic arterial pressure. This results in continued perfusion of gastrointestinal tissues during the early stages of shock, while other organs such as skeletal muscle undergo massive shunting of blood as a result of marked increases in the resistance of resistance vessels. The reasons for these differences in regulation are not entirely clear but may relate to the relatively high level of energy required to fuel the intestinal mucosa and the serious systemic effects of breaches in the mucosal barrier. When blood flow falls below a critical level, regulatory systems are no longer effective and oxygen uptake by the gastrointestinal tissue decreases, culminating in tissue damage.[852]

The villous tip is the most susceptible region affected by hypoxia in the equine small intestine, largely because of the countercurrent exchange mechanism of blood flow in the small intestinal villus.[852] This countercurrent exchange mechanism is attributable to the vascular architecture, which consists of a central arteriole that courses up the core villus, arborizes at the tip, and is drained by venules coursing down the periphery of the villus.[854] As oxygenated blood flows into the central arteriole, oxygen tends to diffuse across to the adjacent venules, which are flowing in the opposite direction. This series of events takes place along the length of the villus, resulting in a villous tip that is relatively hypoxic even under normal conditions. Furthermore, when blood flow is reduced, as occurs in hypovolemic or septic shock, the countercurrent exchange of oxygen is enhanced, and the tip becomes absolutely hypoxic.[852] This mechanism might explain why the small intestinal mucosa is more susceptible to ischemic injury, compared with the colon, which has no villi. The duration of ischemia required to produce severe morphologic damage to the equine colon is approximately 25% longer than the small intestine.[855]

Ischemic Epithelial Injury

Intestinal mucosal epithelium is very susceptible to hypoxia because of the relatively high level of energy required to fuel the Na^+/K^+-ATPase that directly or indirectly regulates ion and nutrient flux. The first biochemical event to occur during hypoxia is a loss of oxidative phosphorylation. The resulting diminished ATP concentration causes failure of the energy-dependent Na^+/K^+-ATPase and the accumulation of sodium and subsequently intracellular water. The pH of the cytosol drops as lactic acid and inorganic phosphates accumulate from anaerobic glycolysis. The falling pH damages cell membranes, including lysosomal membranes, resulting in the release and activation of lysosomal enzymes into the cytosol, further damaging cellular membranes. Damage to the cell membrane allows the accumulation of high concentrations of calcium in

TABLE **12.6 Grading System for Ischemia/Reperfusion Injury in Small Intestinal Mucosa**

Grade	Description
1	Separation of epithelium at the tip of the villus, creating a small space between the epithelium and basement membrane called Grüenhagen's space
2	Loss of epithelium from the tip of the villus
3	Loss of epithelium from the upper third of the villus
4	Complete loss of villous epithelium
5	Injury or loss of epithelium within the crypt in addition to complete loss of villous epithelium

the cytosol, which activates calcium-dependent degradative enzymes.[856] These events result in cytoplasmic blebbing of the basal membrane, with subsequent detachment of cells from the underlying basement membrane.

Recent studies on epithelial injury during ischemia suggest that the majority of epithelial cells undergo programmed cell death (apoptosis) during ischemia and reperfusion rather than necrosis, allowing retention of reusable components of irreversibly injured cells.[857] In one study, 80% of detached epithelium during small intestinal ischemia/reperfusion underwent apoptosis.[858] Although the most obvious result of apoptosis is loss of surface epithelium, a number of cells on the lower portion of the villus (in the small intestine) and cells within the crypts may also undergo apoptosis that only becomes evident up to 24 hours following reperfusion of ischemic tissue.[859]

Morphologic changes observed in ischemic-injured small intestinal mucosa follow a similar sequence regardless of whether injury is induced by ischemia alone or ischemia/reperfusion (Table 12.6).[860] Initially, epithelium separates from the underlying basement membrane, forming a fluid-filled space termed *Grüenhagen's space* (Fig. 12.7). The mechanism of fluid accumulation in this space is not entirely understood but may result from continued epithelial absorption of NaCl and water before it has fully detached from neighboring epithelial cells. This fluid accumulation likely exacerbates epithelial separation from the basement membrane. Subsequently, epithelium progressively sloughs from the tip of the villus toward the crypts, which are the last components of the intestinal mucosa to become injured.[163,406,861] This likely relates to the vascular architecture, because crypts receive a blood supply that is separate from the vasculature involved in the villous countercurrent exchange mechanism. The early morphologic changes observed in the equine large colon during ischemia are somewhat different from those described in the equine small intestine because of the lack of intestinal villi. As might be expected, the more superficially located surface cells are sloughed before those in crypts.[855,862] The orderly progression of tissue injury has been used by one group of investigators to accurately predict survival in horses with large colon volvulus. Biopsies were taken from the pelvic flexure, which has been previously shown to accurately reflect mucosal changes along the length of the colon,[863] and histologically examined for the width of the crypts and intercrypt interstitial space. The latter measurements were expressed as an interstitium: crypt width (I:C) ratio. Nonviable colon was defined as that which had

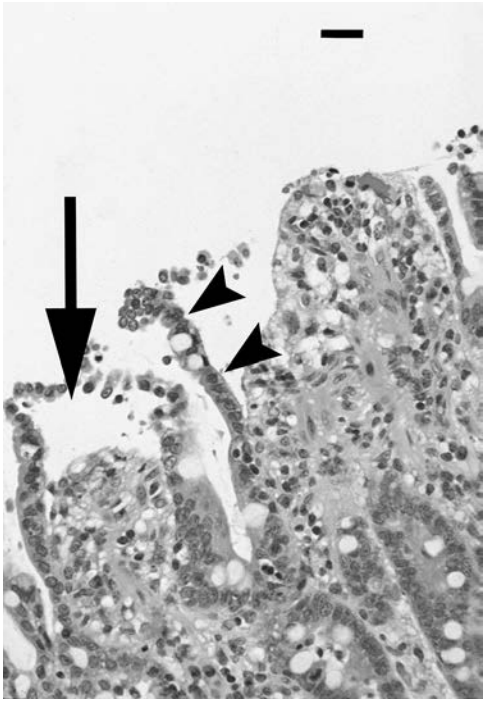

FIG. **12.7** Histologic appearance of Grüenhagen's space in ischemic injured ileal mucosa. Note separation of epithelium at the tip of the villus from its basement membrane, creating a space *(arrows)*. Epithelium subsequently sloughs into the lumen *(arrowheads)*. 1-cm bar = 100 μm.

>60% loss of crypt and an I:C ratio >3. Using this methodology, survival was correctly predicted in 94% of horses.[864]

Strangulating Obstruction

Since the dramatic decline in *S. vulgaris*–induced colic, which was frequently associated with infarction of intestinal arterial blood supply,[865] the vast majority of ischemic lesions are associated with strangulating obstruction. Therefore it is important to consider mechanisms of ischemic injury in horses with naturally occurring strangulating lesions. The majority of experimental work has either assessed complete ischemia (complete occlusion of the arterial blood supply)[855] or low-flow ischemia (reduction of arterial blood flow).[866,867] During intestinal strangulation, however, a disparity between the degree of occlusion of the veins and arteries occurs in which veins are occluded before arteries because of differences in the compliance of vascular walls. Strangulating lesions are typically hemorrhagic (hemorrhagic strangulating obstruction), because the arteries continue to supply blood to tissues that have little or no venous drainage. This results in ischemic injury, as previously outlined, but also in tremendous congestion of the tissues. Such hemorrhagic congestion has two opposing effects: it disrupts tissue architecture, including the mucosa and its epithelium, but it continues to provide oxygenated blood to the tissues during much of the ischemic episode. In contrast, when strangulation results in sudden cessation of arterial blood flow (ischemic strangulating obstruction), tissues appear pale, and the mucosa rapidly degenerates because of a complete lack of oxygenated blood.[163] From a clinical standpoint, this makes it difficult to assess the degree of mucosal injury in horses with strangulating injuries, because intestine that may look nonviable (dark red) may in fact have less mucosal injury than that of ischemic strangulated intestine.[868]

An additional consideration in clinical strangulating obstruction is the degree of ischemia that may be induced by intestinal distention. For example, experimental distention (18 cm of H_2O for 2 hours) and decompression (2 hours) of the jejunum resulted in a significant increase in microvascular permeability and a significant decrease in tissue oxygenation similar to what would be expected with low-flow ischemia.[869,870] In particular, microscopic evaluation of vasculature revealed capillary endothelial cell damage and local edema formation.[871] These data suggest that distended intestine proximal to an obstruction may undergo mucosal injury despite its relatively normal appearance. Indeed, in one study, intraluminal pressures greater than 15 cm H_2O in naturally occurring cases of colic correlated with a poor prognosis for survival.[872]

Reperfusion Injury

Although it has recently been taken for granted that reperfusion of ischemic tissues results in exacerbation of mucosal injury, it should be remembered that mechanisms underlying intestinal reperfusion injury have been largely defined in laboratory animals under specific conditions.[104,410,873-875] On the other hand, studies on reperfusion injury in horses have had some conflicting results.[861,867,876] This may be attributed to the way in which the studies have been performed. In particular, the type of ischemia used in most laboratory animal studies has been "low-flow ischemia" (in which the blood flow is typically reduced to 20% of baseline flow), whereas studies in horses have used a number of different ischemic models, including various types of strangulating obstruction. Although strangulating obstruction is of great clinical relevance, this type of ischemic insult is less likely to develop reperfusion injury.[861,877,878] Conversely, low-flow ischemia appears to prime tissues for subsequent injury once the tissue is reperfused, and there is considerable evidence to support the presence of reperfusion injury in horses following low-flow ischemia.[866,867,871,879] Nonetheless, low-flow ischemia may not be a common clinical entity.

In addition to the type of ischemia, there are other factors involved in priming tissues for reperfusion injury, including species and anatomic-specific variation in oxidant enzyme and neutrophil levels. For example, the foal appears to have very low levels of small intestinal xanthine oxidase, an enzyme that plays a critical role in triggering reperfusion injury in laboratory animals,[410,875,880] whereas adult levels are much greater, particularly in the proximal small intestine.[881] In addition, horses appear to have low numbers of resident neutrophils in the intestinal mucosa,[882] and it is this population of neutrophils (rather than those recruited from the circulation) that appear to be most critical for induction of reperfusion injury.[104] Studies demonstrating reperfusion injury in the equine colon following low-flow ischemia have shown significant accumulation of neutrophils within the mucosa.[866] A complete understanding of the mechanisms of neutrophilic infiltration and the mechanisms by which they damage tissue will require further study.

Reperfusion injury is initiated during ischemia when the enzyme xanthine dehydrogenase is converted to xanthine oxidase, and its substrate, hypoxanthine, accumulates simultaneously because of ATP utilization (Fig. 12.8).[850,883] There is little xanthine oxidase activity during ischemia, because oxygen is required as an electron acceptor. During reperfusion, xanthine oxidase rapidly degrades hypoxanthine in the presence of oxygen, producing the superoxide radical as a byproduct.[850] The superoxide radical contributes to oxidative tissue damage and, most importantly, activates neutrophil chemoattractants.[410,875] Inhibition of xanthine oxidase in feline studies of intestinal ischemia/reperfusion injury prevents infiltration of neutrophils and subsequent mucosal injury.[410,874] Inhibition of xanthine oxidase has had no effect on ischemia/reperfusion injury in equine small intestine[876] and colon,[407] suggesting that either reperfusion injury is simply a continuation of injury initiated during ischemia, as suggested in some equine studies,[856] or that the classic reperfusion injury pathway is activated by alternate sources of ROMs. The latter has been suggested by studies in feline models of ischemia/reperfusion injury, in which the source of a significant proportion of ROMs is unknown, and independent of xanthine oxidase and neutrophils.[874]

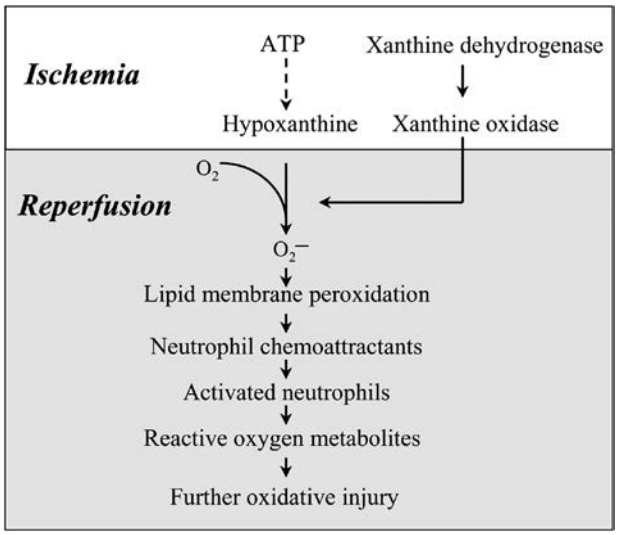

FIG. **12.8** Intestinal reperfusion injury cascade. Reperfusion injury is initiated by elaboration of superoxide by metabolism of hypoxanthine by xanthine oxidase and subsequent infiltration of neutrophils.

In a veterinary review of the pathogenesis of intestinal reperfusion injury in the horse, the concept of a therapeutic window in which treatment of reperfusion injury would be beneficial was suggested.[850] The basis of this concept is that there are certain conditions under which ischemic injury is minimal and that tissues are severely damaged during reperfusion.[877] Thus under conditions of low-flow ischemia, very little injury is demonstrated during 3 hours of ischemia, but remarkable injury occurs during 1 hour of reperfusion.[410,874,875] A therapeutic window may not exist under conditions of strangulating obstruction in which severe injury occurs during ischemia and minimal injury occurs during reperfusion.[884] This in turn greatly reduces clinicians' abilities to ameliorate ischemia/reperfusion injury with treatments such as antioxidants at the time of reperfusion.

MECHANISMS OF GASTROINTESTINAL MUCOSAL REPAIR

Gastric Reparative Mechanisms

Mechanisms of gastric repair are highly dependent on the extent of injury. For instance, superficial erosions can be rapidly covered by migration of epithelium adjacent to the wound, a process termed *epithelial restitution*. Ulceration

(full-thickness disruption of mucosa and penetration of the muscularis mucosa), however, requires repair of submucosal vasculature and ECM. This is initiated by the formation of granulation tissue, which supplies connective tissue elements and microvasculature necessary for mucosal reconstruction. Connective tissue elements include proliferating fibroblasts that accompany newly produced capillaries that form from proliferating endothelium. Recent studies indicate that nitric oxide is critical to both of these processes,[835,885] which likely explains the reparative properties of it in the stomach.[886]

Once an adequate granulation bed has been formed, newly proliferated epithelium at the edge of the wound begins to migrate across the wound. Gastric glands at the base of the ulcer begin to bud and migrate across the granulation bed in a tubular fashion.[887] Epidermal growth factor (EGF) is expressed by repairing epithelium and appears to facilitate these processes.[888] These events are facilitated by a mucoid cap, which retains reparative factors and serum adjacent to the wound bed.[845] Once the ulcer crater has been filled with granulation tissue, and the wound has been reepithelialized, the subepithelial tissue remodels by altering the type and amount of collagen. Despite the remodeling process, ulcers tend to recur at sites of previous ulceration, and there is concern that this remodeling can result in excessive deposition of collagen and fibrosis.[821]

Intestinal Reparative Mechanisms

Reparative mechanisms are similar in the intestine, except that in the small intestine, mucosal villi contribute to mucosal repair. Once intestinal epithelium is disrupted, there are two events that occur almost immediately to reduce the size of the denuded portion of the villus: contraction of the villus and epithelial restitution (Fig. 12.9). For example, in porcine ileum subjected to 2 hours of ischemia, villi were 60% of their former height, and 50% of the denuded villous surface area was covered in flattened epithelium within 6 hours.[836] Villous contraction appears to be regulated by enteric nerves, because inhibition of enteric nerve conduction prevents villous shortening following injury. The contractile component of the villus is a network of myofibroblasts distributed throughout the lamina propria of the villus and along the central lacteal. Inhibition of villous contraction results in retarded epithelial repair because of the larger denuded surface that remains to be covered by migrating epithelium compared with similarly injured villi that have contracted.[837] PGE_2 has also been implicated in regulating villous contraction, because application of PGE_2 resulted in villous contraction when perfused through normal rat ileum.[889] As villi contract, assuming there is an intact basement membrane, epithelium from the margins of the wound migrates in a centripetal direction to resurface toward the tip of the villus.[837] The process of restitution is similar in denuded colonic mucosa, except that it may proceed more rapidly because of the lack of villi.[207] Epithelial restitution is solely a migratory event that does not depend on provision of new enterocytes by proliferation. Cellular migration is initiated by extension of cellular lamellipodia that receive signals from the basement membrane via integrins. Intracellular signaling converges on the actin cytoskeleton, which is responsible for movement of lamellipodia. Specific components of the basement membrane appear to be critical to the migratory process. For example, application of antibodies to collagen types III and IV, which are important components of intestinal mucosal basement membrane, impeded epithelial restitution.[890,891] Other elements of the basement membrane, including proteoglycans, hyaluronic acid, and noncollagenous proteins, such as fibronectin and laminin, may also provide important signals.[892] The subepithelial matrix components that facilitate restitution may form the basis for clinical treatments designed to speed up the repair process, analogous to the administration of matrix components to horses with articular cartilage damage.

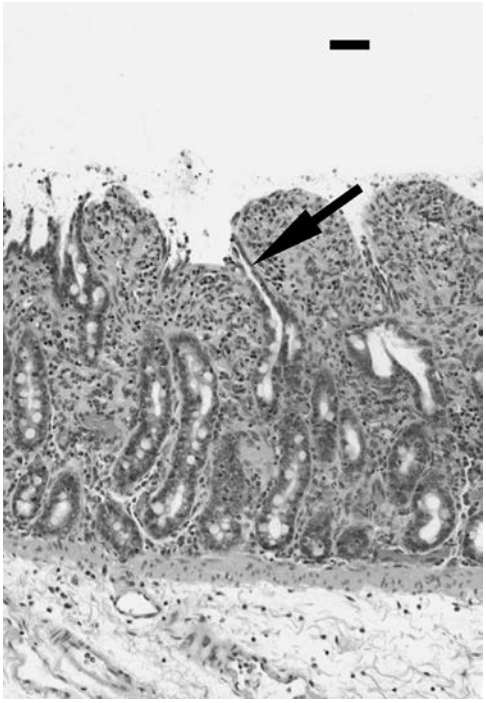

FIG. **12.9** Histologic appearance of repairing intestinal mucosa 6 hours after a 2-hour ischemic episode. Note blunting of the villus, attributable to villous contraction, and evidence of epithelial restitution *(arrows)*. 1-cm bar = 100 μm.

Although epithelial restitution results in gross closure of previously denuded regions of gastrointestinal mucosa, the closure of interepithelial spaces is ultimately required to restore normal epithelial barrier resistance.[893] Because the tight junction is principally responsible for regulating the permeability of the interepithelial space, it is likely that repair and closure of this structure is critical to restore intestinal barrier function. Recent research indicates that prostaglandins play a vital role in the recovery of tight junction resistance,[893] indicating that the administration of nonselective COX inhibitors to horses with colic, particularly those recovering from strangulating obstruction, may be deleterious. Judicious use of NSAIDs is appropriate until more selective drugs that allow continued production of reparative prostaglandins are available for use in horses. Recent studies have shown that NSAIDs preferential for COX-2 allow for optimal repair of injured intestine compared with traditional nonselective NSAIDs.[392]

Once the epithelial barrier has been restored, normal mucosal architecture must be reestablished to allow normal gut absorptive and digestive function. In porcine ileum subjected to 2 hours of ischemia, the epithelial barrier was restored within 18 hours, but villi were contracted and covered in epithelium with a squamous appearance. Restoration of normal villous architecture required a further 4 days.[836] The flattened villous epithelium that characterizes restitution

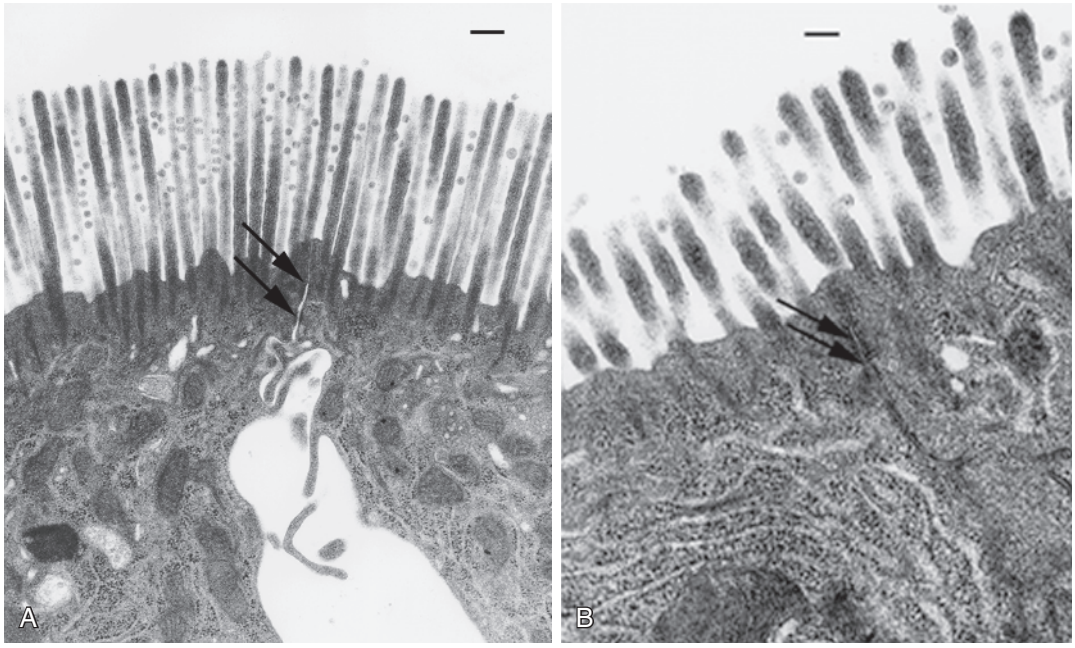

FIG. **12.10** Ultrastructural appearance of repairing ischemic-injured mucosa. (A) Restituting epithelium 2 hours after a 1-hour ischemic episode in the presence of the nonselective cyclooxygenase inhibitor indomethacin. Note dilation of the interepithelial space and the apical tight junction *(arrows),* which correlates with a "leaky" intestinal barrier. Note the close apposition of the tight junction *(arrows)* and the interepithelial space correlated with normalization of intestinal barrier function. 1-cm bar = 6 μm.

is replaced by newly proliferated crypt epithelium. Under normal circumstances, new enterocytes are formed by the division of stem cells, of which there are approximately four at the base of each mucosal crypt. Newly divided enterocytes migrate from the crypt onto the villus.[894] During migration, enterocytes differentiate and acquire specific absorptive and digestive functions. Fully differentiated enterocytes reside on the upper third of the villus for 2 to 3 days and are then sloughed into the intestinal lumen.[895] This process is accelerated during mucosal repair, which requires increased proliferative rates. Increased proliferation may be stimulated within 12 to 18 hours by a variety of locally available gut-derived factors, including luminal nutrients, polyamines, and growth factors.[836] The return of the normal leaf-like shape of the villus occurs subsequent to the appearance of normal columnar epithelium.

MEDIATORS OF REPAIR

Prostaglandins

Although prostaglandins have been strongly implicated in mucosal cytoprotective function, relatively few studies have assessed their importance in mucosal repair. One study implicated prostaglandins in growth factor–stimulated restitution,[896] but a more prominent role of prostaglandins in mucosal repair is their ability to close interepithelial tight junctions.[893,897,898] For instance, ischemic-injured small intestine rapidly recovered barrier function (as measured in vitro as transepithelial resistance) in the presence of prostaglandins I_2 and E_2, despite the fact that these prostanoids had relatively little effect on villous contraction and epithelial restitution. However, electron microscopic examination of tissues reveals dilation of tight junctions in tissues treated with NSAIDs,[898] whereas those additionally treated with prostaglandins have closely apposed tight junctions (Fig. 12.10). Prostaglandins stimulate closure of tight junctions via the second messengers cAMP and Ca^{2+},[893] which interestingly were among the first mediators found to modulate tight junction permeability.[899,900] Such tight junction closure is of considerable importance to patients with intestinal injury that are treated with nonsteroidal antiinflammatory agents, because reduced prostaglandin levels may result in increased intestinal permeability. For example, in a study on ischemic-injured porcine ileum, treatment with the NSAID indomethacin resulted in a significant increase in intestinal permeability to inulin and lipopolysaccharide compared with tissues that were additionally treated with PGI_2 and PGE_2.[893]

Polyamines

The process of restitution is absolutely dependent on a group of compounds called polyamines.[901,902] The rate-limiting enzyme in the formation of the polyamines spermine, spermidine, and putrescine is ornithine decarboxylase (ODC). In rats with stress-induced duodenal ulcers, systemic administration of the ODC inhibitor DL-alpha-difluoromethyl ornithine significantly reduced polyamine levels and markedly reduced epithelial restitution. Intragastric treatment of these same rats with putrescine, spermidine, and spermine prevented the delayed mucosal repair induced by DL-alpha-difluoromethylornithine.[901] Interestingly, gastric tissue levels of ODC were increased in rats with stress-induced gastric ulcers, suggesting that polyamine production is enhanced during tissue injury and may contribute to the normal rapid rate of epithelial restitution.[903]

The mechanisms by which polyamines stimulate epithelial restitution are not clear. McCormack et al. hypothesized that polyamines increased transglutaminase activity, an enzyme that catalyzes the cross-linking of cytoskeletal and basement membrane proteins.[904] Further investigation of the role of polyamines in IEC-6 cell migration showed that depletion of polyamines resulted in disruption of the cytoskeleton and reduced the physical extension of lamellipodia.[905] More recent studies have clarified this pathway. Polyamines regulate cytoskeletal cellular migration via activation of the small GTPase Rho-A by elevating intracellular Ca^{2+} levels. These elevations in Ca^{2+} result from polyamine regulation of expression of voltage-gated K^+ channels and altered membrane electrical potential.[906]

Polyamines also play a role in the normal physiologic regulation of crypt cell proliferation and differentiation.[907,908] They are produced by fully differentiated enterocytes at the villous tip and may reach the crypt either within sloughed luminal epithelium or via local villous circulation.[909] Following intestinal injury, polyamines appear to stimulate enhanced proliferation by increasing the expression of protooncogenes, which control the cell cycle.[910] The mechanism by which polyamines influence gene expression likely relates to the cationic nature of these compounds, which may influence the tertiary structure of negatively charged DNA and RNA.[901]

Growth Factors

Locally produced growth factors, including EGF, TGF-α, TGF-β, and hepatocyte growth factor, have the ability to modulate mucosal recovery. The most important of these growth factors in early mucosal repair events is TGF-β, which is a potent stimulus of epithelial restitution and modulator of the ECM.[821] Neutralization of TGF-β retards epithelial migration in vitro, and it appears that TGF-β may serve as a point of convergence for mediators of restitution, because neutralizing TGF-β also inhibits the effects of other peptides. However, TGF-β paradoxically inhibits epithelial proliferation, reducing the supply of new enterocytes for mucosal repair. Conversely, EGF, produced by the salivary glands and duodenal Brunner's glands, and the related TGF-α, produced by small intestinal enterocytes, are potent stimulants of enterocyte proliferation. These growth factors share approximately 30% of their amino acid structure, bind to the same receptor on the basolateral surface of enterocytes, and are not related to TGF-β.[911] The physiologic role of EGF is somewhat difficult to discern because it is present in the intestinal lumen, with no apparent access to its basally located receptor.[912] It has been proposed that EGF acts as a "surveillance agent" that gains access to its receptor during epithelial injury (when the EGF receptor would likely be exposed) to stimulate proliferation.[912] TGF-α presumably has a similar role, but it is present in greater concentrations in the small intestine because it is produced by differentiated villous enterocytes. The mature peptide is cleaved from the extracellular component of the transmembrane TGF-α precursor and released into the lumen.[911]

Trefoil Peptides

Another group of proreparative peptides that are locally produced within the gastrointestinal tract are the trefoil peptides. Under physiologic conditions, trefoil peptides are secreted by mucus-producing cells at distinct anatomic sites. For example, the trefoil peptide pS2 is produced by gastric epithelium, whereas ITF is produced by small and large intestinal mucosa.[701] However, any of the trefoil peptides may be upregulated within repairing epithelium regardless of the anatomic site.[821,913] In addition, trefoil peptides have the ability to induce their own expression, amplifying the level of these reparative factors at sites of mucosal repair.[914] Trefoil peptides are the most potent stimulants of epithelial migration in vitro, and their effects are independent of growth factors, including TGF-β.[915] Recent evidence suggests that EGF receptor activation is required for the induction of pS2 and another of the trefoil peptides called spasmolytic peptide in gastric epithelium in vitro. The importance of trefoil peptides to the mucosal repair response in vivo is illustrated by gene knockout studies, in which mice deficient in ITF have a dramatically reduced ability to repair intestinal injury.[916] Detergent-induced mucosal injury was lethal because of a lack of restitution compared with wild-type mice that fully recovered from similar mucosal injury. The fact that restitution was restored by administration of ITF has important therapeutic implications. The mechanism by which trefoil peptides stimulate epithelial migration has yet to be fully characterized, but it appears to involve translocation of the adherens junction protein E-cadherin, allowing cells to become untethered from neighboring cells.[821]

Intestinal Nutrients

The principal metabolic fuel of enterocytes is glutamine, and for colonocytes it is butyrate. However, recent studies suggest that glutamine and butyrate have more specific proliferative actions aside from their role as nutrients. For example, in the piglet IPEC-J2 enterocyte cell line, glutamine enhanced gene transcription by increasing MAPK activity.[917,918] Similarly, butyrate stimulated mucosal growth following colonic infusion in the rat.[919] Because of such growth-promoting actions, glutamine was shown to prevent the intestinal mucosal atrophy and dysfunction that accompany starvation[920,921] and long-term total parenteral nutrition.[922,923] Glutamine improves the function of transplanted small intestine[924,925] and protects intestinal mucosa from injury if administered before chemotherapy[926] and radiation.[927,928] Intestinal nutrients may also synergize with other proliferative agents. For example, administration of glutamine and TGF-α to porcine ileum that had been subjected to 2 hours of ischemia resulted in a synergistic increase in MAPK activity, enterocyte proliferation, and villous surface area.[836] Although there has been a concern that such early return to normal surface area may result in dysfunctional mucosal digestive and absorptive function because of resurfacing denuded mucosa with immature epithelium, nutrients and growth factors also appear to promote early differentiation. In the case of glutamine and TGF-α restoration of postischemic small intestine, rapid recovery of digestive enzymes was also documented.[929]

Gastrointestinal Ileus

Effective gastrointestinal motility involves a complex interaction between the ENS, muscular wall, and luminal contents. Additional factors that influence the net transit of digesta include gravity, the volume and viscosity of the contents, and pressure gradients created by simultaneous contraction and relaxation of adjacent segments of bowel. Casual use of the term *intestinal motility* in veterinary medicine often underestimates the complexity of the processes involved in the transit of intestinal contents. This is particularly true when the term is used to describe the frequency and or intensity of intestinal sounds, or borborygmi. The existence of borborygmi does not always equate with progressive movement of intestinal contents.

Disruption to normal motility occurs commonly in horses for a variety of reasons. Examples of diseases in which altered motility may be present include grass sickness, gastroduodenal ulceration, intraluminal obstruction or impaction, excessive wall distention, strangulating obstruction, peritonitis, and inflammatory disorders such as duodenitis proximal jejunitis or colitis. Ineffective intestinal motility is also a feature of several neonatal diseases, including prematurity, systemic sepsis, and perinatal asphyxia. Certain parasitic infections, electrolyte derangements, and endotoxemia can modify digesta transit in horses of all ages. General anesthesia and specific sedatives, such as xylazine, romifidine, or detomidine, also disturb motility.

MANIFESTATIONS OF ILEUS

The inhibition of propulsive bowel activity usually is referred to as ileus. Ileus is ascribed most frequently to the condition that occurs after laparotomy and is termed *simple* or *uncomplicated POI*. The term *complicated* or *paralytic ileus* describes intestinal motility disturbed for longer periods after surgery. POI in horses is associated most commonly with surgery of the small intestine, particularly after resection and anastomosis,[930,931] and can have a negative effect on short-term postoperative survival.[932-935] Motility dysfunction likely is present in all horses after laparotomy, but many are affected subclinically and require minimal or no specific intervention. In symptomatic animals, clinical signs are apparent shortly after recovery and include colic, tachycardia, dehydration, decreased borborygmi and fecal output, and sequestration of fluid within the stomach. Rectal examination and ultrasound reveal small intestinal distention with rare or absent wall movement. The severity and duration of intestinal stasis varies, lasting from minutes to days.

A specific motility disorder involving the cecum or ileocecocolic region occurs sporadically in horses.[936-938] The condition most commonly occurs after general anesthesia and extraabdominal surgery, particularly orthopedic and upper airway procedures, and often is categorized as a form of POI. Other cases occur spontaneously, often in animals with painful primary conditions such as uveitis or septic tenosynovitis. In a study of 114 horses diagnosed with cecal impaction, 12 were hospitalized for a condition other than colic at the time of diagnosis, and 9 others were being treated with phenylbutazone, most for a musculoskeletal injury.[939] Eight of the 114 horses had undergone general anesthesia in the 8 days preceding diagnosis. The syndrome is frustrating in that clinical signs are often subtle unless cecal perforation has occurred. In horses with a cecal emptying defect after anesthesia, overt signs are usually apparent 3 to 5 days after the procedure. The earliest detectable signs include depression and a reduction in feed intake and fecal output. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifested by signs of mild to moderate colic. If the condition is recognized late or untreated, the cecum may rupture and result in fatal peritonitis.

PHYSIOLOGY

Current understanding of motility throughout the equine gastrointestinal tract is remarkably limited, and much of our presumptive knowledge comes from work in other species. The ENS is involved in all aspects of motility, either directly via neurotransmitters or indirectly via interstitial cells of Cajal (ICC) or immune or endocrine regulation. The inherent rhythmicity of electric activity in the intestine is controlled by the ICC, which is specialized cells that are electrically coupled to myocytes via gap junctions.[940] These cells are responsible for generating and propagating slow-wave activity; hence, they are deemed the pacemaker cells of the intestine. A decrease in ICC density has been observed in horses with obstructive disorders of the large intestine[941] and in the ileum and pelvic flexure of horses diagnosed with equine grass sickness (dysautonomia),[942] although such a decrease was not evident in a horse with dysautonomia that recovered.[943] This alteration in ICC infrastructure appears to result in reduced slow-wave activity in vitro.[944]

The ENS primarily controls and coordinates intestinal contraction. A combination of central and autonomic innervation influences events, but contraction does not require external neural input. The parasympathetic supply to the gastrointestinal tract is via the vagus and pelvic nerves, and the sympathetic supply is through postganglionic fibers of the cranial and caudal mesenteric plexuses. A complex network of interneurons within each plexus integrates and amplifies neural input; the intensity and frequency of resultant smooth muscle contractions are proportional to the amount of sympathetic and parasympathetic input. Additional binding sites for a number of other endogenous chemicals, including dopamine, motilin, and serotonin, exist within the ENS and on smooth muscle cells.[945] Acetylcholine is the dominant excitatory neurotransmitter in the gastrointestinal tract and exerts its action through muscarinic type 2 receptors on smooth muscle cells. Sympathetic fibers innervating the gastrointestinal tract are adrenergic, postganglionic fibers with cell bodies located in the prevertebral ganglia. Activation of α_2-adrenergic receptors on cholinergic neurons within enteric ganglia inhibits the release of acetylcholine, reducing intestinal contraction. β_1-, β_2-, and β-atypical receptors are directly inhibitory to the intestinal smooth muscle.[946] Inhibitory nonadrenergic, noncholinergic neurotransmitters include adenosine triphosphate, vasoactive intestinal peptide, and nitric oxide.[947,948] These neurotransmitters are critical for mediating descending inhibition during peristalsis and receptive relaxation. Substance P is a nonadrenergic, noncholinergic neurotransmitter that may be involved in contraction of the large colon.[949,950]

The rate and force of intestinal contractions along the small intestine and large colon of the horse are important determinants of intestinal motility; of even greater importance to the net propulsion of digesta are the cyclical patterns of contractile activity. These patterns are known as the small intestinal and colonic migrating motility (or myoelectric) complexes (MMCs).[951,952] The colonic complex usually originates in the right ventral colon and variably traverses the ascending and descending colons. Many of these complexes are related temporally to a specialized motility event of the ileum, the migrating action potential complex.[953]

PATHOPHYSIOLOGY

Inflammation

Local inflammation within the intestinal muscularis and inhibitory neural events are important initiators of intestinal ileus.[954,955] Intestinal inflammation not only is important in primary intestinal diseases in horses, such as DPJ and colitis, but also is induced after simple intestinal handling during laparotomy. In rodents, simple intestinal manipulation causes

a cascade of inflammation within the muscularis, resulting in leukocyte infiltration and subsequent suppression of muscle contractility. Similar inflammatory effects were evident with mechanical manipulation of the equine jejunum.[956] The inflammatory response to bowel manipulation is not limited to the affected tissue, but it can also result in global inflammation and ileus throughout the gastrointestinal tract.[957]

The associated inflammatory events are extremely complex, involving a milieu of proinflammatory cytokines, prostaglandins, and leukocytes. Depletion or inactivation of muscularis macrophage function can prevent inflammation associated with intestinal manipulation and associated decreased contractility.[958] Mast cell activation is involved in intestinal manipulation-associated POI in humans.[959] Inflammation associated with colonic manipulation may involve gut-derived bacterial products.[960] Another factor in the development of intestinal stasis after inflammation is the local overproduction of nitric oxide caused by the upregulation of iNOS by resident macrophages.[961] The iNOS upregulation was important for initiation of the inflammatory response and inhibition of motility. Nitric oxide is a key inhibitory neurotransmitter of the nonadrenergic, noncholinergic system.[948]

In the horse, significant neutrophilic inflammation is apparent in the jejunum from clinical cases necessitating resection and following a period of recovery in the jejunum subjected to 1 or 2 hours of ischemia.[962] The ischemic tissue also had evidence of leukocyte activation, as demonstrated by calprotectin-positive cells in associated tissue histologically.

Pharmacologic Alteration

The inhibitory effects of α_2-adrenergic agonists such as xylazine and detomidine on duodenal, cecal, and large colon motility are well described, because these drugs activate presynaptic receptors within the ENS.[4,963,964-968] IV-administered xylazine inhibits cecal and large colon motility for 20 to 30 minutes without seriously disrupting small intestinal myoelectric activity, and detomidine can reduce large intestinal myoelectric activity for up to 3 hours. Detomidine decreases duodenal motility in a dose-dependent fashion.[969] The α_2-antagonist yohimbine has a weak but positive effect on cecal emptying in normal ponies, suggesting that normal motility is under constant α_2-adrenergic tone.[4]

Several opioid agonists also have documented inhibitory effects on equine gastrointestinal motility at both a central and peripheral level. Morphine administration decreased frequency of defecation and fecal moisture content while increasing gastrointestinal transit time in normal horses at a dose of 0.5 mg/kg twice daily for 6 days.[970] Single doses of fentanyl or morphine decrease jejunal and colonic MMC activity in ponies, whereas the antagonist naloxone elicited increased propulsive activity in the colon.[971] Fentanyl administered as an IV constant rate infusion did not have an apparent deleterious effect on duodenal motility.[972] Butorphanol, an opioid agonist-antagonist, decreases myoelectrical activity in the jejunum but not pelvic flexure.[973] In another series of experiments, butorphanol alone did not decrease gastric or duodenal motility,[974] but administration in combination with xylazine resulted in a synergistic inhibitory effect, which was more pronounced than that obtained by administration of xylazine alone.[968] Administration of butorphanol as a constant rate infusion appears to have a minimal to no effect on global gastrointestinal[470,975] or duodenal motility.[976] When lidocaine, ketamine, and butorphanol were administered alone or in combination as constant rate infusions to healthy horses, combinations containing butorphanol (butorphanol/lidocaine, or a combination of all three drugs) delayed total gastrointestinal transit time.[977]

N-Butylscopolammonium bromide has a profound but very short-lived negative effect on duodenal motility, but this effect was not significant between groups.[976] Atropine is a postganglionic blocking agent that binds to muscarinic receptors. When administered at 0.04 mg/kg, atropine inhibits individual small intestinal, cecal, and colonic contractions for about 120 minutes but suppresses small intestinal and colonic migrating complexes for up to 8 hours.[978]

Neural Reflexes

Neural reflexes may mediate inhibition of motility associated with peritoneal inflammation.[979,980] The afferent segment is composed partly of capsaicin-sensitive visceral afferent C fibers that terminate in the dorsal horn of the spinal cord, in which they can activate inhibitory sympathetic fibers or synapse directly on the sympathetic ganglia. Consequently, the efferent limb of the reflex expresses increased sympathetic outflow, primarily mediated through stimulation of α_2-adrenoreceptors, and inhibition of acetylcholine release, which provides the rationale for α_2-blockade in treating ileus. Intraluminal infusion of capsaicin before abdominal surgery ameliorated the severity of POI in experimental rats. This finding highlights the importance of visceral afferent fibers in the development of POI.[981]

Distention

Ileus also can occur in association with intestinal obstruction or displacement. Mild to moderate distention of the bowel, such as that occurring in the early stages of an intraluminal obstruction, evokes an increase in local contractile activity.[982,983] Excessive distention results in the inhibition of motility within the distended segment of bowel. Intestinal stasis is not always detrimental and under certain conditions may be protective. Repeated distention for determination of nociceptive threshold results in an overall decrease in duodenal motility over time, irrespective of other interventions.[972,976]

Endotoxin

Endotoxemia is a clinical feature of many diseases of the equine gastrointestinal tract, and endotoxins independently can exert a negative effect on intestinal motility and transit.[214] A variety of mediators likely are involved, but the activation of α_2-adrenoreceptors and production of prostanoids appear to be important, because pretreatment with yohimbine or NSAIDs (phenylbutazone or flunixin), respectively, ameliorates the inhibitory effects of experimental endotoxin infusion.[201,984-986] Pretreatment with metoclopramide or cisapride had a similar effect.[71,987] Endotoxin infusion induced an inflammatory response in the intestine of rats that mimicked the response induced by handling during laparotomy.[988] The similarity of the responses was highlighted in a recent study that demonstrated that prior exposure of the muscularis to endotoxin protected the intestine from the effects of manipulation.[989] In rats, colonic manipulation alone causes transference of intraluminal LPS to the muscularis, which likely contributes to the global gastrointestinal inflammatory response and decrease in contractility associated with tissue manipulation.[960] In response to endotoxin alone, the inflammatory response within the jejunal muscularis is predominantly monocytic, whereas the response to polymicrobial sepsis is predominantly neutrophilic.[990]

Other Effects

Temperature also appears to affect in vitro slow-wave activity in the horse. In a recent study, the slow-wave frequency was approximately linearly related to temperature in the range studied (27–41°C) and was highly temperature sensitive in isolated equine ileal segments.[991]

The pathophysiology of cecal emptying defect is not known. This syndrome may best mimic POI in human beings, which is generally considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extraabdominal surgical procedures. The disorder, therefore, is probably not appropriately considered as a form of POI in horses. General anesthesia itself is a potent inhibitor of gastrointestinal motility in horses, but these effects are short-lived and reversible within hours of anesthetic withdrawal.[952] The return of normal motility in horses after experimental ileus was most delayed in the cecum, suggesting that this may be a common site of ileus in horses.[992] A link between routine postoperative medications, such as phenylbutazone and aminoglycoside antibiotics, has been suspected but not established. An inhibitory effect of NSAIDs on large colon contractility has been demonstrated using in vitro techniques.[993] Primary sympathetic overstimulation could be involved, because many of the affected animals are young, male horses or animals with painful diseases.

The duration of surgery influences the development of small intestinal POI but not cecal emptying dysfunction.[938,994] Technique may have a weak influence on small intestinal POI after jejunojejunostomy. The duration of intestinal ileus was shorter in animals that received a side-to-side stapled anastomosis than those that had a hand-sewn end-to-end procedure.[932] The duration of ileus after stapled end-to-end anastomosis was not different from that after either procedure. Jejunocecostomy more commonly results in POI than other types of small intestinal resection and anastomosis, whether related to diseases necessitating this procedure or the procedure itself.[995]

Other reported risk factors for the development of POI include age (>10 years), small intestinal resection and anastomosis, breed (Arabians had a greater risk than other breeds), and duration of surgery.[994] A prospective study found small intestinal lesion, high packed cell volume, and duration of anesthesia to increase the risk of POI, whereas performance of a pelvic flexure enterotomy and intraoperative administration of lidocaine may have a modest protective effect against POI.[996]

DIAGNOSIS

The diagnosis of ileus is based on history and physical examination findings. Case inclusion criteria for clinical studies of POI have varied.[994-997] Recent surveys of the Diplomates of the European Colleges of Equine Internal Medicine and Veterinary Surgery and the American Colleges of Veterinary Surgery, Veterinary Internal Medicine, and Veterinary Emergency and Critical Care revealed that the presence of reflux on passage of a nasogastric tube, evidence of multiple fluid-distended loops of small intestine on ultrasonographic examination, and the presence of multiple fluid-distended loops of small intestine on rectal palpation were the features most commonly identified as "extremely important" for a diagnosis of POI.[998,999] One can palpate cecal distention with digesta in horses with advanced cecal dysfunction.

Distinguishing functional ileus from mechanical obstruction is important and can be difficult, but horses with mechanical obstruction typically have sustained high volumes of gastric reflux that vary little over time and abdominal pain, which is typically not relieved by gastric decompression. Abdominal ultrasound in horses with ileus typically reveals mild to moderately fluid-filled hypomotile to immotile small intestine, without alteration in the amount or character of PF or small intestinal wall thickness. Horses with reflux from other causes (peritonitis and mechanical obstruction) will have changes reflective of their disease process. This differentiation is important for appropriate case management, because horses with a mechanical obstruction often need either primary or repeat laparotomy, which should not be delayed.

TREATMENT

The management of intestinal ileus depends on the segment of gastrointestinal tract involved. Therapy for ileus of the proximal gastrointestinal tract involves a combination of gastric decompression, fluid and electrolyte therapy, and antiinflammatory therapy. Electrolyte therapy is critical, particularly for maintaining adequate extracellular concentrations of potassium, calcium, and magnesium. Calculation of the volume of fluid to be administered should include maintenance requirements plus an estimate of losses, especially those lost through gastric decompression. Parenteral provision of calories should be considered when feed has been withheld for more than 96 hours, particularly after surgery. Hand walking also may provide some benefit to these animals but is not likely to have a direct effect on intestinal motility.

Drugs that can have an inhibitory effect on motility should be avoided or used sparingly. Horses with primary cecal impaction or impaction caused by an emptying defect may require surgery to prevent fatal rupture. The surgical management of these cases is controversial and may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.[1000] Most horses that undergo simple typhlotomy have an uneventful recovery.[1001] In a large retrospective study, 44/54 horses treated medically survived to discharge, whereas 37 of 49 horses treated surgically were allowed to recover, 35 of which survived to discharge.[939] Ileocolostomy was only performed in two of the 37 horses treated surgically (one of which survived to discharge), with the remainder receiving typhlotomy without bypass. Survival to 1 year was not statistically different between horses treated medically (18/19) or surgically (25/28), although 6 horses had a recurrence of cecal impaction.[939]

Experimental and anecdotal evidence provides a strong rationale for using antiinflammatory drugs to prevent and treat gastrointestinal ileus, particularly in animals that may have endotoxemia.[1002] Flunixin meglumine is used widely in equine practice as an analgesic and antiinflammatory agent, and it ameliorates many of the adverse systemic effects of endotoxin, particularly those on the cardiovascular system. A potential negative effect of NSAIDs on large intestinal contractility has been suggested. A differential effect on contractility between selective and nonselective COX inhibitors is currently unknown. Broad-spectrum antimicrobials are indicated when one suspects sepsis or in cases of profound neutropenia. High concentrations of aminoglycoside antimicrobials inhibited intestinal contractions in exposed sections of intestine in vitro, but this inhibitory effect is unlikely to occur at clinically relevant doses.[1003]

Motility-enhancing drugs have been advocated to treat gastrointestinal ileus. Unfortunately, information directly pertinent to horses is limited and must be extrapolated cautiously from that of other species because of the differences in intestinal anatomy and physiology. Prokinetic drugs potentially can shorten the length of hospitalization, reducing the cost of treatment and the number of potential complications such as weight loss, thrombophlebitis, and laminitis. Experimental evidence indicates that prokinetic drugs can minimize the development of postoperative abdominal adhesions.[1004] Most prokinetic drugs require a healthy gut wall to enhance intestinal contraction, and downregulation of motilin receptors has been demonstrated in the inflamed equine jejunum.[473] Therefore one should not assume that many of these drugs would be effective in the presence of an inflammatory injury such as that which can occur after intestinal manipulation at surgery or that associated with DPJ.

Cholinomimetics

Bethanechol is a parasympathomimetic agent that acts at the level of the myenteric plexus and directly on intestinal smooth cells through muscarinic receptors. In the horse, this effect is mediated predominantly by the M3 receptor, but the M2 receptor may also play a role.[1005] Bethanechol is a synthetic ester of acetylcholine and is not degraded by anticholinesterase. Bethanechol has cholinergic side effects, including abdominal discomfort, sweating, and salivation, although these are minimal when the drug is administered at 0.025 mg/kg body mass SC or orally. Bethanechol has efficacy in diseases that involve abnormal gastric emptying and delayed small intestinal transit and increases gastric contractility and hastens the emptying of liquid and solid phase markers from the stomach of normal horses.[1006] Bethanechol also increases the strength and duration of wall contractions in the cecum and right ventral colon, consequently speeding up cecal emptying.[4]

Neostigmine increases receptor concentration of acetylcholine by inhibiting cholinesterase. The drug (0.022–0.025 mg/kg IV) promotes cecal and colonic contractile activity and hastens the emptying of radiolabeled markers from the cecum.[4] Neostigmine has been used to manage small intestinal ileus, but it significantly delayed the emptying of 6-mm beads from the stomach of normal adult horses.[1007]

Benzamides and Dopamine Antagonists

Metoclopramide acts principally as a 5-hydroxytryptamine 4-receptor (5HT-4) agonist and 5HT-3–receptor antagonist. In contrast to newer generation benzamides, metoclopramide is also an antagonist at dopamine 1 (DA1) and dopamine 2 (DA2) receptors. Antagonism of prejunctional DA2 receptors facilitates acetylcholine release and smooth muscle contraction. Metoclopramide crosses the blood-brain barrier, where its antagonist properties on central DA2 receptors can result in extrapyramidal signs, including seizure. Metoclopramide increased contractility of muscle strips in vitro in the pyloric antrum, proximal duodenum, and midjejunum.[1008] These in vitro data support previous work in which metoclopramide administration restored gastroduodenal coordination of motility in a model of POI.[1009] In another study, metoclopramide had no effect on jejunal or pelvic flexure myoelectrical activity.[973] Constant IV infusion (0.04 mg/kg/h) of metoclopramide was well tolerated in a population of postoperative horses and significantly decreased the volume and duration of gastric reflux over control and intermittent drug infusion groups.[1010]

Cisapride is a second-generation benzamide that acts as a 5HT-4 agonist and 5HT-3–receptor antagonist but is without antidopaminergic action. Stimulation of 5HT-4 receptors within the ENS enhances release of acetylcholine from the myenteric plexus. Several reports suggest the efficacy of cisapride in managing intestinal disease in horses, including the resolution of persistent large colon impaction, treatment of equine grass sickness, and as a preventative for POI in horses after small intestinal surgery (0.1 mg/kg body mass intramuscularly during the postoperative period).[1011-1014] The horse erratically absorbs tablets administered rectally, but a method for preparing a parenteral form of the drug from tablets has been described.[1015] Cisapride has the potential to cause adverse cardiac side effects mediated through blockage of the rapid component of the delayed rectifier potassium current that include lengthening of the QT interval and development of torsades de pointes, a potentially fatal arrhythmia.[1016] These adverse effects have resulted in withdrawal of the drug in the United States but have not been reported in the horse.

Tegaserod, a 5HT-4 agonist, increases pelvic flexure smooth muscle contractility (0.27 mg/kg PO)[1017] and hastens gastrointestinal transit time (0.02 mg/kg IV) in healthy horses.[1018] It has not, to the author's knowledge, been objectively evaluated in abnormal horses, but it may prove useful. In humans, this drug was marketed for women with constipation-predominant or mixed symptom irritable bowel syndrome and demonstrated clear benefits in quality of life and gastrointestinal symptoms but is currently only available in a restricted fashion because of an association with ischemic colitis and cardiovascular disease.[1019]

Domperidone acts as a competitive antagonist at peripheral DA2 receptors. The drug is a therapeutic agent (1.1 mg/kg/day) for mares grazing endophyte-infected tall fescue, principally because of drug-enhanced prolactin release. Modest efficacy of domperidone (0.2 mg/kg IV) has been demonstrated in experimental ileus in ponies.[1011] In another study, a much higher oral dosage (5 mg/kg) was required to increase gastric emptying; 1.1 mg/kg orally had limited effects on the gastrointestinal tract in healthy horses.[1020]

Antimicrobials

Erythromycin, a macrolide antibiotic, is a direct motilin receptor agonist on smooth muscle cells and may act within the ENS to facilitate the release of acetylcholine and motilin. Erythromycin displaces motilin from its receptor in the equine duodenum, jejunum, cecum, and pelvic flexure.[476] Erythromycin enhances gastric emptying in normal horses but has a more pronounced effect on the hindgut.[1006,1021] Erythromycin lactobionate (1.0 mg/kg IV) hastens cecal emptying in normal animals and induces colonic MMC-like activity across the colon. Administration often is associated with defecation and abdominal discomfort. The prokinetic effect of erythromycin apparent in the ileum, cecum, and pelvic flexure documented in normal horses was reduced in the immediate postoperative period.[686] Luminal distention and decompression resulted in inflammation and a decreased response to erythromycin.[1022] A decrease in motilin receptors in response to luminal distention has been documented in the equine jejunum,[473] and this may explain the difference in response between normal and clinically affected horses. Repeated dosing can cause downregulation of motilin receptors in other species.[1023] Erythromycin can induce diarrhea in adults; therefore, one should avoid dosing over many days.

Potassium penicillin (20 million IU IV to adult horses) can stimulate defecation and increase myoelectrical activity in the

cecum and pelvic flexure, and these effects are not produced by an equimolar amount of potassium ion given IV as potassium chloride.[1024]

Opioid and α_2-Adrenoreceptor Antagonists

Naloxone (0.05 mg/kg IV) induces contractile activity in the cecum and left colon.[971] Defecation commonly follows administration of naloxone within 15 to 20 minutes. *N*-methylnaltrexone increases jejunal and pelvic flexure contractility in vitro[1025] and prevents the negative effects of morphine on fecal output and intestinal transit time when administered concurrently.[1026]

α_2-Adrenoreceptor antagonists such as yohimbine or tolazoline counteract increased sympathetic outflow in response to nociceptive stimulation. Yohimbine infusion (75 μg/kg) also may attenuate the negative effects of endotoxin on motility.[201,985]

Local Anesthetics

The use of IV lidocaine as a prokinetic has gained tremendous popularity and was reported to be the agent most commonly used by equine surgeons for treatment of POI.[1027] In more recent surveys, flunixin meglumine and lidocaine were used most frequently for the treatment of POI by specialists in Europe and North America.[998,999] Lidocaine may exert prokinetic effects by suppressing primary afferent neurons, limiting reflex efferent inhibition of motility.[1028] Other proposed mechanisms of action include antiinflammatory properties, potentially through NF-κB signaling[1029] or improving mucosal repair.[413] IV lidocaine also has analgesic effects, although it was shown to alter somatic but not visceral antinociception in clinically normal horses in one study.[1030] Lidocaine increased contractile activity in isolated strips of proximal duodenum in vitro.[1008] The most commonly cited dosage is a 1.3-mg/kg bolus, typically over 15 minutes, followed by a 0.05-mg/kg/min constant rate infusion. This dosage did not alter MMC duration or spiking activity, reset the MMC in the jejunum in clinically normal horses[1031] or significantly alter a variety of indicators of POI after colic surgery.[1032] Significantly more horses with POI stopped refluxing within 30 hours following the institution of lidocaine infusion, relative to saline infusion.[475] Lidocaine administration did not affect the prevalence of POI, duration or volume of reflux, or survival in horses requiring surgery for treatment of small intestinal colic.[1033] Lidocaine infusion can be associated with reversible side effects that include muscle fasciculations, ataxia, and seizure. Consequently, the rate of infusion requires close monitoring. Prolonged infusion of lidocaine in the horse appears safe, although accumulation of the GX metabolite has been documented.[1034]

Ischemic Disorders of the Intestinal Tract[g]

PATHOPHYSIOLOGY OF STRANGULATING OBSTRUCTION

Strangulating obstruction of the intestine is characterized by simultaneous occlusion of the intestinal lumen and its blood supply. Although strangulation of the intestinal lumen results in clinical signs similar to those of simple obstruction, occlusion of the blood supply results in a more rapid deterioration of the intestinal mucosa and subsequent onset of sepsis. Although there has been a great deal of interest in the relevance and treatment of intestinal reperfusion injury,[851,861,882] the lesion that develops during strangulation is often severe, leaving little viable bowel for further injury during reperfusion.[882] Although extensive lengths of strangulated small intestine may be resected, strangulation of the large colon presents a much greater treatment dilemma because strangulated intestine usually extends beyond the limits of surgical resection.[1035] Therefore horses with large intestinal strangulation are often recovered with extensive intestinal injury left in place. As a result, subtle degrees of reperfusion injury may be very important in horses with large colon disease, warranting further work in this area in an attempt to reduce mortality.[851]

Strangulating obstruction may be divided into hemorrhagic and ischemic forms.[163] In hemorrhagic strangulating obstruction, which is most common, the veins become occluded before the arteries because of the greater stiffness of arterial walls. This lesion is noted by a darkened appearance in affected bowel and increased thickness as blood is pumped into the lesion. Ischemic strangulating obstruction occurs if the intestine is twisted tightly enough to simultaneously occlude both arteries and veins. In the case of the colon, some researchers suggest that this may be determined by how much ingesta is in the colon, because intestinal contents may prevent the intestine from twisting tightly.[1036] Tissue involved in ischemic strangulating obstruction appears pale and of normal or reduced thickness because of a complete lack of blood flow (Fig. 12.11). Bowel peripheral to strangulating lesions may also become injured as a result of distention, which reduces mural blood flow once it reaches critical levels. As this intestine is decompressed, it may also undergo reperfusion injury.[879,1037,1038]

SMALL INTESTINAL STRANGULATION

Clinical Signs

Horses with small intestinal strangulating obstruction typically have moderate to severe signs of abdominal pain that is only intermittently responsive to analgesic medications. During the latter stages of the disease process, horses may not experience much pain but rather become profoundly depressed as affected intestine undergoes necrosis. Affected horses have progressive signs of sepsis, including congested mucous membranes, delayed capillary refill time, and an elevated heart rate (>60 beats/min in most cases). Reflux is typically obtained after passage of a stomach tube, and loops of distended small intestine are usually detected on rectal palpation of the abdomen. These latter findings are variable, depending on the duration and location of the obstruction. For example, horses with ileal obstructions tend to reflux later in the course of the disease process than horses with jejunal obstructions. A horse that has an entrapment of small intestine in the epiploic foramen or a rent in the proximal small intestinal mesentery may not have palpable loops of small intestine because of the cranial location of these structures.[1039] Abdominocentesis can provide critical information on the integrity of the intestine and is indicated in horses with suspected strangulation of the small intestine. Affected horses typically have serosanguineous abdominal fluid with an elevated protein concentration

FIG. **12.11** Ischemic strangulating obstruction of the small colon by a mesenteric lipoma. (A) Note the lipoma *(arrow),* which has tightly encircled a segment of small colon. (B) After resection of the lipoma, a pale area of strangulated small colon is clearly demarcated *(arrows),* the appearance of which is consistent with ischemic strangulating obstruction.

(>2.5 mg/dL) and an increase in PF:plasma lactate, although these cases must be differentiated from proximal enteritis.[11,22,783] When an initial sample is inconclusive, repeated measurement of PF lactate may provide additional support for a diagnosis of a strangulating lesion.[27] Generally, horses with small intestinal strangulation show continued signs of abdominal pain, whereas horses with proximal enteritis (discussed in Duodenitis-Proximal Jejunitis previously in this chapter) tend to be depressed after initial episodes of mild abdominal pain.[1040] In addition, horses with small intestinal strangulation continue to deteriorate clinically despite appropriate medical therapy and begin to show elevated WBC counts (>10,000 cells/μL) in the abdominal fluid as the duration of strangulation increases. There are horses in which small intestinal strangulation and proximal enteritis cannot be not readily distinguished, at which point surgery may be elected rather than prolonging the decision to perform abdominal exploration on a horse with a potential strangulating lesion.[1040]

Prognosis

The prognosis for survival in horses with small intestinal strangulating lesions is generally lower than for most forms of colic,[995] but some reports indicate that more than 80% of horses with small intestinal strangulating lesions will survive to discharge from the hospital.[1041] Owners should be warned that long-term survival rates are less than 70%,[1042] in part because of long-term complications such as adhesions.[1043,1044] The prognosis is particularly poor for some forms of strangulation, including entrapment of small intestine within a mesenteric rent.[1045] Some horses with small intestinal strangulation can be managed surgically without resection, with favorable short- and long-term prognosis.[1046] Geriatric horses have a higher likelihood of small intestinal strangulation, relative to mature counterparts undergoing colic surgery, but carry a similar prognosis.[1047] In one hospital, horses with gastrosplenic ligament entrapment (GLE) had higher short-term survival (72.7%), relative to horses with other small intestinal strangulating lesions (50%),[1048] whereas short-term survival was similar between horses with GLE (88%) and EFE (85%) at another hospital.[1049] Short-term survival in horses with EFE was higher (95%) than for other causes of small intestinal strangulation in another report.[1050]

Epiploic Foramen Entrapment

The epiploic foramen is a potential opening (because the walls of the foramen are usually in contact) to the omental bursa located within the right cranial quadrant of the abdomen. It is bounded dorsally by the caudate process of the liver and caudal vena cava and ventrally by the pancreas, the hepatoduodenal ligament, and the portal vein.[1039] Intestine may enter the foramen from the visceral surface of the liver toward the right body wall or the opposite direction. Studies differ as to which is the most common form. In the case of entrapments that enter the foramen in a left-to-right direction, the omental bursa is ruptured as the intestine migrates through the epiploic foramen, which may contribute to the intraabdominal hemorrhage often seen with this condition. Clinical signs include acute onset of severe colic with examination findings compatible with small intestinal obstruction. The stereotypic behavior of crib biting is a significant risk factor for EFE,[1051] possibly because of changes in abdominal pressure as the horse prepares the esophagus to ingest air. Other risk factors include increased height of the horse and previous colic surgery.[1051] The condition was once believed to be more prevalent in older horses,[1039] but this has been refuted.[1051] The disorder has also been recognized in foals as young as 4 months of age.[1052] The diagnosis is definitively made at surgery, although ultrasonographic findings of distended loops of edematous small intestine adjacent to the right middle body wall are suggestive of EFE.[1039] Generally, thickened, immotile intestine on ultrasonographic examination is highly predictive for small intestinal strangulating obstruction.[1053,1054] Small intestine entrapped in the epiploic foramen may be limited to a portion of the intestinal wall (parietal hernia),[1055] and the large colon may become entrapped within the epiploic foramen.[1051] In treating EFE, the epiploic foramen must not be enlarged either by blunt force or with a sharp instrument, because rupture of the vena cava or portal vein and fatal hemorrhage may occur. Prognosis has substantially improved over the past decade, with current short-term survival rates (discharge from the hospital) ranging from 74% to 95%.[1039,1049-1051,1056] Survival to 1 year (50.6%) and 2 years (34.3%) postoperatively declines substantially, with a median survival time of 397 days in one report.[1051] Preoperative abdominocentesis,[1039,1056] packed cell volume, length of small intestine resected, and POI[1051] have been associated with postoperative survival.

Strangulation by Pedunculated Mesenteric Lipoma

As horses age, lipomas form between the leaves of the mesentery and develop mesenteric stalks as the weight of the lipoma tugs on the mesentery. The stalk of the lipoma may subsequently wrap around a loop of small intestine or small colon, causing strangulation. Strangulating lipomas should be suspected in aged (>15 years) geldings with acute colic referable to the small intestinal tract.[1057-1059] Ponies also appear to be at risk for developing disease,[1059] suggesting alterations in fat metabolism may predispose certain horses to the development of mesenteric lipomas. The diagnosis is usually made at surgery, although on rare occasions a lipoma can be palpated rectally. Treatment involves surgical resection of the lipoma and strangulated bowel, although strangulated intestine is not always nonviable.[1059] Studies indicate that approximately 50%[1058] to 78%[1059] of horses are discharged from the hospital after surgical treatment.

Small Intestinal Volvulus

A volvulus is a twist along the axis of the mesentery, whereas torsion is a twist along the longitudinal axis of the intestine. Small intestinal volvulus is theoretically initiated by a change in local peristalsis or the occurrence of a lesion around which the intestine and its mesentery may twist (e.g., an ascarid impaction).[1060] It is reportedly one of the most commonly diagnosed causes of small intestinal obstruction in foals.[1061,1062] It has been theorized that young foals may be at risk for small intestinal volvulus because of changing feed habits and adaptation to a bulkier adult diet. Onset of acute, severe colic; a distended abdomen; and radiographic evidence of multiple loops of distended small intestine in a young foal would be suggestive of small intestine volvulus. However, it is not possible to differentiate volvulus from other causes of small intestinal obstruction preoperatively. In adult horses volvulus frequently occurs in association with another disease process, during which small intestinal obstruction results in distention and subsequent rotation of the small intestinal around the root of the mesentery. Although any segment of the small intestine may be involved, the distal jejunum and ileum are most frequently affected because of their relatively longer mesenteries.[1060] The diagnosis is made at surgery by palpating a twist at the origin of the cranial mesenteric artery. Treatment includes resection of devitalized bowel, which may not be an option because of the extent of small intestinal involvement (similar to large colon volvulus). Prognosis is based on the extent of small intestine involved and its appearance after surgical correction of the lesion. Generally, horses in which more than 50% of the small intestine is devitalized are considered to have a grave prognosis.[1063]

Strangulation by Way of Mesenteric or Ligamentous Rents

There are a number of structures that, when torn, may incarcerate a segment of intestine (typically the small intestine), including intestinal mesentery,[1045] the gastrosplenic ligament,[1048,1049,1064] the broad ligament,[1065] and the cecocolic ligament.[1066] Horses with such incarcerations present signs typical of a horse with strangulating small intestine. The prognosis for many of these cases appears to be worse than for horses with other types of small intestinal strangulations. Of horses with small intestine entrapped in a mesenteric rent, only 7 of 15 horses were discharged from the hospital, and only 2 of 5 horses for which follow-up information was available survived long term (>5 months).[1045] Poor outcome may result from the difficulty in releasing the incarcerated intestine, the degree of hemorrhage, and the length of intestine affected.

Inguinal Hernia

Inguinal hernias are more common in Standardbred and Tennessee Walking Horses that tend to have congenitally large inguinal canals.[1060] Inguinal hernias may also occur in neonatal foals but differ from hernias in mature horses in that they are typically nonstrangulating. The nature of the hernia (direct versus indirect) is determined on the basis of the integrity of the parietal vaginal tunic. In horses in which the bowel remains within the parietal vaginal tunic, the hernia is referred to as *indirect* because, strictly speaking, the bowel remains within the peritoneal cavity. Direct hernias are those in which strangulated bowel ruptures through the parietal vaginal tunic and occupies an SC location. These direct hernias most commonly occur in foals and should be suspected when a congenital inguinal hernia is associated with colic, swelling that extends from the inguinal region of the prepuce, and intestine that may be palpated SC.[1067,1068] Although most congenital indirect inguinal hernias resolve with repeated manual reduction or application of a diaper, surgical intervention is recommended for congenital direct hernias.[1068]

Historical findings in horses with strangulating inguinal hernias include acute onset of colic in a stallion that had recently been used for breeding. A cardinal sign of inguinal herniation is a cool, enlarged testicle on one side of the scrotum.[1069-1071] However, inguinal hernias, including of the large colon, have also been reported in geldings.[1072,1073] Inguinal hernias can be detected on rectal palpation, and manipulation of herniated bowel per rectum has been used to reduce a hernia, but this procedure is not recommended because of the risk of rectal tears. In many horses the short segment of herniated intestine will markedly improve in appearance once it has been reduced and does not always have to be resected.[1074] The affected testicle will be congested because of vascular compromise within the spermatic cord, and although it may remain viable, it is generally recommended that it be resected.[1074] The prognosis in adult horses is good, with up to 75% of horses surviving to 6 months of age.[1069-1071] Horses that have been treated for inguinal hernias may be used for breeding. In these horses the remaining testicle will have increased sperm production, although an increased number of sperm abnormalities will be noticed after surgery because of edema and increased temperature of the scrotum.

Strangulating Umbilical Hernias

Although umbilical hernias are common in foals, strangulation of herniated bowel is rare. In one study, 6 of 147 (4%) horses with umbilical hernias had incarcerated intestine.[1075] Clinical signs include a warm, swollen, firm, and painful hernia sac associated with signs of colic. The affected segment of bowel is usually small intestine, but herniation of cecum or large colon has also been reported.[1076] In rare cases a hernia that involves only part of the intestinal wall may be found; this is termed a *Richter's hernia.* In foals that have a Richter's hernia, an enterocutaneous fistula may develop.[1076] In one study, 13 of 13 foals with strangulating umbilical hernias survived to discharge, although at least 3 were lost to long-term complications.[1076]

FIG. **12.12** Jejunojejunal intussusception in a horse with colic. Note the intussusceptum, which has become ischemic as a result of invagination of intestine and its mesenteric blood supply into the intussuscipiens.

Intussusceptions

An intussusception involves a segment of bowel (intussusceptum) that invaginates into an adjacent aboral segment of bowel (intussuscipiens). The reason for such invagination is not always clear, but it may involve a lesion at the leading edge of the intussusception, including small masses, foreign bodies, or parasites. In particular, tapeworms *(Anoplocephala perfoliata)* have been implicated.[1077] Ileocecal intussusceptions are the most common intestinal intussusceptions in the horse and typically affect young animals. In one study evaluating 26 cases of ileocecal intussusception, the median age of affected horses was 1 year.[1078] Acute ileocecal intussusceptions are those in which the horses have a duration of colic of less than 24 hours and involve variable lengths of intestine, which ranged in one study from 6 cm to 457 cm in length. In acute cases the involved segment of ileum typically has a compromised blood supply. Chronic ileocecal intussusceptions typically involve short segments of ileum (up to 10 cm in length), and the ileal blood supply is frequently intact.[1078] Abdominocentesis results are variable because strangulated bowel is contained within the adjacent bowel. There is often evidence of obstruction of the small intestine, including nasogastric reflux and multiple distended loops of small intestine on rectal palpation. Horses with chronic ileocecal intussusceptions have mild, intermittent colic, often without evidence of small intestinal obstruction. In one study a mass was palpated in the region of the cecal base in approximately 50% of affected horses.[1078] Transabdominal ultrasound may be helpful in discerning the nature of the mass. The intussusception has a characteristic target appearance on cross section[1079-1081] and has been reported as a frequent incidental finding in Standardbred foals.[1082] Other segments of the small intestine may also be intussuscepted, including the jejunum (Fig. 12.12). In one study of 11 jejunojejunal intussusceptions, the length of bowel involved ranged between 0.4 and 9.1 m.[1083] Attempts at reducing intussusceptions at surgery are usually futile because of intramural swelling of affected bowel. Jejunojejunal intussusceptions should be resected.

For acute ileocecal intussusceptions the small intestine should be transected as far distally as possible, and a jejunocecal anastomosis should be performed. In cases with particularly long intussusceptions (up to 10 m has been reported), an intracecal resection may be attempted.[1084] For horses with chronic ileocecal intussusceptions, a jejunocecal bypass without small intestinal transection should be performed. The prognosis is good for horses with chronic ileocecal intussusceptions and guarded to poor for horses with acute ileocecal intussusceptions, depending on the length of bowel involved.[1078]

Diaphragmatic Hernias

Herniation of intestine through a rent in the diaphragm is rare in the horse. Any segment of bowel may be involved, although small intestine is most frequently herniated.[1085] Diaphragmatic rents may be congenital or acquired, but acquired hernias are more common.[1085] Congenital rents may result from incomplete fusion of any of the four embryonic components of the diaphragm: pleuroperitoneal membranes, transverse septum, body wall, and esophageal mesentery.[1085] Abdominal compression of the foal at parturition may result in a congenital hernia.[1085] Acquired hernias are presumed to result from trauma to the chest or a sudden increase in intraabdominal pressure, such as might occur during parturition, distention of the abdomen, a sudden fall, and strenuous exercise.[1086] Hernias have been described in a number of different locations; large congenital hernias are typically present at the ventralmost aspect of the diaphragm, and most acquired hernias are located at the junction of the muscular and tendinous portions of the diaphragm.[1085] A peritoneopericardial hernia has been documented in at least one horse.[1087]

The clinical signs are usually associated with intestinal obstruction rather than respiratory distress.[1086] Careful auscultation may reveal an area of decreased lung sounds associated with obstructed intestine and increased fluid within the chest cavity.[1088] Such signs may prompt thoracic radiography or ultrasound, both of which can be used to make a diagnosis. Auscultation may also reveal thoracic intestinal sounds, but it is typically not possible to differentiate these from sounds referred from the abdomen. In one report, two of three horses diagnosed with small intestinal strangulation by diaphragmatic hernia had respiratory acidemia, attributable to decreased ventilation.[1089] Treatment of horses with diaphragmatic hernia is fraught with complications because of the need to reduce and resect strangulated bowel and the need to repair the defect in the diaphragm; prognosis has not appeared to improve over time.[1089-1092] Because dorsal defects in the diaphragm are among the most common forms of diaphragmatic defect, it may not be possible to close the diaphragmatic hernia by way of the approach used for abdominal exploratory. Because herniation is likely to recur, it is appropriate to schedule a second surgery using an appropriate approach to resolve the diaphragmatic defect.

LARGE COLON VOLVULUS

Clinical Signs

Horses with large colon volvulus have rapid onset of severe, unrelenting abdominal pain. Postpartum broodmares appear to be at risk for this form of colic.[1035] Once the large colon is strangulated (>270-degree volvulus), gas distention is marked, leading to gross distention of the abdomen, compromised respiration as the distended bowel presses up against the diaphragm, and visceral pooling of blood as the caudal

vena cava is compressed. Horses with this condition are frequently refractory to even the most potent of analgesics. These horses may prefer to lie in dorsal recumbency, presumably to take weight off the strangulated colon. An abbreviated physical examination is warranted in these cases because the time from the onset of strangulation to surgical correction is critical. Under experimental conditions the colon is irreversibly damaged within 3 to 4 hours of a 360-degree volvulus of the entire colon.[855] Despite severe pain and hypovolemia, horses may have a paradoxically low heart rate, possibly related to increased vagal tone. Results of abdominocentesis often do not indicate the degree of colonic compromise,[1035,1093] and in many cases it is not worth attempting to obtain abdominal fluid because of extreme colonic distention.[1093] Rectal palpation reveals severe gas distention of the large colon, frequently associated with colonic bands traversing the abdomen. Severe colonic distention may restrict access to the abdomen beyond the pelvic brim. One study has shown that plasma lactate levels below 6.0 mmol/L had a sensitivity of 84% and a specificity of 83% in predicting survival in horses with large colon volvulus.[1094]

Surgical Findings

At surgery the volvulus is typically located at the mesenteric attachment of the colon to the dorsal body wall, and the most common direction of the twist is dorsomedial when the right ventral colon is used as a reference point.[1035] However, the colon may twist in the opposite direction, twist greater than 360 degrees (up to 720 degrees has been reported), or twist at the level of the diaphragmatic and sternal flexures.[1035] In all cases the colon should be decompressed as much as possible, and in many cases a colonic evacuation by way of a pelvic flexure enterotomy will greatly aid correction of the volvulus. After correction of the volvulus, a determination must be made as to whether the colon has been irreversibly injured. This should be based on mucosal color and bleeding (if an enterotomy has been performed), palpation of a pulse in the colonic arteries, serosal color, and appearance of colonic motility.[1036] If the colon is judged to be irreversibly damaged, the feasibility of a large colon resection can be considered. Although 95% of the colon can be resected (that part of the colon distal to the level of the cecocolic fold), damage from the volvulus may exceed that which can be resected. In these cases surgeons may elect to resect as much damaged bowel as possible or advise euthanasia.[1036]

Prognosis

Although early reports of short-term survival were low (35%),[1093] survival can vary with degree of volvulus. Short-term survival was reported as 36% for horses with 360-degree volvulus compared with 71% for horses with 270-degree volvulus.[1035] More recent studies report higher short-term survival (88%), with duration of disease as a major factor associated with survival.[1095] Impression of improved prognosis was echoed in a recent survey of the American Colleges of Veterinary Surgery Diplomates, who also note time to surgery as the most important factor associated with survival.[1096] Another study reports much higher short-term survival (74%) with large colon resection, along with positive survival rates at 1 year (67.8%), 2 years (66%), and 3 years (63.5%) postoperatively.[1097] Postoperative complications include hypovolemic and endotoxemic shock, extensive loss of circulating protein, DIC, diarrhea, and laminitis. Large colon volvulus may have a propensity to recur. Although one study documented a recurrence rate of less than 5%,[1093] some authors believe recurrence may be as high as 50%.[1036] Methods to prevent recurrence may be considered in patients at risk for recurrence, particularly broodmares that tend to suffer from the disease recurrently during the foaling season.[1098]

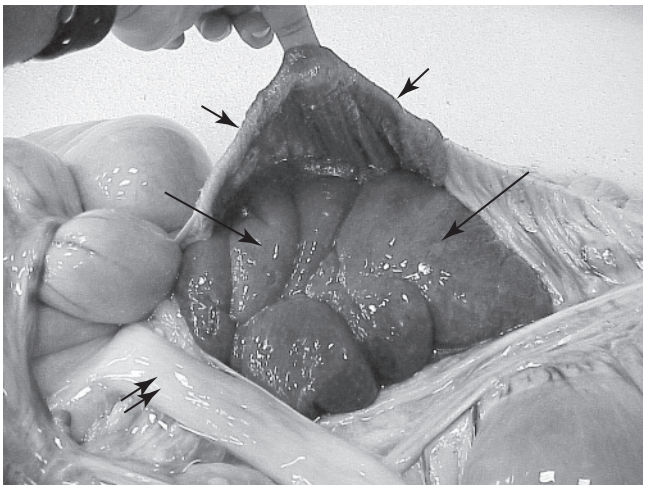

FIG. **12.13** Cecocolic intussusception in a horse with colic. An enterotomy has been made in the right ventral colon *(short arrows)* to reveal an intussuscepted cecum *(arrows)*. Although this picture was taken at necropsy, an enterotomy such as the one shown in this figure can be used to exteriorize and resect the majority of the compromised cecum. Note the ileum adjacent to the colon *(double arrow)*.

Intussusceptions

The most common intussusceptions of the large intestine are cecocecal and cecocolic.[1099] Both are likely attributable to the same disease process, with variable inversion of the cecum. These conditions tend to occur in young horses (63% were younger than 3 years old in one study) and may be associated with intestinal tapeworms.[1099] Clinical signs are variable, including acute, severe colic, intermittent pain over a number of days, and chronic weight loss.[1099] These variable presentations likely relate to the degree to which the cecum has intussuscepted. Initially, the cecal tip inverts, creating a cecocecal intussusception, which does not obstruct the flow of ingesta. As the intussusception progresses, the cecum inverts into the right ventral colon (cecocolic intussusception), which obstructs the flow of ingesta and often causes severe colic (Fig. 12.13). The cause of abdominal pain is often difficult to differentiate in these cases, although it is sometimes possible to detect a mass on the right side of the abdomen by either rectal palpation or ultrasound examination.[1099] Treatment involves manual surgical reduction by retracting the intussusceptum directly or by way of an enterotomy in the right ventral colon.[1099,1100] Sometimes the cecum cannot be readily reduced because of severe thickening, and in other cases surgical procedures result in fatal contamination. In one report 8 of 11 horses were euthanized in the perioperative period because of complications,[1101] and in another report 12 of 30 horses were euthanized either before or during surgery. The latter included all of the horses with chronic disease because of irreversible

TABLE **12.7 Classification of Rectal Prolapse**

Grade	Description	Prognosis
I	Prolapse of rectal mucosa	Good
II	Prolapse of full-thickness rectum	Fair
III	Grade 2 prolapse with additional protrusion of small colon	Guarded
IV	Intussusception of rectum and small colon through the anus	Poor

changes to the cecum.[1099] One report on cecocolic intussusceptions indicated that 7 of 8 horses that underwent right ventral colon enterotomy and cecal resection survived long term,[1100] suggesting that continued improvements in surgical techniques may improve the prognosis.

Colocolic intussusceptions are exceptionally rare but have reportedly affected the pelvic flexure and the left colon.[1102-1104] Although the condition is reportedly more common in young horses,[1102,1104] older horses may be affected.[1103] Clinical findings may include a palpable mass on the left side of the abdomen.[1102] Ultrasonography may also be useful. Treatment requires manual reduction of the intussusception at surgery or resection of affected bowel. Because the left colons can be extensively exteriorized and manipulated at surgery, the prognosis is fair.[1102-1104]

RECTAL PROLAPSE

Rectal prolapse may occur secondary to any disease that causes tenesmus, including diarrhea, rectal neoplasia, and parasitism,[1105] or it can occur secondary to elevations in intraabdominal pressure during parturition or episodes of coughing.[1106] Rectal prolapse is classified into four categories (Table 12.7) depending on the extent of prolapsed tissue and the level of severity.[1107] Type I rectal prolapse is most common and is characterized by a doughnut-shaped prolapse of rectal mucosa and submucosa (Fig. 12.14). Type II prolapse involves full-thickness rectal tissue, and type III prolapse additionally has invagination of small colon into the rectum. Type IV prolapse involves intussusception of proximal rectum or small colon through the anus in the absence of prolapse of tissue at the mucocutaneous junction at the anus.[1107] These can be differentiated from other forms of prolapse by their appearance and a palpable trench between prolapsed tissue and the anus.

Type I prolapses are most frequently seen in horses with diarrhea, and the rectal mucosa becomes irritated and protrudes intermittently during episodes of tenesmus. If tenesmus persists, rectal mucosa can remain prolapsed. Rectal mucosa rapidly becomes congested and edematous under these conditions and should be treated with osmotic agents such as glycerin or magnesium sulfate and by massaging and reducing the prolapse.[1108] A purse-string suture may be necessary to keep the mucosa inside the rectum. Topical application of lidocaine solution or jelly, epidural anesthesia, and sedation may help reduce tenesmus that incites and exacerbates rectal prolapse. Similar treatments can be applied with type II rectal prolapses. However, these more severe prolapses may not be reducible without surgical resection of mucosa and submucosa from the prolapsed bowel.[1105,1106]

FIG. **12.14** Type I rectal prolapse in a horse. Note circumferential protrusion of partial-thickness rectal tissue *(arrows)* that is becoming congested as a result of pressure from the surrounding anus.

Types III and IV rectal prolapses are more serious injuries because the small colon is involved.[1109] In horses with type III prolapse, an abdominocentesis should be performed to determine whether the injury to the small colon has resulted in peritonitis. The small colon component should be reduced manually if possible, whereas prolapsed rectal tissue typically requires mucosal or submucosal resection. Surgical exploration of the abdomen should be performed to determine the status of the small colon, although serial abdominocenteses can be used in lieu of surgery to detect progressive necrosis of the bowel. Type IV prolapses are seen most commonly in horses with dystocia.[1106] This type of prolapse is almost always fatal because of stretching and tearing of mesenteric vasculature, with subsequent infarction of affected bowel. Euthanasia is often warranted on the basis of physical examination findings. Confirmation of severe small colon injury requires abdominal exploration using either a midline approach or laparoscopy.[1110] It is conceivable that a horse with a compromised small colon could undergo a colostomy of the proximal small colon, but the compromised small colon will typically necrose beyond that which can be resected using a midline abdominal approach.[1108]

NONSTRANGULATING INFARCTION

Nonstrangulating infarction occurs secondary to cranial mesenteric arteritis caused by migration of *S. vulgaris*[1111] and has become a relatively rare disorder since the advent of broad-spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases.[1111] These findings suggest that vasospasm plays an important role in this disease.[1060] Clinical signs are highly variable, depending on the extent to which arterial flow is reduced and the segment of intestine affected. Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved.[1111] There are no clinical variables that can be used to reliably differentiate this disease from strangulating obstruction.[1099] In some cases massive infarction results

in acute, severe colic.[1111] Occasionally, an abnormal mass and fremitus may be detected on rectal palpation of the root of the cranial mesenteric artery. This disease should be considered a differential diagnosis in horses with a history of inadequate anthelmintic treatment and the presence of intermittent colic that is difficult to localize. Although fecal parasite egg counts should be performed, they are not indicative of the degree of parasitic infestation.

In addition to routine treatment of colic, dehydration, and endotoxemia, medical treatment may include aspirin (20 mg/kg/day) to decrease thrombosis.[11] Definitive diagnosis requires surgical exploration. Affected horses can be difficult to treat because of the patchy distribution of the lesions and the possibility of lesions extending beyond the limits of surgical resection. Further infarction may occur after surgery. The prognosis is fair for horses with intermittent mild episodes of colic that may be amenable to medical therapy but poor in horses that require surgical intervention.[1111]

Obstructive Disorders of the Gastrointestinal Tract

Examination and approach to the horse with colic are discussed in Chapter 7; pain management is discussed in Chapter 3. These are critical factors in the diagnosis and treatment of a horse with obstructive disease.

SMALL INTESTINAL SIMPLE OBSTRUCTION

Simple obstruction involves intestinal obstruction of the lumen without obstruction of vascular flow. Because there is a tremendous volume of fluid that enters the small intestinal lumen on a daily basis, the obstructed intestine tends to become distended, which in turn may cause reduced mural blood flow.[879] Ultimately, such distention can result in necrosis of tissues, particularly in the immediate vicinity of the obstruction.[1112] There are relatively few causes of simple obstruction in the small intestine, and the incidence of these types of obstructions is low (approximately 3% of all referred horses in one large hospital-based study).[1041] In some geographic regions this type of obstruction has a higher prevalence. For example, in the southeastern United States, ileal impactions are relatively common.[1113-115]

Ascarid Impaction

Impactions caused by *Parascaris equorum* typically occur in foals younger than 6 months of age that have been on a poor deworming program and have a heavy parasite burden. Products that cause sudden ascarid death, including organophosphates, ivermectin, and pyrantel pamoate, have been incriminated in triggering acute intestinal obstruction by dead parasites.[1116] This is a particular problem with ascarids because of the relatively large size of the adult parasite. Clinical signs include acute onset of colic after administration of an anthelmintic and signs compatible with small intestinal obstruction, including nasogastric reflux. Occasionally, dead parasites are present in the reflux. The onset of the disease varies according to the degree of obstruction.[1116] A tentative diagnosis may be made on the basis of the history and signs referable to small intestinal obstruction. Abdominal ultrasound may indicate the presence of multiple loops of distended small intestine and can be used to estimate ascarid burden within the small intestine.[1117] Initial medical treatment should include pain management and supportive care. Surgical treatment may involve an enterotomy removal of ascarids, although manual reduction without enterotomy was associated with improved survival in one report.[1118] The prognosis is fair in cases that are rapidly addressed but poor in foals with evidence of hypovolemia and septic shock. In one study, long-term survival of 25 affected horses was 33%.[1116] Another reported 80% short-term survival and 60% survival to 1 year.[1118]

Ileal Impaction

Ileal impactions occur most commonly in adult horses in the southeastern United States. Although feeding of coastal Bermuda hay has been implicated in this regional distribution,[1115] it has been difficult to separate geographic location from regional hay sources as risk factors.[1119] Nonetheless, it is likely that feeding suboptimal quality coastal Bermuda hay puts horses at risk for ileal impaction, possibly because this type of hay may have a high fiber content and thin strands that can lead to premature swallowing. The relationship between fiber content and eating patterns is theoretical and remains to be proved. Sudden changes in feed from an alternative type of hay to coastal Bermuda hay likely put a horse at risk for ileal impaction.[1119] Studies in the United Kingdom have revealed tapeworm infection as an important risk factor for ileal impaction. Based on risk analysis, the data suggested that more than 80% of the ileal impaction cases studied were associated with serologic or fecal evidence of tapeworm infection.[1120] Because of the poor sensitivity of fecal analysis for tapeworms, a serologic test (ELISA) has been developed by Proudman et al. with a sensitivity of approximately 70% and a specificity of 95%.[1121,1122]

Clinical signs of horses with ileal impaction are typical for a horse with small intestinal obstruction, including onset of moderate to severe colic and rectally palpable loops of distended small intestine as the condition progresses. Because the ileum is the distal-most aspect of the small intestinal tract, nasogastric reflux may take a considerable time to develop and is found in only approximately 50% to 60% of horses requiring surgical correction of impacted ileum[1113,1123]; reflux is more likely in horses with ileal impaction taken to surgery.[1113] A definitive diagnosis is usually made at surgery, although an impacted ileum may on occasion be palpated rectally.[1114] Multiple loops of distended small intestine make the impaction difficult to palpate. More than 50% of ileal impactions may resolve with medical treatment.[1113] Most reports indicate a good to excellent prognosis for short-term survival[1113, 1115, 1123] with 1-year survival of 91% to 92% in horses treated surgically or medically.[1113]

Ileal Hypertrophy

Ileal hypertrophy is a disorder in which the muscular layers (both circular and longitudinal) of the ileum thicken for unknown reasons (idiopathic) or secondary to an incomplete or functional obstruction. A proposed mechanism for idiopathic ileal hypertrophy is parasympathetic neural dysfunction resulting in chronically increased muscle tone and subsequent

hypertrophy of the muscular layers of the ileal wall. Such neural dysfunction possibly results from parasite migration.[1124] Alternative hypotheses include chronic increases in the muscular tone of the ileocecal valve, leading to muscular hypertrophy of the ileum as it contracts against a partially occluded ileocecal valve. The jejunum may also be hypertrophied, either alone or in combination with the ileum.[1124] Clinical signs include chronic intermittent colic as the ileum hypertrophies and gradually occludes the lumen. Partial anorexia and chronic weight loss (1–6 months) were documented in 45% of affected horses, most likely because of intermittent colic and reduced appetite.[1124] Because the ileal mucosa is not affected by this condition, there is no reason to believe that these horses experience malabsorption of nutrients. The diagnosis is usually made at surgery, although the hypertrophied ileum may be palpated rectally in some cases.[1124] An ileocecal or jejunocecal anastomosis to bypass the hypertrophied ileum is usually performed in affected horses. Without surgical bypass intermittent colic persists, and the thickened ileum may ultimately rupture.[1124] The prognosis is fair with surgical treatment.[1125]

Secondary ileal hypertrophy is most commonly noted in horses that have previously had colic surgery and that may have a partial or functional obstruction at an anastomotic site. For example, in one case report a horse developed ileal hypertrophy after surgical correction of an ileocecal intussusception.[1126] Ileal hypertrophy was also observed in a horse in which an ileocolic anastomosis was incorrectly oriented during surgical treatment of a cecal impaction.[1000] Horses are typically reexamined for recurrence of colic in these cases. Surgical therapy is directed at addressing the cause of small intestinal obstruction and resecting hypertrophied intestine.

Meckel's Diverticulum

Meckel's diverticulum is an embryonic remnant of the vitelloumbilical duct, which fails to completely atrophy and becomes a blind pouch projecting from the antimesenteric border of the ileum.[1127,1128] Similar diverticula have also been noted in the jejunum.[1129] These diverticula may become impacted, resulting in partial luminal obstruction, or may wrap around an adjacent segment of intestine, causing strangulation.[1128] Occasionally, an associated mesodiverticular band may course from the diverticulum to the umbilical remnant and serve as a point around which small intestine may become strangulated. Mesodiverticular bands may also originate from the embryonic ventral mesentery and attach to the antimesenteric surface of the bowel, forming a potential space within which intestine may become entrapped.[1038] Clinical signs range from chronic colic, for an impacted Meckel's diverticulum, to acute, severe colic if a mesodiverticular band strangulates intestine. The diagnosis is made at surgery, and treatment requires resection of the diverticulum and any associated bands.[1038] The prognosis is good for horses with simple impaction of a Meckel's diverticulum and guarded for horses with an associated small intestinal strangulation.[1038]

Adhesions

Adhesions of one segment of bowel to another or of a segment of intestine to other organs and the body wall typically occur after abdominal surgery and may be clinically silent, cause chronic colic attributable to partial obstruction, or result in acute obstruction. These differing clinical syndromes are attributable to the type of adhesions that develop. For example, a fibrous adhesion that does not by itself obstruct the intestinal lumen might serve as the pivot point for a volvulus, whereas an adhesion between adjacent segments of the intestinal tract may create a hairpin turn that causes chronic partial obstruction.[1130] The number of adhesions that develop may also vary dramatically from horse to horse. Some horses may develop a single adhesion adjacent to an anastomotic site or a discrete segment of injured intestine, whereas other horses may develop diffuse adhesions involving multiple segments of intestine, likely because of widespread inflammatory disease at the time of the original surgery.

The mechanisms by which adhesions develop are complex but likely involve injury to the serosa initiated by intestinal ischemia, reperfusion injury, and luminal distention.[1037] Such injury involves infiltration of neutrophils into the serosa, accompanied by loss of mesothelial cells. In one study assessing the margins of resected small intestine, extensive neutrophil infiltration was documented in the serosa, particularly in the proximal resection margin that had been distended before correction of a variety of strangulating lesions.[868] Regions of serosal injury and inflammation subsequently undergo reparative events similar to those of any wound, including local production of fibrin, de novo synthesis of collagen by infiltrating fibroblasts, and ultimately maturation and remodeling of fibrous tissue. Unfortunately, during this process fibrin may result in injured intestinal surfaces adhering to adjacent injured bowel or an adjacent organ. Once a fibrinous adhesion has developed, new collagen synthesis may result in a permanent fibrous adhesion. Alternatively, fibrinous exudate may be lysed by proteases released by local phagocytes, reversing the adhesive process. Formation of adhesions may be viewed as an imbalance of fibrin deposition and fibrinolysis.[1131]

Prevention of adhesions relies on inhibition of the mechanisms involved in adhesion formation, including reduction of serosal injury with early intervention and good surgical technique, reduction of inflammation by administration of antiinflammatory medications, physical separation of inflamed serosal surfaces (e.g., carboxymethylcellulose, hyaluronan),[1132-1134] and pharmacologic modulation of fibrinous adhesion formation (e.g., heparin[1135]). Early return of motility in the small intestine after surgery may reduce contact time between inflamed surfaces of intestine, reducing the chances of adhesion formation.[1131]

Horses at greatest risk of developing adhesions after colic surgery appear to be those that have small intestinal disease.[1130] In one study of horses undergoing surgical correction of small intestinal obstruction, 22% developed a surgical lesion associated with adhesions. Foals appear to have an increased incidence of adhesions compared with mature horses, regardless of the nature of the abdominal surgery.[1130] One study indicated that 17% of foals developed lesions attributable to adhesions regardless of the type of the initial surgery.[1136] Studies conflict as to whether the degree of surgical intervention influences adhesion formation,[1130] but horses that require enterotomy or resection and anastomosis were at greatest risk of developing adhesions in one study.[1137] Adhesions are among the most important reasons for repeat laparotomy in postoperative colic patients.[1137,1138]

Clinical signs in horses with adhesions are highly variable, depending on whether the adhesion is causing partial obstruction, complete luminal obstruction, or involvement of intestinal vasculature. Adhesions are an important differential for intermittent colic in the postoperative period, particularly if such colic was not relieved by nasogastric decompression

of the stomach. Continued intermittent colic should prompt abdominocentesis to determine whether there is evidence of septic peritonitis, which may contribute to adhesion formation. If postoperative colic persists, repeat laparotomy or laparoscopy may be elected. In one study on adhesions, 70% of repeat laparotomies were performed within 60 days, suggesting that surgical colic attributable to adhesions typically occurs within 2 months of an initial surgical procedure. Unfortunately, the prognosis for horses with colic attributable to adhesions is poor, with only 16% of horses surviving adhesion-induced colic in one study.[1130]

LARGE INTESTINAL SIMPLE OBSTRUCTION

Simple obstructions of the large intestine, such as impaction, tend to have a more gradual onset than those of the small intestine, although horses may experience acute and severe pain with some forms of colon displacement. In fact, some of these cases mimic and may progress toward large colon volvulus. Medical therapy is frequently successful in correcting large colon impactions. However, cecal impactions present much more of a dilemma because of the greater propensity of this organ to rupture, the relative difficulty of surgically manipulating the cecum, and the onset of cecal dysfunction that may prevent the cecum from emptying after surgical resolution of impaction.

Cecal Impaction

Cecal impaction may be divided into two syndromes: primary cecal impactions that result from excessive accumulation of ingesta in the cecum and secondary cecal impactions that develop while a horse is being treated for a separate problem.[936,1139] Although primary impactions typically consist of impacted, relatively dry fecal material and secondary cecal impactions tend to have very fluid contents, there is considerable overlap between the two syndromes. In horses with primary cecal impactions, there is a gradual onset of abdominal pain over a number of days reminiscent of the development of a large colon impaction. Cecal impactions should be differentiated from large colon impactions on the basis of rectal palpation findings. These impactions have a propensity to rupture before the development of severe abdominal pain or systemic deterioration and therefore must be closely monitored.[1139] Secondary cecal impactions typically develop after unrelated surgical procedures that result in postoperative pain (particularly orthopedic surgeries).[1140] Secondary cecal impactions may be even more difficult to detect because postoperative depression and decreased fecal output may be attributed to the operative procedure rather than colic. By the time horses with secondary cecal impactions show noticeable signs of colic, the cecum may be close to rupture. In many cases there will be no signs of impending rupture.[1140] Therefore the feed intake and manure production of all horses that undergo surgery in which considerable postoperative pain may develop should be closely monitored. A recent study indicated that horses producing less than three piles of manure daily in the postoperative period are at risk of developing a large intestinal impaction. Horses that underwent prolonged (>1 hour) orthopedic surgery that received inadequate treatment with phenylbutazone were at considerable risk of reduced postoperative fecal output.[1141]

A diagnosis of cecal impaction is based on rectal palpation of a firm, impacted or fluid-filled cecum. In some cases, cecal impactions may be difficult to differentiate from large colon impactions. Careful palpation, however, will reveal the inability to move the hand completely dorsal to the impacted viscus because of the cecum's attachment to the dorsal body wall.

Treatment may include initial medical therapy with IV or oral fluids and analgesics, or surgical intervention with typhlotomy alone or jejunocecostomy. In two recent larger scale retrospective studies, the prognosis appeared to vary significantly by geographic region.[1139,939] In one, a very favorable short-term outcome was achieved with either medical (81%) or surgical (95%) management.[939] In the majority of surgical cases, typhlotomy alone was performed. In another, short-term outcome was less favorable with either medical (61%) or surgical (82%) management.[1139] Many (68%) cases in the latter report appeared to have secondary cecal impactions as they had recent illness or surgery unrelated to gastrointestinal disease. This report underscores the importance of prompt diagnosis and supports the benefit of early surgical intervention.

Large Colon Impaction

Ingesta impactions of the large colon occur at sites of anatomic reductions in luminal diameter, particularly the pelvic flexure and the right dorsal colon.[1142] Although there are a number of reported risk factors, most have not been proved. A sudden restriction in exercise associated with musculoskeletal injury appears to be frequently associated with onset of impaction.[1143] Twice-daily feeding of concentrate results in large fluxes of fluid into and out of the colon, associated with readily fermentable carbohydrate in the colon and subsequent increases in serum aldosterone, respectively.[1144] These fluid fluxes, which may cause dehydration of ingesta during aldosterone-stimulated net fluid flux out of the colon, may be prevented with frequent small feedings.

Impaction of the ascending colon can be induced by the drug amitraz, an acaricide associated with clinical cases of colon impaction,[1145,1146] providing some clues as to the pathogenesis of large colon impaction. Amitraz appears to alter pelvic flexure pacemaker activity, resulting in uncoordinated motility patterns between the left ventral and left dorsal colon and excessive retention of ingesta. Absorption of water from the ingesta increases with retention time, dehydrating the contents of the colon and resulting in impaction. It is conceivable that parasite migration in the region of a pacemaker may have a similar action.[653] Other factors implicated in large colon impaction include limited exercise, poor dentition, coarse roughage, and dehydration.

Clinical signs of large colon impaction include slow onset of mild colic. Fecal production is reduced, and the feces are often hard, dry, and covered with mucus because of delayed transit time. The heart rate may be mildly elevated during episodes of pain but is often normal. Signs of abdominal pain are typically well controlled with administration of analgesics but become increasingly more severe and refractory if the impaction does not resolve. The diagnosis is based on rectal palpation of a firm mass in the large colon. The extent of the impaction may be underestimated by rectal palpation alone because much of the colon remains out of reach.[1142] Adjacent colon may be distended if the impaction has resulted in complete obstruction. Initial medical treatment should include pain management and enteral fluid therapy if reflux is not obtained on nasogastric intubation. Hydration of colonic contents is superior with

enteral fluid therapy compared with IV fluid therapy.[1147,1148] Saline cathartics such as magnesium sulfate (0.1 mg/kg in 2–4 L by nasogastric tube) may also be useful. Access to feed should not be permitted. If the impaction remains unresolved, the horse's pain becomes uncontrollable, or extensive gas distention of the colon occurs, surgery is indicated. At surgery the contents of the colon are evacuated by way of a pelvic flexure enterotomy. Long-term survival is good with medical management (95%) and fair (58%) in horses that require surgical intervention.[1143]

Enteroliths

Enteroliths are mineralized masses typically composed of ammonium magnesium phosphate (struvite).[37] However, magnesium vivianite has also been identified in enteroliths, along with variable quantities of Na, S, K, and Ca. The formation of Mg-based minerals is puzzling because of the relative abundance of Ca in colonic fluids, which would favor the formation of Ca phosphates (apatite) rather than struvite. Elevated dietary intake of magnesium and protein may play a role. Feeding of alfalfa hay and decreased dietary proportions of grass hay and pasture grass have been consistently identified as risk factors in horses with enterolithiasis.[1149-1151] Alfalfa hay has a concentration of magnesium approximately six times the daily requirements of the horse.[1152] The high protein concentration in alfalfa hay may contribute to calculus formation by increasing the ammonia nitrogen load in the large intestine. Enteroliths most commonly form around a nucleus of silicon dioxide (a flintlike stone), but nidi have included nails, rope, and hair that have been ingested.[1153] Enteroliths are usually found in the right dorsal and transverse colons.[1152] Although enterolithiasis has a wide geographic distribution, horses in California have the highest incidence. In one California study, horses with enterolithiasis represented 28% of the surgical colic population, and Arabians, Morgans, American Saddlebreds, and donkeys were at greatest risk of this disease.[37] In a study of enterolithiasis in Texas, risk factors also included feeding of alfalfa hay and the Arabian breed. In that study, Miniature Horses were also found to be at risk.[1149] Horses with enteroliths are rarely younger than 4 years old, with a median age of 11 in one report[37]; an enterolith has been reported in an 11-month-old Miniature Horse.[1154]

The most common reported clinical signs are episodic mild to moderate abdominal pain.[37,1152] Enteroliths may be diagnosed by abdominal radiography or at surgery.[40,1155] On rare occasions an enterolith may be palpated rectally, particularly if it is present in the distal small colon.

Generally, surgery is required, although there are reports of enteroliths being retrieved rectally. In one study 14% of horses that required treatment of enterolithiasis had a history of passing an enterolith in the feces.[37] Enteroliths are typically located in the right dorsal colon, transverse colon, or small colon. After removal of an enterolith, further exploration must be conducted to determine whether other enteroliths are present. Solitary enteroliths are usually round, whereas multiple enteroliths have flat sides. The prognosis is good (92% 1-year survival in 900 horses), unless the colon is ruptured during removal of an enterolith, which was reported in 15% of cases.[37]

Sand Impaction of the Large Colon

Sand impactions are common in horses with access to sandy soils, particularly horses whose feed is placed on the ground. Some horses, especially foals, deliberately eat sand. Fine sand tends to accumulate in the ventral colon, whereas coarse sand may accumulate in the dorsal colon.[737,1156] Individual differences in colonic function may contribute to accumulation of sand because some horses can clear consumed sand, whereas others cannot. Distention resulting from the impaction itself, or gas proximal to the impaction, causes abdominal pain. Sand may also trigger diarrhea, presumably as a result of irritation of the colonic mucosa.[738] In horses with sand impactions, clinical signs are similar to those of horses with large colon impactions. Sand may be found in the feces, and auscultation of the ventral abdomen may reveal sounds of sand moving within the large colon.[1157] The diagnosis is made via radiography or surgery but may be tentatively based on clinical signs compatible with a large colon impaction and evidence of sand in the feces. Sand sedimentation is performed by mixing feces with water in a rectal palpation sleeve or other container. Abdominal radiographs can be used to detect mineral opacity within the ventral colon.[38,1158] Ultrasonography can also be used to support the diagnosis but is not as accurate as radiography.[1159] Abdominal paracentesis is not recommended in suspected cases, because large quantities of sand in the ventral colon make inadvertent perforation of the colon more likely.[737]

Medical management typically offers a good prognosis.[1160] Administration of psyllium hydrophilic mucilloid (0.25–0.5 kg/500 kg in 2 L mineral oil by stomach tube) may facilitate passage of sand. If mixed with water, it should be administered rapidly because of formation of a viscous gel. The psyllium leaves the oil phase and mixes with the water, forming a gel within the stomach. Psyllium is thought to act by stimulating motility or agglutinating the sand. However, one experimental study failed to show a benefit of this treatment.[1161] If a severe impaction is present, then psyllium should not be given until the impaction is softened by administering IV or oral fluids and other laxatives. Perforation is a potential complication in horses with sand impactions because the sand stretches and irritates the intestinal wall and causes inflammation. If colic becomes intractable, surgical evacuation of the large colon should be performed. The prognosis is generally regarded as good.[737,1156]

Large Colon Displacement

Displacement of the ascending colon is a common cause of large intestinal obstruction. The ascending colon is freely movable except for the right dorsal and ventral colons. Contact with adjacent viscera and the abdominal wall tends to inhibit movement of the ascending colon from a normal position; accumulation of gas and fluid or ingesta, however, may cause the colon to migrate.[1162] Feeding behavior, including feeding of large concentrate meals, likely plays a role in initiating displacement of the large colon. Large concentrate meals increase the rate of passage of ingesta, allowing a greater percentage of soluble carbohydrates to reach the large intestine.[1163] This in turn increases the rate of fermentation and the amount of gas and volatile fatty acids that are produced. The production of large amounts of volatile fatty acids stimulates the secretion of large volumes of fluid into the colon.[2] The association between feeding concentrate and development of displacements of the large colon is illustrated by studies indicating that ascending colon displacement is more prevalent in horses fed a high-concentrate, low-roughage diet.[1164] Abnormal motility patterns of the ascending colon may also contribute to the development of colonic displacement. Feeding stimulates colonic motility by way of the gastrocolic reflex, but large meals may alter normal

motility patterns and concurrently allow rapid accumulation of gas and fluid resulting from fermentation.[1163,1165] Migration of parasite larvae (strongyles) through the intestinal wall also alters colonic motility patterns.[650] *S. vulgaris* infection results in reduced blood flow to segments of the large intestine without necessarily causing infarction. Electrical activity of the colon and cecocolic junction increases after infection with *S. vulgaris* and cyathostome larvae, probably reflecting a direct effect of migration through the intestine and an early response to reduced blood flow.[650]

Displacements of the ascending colon are generally divided into three types: left dorsal displacement, right dorsal displacement, and retroflexion.[1162,1166] Left dorsal displacement is characterized by entrapment of the ascending colon in the renosplenic space. The colon is often twisted 180 degrees, such that the left ventral colon is situated in a dorsal position relative to the left dorsal colon. The entrapped portion may be only the pelvic flexure or may involve a large portion of the ascending colon, with the pelvic flexure situated near the diaphragm. The colon may become entrapped by migrating dorsally between the left abdominal wall and the spleen or may migrate in a caudodorsal direction over the nephrosplenic ligament.[1166] Occasionally, the ascending colon can be palpated between the spleen and abdominal wall, lending support to the first mechanism of displacement. Gastric distention is thought to predispose horses to left dorsal displacement of the ascending colon by displacing the spleen medially, allowing the colon room to migrate along the abdominal wall.[1166] Right dorsal displacement begins by movement of the colon cranially, either medial (medial flexion) or lateral (lateral flexion) to the cecum. According to one author, the proportion of right dorsal displacements with medial versus lateral flexion is approximately 1:15.[1166] In either case the pelvic flexure ends up adjacent to the diaphragm. Retroflexion of the ascending colon occurs by movement of the pelvic flexure cranially without movement of the sternal or diaphragmatic flexures.

Displacement of the ascending colon partially obstructs the lumen, resulting in accumulation of gas or ingesta and causing distention. The distention may be exacerbated by the secretion of fluid in response to the distention. Tension and stretch of the visceral wall are important sources of the pain associated with colonic displacement. Tension on mesenteric attachments and the root of the mesentery by the enlarged colon may also cause pain.[1162] Ischemia is rarely associated with nonstrangulating displacement of the colon. Congestion and edema, however, are often seen in the displaced segments of colon because of increased hydrostatic pressure from reduced venous outflow. Morphologic damage to tissues is usually minor.

Clinically, displacement of the ascending colon is often characterized by intermittent signs of mild to moderate abdominal pain of acute onset, but an insidious onset may also be noted.[1166] Dehydration may occur if the duration of the displacement is prolonged. The heart rate may be increased in conjunction with abdominal pain but is often normal. Abdominal distention may be present, and fecal production is reduced. Left dorsal displacements are often diagnosed by rectal palpation, because the ascending colon can be traced to the nephrosplenic space, and the spleen may be displaced medially. Alternatively, a tentative diagnosis can be reached using abdominal ultrasonography.[1167] The spleen can be imaged on the left side of the abdomen, but the left kidney will be obscured by gas-distended bowel. Evaluation of this technique indicates that there are very few instances of false-positive results, although false-negative results may occasionally occur.[1167] A definitive diagnosis may require surgery. Right dorsal displacements are characterized by the presence of the distended ventral colon running across the pelvic inlet and may be felt between the cecum and the body wall if a lateral flexion is present. The pelvic flexure is usually not palpable. Retroflexion of the ascending colon may produce a palpable kink in the colon. If the displaced colons are not distended by gas in the instance of right dorsal displacement and retroflexion, the ascending colon may not be palpable and is conspicuous by its absence from a normal position. Horses with right dorsal displacement often have an increased GGT, relative to horses with left dorsal displacement, which is presumptively caused by compression of the bile duct and temporary extrahepatic obstruction.[17]

For nephrosplenic entrapment of the large colon, medical management is often effective.[1167-1169] Medical therapy with phenylephrine and rolling under anesthesia (84%) was significantly more effective than phenylephrine (3–6 μg/kg/min over 15 minutes) and exercise (63.2%) in a recent report.[1169] There are reports of fatal internal hemorrhage caused by rupture of large blood vessels after treatment of older horses with phenylephrine, and the drug should probably be used with caution in horses older than 15 years.[1170]

Medical therapy has also been reported effective (64%) in horses with right dorsal displacement,[1171] although definitive diagnosis of that condition is challenging without surgical confirmation. If medical management is not successful, horses should undergo surgery promptly. Surgical prognosis for horses with large colon displacement is good. A number of horses will suffer recurrence of nephrosplenic entrapment of the colon. Currently, the least invasive method of preventing this complication is laparoscopic closure of the nephrosplenic space.[78,1172,1173]

Foreign Body and Fecalith Obstruction

Foreign material such as bedding, rope, plastic, fence material, and feedbags can cause obstruction and may be ingested, particularly by young horses. These foreign bodies may result in impaction with ingesta and distention of the intestine, typically in the transverse or descending colon. Young horses are usually affected. In one study the obstructing mass could be rectally palpated in three of six horses.[1174] Fecaliths are common in ponies, miniature horses, and foals.[1175] Older horses with poor dentition may also be predisposed to fecaliths because of the inability to fully masticate fibrous feed material. Fecaliths commonly cause obstruction in the descending colon and may cause tenesmus.[1174] Other clinical signs are similar to those of enterolithiasis. Abdominal radiography may be useful in smaller patients to identify the obstruction, especially if gas distention around the foreign body or fecalith provides contrast. Surgical treatment is usually required.

Mural Masses and Strictures

Mural masses such as abscesses, tumors (adenocarcinoma and lymphosarcoma), granulomas, and hematomas can cause luminal obstruction and impaction, typically in older horses. Impaction may result from obstruction of the lumen or impaired motility in the segment of intestine with the mass. Abscesses may originate from the lumen of the intestine or may extend from the mesentery or mesenteric lymph nodes. Intramural hematomas form most commonly in the descending colon and cause acute abdominal pain.[1176] Once the acute

pain caused by the hematoma subsides, impaction proximal to the hematoma develops as a result of impaired motility through the affected portion of the colon. Trauma, ulceration of the mucosa, and parasitic damage are speculated causes of intramural hematomas.[1176,1177] Stricture of the large intestine occurs when fibrous tissue forms in a circular pattern around or within the intestine, reducing the luminal diameter and the ability of the wall to stretch. Strictures may be congenital or secondary to peritonitis, previous abdominal surgery, or inflammatory bowel disease. In a report of 11 horses with inflammatory bowel disease, 6 horses had strictures, 4 of which were in the small intestine and 2 of which were in the large colon.[517]

Clinical signs vary according to the degree of luminal obstruction. Partial obstruction and impaction tend to produce mild to moderate abdominal pain of insidious onset. Mural hematomas tend to produce signs of acute abdominal pain.[1176,1177] Rectal palpation of the abdomen may reveal the presence of a mass or simply the impacted segment, without the mass itself being felt. Fever, weight loss, and anorexia may be noted if an abscess or tumor is the cause. An elevated WBC count; hyperfibrinogenemia; hyperglobulinemia; or normocytic, normochromic anemia may be seen with abscesses or tumors. PF may reflect the cause of the mass. Tumor cells may infrequently be seen. Evidence of inflammation with bacteria may be noted if the cause of colic is an abscess or granuloma, in which case the fluid should be cultured. Hematomas may cause hemorrhage into the PF. Treatment usually requires surgical resection of the mass. Abscesses may be treated with appropriate antibiotics if the impaction can be resolved medically with oral or IV analgesics and laxatives. *Streptococcus* spp., *Actinomyces pyogenes, C. pseudotuberculosis, R. equi,* anaerobic bacteria, and gram-negative enteric organisms are commonly involved in abscesses.

Small Colon Impaction

Small colon impaction is distinct from other forms of impaction in its predispositions and clinical appearance. In one study the key risk factor for impaction of this segment of the intestine was diarrhea.[1178] This paradoxic finding may be explained by edema of the colonic mucosa associated with proinflammatory causes of diarrheal disease that is usually noted in the ascending colon but may extend into the transverse and small colons. Once diarrheal disease is initiated, large volumes of ingesta are rapidly expelled from the ascending colon into the small colon, which has a far smaller diameter, especially if it is edematous. This may result in the initial appearance of diarrhea, followed by intermittent episodes of colic that may be explained by impaction. Diagnosis is by rectal examination, during which the rectum typically feels edematous and gritty. The most important point to remember is that horses should be closely assessed for impaction even if diarrheal disease is present. Other parameters that are typically helpful for assessing the severity of colic, such as heart rate, are not predictive of obstruction in horses with small colon impaction.[1178] Horses may be treated medically during the early stages with fluids, laxatives, and analgesics. The key clinical sign that indicates the need for surgery appears to be abdominal distention, associated with distention of the large colon. Other clinical signs, such as elevations in heart rate and refractory colic, are less pronounced in this disease. Postdiarrheal disease is not the only form of small colon impaction. These impactions can be formed as simple collections of ingesta or in response to luminal narrowing.

Atresia Coli

Atresia of a segment of the colon is a rare congenital abnormality in horses.[1179] The heritability and causes of the condition are unknown. One potential mechanism for development of the lesion is intestinal ischemia during fetal life, which secondarily results in necrosis of a segment of intestine.[1179] Clinical signs include a failure to pass meconium and colic within the first 12 to 24 hours of life. Secondary abdominal distention results from complete intestinal obstruction, and abdominal radiographs may reveal a gas-distended colon. The diagnosis is made at surgery. Any portion of the colon may be absent, but the distal segment of the large colon or the proximal small colon (or both) is usually most severely affected. If sufficient tissue is present, anastomosis to the proximal blind end of the colon may be attempted.[1179] The prognosis depends on the segment of the colon that is absent but is usually poor because of an absence of distal colon.

Ileocolonic Aganglionosis

Ileocolonic aganglionosis, commonly known as *lethal white foal syndrome* (LWFS), occurs in white foals with overo-spotted parents. Affected foals are either completely white or have very little pigmented hair around the muzzle, base of the tail, or hooves. They are homozygous for an abnormal endothelin receptor B (EDNRB) gene that results in altered neural crest cell migration or survival, which affects progenitor cells for melanocytes and intestinal ganglia.[1180,1181] The EDNRB genotype is highly correlated with white patterning; frame overo, highly white calico overo, and frame blend overo have the highest incidence of heterozygotes.[1182] Rarely, an LWFS-affected foal may be born to a solid-colored mare. Homozygous foals have aganglionosis of the submucosal and myenteric ganglia of the distal portion of the ileum and large intestine, and extrinsic innervation of the ileum and pelvic flexure has been identified.[1183,1184] This results in a foal that appears normal at birth but develops signs of intestinal ileus and colic within 12 to 24 hours. The eyes are blue, and the skin is pink. A genetic test is available to identify horses that are heterozygous for the defective EDNRB gene.

Diseases of the Oral Cavity, Esophagus, and Stomach

ORAL CAVITY

The mouth is bounded laterally by the cheeks, dorsally by the palate, and ventrally by the body of the mandible and by the mylohyoideus muscles. The caudal margin is the soft palate. The mouth of the horse is long and cylindric, and when the lips are closed, the contained structures almost fill the cavity. A small space remains between the root of the tongue and the epiglottis and is termed the *oropharynx*. The cavity of the mouth is subdivided into sections by the teeth. The space external to the teeth and enclosed by the lips is termed the *vesicle* of the mouth, and in the resting state the lateral margins of the vesicle, that is, the buccal mucosa, are in close contact with the cheek teeth. Caudally, the external space communicates with

the pharynx through the aditus pharyngis. The mucous membrane of the mouth is continuous at the margin of the lips with the skin and during life is chiefly pink but can be more or less pigmented, depending on the skin color and the breed type.

Morphology and Function

The lips are two muscular membranous folds that unite at angles close to the first cheek teeth. Each lip presents an outer and an inner surface. The upper lip has a shallow median furrow (philtrum); the lower lip has a rounded prominence or chin (mentum). The internal surface is covered with a thick mucous membrane that contains small, pitted surfaces that are the openings of the ducts of the labial glands. Small folds of the mucous membrane called the frenulum labii pass from the lips to the gum.

The free border of the lip is dense and bears short, stiff hairs. The arteries of the mouth are derived from the maxillary, mandibular, labial, and sphenopalatine arteries of the major palatine artery. The veins drain chiefly to the lingual facial vein. Sensory nerves originate from the trigeminal nerve (cranial nerve V) and the motor nerves from the facial nerve (cranial nerve VII). The cheeks spread back from the lips and form both sides of the mouth and are attached to the alveolar borders of the bones of the jaws. The cheeks are composed of skin and muscular and glandular layers and then the internal mucous membrane. The skin is thin and pliable. In contrast, the oral mucous membrane is dense and in many areas of the oral cavity is attached firmly to the periosteum so that construction of oral mucosal flaps can be achieved only by horizontal division of the periosteal attachment. Such a feature is important in reconstructive techniques applied to the oral cavity. The blood supply to the cheeks comes from the facial and buccal arteries and the sensory nerves from the trigeminal and motor nerves from the facial nerve.

The hard palate (palatum durum) is bounded rostrally and laterally by the alveolar arches and is continuous with the soft palate caudally. The hard palate has a central raphe that divides the surface into two equal portions. From the line of the rostral cheek tooth, the hard palate is concave to the line of the caudal cheek tooth. Paired transverse ridges (about 18) traverse the concavity and have their free edges directed caudally. The incisive duct is a small tube of mucous membrane that extends obliquely through the palatine fissure. The dorsal component communicates by a slitlike opening in the rostral portion of the ventral nasal meatus, and its palatine end is blind and lies in the submucosa of the palate. When stallions display their flehmen response, watery secretions enter the nose from the glands of the vomeronasal duct. To what extent these secretions aid in pheromone reception is not known.[1185]

That portion of the palatine mucosa immediately behind the incisor teeth frequently is swollen (lampas) during eruption of the permanent teeth. This swelling is physiologic, not pathologic.

The tongue is situated on the floor of the mouth between the bodies of the mandible and is supported by the sling formed by the mylohyoideus muscles. The root of the tongue is attached to the hyoid bone, soft palate, and pharynx. The upper surface and the rostral portion of the tongue are free; the body of the tongue has three surfaces. The apex of the tongue is spatulate and has a rounded border. The mucous membrane adheres intimately to the adjacent structure and on the dorsum is dense and thick. From the lower surface of the free part of the tongue, a fold of mucous membrane passes to the floor of the mouth, forming the lingual frenulum. Caudally, a fold passes on each side of the dorsum to join the soft palate, forming the palatoglossal arch. Dorsally from the soft palate the palatopharyngeal arch attaches and circumvents the aditus laryngis and attaches to the roof of the nasopharynx. The mucous membrane of the tongue presents four kinds of papillae:

1. Filiform papillae are fine threadlike projections across the dorsum of the tongue. They are absent on the root of the tongue and are small on the rostral portion of the tongue.
2. The fungiform papillae are larger and easily seen at the rounded free end. They occur principally on the lateral portion of the tongue.
3. Vallate papillae are usually two or three in number and are found on the caudal portion of the dorsum of the tongue. The free surface bears numerous small, round secondary papillae.
4. Foliate papillae are situated rostral to the palatoglossal arches of the soft palate on which they form a rounded eminence about 2 or 3 cm in length marked by transverse fissures.

Foliate, vallate, and fungiform papillae are covered with taste buds and secondary papillae. The lingual and sublingual arteries supply the tongue from the linguofacial trunk and matching veins. The linguofacial trunk drains into the linguofacial vein. The lingual muscles are innervated by the hypoglossal nerve (cranial nerve XII), and the sensory supply is from the lingual and glossopharyngeal (cranial nerve IX) nerves.

TEETH

The formula for the deciduous teeth of the horse is 2 times I3-3 C0-0 P3-3 for a total of 24. The permanent dental formula is 2 times I3-3 C1-1 P3-3 or P4-3 M3-3 for a total of 40 or 42. In the mare the canine teeth are usually small or do not erupt, reducing the number to 36 or 38. The first premolar tooth (wolf tooth) is often absent and has been reported as occurring in only 20% of the upper dentition of Thoroughbred horses.[1186] The teeth of the horse are complex in shape and are compounded of different materials (dentin, cementum, and enamel). They function as grinding blades to masticate and macerate cellulose food in the important first stage of the digestive process. The cheek teeth in the horse are a well-documented feature of the evolution of *Equus caballus.*

The first deciduous incisor is present at birth or the first week of life. The second incisor erupts at 4 to 6 weeks of age; the third incisor, at 6 to 9 months of age; the first and second premolars, at birth to 2 weeks of age; and the third premolar, at 3 months of age.

The eruption times for the permanent teeth are as follows: first incisor, 2½ years of age; second incisor, 3½ years of age; third incisor, 4½ years of age; the canine tooth, 4 to 5 years of age; the first premolar (wolf tooth), 5 to 6 months of age; the second premolar, 2½ years of age; the third premolar, 3 years of age; the fourth premolar, 4 years of age; the first molar, 10 to 12 months of age; the second molar, 2 years of age; and the third molar, 3½ to 4 years of age. This eruption sequence clearly indicates that the eruption of the second and third permanent premolar teeth have the potential for dental impaction.

The modern horse has six incisor teeth in each jaw that are placed close together so that the labile edges form a semicircle. The occlusal surface has a deep enamel invagination

(infundibulum) filled only partially with cementum. As the incisor teeth wear, a characteristic pattern forms in which the infundibulum is surrounded by rings of enamel, dentin, enamel, and crown cementum in a concentric pattern. Each incisor tooth tapers from a broad crown to a narrow root so as the midportion of the incisor is exposed to wear, the cross-sectional diameters are about equal; that is, at 14 years of age, the central incisor tooth of the horse has an occlusal surface that is an equilateral triangle. Observations on the state of eruption, the angles of incidence of the incisor teeth, and the pattern of the occlusal surfaces are used as guides for the aging of horses. The canine teeth are simple teeth without complex crowns and are curved. The crown is compressed and is smooth on its labial aspect but carries two ridges on its lingual aspect. No occlusal contact occurs between the upper and lower canine teeth.

When erupted, the six cheek teeth of the horse function as a single unit in the mastication of food. Each arcade consists of three premolar and three molar teeth. The maxillary arcade is slightly curved, and the teeth have a square occlusal surface. The occlusal surfaces of the mandibular teeth are more oblong, and each arcade is straighter. The horse is anisognathic—that is, the distance between the mandibular teeth is narrower (one-third) than the distance between the upper cheek teeth. This anatomic arrangement affects the inclination of the dental arcade as the jaws slide across each other in the food preparation process. The unworn upper cheek tooth presents a surface with two undulating and narrow ridges, one of which is lateral and the other medial. On the rostral and lingual side of the medial style is an extra hillock. The central portion of these surfaces is indented by two depressions that are comparable with, but much deeper than, the infundibula of the incisor teeth. When the teeth have been subjected to wear, the enamel that closed the ridges is worn through and the underlying dentin appears on the surface. After a time the chewing surface displays a complicated pattern that may be likened to the outline of an ornate letter B, and the upright stroke of the B is on the lingual aspect. Dentin supports the enamel internally, cementum supports the enamel lakes, and the peripheral cementum fills in the spaces between the teeth so that all six teeth may function as a single unit—that is, the dental arcade. Transverse ridges cross each tooth so that the entire maxillary arcade consists of a serrated edge. The serrations are formed so that a valley is present at the area of contact with adjacent teeth. These serrations match fitting serrations on the mandibular arcade. One should note that the mediolateral mandibular motion while chewing pellets does not provide full occlusal contact as it does when chewing hay.[1187]

The true roots of the cheek teeth are short compared with the total length of the tooth. Cheek teeth have three roots: two small lateral roots and one large medial root. That portion of the crown embedded within the dental alveolus is referred to as the reserve crown, and the term *root* is confined to that area of the tooth that is comparatively short and enamel free. Wear on the tooth gradually exposes the reserve crown, and the roots lengthen. In an adult 1000-lb horse the maxillary cheek teeth are between 8.0 and 8.5 cm in length. Dental wear accounts for erosion and loss of tooth substance at a rate of 2 mm/year. The pulp chambers of the teeth are also complex. The incisors and canines have a single pulp chamber. The mandibular cheek teeth have two roots and two separate pulp chambers. The maxillary cheek teeth, although they have three roots, have five pulp chambers.

As occlusal wear proceeds, deposition of secondary dentin within the pulp chambers protects the chambers (e.g., the dental star, medial to the infundibulum on the incisor teeth). In the mandibular cheek teeth the transverse folding of the enamel anlage (during morphogenesis of the tooth) does not take place, and the occlusal surface is a simple surface of central dentin surrounded by enamel. Each tooth then is conformed to a single arcade by the presence of peripheral crown cementum.

Examination of the Oral Cavity

The oral cavity and oropharynx are subject to a variety of diseases, many of which produce the same clinical signs, regardless of their cause. The classic signs of dental disease in the horse include difficulty and slowness in feeding, together with a progressive unthriftiness and loss of body condition. In some instances, the horse may quid (drop food while chewing), and halitosis may be obvious. Additional problems reported by owners include bitting and riding problems and headshaking or head shyness. Facial or mandibular swelling, nasal discharge (dental disease associated with maxillary sinus), and mandibular fistulae (lower cheek tooth apical infections) are also possible. Some correlation exists between the age of the animal and clinical signs.

One can examine a considerable portion of the mouth and teeth from the outside by palpation of the structures through the folds of the cheek. Most horses allow a cursory oral examination without sedation or the use of an oral speculum. In many horses, however, a detailed oral examination is best achieved after sedation and with the use of an oral speculum and a light source. The mouth should be irrigated to remove retained food material so as to be able to inspect and palpate the lips, cheeks, teeth, and gums.

Ancillary aids for a complete examination of the oral cavity of the horse may include radiology, endoscopic examination, fluoroscopy, biopsy, and culture. Oral endoscopy should be performed with either sedation and an oral speculum or under general anesthesia to prevent inadvertent mastication of the endoscope. CT allows detailed imaging of the oral cavity and sinuses.

Dysphagia

The lips of the horse are mobile and prehensile. Consequently, loss of motor function (e.g., facial palsy) affects the efficiency of the prehensile system. The lips grasp food in grazing or browsing, and the incisor teeth section the food. With mastication and lubrication with saliva, the bolus of food forms and is manipulated from side to side across the mouth, assisted by the tight cheeks of the horse and the palatine ridges. Swallowing begins as the food bolus contacts the base of the tongue and the pharyngeal walls. During swallowing, the soft palate elevates to close the nasopharynx, the base of the tongue elevates, and the hyoid bone and the larynx move rostrally following contraction of the hyoid muscles. During this process, the rima glottidis closes and the epiglottis tilts dorsally and caudally to protect the airway so that food is swept through lateral food channels around the sides of the larynx into the laryngoesophagus. Fluoroscopic studies in nursing foals in the dorsoventral view showed that contact occurs between the lateral food channels in the midline so that in outline the food bolus achieves a bow-tie shape.[1188]

Dysphagia is defined as a difficulty or inability to swallow. Anatomic classifications for dysphagia include prepharyngeal,

pharyngeal, and esophageal (postpharyngeal) dysphagias. The site of the cause for dysphagia influences the clinical signs. Prepharyngeal dysphagia is characterized by dropping food (quidding) or water from the mouth, reluctance to chew, hypersalivation, or abnormalities in prehension. Pharyngeal and esophageal dysphagias are characterized by coughing; nasal discharge containing saliva, water, or food material; gagging; anxiousness; and neck extension during attempts to swallow. The following section describes esophageal dysphagia in more detail. Causes of dysphagia can be divided into four types: painful, muscular, neurologic, or obstructive (Table 12.8). Pain and obstruction cause dysphagia by interfering with the mechanics of prehension, bolus formation and transfer to the pharynx, and deglutition. Muscular and neurologic causes of dysphagia impede prehension and swallowing by affecting the motor function of the lingual or buccal musculature, muscles of mastication (temporal and masseters), and pharyngeal and cranial esophageal muscles. Sensory loss to the lips, buccal mucous membranes, pharynx, or tongue also may cause dysphagia. Neurologic causes of dysphagia may affect the forebrain, brainstem, or peripheral nerves that control prehension (cranial nerves Vm, Vs, VII, and XII), transfer of the food bolus to the pharynx (cranial nerves Vs and XII), and swallowing (cranial nerves IX and X). The latter point was classical thinking, but recent evidence suggests that, while stimulation of cranial nerve IX stimulates swallowing, bilateral blockade of that nerve does not prevent normal swallowing of either liquid or solid material.[1189]

Diagnosis of the cause of dysphagia is based on physical examination including a careful oral examination; neurologic examination; clinical signs; and endoscopy of the pharynx, esophagus, and guttural pouches. Radiology may be useful to assess the bony structures of the head and throat. Ultrasonography is valuable for examining the retropharyngeal space and esophagus to detect and evaluate masses. Pharyngeal or esophageal causes of dysphagia may be detected with routine endoscopic examination or with contrast radiography. Endoscopy may also be used to assess deglutition, but this function may be adversely affected by sedation of the horse. Deglutition may also be assessed using fluoroscopy[1190] or manometry,[1191] but these techniques require specialized equipment. Specific diagnostic procedures for nonalimentary causes of dysphagia are covered elsewhere in this text (see Chapter 7).

TABLE **12.8 Differential Diagnoses for Dysphagia**

Class of Dysphagia	Differential Diagnoses
Painful	Tooth root abscess or periodontal disease
	Broken teeth
	Abnormal dentition or wear
	Stomatitis, glossitis, or pharyngitis
	Nonsteroidal antiinflammatory drug toxicity
	Chemical irritation
	Thrush (candidiasis)
	Influenza
	Streptococcus equi subsp. *equi*
	Vesicular stomatitis virus
	Actinobacillus lignieresii
	Buccal, gingival, or glossal trauma (bits or chains)
	Foreign bodies
	Retropharyngeal lymphadenopathy or abscess
	Mandibular trauma
	Temporohyoid osteoarthropathy
	Temporomandibular osteopathy
Muscular	Hyperkalemic periodic paralysis
	Nutritional myopathy (white muscle disease)
	Polysaccharide storage disease
	Glycogen branching enzyme deficiency
	Masseter myositis
	Hypocalcemia tetany or eclampsia
	Myotonia
	Rectus capitis ventralis rupture
	White snakeroot toxicity
	Megaesophagus
Obstructive	Retropharyngeal abscess and lymphadenopathy
	Oral, pharyngeal, retropharyngeal, laryngeal, or esophageal malformations, injury, edema, or neoplasia
	Pharyngeal or epiglottic cysts
	Pharyngeal abscess or foreign body
	Dorsal displacement of the soft palate
	Cleft palate

TABLE **12.8 Differential Diagnoses for Dysphagia—cont'd**

Class of Dysphagia	Differential Diagnoses
Neurologic forebrain disease; generalized neuropathy; disorders of cranial nerves V, VII, IX, X, or XII	Guttural pouch tympany or empyema Follicular pharyngitis Esophageal obstruction Pharyngeal cicatrix Retropharyngeal abscess or neoplasia Guttural pouch empyema, mycosis, or neoplasia Stylohyoid osteopathy Lead poisoning Petrous temporal bone osteomyelitis or fracture Retropharyngeal abscess Botulism Yellow star thistle toxicity Viral encephalitis Cerebral edema Cerebral or brainstem hemorrhage Intracranial masses (hematoma, neoplasia, and abscess) Meningitis Verminous encephalitis Equine protozoal myeloencephalitis Equine herpesvirus 1 Equine dysautonomia Hepatoencephalopathy Tetanus Polyneuritis equi

Specific treatments aimed at resolving the underlying disorder causing dysphagia are discussed in detail elsewhere. Most horses with dysphagia should not be fed roughage with long fiber length (hay or grass). Dietary modifications that promote swallowing, such as feeding slurries made from complete pelleted feeds, may be sufficient to manage some cases of partial dysphagia. Aspiration pneumonia is a potential complication in horses with pharyngeal or esophageal dysphagia. Foals may be managed by feeding mare's milk or a suitable substitute via nasogastric tube. Pellet slurries or formulated liquid diets may be fed via nasogastric tube to older horses. Prolonged nutritional management of dysphagic horses may require extraoral feeding using a tube placed through an esophagostomy.[1192]

Formulated pelleted diets are often easy to administer through a tube as slurry and are balanced to meet the nutritional requirements for healthy horses. Sufficient quantities must be fed to deliver adequate calories (16–17 Mcal/day for a 500-kg horse). Adjustments may be necessary for horses that are cachectic or have extra metabolic demand (such as pregnancy). Adding corn oil to the ration (1 cup every 12 or 24 hours) is a common method of increasing fed calories. Equine-specific enteral formulations are also available (Well-Gel, Land O'Lakes Purina Feed LLC, Arden Hills, MN). Regardless of the method of nutritional management, salivary losses of electrolytes should be monitored and electrolyte replacement therapy provided as needed. Saliva contains high concentrations of Na, K, and Cl. A group of ponies with experimental esophagostomies[1193] and a horse with esophageal squamous cell carcinoma[1194] were fed a complete pelleted diet through esophagostomy tubes but developed metabolic acidosis, hyponatremia, and hypochloremia apparently because of salivary losses. Surprisingly, salivary losses of potassium did not result in hypokalemia in these cases, presumably because of replacement in the diet. Electrolyte replacement may be accomplished by adding NaCl and KCl to the diet. Horses can be maintained for months with frequent feedings through an esophagostomy tube.[1194] Parenteral nutrition (total or partial) may be useful in the short term but is not often feasible for long-term management.

DENTAL DISEASES

Eruption Disorders

Tooth eruption is a complex phenomenon involving the interplay of dental morphogenesis and those vascular forces responsible for creating the eruption pathway. These changes are responsible for osteitis and bone remodeling within the maxilla and mandible. Young horses frequently show symmetric bony swelling resulting from these eruption cysts. In some cases, additional clinical signs of nasal obstruction with respiratory stridor or nasal discharges may be apparent.

Pathologic problems associated with maleruption include a variety of dental diseases.[1195] Oral trauma can displace or damage erupting teeth or the permanent tooth buds. As a result, teeth may be displaced and erupt in abnormal positions or may have abnormal shapes. Supernumerary teeth, incisors and molars, can develop, as well as palatal displacement of impacted teeth (maxillary P3-3, or third cheek tooth). In almost all of these conditions some form of surgical treatment is necessary, but depending on the number and location, conservative therapy can be successful.[1196]

Dental impaction is a major cause of dental disease in the horse. In a series of 142 extracted teeth, 63 were P3-3 or P4-4 (cheek tooth 2 or 3, respectively).[1197] Early observations had indicated that the first molar (M1, or cheek tooth 4) was the most commonly diseased tooth, and an "open infundibulum" in this tooth has been suggested as the cause.[1198] In a later study, the mandibular cheek teeth 2 and 3 were the most commonly affected, whereas cheek teeth 2 and 4 were most commonly affected in the maxillary arcade, which was the more commonly affected arcade.[1199] Studies on cementogenesis of the maxillary cheek teeth have shown, however, that most maxillary cheek teeth have a greater or lesser degree of hypoplasia of cementum within the enamel lakes and that this "lesion" rarely expands into the pulp. The central infundibular hole is the site of its vascular supply to the unerupted cement lake. On those occasions in which caries of cementum occurs—that is, secondary inflammatory disease and acid necrosis of the cementum—apical osteitis may develop.

Dental Decay

Pulpitis is key to the pathogenesis of dental decay in the horse. The initiation of inflammatory pulp changes may be a sequela to dental impaction or dental caries or may result from fracture of a tooth. If the onset of the inflammatory process is slow, then formation of secondary dentin within the pulp chambers may protect the pulp and the tooth. Secondary dentin formation occurs from stimulation of odontoblasts within the pulp chamber. Such changes are the normal process of protection during dental wear and attrition as crown substances wear away and the reserve crown comes into wear. In acute disease, however, this defense mechanism is ineffective, and the changes that occur and that are sequelae to pulpitis reflect the location of each affected tooth. For example, pulpitis and apical osteitis of the third mandibular cheek tooth most commonly results in the development of a mandibular dental fistula. Pulpitis of the third maxillary cheek tooth, however, results in an inflammatory disease within the rostral maxillary sinus and in development of chronic maxillary sinus empyema.

Oblique radiographs greatly assist the diagnosis of dental decay by demonstrating sinus tract formation, sequestration of bone, mandibular osteitis, hyperplasia of cementum, and new bone formation (so-called alveolar periostitis).[1200] Nuclear scintigraphy and CT can aid in an accurate diagosis.[49,53] The management of dental decay in the horse usually involves surgical extraction of the diseased tooth. In some horses, apicoectomy and retrograde endodontic techniques may be used to save the diseased tooth. Care must be taken, however, in selection of patients. In most cases of apical osteitis in the horse that result from dental impaction, immature root structures make achieving an apical seal of the exposed pulp difficult.

Periodontal Disease

Gingival hyperemia and inflammation occur during the eruption of the permanent teeth and are common causes of a sore mouth in young horses (particularly 3-year-olds as the first dental caps loosen). Such periodontal changes usually resolve as the permanent dental arcade is established. During normal mastication, the shearing forces generated by the occlusal contact of the cheek teeth essentially clean the teeth of plaque and effectively inhibit deposition of dental calculus. Wherever occlusal contact is ineffective, periodontal changes and calculus buildup occur; for example, the deposition of calculus on the canine teeth of mature geldings and stallions is common. Routine dental prophylaxis forms an important component of maintaining normal occlusal contact, and for this reason arcade irregularities that result in enamel point formation on the buccal edges of the maxillary cheek teeth and the lingual edges of the mandibular cheek teeth should be corrected. These edges may be smoothed annually in horses that are at grass and twice yearly in young horses, aged horses, and stabled horses. Horses at grass have a greater range of occlusal contact and therefore better periodontal hygiene than stabled horses. In stabled horses the range of occlusal contact is narrower, and the formation of enamel points occurs more frequently with subsequent buccal ulceration and the initiation of a cycle of altered occlusal contact and, hence, irregular arcade formation. This process leads to severe forms of periodontal disease and wave mouth formation.

Periodontal disease occurs with abnormal occlusal contact and initiation of the cycle of irregular wear and abnormal contact. Such changes progress to loss of alveolar bone, gross periodontal sepsis, and loss of tooth support. In this sense periodontal disease truly is the scourge of the equine mouth and results in tooth loss.[1201]

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES

Cleft Palate

Palatine clefts may result from an inherited defect and are caused by failure of the transverse palatal folds to fuse in the oral cavity. Harelip accompanies few palatine clefts in the horse. The degree of palatine clefting depends on the stage at which interruption in the fusion of the palatopalatal folds occurs. Toxic or teratogenic effects are documented in other species, but few data are available in the horse.

Treatment for repair of uncomplicated palatine defects has been recommended, but prognosis is generally poor because of the considerable nursing care required and the high incidence of surgical failures. Early surgery and the use of mandibular symphysiotomy in affording surgical exposure should be emphasized. The combination of mandibular symphysiotomy and trans-hyoid pharyngotomy to approach the caudal margins of the soft palate affords surgical access, and mucosal flaps can be constructed to repair the defects. The incidence of breakdown in the surgical repair is high, and healing by first intention is the exception rather than the rule. A surgical report documented the successful closure of a median cleft of the lower lip and mandible in a donkey.[1202]

Campylorhinus Lateralis

Foals born with a severely deviated premaxilla and palate have a wry nose. One can achieve a good functional and cosmetic outcome with surgical correction.[1203] Circumstantial evidence indicates that such a defect has a genetic cause, and the defect occurs most frequently in the Arabian breed.

Cysts

Subepiglottic cysts are congenital abnormalities resulting from cystic distortion of remnants of the thyroglossal duct, which may cause dyspnea and choking in foals. Surgical removal of these cysts results in normal function.

Brachygnathism

The most significant developmental defect of dental origin is a maxilla that is longer than the mandible (parrot mouth). An overbite of 2 cm in the incisor arcade may be present in a horse with a mismatch of less than 1 cm between the first upper and lower cheek teeth. Parrot mouth and monkey or sow mouth are thought to be inherited conditions. Some correction of minor incisor malocclusion occurs up to 5 years of age. Recognition and detection of parrot mouth are important in the examination of potential breeding stock. Surgical attempts to inhibit overgrowth of the premaxilla by wiring or by the application of dental bite plate procedures have been documented.[1204]

Oral Wounds

Wounds of the lips, incisive bone, and the mandibular incisor area occur commonly in the horse and usually result from the horse getting the lips, jaw, or teeth caught in feeding buckets, in fence posts, or in halters or having a segment of tongue encircled with hair in tail chewing. As the horse panics and pulls away from its oral entrapment, considerable trauma can occur to the lips, teeth, and gums. Most wounds repair satisfactorily, provided they are identified early after the injury and basic principles of wound hygiene, excision of necrotic tissue, and wound closure are observed. Oral mucosal defects should be closed and effective oral seals made before external wounds are closed. In some horses, offering specially constructed diets or feeding the horse by nasogastric tube or esophagostomy during the healing processes may be necessary.

Stomatitis and Glossitis

Foreign body penetration of the tongue, cheek, or palate has been reported in grazing and browsing horses and in particular in horses that have certain hay sources that contain desiccated barley awns or yellow bristle grass.[1205] Other plant material and grass awns occasionally may penetrate the tongue, gingiva, or cheek, causing inflammation or abscesses. Metallic foreign bodies have been reported in the tongue, and a history of feeding hay or the use of cable-framed tractor tires was often reported as part of the history.[1206] Ulcerative stomatitis may occur as the result of phenylbutazone toxicity.[1207] Vesicular stomatitis is a highly contagious viral blistering disease of horses and other animals. Treatment of glossitis and stomatitis primarily aims at removing the inciting cause. *A. lignieresii,* the causative agent of actinobacillosis, has been isolated and identified from ulcers on the free border of the soft palate and oral and laryngeal granulomata. The bacterium also was reported in a sublingual caruncle in a horse with a greatly swollen tongue.[1208] Therapy with 150 mL of 20% sodium iodide and 5 g of ampicillin every 8 to 12 hours effected a clinical cure.

Salivary Glands

Saliva is important for lubricating and softening food material. The horse has paired parotid, mandibular, and polystomatic sublingual salivary glands. The parotid gland is the largest of the salivary glands in the horse and is situated in the space between the ramus of the mandible and the wing of the atlas. The parotid duct is formed at the ventral part of the gland near the facial crest by the union of three or four smaller ducts. The duct leaves the gland above the linguofacial vein, crosses the tendon of the sternocephalicus muscle, and enters the mouth obliquely in the cheek opposite the third upper cheek tooth. The parotic duct orifice is small, but some dilation of the duct and a circular mucous fold (the parotid papillae) exist at this point. The mandibular gland is smaller than the parotid gland and extends from the atlantal fossa to the basihyoid bone. For the most part, the mandibular gland is covered by the parotid gland and by the lower jaw. The mandibular duct is formed by the union of a number of small duct radicles that emerge along the concave edge of the gland and run rostral to the border of the mouth opposite the canine tooth.

The orifice is at the end of a sublingual caruncle. The mandibular gland possesses serous, mucous, and mixed alveolar glandular components. The parotid gland is a compound alveolar serous gland. The parotid salivary gland can secrete saliva to yield rates of 50 mL/min, and a total daily parotid secretion can be as much as 12 L in a 500-kg horse. Parotid secretion only occurs during mastication, and administration of atropine or anesthesia of the oral mucosa can block secretion. Parotid saliva is hypotonic compared with plasma, but at high rates of flow, concentrations of sodium, chloride, and bicarbonate ions increase.

Parotid saliva of the horse has a high concentration of calcium, and occasionally calculi (sialoliths) form within the duct radicles of the parotid salivary gland.[1209] Congenital parotid duct atresia, acquired stricture from trauma to the duct, or obstruction by plant material (sticks or foxtails and other seeds) also may occur. The clinical signs of sialolithiasis or other forms of ductule obstruction include a fluid swelling in the form of a mucocele proximal to the stone and occasionally inflammation of the parotid gland. Ultrasonography is useful to diagnose salivary mucoceles and to detect foreign bodies or sialoliths. Measurement of electrolyte concentrations in aspirates from suspected mucoceles might be helpful to distinguish them from hematomas. Salivary potassium and calcium concentrations are higher than plasma. Treatment may require surgical removal of the stone or plant material in the case of sialolithiasis or foreign body obstructions. Other causes of obstruction may require resection of the affected portion of the duct or chemical ablation of the gland.[1210]

Primary sialadenitis is unusual but can occur in one or both glands. The condition is painful and may be associated with a fever and anorexia. Secondary sialadenitis is more common and usually is associated with trauma. Infectious sialadenitis from *C. pseudotuberculosis*[1211] or other bacterial pathogens also may occur. Diagnosis is by physical examination and by finding an enlarged edematous parotid gland tissue on ultrasonographic examination. Culture and cytologic examination of aspirates may be useful for diagnostic purposes. Treatment in usually palliative, consisting of NSAIDs. Appropriate antibiotic therapy is indicated as directed by culture and sensitivity results.

Chemical irritation, glossitis, stomatitis, or other causes of prepharyngeal dysphagia cause ptyalism or excessive salivation in horses. Specific therapy for the ptyalism usually is not required as long as salivary losses are not excessive, resulting in dehydration and electrolyte imbalances. Ingestion of the fungal toxin slaframine also causes hypersalivation in horses.[1212] The fungus *Rhizoctonia leguminicola,* which produces slaframine, causes black patch disease in red clover. Slaframine is a parasympathomimetic compound that stimulates exocrine secretion in the parotid gland.

Slaframine toxicosis most commonly occurs in the spring or early summer and rarely requires treatment other than removal from the pasture. Mowing removes the source in most cases because regrowth in pastures often has less fungal contamination.[1213]

ESOPHAGUS

The esophagus is a musculomembranous tube that originates from the pharynx dorsal to the larynx and terminates at the cardia of the stomach.[1214] In adult Thoroughbred horses the esophagus is approximately 120 cm long. The cervical portion is approximately 70 cm long; the thoracic portion, approximately 50 cm long; and the short abdominal portion, only approximately 2 cm long. The cervical esophagus generally lies dorsal and to the left of the trachea in the cervical region. In the thorax the esophagus courses through the mediastinum lying dorsal to the trachea and crosses to the right of the aortic arch dorsal to the heart base.

The esophagus has no digestive or absorptive functions and serves as a conduit to the stomach for food, water, and salivary secretions. The esophageal mucosa is a keratinized stratified squamous epithelium.[1214] The submucosa contains elastic fibers that contribute to the longitudinal folds of the esophagus and confer elasticity to the esophageal wall. A transition occurs in the muscle type composing the tunica muscularis from striated skeletal muscle in the proximal two thirds of the esophagus to smooth muscle in the distal third. In the proximal esophagus the skeletal muscle layers spiral across one another at angles. Within the smooth muscle layers of the distal esophagus the outer layer becomes more longitudinal, whereas the inner layer thickens and becomes circular. The wall of the terminal esophagus can be 1 to 2 cm thick. Deep cervical fascia, pleura, and peritoneum contribute to the thin fibrous tunica adventitia of the esophagus. Motor innervation to the striated skeletal muscle of the esophagus includes the pharyngeal and esophageal branches of the vagus nerve, which originate in the nucleus ambiguus of the medulla oblongata. Parasympathetic fibers of the vagus nerve supply the smooth muscle of the distal esophagus. Sympathetic innervation of the esophagus is minimal.

Passage of ingesta through the esophagus can be considered part of the swallowing process, which consists of oral, pharyngeal, and esophageal stages. The oral stage is voluntary and involves transport of the food bolus from the mouth into the oropharynx. During the involuntary pharyngeal stage the food bolus is forced through the momentarily relaxed upper esophageal sphincter by simultaneous contractions of the pharyngeal muscles. In the esophageal phase of swallowing the upper esophageal sphincter closes immediately, the lower esophageal sphincter opens, and esophageal peristalsis propels the bolus into the stomach.[1215] Unlike a food bolus, liquids do not require peristalsis to reach the lower esophageal sphincter and may precede the food bolus during swallowing.

The upper esophageal sphincter prevents esophagopharyngeal reflux during swallowing and air distention of the esophagus during inspiration. Upper esophageal pressure increases in response to pressure from a food bolus and to increased intraluminal acidity, as would occur with gastroesophageal reflux. The lower esophageal sphincter is a smooth muscle located at the gastroesophageal junction that is morphologically ill defined but forms an effective functional barrier.[1215] Normally the lower esophageal sphincter is closed in response to gastric distention to restrict gastroesophageal reflux. Relaxation of the lower esophageal sphincter permits passage of ingested material from the esophagus to the stomach. Distention of the stomach with ingesta mechanically constricts the lower esophageal sphincter. Gastric distention also triggers a vagal reflex that increases lower esophageal sphincter tone, which is a safety mechanism against gastroesophageal reflux. The mechanical and vagal mechanisms that promote lower esophageal sphincter tone prevent spontaneous decompression of the stomach, which along with a lack of a vomiting reflex in the horse, increases the risk of gastric rupture during episodes of severe distention.

A wide variety of congenital and acquired disorders of the esophagus have been described in horses. These are summarized in Table 12.9 and discussed in detail in the following section.

Esophageal Obstruction

Esophageal obstruction has many causes (Table 12.10) and most often is manifested clinically by impaction of food material and resulting esophageal dysphagia. Esophageal obstruction may be caused by primary impactions (simple choke) of roughage, particularly leafy alfalfa hay; coarse grass hay; bedding; and even grass.[1216] Prior esophageal trauma or poor mastication caused by dental abnormalities may predispose horses to primary esophageal impaction.[1217] "Wolfing" or gulping food may precipitate primary impactions, particularly if the horse is exhausted or mildly dehydrated after a long ride or is weakened from chronic debilitation. Impactions also may result from disorders that physically impede the passage of food material and fluid by narrowing the luminal diameter, reduce the compliance of the esophageal wall, or alter the conformation of the esophageal wall such that food material accumulates in a pocket or diverticulum. Foreign bodies, intramural or extramural masses, or acquired or congenital anomalies cause these so-called secondary impactions. Intramural causes of esophageal obstruction include tumors (squamous cell carcinoma [SCC]), strictures, diverticula, and cysts.[1218-1226] Mediastinal or cervical masses (tumors or abscesses) may cause extramural obstructions. Congenital anomalies are covered in detail later.

Clinical Signs and Diagnosis

A thorough physical examination, including complete oral and neurologic examination, can help rule out causes of dysphagia and nasal discharge other than esophageal obstruction. Clinical signs associated with esophageal obstructions are related primarily to regurgitation of food, water, and saliva caused by esophageal (postpharyngeal) dysphagia.[1227] Horses with esophageal obstruction are often anxious and stand with their neck extended. Gagging or retching may be observed, particularly with acute proximal obstructions. Bilateral frothy nasal discharge containing saliva, water, and food material; coughing; odynophagia; and ptyalism are characteristic clinical signs, the severity of which varies with the degree and location of the obstruction. Distention in the jugular furrow may be evident at the site of obstruction. Other clinical signs related to regurgitation of saliva, water, and food material, such as dehydration, electrolyte, or

TABLE **12.9** **Esophageal Disorders of Horses**

Disorder	Presenting Complaints	Diagnosis	Treatment	Selected References
ACQUIRED DISORDERS				
Choke	Nasal discharge of saliva and food; retching; excessive salivation; cough; sweating; extension of head and neck	Passage of a nasogastric tube; endoscopy	Medical and surgical treatment options as described in text	1187–1189
Foreign bodies	Acute or recurrent choke	Endoscopy; radiography	Manual retrieval or removal; endoscopic removal; surgery	1190–1194
External compression	Acute or recurrent choke	Endoscopy; radiography; ultrasound	Removal of the obstructive mass	1195
Muscular hypertrophy	No clinical signs observed in most affected horses; may predispose to esophageal diverticula	Incidental finding at necropsy	None	1196
Gastroesophageal reflux disease	Inappetence; bruxism; ptyalism; colic; gastric reflux; weight loss; exercise intolerance	Esophageal and gastric endoscopy	Correct primary problem; decrease gastric acidity; gastric protectants; surgery	1197–1199
Stricture	Recurrent choke; weight loss	Endoscopy; contrast radiography	Bougienage; surgery	49, 53, 1200, 1201–1207
Diverticula[a]	Recurrent choke; weight loss	Endoscopy; contrast radiography	Surgery	1206, 1208–1211
Perforation, trauma	Salivation; bruxism; cough; nasal discharge; sepsis	Endoscopy	Enteral feeding; supportive care	1212, 1213
Megaesophagus[a]	Recurrent choke; intermittent food and saliva from nares; pneumonia; weight loss; colic	Endoscopy; contrast radiography	Nutritional modification as described in text	1214, 1215
Neoplasia	Recurrent choke; weight loss	Endoscopy; biopsy	Surgical resection	1216, 1217
Granulation tissue	Recurrent choke; swelling in the region of the cervical esophagus	Endoscopy; biopsy	Laser surgical resection	1218
CONGENITAL DISORDERS				
Tubular duplication of the esophagus	Young horse; mass caudal to mandible; dyspnea; dysphagia; nasal regurgitation of food and saliva	Radiography and ultrasonography of mass; endoscopy; contrast radiography	Surgical excision	1219, 1220
Cystic duplication of the esophagus	Young horse; mass in cervical or throatlatch area; recurrent choke; bruxism; excessive salivation; nasal regurgitation of saliva and feed; weight loss	Endoscopy; ultrasonography; aspiration of cyst; contrast radiography	Surgical excision; marsupialization of cyst	1224–1231
Vascular ring anomaly	Cervical swelling after introduction to solid feed; chronic respiratory disease	Endoscopy; contrast radiography; computed tomography; magnetic resonance imaging	Surgical correction	1224–1231
Congenital stenosis	Nasal regurgitation of milk; cough	Endoscopy; contrast radiography	Dietary management as described in text	36
Ectasia	Nasal regurgitation of milk	Histologic evaluation	None described	1232, 1233

[a]May occur as congenital or acquired lesions.

TABLE **12.10 Causes of Complete or Partial Esophageal Obstruction in the Horse**

Category	Differential	Examples
Intraluminal	Foreign body	Apples, potatoes
	Feed material	
Extramural	Neoplasia	Squamous cell carcinoma, lymphoma
	Vascular ring anomaly	Persistent right aortic arch
	Granuloma	
Intramural	Esophageal abscess	
	Granuloma	
	Neoplasia	Squamous cell carcinoma, leiomyosarcoma
	Cysts	Intramural cysts, duplication cysts
	Diverticula	
	Stenosis	
Functional disorders	Dehydration	
	Exhaustion	
	Pharmacologic	Acepromazine, detomidine
	Primary megaesophagus	Congenital ectasia
	Esophagitis	
	Autonomic dysautonomia	
	Vagal neuropathies	

acid-base imbalances; weight loss; and aspiration pneumonia may be observed. In extreme cases, pressure necrosis from the impaction or trauma to the esophagus may cause esophageal rupture. If the rupture is in the cervical esophagus, crepitus or cellulitis may be evident along with signs of systemic inflammation. Thoracic auscultation is important to determine whether aspiration pneumonia is present. Intrathoracic esophageal rupture may result in pleuritis and its associated clinical signs.

Passage of a nasogastric tube is an effective way to detect and localize an obstruction but provides little information about the nature of the obstruction or the condition of the esophagus. The most direct method for diagnosis of esophageal obstructions is endoscopic examination. Esophageal obstruction occurs most commonly at sites of natural narrowing of the esophageal lumen, such as the cervical esophagus, the thoracic inlet, base of the heart, or the terminal esophagus; an endoscope greater than 1 m in length is necessary for complete evaluation. Endoscopic evaluation is useful before relief of an impaction to localize the obstruction and to investigate the nature of the impaction if one suspects a foreign body. Foreign bodies may be retrievable via transendoscopic tethering.[1228] Critical diagnostic and prognostic information is also obtained via endoscopy after resolution of the impaction. Assessing the affected esophagus for mucosal ulceration, rupture, masses, strictures, diverticula, and signs of functional abnormalities is important (Figs. 12.15 and 12.16).

Ultrasonography of the cervical region is useful not only to confirm a cervical esophageal impaction but also to provide critical information about the location and extent of the impaction and esophageal wall thickness and integrity. Ultrasonography may provide information about the cause.[1194] Radiographic assessment of the esophagus can confirm the presence of esophageal obstruction in cases in which one cannot view the affected area adequately using endoscopy. Impacted food material in the esophagus may be visualized as a typical granular pattern with gas accumulation proximal to the obstruction. Air or barium contrast radiographic studies are most useful for evaluating the esophagus following relief of the impaction if one suspects a stricture. Esophageal dilation, diverticula, rupture, functional disorder (megaesophagus), or luminal narrowing

FIG. **12.15** Endoscopic view of the cervical esophagus in an adult horse 6 months after an episode of choke that caused circumferential ulceration of the esophageal mucosa. The area of luminal narrowing (stricture) is at the upper right of the image, and the proximal dilation forms an outpouching of the esophageal wall. A contrast esophagram revealed that the outpouching was a pulsion diverticulum.

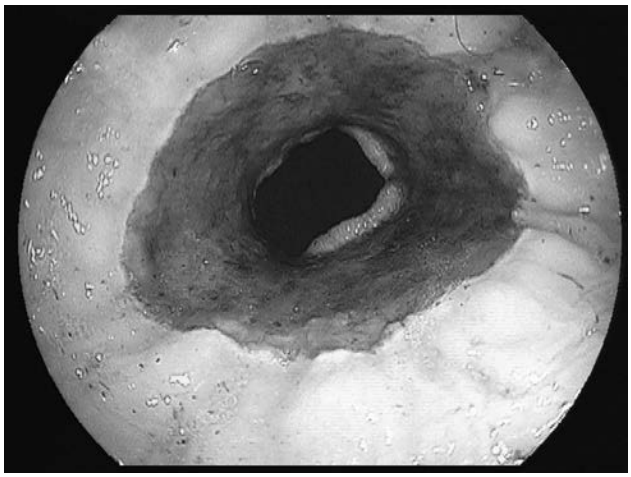

FIG. **12.16** Endoscopic view of the proximal esophagus in a yearling filly with recurrent esophageal obstruction. Circumferential mucosal ulceration is evident proximal to incomplete stricture formation.

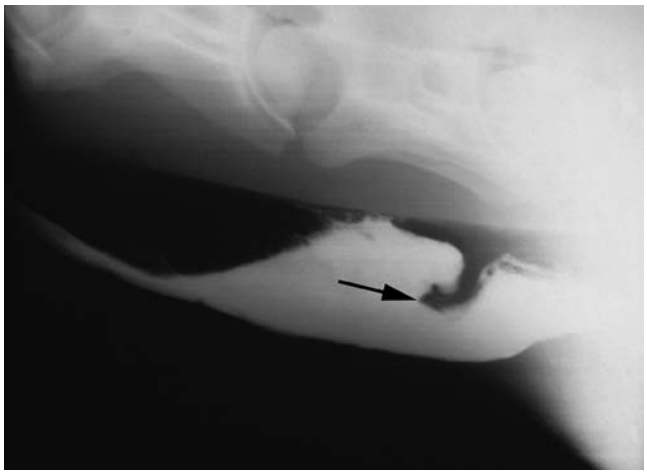

FIG. **12.17** Contrast esophagram in a horse with circumferential esophageal stricture *(arrow)* and a pulsion diverticulum proximal to the stricture.

caused by extraluminal compression are detected more easily using contrast radiographic studies than endoscopy (Fig. 12.17).[1229-1231] Radiographic studies of the esophagus should be interpreted cautiously in sedated horses, particularly after passage of a nasogastric tube or other esophageal manipulations that may contribute to esophageal dilation.[36]

Treatment

The primary goal of treatment for esophageal impaction is to relieve the obstruction. A variety of approaches have been described, ranging from minimal conservative therapy to aggressive intervention to relieving the obstruction. Parenteral administration of acepromazine (0.05 mg/kg IV), xylazine (0.25–0.5 mg/kg IV) or detomidine (0.01–0.02 mg/kg IV), oxytocin (0.11–0.22 IU/kg intramuscularly), and/or esophageal instillation of lidocaine (30–60 mL of 1% lidocaine) may reduce esophageal spasms caused by pain or may decrease esophageal tone.[36,1232,1233] *N*-Butylscopolammonium bromide may reduce smooth muscle tone and has been used to help resolve some obstructions.

In many horses with esophageal obstruction secondary to a feed impaction, the problem may be resolved with conservative management. To facilitate examination, relieve anxiety, and relax the esophagus, one should begin by sedating the horse. A nasogastric tube is then passed to confirm the diagnosis. When an obstruction is encountered, gentle pressure is applied in an attempt to dislodge and move distally the offending feed material. If the choke is not easily dislodged with gentle pressure, the tube is removed. Appropriate sedative, antiinflammatory/analgesic, and smooth muscle–relaxing drugs are administered. The horse is moved to an unbedded stall with absolutely no food or water within reach and muzzled if necessary. The horse is left alone in the stall for several hours. If there is evidence of dehydration, appropriate IV fluid therapy is provided. If there is evidence of aspiration pneumonia, appropriate IV antimicrobial therapy is provided. On reexamination, a stomach tube is passed and gentle pressure is again applied to the area of obstruction. In many horses, the impaction will have softened and can be easily dislodged, if it has not resolved already, with minimal pressure from the stomach tube.

Some clinicians prefer a more interventional approach to the resolution of an impaction, and some impactions are severe enough to require physical dispersal of the material.[1232] A nasogastric tube can be used to displace the impacted material along with external massage if the obstruction is in the cervical region. Careful lavage of the esophagus with water via an uncuffed or a cuffed nasogastric tube while the head is lowered may be a useful aid in breaking up the impaction. Some clinicians advocate a dual tube method in which a tube is placed through each nasal passage into the esophagus for ingress and egress of the lavage fluid. Because of the risk of aspiration of water and food material, esophageal lavage sometimes is done under general anesthesia with a cuffed nasotracheal tube. In refractory cases, IV administration of polyionic fluids provides hydration and alleviates any electrolyte or acid-base imbalances resulting from salivary losses of chloride, sodium, and potassium.[1193] Oxytocin may or may not provide a direct effect for the resolution of an esophageal obstruction. Oxytocin reduced the area under the curve for esophageal smooth muscle strip contractions but had no effect on skeletal muscle strips in vitro.[1234] In one in vivo report, oxytocin administration resulted in decreased esophageal tone in the proximal esophagus (aborad to the larynx and thoracic inlet).[1233] In a separate study, oxytocin administration did not affect esophageal manometric recordings.[1235] Rarely, esophageal obstruction ultimately may require esophagotomy to relieve the impaction. Strict restriction of food and water, including access to bedding material, must be enforced until the obstruction is resolved and the esophagus has regained function. Surgical removal of esophageal foreign bodies can be considered if the size and/or orientation of the object is such that transendoscopic retrieval is considered unlikely to be successful.[1226,1236] In one report, an intraluminal mass comprised of exuberant granulation tissue was removed via serial transendoscopic Nd:YAG laser ablation.[1237]

Systemic effects of dysphagia associated with esophageal impaction include dehydration, hyponatremia, hypochloremia, and metabolic alkalosis from prolonged loss of salivary free water and electrolytes.[1193]

Esophageal endoscopy should be performed after relief of the impaction to determine whether any complications of the

impaction have developed or if a primary cause of the obstruction is present. Endoscopic examination is critical to determine the postobstruction treatment plan and for follow-up evaluation of esophageal healing. The horse should be reevaluated every 2 to 4 weeks following resolution of the impaction if esophageal dilation or mucosal injury is observed. In one report, male sex, age >15 years, and need for general anesthesia to relieve the obstruction were associated with an increased risk of complications.[1238]

Dilation proximal to the site of obstruction, mucosal injury from trauma, stricture formation, formation of a diverticulum, megaesophagus, and esophagitis are sequelae to esophageal obstruction that predispose patients to reobstruction. Underlying functional or morphologic abnormalities were much more likely in cases of recurrent, relative to first time, obstruction in a retrospective study.[1216]

The rate of reobstruction may be as high as 37%. Depending on the duration of the obstruction and the degree of trauma or dilation, the risk of reobstruction is high for 24 to 48 hours or longer. Food should be withheld for at least 24 to 48 hours after resolution of the obstruction. Sucralfate (20 mg/kg orally every 6 hours) may hasten healing if esophageal ulceration is evident, but the efficacy of sucralfate for this purpose is not established. Some clinicians suggest that administration of an NSAID may reduce the development of strictures, although judicious use of NSAIDs is recommended to prevent worsening of esophageal mucosal injury. Orally administered NSAIDs should be avoided if esophagitis is present. After 48 to 72 hours or when the esophageal mucosa has recovered as assessed by endoscopy, the horse may be fed soft food (moistened pellets and bran mashes) then transitioned gradually to a high-quality roughage diet over 7 to 21 days, depending on the degree of esophageal damage induced by the impaction and the nature of any underlying disease. The prognosis for survival is good (78–88%), but some horses may require permanent dietary modification if persistent chronic obstruction is a problem.[1216,1220,1238]

Aspiration pneumonia is a potential complication in every case of esophageal obstruction, and perforation is possible with severe or prolonged obstruction. In one report, duration of obstruction before presentation was a good predictor of pneumonia, whereas endoscopic evidence of tracheal food contamination was not.[1216] Administration of broad-spectrum antibiotics that are effective against gram-positive and gram-negative organisms, including metronidazole for anaerobes, is highly recommended if the duration of obstruction is either unknown or prolonged or if aspiration is suspected.

Esophagitis

Esophagitis refers to a clinical syndrome of esophageal inflammation that may or may not be ulcerative. The major protective mechanisms of the esophageal mucosa include salivary and food material buffers, normal peristaltic motility, and the barrier formed by the gastroesophageal sphincter. Reflux esophagitis is caused by repeated episodes of gastric fluid regurgitation into the distal esophagus and subsequent chemical injury to the mucosa.[1239] Esophageal mucosal ulceration also can occur if the clearance of gastric fluid from the esophagus is delayed, such as in functional disorders of the esophagus. Like ulceration of the squamous portion of the stomach in horses, gastric acid and bile salt chemical injury is a major mechanism of esophageal squamous epithelial ulceration.[838,1239] Reflux esophagitis may occur along with gastric ulcer disease, motility disorders, increased gastric volume from gastric outflow obstructions, gastric paresis, intestinal ileus, or impaired lower esophageal sphincter function.[1222,1239] Other causes of esophagitis in horses include trauma (foreign bodies, food impactions, and nasogastric tubes), infection (mural abscesses), or chemical injury (pharmaceuticals and cantharidin; Fig. 12.18).[1236,1240,1241]

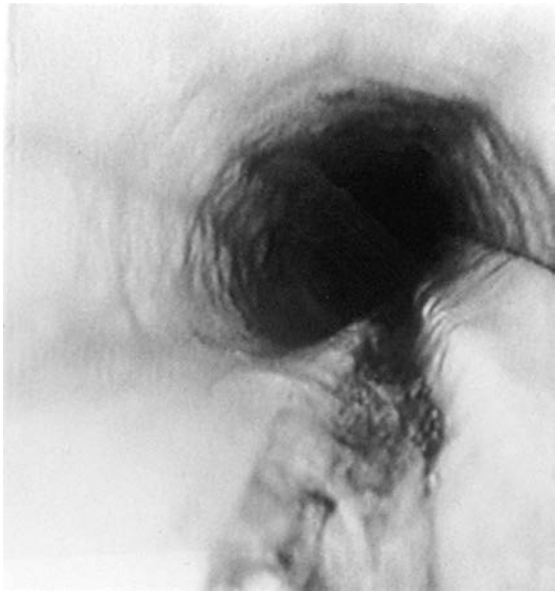

FIG. **12.18** Endoscopic view of the cervical esophagus of a horse that had repeated passages of a stiff nasogastric tube. The deep, linear ulceration of the esophageal mucosa is notable.

Clinical Signs and Diagnosis

The clinical signs of esophagitis are nonspecific and similar to esophageal obstruction and gastric ulceration. Gagging or discomfort when swallowing may be evident, along with hypersalivation and bruxism. Esophageal (postpharyngeal) dysphagia may be evident. Partial or complete anorexia with resultant weight loss may be observed in affected horses. Esophageal hypomotility dysfunction caused by the inflammatory process may result in esophageal impaction. Clinical signs of underlying diseases that predispose to esophagitis may predominate or mask the signs of esophagitis. Horses with gastrointestinal motility disorders such as proximal enteritis or gastric outflow obstruction are at a high risk of developing reflux esophagitis because of the presence of gastric acid and bile salts in the fluid reflux. Foals with obstructive gastroduodenal ulcer disease (GDUD) commonly have reflux esophagitis.

Diagnosis requires endoscopic examination, with diffuse, patchy, linear, or coalescing erosion or ulcerations or significant edema or hyperemia. Determining whether an underlying disease, such as infection, neoplasia, esophageal strictures, or diverticula, is present is important. Evaluation of the stomach is important to rule out gastric outflow obstruction. Contrast radiography may be helpful to assess esophageal motility and transit time.[1230]

Treatment

The principles of therapy for reflux esophagitis include control of gastric acidity, mucosal protection, and correction of any underlying disorder contributing to gastroesophageal reflux. Reduction of gastric acid production with proton pump antagonists or H_2 receptor antagonists is critical for resolution. Some clinicians advocate using sucralfate to promote healing of ulcerated esophageal mucosa. The ability of sucralfate to bind ulcerated esophageal mucosa or hasten ulcer healing, however, is not proven in the horse.

If a primary gastric outflow obstruction is present, surgical intervention is warranted. Horses with delayed gastric outflow without obstruction may benefit from prokinetics such as metoclopramide (0.02–0.1 mg/kg SC every 4–12 hours) or bethanechol (0.025–0.035 mg/kg SC every 4–24 hours). For esophagitis from trauma or pressure injury after esophageal impaction, judicious use of NSAIDs may be warranted to reduce inflammation and pain.

Dietary modification may be necessary for patients with esophagitis, depending on the degree of ulceration or if motility is impaired. Horses with mild esophagitis should be fed frequent small meals of moistened pellets and fresh grass. Severe esophagitis may necessitate withholding food and complete esophageal rest for several days. Although the prognosis for esophagitis is good in the absence of underlying disease, the risk of stricture formation is high if severe circumferential or coalescing ulcerations are present. Esophagitis from severe trauma or infection may be prone to stricture formation.

Motility Disorders

Motility dysfunction of the equine esophagus is most often manifest as hypomotility resulting in esophageal dilation (ectasia) or megaesophagus. Although megaesophagus in horses most commonly is acquired, reports indicate idiopathic megaesophagus in young horses may be congenital.[1191,1242-1245] Acquired megaesophagus in horses may be a consequence of chronic or recurrent esophageal obstruction.[1220,1222] Esophageal impactions of a short duration cause a proximal dilation of the esophagus that is generally reversible.[1230] If the duration of the obstruction is long enough, the motility of the esophagus proximal to the site of obstruction may be impaired permanently. Other causes of acquired megaesophagus include extraesophageal obstruction by tumors or abscesses, pleuropneumonia, and vascular ring anomalies.[1220,1223] A retrospective report of horses with megaesophagus reveals an overrepresentation of Friesian horses (14 of 18 cases) suggesting the possibility of a predisposition for esophageal disorders in this breed.[1214] The authors state that preliminary pedigree analyses suggest the possibility of a recessive pattern of inheritance.[1214]

Megaesophagus also may result from neurologic, neuromuscular, and muscular disorders. Neurologic diseases that cause vagal neuropathy, such as equine protozoal myeloencephalitis, equine herpesvirus myeloencephalitis, and idiopathic vagal neuropathy, have been associated with megaesophagus in horses. Pleuropneumonia may be associated with a vagal neuropathy resulting in megaesophagus. Megaesophagus is an early sign of equine dysautonomia[1246] and may be observable in patients with botulism. Myasthenia gravis is a well-known cause of megaesophagus in nonequine species but has not been reported in horses. Also in other species, electrolyte disorders, cachexia, primary myopathies, myositis, and Addison's disease may affect esophageal motility but have not been associated with megaesophagus in horses. Iatrogenic megaesophagus can be induced by the α_2-adrenergic agonist detomidine but is transient and reversible.[36,1247] Acepromazine, detomidine, and a combination of xylazine and butorphanol can alter proximal esophageal motility by disrupting coordinated peristalsis and decreasing spontaneous swallowing, but only acepromazine affected the manometric profile of the distal esophagus.[1235] None of these drugs altered contractility of isolated esophageal smooth or striated muscle strips in vitro.[1234] Nonetheless, the use of these drugs may complicate clinical evaluation of esophageal motility. Esophageal disorders including megaesophagus, esophageal diverticulum, and esophageal rupture appear to be more common in young Friesian horses, suggesting the possibility of a genetic predisposition in this breed.

Esophageal inflammation, particularly reflux esophagitis, may affect motility and cause megaesophagus. Because esophageal hypomotility affects the tone and function of the lower esophageal sphincter, reflux esophagitis also may be a complication of a primary functional disorder. Assessing esophageal motility in horses with esophagitis that is not responding appropriately to treatment is important.

Clinical Signs and Diagnosis

Thorough neurologic examination is important to help rule out primary neurologic causes of megaesophagus. Because esophageal hypomotility is a functional obstruction, the clinical signs are similar to esophageal obstruction, although the onset is typically insidious. The clinical signs include those associated with esophageal dysphagia.[1191,1222,1223,1243-1245] The cervical esophagus may be dilated enough to be evident externally, and weight loss is common.

Diagnosis of esophageal hypomotility requires evaluation of transit via fluoroscopy or contrast radiography.[1230,1246] Endoscopy may reveal a dilated esophagus and an absence of peristaltic waves[1191,1222] or evidence of underlying disease causing obstruction or esophageal dilation.[1220,1222] Esophageal manometry may be useful to document abnormal postdeglutition contraction pressures, contraction time, and propagation times but is not often available for routine clinical application.[1248] If neurologic or neuromuscular disease is suspected, cerebrospinal fluid analysis or electromyography may be indicated.

Treatment

Treatment of an underlying cause should be initiated, if applicable. Dietary modification should include a soft/slurry diet and feeding from an elevated position to promote transit by gravity flow. Metoclopramide or bethanechol may benefit patients with reflux esophagitis associated with megaesophagus. The prognosis depends on the underlying cause and the degree of dilation. Although many cases of megaesophagus associated with reflux esophagitis respond well to treatment, many other forms of megaesophagus including congenital megaesophagus have a poor prognosis.

Esophageal Stricture

Strictures most commonly are caused by pressure necrosis from esophageal impactions that induce circumferential erosion or ulceration of the esophageal mucosa, although

esophageal injury caused by oral administration of corrosive medicinal agents and trauma to the neck may also result in stricture formation.[1249] Congenital strictures also have been reported.[1250] Strictures caused by mucosal and submucosal trauma are termed *esophageal webs* or *rings*. Strictures may also originate in the muscular layers and adventitia of the esophagus (mural strictures) or in all of the layers of the esophagus (annular stenosis).[1217,1250] Horses with these lesions have a presentation similar to those with simple obstructions, because strictures result in partial obstruction and impaction of food material in the lumen. Esophageal webs or rings may be detected with endoscopy (see Figs. 12.15 and 12.16), whereas identification of mural strictures or annular stenosis may require a double-contrast esophagram (see Fig. 12.17). In a retrospective study of horses with esophageal stricture following simple obstruction, maximal reduction in esophageal lumen diameter occurred within 30 days of the esophageal obstruction. Although surgery has been used to relieve such strictures, initial medical management is warranted because strictures may resolve with conservative therapy, and the esophagus continues to remodel for up to 60 days following ulceration. In one report, seven horses with esophageal obstruction–induced stricture were treated conservatively by feeding a slurry diet and administering antiinflammatory and antimicrobial medications, and five of seven were clinically normal within 60 days.[1249] One of the five successfully treated horses had a 10-cm area of circumferential ulceration, suggesting that the potential exists for extensive mucosal injury to resolve without permanent stricture formation.

If resolution of strictures within 60 days is insufficient, other methods to increase esophageal diameter should be investigated. Balloon dilation has been used successfully in several reports.[1251-1256] Commercial balloon dilators have been adapted for use in the horse, although it is important to note that repeated dilation is necessary.[1251,1252,1257] Corticosteroid injection was used successfully in conjunction with this procedure in foals.[1251] Alternatively, a number of surgical techniques have been used to resolve strictures, including resection and anastomosis,[1258,1259] temporary esophagostomy with fenestration of the stricture,[1217] esophagomyotomy for strictures of the muscularis and adventitia,[1260,1261] or patch grafting with local musculature.[1262] Such surgeries, however, are fraught with complications, largely because of the propensity of the traumatized esophagus to restricture.[1220,1249] The esophagus lacks a serosal layer and does not rapidly form a fibrin seal as does the remainder of the intestinal tract, so anastomoses tend to leak.[1259] In addition, tension on the esophagus during swallowing and movement of the neck impairs healing of anastomoses.[1217,1258] In spite of these difficulties, the long-term prognosis for horses with chronic esophageal strictures treated surgically is better than for those treated nonsurgically.[1220] Two recent reviews describe surgical approaches to the esophagus in detail.[1263,1264]

Esophageal Diverticula

Esophageal diverticula may be classified as traction (true) diverticula and pulsion (false) diverticula. Traction diverticula result from wounding and subsequent contraction of periesophageal tissues, with resultant tenting of the wall of the esophagus. Pulsion diverticula arise from protrusion of esophageal mucosa through defects in the muscular wall of the esophagus and usually result from trauma or acute changes in intraluminal pressure.[1250] Traction diverticula appear as a dilation with a broad neck on contrast esophagography, whereas pulsion diverticula typically have a flask shape with a small neck on an esophagram (see Fig. 12.17).[1225,1265] Although traction diverticula are usually asymptomatic and of little clinical significance, pulsion diverticula may fill with feed material, ultimately leading to esophageal obstruction and rupture.[1265-1267]

A movable mass in the midcervical region may be noticeable before onset of complete obstruction.[1250] Pulsion diverticula may be corrected surgically by inverting or resecting prolapsed mucosa and closing the defect in the wall of the esophagus.[1225,1265,1266] Inversion of excessive mucosa may reduce the diameter of the esophageal lumen and predispose horses to esophageal obstruction; therefore, it should be reserved for small diverticula.[1225]

Congenital Disorders

Congenital disorders of the esophagus are rare. Reported congenital abnormalities include congenital stenosis,[1268] persistent right aortic arch,[1223,1269-1273] other vascular anomalies,[1274] esophageal duplication cysts,[1275-1277] intramural inclusion cysts,[1224,1278] and idiopathic megaesophagus.[1243-1245] In the one report of congenital stenosis, double-contrast radiography revealed concentric narrowing of the thoracic esophagus in the absence of any vascular abnormalities at the base of the heart. Successful treatment included having the foal stand with the forelimbs elevated off the ground following each feeding.[1268]

Persistent right aortic arch is a congenital anomaly in which the right fourth aortic arch becomes the definitive aorta instead of the left aortic arch, which results in constriction of the esophagus by the ligamentum arteriosum as it extends between the anomalous right aorta and the left pulmonary artery.[1279] Clinical signs may include those associated with esophageal (postpharyngeal) dysphagia, drooling, and distention of the cervical esophagus resulting from partial obstruction of the thoracic esophagus.[1223,1269] Endoscopic examination typically reveals dilation of the esophagus cranial to the obstruction with evidence of diffuse esophagitis. Surgical treatment of persistent right aortic arch has been reported in foals, with varying degrees of success.[1269,1271,1273] In one report, preoperative CT was used to identify the exact anatomic location of the offending lesion and guide the surgical approach.[1273]

Esophageal duplication cysts and intramural inclusion cysts cause typical signs of esophageal obstruction, including salivation, esophageal dysphagia, and swelling of the cervical esophagus as the cysts enlarge.[1275,1277,1278] Such signs can make them difficult to differentiate from other forms of esophageal obstruction. Endoscopic examination may reveal compression of the esophageal lumen and communication with the esophageal lumen if it exists.

Ultrasonographic examination may be the most useful method of antemortem diagnosis if the cyst is in the cervical esophagus. Examination of an aspirate of the mass may aid in the diagnosis by revealing the presence of keratinized squamous cells.[1275,1278] Surgical treatments have included complete surgical resection and surgical marsupialization.[1275,1277,1278] The latter appears to be more successful and results in fewer complications.[1277,1280] Possible complications of surgical resection include laryngeal hemiplegia following surgical trauma to the recurrent laryngeal nerve in the region of the esophagus and esophageal fistula formation.[1278]

Esophageal Perforation

Esophageal perforation typically occurs in the cervical region in response to external trauma, necrosis of the esophageal wall caused by a food impaction, or rupture of an esophageal lesion such as an impacted diverticulum. The esophagus is particularly vulnerable to external trauma in the distal third of the neck because only a thin layer of muscle covers it at this point.[1281] Iatrogenic perforation may occur in response to excessive force with a stomach tube against an obstruction or a compromised region of the esophagus.[1240] Esophageal perforations may be open or closed and tend to cause extensive cellulitis and necrosis of tissues surrounding the wound because of drainage of saliva and feed material within fascial planes. Systemic inflammation from septic cellulitis may occur. Closed perforations of the esophagus are particularly troublesome because food material, water, saliva, and air may migrate to the mediastinum and pleural space via fascial planes.[1240,1281] Because of the leakage of air into the tissues surrounding the rupture, extensive SC and fascial emphysema frequently develops and is usually evident clinically and on cervical radiographs. Pneumomediastinum and pneumothorax are potentially fatal complications of esophageal ruptures. If the esophagus ruptures into the mediastinum, horses most commonly present with signs of acute SIRS that may be mistaken for colic.

Treatment should include converting closed perforations to open perforations if possible,[1282] extensive debridement and lavage of affected tissues, broad-spectrum antibiotics, tetanus prophylaxis, and esophageal rest. The clinician may achieve the latter by placing a feeding tube into the esophagus via the wound. Alternatively, a small nasogastric tube (12-Fr diameter) may be placed.[1240] For open perforations, once the wound has granulated and contracted to a small size, oral feeding may be attempted.[1281] Extensive loss of saliva via esophageal wounds may lead to hyponatremia and hypochloremia. Transient metabolic acidosis may occur because of salivary bicarbonate loss, followed by progressive metabolic alkalosis.[1193] Although reports of esophageal wounds healing well by second intention exist, healing takes a prolonged time.[1283] In addition, some perforations never completely heal and form permanent esophagocutaneous fistulae that may require surgical correction. The development of esophageal strictures is not common because wounds are usually linear and not circumferential. However, traction diverticula may develop. Other potential complications of esophageal wounds include Horner's syndrome and left laryngeal hemiplegia.[1281]

In a retrospective study on esophageal disorders, only 2 of 11 horses with esophageal perforations survived long term,[1220] and in a report of esophageal trauma following nasogastric intubation, 4 of 5 horses were euthanized.[1240] The prognosis is poor in horses with esophageal perforations, largely because of the extent of cellulitis, tissue necrosis, shock, and local wound complications.

DISEASES OF THE STOMACH

Gastroduodenal Ulceration

Pathophysiology of mucosal injury and repair is detailed previously in this chapter in Mucosal Injury and Repair. Of importance, ulceration can occur in either the stratified squamous or glandular epithelium, although different clinical syndromes and pathophysiologic mechanisms apply. As a result, the broad term "*equine gastric ulcer syndrome*" (EGUS) has been used to encompass the wide array of associated clinical syndromes,[1284] although separation into equine squamous gastric disease (ESGD) and equine glandular gastric disease (EGGD) has recently been proposed.[1285] GDUD primarily affects weanling/suckling foals and is typically considered a separate entity.[1286] Regardless of terminology, EGUS in its various forms is arguably the most clinically and economically important clinical entity of the equine stomach.

Prevalence

The prevalence of gastric ulceration has been reported for a variety of breeds and usages. The prevalence of squamous ulceration in horses in race training varies from 70% to 95%[1287-1295] and can be as high as 100% when limited to animals actively racing.[1291] Horses performing in other disciplines have also been evaluated, including active show horses (58% prevalence),[1296] endurance horses (67% overall[1297]; 48% interseason and 93% during competition season[1298]), Western performance horse (40%),[1299] Thoroughbred broodmares (67% pregnant; 77% nonpregnant),[1300] and nonracing performance horses (17% precompetition; 56% postcompetition).[1301] In one large retrospective study (3715 adult horses from the years 1924–1996) evaluating incidences of gastric ulceration identified at necropsy, an overall prevalence of 10.3% was found, with the highest prevalence in Thoroughbreds (including Arabians) and Standardbred trotters (19%).[1302] Horses in a university riding program demonstrated a low squamous ulceration prevalence (11%).[1303] Approximately 49% of horses presented to a referral hospital for colic had evidence of gastric ulceration.[1304] The reported prevalence of gastric ulceration in foals varies from 25% to 57%.[1305-1307]

Many earlier studies investigating prevalence of gastric ulceration do not differentiate between nonglandular and glandular lesions, and many evaluate only the nonglandular region of the stomach, but this trend is changing. In 1 of 162 horses in a hospital setting, 58% had antral or pyloric erosions or ulcerations, 58% had squamous mucosal lesions, and 8% had lesions involving the glandular body.[1308] In other studies, 56% of Thoroughbreds had EGGD,[1293] and 47% of racehorses (Thoroughbred and Standardbred) had EGGD.[1295] In the former,[1293] all horses with glandular lesions also had squamous disease, whereas such an association was not seen in the latter study.[1295] In one report of endurance horses with a 67% overall lesion prevalence, 27% had EGGD.[1297] In another, prevalence varied by season, with 16% EGGD prevalence out of competition and 33% during competition season.[1298] In Danish horses, the prevalence of EGGD was 57% in two separate reports.[1309,1310] In a postmortem evaluation, lesions were most commonly located in the squamous mucosa along the margo plicatus, followed by the glandular body, proximal squamous mucosa, and antrum.[1302] Overall, glandular lesions tend to occur near the pylorus.

Pathophysiology

Because the pathophysiology of mucosal injury and repair was documented earlier, it will not be reviewed here. Acid secretion clearly plays a role in squamous mucosal ulceration, and key components of acid regulation will be summarized. Horses secrete acid continuously, and measured pH of equine gastric

contents is variable from less than 2 to greater than 6 depending on the horse's dietary state (fed/fasted).[818,1311] A protocol of repeated 24-hour periods of fasting and feeding has been shown to induce squamous erosion and ulceration.[841] Because this protocol results in periods of prolonged gastric acidity (pH <2.0) and concurrent administration of the H_2 receptor antagonist ranitidine reduces lesion severity, it supports the role of acid exposure in the pathogenesis of squamous ulcer disease. This effect was also noted as pH of the proximal, but not ventral, stomach decreased in early morning hours, corresponding to periods of decreased hay intake.[1312]

Several peptides can stimulate or inhibit the secretion of acid by the parietal cell. The predominant stimuli to hydrochloric acid secretion are gastrin, histamine, and acetylcholine via the vagus nerve.[1313] Gastrin is released by G cells within the antral mucosa, whereas histamine is released by mast cells and ECL-like cells in the gastric gland. Histamine binds to type 2 receptors on the parietal cell membrane, causing an increase in adenosine monophosphate (cAMP), resulting in phosphorylation of enzymes that activate the proton pump. Gastrin and acetylcholine can act via calcium-mediated intracellular pathways and also stimulate histamine release directly.[1314] Isolated equine parietal cells respond maximally to histamine stimulation and only minimally to carbachol and pentagastrin.[1315] In vivo, histamine or pentagastrin infusion can stimulate similar maximal acid output.[1316] Interestingly, pentagastrin stimulation also induces a marked duodenal secretion of a sodium chloride–rich fluid, which can reflux back into the stomach under fasting conditions.[1316] Gastrin release is primarily controlled by gastrin-releasing peptide, which is stimulated by gastric distention and increased luminal pH, but the interaction between gastrin and histamine has not been fully elucidated in the horse.

Gastric acid secretion by parietal cells is primarily inhibited by somatostatin, which is released by fundic and antral D cells. The inhibitory effect of somatostatin is primarily paracrine, but plasma levels of somatostatin negatively correlate with gastric luminal acidity.[1317] Gastric acid secretion also is inhibited by EGF, a peptide produced in saliva.[1318]

Foals can produce significant amounts of gastric acid by the second day of life, with consistent periods of acidity (pH <2.0) in clinically normal animals.[1319,1320] In one study, foals tended to have a high gastric pH at day 1 of age,[1319] but in a study of critically ill foals, some foals demonstrated periods of gastric acidity on the first day of life.[1321] Suckling was associated with an immediate rise in gastric pH, whereas periods of rest in which foals did not suck for more than 20 minutes were associated with prolonged periods of acidity.[1320] Premature human infants are capable of gastric acid production at 28 weeks of gestation.[1322] Only 1 of 7 premature foals demonstrated an acidic pH recording in a study of gastric pH profiles in critically ill foals.[1321] Although multiple factors were likely involved in those foals, the true ontogeny of gastric acid production in foals is currently unknown.

Equine squamous mucosa is very thin at birth but becomes hyperplastic and parakeratotic within days (Fig. 12.19).[814] The parallel between decreasing pH and proliferation of squamous epithelium correlates with that seen in other species.[1323] The combination of a relatively thin gastric epithelium with a high acid output may leave neonatal foals susceptible to ulcer formation at a very young age. The difference in the normal appearance of the squamous mucosa should be considered when interpreting gastric endoscopy in a neonatal population.

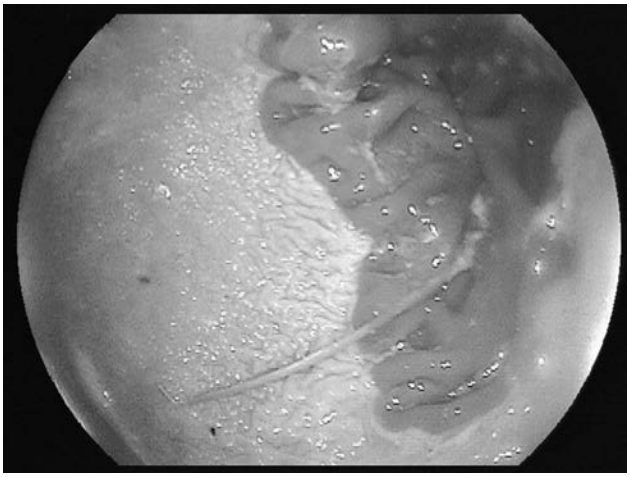

FIG. **12.19** Endoscopic image of the greater curvature of the stomach in a 3-day-old Thoroughbred colt.

Overall, acid remains the major contributing factor to nonglandular mucosal damage, although other factors such as pepsin and bile salts may play an important role as well, either in the initiation or perpetuation of disease.

Risk Factors

Many aspects of diet and management are associated with the development of nonglandular ulceration in adult horses, although some data are conflicting. Risk factors associated with ESGD are clearer than are those associated with EGGD.

Horses in race training have a high incidence of ESGD and are frequently fed high-concentrate, low-roughage diets. A diet high in concentrate and either high or low in forage, in conjunction with stall confinement but no exercise, induce ESGD within 2 weeks.[1324] In one study, higher volatile fatty acid concentrations, higher gastric juice pH, and lower number and severity of ESGD were documented after feeding an alfalfa hay–grain diet compared with a bromegrass hay diet.[1325] Many factors differed between the diets, however, such as digestible energy, bulk, crude protein, and mineral content (especially calcium). These findings were supported by a study in which an alfalfa hay/pelleted concentrate diet significantly reduced ESGD severity scores and/or prevented ulcer development relative to a coastal hay/concentrate diet in horses managed with dry lot housing and regular exercise.[1326] Intermittent feeding has clearly been shown to induce ESGD and is a consistent model of ulcer induction.[841,1311,1327] Similarly, quality of forage (straw versus other types) and increased time between forage meals was associated with higher incidence of ESGD in one report.[1328]

The pathophysiologic correlation between exercise and ESGD has not yet been defined despite the high prevalence of disease in performance horses. In one large epidemiologic study, there was a significant association between ESGD and individual trainer, urban versus rural area, lack of direct contact with other horses, solid barriers, and talk versus music radio.[1329] ESGD can develop within 8 days of exercise varying from light halter to active race training,[1330] and time in work was found to be a risk factor for ESGD in racing Thoroughbreds.[1331] Elevations in postfeeding serum gastrin concentration have been demonstrated after treadmill exercise.[1332]

During treadmill exercise at gaits faster than a walk, proximal gastric size decreases in conjunction with an increase in intraabdominal pressure, resulting in a simultaneous decrease in proximal gastric pH.[1333] Both proximal gastric size and pH return to baseline levels as soon as the horse returned to a walk, and the resultant theory was that gastric contracture could result in increased acid exposure to the squamous mucosa by raising the level of liquid gastric contents.

Stall confinement[1327] and transport[1334] are associated with ESGD, but a distinct mechanism for these associations has not been definitively determined. A recent study did not detect a difference in pH in the proximal or ventral stomach in response to three different environmental situations (stall confinement alone in a barn, stall confinement with a horse in an adjacent stall, and paddock turnout with a companion horse), each for 24 hours.[1312] This work suggests that increased acid exposure to the proximal stomach alone is not causative.

Several studies have failed to document a correlation between NSAID administration and naturally occurring ulcer disease.[1287,1288,1290,1291,1302] NSAID administration, however, is a well-known cause of gastric ulceration under experimental conditions.[393,691,692,1335,1336] NSAID-related ulceration is typically described as predominantly glandular in nature, although nonglandular ulceration can also occur by a mechanism that has not yet been fully characterized. NSAIDs cause a decrease in PGE_2 synthesis caused by inhibition of the COX pathway. A resultant decrease in glandular mucosal protection, most notably via decreased mucosal blood flow and mucous production, is the most likely mechanism of action. In one study, however, phenylbutazone administration resulted in ulceration of the glandular mucosa at the pyloric antrum but did not significantly alter mucosal PGE_2 concentration.[1335]

Other risk factors associated with gastric ulceration include gender and age, and the reported prevalence of gastric ulcers has increased over time. In one study, the frequency of gastric ulceration increased from <6% before 1945 to approximately 18% after 1975.[1302] The association between sex or age and ulceration has not been consistent among studies.[1291,1293,1302,1337] Crib biting has also been discussed as a risk factor for ESGD.[1331,1338] In foals, risk factors are less clearly defined and will be discussed along with the clinical syndrome in each age group. Limited access to water has been associated with ESGD.[1328]

Clinical Syndrome: Neonatal Foals

Clinical signs typically associated with gastric ulceration in foals include poor appetite, diarrhea, and colic. Many foals probably never exhibit clinical signs, and some do not exhibit clinical signs until ulceration is severe or fatal perforation has occurred. Glandular ulceration is typically considered the most clinically significant type of disease in this population.

The physiologic stress of a concurrent illness has been associated with gastric ulceration in foals. Retrospectively, 14 (23%) of 61 foals up to 85 days of age with a clinical disorder had lesions in the gastric glandular mucosa,[1307] and prospectively 8 (40%) of 20 foals up to 30 days of age with a clinical disorder had glandular ulceration.[1339] In contrast, only 4% to 9% of clinically normal foals examined in endoscopic surveys had lesions in the gastric glandular mucosa.[1306,1340]

Critically ill neonatal foals can have a markedly different pH profile compared with that seen in clinically normal foals, potentially caused by alterations in gastric motility and acid secretion.[1321] Gastric ulceration was not identified in any animals at necropsy in that study; however, ulceration has been documented in a similar population.[1305] Thus factors other than acid exposure, most notably mucosal perfusion, may play an important role in the "stress"-related ulceration seen in neonates. Gastric ulceration and rupture in the hospitalized neonatal population appears to occur less commonly now than in previous reports, despite a decline in the use of ulcer prophylaxis in one hospital.[1341] Advances in overall neonatal care, especially supportive care, have likely contributed to this decline.

FIG. **12.20** Endoscopic image of the lesser curvature in a 3-month-old foal diagnosed with gastroduodenal ulcer disease and a gastric outflow obstruction.

Gastroduodenal Ulcer Disease

GDUD occurs almost exclusively in suckling and early weanling foals. Clinical signs of duodenal ulceration are similar to those described for gastric ulceration (bruxism, colic, ptyalism, and diarrhea), but the consequences are often more severe. Lesions occur primarily in the proximal duodenum, ranging from diffuse inflammation to severe ulceration, but affected foals typically have severe squamous and/or glandular ulceration as well (Fig. 12.20). Foals with duodenal ulceration often have delayed gastric emptying and may have gastroesophageal reflux. Complications can include gastric or duodenal rupture, pyloric or duodenal stricture (Fig. 12.21), and ascending cholangitis. Severe squamous and esophageal ulceration and aspiration pneumonia can occur secondary to gastroesophageal reflux.[1222,1342-1345]

GDUD syndrome can occur in outbreaks and is most commonly identified in intensive breeding operations. The cause of duodenal lesions in foals is not known. One theory is that the problem begins with diffuse duodenal inflammation that can coalesce down to a focal area of ulceration (G.D. Lester and A.M. Merritt, personal communication). A temporal relationship between GDUD and rotaviral diarrhea has been suggested, but an infectious etiology remains unproven. Although lesion location and severity associated with rotaviral infection varies among species, duodenal ulceration has not been reported.[1346]

Clinical Signs: Adults

Reported clinical signs attributable to EGUS in adult horses are variable and classically include anorexia and intermittent or recurrent postprandial colic of varying severity.[1347] Overall,

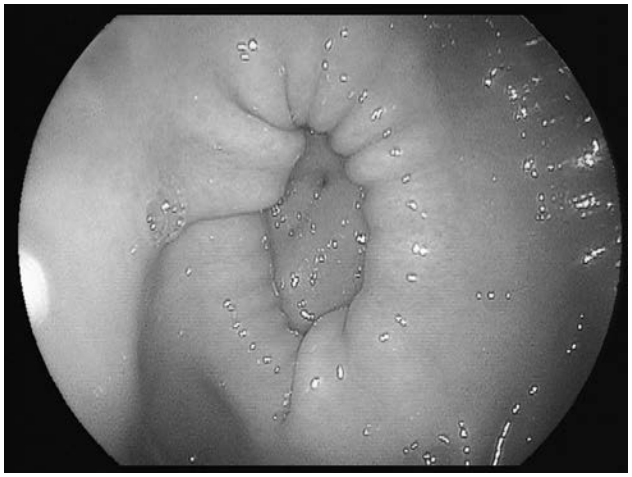

FIG. **12.21** Endoscopic image of the pylorus in the foal depicted in Fig. 2, 2 months after surgery. Note the extremely small pyloric opening, which had formed a mechanical obstruction to gastric outflow.

clinical signs are nonspecific and poorly associated with the presence of EGUS.[1285] Many horses with endoscopic evidence of disease may appear to be clinically normal. Vague signs including decreased consumption of concentrates, postprandial episodes of colic, poor performance or failure to train up to expectations, poor quality hair coat, and diminished condition or failure to thrive have been reported. Diarrhea is not typically associated with gastric ulceration in adult horses, although ulceration can occur concurrently with other causes of diarrhea. Bleeding from ulcers in the gastric squamous mucosa is typically not associated with anemia or hypoproteinemia.

Diagnosis

Gastroscopy is the only reliable method for diagnosis of EGUS in the live animal.[1285] Evaluation of the entire stomach and, preferably, proximal duodenum is critical to a diagnosis, because there is no relationship between the presence of squamous and glandular ulceration.[1295,1308,1309] Urine[1348] and blood[1349] sucrose absorption testing or fecal albumin or hemoglobin[31] is not reliable. Various ulcer scoring systems have been promoted, but the system proposed by the Equine Gastric Ulcer Council[1284] (Table 12.11) has been recommended because of its repeatability and ease of use.[1285,1350]

Duodenal ulceration can be difficult to confirm, and duodenoscopy is the most specific means of diagnosis, although the procedure is more difficult than gastroscopy. Diffuse reddening or inflammation may be the only recognizable lesion in foals with early duodenal disease. In older foals with GDUD, detection of gastric outflow obstruction is critical to the therapeutic plan and appropriate prognosis. A distended stomach is typically evident with ultrasound. Abdominal radiography without contrast in foals with outflow obstruction typically reveals a distinctly enlarged, gas-filled stomach. Liquid barium contrast will either have markedly delayed (with incomplete obstruction) or no (complete obstruction) outflow. Clinically, foals with outflow obstruction will develop reflux after suckling, or marked reflux even with limited to no suckling if the duodenal obstruction is distal to the common bile duct.

TABLE **12.11** **Equine Gastric Ulcer Syndrome Lesion Scoring System**[1284]

Lesion Grade	Description
0	Intact epithelium with no appearance of hyperemia or hyperkeratosis
1	Intact mucosa with areas of reddening or hyperkeratosis (squamous)
2	Small single or multifocal lesions
3	Large single or multifocal lesions or extensive superficial lesions
4	Extensive lesions with areas of deep ulceration

Diseases of the teeth. In: Colohan PT, Mayhew IG, Merritt AM, et al., eds. *Equine medicine and surgery,* 4th ed., Vol. 1, Goleta, CA: American Veterinary Publications; 1991.

Treatment

Multiple pharmacologic treatments have been suggested for the treatment of EGUS, and these can vary for ESGD, EGGD, and GDUD. Because acid has been implicated as the most important pathophysiologic component of ESGD, acid suppression is critical. The principal therapeutic options for ulcer treatment include H_2 antagonists (cimetidine, ranitidine, famotidine, and nizatidine), proton pump inhibitors (PPIs; omeprazole, pantoprazole, rabeprazole, and esomeprazole), the mucosal adherent sucralfate, and antacids.

The H_2 antagonists suppress hydrochloric acid secretion through competitive inhibition of the parietal cell histamine receptor that can be partially overcome with exogenous pentagastrin.[1351] Use of H_2 antagonists has been successful in raising gastric pH and resolving gastric lesions in both foals and adult horses.[1320,1344,1352] Clinical and experimental evidence has demonstrated greater individual variability with lower dosages of H_2 antagonists.[1339] Thus dosage recommendations are based on levels necessary to increase gastric pH and promote ulcer healing in a majority of horses. Commonly recommended ranitidine dosages are 6.6 mg/kg orally every 8 hours or 1.5 to 2 mg/kg IV every 6 hours. Although clinically normal foals respond predictably to ranitidine,[1320] sick neonates have shown variability in pH response to IV ranitidine, with a much shorter duration of action and, in some cases, no noticeable response.[1321]

PPIs block secretion of H^+ at the parietal cell membrane by irreversibly binding to the H^+, K^+-ATPase proton pump. The powder form of omeprazole is rapidly degraded in an acidic environment; an enteric-coated capsule or a specially formulated paste must be used to allow delivery of the active drug to the small intestine for absorption. An increase in gastric pH and a decrease in acid output are evident 5 to 8 hours after omeprazole paste administration.[1353] Omeprazole (GastroGard, Merial, Ltd., Duluth, GA) is the only currently FDA-approved agent for the treatment of EGUS in the United States; other preparations, including enteric-coated granules and buffered formulations, are available elsewhere.[1354-1356] In the United States, compounded preparations have shown limited to no efficacy in pharmacodynamic and clinical trials,[1357,1358] and GastroGard was the only product (including buffers, H_2-receptor antagonists, sucralfate, and compounded preparations) that decreased the odds of gastric ulceration in a

population of racehorses.[1359] Several studies have documented the safety of oral omeprazole in foals and adult horses.[1360,1361] Omeprazole appears more effective for ulcer healing than either ranitidine or cimetidine.[1362,1363] Omeprazole (4 mg/kg PO q 24 h) has consistently demonstrated efficacy of (70%–80% healing) for ESGD, including Thoroughbreds maintained in race training.[816,815,1362,1364-1366]

Treatment with 1 mg/kg, 2 mg/kg, or 4 mg/kg orally every 24 hours decreases or prevents disease or the recurrence of disease in horses maintained in training.[815,1330,1367,1368] Other preparations have shown efficacy for ESGD healing at lower dosages (1 mg/kg or 2 mg/kg PO q 24 h) in clinical trials,[1354,1369,1370] although a lower dosage is not yet recommended for treatment. Preexercise versus postexercise administration did not have a significant effect on healing of ESGD or EGGD in a recent trial.[1371] Duration of therapy for ESGD has been recommended for 28 days, although most healing likely occurs within 21 days.[1364] In summary, the primary current recommendation for treatment of ESGD is omeprazole, 4 mg/kg PO q 24 h for 21 to 28 days. In locations in which the enteric-coated granule formation is available, 1 mg/kg may be substituted. Alternate recommendations include ranitidine or lower dosages of omeprazole.[1285]

Lower healing rates (25%) have recently been reported following omeprazole treatment for EGGD.[1354,1370,1371]

Omeprazole (4 mg/kg) also has demonstrated efficacy for raising intragastric pH in clinically normal[1372] or critically ill[1373] foals and for ulcer healing in foals.[1366] The definitive reason for this is unknown but may be related to timing or duration of acid suppression. A bacterial role in EGGD has not been established, despite solid efforts, and the addition of trimethoprim-sulfa did not have apparent benefit in ulcer healing.[1374] Because these factors and basic principles of responsible antimicrobial use, antimicrobial therapy is not recommended for treatment of EGUS in general or EGGD specifically.[1285]

Sucralfate is effective in the treatment of peptic ulcers and prevention of stress-induced ulcers in humans, likely via adherence to ulcerated mucosa, stimulation of mucous secretion, enhanced PGE synthesis, and concentration of growth factor at the site of ulceration.[1375] These are all factors relevant to glandular mucosa; thus, its use seems reasonable for treatment of EGGD. In one study, sucralfate did not promote subclinical ulcer healing in foals, relative to corn syrup.[1376] In a recent study, sucralfate (12 mg/kg PO q 12 h) combined with omeprazole (4 mg/kg PO q 24 h) resulted in a 67.5% EGGD healing rate.[1377] Current recommendations for EGGD include omeprazole plus sucralfate at the previously mentioned dosages for a minimum of 4 weeks, followed by repeat gastroscopy.[1285] Therapy for at least 8 weeks should be pursued before the addition of adjunctive therapy.

The use of synthetic PGE_1 analogs, such as misoprostol, has been effective in the treatment of gastric and duodenal ulcers in humans, and the proposed mechanism of action involves both inhibition of gastric acid secretion and mucosal cytoprotection.[1378] In horses, misoprostol (5 μg/kg) increases gastric pH[1379] and ameliorates deleterious effects of flunixin on mucosal recovery after ischemic injury in vitro,[391] but data supporting its use in clinical trials are currently lacking. Misoprostol is contraindicated in pregnant mares.

Prokinetic drugs should be considered in foals with duodenal disease, gastroesophageal reflux, and when delayed gastric emptying without a physical obstruction is suspected. Bethanechol and erythromycin have been shown to increase the rate of gastric emptying in horses.[1006] In foals with acute gastric atony, bethanechol 0.025 to 0.030 mg/kg SC every 3 to 4 hours has been effective in promoting gastric motility and emptying, followed by oral maintenance dosages of 0.35 to 0.45 mg/kg three to four times daily. Adverse effects can include diarrhea, inappetence, salivation, and colic, but at the dosages stated, adverse effects have been infrequent and mild.

For foals with severe GDUD that have developed duodenal stricture, surgical therapy is necessary.[1343,1380] These animals require a serious financial commitment because intensive perioperative medical therapy is critical for a successful outcome. Prognosis in two recent abstracts has improved over that previously reported. In one, 98% of surgically treated foals survived to discharge from the hospital, with 68% survival 8 months following discharge from the hospital.[1381] In that study, of the surviving Thoroughbreds of racing age, 71% had started a race. In another, short-term survival was reported as 80% for those foals treated surgically and 50% for those treated medically.[976]

A compounded IV preparation of omeprazole (0.5 mg/kg) increases gastric juice pH and decrease the number of nonglandular lesions in horses.[1382] From a regulatory standpoint, omeprazole (4 mg/kg PO q 24 h) does not appear to affect quantitative measurements of performance in Standardbreds.[1383]

Prophylaxsis

Because gastric perforation caused by glandular ulcer disease has been reported in hospitalized neonates, many clinicians routinely use prophylactic antiulcer therapy in this population. Because some critically ill foals have a predominantly alkaline gastric pH profile, and because gastric acidity may be protective against bacterial translocation in neonates, the need for prophylactic ulcer therapy is controversial. In critically ill human neonates, although IV ranitidine therapy increases gastric pH and gastric bacterial colonization, it does not increase the risk of sepsis.[1384] In a retrospective study of 85 hospitalized foals <30 days of age, no difference in the frequency of gastric ulceration at necropsy was found between those foals that received prophylactic treatment for gastric ulcers and those that did not; none died as a result of gastric ulcer disease.[1341] In a multicenter retrospective study, acid prophylaxis was associated with an increased incidence of diarrhea but not with alteration in clinical outcome.[1385] Many clinicians no longer recommend routine ulcer prophylaxis in all ill neonates. Exceptions could potentially include those foals requiring significant doses of NSAIDs for painful orthopedic disorders.

In adults, dietary and environmental management can help prevent gastric ulceration. Pasture turnout and continuous access to good quality forage, especially alfalfa, are currently recommended. For horses at high risk, the best proven pharmacologic approach to prevention involves administration of omeprazole 1 to 2 mg/kg orally every 24 hours.[815,1363,1367,1368] Further work on these recommendations will likely be forthcoming.

Neutraceuticals and Antacids

Although appealing, most agents have not yet been shown to promote healing of EGUS. Some products—including those containing sea buckthorn berries[1386]; organic acids and B vitamins[1387]; and a combination of yeast, magnesium hydroxide, and Apolectol[1388]—have shown promise for prevention of EGUS. Various other products, including a pectin-lecithin complex, have not demonstrated efficacy despite initial promise.[1389]

The use of antacids in the treatment of gastric ulcers has not been critically examined in the horse. Research in horses has shown that 30 g aluminum hydroxide/15 g magnesium hydroxide will result in an increase in gastric pH above 4 for approximately 2 hours.[1390] Although antacids may be useful for the treatment of ulcers in horses, a dose of approximately 180 to 200 mL every 2 to 4 hours is necessary for a standard adult horse, and the use of antacids is not justified or recommended.

Other Disorders of the Stomach

Pyloric Obstruction and Delayed Gastric Emptying

Pyloric stenosis is a structural resistance to gastric outflow. Congenital pyloric stenosis has been reported in foals and one yearling and results from hypertrophy of the pyloric musculature.[1061,1391,1392] Acquired pyloric stenosis can result from neoplasia or duodenal ulceration.[1393-1396] Clinical signs are dependent on the degree of obstruction but include abdominal pain, salivation, and teeth grinding. Complete or near complete obstruction can result in gastric reflux and reflux esophagitis. In foals with congenital pyloric hypertrophy, clinical signs may begin with the consumption of solid feed. In foals, a presumptive diagnosis can be made via gastric endoscopy and radiography (plain and contrast studies). Depending on the cause and severity of disease, gastric endoscopy may provide a presumptive diagnosis in the adult horse. Measurement of gastric emptying can aid the diagnosis. Several methods of measurement are currently available, including nuclear scintigraphy, acetaminophen absorption, and postconsumption [^{13}C]octanoic acid blood or breath testing.[986,1006,1397] During an exploratory laparotomy, a distended stomach and thickened pylorus are accompanied by a relatively empty intestinal tract.

If complete obstruction is not present, medical therapy with a prokinetic such as bethanechol can increase the rate of gastric emptying.[1006] Phenylbutazone and cisapride have also been shown to attenuate the delay in gastric emptying caused by endotoxin administration.[986,987] Surgical repair is necessary for definitive treatment of complete or near-complete obstruction and consists of either gastroenterostomy or pyloroplasty.[1075,1380] Pyloric-duodenal intussusception has been reported in an adult horse presenting for colic.[1398]

Gastric Dilatation and Rupture

Gastric dilatation can be classified as primary, secondary, or idiopathic. Causes of primary gastric dilatation include gastric impaction, grain engorgement, excessive water intake after exercise, aerophagia, and parasitism.[1396,1399] Secondary gastric dilatation occurs more commonly and can result from primary intestinal ileus or small or large intestinal obstruction. Time to development of gastric reflux is proportional to the distance to the intestinal segment involved, with duodenal obstruction resulting in reflux within 4 hours.[1400] Clinical signs of gastric dilatation include those associated with acute colic and, in severe cases, ingesta appearing at the nares. Associated laboratory abnormalities include hemoconcentration, hypokalemia, and hypochloremia.[1396]

The most common cause of gastric rupture in horses varies among reports. In a retrospective study of 54 horses, gastric rupture occurred most commonly as a secondary phenomenon (65%), usually caused by small intestinal obstruction, with primary gastric dilatation and idiopathic rupture occurring almost equally (15% and 17%, respectively).[1399] In another retrospective study of 50 horses in combination with a search of the Veterinary Medical Database (VMDB), 60% of the gastric rupture cases were classified as idiopathic.[1401] Risk factors for gastric rupture include feeding grass hay, not feeding grain, gelding, and a nonautomatic water source.[1399,1401] Nasogastric intubation does not preclude the possibility of gastric rupture, and the amount of reflux obtained before rupture is highly variable.[1399] Because of the retrospective nature of these reports, one cannot rule out confounding factors with certainty.

Regardless of the initiating cause, gastric rupture usually occurs along the greater curvature. In horses with rupture caused by gastric dilatation, tears in the seromuscular layer are frequently larger than the corresponding tears in the mucosal layer, indicating that the seromuscularis likely weakens and tears before the mucosa.[1399,1401] In contrast, horses with gastric rupture secondary to gastric ulceration usually demonstrate full-thickness tears of equal size in all layers. Gastric rupture is usually fatal because of widespread contamination of the peritoneal cavity, septic peritonitis, and septic shock. Initial clinical signs vary with the primary disease; however, when rupture occurs, an animal previously in pain can exhibit signs of relief. Subsequent signs are consistent with peritonitis and shock, including tachypnea, tachycardia, sweating, and muscle fasciculations. Surgical repair is difficult but has been reported for partial-thickness tears,[1402] and, in one case of a combined tear of the mucosa and muscularis with only a focal serosal tear, a full-thickness repair was performed with a favorable outcome.[1403]

Gastric Impaction

Gastric impaction can result in either acute or chronic signs of colic in the horse. Although a specific cause is not always evident, ingestion of coarse roughage (straw bedding and poor-quality forage), foreign objects (rubber fencing material), and feed that may swell after ingestion or improper mastication (persimmon seeds, mesquite beans, wheat, barley, and sugar beet pulp) has been implicated.[1404-1407] Possible predisposing factors include poor dentition, poor mastication and rapid consumption of feedstuffs, and inadequate water consumption. Clinical signs can vary from anorexia and weight loss to those consistent with severe abdominal pain. In severe cases, spontaneous reflux may occur, with gastric contents visible at the nares. In cases presenting with acute severe abdominal pain, a diagnosis is often made during exploratory celiotomy. In animals not exhibiting signs of colic warranting surgical intervention, an endoscopic finding of a full stomach after a normally adequate fast (18–24 hours) can often confirm the diagnosis. Abdominal radiographs are reserved for smaller horses and ponies. In addition to pain management, specific treatment consists of gastric lavage via nasogastric intubation or massage and injection of fluid to soften the impaction during laparotomy.[1404-1406]

Miscellaneous Causes of Gastritis

Nonulcerative gastritis rarely appears to be a clinical problem in the horse, but it has been reported at necropsy in a large retrospective study.[1302] Emphysematous gastritis caused by *C. perfringens*[1408] and *C. septicum*[1409] has been reported.

Neoplasia of the Alimentary Tract

Neoplasia in the alimentary tract of the horse is uncommon.[1410] Primary and metastatic neoplasia can affect multiple locations within the oral cavity and gastrointestinal tract, and occurrence is not isolated to geriatric horses. The alimentary form of lymphoma occurs commonly in horses less than 5 years of age.[1411] In one study, Arabian horses were 4.5 times more likely to have intestinal neoplasia relative to other breeds.[1412] Identification of tumor type is important for formulating a prognosis and therapeutic plan.

CLINICAL SIGNS

The clinical signs associated with alimentary neoplasia are related to the tumor location. For example, oral tumors can cause cutaneous enlargement; tumors of the tongue can cause quidding, dysphagia, and halitosis[1413]; tumors of the esophagus cause dysphagia, ptyalism, intermittent colic, weight loss, and halitosis[1219,1414,1415]; and gastric neoplasia is associated with anorexia, weight loss, abdominal distention, and intermittent fever.[1416] Abdominal neoplasia has been implicated in 4% of horses with intermittent or chronic colic.[1417,1418] Weight loss is the most common clinical sign of horses with intestinal neoplasia.[1412] Acute signs of colic can occur with intestinal obstructions from malignant or benign tumors. Paraneoplastic syndromes can occur in the horse. These include weight loss despite adequate caloric intake (cancer cachexia), ectopic hormone production, anemia, leukocytosis, thrombocytopenia, hypergammaglobulinemia, fever, and neurologic abnormalities.[1419]

Diagnostic Evaluation

Diagnosis of alimentary neoplasia can be challenging. Data collected from a complete blood count, biochemistry panel and urinalysis are rarely confirmatory. Normocytic normochromic anemia of chronic disease is the most common red cell abnormality associated with abdominal neoplasia; blood loss and hemolytic anemia occur less frequently.[1420] Peripheral eosinophilia and MEED have been reported with lymphoma.[1421] Leukocytosis and hyperfibrinogenemia are common. The most common biochemical abnormalities include hypoalbuminemia, hyperglobulinemia, and hypercalcemia.[1422,1423] Hypoglycemia can occur with pancreatic or hepatic neoplasia.[1423]

Rectal examination may detect an abdominal mass, thickening of the intestinal wall, or lymph node enlargement. Rectal biopsy can detect diffuse lymphoma in some cases.[489] Some tumors can exfoliate into the peritoneal cavity, allowing diagnosis via abdominocentesis.[1414,1424-1426] Collecting a large volume of fluid followed by Cytospin and subsequent cytologic evaluation may improve the diagnostic potential; characterization as an inflammatory exudate or modified transudate without any neoplastic cells present is common. Neoplasia was the apparent cause of hemoperitoneum in 13% of cases in one report of 54 cases.[1427] Abdominocentesis accurately predicted neoplasia in 11 of 25 cases in another study.[769]

Specific immunoglobulin testing for IgM deficiency may aid in the diagnosis of lymphoma.[1428] DNA cell cycle analysis of suspect neoplastic cells has been used to detect lymphoma in equine patients confirmed with the disease. This method of evaluating fluid or tissue aspirates may increase the accuracy for diagnosing neoplasia in the future.[1429]

Previously mentioned diagnostics, such as endoscopy, contrast radiography, and cross-sectional imaging may be helpful depending on tumor location. For abdominal neoplasia, transcutaneous ultrasonography is often most useful. An experienced sonographer and thorough examination are likely to improve diagnostic yield.[46] Laparoscopy or exploratory laparotomy may be required to obtain a final diagnosis.

Specific Tumors

Lymphoma is the most common neoplasia in the horse and has been divided into four categories[1412]; only the intestinal/alimentary form will be discussed. The term *lymphoma* is preferred over lymphosarcoma because there is no benign form of this disease.[1423] Lymphoma originates from lymphoid tissue and predominantly affects intestinal lymph nodes. Chronic weight loss, intermittent colic, and fever are the most common clinical findings[502,1430]; chronic diarrhea,[1431] pruritus, and alopecia[1432] have been reported. Peripheral lymphadenopathy is not generally noted, but enlargement of mesenteric lymphadenopathy may be palpable rectally. Therapeutic large colon resection has been reported in two horses with lymphoma.[1433]

SCC is the second most common neoplasia in the horse and is the most common tumor of the proximal gastrointestinal tract.[1434] In the oral cavity SCC may affect the lips, tongue, hard palate, pharynx, and oral mucosa.[1435,1436] Metastasis beyond the regional lymph nodes is rare for oral, esophageal, and SCC, although it is possible. Abnormal masses were palpable rectally in 4 of 5 cases of gastric SCC.[1416] Most discussions of SCC treatment about the head are based on dermal, ocular, and adnexal SCC, which are more common. Available treatment includes surgical resection, iridium-192 brachytherapy, 5-fluorouracil, and intralesional cisplatin or carboplatin.[1437-1441] The prognosis for survival is good if complete resection is possible, although it typically is not for gastric SCC.[1423] Local recurrence is possible. One report of recurring SCC on the lip with metastasis to the lymph nodes was successfully treated with piroxicam over 58 months.[1442] Hypertrophic osteopathy secondary to gastric SCC has been documented in one horse.[1443]

Adenocarcinoma has been reported in the small intestine, cecum, and large colon.[1412,1434,1444] The tumor arises from the glandular crypts of the gastrointestinal tract and has been reported in middle-aged and older horses. Metastasis to the lymph nodes, liver, and lungs is possible; osseous metaplasia has also been reported.[1445] In a retrospective study of intestinal neoplasia, adenocarcinoma represented 32% of cases, 82% of which involved the small intestine.[1412] The short-term prognosis for resectable adenocarcinoma is fair; long-term prognosis remains poor.[1412,1446]

Leiomyosarcoma and leiomyoma are malignant and benign, respectively, tumors of the smooth muscle lining the gastrointestinal tract. Both have been reported in the stomach, small intestine, and small colon/rectum; leiomyoma has also been reported in the omentum.[1434,1447-1453] Clinical signs are consistent with intestinal obstruction, and prognosis is favorable with resection of the affected intestinal segment.

Lipoma is a benign tumor that occurs in older horses arising from mesenteric adipocytes. Clinical signs do not typically occur unless the tumor stalk results in intestinal obstruction.

Oral cavity neoplasia may involve the dental tissue (odontogenic tumors), bone (osteogenic tumors), or soft

tissues. Ameloblastoma occurs in horses >10 years old, and it mainly affects the mandible. Ameloblastic odontoma affects younger horses and usually involves the maxilla. Both are benign but locally invasive. Radiographs may distinguish between an ameloblastoma (radiolucent lesion) and ameloblastic odontoma (radiolucent lesion with partially mineralized density). The best treatment option is surgical resection and/or radiation therapy regardless of the type.[1454]

Juvenile mandibular ossifying fibroma occurs in the rostral mandible of young horses between the age of 2 months and 2 years. It may cause significant distortion of the bone. Surgical excision of the mass has a good prognosis if diagnosed early.[1455]

Melanomas, sarcoids, SCC, and papilloma can occur on the mouth and lips. Melanomas are commonly found in the commissure of the lips and parotid salivary glands and can metastasize to regional lymph nodes. Sarcoids can cause local ulcerations of the buccal mucosa, which are difficult to treat. Intralesional cisplatin, cryosurgery, radiation, and laser excision have been tried with limited success. Equine papilloma virus is responsible for the common skin wart that is found on the lips and muzzle of young horses. These lesions are typically self-limiting, but cryosurgery or excision can be used for removal, if desired.

CHAPTER 13

Disorders of the Liver

Thomas J. Divers and Michelle Henry Barton

NORMAL LIVER

Anatomy

The liver is the second largest single organ in the horse (skin is first), accounting for approximately 1.5% of body weight.[1] In the adult horse, the liver is positioned obliquely in the cranial abdomen, with the left lobes located ventrally near the ninth to tenth intercostal spaces and the right lobes positioned more dorsally and opposite the ninth to sixteenth intercostal spaces. The smaller ventral quadrate and right dorsal caudate lobes are located midabdomen.[2] The adult horse liver is completely contained within the rib cage and does not contact the ventral abdominal floor, although in disease processes resulting in hepatomegaly, the liver may extend beyond the caudal border of the last rib. In the fetus and newborn foal, the liver is relatively much larger, and on fetal ultrasound the liver is the easiest organ to identify.[1] The liver on the left encompasses approximately one third of the liver mass and is often adjacent to the more caudally located spleen; this provides an opportunity, when visualized with ultrasound, to compare the relative echogenicity of each organ. The liver should be hypoechoic compared to the spleen, and with hepatic fibrosis the liver and spleen appear more similar in echogenicity.[3] An unusual anatomic variant in horses is atrophy of the right lobe of the liver that occurs in some middle-aged to older horses. In this condition, there is a loss of hepatocytes with condensation of the hepatic stroma, and a thick, wrinkled hepatic capsule develops.[4] This atrophy may occasionally prevent ultrasound visualization of the right liver. The cause of this atrophy is somewhat unique to the horse and is not believed to be a result of divergence of arterial or venous blood flow. Instead, it is believed to result from compression of this portion of the liver by the right dorsal colon and cecum.[4]

The equine liver consists of two surfaces, diaphragmatic and visceral. The visceral surface of the liver in situ is malleable and contains impressions of the organs with which it is in contact. The visceral surface also contains the hilum, or *porta* (door), of the liver, through which blood vessels, lymphatics, and nerves enter, and the hepatic duct exits. In the horse, six ligaments secure the liver in the abdominal cavity.[2] The *coronary ligament* has two laminae, right and left, which attach the diaphragmatic surface of the liver to the caudal vena cava and the abdominal esophagus. The two laminae of the coronary ligament unite ventrally to form the *falciform ligament.* The falciform ligament, a remnant of the fetal ventral mesentery that extends from the diaphragm to the umbilicus, attaches the quadrate and left lobes to the sternal diaphragm and ventral abdominal floor. The *round ligament,* the remnant of the fetal umbilical vein, is contained within the free border of the falciform ligament. The right and left *triangular ligaments* attach the dorsal right lobe to the right costal diaphragm and the dorsal left lobe to the tendinous center of the diaphragm. The *hepatorenal ligament* connects the caudate process of the quadrate lobe to the right kidney and the base of the cecum.

Seventy percent of blood flow to the liver is deoxygenated blood from the hepatic portal vein.[5] The hepatic portal vein receives blood from the stomach, spleen, pancreas, small intestines, cecum, and large colon. The portal vein does not receive blood from the most distal colon and rectum, kidneys, reproductive organs, or mammary gland.[6] The other 30% of blood to the liver is oxygenated, provided by the accompanying hepatic artery.[5,7] Approximately 10% of the total blood volume at any one time is found in the liver.[5]

Bile ducts from each lobe join and eventually form the left and right hepatic ducts. These unite to form the common bile duct. Both the bile duct and pancreatic duct empty into the duodenum at the major duodenal papilla, located on a slightly raised mucosal ridge.[1] This ridge can be seen on endoscopic examination of the duodenum, just before the cranial flexure of the duodenum at the beginning of the sigmoid loop. Opposite the major duodenal papilla is a smaller projection into the bowel, the minor duodenal papilla, which contains the opening of the accessory pancreatic duct.

Histology

At the hilum of the liver, a tree of connective tissue consisting of collagen and fibroblasts enters the hepatic parenchyma. The parenchymal cells, or hepatocytes, compose approximately 50% to 60% of the mass of the liver and are epithelial cells.[8,9]

At the light microscopic level, the liver can be divided into structural arranged units called *hepatic lobules,* portal lobules, or acinus[1,5,6] (Fig. 13.1A). The classic hepatic lobule is a polygonal histologic unit composed of numerous plates of liver cells (hepatocytes), radiating centrifugally toward a *central vein.* Situated around the perimeter, at each "corner" of the hepatic lobule, are branches of the hepatic artery, hepatic portal vein, and bile duct (together called the *hepatic*

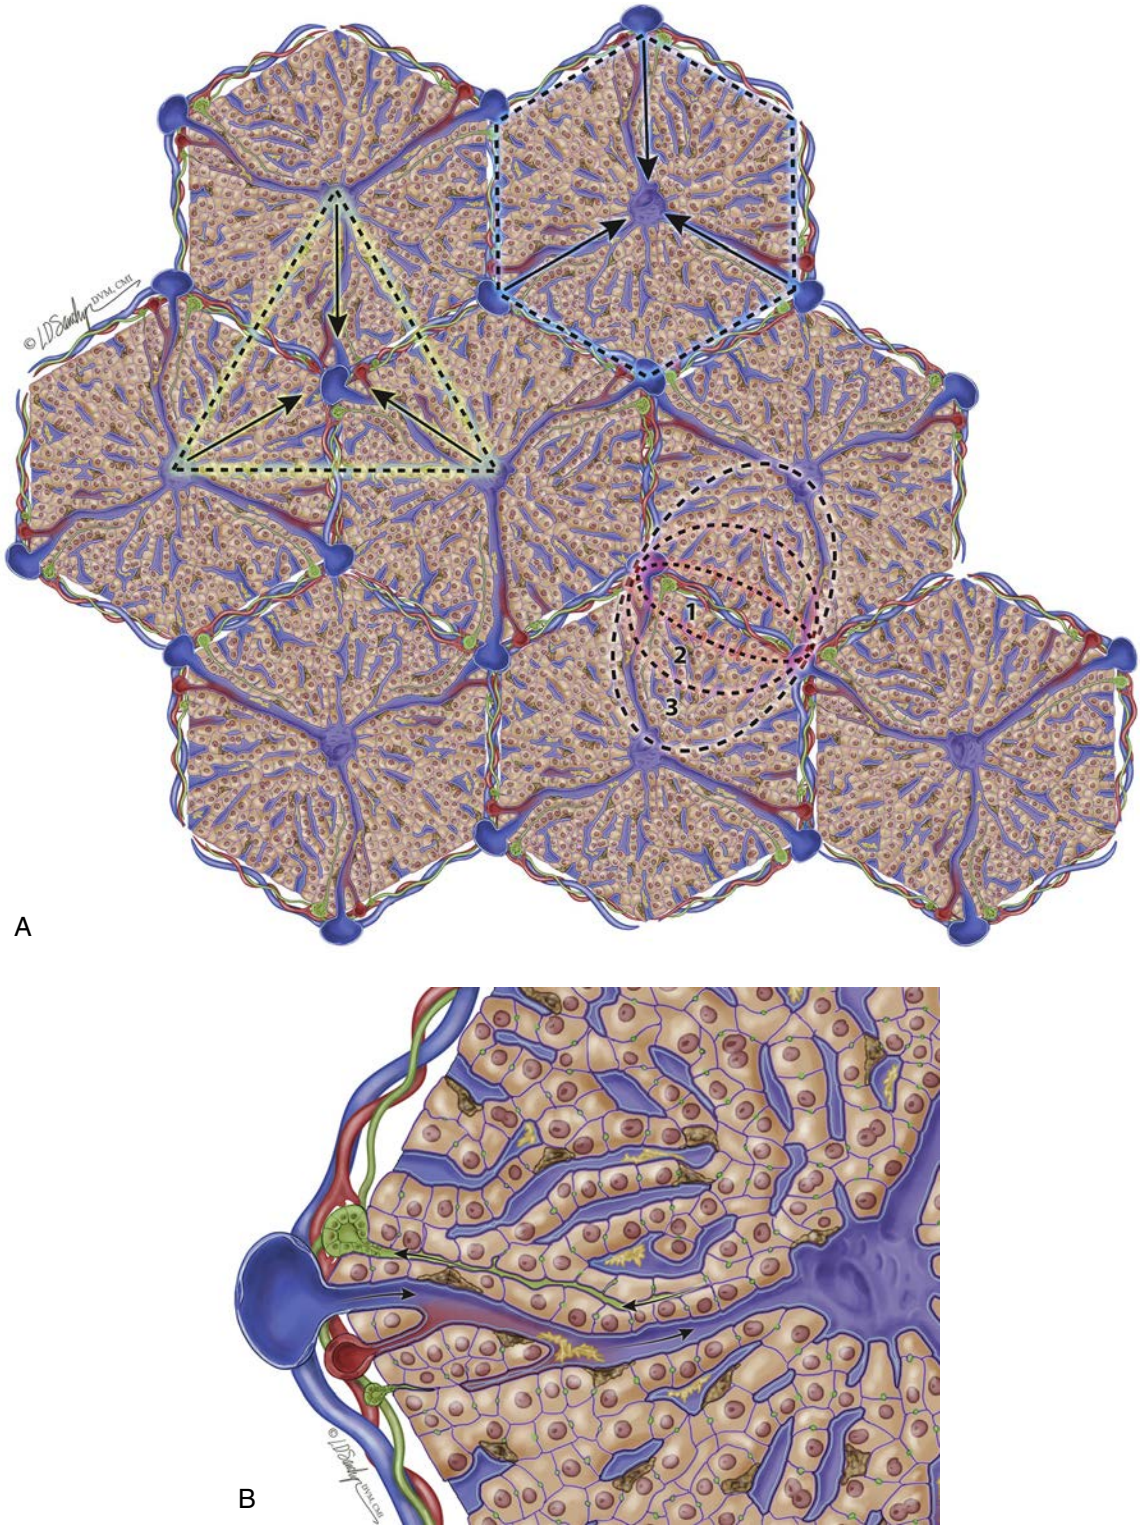

FIG. **13.1** (A) Anatomic and functional divisions of the liver. *Top right:* Classic hepatic lobule (emphasizes blood flow); cross-sectional view with portal triads centered around a single central vein. *Top left:* Portal lobule (emphasizes exocrine function/bile flow). Three central veins centered around a portal tract. *Lower right:* Hepatic acinus (emphasizes hepatic oxygen concentration to liver)—blood flowing from two hepatic triads (hepatic artery and portal vein) toward a central vein. Zone 1 has the highest oxygen content and zone 3 the lowest. (B) Basic liver structures. Hepatic arteries and portal veins perfuse the liver via the liver sinusoids that run between adjacent hepatic cords. The sinusoidal blood flows toward and drains into the central vein. Kupffer cells (depicted in the illustration as "shaggy"-appearing structures) are phagocytic cells of the mononuclear phagocyte series found on the luminal surface of the hepatic sinusoids. The space of Disse is located between the hepatocytes and the endothelium of the sinusoids, where blood components can be absorbed by the hepatocytes. Triangular-shaped cells in the illustration depict hepatic stellate cells (Ito cells), which are located in the space of Disse. On the opposite side of the hepatic cord from the sinusoid is the bile canaliculus draining bile toward the bile duct at the portal triad. The bile flow is opposite direction of blood flow *(arrows).* (Illustration courtesy of Dr. Lauren D. Sawchyn.)

triad), plus lymphatics. Blood from hepatic arterioles and portal venules, comprising approximately one third of the cardiac output, mixes together in *hepatic sinusoids* that surround the plates of hepatocytes, thus bathing each hepatocyte in a mix of arterial blood and venous blood. Sinusoidal blood then travels along the plates of hepatocytes toward the central vein, eventually entering larger hepatic veins that converge near the diaphragm to enter the caudal vena cava. Hepatic sinusoids (Fig. 13.1B) are larger than capillaries and are lined with endothelial cells and Kupffer cells. Kupffer cells are tissue-fixed macrophages and are estimated to make up 20% of the mass of the liver.[9] The endothelial cells make up approximately 20% of the mass of the liver.[9] A cleft, called the *space of Disse,* lies between the hepatocytes and the cells lining the sinusoids. The space of Disse contains fluid similar to the composition of blood but does not contain erythrocytes. The space of Disse also contains Ito cells, also called *hepatic stellate cells*, which store fat or fat-soluble vitamins (e.g., vitamin A).[5]

The space between contiguous hepatocytes in a cord forms a bile canaliculus through which bile excreted by the hepatocytes drains into bile ductules and ducts. The bile canaliculi thus are formed solely by the cell membranes of the hepatocytes. The bile ductules and ducts are lined with cuboidal and columnar epithelial cells, respectively, that make up approximately 7% of the mass of the liver.[9] The bile ducts run in the connective tissue tree, adjacent to branches of the portal vein and hepatic artery, to form a distinct portal tract, radicle, canal, or triad (see Fig. 13.1). The bile ducts converge at the hilum to form the *hepatic duct,* which drains into the duodenum just distal to the pylorus. Because the horse does not have a gallbladder or a sphincter at the entry site of the hepatic duct into the intestine, the bile is unconcentrated and flows almost continuously in a direction opposite that of the blood flow in the portal vein and hepatic artery.[2]

In contrast to the structural units, *hepatic lobules,* the portal lobule is viewed as a triangular (three central veins centered on a portal triad) oriented functional unit describing the exocrine (bile secretion) duties of the liver. The acinus lobules describe the vascular supply to the hepatic parenchyma, divided according to the tissue oxygen content. Zone I (periportal zone) of the acinus lobule is located immediately adjacent to branching hepatic arteries and portal veins, is the most metabolically active zone, and receives the best oxygen supply. Zone 1 hepatocytes are therefore especially suited for oxidative liver functions such as gluconeogenesis and β-oxidation of fatty acids. Zone 1 hepatocytes are the primary site for deposition of hemosiderin, which can be especially pronounced even in normal horses. Zone III is located adjacent to central veins, has the highest cytochrome P-450 mixed-function oxidase activity, is least favorably situated with respect to oxygen content, and thus is most susceptible to toxins that are metabolized in the liver and hypoxic damage.[10] Zone II is situated between zones I and III, and toxins such as creeping indigo *(Indigofera spicata)* may have a predominant zone II distribution pattern of disease.[11]

Physiology

The liver is both anatomically and functionally arranged such that it is the most important organ for assimilation and metabolism of nutrients, orally administered drugs, and gut-derived toxins or bacteria. The liver is the main organ involved in the regulation of nutrient distribution.[12] The majority of nutrients absorbed from the gastrointestinal tract pass directly to the liver via the portal circulation. The incoming nutrients are metabolized for energy, transformed to other nutrient classes, packaged and exported to peripheral tissues, or stored by the liver. The liver is capable of adjusting to the carbohydrate, protein, and lipid load from the gastrointestinal tract, as well as maintaining consistent blood levels of nutrients between feedings and in response to special needs. In addition to its role in nutrient metabolism and homeostasis, the liver is involved in excretion (bile), detoxification and metabolism of endogenous and exogenous substances, and hematopoiesis.[9]

Protein Metabolism

Amino acids, which are transported to the liver via the portal or hepatic blood, may be used in the biosynthesis of intrinsic hepatocellular proteins, plasma proteins, porphyrins, polyamines, purines, and pyrimidines.[12] The liver synthesizes 90% of the plasma proteins, including albumin, many factors involved in coagulation and fibrinolysis (fibrinogen and factors II, V, VII–XIII; antithrombin III; protein C; plasminogen; plasminogen activator inhibitor; α_2-antiplasmin; α_2-macroglobulin; and α_1-antitrypsin), transport proteins (haptoglobin, transferrin, ceruloplasmin, hormone transport proteins), and acute phase reactant proteins (α- and β-globulins).[9] The liver is the only site of synthesis of albumin, fibrinogen, and C-reactive protein and is a predominant site for production of amyloid A and hepcidin.[13] Hepcidin is a peptide hormone synthesized mainly in the liver. It reduces dietary iron absorption by reducing iron transport across the gut mucosa (enterocytes) and reduces iron exit from macrophages and the liver, the main sites of iron storage. In horses and many other species, endotoxemia and systemic inflammation therefore cause a rapid decline in serum iron.[14]

The liver is also capable of transamination, or the reversible transfer of an amino group on one amino acid to an α-keto acid, thus forming a new amino acid and a new keto acid. If the liver receives an excess of amino acids or if carbohydrates are unavailable as an energy source, the liver deaminates the amino acids and converts them to pyruvate, acetoacetate, and intermediates of the tricarboxylic acid cycle[12] (Fig. 13.2). These intermediates may be oxidized for energy or used as precursors in *gluconeogenesis,* the synthesis of glucose from noncarbohydrate precursors. Endogenous and exogenous glucocorticoids, glucagon, and thyroid hormone act directly on the liver to increase gluconeogenesis (Fig. 13.3). Simultaneously, glucocorticoids indirectly influence liver gluconeogenesis by promoting peripheral protein catabolism, thus increasing the availability of amino acids. Insulin inhibits gluconeogenesis in the liver.[15]

In addition to protein synthesis and gluconeogenesis, the liver plays an important role in eliminating the major toxic byproduct of amino acid catabolism, *ammonia.*[12,16] Tissues and intestinal microflora generate ammonia, which is subsequently released into the circulation. One method by which the liver, as well as certain peripheral tissues, eliminates ammonia is by synthesizing nonessential amino acids from α-keto acids and ammonia in a reversal of deamination. A fundamental reaction in the synthesis of nonessential amino acids is the formation of *glutamate* from α-ketoglutarate and ammonia

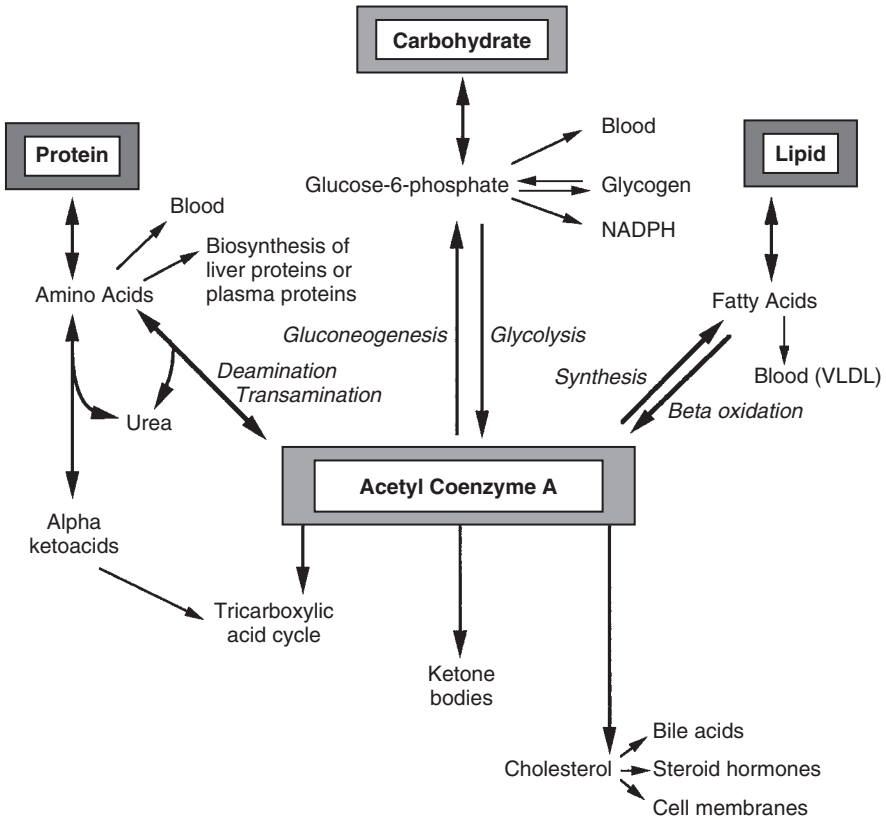

FIG. **13.2** Role of the liver in the metabolism of nutrients. *NADPH,* Nicotinamide adenine dinucleotide phosphate; *VLDL,* very low-density lipoprotein.

(Fig. 13.4). Subsequently, glutamate is used in transamination reactions to form other amino acids. Glutamate also participates in the conversion of cytotoxic free ammonia into a nontoxic (except in neuronal glial cells) transport form, *glutamine.* Glutamine may be delivered to the kidney, converted back to free ammonia and excreted, or delivered to the liver for urea synthesis. Excessive glutamine in the brain, mostly as a result of glial cell metabolism of excessive ammonia, may cause cerebral edema.[17]

The liver has sole responsibility for converting free ammonia or glutamine into *urea,* the principal form of amino group nitrogen excretion by mammals.[9] Urea is formed by the irreversible condensation of two ammonia molecules with carbon dioxide (see Fig. 13.4). The reaction takes place in the hepatocyte mitochondria via the Krebs-Henseleit cycle.[12] The newly formed urea is released from the hepatocyte, secreted into the sinusoidal blood, and transported to the kidney as *blood urea nitrogen* (BUN) for excretion.

Carbohydrate Metabolism

The liver is responsible for the synthesis, storage, and release of glucose.[12] Most soluble carbohydrates such as starches and sugars are readily broken down to glucose or other monosaccharides in the small intestine, absorbed and delivered via portal blood to the liver. In the hepatocyte the majority of glucose is phosphorylated to *glucose-6-phosphate* by the enzyme hexokinase (see Fig. 13.2). The remaining glucose is released into the systemic circulation. Other monosaccharides (fructose, galactose) are phosphorylated and converted in the liver to glucose-6-phosphate. The majority of glucose-6-phosphate is converted to glycogen for storage. A small amount of glucose-6-phosphate is oxidized to form adenosine triphosphate, although the major source of adenosine triphosphate in the liver is amino acid and fatty acid oxidation. Approximately half of the liver glucose enters the phosphogluconate pathway for generation of nicotinamide adenine dinucleotide phosphate, which is required as a reducing agent in the biosynthesis of fatty acids and cholesterol. Glucocorticoids, catecholamines, glucagon, and thyroid hormone increase gluconeogenesis and glycogenolysis in the liver, whereas insulin inhibits gluconeogenesis[15] (see Fig. 13.3). Structural carbohydrates are converted to volatile free fatty acids (VFAs) in the large bowel of the horse and are an important source of energy. Some of the VFAs (e.g., acetate) may be used directly for energy whereas others (e.g., propionate and lactate) undergo hepatic gluconeogenesis.[18,19]

Lipid Metabolism

Short-chain fatty acids (fewer than 10 carbon atoms) can be absorbed directly from the gastrointestinal tract, bound to albumin, and delivered to the liver via the portal circulation.[12] However, the majority of short-chain fatty acids are incorporated into phospholipid or triglyceride by the intestinal epithelium and transported to the liver via the portal blood. The remaining small percentage of fatty acids are absorbed from the gastrointestinal tract and are transported as triglyceride in *chylomicrons.* After formation in the intestinal epithelial cells and absorption into lymphatics, chylomicrons enter the systemic circulation via the thoracic duct and subsequently are delivered to the liver. The liver also may take up albumin-bound fatty acids released from adipose tissue.

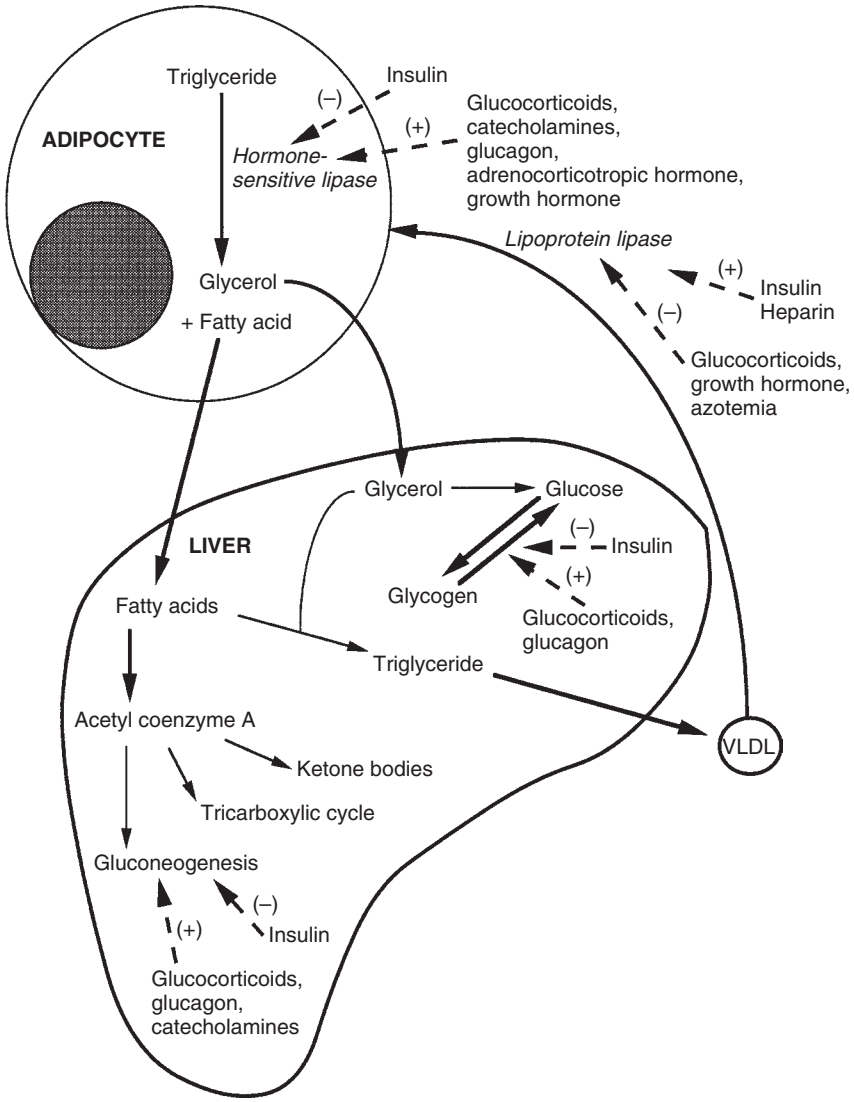

FIG. **13.3** Hormonal control of metabolism. –, Inhibitory effect; +, stimulatory effect.

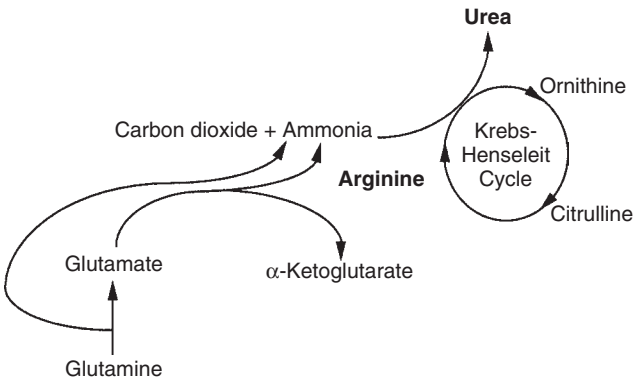

FIG. **13.4** The urea cycle.

The fate of fatty acids in the liver depends on the state of energy demand, the rate of fatty acid delivery, and hormonal influences. One of the primary roles of the liver in lipid metabolism is to esterify free fatty acids into triglycerides for export to other tissues[12] (see Fig. 13.3). The triglycerides are packaged with protein, carbohydrate, and cholesterol in the endoplasmic reticulum of the hepatocyte into *very low-density lipoproteins* (VLDLs), which primarily contain triglyceride, and *high-density lipoproteins* (HDLs), which primarily contain protein and phospholipid.[20] The VLDLs and HDLs are released into the hepatic sinusoids. Once the VLDLs are in the systemic circulation, the adipose tissue takes them up or endothelial cell lipases alter their composition by removing triglyceride, forming *intermediate-* and *low-density lipoproteins.*

In addition to exporting plasma lipoprotein, the liver can oxidize free fatty acids for energy to acetyl coenzyme A (acetyl CoA), a fundamental compound in the tricarboxylic acid cycle (see Fig. 13.2). The acetyl CoA thus formed also may be used in the synthesis of other fatty acids, cholesterol, steroids, and ketone bodies, acetoacetate, and β-hydroxybutyrate.[12] Furthermore, through the synthesis of acetyl CoA from glucose and most amino acids, the liver is capable of converting carbohydrates and proteins into lipids. Ketone bodies may occur from incomplete oxidation of free fatty acids in the liver and in other species are used for energy by peripheral tissues, especially the brain, when glucose is deficient. However, in the horse this does not appear to be a significant route for free fatty acid metabolism.

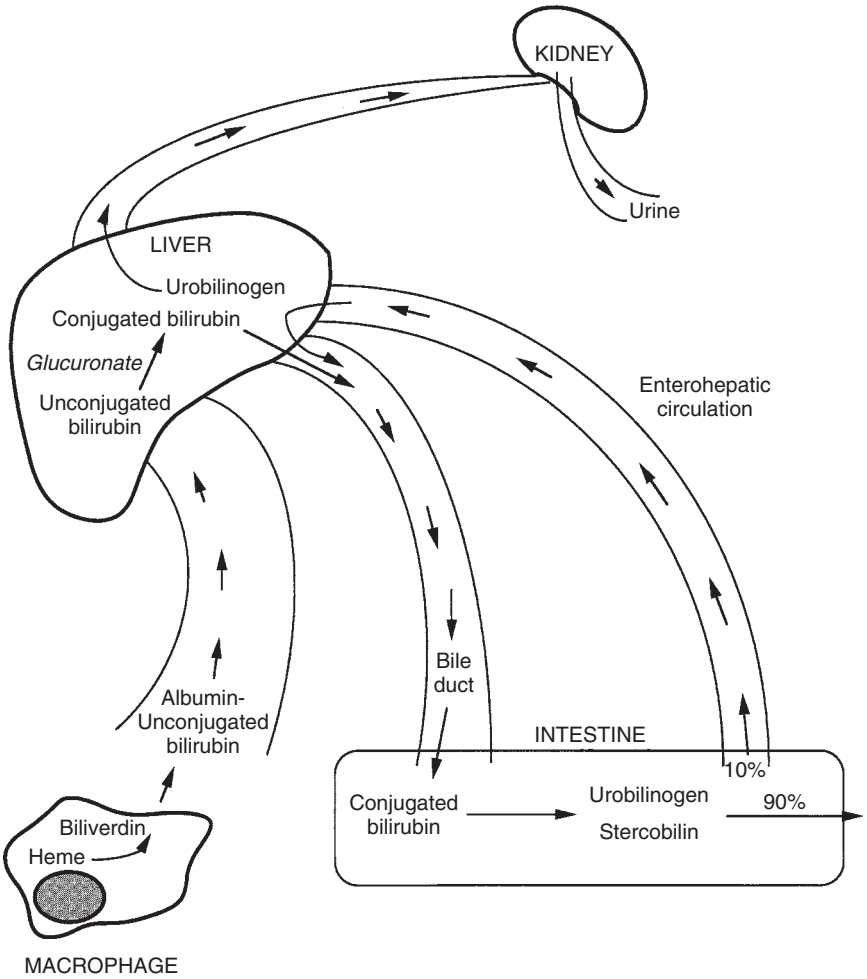

FIG. **13.5** Metabolism and excretion of bile.

Insulin and glucocorticoids closely regulate lipid metabolism[15] (see Fig. 13.3). Glucocorticoids function primarily to increase fatty acid mobilization from the periphery, whereas insulin decreases adipose tissue release of fatty acids by activating lipoprotein lipase and inhibiting hormone-sensitive lipase. Insulin acts on the liver to increase fatty acid synthesis from glucose.

Excretion of Bile

Bile consists of several components, including conjugated bilirubin, bile acids, cholesterol, lecithin, water, and electrolytes.[9] Bile is released by hepatocytes into the bile canaliculi where water diffuses passively. Bile then is transported by large bile ducts and the hepatic duct to the intestine. Water and electrolyte exchange takes place between the bile and the bile duct epithelium; however, isotonicity is maintained. Because the horse does not have a gallbladder or a sphincter at the site of entry of the hepatic duct into the duodenum, the bile is unconcentrated and flow is nearly continuous.[2]

Primary bile acids are produced in the liver, mostly from cholesterol, and compose 90% of the organic portion of bile.[21] Bile acids are amphoteric molecules that act as detergents. These detergents facilitate the excretion of cholesterol and phospholipid from the liver into bile and facilitate the digestion and absorption of lipids and lipid-soluble compounds (vitamins A, D, E, and K) from the intestinal tract. The principal *primary bile acids* (i.e., nondegraded) in the horse are *cholate* and *chenodeoxycholate,* both of which are conjugated with taurine.[21] Once secreted into the lumen of the intestinal tract, cholate and chenodeoxycholate may be reabsorbed or degraded by bacteria, forming the *secondary bile acids, deoxycholate* or *lithocholate,* respectively. More than 90% of the conjugated bile acids excreted in bile and released into the intestinal lumen are reabsorbed by the jejunum and ileum and returned to the liver via the *enterohepatic circulation.* Deoxycholate acts as a normal bile acid and can undergo enterohepatic circulation, whereas lithocholate is only reabsorbed once. Bile acids are estimated to be recycled at least 38 times a day in healthy ponies.[21]

Bilirubin is the breakdown product of tetrapyrroles that function as electron transport pigments.[4] The majority of bilirubin is formed from hemoglobin and myoglobin, but nonheme pigments such as the cytochromes also serve as a source of bilirubin. Macrophages in the spleen, bone marrow, and liver (Kupffer cells) engulf the pigments first, convert it to biliverdin (Fig. 13.5), and then convert biliverdin to bilirubin and release it from the cell as free, insoluble bilirubin. This form of bilirubin also is referred to as *indirect-reacting* or *unconjugated bilirubin.* Unconjugated bilirubin is bound with albumin in the plasma to decrease its hydrophobicity and is delivered to the liver. At the surface of the hepatocyte, the bilirubin is transferred from albumin to *ligandin,*

an intrahepatic transport and storage protein.[9,21] Within the hepatocyte, the bilirubin is conjugated with glucuronide in the endoplasmic reticulum. *Conjugated bilirubin,* also called *direct-reacting bilirubin,* is water soluble and is excreted into the bile canaliculi. Under normal circumstances, little conjugated bilirubin escapes into the general circulation. With severe liver disease increased amounts of conjugated bilirubin will escape into circulation and be freely filtered in the urine.

Microflora in the intestinal tract reduce conjugated bilirubin to *urobilinogen* and *stercobilin* (see Fig. 13.5), which impart a yellow-brown color to feces. In herbivores, the presence of chlorophyll pigments in the feces masks the color of urobilinogen.[22] Only in the neonatal herbivore receiving a milk diet are the feces yellow. Urobilinogen is absorbed by the intestinal mucosa and transported back to the liver via the enterohepatic circulation. A small amount of conjugated bilirubin in the intestinal lumen is hydrolyzed to unconjugated bilirubin and subsequently is reabsorbed. The liver extracts most of the urobilinogen; however, a small amount spills over into the urine. Urobilinogen is concentrated in the normally alkaline urine of horses and thus is detectable.[22]

Detoxification

The liver is responsible for the *biotransformation* of numerous endogenous and exogenous compounds. Biotransformation involves a series of enzymatic reactions that alter the physical properties or activity of compounds. Biotransformation occurs in two phases.[23] In phase 1, polar groups are added to the compound or existing polar groups are exposed by oxidation, hydroxylation, deamination, or reduction. In phase 2, the product of phase 1 is conjugated, usually with glucuronate or sulfate. Substrates for detoxification usually are water insoluble, and biotransformation renders them more susceptible to renal or biliary excretion.[9,24] Examples of endogenous substances biotransformed by the liver include ammonia, bilirubin, and steroid hormones (estrogen, cortisol, aldosterone). The liver biotransforms countless exogenous substances (xenobiotics), including many drugs, plant toxins such as pyrrolizidine alkaloids, insecticides, and mercaptans.

Phase 1 of biotransformation occurs primarily on the enzyme-bound systems of the endoplasmic reticulum, called *microsomes.*[9,24] Most of these enzymes are iron-containing enzymes of the P-450 system, thus named because they absorb light at 450 nm. The P-450 enzymes are also called *mixed function oxidases.* Some substrates, referred to as *inducers,* are capable of saturating the enzymes involved in biotransformation. Enzyme saturation and induction causes hypertrophy of the endoplasmic reticulum and all contained enzymes, thus accelerating substance removal rates. Inducers not only accelerate their own removal rate but also may accelerate the biotransformation of other endogenous and exogenous substances. Examples of enzyme inducers are the barbiturates, phenylbutazone, and chlorinated hydrocarbons. Other agents presented for biotransformation, including chloramphenicol, cimetidine, organophosphates, morphine, and quinidine, may inhibit microsomal enzymes, thus prolonging the effect of other substrates. Hepatic biotransformation sometimes results in the formation of a toxic metabolite from a nontoxic parent compound, examples being aspirin and halothane.[24] Compared to adult horses, young horses may have less ability to metabolize aromatic hydrocarbons and less conjugative ability and may be at greater risk when exposed to xenobiotics requiring metabolism by these systems.[25] This might explain why we have seen more markedly increased hepatic enzymes in foals versus adult horses exposed to the same toxic pasture containing red fescue (authors' experience).

Mononuclear Phagocyte System

Hepatic macrophages, or Kupffer cells, make up a major portion of the mononuclear phagocyte system. Cells of the mononuclear phagocyte system are derived from bone marrow myeloid progenitors and serve two main functions: (1) phagocytosis and (2) to act as antigen-processing cells for lymphocytes. Kupffer cells respond to opsonins and synthesize a vast array of inflammatory mediators, including interleukins, tumor necrosis factor (TNF), and eicosanoids. Unlike other macrophages in the mononuclear phagocyte system, Kupffer cells function mainly in phagocytosis and are located strategically along the hepatic sinusoids, where portal blood can be cleansed, for example, of bacterial endotoxin, before exposure to the hepatocytes and subsequently the systemic circulation.[5] Kupffer cells also help cleanse systemic blood entering via the hepatic artery by removing *fibrin degradation products (FDPs),* tissue plasminogen activators, hemoglobin, microbes, foreign antigens, and other particulate debris. They also help in recycling iron from senescent or injured red blood cells, and, as a result, Kupffer cells accumulate hemosiderin and this can be pronounced even in disease-free horses.[26]

Miscellaneous Functions

The liver serves as a storage site for several vitamins and trace minerals, including vitamins A, D, and B_{12}; copper; zinc; and iron. Vitamin D is first converted in the liver to 25-hydroxycholecalciferol and exported to the kidney, where it is transformed into 1,25-dihydroxycholecalciferol, the active form of the vitamin.[15] In the fetus the liver is involved in *hematopoiesis.*[9] In the adult the bone marrow serves as the primary site for hematopoiesis; however, the liver may serve as an extramedullary site of hematopoiesis under intense conditions of erythrocyte regeneration or if a large portion of the bone marrow is destroyed.

HEPATIC DISEASE AND HEPATIC INSUFFICIENCY

Definition

Hepatic disease is any type of damage (mild to severe and focal to diffuse) to the liver. Disease is best detected by increases in the serum of liver derived enzymes. *Hepatic insufficiency* or failure refers to the inability of the liver to perform its normal functions properly and is detected by both clinical signs and laboratory test of hepatic dysfunction. Because the liver is involved in such a diverse array of physiologic activities, any pathologic process may hinder one or several functions without impeding others. Furthermore, most hepatic functions are not impaired until greater than 80% of the hepatic mass is lost.[9,20,22] The liver also has the capability to regenerate under certain conditions. Although hepatocytes are fully differentiated cells, they are capable of active proliferation by self-duplication in response to acute external stimulation and upregulation of humoral factors, all without any contribution

from hepatic stem or progenitor cells.[27-29] However, in the chronically injured liver hepatocytes do not proliferate as well or as uniformly, and biliary cells commonly proliferate and form ductules around the portal veins. This biliary cell proliferation associated with chronic injury may contain progenitor cells, which can give rise to both hepatocyte and biliary cells in an attempt to repair the liver.[27,30]

If hepatocyte loss is gradual and regeneration parallels destruction, hepatic failure does not necessarily ensue. Thus hepatic disease may be present without accompanying hepatic failure. Consequently, hepatic disease does not always manifest clinically.

Patterns and Pathology of Hepatic Injury

The severity of the accompanying clinical signs and the course of hepatic disease vary depending on the pattern, location, rate, and extent of hepatic damage. The disease may be predominantly biliary or hepatocellular in origin or may affect both parts of the functional unit equally. This determination can sometimes be detected by degree of elevation in liver-derived enzymes in the serum. Hepatocyte injury may be reversible (fatty degeneration, cloudy swelling) or irreversible (necrosis), focal or zonal, generalized, acute, chronic, inflammatory, anatomic, or functional.

Acute Focal or Multifocal Hepatic Injury

Focal hepatic injury occurs with uniform damage to one small area of the liver. Examples of focal hepatic injury include hepatic abscesses, solitary infarctions, and neoplastic growths. Because adequate hepatic reserve exists in the unaffected regions, clinical signs of hepatic failure rarely accompany focal hepatic injury, although evidence of hepatic disease may be demonstrable.[23] Acute multifocal hepatic injury is more likely to result in clinically significant hepatic disease. Acute hepatic injury may be degenerative, infiltrative (fat or neoplasia), necrotizing, apoptotic, or inflammatory. Hepatic *degeneration* refers to a toxic or immunologic insult that causes hepatocytes to swell and take on an edematous appearance.[31] *Ballooning degeneration* is used to describe irregularly clumped cytoplasm with large clear areas.[14] If biliary material has been retained, the hepatocytes appear foamy and swollen *(foamy degeneration). Ischemic coagulative necrosis* refers to poorly stained and mummified hepatocytes with lysed nuclei, whereas *lytic necrosis* describes osmotically swollen and ruptured cells.[31] Necrosis of contiguous hepatocytes that spans adjacent lobules in a portal to portal, portal to central, or central to central fashion is called *bridging necrosis.*[14] In apoptosis, there is no disintegration of the cell membrane (wall); rather there is shrinkage of cellular contents along with clumping of the membrane. This leads to formation of condensed bodies known as *apoptotic bodies*. Necrotic and apoptotic modes of cell death are often intermingled as a continuous process during liver injury.[32]

Hepatic injury may be zonal—that is, affecting certain zones of the liver uniformly throughout the entire organ.[23] The liver often appears pale with an enhanced lobular pattern on the cut surface. The two most common types of zonal hepatic injuries are centrilobular and periacinar. In *centrilobular zonal injury,* the area adjacent to the central veins (zone III) is uniformly affected, whereas in *periacinar* or *(paracentral) zonal injury,* cellular degeneration involves only a wedge around the central vein (see Fig. 13.1). Hepatocytes in these locations are most susceptible to anoxic damage, because the normal oxygen tension is lowest and mixed function oxidase activity is the greatest in these areas. Examples of disease states resulting in centrilobular injury are severe acute anemia, passive congestion caused by congestive heart failure *(nutmeg liver),* and some toxic hepatopathies (e.g., pyrrolizidine alkaloids). Periportal (zone I acinar lobular) injury may occur with infarction of hepatic vessels, as may occur during verminous arteritis, or exposure to gut-derived toxins that do not require metabolism by mixed function oxidases (e.g., phosphorus).

Acute Generalized Hepatic Injury

Acute generalized hepatic injury is often accompanied by clinical signs of hepatic failure, with the extent of damage dictating the severity of the clinical signs.[23] Typically, the liver appears pale and enlarged and is often friable. Acute generalized hepatic injury may be the result of infection, necrosis, apoptosis, inflammation, or hepatotoxic agents.[9] Bacterial or viral infections, parasitic infestations, or immune disorders may cause acute generalized necrosis or inflammation. Despite its cause, any process that results in an inflammatory response in the hepatic parenchyma is referred to as *hepatitis.* Acute inflammation most commonly accompanies necrosis and is characterized by the presence of neutrophils and lymphocytes in the areas of cell death or surrounding portal triads. An inflammatory process primarily involving the biliary system is called *cholangitis,* usually the result of ascending infection from the intestinal tract or after cholestasis.

Chronic Generalized Hepatic Injury

Chronic hepatic injury is accompanied by clinical signs of hepatic failure when greater than 80% of the hepatic mass is destroyed or replaced by fibrosis.[9,20] Fibrosis, the presence of collagen and fibroblasts, occurs when the rate of ongoing necrosis exceeds the rate of regeneration. Following injury, hepatic fibrosis is believed to be promoted predominantly by hepatic stellate cells (also known as perisinusoidal or Ito cells).[5,7,27] These stellate-shaped cells are normally quiescent and are present in relatively small numbers containing intracellular lipids that serve to store vitamin A as retinal ester. However, when the liver is damaged, nearby Kupffer cells produce tumor necrosis factor–α (TNF-α), causing the stellate cells to contract individually but proliferate in numbers. These activated cells become chemotactic, decrease their vitamin A stores, secrete collagen (thus causing fibrosis), and eventually become senescent.[10,27]

Typically, the liver appears smaller than normal although on occasion it may be enlarged. Fibrosis commonly follows conditions resulting in chronic hypoxia, chronic inflammation, chronic cholangitis or cholestasis, metastatic neoplasia, trauma, or ingestion of antimitotic agents such as plants containing pyrrolizidine alkaloids. *Cirrhosis,* or an *end-stage liver disease,* refers to chronic hepatic disease characterized by the presence of widespread fibrosis, nodular regeneration, and biliary hyperplasia.[23] *Nodular regeneration,* or islands of hepatocytes, occurs when the normal architecture and blood supply of the liver are disrupted or destroyed by the presence of fibrosis. *Bridging fibrosis* implies fibrosis that extends from one portal area to another or from portal areas to central areas.[31] The cause of biliary hyperplasia during chronic liver disease is unknown. One form of chronic hepatic disease, called *chronic active hepatitis* (CAH), is characterized by the presence of cirrhosis plus an acute inflammatory response.[23]

BOX 13.1 Clinical Signs of Liver Disease

COMMON SIGNS

Depression
Anorexia
Colic
Hepatic encephalopathy (HE)
Weight loss
Icterus
Pigmenturia (yellow-brown with bilirubinuria; red-brown with hemoglobinuria)

LESS COMMON SIGNS

Photosensitization
Diarrhea
Bilateral laryngeal paralysis
Bleeding
Ascites
Dependent edema

RARE SIGNS

Steatorrhea
Tenesmus
Generalized seborrhea
Pruritus
Endotoxic shock
Polydipsia

Anatomic or Functional Injury

Anatomic or functional shunts cause liver injury by anoxic damage. Additionally, if blood habitually bypasses the liver, the liver cannot perform its normal metabolic regulatory or detoxifying functions; thus clinical signs of hepatic failure become imminent. Anatomic shunts can be either congenital or acquired, intrahepatic or extrahepatic.

Clinical Signs of Hepatic Insufficiency

The clinical signs of hepatic insufficiency are highly variable, are nonspecific, and depend on the extent and duration of hepatic disease (Box 13.1). Usually, greater than 80% of the liver mass must be lost or obstruction of the common bile duct occurs before clinical signs become apparent, regardless of the cause of hepatic disease. Thus despite the duration of hepatic disease, the onset of clinical signs is often abrupt. The most common clinical signs of hepatic insufficiency in horses are depression, anorexia, colic, hepatic encephalopathy (HE), weight loss, orange-colored urine, and icterus.[24,32-34] Less commonly reported clinical signs include hepatogenic photosensitization, diarrhea, abdominal pain, bilateral laryngeal paralysis, and hemorrhagic diathesis. Rarely reported clinical signs of hepatic insufficiency in horses are ascites, dependent abdominal edema, steatorrhea, tenesmus, generalized seborrhea, pruritus, endotoxic shock, polydipsia, and hemolysis. The appearance of specific clinical signs of hepatic disease often reflects the type of hepatic function (or functions) that is altered.

Hepatic Encephalopathy

HE is a complex clinical syndrome characterized by abnormal mental status that accompanies severe hepatic insufficiency.[35-37] Clinical signs are widely variable but represent manifestations of augmented neuronal inhibition. This syndrome occurs in patients with advanced decompensated liver disease of all types or hepatic shunts and may be a feature of acute, subacute, or chronic hepatocellular disease. HE generally is considered to be a potentially reversible metabolic encephalopathy.[36] Whether multiple episodes of HE could lead to irreversible neuronal damage is uncertain.

TABLE 13.1 Clinical Stages of Hepatic Encephalopathy

Stage	Mental Status
I	Mild confusion, decreased attention, slowed ability to perform mental tasks, irritability
II	Drowsiness, lethargy, obvious personality changes, inappropriate behavior, disorientation
III	Somnolent but rousable, marked confusion, amnesia, occasional aggressive uncontrolled behavior
IV	Coma

Adapted from Gammel SH, Jones EA: Hepatic encephalopathy, *Med Clin North Am*. 1989;73:793–813.

Clinical Signs. No specific features of HE allow this syndrome to be distinguished from other causes of cerebral dysfunction. The clinical signs of HE in horses may be mild with only depression, anorexia, and frequent yawning. In other cases the signs can be fulminant and include head pressing, blindness, circling, and coma. Ataxia can be noticeable in some cases but absent in others. Rarely, ataxia may precede HE signs or icterus in acute liver failure.[38,39] Clinical examination may reveal decreased muscle tone of the lower lips, delayed or absent response to touching the inner nares, and cortical blindness often accompanied by mydriasis. These signs are all a result of the cortical disease that occurs with HE. Laryngeal paralysis or dysphagia (presumably due to HE and functional disturbance in the nucleus ambiguous) can be signs of HE.[40] The earliest phase of HE is probably missed in most equine patients because it represents minimal behavioral changes with subtle impairment of intellect because of bilateral forebrain dysfunction[41] (stage I; Table 13.1). In humans, these early signs are more apparent to close friends and family members than to a physician. As encephalopathy progresses, motor function, intellectual abilities, and consciousness become impaired; generally at this stage (corresponding to stage II) horses become obviously affected. Clinical signs include depression, head pressing, circling, mild ataxia, aimless walking, persistent yawning, and other manifestations of inappropriate behavior. Somnolence develops. Next, the horse is rousable but responds minimally or excessively to the usual stimuli. At this stage (III) the horse often manifests aggressive or violent behavior interspersed with periods of stupor. Finally, consciousness fades, the horse becomes recumbent, and coma ensues. Occasionally seizures occur during the later stages of HE, but in general they are atypical. The severity of encephalopathy corresponds to the degree of hepatic dysfunction; however, neither of these parameters correlates with type or reversibility of the underlying hepatic disease.

Cause and Pathophysiology. By definition, the cause of HE is insufficient hepatocellular function, irrespective of the cause of the liver disease. That is, an adequately functioning liver is necessary to maintain normal brain neuron and astrocyte function. With acute liver disease, HE is associated with astrocyte swelling, acute cytotoxic cerebral edema, and intracranial hypertension. In chronic hepatic disease, HE may develop more insidiously or may have peracute onset.

Astrocytes, the star-shaped glial cells in the brain and spinal cord, are swollen but also show evidence of Alzheimer type II changes, which include enlarged nuclei and lack of cytoplasm.[41] In the equine, Alzheimer type II cells can develop rapidly (less than 2 days). The pathophysiology of HE is complex and likely involves several gut-derived neurotoxins, cerebral and systemic inflammation, cerebrovascular dysfunction, and neuroendocrine abnormalities.[42,43] The following mechanisms have been suggested for the development of HE, and any or all may be involved to greater or lesser degree:

1. Gastrointestinal-derived neurotoxins. High concentrations of blood and cerebrospinal fluid (CSF) ammonia have been most commonly incriminated as causing the pathophysiologic events of HE.[44]
2. Augmented activity of γ-aminobutyric acid (GABA) in the brain.
3. Altered expression of benzodiazepine receptors.
4. Increased neurosteroid synthesis.
5. False neurotransmitter accumulation after plasma amino acid imbalance.
6. Increased blood manganese concentrations.
7. Increased inflammatory mediator expression, principally cytokines.
8. Increased permeability of the blood-brain barrier and cerebral hypertension
9. Impaired central nervous system (CNS) energy metabolism.

Perhaps the oldest and most "predominant" hypothesis for HE involves the accumulation of toxic materials in the blood (derived from the metabolism of nitrogenous substrates in the gastrointestinal tract) that bypass the liver through functional or anatomic shunts.[35,41,45] Accordingly, HE may be caused primarily by failure of the liver to adequately remove certain substances from the blood that have the direct or indirect ability to modulate function of the CNS. Ammonia, produced after the degradation of amino acids, amines, and purines by enteric bacteria, has been supported widely as the major neurotoxin of hepatic disease.[45-47] In patients with liver failure ammonia is insufficiently metabolized through the urea cycle; thus plasma concentrations increase and ammonia enters the CNS, where it may cause encephalopathy.[45,48] Evidence also points to zinc deficiency, which is important for the urea cycle, in the pathogenesis of HE.[49]

Ammonia (NH_3, unionized and a weak base) is toxic at high concentrations and believed to easily pass the blood-brain barrier by diffusion while the relatively nontoxic ionized ammonia (NH_4^+) is limited to a transcellular route for translocation.[44] Ammonia has a toxic effect on cell membrane neurons by inhibition of the Na,K-dependent adenosine triphosphatase activity in nerve cell membranes, causing depletion of adenosine triphosphate.[47,49] Hyperammonemia also is associated with a disturbance in CNS energy production caused by alterations in the tricarboxylic acid cycle that result in a decrease in α-ketoglutarate formation and increased synthesis of glutamine.[50] Astrocytes in the brain also detoxify ammonia by synthesizing glutamine through amidation of glutamate. Glutamine accumulation in astrocytes is a major cause of cell swelling and generation of cerebral edema in acute fulminate hepatic failure.[46,49] Another effect of prolonged neuronal exposure to ammonia is alteration of glutamatergic function. Extracellular glutamate may be increased as a result of increased release at the neuronal presynaptic junction or because of decreased uptake in the glutamine and ammonia-saturated glial cells. Because glutamate is the major excitatory neurotransmitter in the mammalian brain, in acute liver failure increased synaptic release of glutamate results in overactivation of glutamate receptors with resultant hyperexcitatory clinical signs. In chronic hepatic failure, downregulation of glutamate receptor activity or increase in GABA activity (see later discussion) likely contributes to the decreased excitatory transmission in HE. Hyperammonemia also induces nitric oxide and reactive oxygen generation, which leads to accumulation of peroxides, oxidative stress, and nerve cell damage. These cumulative effects of ammonia on neural tissue play an important role in the pathogenesis of HE. Experimentally, ammonia can induce encephalopathy[51]; because of congenital enzyme deficiencies, children with hyperammonemia have encephalopathy and horses with primary hyperammonemia (without liver dysfunction) have encephalopathy.[52-54] Furthermore, therapy aimed at reducing the absorption of ammonia from the intestine tends to ameliorate HE.[41] Although older clinical studies argued against the role of ammonia in the pathogenesis of HE because plasma ammonia concentrations correlated poorly with the severity of HE,[36,55] some more recent reviews demonstrate that blood ammonia levels correlate strongly with the severity of HE.[42-44] Thus the actions of ammonia on the CNS are complex, and ammonia likely is involved in, but is not solely responsible for, HE.

The synergistic neurotoxin hypothesis for the pathogenesis of HE implicates not only ammonia but also other gut-derived neurotoxins, specifically mercaptans, short-chain fatty acids, oxindole, and phenols.[41] Members of each of these classes of substances are increased in the blood of patients with hepatic failure in concentrations that alone are insufficient to induce encephalopathy. However, the combination of some or all of them may induce encephalopathy by their synergistic actions and by augmenting endogenous metabolic abnormalities,[41] mostly centering around inhibition of brain Na^+,K^+-ATPase with subsequent impaired neurotransmission.[36] As with ammonia, blood and brain concentrations of mercaptans correlate poorly with the stage of HE.[56]

Another popular theory regarding the pathogenesis of HE involves augmented activity of inhibitory neurotransmitter systems, GABA-benzodiazepine and serotonin, and depression of the function of the excitatory glutamatergic system.[49] Hyperammonemia has been shown to increase GABAergic tone in patients with liver disease.[46] When released from presynaptic neurons, GABA binds to specific receptors on postsynaptic neurons, resulting in increased chloride ion conductance across the postsynaptic neural membrane, membrane hyperpolarization, and generation of an inhibitory postsynaptic potential.[57,58] The GABA receptor is a chloride ionophore supramolecular complex that has interactive binding sites for three classes of synergistic ligands: (1) GABA and agonists, (2) benzodiazepines, and (3) barbiturates.[36,59] The binding of benzodiazepine or a barbiturate on the binding site of the GABA receptor potentiates GABA-induced sedation. The GABA hypothesis of HE originally was based on a series of observations using a model of HE in rabbits in which increased GABA-like activity was identified in the serum and CSF along with an increased density of GABA receptors.[57]

Increased brain levels of natural benzodiazepines probably constitute one mechanism for the increased GABAergic tone in HE.[49] Ammonia, which acts synergistically with natural

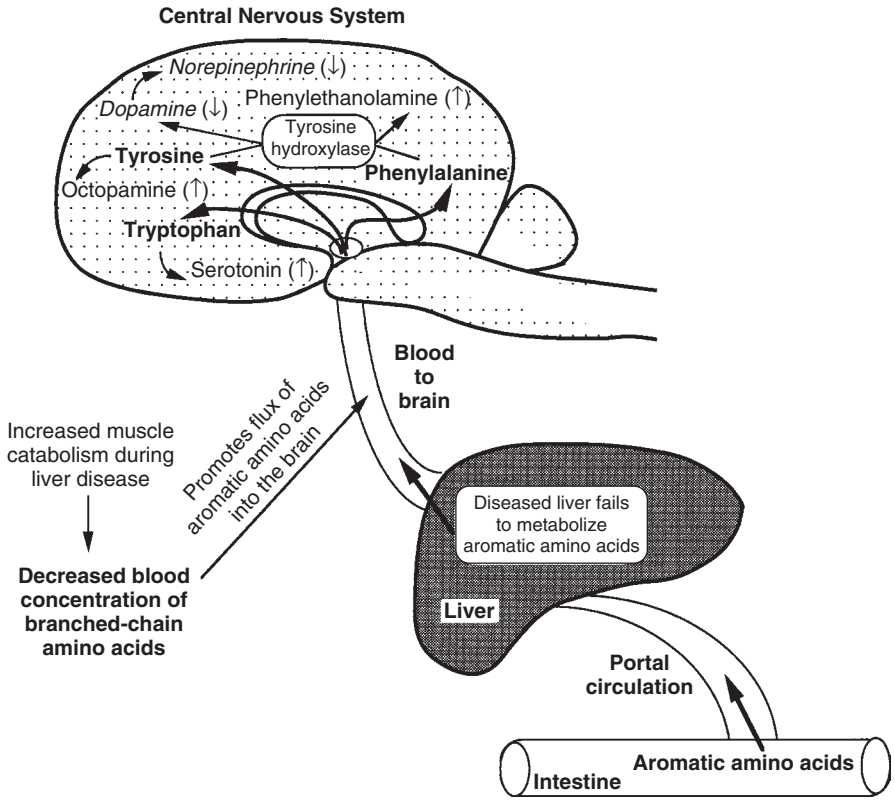

FIG. **13.6** Role of aromatic amino acids in the brain in hepatic encephalopathy. Aromatic amino acids (tryptophan, tyrosine, phenylalanine) enter the central nervous system, where they are metabolized, altering the balance of neurotransmitters. True neurotransmitters (dopamine, norepinephrine) decrease *(arrow down),* and "false" neurotransmitters (octopamine, phenylethanolamine) increase *(arrow up).* The net effect is increased neuronal inhibition and reduced neuronal excitation.

benzodiazepines, also may enhance GABAergic neurotransmission. Agonists of benzodiazepine increase the frequency of GABA-induced chloride channel openings, and barbiturates lengthen the average time that channels are open.[60] Results of studies using electrophysiologic and in vitro techniques to study an animal model of HE provide strong evidence for a functional increase in GABAergic tone that is mediated allosterically through the benzodiazepine receptor by an endogenous diazepam-like substance.[61,62] Clinical studies that showed improved consciousness and reduced electroencephalogram changes of HE in patients treated with the benzodiazepine receptor antagonist flumazenil support this suggestion.[63,64] Neurosteroids also may affect GABAergic tone through benzodiazepine receptors. Activation of benzodiazepam receptors in liver failure facilitates the entry of cholesterol into astrocyte mitochondria, where synthesis of neurosteroids such as tetrahydroprogesterone and tetrahydrodeoxycorticosterone occurs. These substances are potent positive allosteric modulators of GABA receptors that can induce profound sedation and behavioral changes.[65]

A separate and perhaps outdated hypothesis holds that during liver failure, true neurotransmitters in the CNS such as norepinephrine and dopamine become depleted and that false neurotransmitters, especially octopamine and phenylethanolamine, increase.[37,66] The net neurophysiologic effect of such changes is reduced neuronal excitation and increased neural inhibition. The mechanism of this effect is related to the increased serum concentrations of aromatic amino acids (AAAs; phenylalanine, tyrosine, tryptophan) and decreased concentrations of branched-chain amino acids (BCAAs; valine, leucine, isoleucine) that occur in liver failure.[67,68] Serum glucagon increases in hepatic failure, leading to muscle catabolism and release of amino acids. However, hepatic metabolism of AAAs is reduced, and because BCAAs are metabolized by muscle and adipose tissue, a relative increase in AAAs and a decrease in BCAAs occurs. The decreased plasma BCAA-to-AAA ratio during liver failure and increased brain glutamine concentration (presumably a consequence of increased ammonia metabolism) are considered to promote an influx of AAA into the brain and an efflux of glutamine from the brain by exchange transport processes at the blood-brain barrier.[36] Phenylalanine can compete with tyrosine for tyrosine hydroxylase, resulting in decreased production of dopamine[68] (Fig. 13.6). The displaced tyrosine may be decarboxylated to tyramine and then converted to the false neurotransmitter octopamine. Accumulated tyrosine also competes for dopamine β-oxidase and reduces the formation of norepinephrine. Phenylalanine and tryptophan in the CNS are ultimately converted to phenylethanolamine and serotonin, a false neurotransmitter and a neuroinhibitor, respectively. Tryptophan is also metabolized to serotonin and oxindole, which has a strong sedative effect.[49]

Consistent with this theory are the observations of increased serum concentrations of AAAs accompanied by increased CSF concentrations of octopamine, serotonin, and phenylethanolamine in patients with HE.[66] However,

octopamine alone cannot induce encephalopathy, and the plasma BCAA-to-AAA ratio is expected in most cases of severe liver disease and correlates poorly with HE in human beings.[69] Controlled clinical trials of oral or intravenous BCAA therapy demonstrate inconsistent amelioration of signs of HE.[68,70-72]

Manganese is a trace element that is excreted by the liver. Patients with chronic liver disease have increased blood and brain concentrations of manganese. Chronic exposure to manganese causes neuronal and glial loss and Alzheimer type II changes in astrocytes.[73]

A recent hypothesis on the pathophysiology of HE centers on the role of inflammatory mediators in brain injury. Central to this hypothesis is the fact that human patients with acute liver failure are more likely to progress to severe HE if they concurrently have evidence of a systemic inflammatory response.[38] A variety of stimuli are capable of inducing astrocytes and microglial cells in the brain, as well as peripherally located mononuclear cells, to release inflammatory mediators. Breakdown products of injured hepatocytes, as well as increases in systemic inflammatory cytokine production, free radicals, and metalloproteinases in liver failure, have severe systemic effects in addition to increasing permeability of the BBB.[38] The toxic effect of these events on the brain with HE is believed to result in both cytotoxic (intracellular swelling without increased permeability of BBB) and vasogenic (increased permeability of BBB with net gain of fluid) brain edema.[42,74,75] Several studies have demonstrated significantly increased levels of the cytokine TNF-α in patients with both acute and chronic liver disease. Furthermore, TNF-α concentrations correlate with the severity of HE and prognosis, and therapeutic strategies aimed at reducing TNF-α levels ameliorate HE.[76] Several key mechanisms whereby increased TNF-α concentrations have been shown to be involved in the pathogenesis of HE include increasing ammonia diffusion into the brain, inhibition of astrocyte uptake of glutamate and inhibition of glutamate synthetase, increased expression of benzodiazepine receptors in the brain, and increasing brain capillary fluid leakage and cerebral edema formation. It has also been demonstrated that excess manganese potentiates the production of TNF-α in microglia.[76]

Finally, alterations in cerebral blood flow and blood-brain barrier permeability leading to cerebral hypertension and edema and changes in cerebral metabolism are present in patients with HE. Although the mechanisms responsible for these changes are not fully known, changes in astrocyte function, either directly or indirectly by increased blood ammonia concentrations, are likely to be involved in the cytotoxic edema.[46]

Diagnosis. The diagnosis of HE is based on the presence of neurologic signs of cerebral dysfunction in a horse, with physical examination and laboratory findings compatible with liver disease (see Diagnosis and Laboratory Findings of Hepatic Disease and Insufficiency). Other possible causes for the neurologic signs should be excluded because no specific features of HE allow one to distinguish this syndrome definitively from other encephalopathies. A partial list of conditions to be ruled out includes primary hyperammonemia, trauma, viral encephalomyelitis, rabies, moldy corn toxicity (leukoencephalomalacia), brain abscess, equine protozoal myeloencephalitis, parasite larval migrans, blister beetle toxicosis, organophosphate toxicity, nigropallidal encephalomalacia, botulism, fluphenazine or other sedative overdose, uremic encephalopathy, and heavy metal toxicosis. Many of these conditions have other characteristic clinical signs, the absence of which would exclude them from the differential diagnosis. Access to potential toxins or drugs should be carefully gleaned from the history.

Serum electrolyte analysis, calcium and creatinine values, and a complete blood count may aid in ruling out other encephalopathies. Serology for the viral encephalitides and toxicologic screening for organophosphates and heavy metals may be appropriate. CSF analysis may be indicated if other causes of encephalopathy are highly suspect. The CSF is normal in horses with HE. In human beings, electroencephalogram changes of symmetric generalized slowing of cerebral electrical activity are sensitive indicators of HE; however, they are not specific for this disorder because other metabolic encephalopathies can cause similar abnormalities.[35,47] Visual evoked potentials are superior to conventional electroencephalogram in terms of specificity and ease of quantitation.[77] An average visual evoked potential reflects the pattern and magnitude of postsynaptic neuronal activity evoked by a visual afferent stimulus. Hepatoencephalopathy in humans is attended by a distinctively abnormal visual evoked potential trace; however, this testing would be technically difficult in horses and has not been explored. As a general rule, the brain may not show definite light or electron microscopic structural changes, although horses with hepatic failure and portosystemic shunts frequently have an increase in the number and size of astrocytes (Alzheimer type II) in the gray matter of the cerebrum and cerebellum.[36] These changes appear to be reversible and specific for portosystemic shunting of blood. The relevance of these changes, if any, to behavioral dysfunction of HE is unknown.

Icterus

Icterus, or *jaundice,* is caused by *hyperbilirubinemia* with subsequent deposition of the pigment in tissues causing yellow discoloration. Icterus is most apparent in nonpigmented skin such as mucous membranes, especially the vulvar mucosa and the sclerae. Approximately 10% to 15% of horses normally have slightly yellow sclerae.[24] Disease states that result in hyperbilirubinemia can be categorized as follows: increased production of bilirubin, impaired hepatic uptake or conjugation of bilirubin, and impaired excretion of bilirubin.[20] Increased production of bilirubin occurs with hemolysis, both intravascular and extravascular, and after reabsorption of erythrocytes after massive intracorporeal hemorrhage. This form of hyperbilirubinemia, often called *hemolytic* or *prehepatic icterus,* occurs despite a normally functioning liver, because the rate of bilirubin production by the reticuloendothelial system temporarily exceeds the ability of the liver to conjugate and excrete. Classically, this form of icterus is caused by the increased concentration of unconjugated bilirubin in the blood. However, on occasion, the concentration of conjugated bilirubin also mildly increases in the blood because of hepatic spillover when the liver processes the excessive bilirubin or the enterohepatic circulation reabsorbs it. The rate and extent of erythrocyte destruction and the rate of uptake of bilirubin determine the presence and intensity of hemolytic icterus by the liver.

Impaired uptake and conjugation of bilirubin also result in increased blood levels of unconjugated bilirubin with subsequent icterus. This form of icterus is referred to as *retention* or *hepatic icterus* and is the most common form in horses with liver disease, usually the result of acute hepatocellular

disease.[20,22] In horses the presence of icterus is highly inconsistent with chronic hepatocellular disease.[21,34] In addition to hepatocellular disease, certain drugs, anorexia, or prematurity can impede bilirubin uptake and conjugation by hepatocytes, despite an otherwise normally functioning liver.[9,20,22] Steroids can inhibit bilirubin uptake in all species. Heparin administration to horses sometimes results in icterus and is believed to be caused in part by impaired uptake of bilirubin by hepatocytes.[21] Anorexia in horses causes variable degrees of hyperbilirubinemia and may be related to the half-life of ligandin.[21,22] Ligandin is the intrahepatic protein responsible for extracting unconjugated bilirubin from albumin in the sinusoidal blood. The half-life of ligandin is relatively short (days), and starvation in other species reduces the store of ligandin in the hepatocytes, thus impeding bilirubin uptake.[9] Premature and neonatal foals are also more susceptible to retention icterus, in the absence of hepatic disease. The cause of icterus in equine neonates is presumably a result of lower hepatocellular ligandin concentrations, compared with the adult.[78] In human beings, inherited or congenital deficiencies in enzymes responsible for conjugation (bilirubin-uridine diphosphate glucuronyl transferase) may result in intermittent or persistent icterus (Gilbert's syndrome or Crigler-Najjar syndrome type II) that often is not recognized until the patient is several years of age. The icterus occurs without other clinical or laboratory evidence of liver disease.[22] Persistent hyperbilirubinemia without anorexia, hemolysis, or evidence of acquired liver disease was reported in an otherwise healthy 4-year-old Thoroughbred gelding and has been seen by the authors in several other horses.[79] Conjugated bilirubin concentrations were normal, but total serum bilirubin concentrations ranged from 9.0 to 12.3 mg/dL during a 2.5-year monitoring period. The case most closely resembled Gilbert's syndrome.[79]

If the excretion of conjugated bilirubin into the biliary tract is impeded, *regurgitation icterus* occurs.[20] Blockage of bile flow with resultant regurgitation icterus can accompany cholangitis, hepatitis, obstructive cholelithiasis, neoplastic infiltration, fibrosis, physical obstruction of the biliary tract associated with colon displacements or duodenal ulcers, or hyperplasia of the biliary tract. Because conjugated bilirubin is water soluble, this form of icterus may be accompanied by bilirubinuria and produce "greenish"-orange discoloration of the urine.

In hepatocellular disease, icterus most often is the result of a combined increase in both unconjugated and conjugated bilirubin.[20] Of the two fractions, the majority of the increase in the total bilirubin is from unconjugated bilirubin. Increases in the conjugated fraction less than 25% of the total are usually indicative of predominant hepatocellular disease, and increases greater than 30% are usually indicative of cholestasis.[22]

Weight Loss

Significant weight loss and failure to thrive are most consistently present during chronic hepatic insufficiency. However, chronic liver disease may be present without apparent weight loss. Weight loss is due to anorexia and the loss of normal hepatocellular metabolic activities.

Hepatogenic Photosensitization

Photosensitization refers to abnormally heightened reactivity of the skin to ultraviolet sunlight because of the increased blood concentration of a photodynamic agent. In the case of hepatogenic photosensitization, the photodynamic agent is *phylloerythrin*. Phylloerythrin is normally formed in the gastrointestinal tract as a result of bacterial degradation of chlorophyll and is absorbed into the general circulation, conjugated, and excreted by the liver. During hepatic insufficiency, the blood concentrations of this photodynamic agent are increased. Subsequent exposure of phylloerythrin to ultraviolet light causes activation of electrons within the molecule to an excited state, with resultant free radical formation. The local production of free radicals causes cell membrane damage and necrosis. Unpigmented areas most efficiently absorb ultraviolet light; thus the lesions of photosensitization are restricted to white skin. The skin first appears erythematous and edematous. Pruritus, pain, vesiculation, ulceration, necrosis, and sloughing may ensue. Mucous membranes may also be affected.[80]

Colic, Diarrhea, Tenesmus, Ascites, Steatorrhea

Abdominal pain associated with acute hepatocellular disease may be a result of an acute change in hepatic size (most commonly hepatic swelling) or biliary obstruction (cholelithiasis).[9,81] Signs of anterior abdominal pain include anorexia, bruxism, sitting like a dog, recumbency, and rolling up onto the dorsum. Palpation over the last few ribs (especially on the right) or immediately caudal to the last rib may elicit a pain response. Alternations in intestinal motility also may cause concurrent signs of colic with liver disease. McGorum et al.[34] reported that 10 of 25 horses with liver disease and signs of colic had clinically significant gastric impactions. Of the horses with gastric impactions, seven also had signs of HE; none of these horses survived.

Diarrhea infrequently may accompany chronic hepatic insufficiency in horses. Alterations in the intestinal microflora, portal hypertension, intestinal hyperemia, and deficiency of bile acids may be involved in the pathogenesis.[9] Though uncommon in horses, portal hypertension can lead to increased hydrostatic and oncotic pressure in the intestinal mucosa, with resultant water and protein loss into the lumen of the bowel and the peritoneal cavity (ascites). Tenesmus may be the result of constipation but has been rarely reported to be a sign of hepatoencephalopathy in horses.[34]

Decreased excretion of bile may result in lipid malabsorption and excessive amounts of fat in the feces, or *steatorrhea,*[9] which subsequently may cause osmotic diarrhea. Because the normal equine diet is low in fat, steatorrhea is rare in horses. Chronic cholestasis may cause clay-colored feces because of lack of fecal urobilinogen and stercobilin. This coloration rarely is observed in adult herbivores, because the normal fecal color is generated primarily by plant chlorophylls and not by bilirubin metabolites.[22]

Hemorrhagic Diathesis

Because the liver is responsible for the synthesis of numerous factors involved in coagulation and fibrinolysis, abnormal hemostasis may be a sequela to hepatic insufficiency. Clinical signs may vary from petechial or ecchymotic hemorrhages to hemorrhage after trauma or venipuncture to spontaneous hemorrhage (epistaxis, melena, hemoptysis, hematuria, or hematomas).[9,20,22,41,82] Especially sensitive to hepatic disease is the synthesis of fibrinogen and the vitamin K–dependent factors (II, VII, IX, X, and protein C), which have short half-lives. Factor VII has a half-life of only 4 to 5 hours. Other vitamin K–dependent factors and fibrinogen have half-lives

in the range of 4 to 5 days. Because vitamin K is fat soluble and requires bile acids for proper absorption from the intestinal tract, vitamin K–dependent factors are affected particularly during hepatic insufficiency when bile excretion is decreased.

During hepatic insufficiency, the synthesis of protein C and antithrombin III may be altered. Decreased plasma concentrations of these two anticoagulants would result in uncontrolled clot formation and consumption of other coagulation factors. In chronic hepatic disease the plasma concentration of protein C is normal or decreased; however, antithrombin III may be normal, increased, or decreased.[41] Pregnant women with fatty livers have decreased antithrombin III activity, but patients with biliary cirrhosis or biliary obstruction have increased antithrombin III activity.[41] Horses with liver disease have increased antithrombin III activity and theoretically should tend to bleed.[83] Alterations in the factors controlling fibrinolysis vary in chronic liver disease.[41] Conditions that promote fibrinolysis—such as increased plasminogen and plasminogen activator, or decreased plasminogen activator inhibitor, α_2-antiplasmin, and α_2-macroglobulin—result in bleeding tendencies. Conditions that aid thrombus formation, such as decreased plasminogen, further promote consumptive coagulopathy. The fibrinolytic factors have not been evaluated in horses with liver disease.

Finally, the liver plays an important role in balancing normal hemostasis by Kupffer cell removal of activated coagulation factors and FDPs from the general circulation.[41] Failure to remove activated coagulation factors further promotes coagulation, and FDPs interfere with platelet function and fibrin clot formation.

Fever

Horses with hepatic abscesses, acute bacterial hepatitis, CAH, obstructive cholelithiasis, fatty liver failure, or neoplasia may have constant or intermittent fevers.[81,84-89]

Hemolysis

Hemolysis is a rarely seen but grave prognostic indicator of fulminant hepatic failure in horses.[32] The exact cause of hemolysis is not known but is believed to be the result of increased erythrocyte fragility or destruction of erythrocytes as they pass through the damaged liver.

Pruritus and Seborrhea

Retention of bile acids and accumulation in the skin may cause pruritus and seborrhea. This finding is rarely reported in horses.[32] A hepatocutaneous syndrome affecting the hoof wall and coronary bands has been discussed in horses, but documentation is rare.[90]

Edema

Hypoalbuminemia and water retention can occur with chronic liver failure and may result in dependent edema. Because the half-life of albumin is long (19 to 20 days) in the horse, edema is a rare clinical sign.[91] Ponies with hyperlipemia may develop dependent abdominal edema after vascular thrombosis[88] or as a result of increased blood flow and hydrostatic pressure in the subcutaneous abdominal vein caused by partial obstruction of the caudal vena cava by the rapidly enlarged liver. Dependent abdominal edema also may form if significant portal hypertension and ascites exist.

Endotoxemia

Kupffer cells are specialized macrophages that are part of the reticuloendothelial system. The Kupffer cell plays an important role in removing bacterial endotoxin that is normally absorbed from the lumen of the intestinal tract and carried to the liver via the portal circulation.[9] Failure of Kupffer cell phagocytosis of endotoxin may result in clinical and laboratory evidence of endotoxemia. Kupffer cells also help in recycling iron from senescent or injured red blood cells and, as a result, they accumulate hemosiderin, and this can be pronounced even in disease-free horses.[22]

Polydipsia, Polyuria, and the Hepatorenal Syndrome

Alterations in renal function, including deranged sodium concentrations, impaired water excretion, and urine-concentrating ability, may accompany severe liver disease.[9,41] Sodium retention results from increased blood aldosterone concentrations because of failure of hepatic biotransformation and a decrease in the effective circulating blood volume as a result of portal hypertension and hypoalbuminemia. Sodium retention raises the osmolality of the extracellular fluid, thereby stimulating the thirst center. Polydipsia has been reported in horses with chronic liver disease.[92,93] Despite the potential increase in exchangeable sodium, the serum sodium concentration is usually normal or decreased, as a result of superimposed water retention. The mechanism for water retention is multifactorial, but increased antidiuretic hormone, reduced effective circulating volume, and altered renal prostaglandin synthesis are most likely involved.[41] Sometimes the urine-concentrating ability is impaired because of reduced medullary interstitial urea, the net effect being polyuria, isosthenuria, or both.

Hepatorenal syndrome is characterized by acute azotemia and anuria and may occur in ponies with hyperlipemia and hepatic lipidosis (see Hyperlipemia and Hepatic Lipidosis later in this chapter). The pathogenesis is obscure, but speculative causes include reduced effective circulating volume, decreased hepatic inactivation of renin, and endotoxemia.[41]

Diagnosis and Laboratory Findings of Hepatic Disease and Insufficiency

Historical information (as discussed under Specific Hepatic Diseases later in this chapter) may be useful in the diagnosis of certain types of hepatic insufficiencies. Nonspecific clinical signs and variable laboratory findings confound the definitive diagnosis of hepatic disease in horses. Hepatic testing can also be divided into disease test (enzymes) and function test (bile acids, conjugated bilirubin, ammonia, partial thromboplastin time, prothrombin time). Hepatic-derived enzymes measured in serum or plasma can be divided into those that leak from hepatocytes (sorbitol dehydrogenase, aspartate aminotransferase, glutamate dehydrogenase) and those that come from biliary epithelium (γ-glutamyl transferase). Comparison of elevations in hepatocellular enzyme with biliary-derived enzymes can often be helpful in anatomic and etiologic diagnosis of liver disease. Paramount to the laboratory diagnosis of hepatic insufficiency in horses is knowledge of the sensitivity and specificity of the tests (Table 13.2). The magnitude of elevation of hepatic-derived enzymes may not correspond to functional abnormalities and should therefore be considered *tests that measure disease and not tests that*

TABLE **13.2 Clinical Pathology of Liver Disease in Horses**

Test	Aberration	Normal Value
SPECIFIC INDICATORS OF LIVER DISEASE		
Serum sorbitol dehydrogenase (SDH)	Increases	<8 U/L
Serum γ-glutamyl-transferase (GGT)	Increases	<25 U/L
Serum bile acids concentration	Increases	<15 μmol/L
Arginase (ARG)	Increases	
Glutamate dehydrogenase (GLDH)	Increases	<11 U/L
Direct bilirubin	>25% of total	0–0.4 mg/dL (0-6.8 μmol/L)
Ammonia	Increases	(Laboratory dependent)
Bromsulphthalein (BSP) half-life	Prolonged	2.8 ± 0.5 min
Branched chain: aromatic amino acid ratio	Decreases	3.5–4.5
Urine bilirubin	Increases	
NONSPECIFIC INDICATORS OF LIVER DISEASE		
Total bilirubin	Increases	
Indirect bilirubin	Increases	
Lactate dehydrogenase-5 (LDH-5)	Increases	
Aspartate aminotransferase (AST)	Increases	
Alanine aminotransferase (ALT)	Increases	
Alkaline phosphatase (ALP)	Increases	
Blood urea nitrogen (BUN)	Decreases	
Globulins	Increase	
Albumin	Decreases	
Glucose	Decreases	
Prothrombin time (PT)	Prolonged	
Activated partial thromboplastin time (APTT)	Prolonged	
Triglyceride	Increases	
White blood cell count	Increases with infection or inflammation; decreases with endotoxemia	

measure function. Because massive hepatic disease must be present before alterations are seen with some function tests, and because different liver functions are variably altered by disease, the specificity of the laboratory diagnosis of hepatic disease increases with the magnitude of abnormal findings. Laboratory findings also may be useful for therapeutic and prognostic considerations.

Evaluation of Bilirubin

Serum bilirubin concentration is not a sensitive indicator of liver disease in horses. In one report on serum biochemical changes in horses with liver disease, only one fourth of the cases had increased serum bilirubin concentrations.[34] The *total bilirubin* concentration in the blood, as determined by the van den Bergh test, is a combination of both unconjugated and conjugated bilirubin. Because the diagnostic value of the bilirubin concentration, when used for evaluation of hepatic disease, depends on which subfraction is increased, the concentrations of both unconjugated and conjugated bilirubin must be determined.

The serum bilirubin concentration is stable for several days if the sample is protected against sunlight.[22] The total bilirubin concentration is determined first in a chromogenic assay by reaction for 30 minutes with a diazo reagent (sulfanilic acid and sodium nitrite) and methyl alcohol.[22] *Conjugated* or *direct-reacting bilirubin* is similarly determined over 5 minutes, without the addition of methyl alcohol. The amount of *unconjugated bilirubin* can then be determined by the difference between the total bilirubin concentration and the direct-reacting bilirubin. Because the unconjugated fraction is determined arithmetically, it is appropriately called *indirect-reacting bilirubin.* In normal horses, the total bilirubin concentration is in the range of 0.2 to 5.0 mg/dL (3.4–85.5 μmol/L) with conjugated bilirubin in the range from 0.0 to 0.4 mg/dL (0–6.8 μmol/L).[20] As discussed previously, increases in the unconjugated bilirubin fraction may occur without hepatic disease. Hemolysis, anorexia, intestinal obstruction, cardiac insufficiency, Gilbert's syndrome, and the administration of certain drugs (steroids, heparin, halothane) may cause an increase in the unconjugated bilirubin concentration.[21] If the unconjugated bilirubin concentration is increased, the erythron should be concurrently evaluated to rule out hemolysis as the causative factor. Hemolysis may cause the unconjugated bilirubin concentration to rise as high as 80 mg/dL (1368 μmol/L).[22] Complete anorexia can cause an increase in the unconjugated bilirubin concentration within 12 hours; however, it is unlikely to rise greater than 6 to 8 mg/dL (102.6–136.8 μmol/L) in horses suffering purely from anorexia,[22] although values as high as 10.5 mg/dL have been reported in anorexic horses.[94] In experimental horses withheld from feed the bilirubin increase did not occur for 72 hours.[30] Finally, the age of the horse and concurrent drug therapy must be considered. Neonates normally have more unconjugated bilirubin than adults. The higher bilirubin concentration in foals most likely is caused by the turnover of fetal hemoglobin to adult hemoglobin and the deficiency of liver-binding and conjugating enzymes compared with the adult.[78] In the absence of liver disease, prematurity or illness in foals can further increase the unconjugated bilirubin fraction.

Keeping the foregoing limitations of interpretation in mind, increases in the unconjugated bilirubin fraction in horses with hepatic disease are most likely to occur with acute hepatocellular disease.[20-22] Rarely does the unconjugated bilirubin fraction in acute hepatic disease exceed 25 mg/dL (427.5 μmol/L).[22] An increase in the bilirubin concentration may be indicative of hepatic disease and dysfunction but not necessarily hepatic failure. Furthermore, a normal bilirubin value, as commonly occurs in chronic hepatic disease, does not necessarily preclude the diagnosis of hepatic insufficiency.

An increase in the conjugated bilirubin fraction in horses more reliably is indicative of hepatic disease.[20-22] If the conjugated bilirubin concentration is less than 25% of the total bilirubin value, hepatocellular disease should be suspected. If the conjugated bilirubin concentration is greater than 30% of the total value, cholestasis should be suspected.[22] Conjugated bilirubin is water soluble and detectable in the urine of horses only if blood concentrations become sufficiently increased to surpass the renal threshold.[22] Therefore when urine tests positive for the presence of bilirubin, cholestatic disease should be suspected. Urine dipstick analysis is less sensitive than analysis with a diazo tablet.[22] A small number of healthy horses will have a positive reading for bilirubin on urine dipstick analysis. Urobilinogen may be detected by dipstick analysis of normal horse urine, and its presence indicates a patent bile duct.[22] Because urobilinogen is highly unstable, it must be determined on a fresh urine sample. Dilute or acidic urine may interfere with accurate determination of urobilinogen. Reagent strips are not sensitive enough to detect the absence of urobilinogen; therefore Ehrlich's reagent must be used. The absence of urobilinogen does not necessarily indicate liver disease, but it may be compatible with failure of excretion of bilirubin into the intestine, biliary obstruction, failure of intestinal bacterial reduction (diarrhea, overuse of oral antimicrobials), or failure to reabsorb it from the ileum.[9] Increased concentrations of urobilinogen in the urine may be caused by the increased production of urobilinogen by intestinal bacteria, failure of the liver to remove it from the enterohepatic circulation, portosystemic shunting, or spillover after severe hemolysis.[9]

Serum Bile Acid Concentration

The enterohepatic circulation normally removes greater than 90% of bile acids. Thus the blood concentration of bile acids may be increased with liver disease, and quantitation provides an excellent screen of liver failure and has essentially replaced foreign dye clearance (e.g., bromosulphthalein) as a functional test of the liver.[21,93,94] Serum bile acids are stable for at least 1 month if stored at −20°C and are measured by radioimmunoassay or by an enzymatic colorimetric method. The concentration of total serum bile acids is not affected by short-term fasting (less than 14 hours) but may be increased by more prolonged fasting.[95] The major serum bile acids in horses include ursodeoxycholic acid, chenodeoxycholic acid, and deoxycholic acid, but the exact composition of serum bile acids varies markedly among normal horses.[96] Reported normal mean values for horses and ponies as determined by radioimmunoassay are 8.2 ± 1.6 μmol/L (n = 9)[93] and 5.3 ± 6.5 μmol/L (n = 51)[94] and 5.0 ± 28.0 μmol/L[96] for the colorimetric method. Increased serum bile acid concentrations greater than 25 μmol/L are highly specific for the presence of liver disease or dysfunction (may increase within 24–48 hours after onset of hepatic disease) but are not specific for the type of liver disease.[21,97] Because bile acids are 90% restricted to the enterohepatic circulation, increases in the blood may occur as a result of shunting or decreased blood flow to the liver (first-pass effect), failure of the liver to remove bile acids from the enterohepatic circulation, failure of the hepatocytes to conjugate the bile acids for excretion, or failure of excretion with subsequent regurgitation of the bile acids into the blood (biliary obstruction). Increases in the primary (nondegraded) bile acids cholate and chenodeoxycholate account for most of the increase in total serum bile acid concentration in horses with liver disease.[96] In relation to the severity of liver disease, a significant shift in composition of serum bile acid profile from taurocholate to free unconjugated cholate also occurs. This finding suggests that hepatocellular excretion, and not resorption, is the most sensitive step in the enterohepatic circulation of bile acids in horses.[96]

Fasting for longer than 3 days in mature horses caused an increase in the serum bile acid concentration of 3 times over baseline values.[95] Ligation of the bile duct caused a sixfold increase in serum bile acid concentration compared with fasted horses.[95] Carbon tetrachloride toxicity resulted in a threefold increase compared with fasted horses.[95] Concentrations of serum bile acids greater than 50 μmol/L in horses with pyrrolizidine toxicosis were associated with a grave prognosis.[93] Increases in serum bile acids may occur with either acute or chronic disease and dysfunction. Levels above 25 μmol/L have been shown to be a poor prognostic indicator for some chronic diseases and failure,[98] but this does not apply to acute disease. A value less than 20 μmol/L appears to be a good predictor in ruling out significant functional liver disease and should be included in the evaluation of horses suspected to have hepatic disease.[94] It is important to note that, compared with mature horses, serum bile acid concentrations are often higher in healthy neonatal foals during the first month of life and frequently exceed 20 μmol/L.[99] Bile acid concentrations are highest in biliary obstructive diseases and portosystemic shunts.

Tests of Protein Synthesis

The blood concentrations of protein or amino acids relate not only to the rate of synthesis by the liver but also to their half-life in the circulation. The half-life of albumin in horses is long (19–20 days); thus a decrease in the albumin concentration is rarely detectable until greater than 80% of the liver mass is lost for more than 3 weeks.[20,22,34,91] It is unusual for the total serum protein concentration to decrease to less than 5 g/dL (50 g/L) in chronic liver disease.[100] Hypoalbuminemia is a nonspecific finding in chronic liver disease, because it may occur secondary to endoparasitism, nephrosis, malnutrition, malabsorption, circulatory failure, and many other chronic diseases.[22,91]

The globulin fraction often is increased in chronic hepatic disease as a result of decreased Kupffer cell mass. Loss of Kupffer cell function may result in wider dissemination of enteric-derived foreign antigens. Plasma cells respond to the general increased antigen load, resulting in polyclonal gammopathy.[9,20,22] Although the globulin fraction may be increased, it is a nonspecific finding with chronic hepatic disease, because polyclonal gammopathy can occur after numerous chronic diseases.[101] The α- and β-globulins may also increase with chronic liver disease. A decreased serum albumin concentration concurrent with an increased globulin concentration in chronic hepatic disease causes the total plasma protein or serum protein to appear normal. Thus serum protein fractionation is paramount. Protein electrophoresis most accurately determines fractionation of the components making up the total serum protein concentration.[20]

The blood concentration of amino acids may be increased after acute hepatocellular necrosis or during protein catabolic states such as illness or starvation, in response to insulin or glucagon.[9] Fractionation of the blood amino acids and

determination of the BCAA-to-AAA ratio is rarely done in clinical practice but is more useful than evaluating either fraction separately (see Hepatic Encephalopathy earlier in this chapter). Decreases in this ratio indicate hepatic insufficiency.[67] The risk of clinical signs of HE may be projected from the BCAA-to-AAA (phenylalanine, tyrosine) ratio. A normal ratio falls between 3.5 and 4.5. The risk of HE is low, medium, or high if the ratio is 3.0 to 3.5, 2.5 to 3.0, and less than 2.5, respectively.[67]

Because the liver is primarily responsible for removing *ammonia* from the circulation and converting it to urea for renal excretion, increases in the blood ammonia concentration or a decrease in the BUN concentration (less than 9 mg/dL; 6.43 mmol/L) may be indicative of subacute to chronic hepatocellular disease.[20,34,100] Daily blood ammonia levels vary widely in normal horses.[33] The compounding effects of ammonia-generating and urea-using bacteria in the gastrointestinal tract, ammonia generation with blood storage, and the effects of the ration may partly account for these fluctuations. In ethylenediaminetetraacetic acid (EDTA), whole blood can be refrigerated anaerobically for up to 6 hours without a significant increase in ammonia content.[102] The effect of the ration and handling can be evaluated by concurrently determining the blood ammonia concentration of a stable mate receiving a similar ration. When a longer period of time will occur before measurement, there should be anaerobic collection, prompt removal of the red blood cells, and the plasma sample frozen until measurement. Oral ammonia challenge tests have not been fully evaluated in horses; however, the sensitivity of the oral challenge test may be decreased because of the effect of enteric bacteria. Normal values for ammonia for horses vary among laboratories but have been reported in the range of 13 to 108 μg/dL (7.63–63.42 μmol/L).[32]

No correlation exists between the blood ammonia concentration and the severity of liver disease in horses, but increased blood ammonia concentration is significantly correlated with the presence of liver dysfunction, hepatoencephalopathy, or both.[33,34] Although hyperammonemia appears to be a sensitive indicator of liver dysfunction in the horse, it is not specific for liver disease. Encephalopathy associated with hyperammonemia without concurrent evidence of liver disease has been reported in horses with acute gastrointestinal disease.[103,104] Hyperammonemia has also been reported as a fatal heritable disorder in Morgan foals and is believed to be caused by a defective mitochondrial transporter protein involved in urea synthesis.[105] The syndrome may be accompanied by mild to moderate increases in serum liver enzyme activities.

Because the liver is also responsible for the synthesis of certain coagulation factors, evaluation of hemostatic function may be useful. Changes in hemostatic function values are not specific for liver disease and must be evaluated in light of the other laboratory findings. The vitamin K–dependent factor with the shortest half-life is factor VII; thus abnormalities are frequently first observed in the *prothrombin time (PT).*[33] However, adequate evaluation of hemostatic function necessitates determination of the *activated partial thromboplastin time* (APTT), the *fibrinogen* and FDP concentrations, and a platelet count. In one retrospective clinical review, almost half of the horses with liver disease had either an abnormally prolonged PT or APTT.[34] Typically, a 50% to 70% decrease in the blood concentration of the coagulation factors is necessary before a change in these clotting time–based assays is detectable.[34] Daily variation in the normal values for clotting times also hinders accurate detection of the abnormal. The clotting times may be standardized more appropriately if one concurrently determines a clotting assay on a normal horse. If the ratio of clotting time (PT or APTT) of the patient with possible hepatic disease to the normal horse's value is greater than 1.3, the test may be interpreted as abnormal.[106] The sensitivity of coagulation factor deficiency during hepatic insufficiency may be increased by diluting the plasma[107] or by determining the concentration of specific factors, by either clot-based, chromogenic, or radioimmunologic assays. These later assays are not widely available.

Hypofibrinogenemia cannot be accurately detected by the heat block precipitation method, the most common method for determination of the plasma fibrinogen concentration.[20] Clotting assays using thrombin more accurately determine the fibrinogen concentration. Fibrinogen concentrations less than 100 mg/dL (1 g/L) indicate either decreased production or increased consumption of fibrinogen. The FDP concentration, as determined by latex agglutination, may be increased during hepatic insufficiency owing to decreased removal by Kupffer cells. Concentrations of FDPs greater than 16 μg/dL are indicative of increased production or reduced removal. The plasma concentration of several factors acting as anticoagulants or involved in fibrinolysis also may be altered in chronic liver failure (see Hemorrhagic Diathesis earlier in this chapter). Tests for these factors are primarily limited to academic and research institutions.

Thrombocytopenia with associated petechiae or nasal mucosal bleeding has been reported in horses with liver disease; therefore in possible cases of liver disease, platelet counts should also be evaluated before invasive diagnostic or therapeutic techniques.[33]

Tests of Carbohydrate Metabolism

Changes in the blood glucose concentration rarely occur in adult horses with liver insufficiency.[34] Hyperglycemia may occur with stress-associated catecholamine and glucocorticoid release. Hypoglycemia (glucose less than 60 mg/dL; 3.33 mmol/L) may occur in adult horses with acute massive hepatic failure but is more likely in chronic liver disease as anorexia progresses, glycogen stores are depleted, and gluconeogenesis and glycolysis are impaired by increased glucagon concentrations. If glucose is administered, blood glucose levels often remain abnormally increased, indicating tissue insulin resistance.[37] Insulin receptor number and binding affinity for insulin are diminished in human beings with chronic liver disease. Changes in the blood glucose concentration are not specific for liver disease and must be evaluated in the light of other laboratory findings. Hypoglycemia is common in foals with hepatic failure.[108]

Tests of Lipid Metabolism

The concentration of blood triglycerides may become increased during hepatic insufficiency because of increased mobilization from adipose tissue to support energy-requiring processes and a decreased clearance by the liver.[9,22] In contrast, the VLDL and esterified cholesterol blood concentrations may be decreased because of failure of liver synthesis. Compared with other species, equids are thought to possess a greater clearance capacity for triglycerides and a greater hepatic exporting capacity for VLDL. Thus changes in the

blood VLDL, esterified cholesterol, or triglyceride concentrations rarely occur in horses.[22] An exception to this is the marked increase in blood triglyceride levels that occurs with hyperlipidemia syndrome in ponies, donkeys, and Miniature Horses (see Hyperlipemia and Hepatic Lipidosis later in this chapter). Because nonhepatic diseases may alter blood lipid concentrations, these tests are neither sensitive nor specific for liver disease in horses.[22] The blood cholesterol and triglyceride concentrations are normally higher in neonates than in adults.[78]

Increased mobilization of triglycerides and fatty acid oxidation by the liver may result in increased production of *ketone bodies,* acetoacetate, and β-hydroxybutyric acid.[12] Although peripheral tissues may use ketone bodies for energy, these compounds are weak acids and increased levels in the blood may result in ketoacidosis. The pathway for ketone formation is poorly developed in horses; thus ketoacidosis is not common.[22] Ketoacidosis could be considered in horses that are acidemic and have an abnormally high anion gap. Ketones may be quantitated in the blood or urine. Because the renal threshold of ketone bodies is low, ketonuria usually precedes marked ketonemia. Routine urine dipsticks only detect acetoacetate.[22]

Liver Enzymes

Acute hepatocellular necrosis or changes in hepatocyte membrane permeability result in the release of soluble cytosolic and mitochondrial enzymes into the sinusoidal blood. Thus increased blood activity of these enzymes may be indicative of active hepatocellular disease. Caution must be exercised when evaluating increases in these enzymes because not all are liver specific. Furthermore, some of these hepatocellular enzymes may be increased because of induction by drugs. Most of these enzymes are quantitated colorimetrically; thus hemolysis or lipemia may interfere with accurate evaluation. Furthermore, wide variation in values can exist because of age differences, stage of hepatic disease, and laboratory methodology. In horses the following cytosolic enzymes are liver specific and are not inducible: sorbitol dehydrogenase (SDH; iditol dehydrogenase), arginase (ARG), ornithine carbamoyltransferase, and the mitochondrial-produced enzyme glutamate dehydrogenase (GLDH).[20,22,108] Although increases in these enzymes in the blood are highly specific for hepatocellular disease, they are not specific for the type of disease, nor are they function tests. Significant increases occur after acute hepatic necrosis. Mild increases in these enzymes may occur after hepatic hypoxemia or toxemia resulting from endotoxemia, septicemia, transient intestinal disease, hyperthermia, or administration of certain drugs (benzimidazole anthelmintics).[20,22,108]

SDH has been widely used in the evaluation of acute liver disease in horses.[78,108,109] The short half-life (less than 12 hours) of this liver cytosolic enzyme makes it ideal for the evaluation of acute ongoing disease, because values usually return to baseline within 3 to 5 days after a transient hepatic insult.[94,110] Its short half-life necessitates analysis within hours of collection. Storage of serum in the freezer (−15°C) or refrigerator results in losses of approximately 1.0% and 3.5%, respectively, of SDH activity per day.[111] Although mild variations exist among laboratories, the normal blood activity of SDH in horses is usually less than 8 U/L.[32] Foals 2 to 4 weeks of age may have SDH activity slightly greater than those of adult horses.[78,109] Increases in SDH have been reported after prolonged halothane anesthesia in horses.[112] ARG is used in the Krebs-Henseleit cycle for urea synthesis. It is found in highest activity in hepatocytes, although minute amounts also exist in renal tissue, brain, skin, testicles, and erythrocytes.[22] Increases in ARG are most indicative of acute hepatic necrosis. Like SDH, ARG has a very short half-life. GLDH is found in hepatocytes, renal tissue, brain, muscle, and intestinal cells. Like SDH and ARG, GLDH has the highest tissue activity in the liver, and increases of this enzyme in the blood can be considered specific for acute liver disease. GLDH is produced in the mitochondria, and although increases occur in almost all hepatocellular diseases, the magnitude of the increase may differ from those of SDH. The stability of the enzyme in serum may be slightly better than SDH.[108] The half-life of GLDH is 14 hours.[22]

Other cytosolic enzymes include aspartate aminotransferase (AST), alkaline phosphatase (ALP), lactate dehydrogenase (LDH), alanine aminotransferase (ALT), and isocitrate dehydrogenase (ICD). These enzymes are also found with high activity in other tissues or are inducible. Thus increases in these enzymes are not specific for liver disease in horses. Because some of these enzymes are frequently reported in equine biochemical profiles, they may serve as a crude indicator of liver disease; however, the limitations of their usefulness must be recognized.

AST, formerly glutamic oxaloacetic transaminase (GOT), is a cytosolic- and mitochondrial-bound enzyme that catalyzes the reaction responsible for aspartate biosynthesis from carbohydrate.[20] Basically, all cells contain AST, but liver and skeletal muscle cells contain the highest activity. Cardiac muscle, erythrocytes, intestinal cells, and the kidney also are sources of AST. Hemolysis and lipemia will falsely increase the value of AST.[20] Increases are most frequently associated with muscle damage but may be seen after acute hepatic necrosis. Often the AST activity is normal in chronic hepatic disease.[100] The half-life of AST is long, and thus it may take longer than 2 weeks for the blood activity to decrease after acute hepatic disease. The AST value is most useful when analyzed with other tissue-specific enzymes. For instance, if a muscle-specific enzyme, such as creatine kinase, also is increased, an increase in AST most likely has its origin in muscle. Serial AST and SDH values can be useful for the determination of ongoing hepatic disease. If the SDH and AST values were initially increased, but subsequent evaluation reveals a normal or decreasing SDH and still elevated AST, a favorable prognosis is often indicated, because hepatic necrosis is most likely subsiding. The normal serum activity of AST is 98 to 278 U/L.[32] ICD has a distribution similar to AST.

ALT, formerly glutamic pyruvic transaminase (GPT), is responsible for alanine synthesis from carbohydrate.[20] Increases may be evident with acute hepatic disease, but myositis will also increase blood levels. Hemolysis will falsely increase the value of this enzyme, and microsomal enzyme inducers (i.e., glucocorticoids) will increase its production and release in the absence of liver disease. This enzyme is not useful for predicting liver disease in horses.[20]

ALP catalyzes the hydrolysis of monophosphate esters. This enzyme is bound to the mitochondrial membrane and thus does not leak into the blood with changes in cell membrane permeability or necrosis. Cholestasis and certain drugs, including glucocorticoids, primidone, and phenobarbital, will induce production and release of ALP. The ALP value most likely is to be increased in chronic or cholestatic liver diseases rather than acute or hepatocellular disease. Other tissues in addition to the liver contain ALP, including bone, intestine,

kidney, placenta, and leukocytes; thus increases are not necessarily indicative of cholestasis. Because of increased osteoblastic activity, foals have ALP values 2 to 3 times those of adults.[22] Pregnancy, hemolysis, and gastrointestinal disease will also cause increases in ALP.

LDH is the name for five major isoenzymes located in liver, muscle, erythrocytes, intestinal cells, and renal tissue. Increases in LDH are not liver specific unless the isoenzyme activity is determined. Isoenzyme 5 (LDH-5) is a useful indicator of acute hepatocellular disease in horses because values typically return to baseline within 4 days after a transient hepatic insult.[94,110] LDH-5 is also present in muscle, so increased serum LDH-5 activity is specific for hepatic disease if other indicators of muscle damage (i.e., creatine kinase) are normal.[110] LDH-5 is stable at room temperature for 36 hours.

γ-Glutamyltransferase (GGT) is involved in glutathione metabolism and transfer of glutamyl groups.[20] GGT primarily is associated with microsomal membranes in the biliary epithelium.[108] Cholestasis induces production and release of GGT. Renal tubule cells contain GGT, but this source is released into urine. The only other potentially significant source of GGT in the blood is pancreatic in origin. Because pancreatic disease is rare in horses and horses and foals with confirmed severe pancreatic disease have not had elevations in GGT, the blood activity of GGT is considered specific for hepatic disease in horses. Some clinicians consider GGT to be the single test of highest sensitivity when evaluating horses for evidence of liver disease.[94] The half-life of GGT is approximately 3 days; GGT is stable in serum for 2 days at room temperature or for 30 days if frozen.[22] Mild increases may be evident after acute hepatocellular necrosis and may continue to rise for 1 to 2 weeks despite improvement in clinical signs.[94] Increases are more persistent in chronic disease, especially with cholestasis.[100] Foals 2 weeks to 1 month old may have greater GGT values than adults.[78,109] The wider variation in younger horses reflects the degree and extent of hepatic maturation. Normal values for GGT in adult horses typically are less than 30 U/L[32] but may be greater in racing Thoroughbreds, healthy donkeys, burros, and asses.[113] In chronic, nonactive hepatic fibrosis and focal hepatic disease, GGT may not be significantly increased. Increased serum GGT activity has been reported in horses with cholestasis secondary to colonic displacement.[114] Racehorses occasionally have mild to moderate increases in GGT (50–140 IU/L) without any other biochemical evidence of liver disease.[115-118] This phenomenon has been observed for at least 30 years, and the elevation in GGT has been temporally linked to poor performance.[115-118] In some situations, multiple horses stabled together may have elevations in GGT. Possible causes include drug administration causing induction of GGT, toxin exposure causing disease specific for the biliary tract, viral infections causing only increases in GGT at the time of sampling, and overtraining with depletion of hepatic glycogen.[116] GGT activity between 70 and 100 U/L has previously been associated with poor health, oxidative stress, and overtraining the horse, and further, those horses with high GGT values showed a markedly reduced incidence of increased GGT following reduction in training intensity in subsequent years.[115] Furthermore, GGT levels in these horses almost always return to normal within a few weeks following rest. Recent studies demonstrated that serum GGT activity was correlated to cumulative training load and racing frequency[117] and maladaptation to training.[118]

In summary, biochemical testing for liver disease in horses should include quantitation of at least SDH or GLDH and of GGT. On rare occasions a horse may have liver disease without elevations in these enzymes. Elevation in liver enzymes are tests of disease and one should interpret these as function test.

Clearance of Pharmaceuticals

In addition to clearance of endogenous substances from the blood, liver function can be evaluated after injection of an exogenous substance. One such exogenous substance that is removed by the liver, conjugated, and excreted into bile is *bromsulfthalein (BSP)*.[22] After intravenous injection of 2.2 mg of BSP per kilogram of body weight, a clearance half-life is determined by periodically obtaining heparinized blood samples over 12 to 15 minutes. One should exercise caution when injecting BSP, because it can be thrombogenic and irritating if administered perivascularly. Blood samples for BSP quantitation should be collected from a site other than the injection site. Suggested collection times are 3, 6, 9, 12, and 15 minutes after injection. Collection of plasma at the suggested times is not crucial; however, recording the exact times at which the samples were obtained is important to ensure accurate determination of the half-life. The half-life of BSP, thus the rate of extraction by the liver, is determined by plotting the plasma concentrations against the collection times on semi-log paper. The normal half-life of BSP in horses is 2.8 to 0.5 minutes.[22]

The BSP half-life is prolonged when greater than 50% of the hepatic function is lost.[20,22] This function test is useful in horses, especially to distinguish hepatoencephalopathy from other causes of abnormal behavior or cerebral signs, and to test liver function in chronic liver disease when bilirubin, SDH, and GGT blood levels may be normal. Proper interpretation of the BSP half-life must take into account the state of hepatic blood and bile flow and the bilirubin and albumin concentrations.[20] If the hepatic blood flow is decreased significantly, as may occur with hepatic congestion or portosystemic shunts, the rate of delivery of BSP to the liver will be decreased; thus the half-life of BSP in the plasma will be prolonged. Because BSP is bound to albumin for delivery to the liver, if the blood concentration of albumin is markedly decreased, a higher proportion of unbound BSP will be delivered to the hepatocytes; thus the half-life of BSP will be shortened.[20] If the blood concentration of bilirubin is increased greatly, the bilirubin will compete with the BSP for binding sites and conjugating enzymes in the liver; thus the apparent half-life of BSP is prolonged. If significant cholestasis is present, the BSP excreted into the biliary tract will be reabsorbed into the circulation, causing an apparent prolongation of its clearance. Therefore although a BSP clearance test is very useful as a test of hepatic function, one must interpret the results in light of these limitations. Furthermore, because pharmaceutical-grade BSP is no longer commercially available, this test is basically limited to academic and research institutions. Quantitation of serum bile acid concentration has essentially replaced BSP clearance as an indicator of hepatic function.

The determination of the BSP clearance time has been suggested to be more useful for detecting liver disease than the BSP half-life.[119] It has also been suggested that the proportionality transfer constants of clearance may be more useful in predicting hepatic disease than the BSP half-life alone.[120] The clearance time is the amount of dye irreversibly removed

from the plasma per unit time. A dose of 5 mg of BSP per kilogram of body weight is given intravenously, and heparinized blood samples are obtained 2, 5, 10, 15, 25, and 30 minutes after injection. The BSP clearance time in fed normal horses is 10 mL/min/kg and 6 mL/min/kg for horses fasted 3 days.[119]

The *indocyanine green* (ICG; Beckmann & Dickinson, Baltimore, MD) clearance test has replaced the BSP clearance test in human beings.[9] Basically, the procedure and the limitations are the same as the BSP clearance test. The ICG clearance time in fed horses is 3.5 to 0.67 mL/min/kg and 1.6 to 0.57 mL/min/kg for fasted horses.[119] Although the clearance of ICG is an excellent predictor of hepatic blood flow and extraction rates, its current expense precludes its routine use in horses. Another disadvantage is that quantitation requires a spectrophotometer that reads infrared wavelengths. These limitations have hindered evaluation of ICG clearance times as a diagnostic test of liver insufficiency in horses.

The hepatic clearance of the radiopharmaceutical technetium-99m mebrofenin is used in human beings and small animals to assess hepatic function. In horses, the plasma clearance of technetium-99m mebrofenin is not affected by withholding feed.[121]

Other Nonspecific Laboratory Findings

Increased formation and release of acidic metabolic products, including ketone bodies, lactate, pyruvate, and amino acids, contribute to acidemia. Other factors that may contribute to acidemia include diarrhea and loss of renal acidification because of impaired urea synthesis. Anorexia may predispose to hypokalemia.

Although infrequently reported in horses, aldosterone and water retention may cause deranged concentrations of sodium and isosthenuria (see Polydipsia, Polyuria, and the Hepatorenal Syndrome). Azotemia may occur with hyperlipemia.[122]

Cholangiohepatitis, CAH, or a focal hepatic abscess may cause an inflammatory leukogram, anemia of chronic disease, and hyperfibrinogenemia.[89] Primary polycythemia has been reported in horses with hepatocellular carcinoma and hepatoblastoma.[123-125] Polycythemia has also been observed in horses with chronic liver inflammation and fibrosis.[116] Because fibrinogen is synthesized by the liver, widespread chronic hepatitis may mask an increase in this acute phase reactant protein. Marked elevations in total serum iron and percentage of transferrin bound iron is relatively common in adult horses with liver disease and infrequently seen in other adult horse organ system disorders.[116]

Diagnostic Imaging of the Liver

Ultrasonography is a safe, noninvasive imaging technique that uses the reflection of high-frequency sound waves from tissue interfaces to produce a visual image. Liver ultrasonography in horses is limited by the ribs, the depth and size of the liver, and its anatomic location deep to the diaphragm and lungs.[3,107] Mechanical sector or linear array scanners with 3.0-MHz crystals are most effective.[3,107] Ultrasonography can be used to assess the right and left sides of the liver and the liver shape, size, position, and texture. Hepatic vein walls are less echogenic than portal vein walls, and the biliary system is not normally visible. Ultrasonography is most useful for determining the general size of the liver; changes in the hepatic parenchyma, including abscesses, cysts, and neoplastic masses; and detecting dilated bile ducts or obstructions with choleliths. The common bile duct cannot be seen in a horse. Abnormal intrahepatic or extrahepatic blood flow or vasculature may be detectable. The liver on the left is often adjacent to the more caudally located spleen; this provides an opportunity, when visualized with ultrasound, to compare the relative echogenicity of each organ. The liver should be hypoechoic compared to the spleen, and with hepatic fibrosis the liver and spleen appear more similar in echogenicity.[3] Ultrasonography is also useful for guiding biopsy instruments into the liver (see Liver Biopsy).

Radionucleotide imaging also may be used to detect alterations in the hepatic parenchyma or blood flow.[121,126,127] Radionucleotide scanning noninvasively evaluates function and yields structural information. Two radionucleotide scanning techniques are available to evaluate the liver: liver scan and biliary scan. In the liver scan, a technetium-99m–labeled sulfur colloid is injected intravenously. Technetium-99m is a gamma-emitting radioactive compound that is detected in the body by a gamma camera. After injection, Kupffer cells phagocytose the technetium-99m sulfur colloid. Subsequent scanning with the gamma camera detects the radioactive emissions from the technetium-99m and resolves them into a two-dimensional image. Thus alterations in blood flow (portosystemic shunt) or hepatic masses such as abscesses, cysts, and neoplasia may be detectable. In the biliary scan, technetium-99m–labeled iminodiacetic acid is injected intravenously. The iminodiacetic acid is extracted by the hepatocytes, conjugated, and excreted in the bile.[128] Subsequent scanning images the biliary system and may be useful for the detection of biliary obstruction, including atresia, cholangitis, and cholelithiasis. Because radionucleotide imaging is somewhat expensive and requires a large gamma camera, this procedure is limited to research and academic institutions.

Operative mesenteric portography can be performed when a portosystemic shunt is suspected. In this procedure, a celiotomy is performed, radiopaque material is injected into a mesenteric vein, and rapid, sequential survey radiographs are obtained. Simultaneous opacification of the portal vein, azygous vein, and caudal vena cava or lack of filling of the intrahepatic portal system is indicative of portosystemic shunting.[126]

Liver Biopsy

A liver biopsy can yield important diagnostic and prognostic information. In a retrospective study of 73 horses with liver disease, a scoring system that graded the degree of fibrosis, reversible and irreversible cytopathology, inflammation, hemosiderosis, and bile duct proliferation was useful in predicting long-term survival.[129] A liver biopsy is usually performed at the right twelfth to fourteenth intercostal spaces at the intersection of a line drawn from the tuber coxae to a point midway between the elbow and the point of the shoulder. A recent study reported that using these traditional landmarks as biopsy sites may result in unsuccessful sampling of the liver in many horses and could puncture lung or intestine.[130] The study concluded that the practice of blind percutaneous liver biopsy in horses is not recommended because of the potential risk of serious complications.[130] Therefore liver biopsy in the horse should be immediately preceded by ultrasound examination and identification of an appropriate site. The procedure must be performed in a sterile manner. The area is clipped, aseptically prepared, and injected with local-acting anesthetic subcutaneously, and

a stab incision is made with a no. 15 scalpel blade. A Tru-Cut (Baxter-Travenol, St. Louis, MO) or Franklin-modified Vim-Silverman (Mueller & Co., Chicago, IL) biopsy instrument is inserted and directed such that the largest amount of liver can be penetrated. Semiautomatic biopsy instruments (EZ Core, Products Group International, Lyons, CO) and automatic biopsy guns (ProMag 2.2 Biopsy System, Manan Medical Products, Northbrook, IL) equipped with 14-gauge, 16-cm needles are very helpful for a quick and accurate liver biopsy. Ultrasound-guided biopsy will provide a more precise sampling. Samples should immediately be placed in formalin for histopathologic evaluation and, if necessary, in transport media for culture of microorganisms. Precautions to consider before performing the procedure include the risk of hemorrhage, pneumothorax, and peritonitis from bile leakage and colon or abscess puncture, as well as spread from infectious hepatitis. These complications may be reduced by performing a hemostasis profile to assess the risk of hemorrhage and by using ultrasonography to guide needle placement. Although subclinical coagulopathy has been frequently reported in horses with liver disease, clinically significant or fatal hemorrhage after performing a liver biopsy is rarely reported.[131] Biopsies may not be needed in some equine liver disorders. If historical, clinical, and laboratory information clearly indicates a diagnosis such as Theiler's disease or hepatic lipidosis, biopsy is unlikely to be of additional help in managing the case.

Summary of Diagnostic Procedures

The most useful diagnostic tests for evaluation of hepatic disease in horses are quantitation of SDH or GLDH, GGT, and serum bile acids. In the face of clinically significant liver disease, quantitation of both conjugated and unconjugated bilirubins, glucose, PT and PTT, triglycerides and ammonia is recommended. Serial testing of these indices may increase their diagnostic and prognostic value. Abnormal laboratory findings should be further investigated with ultrasonography and biopsy.

Treatment of Hepatic Insufficiency

Management techniques for hepatic insufficiency are largely supportive. (Therapies for specific liver diseases are discussed in more detail under Specific Hepatic Diseases later in this chapter.) The basic goal of treatment is to maintain the animal until enough liver regenerates to provide adequate function. Fortunately, the liver is an amazingly regenerative organ, and most acute diseases do not progress to failure. Although hepatocytes are fully differentiated cells, they are capable of active proliferation by self-duplication in response to acute external stimulation and upregulation of humoral factors, all without any contribution from hepatic stem cell progenitor cells.[27–29] Patients with severe hepatic fibrosis respond poorly because adequate regeneration often is not possible. Horses with signs of HE that are agitated, restless, or uncontrollable must be sedated to enable therapy; however, any medication should be used judiciously because most tranquilizers are metabolized by the liver or potentiate the abnormal neural function of HE. Xylazine or detomidine in small doses is safest and most effective in these instances. Use of diazepam is contraindicated because it enhances the effect of GABA on central inhibitory neurons and may exacerbate signs of HE.[49] Intravenous fluids should correct fluid deficit and acid-base or electrolyte imbalances such as hypokalemia. Because most horses with HE are anorectic and blood glucose may be decreased, particularly in foals, continuous intravenous infusion of 5% dextrose with electrolytes can be beneficial as long as pronounced hyperglycemia, hyponatremia, and hypokalemia are avoided.[116] In human beings, volume expansion with 0.9% saline solution enhances urinary ammonia excretion.[132] If bicarbonate therapy is necessary to treat acidotic patients with hyperammonemia, the rate of administration should be monitored carefully because too rapid of a rate may increase blood levels of ammonia.[49] Hypokalemia or alkalosis results in increased renal production of ammonia and increased diffusion of ammonia into the CNS; thus treatment with potassium or acidifying fluids may be beneficial.[133,134]

Therapy should also be directed at reducing the production of toxic protein metabolites by enteric bacteria or by interfering with their absorption.[135] The administration of mineral oil or magnesium sulfate per nasogastric tube is safe, assuming there is no nasal hemorrhage, and aids in reducing toxin absorption. HE in human beings with acute fulminant hepatic failure is almost always associated with cerebral edema. Thus recommendations for treatment of severe acute HE in human beings currently focus on decreasing blood ammonia levels; reducing systemic inflammation; maintaining organ perfusion, blood pH, and electrolyte balances; treatment of cerebral edema with mannitol or hypertonic saline; and treatment with antioxidants, nutritional support, and, when those fail, use of extracorporeal liver support devices.[43]

Methods to reduce the production of ammonia and other enteric toxins include the oral administration of antibiotics (neomycin, metronidazole, rifaximin, vancomycin)[132] or lactulose or lactitol (not available in the United States).[43,133,135] In horses, neomycin has been recommended at a dosage of 10 to 20 mg/kg PO every 8 hours.[116] This treatment significantly alters the gastrointestinal flora and may cause diarrhea in some horses. However, in one retrospective study in horses with liver disease, oral neomycin therapy subjectively was more helpful than lactulose in alleviating signs of HE.[34] Lactulose, a syrup containing lactose and other disaccharides, passes through the upper small intestine and is metabolized by ileal and colonic bacteria to organic acids, thereby reducing luminal pH. Proposed beneficial mechanisms of action of lactulose include increased bacterial assimilation of ammonia, decreased ammonia production, ammonia trapping in the bowel lumen by increased conversion of ammonia (NH_3) to ammonium (NH_4), enteric microflora changes, and osmotic catharsis.[136] A dose of 0.3 to 0.5 mL/kg of lactulose syrup every 8 hours per oral dose syringe or nasogastric tube has been recommended for horses.[116] If a nasogastric tube is used there should be extreme care in avoiding a nosebleed as ingested blood would increase enteric ammonia production. When given orally 3 times a day at 333 mg (0.5 mL)/kg of body weight, lactulose (Duphalac, Solvay Pharmaceuticals, Marietta, GA) significantly decreased blood ammonia values in healthy adult horses.[136] None of the horses developed diarrhea, although one horse foundered on the sixth day of treatment. Fecal pH did not decrease. As an alternative or adjunct to antimicrobials or lactulose, one may attempt modification of intestinal flora with probiotics, such as *Lactobacillus acidophilus* or *Enterococcus faecium*.[133] Many clinicians prefer not to use oral antimicrobials or lactulose but to rely on institution of a low-protein diet. Low-protein diets are recommended for hepatic diseases causing high blood ammonia or signs of

TABLE **13.3 Clinical Conditions That May Exacerbate Hepatic Encephalopathy**

Dehydration	Systemic inflammation
Constipation	Hyponatremia
Hypokalemia	Abnormally low head position
Gastrointestinal bleeding	Excessive sedation
Intestinal blood (nosebleed)	Jugular thrombosis
Infection	Hyperthermia

HE, but moderate- to normal-protein diets should be given to horses with chronic liver disease, normal mentation, and normal blood ammonia. Oral and intravenous formulations of BCAAs are commercially available for use in horses (BCAA Equine Sports, Inc., Lake Forest, IL; Baxter Healthcare Corp., Deerfield, IL), but controlled clinical trials in human beings have not shown this form of therapy to consistently ameliorate the signs of HE.[72]

As discussed previously, benzodiazepine receptor antagonists have been suggested to induce clinical and electrophysiologic remissions of HE in human beings with both acute and chronic liver failure.[36,137,138] This neuropharmacologic approach to treatment of HE holds promise, although it may not be economically feasible in horses. In human beings with HE, treatment with flumazenil, a benzodiazepine antagonist, and bromocriptine, a dopamine agonist, has provided either short-term or inconsistent results.[139,140] Zinc, levocarnitine, and ornithine aspartate enhance ureagenesis and also may reduce blood ammonia concentrations.[132,133,141] These treatments have not been evaluated in the horse. In summary, the basics for treating HE in horses include providing sedation only when needed and providing appropriate fluid and electrolyte treatments to maintain perfusion of organs and correct electrolyte and glucose abnormalities, decrease ammonia enteric production, prevent infection, control inflammation, provide adequate nutritional support, and prevent complications that may worsen HE (Table 13.3).

Antiinflammatory drugs may be beneficial in treating liver disease and include flunixin meglumine, dimethyl sulfoxide (DMSO), and pentoxifylline. DMSO (0.5–1 g/kg body weight, given intravenously diluted to 10% for 3–5 days) may help dissolve intrabiliary sludge or small calcium bilirubinate stones.[142] *Pentoxifylline* has been shown to reduce hepatic fibrosis in human beings[143] and may be given to horses at 8 mg/kg every 8 to 12 hours.[143a] Silymarin, a standardized extract of the milk thistle seeds *(Silybum marianum),* is commonly used in the treatment of chronic liver diseases in several species including the horse.[144,145] Flavonolignans are the most common class of compounds present in milk thistle extract, and of the group, silybin (silibinin) is considered to have the most hepatoprotective properties.[144] Experimental studies have demonstrated antifibrotic, antioxidant, and metabolic effects of silybin, but human studies have been insufficient in confirming the clinical efficacy in chronic liver disease.[144] In normal horses, a standard bioavailability study of orally administered silibinin found less than 1% available.[145] *S*-adenosylmethionine (SAMe) is another nutritional supplement commonly used in the treatment of chronic liver disease in small animal veterinary medicine. SAMe is a compound made primarily in the liver as a byproduct of methionine metabolism. Following oral administration, absorption, and trans-sulfuration, SAMe is converted into glutathione, a powerful antioxidant. SAMe is believed to stabilize cell membranes, promote secretion of bile, and have antiinflammatory properties. Despite these potentially favorable benefits and information to suggest that SAMe synthesis is depressed in chronic liver disease, high-quality randomized studies to prove clinical efficacy were not found.[146] There are no studies on bioavailability or efficacy in the horse.

The bile salt ursodeoxycholic acid (ursodiol) is the drug of first choice in the treatment of cholestatic liver diseases in humans[147] and has been successfully used in treating obstructive cholangiohepatitis in horses.[116] Ursodiol would not be expected to have an effect on dissolving calcium bilirubinate calculi but is an antiinflammatory and choleretic agent that increases bile production, making bile more liquid and easier to excrete.[148]

Colchicine, an antigout drug, and cyclosporine, a potent T helper cell immunosuppressant, have been used to slow hepatic fibrosis in dogs and people.[149,150] These drugs have not been fully evaluated in horses; however, colchicine has been ineffective in cases of pyrrolizidine alkaloid toxicity and may even be contraindicated due to its antimitotic effect.[149]

If any drugs are to be administered to a horse with hepatic insufficiency, it may be necessary to alter dosage. Alterations in hepatic blood flow, albumin, and biotransformation during hepatic insufficiency may prolong the half-life, as well as the dosage interval. Drugs that rely heavily on the liver for metabolism and excretion, such as chloramphenicol, erythromycin, metronidazole, and corticosteroids, should be used with caution.[24]

Once the appetite returns, a horse with HE or chronic liver disease is best managed by dietary manipulation. The ration should be high in carbohydrates and moderate to normal protein, with the protein source optimally rich in BCAAs. A mixture of two parts soaked beet pulp and one part cracked corn in molasses can be fed at a rate of 2.5 kg/100 kg body weight per day divided into six or more feedings.[113] Sorghum, bran, or milo can be substituted for the beet pulp. In horses with liver failure and neurologic signs of HE, it can be assumed that the amount of protein in the diet should initially be restricted.[116] The old concept of providing a low-protein diet to all animals with chronic liver failure is no longer believed to be standard of care in other species.[151] The beneficial effects of feeding adequate protein include maintenance of muscle mass and therefore deceased ammonia genesis associated with muscle catabolism.[72]

Multiple small feedings are optimal in horses with liver disease because of impaired gluconeogenesis. Oat or grass hay is a preferred roughage.[116] Horses should be encouraged to graze grass pastures provided they are protected from the sun. Alfalfa and legumes should be avoided if signs of HE are present because of their high protein content; however, any caloric intake is important in liver failure and alfalfa, and legumes should be allowed if the horse will not eat other feeds. Vitamins B_1, K_1, and E and selenium, zinc, and folic acid are often supplemented to horses with liver failure. Vitamin K therapy might be most beneficial when cholestasis is present.[9]

Prognosis

The prognosis for hepatic insufficiency in horses depends on the severity and type of the underlying disease. Horses with

focal or mild to moderate acute hepatic disease have the best chance for hepatic regeneration; thus they have a guarded to fair prognosis if adequate and appropriate supportive care is given. Patients with severe hepatic fibrosis and chronic liver disease have a poorer prognosis because of their inability to compensate for lost hepatic function. Regardless of the cause of liver disease, the presence of severe encephalopathy, intravascular hemolysis, profound acidosis, clinical signs of coagulopathy, diarrhea, bilateral laryngeal paralysis, markedly increased serum bile acid concentration in horses with chronic liver disease, BSP half-life greater than 10 minutes, decreased serum albumin, and histologic evidence of marked bridging fibrosis have all been associated independently with a poor to grave prognosis.[98,129,152] If a horse survives more than 5 days after an acute transient hepatic insult, the prognosis is fair. Decreasing blood levels of SBA, GLDL, and GGT are more likely to occur in horses that survive.[33] Therapy is generally unrewarding in horses with severe hepatic fibrosis.

SPECIFIC HEPATIC DISEASES

The wide variety of clinical signs with hepatic disease, coupled with the fact that the majority of the hepatic parenchyma must be affected before function is lost, makes the clinical distinction between acute and chronic liver disease a challenge. The onset of signs may be sudden, even with chronic disease. A history of progressive weight loss or "failure to thrive" may indicate chronicity. Although no single blood test is specific for distinguishing acute from chronic hepatic disease, the presence of hyperglobulinemia or hypoalbuminemia may suggest chronicity. Histopathologically, the hallmark evidence of chronicity is the presence of fibrosis. Fibrosis can be determined by ultrasound examination or preferably liver biopsy. For the purpose of discussion of specific hepatic disorders in the following sections, diseases have been classified as either *acute* or *chronic* based on the known cause of the disease (Box 13.2).

Acute Hepatic Diseases

Theiler's Disease

Sir Arnold Theiler first described this disease in South Africa in 1918 after vaccination of horses against African horse sickness with both live virus and equine-origin antiserum.[153] In 1934 and 1937, a similar disease was described in the United States after vaccination of horses against western equine encephalomyelitis using live virus and equine-origin antiserum.[86,154,155] Despite numerous accounts of this syndrome, the exact cause of Theiler's disease remains unproven. Today this disease is one of the most commonly described causes of acute diffuse hepatic necrosis in adult horses.[32,86,156-160] Theiler's disease is also referred to as *serum-associated hepatitis.* The term *serum sickness* has been used in previous literature erroneously[161]; serum sickness is an immune complex hypersensitivity to foreign protein resulting in multisystem disease within 2 weeks after foreign protein administration.[162]

Clinical Signs. Theiler's or Theiler's disease is limited to adult horses, although one report describes subclinical disease in a 2-month-old foal.[157] The onset of clinical signs of hepatic failure in Theiler's disease is acute to subacute and often rapidly progresses over 2 to 7 days. Most horses are anorectic and icteric; HE is reported in the majority of the cases.[86,156,157] Sudden death, photodermatitis, hemorrhagic diathesis, fever, dependent edema, colic, and bilirubinuria may be present.[86,156,157]

Epidemiology and Pathogenesis. The disease typically occurs sporadically, but outbreaks involving multiple horses on a single farm over several weeks have been reported.[32,86,156,157]

BOX 13.2 Liver Diseases of Horses

ACUTE DISEASE

- Theiler's disease (serum-associated hepatitis)
  - Virus-related Theiler's disease
  - Nonprimate hepacivirus (NPHV)
  - Theiler's disease–associated virus (TDAV)
  - Equine pegivirus (EPgV)
  - Equine parvovirus
- Hyperlipemia
- Tyzzer's disease
- Infectious necrotic hepatitis (black disease)
- Cholangiohepatitis
- Acute biliary obstruction
  - Cholelithiasis
  - Colon displacement
  - Hepatic torsion
- Parasitic hepatitis
  - *Parascaris equorum*
  - Large strongyles
  - *Echinococcus granulosa*
  - Schistosoma
- Toxic hepatopathy
  - Plants
  - Mycotoxins
  - Chemicals
  - Drugs
  - Iron
- Viral hepatitis
  - Equine infectious anemia (EIA)
  - Equine herpesvirus–1 (EHV-1)
  - Equine viral arteritis (EVA)
  - Giant cell hepatopathy

CHRONIC DISEASE

- Pyrrolizidine alkaloid toxicity
- Clover poisoning
- Chronic active hepatitis (CAH)
- Cholelithiasis
- Gastroduodenal obstruction
- Abscess
- Neoplasia
  - Metastatic infiltration of the liver
  - Cholangiocarcinoma
  - Hepatocellular carcinoma
  - Hepatoblastoma
  - Mixed hamartoma
- Amyloidosis
- Chronic hypoxia

CONGENITAL OR HERITABLE DISEASE

- Portosystemic shunt
- Biliary atresia
- Hyperammonemia of Morgans
- Glycogen branching enzyme deficiency

A pattern of seasonality may occur, with a larger percentage of cases presenting in summer and fall.[32,116] Frequently, horses with Theiler's disease have received an equine-origin biologic antiserum 4 to 10 weeks before the onset of hepatic failure, hence the name *serum-associated hepatitis.* Equine-origin biologic antiserums that have been associated with Theiler's disease include antisera for African horse sickness, eastern and western encephalomyelitis, *Bacillus anthracis,* tetanus antitoxin, *Clostridium perfringens, C. botulinum, Streptococcus equi* subsp. *equi,* influenza, equine herpesvirus type 1 (EHV-1), pregnant mare's serum, and plasma.[32,86,156,157,159] Some reports suggest that lactating broodmares given tetanus antitoxin after parturition are particularly prone to Theiler's disease.[156-158] Although the overall incidence of Theiler's disease in adult horses receiving tetanus antitoxin is low, tetanus antitoxin has for the past 40 years been the most common blood product associated with the disease in the United States.[116] Theiler's disease may be more commonly associated with tetanus antitoxin administration than equine plasma because of either the more frequent administration of tetanus antitoxin to horses or the fact that tetanus antitoxin is produced as a pooled product whereas commercial units of normal plasma are most often collected from a single donor. Reports of outbreaks in association with parenteral injection of homologous live virus vaccine and antiserum suggest an infectious blood-borne viral cause, and recently three newly discovered viruses (see below) have been found to be associated with the disease.[116,162] Not all cases of Theiler's disease are associated with recent administration of equine-origin plasma or serum products. Theiler's disease that is not associated with blood products appears to be most common in late summer through autumn, making the possibility of insect transmission of a viral pathogen plausible.[116] The history, onset, clinical signs, and histopathologic findings of Theiler's disease appear most similar to hepatitis B virus in human beings. Hepatitis B virus is present in all body fluids and excreta and is transmitted primarily by parenteral injection.[37]

Other previously suggested causes of Theiler's disease include exposure to hepatotoxic substances, such as mycotoxins (aflatoxin and rubratoxin), plant toxins (pyrrolizidine alkaloids, alsike clover), drugs, or chemicals.[100,158] However, these causes have not been demonstrable and usually are considered separate disease entities.

Pathology. Aside from widespread tissue icterus, pathologic findings are mostly limited to the liver. The liver appears smaller than normal in most cases. Although not pathognomonic, the histopathologic findings in Theiler disease consistently include widespread centrilobular to midzonal hepatocellular necrosis and apoptosis with hemorrhage (Fig. 13.7).[160] Moderate to severe centrilobular hepatocyte vacuolar (fatty) change and granular swelling, hemosiderosis, and bile casts may be seen.[156] A mild inflammatory infiltrate, primarily monocytes and lymphocytes, is present in portal triads. The occasional finding of mild to moderate biliary hyperplasia and fibroblastic infiltration is evidence of a slightly more chronic disease course than the clinical signs alone would suggest.[160]

Diagnosis. Recent (4–10 weeks earlier) inoculation with an equine-origin biologic antiserum or plasma, coupled with an abrupt onset of clinical signs and laboratory evidence of hepatic insufficiency, strongly suggests Theiler's disease. On ultrasound examination, the liver may subjectively appear small and hypoechoic. No single laboratory test is diagnostic. Bilirubinemia and bilirubinuria are usually present.

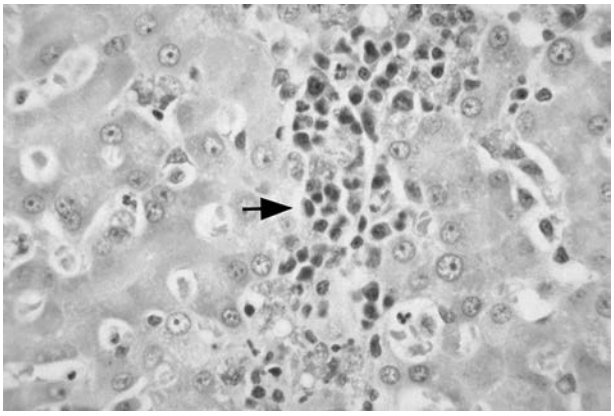

FIG. **13.7** Histopathology of the liver: Theiler's disease. Note the central area of hepatic necrosis *(arrow).*

Although both unconjugated and conjugated levels are increased, the conjugated portion generally remains less than 25% of the total.[116] Liver enzymes, including SDH, GLDH, ARG, and AST, are increased several fold. GGT is increased but not of the magnitude as are the hepatocellular enzymes.[116] The BSP half-life, PT, and APTT are often prolonged, and blood ammonia concentrations are increased. Acidosis, leukocytosis, polycythemia, and increases in serum creatine kinase activity have also been reported.[156-158] Hemolysis may occur terminally. The histopathologic findings on a liver biopsy (see previous pathogenesis section) offer the strongest diagnostic evidence of Theiler's disease.

Treatment. No specific treatment for Theiler's disease exists aside from general supportive care for hepatic insufficiency (see Treatment of Hepatic Insufficiency earlier in this chapter). Although it might be tempting to treat with interferon because of the strong possibility of viral etiology, it should be remembered that the onset of disease might be associated with attempted clearance of the virus.[163]

Prognosis and Client Education. The prognosis is poor to grave in horses with severe HE, hemorrhage, or hemolysis. Horses that survive longer than 1 week usually recover completely, although death or progressive weight loss has on rare occasions been reported during the ensuing months.[157] A favorable prognosis is warranted if serial SDH or GLDH activities are decreasing or clinical signs are waning and the horse is still eating.[116] Increased serum activity of GGT may be sustained for several weeks, despite clinical improvement and long-term survival. [116,156] No preventive agent exists, aside from the judicious use of equine-origin antiserum.

Newly Discovered Equine Hepatitis Viruses

Recently, four distinct equine hepatitis viruses have been discovered in horses: nonprimate hepacivirus (NPHV; also called hepacivirus), Theiler's disease–associated virus (TDAV), and equine pegivirus (EPgV), which are all close Flaviviridae family relatives of human hepatitis C viruses[162,164,165] and a very recently discovered DNA virus called *equine parvovirus.*[116] The horse appears to be unique among domestic animals for harboring these so-called hepatitis viruses.[166] The recent discovery of these *equine hepatitis viruses* is directly related to the use of the newer technology involving nucleic acid deep sequencing of samples. Unknown nucleotides are then reassembled using de novo computerized sequencing to identify new agents.[162]

Nonprimate Hepacivirus. Nonprimate hepacivirus was the first of the three new blood-borne viruses to be reported.[164] NPHV was found in pooled equine serum and in the serum of 8 of 103 (7.8%) normal horses, of which 35% were NPHV antibody positive; samples tested were those submitted for equine infectious anemia testing at Cornell, and it was therefore assumed that horses were healthy. Since that description in the United States, NPHV viremia has been reported during routine serum screening in 3 of 142 horses (2.1%) in Great Britain and in 7 of 210 horses (3.3%) from Germany.[167,168] Multiple NPHV infections have also been reported in Japan and Brazil.[169,170] Similar incidence of NPHV infection in clinically healthy horses is found in France (Stephane Pronost, personal communication). Currently, accumulated data from Europe, North America, and Asia indicate that nearly 40% of all adult horses are seropositive, prevalence of active infection is 4%, and approximately one fifth of those 4% are chronic carriers.[167-169] Infections from either of these three newly discovered flaviviruses (NPHV, TDAV, EPgV) are uncommon in mules or donkeys.[171] NPHV is a member of the *Hepacivirus* genus in which human hepatitis C viruses (HCV) are the prototype members, and of the three hepaciviruses found in horses, NPHV is most closely related genetically to HCV. NPHV has also been found commonly in bats, rodents, and Old World monkeys, and it is the only one of the three recently discovered horse flaviviruses known to be hepatotropic in the horse.[163,166] As regards clinical importance, the testing of a somewhat random assortment of naturally infected horses has indicated that there is little documented association between NPHV infection and clinical hepatic disease in those horses.[167,171] In NPHV experimentally infected horses there is mild disease documented by elevations in liver enzymes and lymphocytic portal inflammation and piecemeal hepatocyte necrosis.[163,172] The elevations in liver enzymes seem to occur shortly after development of measureable antibodies, suggesting that antibody-mediated activity related to the virus could cause some disease. When foals with severe combined immunodeficiency (SCID) were experimentally infected,[172] they produced no antibody and there was no increase in GGT, further supporting an immune response to the infection and association with disease.[172] The only report of clinical disease associated with NPHV infection is a case report of Theiler's disease with a horse having a high level of NPHV viremia and as the viremia diminished the horse recovered.[173] Although the data set is small, most horses that are chronically infected with NPHV do not have biochemical or clinical findings suggestive of liver disease.[116] Most horses infected with NPHV appear to have relatively slow development of NPHV-specific antibody (approximately 6–8 weeks)[163,172] followed by viral clearance in most horses in the following months. A seronegative horse inoculated with infectious clones of NPHV resulted in high RNA titers in the serum and liver of the horse establishing the molecular components of a functional NPHV genome. Delayed seroconversion, with elevated circulating liver enzymes, and mild hepatitis were observed, followed by viral clearance. Hepatotropism was confirmed by level of viremia in the liver and by finding negative-strand RNA in the liver, a hallmark of viral replication.[163]

Theiler's Disease–Associated Virus. The second equine hepatitis virus was discovered in 2012 in association with an outbreak of acute hepatitis in horses that had previously received botulinum antitoxin.[162] Seven of 17 horses treated with one particular lot of botulinum antitoxin developed clinical and/or biochemical evidence of hepatitis 6 to 8 weeks after the antitoxin administration. Hepatitis was not observed in five horses that were treated with a separate lot of botulinum antitoxin produced from different horses or in 53 farm horses that had not received antitoxin.[162]

This flavivirus virus was named *Theiler's disease–associated virus* (TDAV).[162] A reverse transcriptase–polymerase chain reaction (RT-PCR) then was used to test the serum of horses for the newly discovered equine hepatitis-associated virus (TDAV). All 17 of the horses that received the incriminated lot of botulinum antitoxin were positive for the new virus, including the 7 horses with acute hepatitis.[162] The original 17 TDAV-positive horses were retested after 1 year by qRT-PCR, and TDAV was undetectable in 13 of the previously infected horses. However, in 4 horses, persistent TDAV viremia was demonstrated.[162] A large portion of the horses from the index farm have been retested since the hepatitis outbreak, and no additional horses have become PCR positive for the virus, suggesting that direct horse-to-horse transmission or transmission by insect vectors may not occur or is not common. Follow-up studies since 2012 find that TDAV appears to be a relatively rare virus in the horse population, and it has not been found in horses in the United Kingdom and France or in any other species so far.[167] Two divergent strains of the virus were found in a European commercial equine serum product.[174] TDAV has not been found in tetanus antitoxin–associated cases of Theiler's disease. It is therefore likely that TDAV might not be a cause of Theiler's disease and that the liver disease reported in the previous outbreak may have been caused by a coinfecting virus .[116]

Equine Pegivirus. The third equine blood-borne equine flavivirus was reported by Kapoor et al.[165,167] and has been named the *equine pegivirus*. EPgV and TDAV are both members of the *Pegivirus* genus but are genetically distinct.[162,165] Pegiviruses, although a common infection in humans and other species, are not known to cause clinical disease in other species.[165,166] Three of the original 12 EPgV-infected horses from Alabama were reported to have had elevated liver enzymes but were not clinically ill.[165] qRT-PCR testing of both lymph node biopsy and liver biopsy tissue from infected horses failed to demonstrate hepatotropism of the virus.[165] Two of the horses were shown to be carriers of EPgV for at least 3.5 years. Although there are few data to support an association between EPgV infections and clinical equine liver disease at this time, this possibility cannot be ruled out.[167] Although all three equine flaviviruses (NPHV, TDAV, and EPgV) are believed to be transmitted by blood, the high seroprevalence of both NPHV and EPgV suggest that there must be modes of transmission other than plasma and antitoxin inoculations.[164,167] The role and importance of coinfection in disease are unknown.

Equine DNA Virus. The most recently discovered virus is an equine DNA virus called *equine parvovirus*, and it has been found in consecutive horses with Theiler's disease that received tetanus antitoxin or other equine-origin blood products and in a farm outbreak of Theiler's disease not associated with administration of equine-origin blood products. Experimental inoculation of a virus-negative and seronegative aged horse with a commercial product containing the virus caused a late-onset viremia (7 weeks), seroconversion, and severe hepatic disease. Further studies are under way, but this newly discovered DNA virus now appears to be the virus most closely associated with Theiler's disease in the horse and is proven on experimental inoculation to cause liver disease in horses. Some healthy horses are persistently viremic and antibody positive.

Bacterial Hepatitis

Tyzzer's Disease. *Clostridium piliforme* (formerly *Bacillus piliforme*) is a motile, spore-forming, obligate intracytoplasmic bacterium that causes acute necrotizing hepatitis. The disease was first described by E. E. Tyzzer in 1917 in a colony of waltzing mice.[174] The first documented outbreak in foals occurred in Kentucky on a single farm between 1964 and 1973, fatally infecting 23 foals.[175]

Clinical Signs. In horses, Tyzzer's disease is limited to foals between 7 and 42 days of age (average age 20 days).[176-178] The clinical signs are usually nonspecific and include loss of a suckle reflex, depression progressing to recumbency, fever, tachypnea, tachycardia, icterus, petechiation, diarrhea, dehydration, shock, seizures, and coma.[176-182] Often the foals, especially younger ones, are found dead without premonitory signs.

Epidemiology and Pathogenesis. *C. piliforme* is thought to be common in the environment, but because it is difficult to culture little is known about the epidemiology and pathogenesis of the disease. Outbreaks of Tyzzer's disease are sporadic; thus the disease is not believed to be contagious.[178] The overall incidence is likely less than 0.1% of foals per year.[178] Multiple cases have been reported on some farms, and increased environmental contamination and bacterial colonization of the mares leading to increased fecal-oral transmission are possible.[178] This was not believed to be a breed or gender predisposition. Relative risk of disease appears to be greater in the later months of the foaling season.[178] The disease has been reported in the United States, Canada, South Africa, England, and Australia.[176-182] Mice with Tyzzer's disease are infected by an oral route perinatally, with clinical signs and death occurring between 6 and 44 days of age.[178] *C. piliforme* is excreted in the feces of clinically healthy horses and can survive in the soil for at least 1 year.[177,178] Foals are infected by eating contaminated feces of their dams or by ingesting contaminated soil.[178] The bacteria replicate in the intestinal epithelium and reach the liver and heart by way of the lymphatics and blood supply.[178] In rodents and rabbits, administration of corticosteroids or sulfonamides may induce active disease.[177] The presence of antibody to the flagella of *C. piliforme* in the serum of healthy horses suggests that exposure to *C. piliforme* is not uncommon.[183]

C. piliforme causes acute multifocal hepatitis, myocarditis, and enteritis.[178] Grossly, the liver is swollen, with 1- to 5-mm white foci scattered throughout the parenchyma. Tissues are icteric, and petechial hemorrhages are present in many tissues. Microscopically, the foci are areas of coagulative necrosis with an associated inflammatory infiltrate consisting of neutrophils, macrophages, and lymphocytes. The organisms, best demonstrated at the periphery of the lesions by Warthin-Starry or Dietrerle's silver stains, appear as long bacilli organized in bundles. In addition to hepatitis, enterocolitis, myositis, pleural effusion, pulmonary congestion and edema, and lymphoid necrosis or depletion may be present.[177,180]

Diagnosis. The peracute onset and nonspecific signs confound antemortem diagnosis of Tyzzer's disease. Hematologic study may reveal hemoconcentration, leukopenia or leukocytosis, a left shift, and toxic neutrophils.[176-182] Other nonspecific laboratory findings include hyperfibrinogenemia, acidosis, hyperkalemia or hypokalemia, and profound hypoglycemia.[179,181,182] Liver enzymes are increased, including SDH, GGT, AST, ALP, and LDH-5.[176-182]

The definitive diagnosis is determined at necropsy by demonstration of the organism intracytoplasmically using silver stains or by polymerase chain reaction (PCR) analysis.[178,182] *C. piliforme* is fastidious and can only be grown in living tissue, such as embryonated chick eggs.[182] Positive serology may be supportive evidence for exposure.[183] Differential diagnosis for hepatic disease in young foals includes iron hepatotoxicity, perinatal EHV-1, leptospirosis, *Listeria monocytogenes* or *Bartonella* spp. infection, other causes of bacteremia, atresia of the bile duct, and portosystemic shunt.[184-186]

Treatment. Tyzzer's disease is highly fatal in foals. In rodents and rabbits, *C. piliforme* is sensitive to penicillin, tetracycline, erythromycin, and streptomycin. Rare reports exist of successful treatment of foals with Tyzzer's disease using penicillin, TMS, and partial parenteral nutrition.[179,182] The only confirmed case of Tyzzer's disease (PCR positive on liver biopsy) successfully treated occurred in a foal treated with ampicillin, gentamicin, and fluid and nutritional support.[182]

Prognosis and Client Education. Tyzzer's disease in foals is considered highly fatal. No preventive measures are known.

Infectious Necrotic Hepatitis

Clostridium novyi type B is the cause of *infectious necrotic hepatitis*, or *black disease.* The disease is most common in sheep and cattle, but cases have been documented in horses.[84,187-190]

Clinical Signs. The onset of disease may be peracute with sudden death. Acute signs are progressive over 24 to 72 hours and include depression, reluctance to move, fever, icterus, ataxia, colic, petechiae, periods of recumbency, tachycardia, and tachypnea.[84,187-190] Some affected horses remain standing until a short time before death.

Epidemiology and Pathogenesis. Reported cases of infectious necrotic hepatitis in horses have occurred in or adjacent to areas with a large population of sheep.[84,187-190] In sheep and cattle, infectious necrotic hepatitis is the result of multiplication of *C. novyi* in areas of liver compromised by the migration of *Fasciola hepatica.* This fluke normally does not infest horses, but migration of any parasite through the liver may predispose the animal to infectious necrotic hepatitis. Some horses with infectious necrotic hepatitis had parasitic infestations, although migrating parasites in the liver at the time of necropsy was not evident. The onset of disease in one case occurred 48 hours after administration of mebendazole.[84]

The carcass blackens rapidly after death from engorgement of subcutaneous blood vessels; hence the name *black disease.* Often, necropsy findings include serosanguineous effusion in the pericardial sac and the thoracic and abdominal cavities, widespread hemorrhages and icterus, and multifocal areas (1 to 2 mm) of coagulative hepatic necrosis. Smears or histologic sections of the hepatic lesions reveal large numbers of gram-positive rods.

Diagnosis. The acute and nonspecific nature of this disease makes antemortem diagnosis improbable. Liver-specific enzymes and bilirubin are mildly to moderately increased.[84,187-190] An abdominocentesis was performed on one horse and revealed serosanguineous peritonitis.[84] Differential diagnosis should include hepatic lobe torsion, portal vein thrombosis, and other diseases that may cause focal infection and infarction. Definitive diagnosis is based on positive staining with fluorescein-conjugated antiserum specific for *C. novyi* or isolation of the organism at necropsy.[187-190] The organism is difficult to isolate and requires rapid tissue sampling and anaerobic conditions.

Treatment. Treatment with high doses of penicillin or ampicillin is indicated, in addition to general supportive care for hepatic insufficiency.

Prognosis and Client Education. Most reported cases of infectious necrotic hepatitis in horses were fatal.

Miscellaneous Causes of Bacterial Hepatitis

Primary bacterial hepatitis is rare in adult horses. Bacterial septicemia in neonates may result in multifocal hepatitis, although clinical signs of hepatic failure rarely accompany the disease. Bacterial endotoxin, released during acute fulminant gram-negative infection or absorbed from the gastrointestinal tract after mural damage, may cause hepatic ischemia indirectly through hemodynamic alternations. Because Kupffer cells normally phagocytose endotoxin, bombardment of the liver with endotoxin may temporarily impede the function of Kupffer cells. *Cholangiohepatitis* in horses is most often a sequela to biliary stasis, cholelithiasis, CAH, hepatic neoplasia, pancreatitis, intestinal parasitism, intestinal obstruction, and proximal enteritis.[81,191-196] Clinical signs include anorexia, colic, fever, and icterus; HE may be present if there is extensive fibrosis. Laboratory abnormalities may include leukocytosis; toxemia; hyperfibrinogenemia; increased activity of SDH, ARG, GGT; increased direct-reacting bilirubin; and evidence of septic or nonseptic peritonitis.[191] Definitive diagnosis is based on histopathologic findings on liver biopsy and bacterial isolation. Isolates are most commonly enteric organisms such as *Salmonella* spp., *Escherichia coli, Citrobacter, Klebsiella, Aeromonas, Clostridium,* and *Acinetobacter* spp.[81,191,193] Treatment includes general supportive care for hepatic failure (see Treatment of Hepatic Insufficiency earlier in this chapter) and at least 4 to 6 weeks of antimicrobial therapy. The antimicrobial therapy should be based on culture and sensitivity results. Recommended antimicrobials for bacterial cholangiohepatitis in horses include trimethoprim-sulfonamide, ceftiofur, ampicillin or enrofloxacin in combination with metronidazole, penicillin and gentamicin, and chloramphenicol.[81,191]

Multisystemic Viral and Bacterial Causes of Hepatitis

Equine Herpesvirus Infection in Foals. Pregnant mares infected with EHV-1 may abort in the third trimester or deliver stillborn or weak foals. Some foals may appear normal at birth but develop clinical signs of respiratory distress, icterus, fever, and severe depression.[196,197] Secondary bacterial septicemia is common. Despite profound hepatic necrosis in herpesvirus-positive foals, serum enzyme activities were not significantly different from premature foals or foals with septicemia.[197] Pathologic lesions of aborted fetuses or neonatal foals are similar and include severe pulmonary congestion, pneumonitis, bronchiolitis, hyaline membrane disease, and intralobular coagulative hepatocellular necrosis.[196,197] Intranuclear, acidophilic inclusions are present in hepatocytes and biliary epithelium. General supportive care and prophylactic administration of broad-spectrum antimicrobials are indicated. The prognosis is poor to grave. Most affected foals die within a few days of birth. Vaccination of pregnant mares is only partially efficacious for prevention.

Equine Infectious Anemia. The causative organism of equine infectious anemia is a retrovirus that has a tropism for mononuclear phagocytes.[198] Although cyclic fever, anemia, icterus, edema, and weight loss are the systemic manifestations of the disease, the Kupffer cells in the liver are a major site of infection. Icterus is due to increased erythrocyte destruction, as well as acute hepatic necrosis.

Equine Viral Arteritis. This disease is caused by a member of the Arteriviridae family and typically is manifest clinically by depression, fever, acute upper respiratory tract infection, abortion, petechiation, and edema. After ingestion or inhalation, viral septicemia leads to vascular damage. Overt clinical signs of hepatic disease are rare, but vascular damage in the liver may cause icterus.[199]

Giant Cell Hepatopathy. A disease similar to human neonatal hepatitis has been reported in aborted midterm fetuses.[200] Histologically, disorganization of hepatic cords, multifocal necrosis, a mild mononuclear cell infiltrate, and a large hepatocyte syncytium with 8 to 10 nuclei exist. The cause in horses and human beings is unknown but may be the result of viral or bacterial infections including leptospirosis.[200]

Parasitic Hepatitis

Parasitic infestation may cause focal hepatic disease but rarely overt hepatic insufficiency. After their ingestion, as embryonated eggs, larvae of *Parascaris equorum* hatch in the small intestine and then migrate through the liver and lungs. Focal or diffuse hepatic fibrosis may result.[113] Migration of *Strongylus edentatus* or *S. equinus* through the hepatic portal veins may cause focal hepatitis, subcapsular hemorrhage, and edema, followed by focal parenchymal fibrosis and capsular fibrin deposits.[113] Focal hepatic infarcts may occur secondary to thrombotic emboli because of migrating *S. vulgaris* in mesenteric arteries. *Heterobilharzia americana* causes a remarkable starry sky image of the liver on ultrasound examination, but horses have no signs of liver disease.[201] Protozoal schizonts consistent with a *Sarcocystis* spp. other than *S. neurona* were reported at necropsy in the liver of a horse with concurrent bacterial osteomyelitis, a plasma cell tumor of the maxilla, and hepatic salmonellosis.[202] The canine cestode, *Echinococcus granulosa,* may form hydatid (larval) cysts in the liver, which is usually an incidental finding.[203,204]

Fibrosing granulomas were found in the liver, intestinal and diaphragmatic serosae, and lung of several horses submitted for necropsy.[205] The granulomas consisted of dense fibrous tissue surrounding a necrotic, laminated, mineralized center. The periphery of the granuloma contained a small rim of inflammatory cells. The typical architecture of the granulomas, combined with the finding of a residual eggshell typical of *Schistosoma* (a trematode) in one horse, led to the conclusion that the granulomas were caused by chronic schistosomiasis. Although the granulomas were considered to be incidental findings of undetermined origin in most of the horses, they caused liver failure in one horse.

Toxic Hepatopathy

Numerous chemicals, drugs, mycotoxins, and plant toxins are hepatotoxic, but only occasionally do these cause hepatic failure in horses. Clinical signs and routine laboratory diagnostic tests will generally not distinguish among these toxins; thus diagnosis largely relies on exclusion of other causes, history of exposure, and, in some cases, documentation of the toxin in the blood or liver. Some substances cause fatty change, cloudy swelling, necrosis, mild inflammatory infiltration, and fibrosis, primarily in the centrilobular location where the oxygen tension is lowest. Other substances cause the same lesions

periportally, in the area of initial exposure. Some substances are directly hepatotoxic, whereas others require biotransformation by the liver to toxic metabolites.

Hepatotoxic Plants. Plants best known for causing hepatic disease in horses are those containing pyrrolizidine alkaloids. Although pyrrolizidine alkaloid toxicity can cause acute hepatic necrosis, it more often results in hepatic fibrosis (and is discussed as a separate entity under Chronic Hepatic Diseases later in this chapter). Other plants that have been reported to cause hepatic necrosis in horses in North America include kleingrass *(Panicum coloratum, P. dichotomiflorum, P. virgatum),* lantana, lechuguilla *(Agave lechuguilla),* alsike clover *(Trifolium hybridum),* whitebrush (*Lippia* spp.), sneezeweed (*Helenium* spp.), blue-green algae (*Microcystis* and *Nodularia* spp.), lupine (*Lupine* spp.), ryegrass, and some poisonous mushrooms (*Amanita* and *Galerina* spp.).[149]

Chemical Hepatotoxins. Horses are rarely exposed to hepatotoxic chemicals in sufficient amounts to induce hepatic failure. Potential hepatotoxic chemicals include arsenic (pesticide), carbon tetrachloride (fumigant), chlorinated hydrocarbons (insecticide), carbon disulfide (botacide), pentachlorophenols (wood preservative, herbicide, fungicide), phenol (disinfectant, wood preservative), phosphorus (fertilizer), polybrominated biphenyl (fire retardant), and paraquat (herbicide).[113] Phosphine gas, associated with feeding a pelleted ration treated with aluminum phosphide, has also caused hepatic failure in a group of horses.[206] All of the above cause centrilobular necrosis, except phosphorus, which causes primarily periportal changes.

Drugs. Pharmaceutical agents can have a wide range of effects on the liver depending on the drug type, dose, frequency, duration, and route of administration; age of the animal; diet; and concurrent treatment.[207] The hepatic damage may be acute or chronic, cholestatic, zonal, vascular, or hypersensitivity mediated. Certain drugs alter hepatocellular permeability without visible injury or loss of function.

Drugs that are intrinsically hepatotoxic reproducibly cause hepatocellular necrosis.[37,113] Examples of intrinsic hepatotoxic drugs that cause zonal centrilobular necrosis include carbon disulfide and carbon tetrachloride.[113] These drugs cause hepatocellular damage in a dose-related manner, and toxicity often results in hepatic failure. Anabolic steroids cause cholestasis with little or no evidence of hepatic damage or inflammation, resulting in mild icterus, which is completely and rapidly reversible once the drug is discontinued.[37,207] Phenothiazines and macrolide antibiotics on rare occasions cause cholestatic injury, which is accompanied by significant hepatocellular necrosis and periportal inflammation.[37] Imidocarb can cause severe hepatic disease in donkeys but does not appear to do so in horses.[208] Recovery is usually expected after discontinuation of the drug. Some drugs, such as tetracycline, cause fatty infiltration of the liver but rarely cause liver dysfunction.

Idiosyncratic hepatotoxicity has been reported after administration of erythromycin, rifampin, tetracycline, isoniazid, halothane, fluothane, phenothiazines, dantrolene, diazepam, sulfonamides, phenobarbital, phenytoin, and aspirin.[37,113,149] Injury varies from mild focal hepatitis to massive necrosis. A severe toxic hepatopathy has been described in nursing foals being treated for *Rhodococcus equi* with both rifampin and doxycycline.[209] Idiosyncratic hepatopathy has a low incidence, is not dose related, and often resolves on discontinuation of the drug. Rarely, progressive liver failure ensues. Some idiosyncratic drug hepatopathies may have a pathogenesis similar to drug allergy; others may be related to biotransformation properties of the liver. For example, if an individual has enhanced biotransformation of a certain drug and the metabolite of the drug is more cytotoxic than the original unaltered drug, hepatic damage may ensue.

Finally, some drugs induce increased hepatic enzyme activities or alter hepatocellular permeability but do not cause significant hepatic damage or clinical signs. Examples include benzimidazole anthelmintics, phenobarbital, phenylbutazone, and corticosteroids. Compared with humans and dogs, corticosteroids are apparently less likely to cause hepatopathy in horses; however, one report describes steroid hepatopathy in a horse that received an overdose of triamcinolone for treatment of pruritus.[210] Three weeks after the overdose, the horse developed muscle wasting, depression, polydipsia, and laminitis. Mature neutrophilia, lymphopenia, hyperglycemia, increased serum activities of AST and GGT, and multizonal hepatocellular vacuolation were reported.

Iron Toxicity. Acute, fatal toxic hepatopathy was reported in numerous newborn foals given an oral microbial inoculum.[211] The syndrome is reproducible if *ferrous fumarate* is given orally prior to administering colostrum.[211] The incidence of hepatic failure was highest when the foals were given the inoculum before nursing. Colostrum contains abundant vitamin E and essential cofactors for glutathione. Glutathione protects against free radical damage, a proposed mechanism for iron toxicity. Thus foals that are given iron supplements before ingesting colostrum presumably are most susceptible to iron toxicity.[211] This is exacerbated by high serum iron concentrations and high percent saturation of transferrin in foals during the first 24 hours of life. Supplementation of iron during this time period results in excessive free iron and increased risk of fatal hepatotoxicity.

Clinical signs include HE, icterus, and peracute death. Laboratory abnormalities include increased blood levels of bilirubin, SDH, GGT, and ammonia; reduced BCAA-to-AAA ratio; hypoglycemia; and prolonged PT.[211] At necropsy the liver was abnormally small; histologic study revealed massive hepatic necrosis with blood-filled reticula. Some livers had mild biliary hyperplasia and periportal fibrosis. Two interesting findings from the unfortunate outbreak were that periportal fibrosis and presence of Alzheimer type 2 cells in the brain could both occur within 48 hours of toxin administration.[212] Supportive therapy may prolong life, but most foals with iron hepatotoxicosis and clinical signs die. Another less well-understood hepatic failure possibly associated with iron overload has occurred in foals with neonatal isoerythrolysis that required one or more blood transfusions.[213] Affected foals may have progressive liver disease (rising liver enzymes) within days after they receive one or more transfusions, and these foals may exhibit liver failure as soon as 5 days following transfusion or up to 3 months later. Histologic lesions in the liver consist of hepatocellular necrosis with extensive biliary proliferation. An experiment to reproduce the disease by giving young healthy foals multiple blood transfusions was unsuccessful, suggesting that a combination of hypoxia from neonatal isoerythrolysis and iron from the transfused red blood cells may be responsible for the hepatic disease.[214]

Adult horses appear to be less susceptible to iron toxicity than many other species. In one study ponies fed 50 mg/kg of ferrous sulfate for 8 weeks (National Research Council requirement is 1–2 mg/kg body weight) had no clinical signs or

histopathologic lesions in the liver although hepatic iron, serum iron, and percent saturation of transferrin increased.[215] However, rare cases of hemochromatosis have been reported.[216,217] Hemochromatosis is characterized by tissue damage and dysfunction caused by deposition of hemosiderin in parenchymal cells.[216] Hemochromatosis was diagnosed in three adult horses by histopathology and use of Prussian blue stain, which detects iron deposition (hemosiderin pigment).[216] Excessive dietary iron was not apparent. All three of the horses had signs and laboratory evidence of liver disease. Serum iron concentration was normal, and there was no evidence of saturation of the iron transport system in the serum. Hemochromatosis was accompanied by bile duct hyperplasia and hepatic fibrosis. All three horses died or were euthanized because of deterioration. Hemochromatosis was diagnosed in a pony receiving approximately 4 times the daily recommended amount of iron.[217] The diagnosis was confirmed by histopathology (severe periportal fibrosis, hemosiderosis, biliary hyperplasia) and increased serum and liver concentrations of iron. *Hemosiderosis* is the term used to describe iron deposits in Kupffer cells and hepatocytes without destruction of liver parenchyma and is a common finding during histologic examination of the normal equine liver, much of which is due to phagocytosis of heme from broken-down red blood cells. Both processes are more commonly seen around the periportal region of the liver.[26]

Mycotoxins. Feeding horses grains that are sufficiently contaminated with *Fusarium* causes the classic disease leukoencephalomalacia. The mycotoxin can also cause a concurrent hepatopathy with marked elevations in AST, GGT, and bilirubin. Lesions in the liver include hepatocyte vacuolation with centrilobular fatty change, hepatocyte necrosis, mild mononuclear infiltrate, mild bile duct proliferation, and periportal fibrosis.[218,219] Unlike in swine and some other species, liver failure caused by aflatoxins in horses is rare. It has been reported that the difference in aflatoxin toxicity in the horse could be related to differences in some of the hepatic P450 activity detoxifying aflatoxin.[220] This finding suggested that horses have microsomal-associated glutathione *S*-transferase with the capacity to collapse GSH-conjugation of reactive and toxic aflatoxin B_1, B_8, B_9 epoxide.

Experimental administration of aflatoxin B_1 to ponies has produced variable responses, from no or minimal disease (elevated liver enzymes but no clinical signs), to severe illness and death.[221-223] Prior exposure to the mycotoxin AFB_1, which affects hepatic metabolism on subsequent exposure, and duration of exposure before studies may explain the different results.[224] The target organ in horses, as in other animal species, is the liver, and horses suffering from aflatoxicosis show signs of inappetence, depression, fever, tremor, ataxia, and cough. Necropsy findings include a yellow-brown liver with centrilobular necrosis, icterus, hemorrhage, tracheal exudates, and brown urine.[222]

Acute Biliary Obstruction

Acute obstruction of the common bile duct causes icterus and signs of abdominal pain. Acute biliary occlusion may occur secondary to cholelithiasis (see Cholelithiasis) or colon displacement. Intense icterus, colic, and increased levels of direct bilirubin (greater than 85.5 µmol/L or greater than 5 mg/dL), GGT (greater than 400 U/L), and bile acids (greater than 150 µmol/L) were reported in two horses with acute colon displacements.[225] These abnormalities quickly abated after surgical correction of the displaced colon. In a comparative study of cases of colon displacement, 49% of horses with a right dorsal colon displacement had increased GGT, compared with 2% of horses with a left dorsal displacement.[114] Torsion of the left lobe of the liver was the cause of acute colic, hepatic congestion, necrosis, and focal hepatitis in a 14-year-old Arabian gelding.[226] Resection of the affected lobe resulted in complete recovery. Additional mechanical causes of biliary obstruction include hepatic neoplasia, pancreatitis, and duodenal ulcerations in foals that occur either at or just caudal to the opening of the bile duct.[116]

Hyperlipemia and Hepatic Lipidosis

Hyperlipemia, a syndrome defined as a serum triglyceride concentration in excess of 500 mg/dL with grossly discolored plasma or serum (lipemia), occurs primarily in ponies and Miniature Horses and donkeys and may lead to fatty infiltration of the liver, often accompanied by clinical signs of liver disease and a guarded prognosis.[227] *Hyperlipidemia* refers to an increase in serum triglyceride concentration (generally less than 500 mg/dL) without grossly lactescent blood or fatty infiltration of the liver. Obesity, stress, inability to satisfy metabolic energy demands, and hormonal imbalance are the major precipitating factors for hyperlipemia.[227-233]

Epidemiology and Clinical Signs. Ponies (especially Shetland Ponies and mare ponies), Miniature Horses, and donkeys (especially miniature or aged) are most susceptible to hyperlipemia. Rarely, other breeds, such as the Quarter Horse, Paso Fino, and Tennessee Walking Horse, may be affected as are a low percentage of horses with Cushing's disease. Affected ponies are usually obese, have a recent history of stress or weight loss, and are in late gestation or early lactation during the winter months.[88] Females are most commonly affected because late pregnancy and lactation appear to be significant risk factors for the disease. The disorder appears to be common in older donkeys, which could be a reflection of concurrent Cushing's disease or dental problems in those animals.[234] In Miniature Horses and donkeys, hyperlipemia can occur at any age and frequently develops as a sequela to an underlying primary illness lasting several days. The most commonly reported primary diseases predisposing Miniature Horses to hyperlipemia are enterocolitis, endotoxemia, parasitism, pituitary dysfunction, azotemia, and neonatal septicemia.[232,233] The onset of clinical signs of hyperlipemia is often acute and includes icterus, anorexia, weakness, severe depression, ataxia, muscular weakness, recumbency, diarrhea, mild colic, fever, and dependent edema.[88,228-230] In severe cases, clinical signs of hepatic failure may prevail (see Clinical Signs of Hepatic Insufficiency earlier in this chapter). Sudden death because of hepatic rupture may occur.[229] Signs of predisposing primary disease in Miniature Horses may overshadow signs of hyperlipemia.

Pathogenesis. The liver serves a unique role in energy homeostasis (see Physiology), especially in large animals in which volatile fatty acids, and not glucose, are a major energy source. Glucose is primarily manufactured in the liver from fatty acids and amino acids and is stored as glycogen for future use. If intake is decreased or energy demands are increased, glycogen stores become depleted and the major source of energy is provided by fatty acid oxidation. Obesity sets the stage for hyperlipemia by providing excessive adipose tissue stores of fatty acids, available for immediate and rapid

mobilization. Fatty acid mobilization is usually first triggered by a stress or inability to maintain energy homeostasis. Concurrent or underlying primary diseases such as enterocolitis, azotemia, infection, parasitism, or neoplasia, as well as any stressful event, such as transport or weaning, may precipitate fatty acid mobilization. Stress increases the release of catecholamines and glucocorticoids, which stimulate fatty acid release from the adipose tissue. A negative energy balance, as may occur during late gestation, early lactation, starvation, or secondary to anorexia induced by some other primary disease, exacerbates hyperlipemia by further promoting fatty acid mobilization.

After lipolysis of adipose tissue triglyceride occurs, free fatty acids, nonesterified fatty acids, and glycerol are released into the blood. Glyceride, fatty acids bound to albumin, and nonesterified fatty acids are carried to the liver, where the glyceride is converted to glucose. In the liver, free fatty acids may be oxidized to acetyl CoA and used in the tricarboxylic acid cycle for ATP production, resynthesized to triglycerides and stored in the liver, or used to make triglycerides that are released into the sinusoidal blood as VLDLs (see Fig. 13.3). Ponies with hyperlipemia have larger-diameter VLDLs containing greater concentrations of triglycerides than normal ponies.[235,236] Thus hyperlipemia in ponies and Miniature Horses is the result of efficient and excessive hepatic synthesis of triglycerides from mobilized free fatty acids, with subsequent secretion of triglyceride-laden VLDL into the blood. Endothelial lipoprotein lipase is the rate-limiting enzyme responsible for the removal of VLDL from the blood back into adipose tissue. In hyperlipemic ponies, the activity of lipoprotein lipase is not impaired and in fact is increased several fold.[235] Thus it is the overproduction of VLDL by the liver, not impairment of their removal, which is primarily responsible for hyperlipidemia in ponies.[235,236]

If the oxaloacetate supply is limited when free fatty acids are mobilized to the liver, acetyl CoA is shuttled away from the tricarboxylic acid cycle and used to make ketone bodies. Because the equine liver is quite efficient in synthesizing triglycerides, ketosis is less common than in other species.[231] However, if fatty acid mobilization and synthesis of triglycerides exceed oxidation and VLDL secretion, hepatic lipidosis ensues. Fat infiltration disrupts hepatic function, and excessive amounts of fat in the liver can result in hepatic failure and even hepatic rupture.[229]

Hormonal factors may contribute to the development of hyperlipemia and hepatic lipidosis. Insulin normally impedes the development of hyperlipemia by inhibiting tissue hormone-sensitive lipase, the enzyme responsible for lipolysis of adipose tissue. Insulin also curtails the development of hyperlipemia by stimulating gluconeogenesis in the liver and by activating lipoprotein lipase, the enzyme responsible for uptake of VLDL by adipose tissue. Despite often normal insulin levels, ponies appear to have tissue insulin insensitivity compared with horses.[229] Fasting in donkeys has been shown to cause a reduction in tissue sensitivity to insulin.[237] Glucocorticoids, catecholamines, adrenocorticotropic hormone, thyroid-stimulating hormone, growth hormone, antidiuretic hormone, and progesterone may contribute to the development of hyperlipemia by opposing the biologic actions of insulin (see Fig. 13.3). This may account for the high incidence of hyperlipemia during periods of increased cortisol levels (stress, pituitary adenoma, late pregnancy) and increased progesterone (pregnancy). In ponies, norepinephrine linearly stimulates the release of free fatty acids from adipose tissue, an effect that does not occur in horses.[238] Considering the unique effects of insulin and catecholamines on fat metabolism in ponies, it is not surprising that ponies are more susceptible than horses to the development of hyperlipemia.

Vascular thrombosis can occur secondary to hyperlipemia and fat embolism and may be seen in the lung, kidney, brain, and subcutaneous vessels. Subcutaneous thrombosis causes dependent edema. Renal nephrosis and necrotizing pancreatitis are sometimes present.[88,229] Renal disease most likely is a sequela of occlusive thrombosis. The exact cause of pancreatitis is not known; however, hyperlipemia precedes pancreatitis in the equine hyperlipemia–hepatic lipidosis syndrome. Researchers speculate that excessive lipid is deposited in and around the pancreas, which is subsequently hydrolyzed by pancreatic lipase and released as free fatty acids. Free (unbound to albumin) fatty acids are cytotoxic; when the albumin-binding capacity is exceeded, pancreatic vascular injury occurs.[239]

Azotemia inhibits lipid removal from the blood by inhibiting lipoprotein lipase. The degree of hyperlipidemia is directly correlated with the degree of azotemia.[122] Almost half of hyperlipemic Miniature Horses are azotemic.[232,233] Compared with ponies and Miniature Horses, hyperlipemia rarely develops in horses except in horses with Cushing's disease, and in those horses, hyperlipemia does not cause the fulminant hepatic lipidosis seen in ponies, miniature equines, and donkeys.[240] Marked increases in serum triglycerides without hyperlipemia may occur in horses that are anorexic, especially horses with critical illnesses.[227]

Mild increases in triglycerides (less than 500 mg/dL) may develop during azotemia.[122,230] Mild hepatic lipidosis may ensue in these cases, but hyperlipemia does not occur, and the hyperlipidemia rarely results in clinically recognizable disease.

Diagnosis. Hyperlipemia should be considered in the differential diagnosis for any obese pony, donkey, or Miniature Horse with clinical signs of severe depression, anorexia, ataxia, and icterus. The normal triglyceride level in horses and ponies should be less than 85 mg/dL but may be up to 290 mg/dL in some clinically healthy donkeys and up to 250 mg/dL in some clinically healthy pregnant pony mares.[236] In hyperlipemia, the blood grossly appears opalescent (Fig. 13.8) and the concentrations of all lipids are increased, especially triglycerides (greater than 500 mg/dL), nonesterified fatty acids, and VLDLs. Laboratory evidence of hepatic disease may include increased serum activity of SDH and GGT; increased concentrations of serum bile acids, bilirubin, and ammonia; and decreased glucose, BUN, and albumin.[228] In hyperlipemic Miniature Horses, only about half of affected patients have significant hepatic impairment.[232] The BSP half-life is prolonged. Oral and intravenous glucose challenge tests may reveal glucose intolerance because of insulin insensitivity. Metabolic acidosis is frequent, and ketoacidosis should be suspected if the anion gap is increased. Lipemia may increase serum creatinine values falsely and interfere with accurate determination of other serum chemistries. A definitive diagnosis of hepatic lipidosis is confirmed by the concurrent demonstration of increased blood concentrations of lipid, laboratory evidence of hepatic dysfunction, and ultrasonographic or histopathologic findings of fatty infiltration in the liver (Fig. 13.9). The serum concentrations of creatinine and electrolytes should be determined as an adjunct

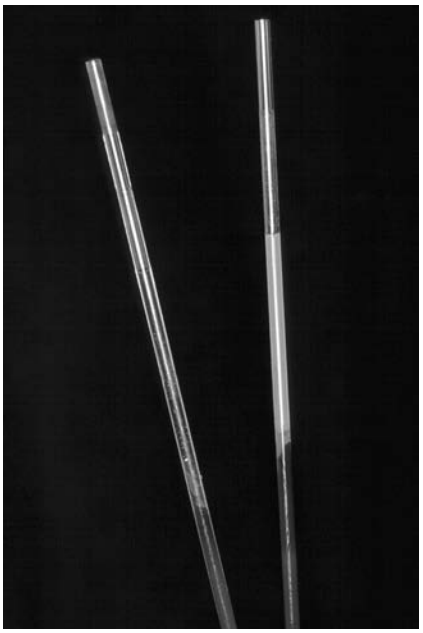

FIG. **13.8** Hyperlipemia. The spin hematocrit tube on the right is from a Miniature Horse with hyperlipemia. The hematocrit tube on the left is from an unaffected horse.

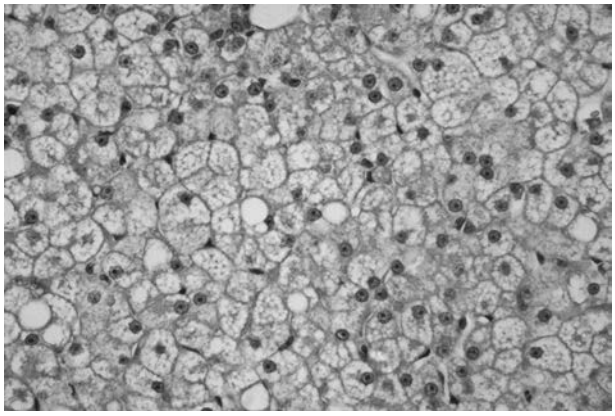

FIG. **13.9** Histopathology of the liver: fatty liver.

to therapy. Because of the incidence of hyperlipemia in ill Miniature Horses and donkeys, monitoring blood triglyceride levels would facilitate early recognition of hyperlipidemia in these patients.

Necropsy findings in affected ponies include widespread fatty change in the liver, skeletal muscle, kidney, adrenal cortex, and myocardium.[88,229] The liver and kidney are enlarged, yellow, friable, and greasy. One report has suggested that one of every five ponies with hepatic lipidosis has a ruptured liver.[229] Microscopically, hepatocytes are engorged with lipid. The nucleus is often displaced, and hepatocellular necrosis may ensue.

Treatment. The major therapeutic objectives for hyperlipemia and hepatic lipidosis include the following:

1. Treatment of hepatic failure, including hepatic encephalopathy
2. Improvement of energy intake and balance
3. Elimination of stress or treatment of concurrent disease
4. Inhibition of fat mobilization from adipose tissue
5. Increased triglyceride uptake by peripheral tissues

Treatment of hepatic failure is addressed elsewhere (see Treatment of Hepatic Insufficiency earlier in this chapter). Concentrated carbohydrate feed, such as molasses-coated grain and high-quality pasture or hay, should be encouraged. Anorectic ponies should receive 5% dextrose as a continuous infusion at a rate of 2 mL/kg per hour, and enteral nutrition should be attempted. NutriFoal, NutriPrime (KenVet, Ashland, OH), and Osmolyte HN (Ross Laboratory, Columbus, OH) have successfully been used as sources of enteral nutrition in hyperlipemic Miniature Horses.[232] Fat-free diet formulas have been proven successful when given via nasogastric tube in treating ponies with hyperlipemia.[241] These generally include glucose as the carbohydrate supply and are mixed with casein and alfalfa meal as a protein source; the combination of carbohydrate and protein intake is likely ideal. When commercially available enteral nutrition products are used, a low-fat or medium-chain triglyceride fat supplement is preferred for forced enteral feeding.[232]

If enteral nutrition is not possible, partial parenteral nutrition should be provided with equal volumes of 50% dextrose and 8.5% amino acids.[232,242] Monitoring blood glucose concentrations closely is mandatory, because some ponies have glucose intolerance (and excessive glucose will worsen acidosis and induce hypokalemia). The weaning of suckling foals may help reduce stress and the energy demand imposed on lactating mares. Concurrent diseases amenable to therapy, such as parasitism, chronic infection, and musculoskeletal disease, should be appropriately treated with anthelmintics, antimicrobials and antiinflammatory agents, or analgesics, respectively.

In addition to supplying immediate energy, glucose therapy stimulates the release of insulin. Concurrent carbohydrate and insulin administration has been used successfully to manage hyperlipemia in ponies.[228,243] The following regimen has been suggested for a 200-kg pony.[243] On day 1 the patient is administered 30 IU of protamine zinc insulin intramuscularly and 100 g of glucose orally (both twice daily). On day 2 the patient is administered 15 IU of insulin intramuscularly, twice daily, and 100 g of galactose once. Galactose is slowly converted to glucose; thus lactic acid production is minimized. This regimen may be continued for 3 days. Other insulin dose regimens are also reported.[227] Blood glucose and insulin concentrations should be closely monitored. Insulin treatment may not lower triglyceride levels, but it may help control hyperglycemia if partial parenteral nutrition is provided.[232] Nicotinic acid, thought to act by inhibiting hormone-sensitive lipase, has been used in cattle with fatty liver; however, nicotinic acid has not been evaluated in ponies with hepatic lipidosis.

Heparin potentiates the activity of lipoprotein lipase and may increase triglyceride removal from the blood. However, because lipoprotein lipase activity is already at maximum rate in affected ponies, whether or not heparin provides additional benefit is questionable.[236] Recommended dosages range between 40 and 250 IU/kg twice daily.[228,243] Because of the potential for hemorrhage, heparin therapy should be used with discretion and monitored by daily hemostatic testing. If azotemia, acidosis, and electrolyte abnormalities are present, appropriate fluid therapy is suggested.

Lipotropic agents such as choline and methionine are unlikely to be useful in horses with hyperlipemia, because triglyceride synthesis and release in the liver is usually sufficient.

Prognosis and Client Education. The prognosis for hyperlipemia in equids is reported to be poor but the prognosis is

TABLE **13.4 Pyrrolizidine Alkaloid–Containing Plants**

Species Name	Common Name	Alkaloids
Senecio jacobea	Tansy or common ragwort, stinking Willie	Jacobine, jacodine, senecionine
Senecio riddellii	Reddell's groundsel	Ridelline
Senecio longilobus	Threadleaf groundsel	Longilobine
Senecio vulgaris	Common groundsel	Senecionine, seneciphylline, retrorsine
Senecio spartioides	Broom groundsel	Seneciphylline
Senecio integerrimus	Lamb's tongue groundsel	Intergerrimine
Amsinckia intermedia	Fiddleneck, fireweed, tarweed	
Crotalaria species	Rattlebox	Monocrotaline, fulvine, crispatine
Echium plantagineum	Viper's bugloss	
Heliotropium europaeum	Common heliotrope or potato weed	Heliotrine, lasiocarpine

variable, depending on the successful and prompt correction of the predisposing cause(s) and on the ability to supply adequate nutritional support (enteral or parenteral or both). Mortality has been estimated in some studies to occur in 60% to 100% of affected ponies.[228,229] Survival rate is reportedly better in Miniature Horses, and death often results from the underlying disease and not fatty liver failure.[232,233] Most Miniature Horses with blood triglyceride levels less than 1200 mg/dL survive.[233] Prognosis should not be based upon the level of triglyceride in the serum or on liver enzyme elevations.[116]

The prevention of hepatic lipidosis revolves around identifying "at risk" equines, especially pregnant or lactating pony mares, obese or geriatric ponies and donkeys, and Miniature Horses with diarrhea and other predisposing disorders. Donkeys that have any change in their social status, such as loss of a companion, should be considered at high risk for disease. Providing adequate caloric intake is important in late pregnant and early lactation mares.[242] As a preventive, fat could be fed to increase caloric density, and feeding fat to healthy ponies increases lipoprotein lipase and decreases circulating triglycerides.[244] This would not be recommended in "at risk" equines that already have hyperlipidemia. Performing routine body condition scoring and periodic sampling of "at risk" equines for triglycerides and free fatty acids could be helpful in identifying metabolic abnormalities before the onset of clinical signs. Proper maintenance health care and husbandry are of utmost importance in "at risk" equines. Testing for Cushing's disease and dental examinations should be instituted in all older "at risk" animals.[116]

Chronic Hepatic Diseases

The distinction between acute and chronic hepatic disease is difficult. Often horses with chronic liver disease display abrupt onset of signs. With the possible exception of hyperglobulinemia, no serum biochemical parameters reliably distinguish acute from chronic hepatocellular disease. Regardless of the cause or site of injury, histopathologic evidence of fibrosis develops after chronic injury.[245] The following diseases are classified as chronic based on the presence of fibrosis in the liver or because the cause is known to result in gradual hepatic dysfunction.

Chronic Megalocytic Hepatopathy

Megalocytic hepatopathy occurs worldwide and is the most common cause of chronic liver failure in horses in certain parts of the United States.[32] It is caused by the ingestion of *pyrrolizidine alkaloid*–containing plants. The intoxication typically results in the delayed onset of chronic, progressive liver failure.

FIG. **13.10** Picture of *Crotalaria* spp. plant containing toxic pyrrolizidine alkaloids. (Courtesy Susan White.)

Clinical Signs. The development of clinical signs of liver disease is usually delayed 4 weeks to 12 months after the consumption of pyrrolizidine alkaloid–containing plants. However, individual differences in susceptibility occur (not all horses consuming the plants develop clinical signs).[246,247] The onset of obvious hepatic failure, characterized by HE and photosensitization, usually is abrupt and occurs late in the disease despite the time interval since ingestion. Premonitory signs of insidious onset may include anorexia, weight loss, exercise intolerance, and mild to moderate icterus. Diarrhea, edema, polydipsia, pruritus, laryngeal hemiparalysis, and hemolysis also have been reported to occur late in the disease.[93,113,246] Sometimes oral ulcers and halitosis develop.[248] Although uncommon, if sufficient consumption occurs during a single exposure, abortion or clinical signs of liver disease may develop acutely.

Epidemiology and Pathogenesis. Numerous species of pyrrolizidine alkaloid–containing plants exist (Table 13.4). In the United States, *Senecio jacobea* and *S. vulgaris* are found primarily along the Pacific Coast and in the western states, *Amsinckia intermedia* in the West, and *Crotalaria sagittalis* (Fig. 13.10), *C. spectabilis,* and *Heliotropium europaeum* primarily in the Southeast.

Pyrrolizidine alkaloid–containing plants are not palatable, and horses will not typically consume them unless pastures are heavily contaminated or no alternative feed source exits.[247] Some herbicides may increase palatability.[113] Pyrrolizidine

alkaloids are stable, and most intoxication occurs after ingestion of contaminated hay, pellets, or grain. *S. vulgaris* is a common contaminant in alfalfa hay, especially at the first cutting. Not all parts of the plant contain pyrrolizidine alkaloids, and the concentration may vary with the season.[249] *Amsinckia* and *Crotalaria* spp. concentrate pyrrolizidine alkaloids in their seeds; thus intoxication may occur after ingestion of contaminated oat hay or grain screenings.[249]

Horses and cattle are relatively sensitive to pyrrolizidine alkaloid intoxication compared with goats and sheep. Consumption of the plants at a dose of 2% to 5% of the body weight, fed at one time or over a few days, can result in acute toxicity.[113] The effects of pyrrolizidine alkaloids are cumulative; thus it is more common for toxicity to occur after chronic low-level exposure. Hundreds of different pyrrolizidine alkaloids exist, but only a few have proved to be toxic (see Table 13.4). The toxic pyrrolizidine alkaloids vary among plants, but they all cause the same basic lesion. Ingested pyrrolizidine alkaloids are carried to the liver via the portal circulation and are metabolized by the microsomal enzymes in zone 3 to toxic pyrrole derivatives.[248] Drugs that induce microsomal enzymes, such as mixed function oxidases, will increase the toxicity of pyrrolizidine alkaloids. The pyrroles are chemically highly reactive and capable of alkylating nucleic acids and protein; consequently the pyrroles inhibit cellular replication and protein synthesis. Because the cells cannot divide, hepatocytes enlarge, forming *megalocytes.* When the megalocytes die, fibrosis ensues. When fibrosis becomes extensive, the liver shrinks, develops a firm texture, and failure is inevitable.

Histopathologic lesions include hepatic hemorrhage and necrosis, periportal megalocytosis, portal fibrosis, bile duct hyperplasia, and multinucleate hepatocytes. When acute massive consumption exists, extensive centrilobular hepatocellular necrosis occurs, and lesions may look similar to those found in Theiler's disease. Megalocytes may not be seen in the liver on microscopic examination until 30 days or more after exposure to the pyrrolizidine alkaloid.[250]

Fibrosis around the portal vessels can cause portal hypertension, ascites, and diarrhea. Endothelial cell swelling in the portal vein is especially common with *Crotalaria* spp., further promoting veno-occlusion. Despite periportal fibrosis and veno-occlusion, portal hypertension rarely develops in horses, although it is a common manifestation of pyrrolizidine alkaloid toxicity in cattle.[113] Additional pathologic findings include myocardial necrosis, colitis, widespread hemorrhages, and adrenal cortical hypertrophy.[93] The toxic pyrrolizidine alkaloid in *Crotalaria* spp., monocrotaline, also is pneumonotoxic and may cause hydrothorax, pulmonary edema, epithelialization, and pulmonary arteritis.[248]

Pyrrolizidine alkaloids are rapidly excreted in body fluids such as milk and urine, and they can pass the placenta.[248] A report describes pyrrolizidine alkaloid toxicosis in a 2-month-old foal with a dam that consumed pyrrolizidine alkaloid–containing plants during pregnancy.[251]

Diagnosis. A presumptive diagnosis of megalocytic hepatopathy can be made from history of exposure to pyrrolizidine alkaloids, clinical signs, and laboratory evidence of hepatic disease. Early in the disease, SDH and AST may be increased, but by the time clinical signs develop, these enzymes are often normal or only mildly increased. Because fibrosis occurs periportally, GGT, ALP, and serum bile acid concentration are persistently increased. Bilirubin may be increased and the BCAA-to-AAA ratio may be decreased.[252] The BSP half-life is prolonged, and serum bile acids are usually increased late in the disease.[93]

A definitive diagnosis of pyrrolizidine alkaloid intoxication requires a liver biopsy. The histopathologic findings of megalocytosis, biliary hyperplasia, and fibrosis are highly suggestive of the disease; megalocytosis may rarely be seen with other causes of liver disease. Pyrrolizidine alkalosis must be distinguished from aflatoxicosis and alsike clover toxicity. The latter two toxicities are less common worldwide compared with pyrrolizidine alkaloids and cause periportal fibrosis and biliary epithelial hyperplasia, but generally without megalocytosis. Pyrrolizidine alkaloids can be detected in feed by high-performance liquid chromatography.[250] Some pyrrolizidine alkaloids can be identified in liver tissue. Unfortunately, because of the prolonged delay in development of clinical signs, often the original source of contamination remains unidentified.

Treatment and Prognosis. No specific antidote for pyrrolizidine alkaloid intoxication exists. Despite general supportive care, death often occurs within 10 days of the onset of obvious clinical signs of hepatic failure. A serum bile acid concentration greater than 50 μmol/L is suggestive of a poor prognosis.[93] A small number of horses with signs of liver failure and elevated bile acids may survive for many months or even years.[253] Because regeneration is not possible, if extensive megalocytosis and fibrosis are present, treatment is not warranted. Treatment with BCAA may decrease the severity of neurologic signs but does not prevent death.[93] If clinical signs or histologic changes are mild, a moderate-protein, high-energy (molasses concentrate grain) ration may be beneficial.

Attention should be directed toward asymptomatic horses that also may have consumed the plants. The source of contamination should be identified by locating the plant in hayfields or pasture or by analysis of feed. Progress can be monitored by serial liver enzyme quantitation and biopsies. Serum GGT activity may be helpful in detecting subclinical cases of pyrrolizidine alkaloid toxicity.[254]

Clover Poisoning

Alsike clover *(Trifolium hybridum)* and red clover *(Trifolium pratense)* poisoning rarely occurs in horses pastured or fed hay containing these types of clovers.[255-257] The toxic principle in alsike clover has yet to be identified. It is not known whether the agent is a toxic metabolite from the plant itself or a mycotoxin produced by a fungus *(Cymodothea trifolii)* living on the plant.[258] Both photodermatitis and liver disease have been reported. Signs of liver disease may become apparent after 2 weeks of consumption and when the diet consists of at least 20% of clover.[255] The likelihood of poisoning reportedly is greater when the pasture is heavily covered with the clover in full bloom during wet seasons. The disease is characterized histopathologically by the presence of biliary hyperplasia and periportal fibrosis without severe bile obstruction. The liver of horses that die from the disease may be noticeably enlarged with rounded edges, sometimes weighing 5% of body weight or 25 kg in a 500-kg horse. Other cases may have normal or even smaller than normal livers if there is extensive fibrosis.[256] Minimal parenchymal lesions distinguish alsike clover poisoning from pyrrolizidine alkaloid toxicity.

Chronic Active Hepatitis

Chronic active hepatitis in horses is an idiopathic, chronic, progressive hepatopathy characterized histopathologically by biliary hyperplasia, with concomitant periportal or biliary inflammation (or both) and associated hepatocellular damage.

Clinical Signs. The onset of clinical signs of CAH is insidious. Signs are compatible with progressive liver failure and include depression, exercise intolerance, weight loss, anorexia, colic, icterus, and in many cases fever. The signs may be intermittent. Although uncommon, some horses with CAH have moist exfoliative coronary dermatitis.[89]

Cause and Pathogenesis. The exact cause of CAH in horses is not known. A similar syndrome occurs in human beings and has been linked to autoimmune disease, chronic hepatitis B virus infection, non-A and non-B (viral) hepatitis, Wilson's disease, α_1-antitrypsin deficiency, and drug allergy.[259] Human beings with autoimmune-associated CAH often have marked polyclonal gammopathy and hepatic actin, smooth muscle, and antinuclear antibodies.[259] Histologic study of the liver reveals mononuclear and plasma cell infiltrates, large areas of necrosis, and fibrosis. Extrahepatic signs of autoimmune disease, including dermatitis, arthritis, and glomerulonephritis, may be present. Some horses with CAH have polyclonal gammopathy, but this is a nonspecific finding in many types of chronic hepatic diseases and is not necessarily indicative of autoimmunity.[101] Occasionally, horses with CAH have predominantly plasma and mononuclear cell infiltrates in the liver, suggesting heightened humoral activity. The presence of coronary dermatitis in horses with CAH may be a manifestation of autoimmune disease, although this has not been confirmed by immunohistologic staining. No reports have surfaced of antinuclear antibodies in horses with CAH. In addition, Wilson's disease and α_1-antitrypsin deficiency have not been documented in these animals. Idiosyncratic drug hypersensitivity has been reported in horses although not as a consistent feature of CAH.

In addition to the possibility of an autoimmune, chronic viral or hypersensitivity reaction, CAH in horses may be a manifestation of chronic cholangitis. Many horses with CAH have a suppurative inflammatory response involving the biliary system, in addition to periportal inflammation and hepatocellular necrosis.[89] Often the cholangiohepatitis is accompanied by biliary hyperplasia, fibrosis, and cholestasis. In some cases, coliform organisms have been isolated from the liver, suggestive of ascending infection from the gastrointestinal tract. In a large number of horses, histopathologic evidence of fibrosis, acute inflammation, and hepatocellular necrosis is seen, but no specific cause can be determined.

Diagnosis. The diagnostic criteria for CAH in human beings include abnormally increased serum transaminase activity for longer than 6 months, abnormal immunologic findings, and characteristic histopathologic findings.[259] In horses, serum SDH and AST activity may be mildly increased, but GGT and ALP are often markedly increased in CAH. The serum bile acid, total protein, and bilirubin (especially the direct-reacting fraction) concentrations may be increased. Bilirubinuria may be present, and the BSP half-life is usually prolonged. Hematology may reveal an inflammatory leukogram, with or without a left shift.[89] Immunodiagnostics, including antinuclear antibody titer and anti-immunoglobulin immunofluorescent staining of skin lesions, may help confirm an autoimmune phenomenon.

In the face of clinical signs and the demonstration of significant laboratory findings indicative of liver disease, a liver biopsy should be obtained (see Liver Biopsy). A sample should be submitted for histopathologic examination and for bacterial isolation and antimicrobial sensitivity testing. The definitive diagnosis of CAH depends on the presence of characteristic histopathologic findings. Progressive periportal hepatocellular necrosis obscures and distorts the limiting plate, the cord of hepatocytes that surrounds the portal triad. As this destructive process continues, bands of necrotic hepatocytes and inflammatory cells connect one liver lobule to another or extend from the portal tract to the central vein. This feature is called *bridging necrosis.* As bridging necrosis progresses, fibrosis and cirrhosis prevail. Mononuclear cells may be the predominant inflammatory infiltrate; however, neutrophils predominate if cholangiohepatitis is a feature. Biliary hyperplasia may be evidence of concurrent cholangiohepatitis.

Treatment. General supportive care for hepatic failure (see Treatment of Hepatic Insufficiency earlier in this chapter) is indicated whenever clinical signs are apparent. Specific therapy for CAH depends on the histopathologic findings. If the liver biopsy reveals abundant plasma cells, or other diagnostic tests suggest autoimmune or hypersensitivity disease, corticosteroid therapy may be beneficial. In human beings with autoimmune-associated CAH, corticosteroids improve appetite and attitude, reduce inflammation and serum transaminase activity, and hinder fibrosis. Despite short-term improvement, corticosteroids do not alter survival time, and the long-term prognosis remains poor. In horses, initial treatment with dexamethasone at 0.05 to 0.1 mg/kg/day for 4 to 7 days, followed by a gradual reduction in dose over 2 to 3 weeks, has been suggested.[116] Additional treatment with prednisolone (1 mg/kg/day) may be necessary for several weeks. In human beings, azathioprine (2 mg/kg every 24 hours) has also been used to control cases refractory to steroids,[259] although recent studies suggest that oral bioavailability of this drug in the horse is quite low, ranging from 1% to 7%.[260] If the liver biopsy reveals cholangitis, long-term (4–6 weeks) antimicrobial therapy is indicated. The choice of antimicrobial is best determined by culture and sensitivity results. Antimicrobials that are excreted in bile, such as chloramphenicol, ceftiofur, ampicillin, or broad-spectrum antimicrobials such as penicillin and gentamicin, are recommended. The decision for corticosteroid therapy should be carefully scrutinized in these cases of CAH.

Prognosis. The prognosis for CAH is variable, depending on the cause and duration of disease. The presence of cirrhosis warrants a grave prognosis.

Cholelithiasis

Bacterial cholangiohepatitis (CH) and cholelithiasis (CL) are two of the most frequent causes of obstructive hepatic disease in horses. Inflammation of the biliary tract is called *cholangitis* but in adult horses with clinical disease there is usually a concurrent inflammation of hepatocytes, hence the term *cholangiohepatitis.* CH may be an acute or chronic disease; when choleliths are present it is most likely a chronic disease, but acute onset of clinical signs is common. Studies have identified CH and CL as diseases of middle-aged to older horses with no obvious sex or breed predilection.[81,191,261,262] It should be noted that in human medicine, the term *cholelithiasis* refers to gallstones and *choledocholithiasis* refers to stones in the common bile duct. In the horse cholelithiasis has been commonly used to describe stones in any portion of the biliary system. Some publications may classify biliary stones by their location within the biliary tree: hepatoliths (within the liver) or choleliths (outside the liver).

Etiology and Pathophysiology. Although the etiopathogenesis of CH and CL in horses is uncertain, retrograde bacterial infection from the small intestine is considered probable,

and this hypothesis is supported by several reports.[81,191,263] The isolation of enteric, predominantly gram-negative organisms from clinical cases of CH and CL is consistent with this hypothesis.[81,191,261,263,264] Plant material has occasionally been found inside the stones, further supporting retrograde invasion of bacteria and even ingesta from the duodenum as a predisposing cause of the disease.[263] As bacteria gain entrance to the biliary system from the duodenum (bile is normally sterile), it would be expected that an inflammatory response would occur with tissue swelling, thus potentially increasing the pressure within the common bile duct and forcing infection into the biliary canaliculi. The ascending infection is thought to initiate a cholangitis, which may then extend into the periportal region of the liver causing CH.[81] The occurrence of enteritis or inflammatory bowel disease before the onset of CH in some cases may also support the ascending enteric bacterial infection hypothesis,[195,265] although most cases of CH do not have a clear history of those diseases.[191] The most common organisms cultured from the affected horses are *E. coli, Actinobacillus equuli, Streptococcus* spp., *Klebsiella* spp., *Enterococcus* spp., *Clostridium* spp., and *Bacteroides* spp.[191,195,266] CH may predispose to intrahepatic (hepatolith) or extrahepatic (cholelith) formation. Equine choleliths are predominantly composed of calcium bilirubinate and to a lesser extent calcium phosphate.[191,263,267,268] Ascending enteric bacterial infection is thought to be critical in the development of brown pigment stones (calcium bilirubinate) in humans.[269,270] Deconjugation of bilirubin diglucuronide by bacterial β-glucuronidase such as *Clostridium* spp., *Bacteroides* spp., *E. coli,* and *Peptococcus* spp. occurs with subsequent precipitation of calcium bilirubinate, and cementation by anionic glycoproteins is thought to result in the formation of these calculi.[269] It is clinically important to realize that calcium bilirubinate crystals may form initially, followed by sludge formation and then stone formation. If that is true, each stage of the process may signal further decreases in the efficacy of medical treatment. In the majority of clinical cases of equine CL, stones are found in more than one area of the biliary tree and can include intrahepatic and extrahepatic choleliths including choledocholiths (stones of the common bile duct).[263] Multiple stones are common, with one extreme case reported as having 1120 stones.[271] Stones in the common bile duct would almost always be expected to produce signs characteristic of obstructive failure whereas stones in other areas of the biliary tree may be silent.

Clinical Findings. Clinical signs associated with these conditions include pyrexia, colic, icterus, and, in chronic cases, significant weight loss.[81,191,261,263,272-275] In a small percentage of cases, both neurologic signs caused by hepatic encephalopathy (HE) and photosensitization may be seen.[81,276] Unless the disease is chronic and extensive fibrosis has occurred, hepatocellular function is not severely compromised, thus accounting for the absence of HE in many cases. Although nonspecific, colic and marked icterus are the most common clinical findings in horses with obstructive CH and CL.[81,191,261,267] Fever would be expected but is not always evident on a single examination. Some degree of depression may be present. Affected horses have markedly elevated serum concentrations of the hepatobiliary enzymes GGT and ALP, as well as bilirubin. A proportionate increase in the conjugated bilirubin fraction to greater than 25% of the total bilirubin is common,[81,261,267,268] but in approximately one third of cases the percentage of conjugated/total bilirubin is lower than 25%.[191] Affected horses generally have an increase in hepatocellular enzymes SDH, GLDH, and AST (commonly 2–4 times normal), although the proportionate increase above normal values is usually less than that seen with serum GGT elevations (commonly 7–20 times normal). Hyperfibrinogenemia may or may not be present.[81,191] Other notable serum biochemical abnormalities with CH include increased serum bile acids and hyperglobulinemia.[81,191] Clotting function tests (PT and PTT) are often normal but can be abnormal.[81,191,261]

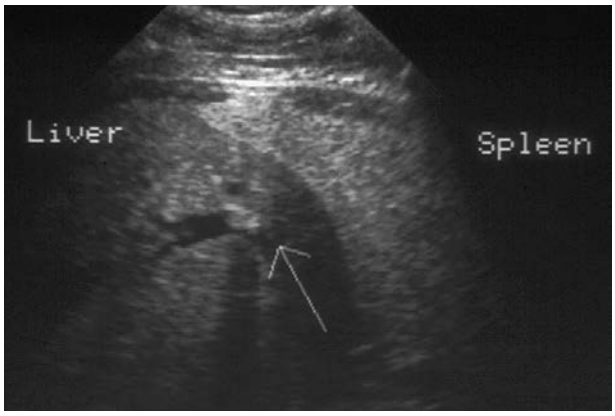

FIG. **13.11** Ultrasound image of the liver showing a hepatolith *(arrow)* casting an acoustic shadow in a dilated bile duct in a horse with obstructive cholelithiasis.

The ultrasonographic findings in horses with CH include subjective evidence of liver enlargement and distended, thickened bile ducts with variable liver echogenicity. In horses with CL, increased hepatic echogenicity, hepatomegaly, distended bile ducts, and occasional calculi are the salient features of the condition.[81,263,267,277] Stones can often best be visualized in the seventh to tenth intercostal spaces on the right side, just ventral to the lung border, and are seen in approximately 50% to 75% of horses with CL[263]; stones are uncommonly seen on the left. The biliary tree is usually not detectable ultrasonographically in normal horses, but dilated bile ducts can be seen as enlarged channels running parallel to the portal veins in approximately 40% of horses with obstructive CL, and this finding should be considered suspicious for either intrahepatic or extrahepatic biliary obstruction even if no stones are seen.[3,263] Hyperechoic choleliths with acoustic shadowing can occur, whereas other less mineralized calculi or sludge may have only faint or no acoustic shadowing (Fig. 13.11). If several bile ducts are severely distended that indicates a likely obstruction (choledocholith) in the common bile duct. If stones can be seen in the image field with classic findings of hepatic failure caused by obstruction, one can assume there is at least one other stone obstructing the common bile duct and the presence of multiple stones may lower the prognosis. Stones obstructing the common bile duct cannot be imaged on transcutaneous abdominal ultrasound, but when endoscopic examination of the duodenum is performed, the stone or a "bulge" may be noted at the bile duct opening.

Histopathology of biopsy material can provide valuable information as to the severity of inflammatory CH and the extent of accompanying hepatic fibrosis. Historically, marked periportal and bridging fibrosis have been interpreted as poor prognostic indicators in horses with suspected or known CH or CL.[191,267] Case reviews suggest that extended (months or years) survival times may be possible in some

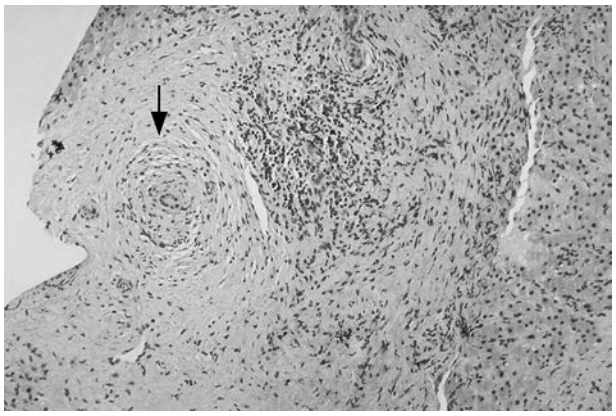

FIG. **13.12** Histopathology of the liver: concentric fibrosis *(arrow)* around a bile duct characteristic of obstruction of the common bile duct. (Photo courtesy of Dr. Kelly Butterworth.)

horses despite histologic evidence of chronic hepatobiliary damage (severe periportal and bridging fibrosis).[191] An estimate of the degree of fibrosis, based on hepatic echogenicity, can also be determined by ultrasound examination. Horses with biliary obstruction may have circumferential biliary hyperplasia and fibrosis on microscopic examination of a liver biopsy (Fig. 13.12), and this can be an extremely helpful finding in the diagnosis and prognosis when an obstructing stone cannot be seen on ultrasound or duodenoscopy and surgery is being contemplated (authors' observations). This finding does not have 100% sensitivity, so if all other clinical and laboratory findings are characteristic of CL, surgery (if an option and appropriate) should not be ruled out based on the absence of this microscopic finding. Another indication for biopsy is to provide a sample for bacterial culture, in hopes of determining the etiologic agents such that specific antimicrobial therapy can be chosen. Unfortunately, cultures obtained from biopsy samples are negative in approximately 50% of cases.[191]

Treatments and Prognosis. Based on previous studies, it would appear that long-term administration of systemic antibiotics is critical for the successful treatment of CH and in some cases of CL in horses.[191] Median treatment period in one study, where seven of nine horses had liver failure due to CH but survived, was 51 days (range 17–124 days).[191] Antibiotic selection should ideally be based on culture and sensitivity results from hepatic biopsy material, but clinicians are frequently required to select an initial antimicrobial agent empirically or when the culture results are negative. The isolation of predominantly gram-negative enteric and mixed anaerobic organisms from cases of CL[81,191,263] suggests that antibiotics with good gram-negative activity (enrofloxacin, third-generation cephalosporins, aminoglycosides, and possibly trimethoprim-sulfonamide) in addition to antimicrobials effective against enteric anaerobes (penicillin, metronidazole, chloramphenicol) would be reasonable choices. Although the liver metabolizes nearly 50% of metronidazole, its use in CH is unlikely to be a problem or require a dose adjustment unless there is marked liver fibrosis. In the absence of positive culture results, clinicians may not only have to select an agent empirically but should also be prepared to change antibiotics according to clinical response. In one study, in all horses that improved, clinical improvement was seen days to several weeks before normalization of serum biochemical indices of hepatobiliary disease (GGT, ALP, bilirubin, and bile acids).[191] Furthermore in that study, serum GGT actually increased during the initial period of clinical improvement in all horses. There is no reported level of GGT that accurately predicts treatment failure in CH, as long as the horse is clinically stable, the ultrasound examination does not reveal numerous obstructing stones or diffuse fibrosis, and both clinical and laboratory findings improve within 7 to 10 days after medical therapy commences. Continuing antimicrobial therapy until both clinical and biochemical recovery has occurred may be important in achieving a successful outcome. Supportive medical care using intravenous fluids and antiinflammatory drugs was believed to be a critical part of the treatment in one case series report.[191]

Therapeutic agents, such as the bile salts chenodeoxycholic acid and ursodeoxycholic acid (ursodiol), which are specifically used to encourage dissolution of cholesterol-rich stones in humans, have no effect on calcium bilirubinate calculi but, as antiinflammatory and choleretic agents that increase bile production, may make bile more liquid and easier to excrete.[148] There has been no recognizable evidence of toxic effects of ursodeoxycholic acid treatment in any case, but further studies on safety and efficacy need to be done. Administration of ursodiol may increase serum bile acid concentrations. There is direct experimental support for the use of DMSO in the treatment of brown pigment stones in humans because it is a direct solubilizer of calcium bilirubinate.[142]

Previous reports have described the surgical treatment of cholelithiasis.[267,272,273,276] Choledocholithotripsy (the crushing of choleliths in the bile ducts) and choledochotomy (surgical formation of an opening into the bile duct) have been performed successfully in the horse.[272,273,278] In one report on horses, external massage of the common bile duct, without choledochotomy, successfully dislodged choledocholiths into the duodenum in all of the cases in which it was attempted.[273] Unfortunately, intrahepatic calculi are largely inaccessible to the surgeon, and the fact that many cases of equine cholelithiasis possess multiple intrahepatic and extrahepatic choleliths means that recurrent biliary obstruction would be likely even if an obstructing stone is removed.

Prognosis. The prognosis of cholelithiasis depends on the extent of hepatic fibrosis, severity of clinical signs, and number and location of choleliths. Extensive or bridging fibrosis, multiple choleliths accompanied by clinical signs of hepatic failure, and severe HE warrant a poor to grave prognosis.[40,191,262] Reports of resolution of extensive fibrosis exist after reestablishment of bile flow; thus one should not consider the presence of extensive fibrosis alone to be lethal.[262,279] In contrast to reports of 30% survival for equine cholelithiasis,[81] other reviews indicate 77% to 85% survival with medical or medical and surgical treatment.[191,262] If obstruction of the bile duct requires a choledochotomy, the prognosis is guarded because of limited access to the bile duct in a horse and the risk of peritonitis. The best surgical outcome has been when there is a single stone obstructing the bile duct and when hepatic fibrosis is not severe. Surgery should be considered for horses that have intermittent or persistent abdominal pain, ultrasonographic evidence of obstruction to biliary outflow, concentric biliary fibrosis histopathologically, moderate to no hepatic fibrosis, few or no stones visible on ultrasound examination, and an unsuccessful response to medical therapy.

Neonatal Acquired Biliary Obstruction

Healing duodenal ulcers located adjacent to the hepatopancreatic ampulla in neonatal foals may result in extrahepatic biliary stenosis.[127,280] Clinical signs are compatible with gastroduodenal obstruction and include reduced suckling reflex, depression, prolonged recumbency, colic, bruxism, and firm feces. Nasogastric intubation often produces voluminous reflux. Duodenal stenosis may be confirmed radiographically by delayed gastric emptying of barium sulfate. One should consider a diagnosis of biliary stenosis if the serum levels of conjugated bilirubin and GGT are increased or if nuclear scintigraphy indicates delayed biliary excretion. Cholangiohepatitis may develop because of chronic cholestasis and may be confirmed by histopathologic examination of a liver biopsy. One must differentiate acquired biliary stenosis from congenital biliary atresia (discussed later in this chapter). Successful surgical correction of acquired biliary stenosis secondary to duodenal stricture has been described.[280]

Chronic cholangiohepatitis without biliary stenosis, another potential sequela to duodenitis or duodenal ulceration, should be considered in icteric foals with increased serum conjugated bilirubin and GGT.[32] The diagnosis is confirmed by histopathologic examination. Treatment should consist of long-term antimicrobial therapy directed by bacterial isolation and sensitivity results (see Bacterial Hepatitis).

Hepatic Abscessation

Liver abscessation is uncommon in horses. Clinical signs of hepatic abscessation depend on the extent and location of the abscess or abscesses; however, abscesses are unlikely to result in hepatic failure. Small solitary abscesses or multifocal microabscesses usually remain subclinical. Larger abscesses may be accompanied by weight loss, intermittent fever, and anorexia.[281]

Hepatic abscessation in foals may be hematogenous in origin as a sequela to bacteremia or ascending through the umbilical vein as a sequela to omphalophlebitis.[282] In the adult, bacteremia is less common than in foals, and hepatic infection or abscessation more likely originates in the intestinal lumen and ascends the bile duct or originates in the intestinal wall or mesenteric lymph nodes and is carried to the liver via the portal blood.[283] The latter is a likely sequela to primary abdominal or mesenteric abscessation because of *S. equi* subsp. *equi.* In one retrospective study of abdominal abscesses in horses, only 2 of 25 horses had solely hepatic abscesses, although some horses had abscesses involving several abdominal structures.[284] In a description of three adult horses with hepatic abscesses, disease was postulated to result from primary inflammatory bowel disease, as a sequelae to abdominal surgery, and secondary to penetration of a foreign body from the colon.[285] Laboratory diagnosis of hepatic abscessation is difficult. Smaller abscesses may not result in sufficient hepatocellular damage to impede liver function. Laboratory abnormalities characteristic of chronic inflammation and infection, including anemia of chronic disease, hyperfibrinogenemia, hypergammaglobulinemia, and mature neutrophilia, may occur with larger abscesses. Increased serum activity of liver-specific cytosolic enzymes or serum bile acid concentration rarely occurs unless liver abscessation is extensive. Ultrasonography of the liver may reveal focal changes in echogenicity. A liver biopsy should be guided by ultrasound to avoid penetration of the abscess. One should direct long-term antimicrobial therapy by culture and sensitivity results. Common isolates from abdominal abscesses in horses include *S. equi* subsp. *equi, S. equi* subsp. *zooepidemicus,* and *Corynebacterium pseudotuberculosis.*[284]

Hepatic Neoplasia

Primary hepatic neoplasia is rare in horses. A retrospective survey in 1952 indicated that hepatic tumors accounted for only 1% of all equine neoplasms.[286] Of the documented primary hepatic neoplasms in horses (cholangiocarcinoma, hepatocellular carcinoma, hepatoblastoma, and mixed hamartoma), cholangiocarcinoma is the most common.[125,287-289] Hepatic neoplasia in horses is more likely to occur after metastasis of some other primary tumor, especially lymphosarcoma.[289] Because clinical signs of hepatic failure usually are not apparent and laboratory findings are nonspecifically indicative of chronic inflammatory disease, antemortem diagnosis of hepatic neoplasia is difficult.

In one report, *cholangiocarcinoma* accounted for 9 of 10 primary liver neoplasms in horses.[286] Cholangiocarcinoma originates from the bile duct epithelium and is distinguished from hepatocellular carcinoma by its tendency to form multiple foci, its firm texture, and a whitish color produced by abundant fibrous stroma. The primary mass is typically solitary, with multiple intrahepatic secondaries. Extrahepatic metastasis is common, with transperitoneal lymphatic spread to the peritoneum and diaphragm and hematogenous spread to the lungs.[287,288] In human beings, dogs, and cats, a causative relationship appears to exist between cholangiocarcinoma and liver fluke infestation or a history of biliary tract disease.[288] A report describes cholangiocarcinoma in a horse after treatment for prolonged septic cholangiohepatitis.[290] Aberrant expression of the protein products of the tumor suppressor gene, p53, was reported at necropsy in one horse with cholangiocarcinoma.[291] Loss of function of p53 has been described in other types of carcinomas and may have contributed to malignancy. Microscopically, cholangiocarcinoma is adenocarcinomatous, producing cuboidal or columnar-lined ductules and acini. The neoplastic bile ducts do not contain bile but may contain mucus.

The clinical presentation and progression of cholangiocarcinoma in horses is not well documented, but this disorder appears to be more common in older horses.[286,287] One case report describes a 10-year-old mixed-breed horse in which the presenting signs included anorexia, weight loss, pyrexia, mild icterus, tachypnea, severe dependent edema, and abdominal distention.[292] Abnormal clinicopathologic findings included mature neutrophilia; hyperfibrinogenemia; anemia; moderately increased serum bilirubin, GGT, and SDH; and nonseptic peritonitis and pleuritis. Neoplastic cells were not detected in the body cavity effusions. Definitive antemortem diagnosis of cholangiocarcinoma was made by histopathologic examination of a liver biopsy. Necropsy revealed multiple extrahepatic metastases on the serosal surfaces of the intestine and spleen, diaphragm, omentum, pleural surfaces, and lung.

Hepatocellular carcinoma, or hepatoma, has been reported in several horses, the majority of which were less than 3 years of age.[287] Hepatocellular carcinomas are usually solitary and multilobulated. Extrahepatic metastasis occurs transperitoneally and hematogenously to lungs. Microscopically, the neoplastic cells resemble hepatocytes and retain cord arrangement. However, the normal liver architecture is lost, and sometimes the cells are difficult to differentiate. Mitotic figures are uncommon. Possible causative factors in other species include heredity, parasitism, chemical and plant carcinogens, and viral hepatitis.[288]

Reported clinical signs of hepatocellular carcinoma in horses include depression, anorexia, weight loss, intermittent diarrhea, and abdominal distention.[287] Abnormal laboratory findings included absolute erythrocytosis; persistent hypoglycemia; sanguineous peritoneal effusion; and increased serum SDH, GGT, LAP, and indirect-reacting bilirubin. In one case, absolute erythrocytosis was attributed to erythropoietin secretion by the carcinoma (inappropriate secondary erythrocytosis).[124] The same horse had a high serum concentration of α-fetoprotein, a globulin normally synthesized only by embryonic fetal liver cells that is commonly detectable in human patients with hepatocellular carcinoma.[124]

Several reports describe malignant *hepatoblastoma* in young horses.[125,287,293] Hepatoblastoma is an embryonic tumor of the liver with a wide range of histologic patterns that include both epithelial and mesenchymal elements. Clinical signs included emaciation, pyrexia, and pleural effusion. Laboratory abnormalities included mature neutrophilia, erythrocytosis with increased erythropoietin level in one case, hypergammaglobulinemia, hyperfibrinogenemia, and increased serum activity of GGT and ASP.[125,287] In one of the cases, transabdominal ultrasonography identified abnormal hepatic architecture. Increased serum α-fetoprotein may serve as a tumor marker but cannot be used alone to confirm a diagnosis.[293]

A *mixed hamartoma* was described in the liver of a late-term aborted equine fetus.[294] Histologically, the lesion appeared to be a proliferation of large hepatocyte-like cells with eccentric nuclei and voluminous cytoplasm, abnormal bile ducts, and fibroblastic fibrocystic interstitial tissue, with complete lack of structural organization.

Hepatic Amyloidosis

Amyloidosis refers to a group of diseases that are characterized by the extracellular deposition of a proteinaceous fibril substance, *amyloid,* in the tissues. Amyloid deposits are composed of nonbranching fibrils in β-pleated sheet conformation formed by the proteolytic cleavage of precursor proteins by the mononuclear phagocyte system. Depending on the organ of deposition, amyloid distorts normal tissue architecture and may lead to functional impairment. In horses, the liver and spleen are the most common organs involved in systemic amyloidosis.[295] Two forms of systemic amyloidosis exist and are distinguished by the type of precursor protein and subsequent protein fibril. The precursor in *reactive* or *secondary* systemic amyloidosis is serum amyloid protein AA, an acute-phase protein produced mostly by hepatocytes in response to chronic infection or inflammation. The AA fibrils are identified in tissues by green birefringence in polarized light, after staining with Congo red, which is lost after treatment with potassium permanganate. Most often in horses, hepatic amyloid deposits are AA fibrils and have been associated with hyperimmunization, severe parasitism, or chronic infection and inflammation.[295] Hepatic AA-amyloidosis is most commonly reported in serum-producing horses.[296] One horse in which the liver was the principal organ of amyloid deposition presented for evaluation of chronic weight loss.[295] An antemortem diagnosis of hepatic amyloidosis was not made; however, laboratory abnormalities included severe hypoalbuminemia, polyclonal gammopathy, and large numbers of ascarid and strongylid eggs in the feces. Histopathologically, the liver revealed extracellular deposits of AA amyloid periportally and adjacent to the sinusoids in the space of Disse. The amyloid deposits were accompanied by hepatocytic atrophy and a mild mononuclear cell infiltrate. Horses with hepatic amyloidosis may be asymptomatic or have clinical signs of chronic liver disease and dysfunction. GGT and bile acids may be increased in horses with moderate to marked infiltration of the liver with amyloid.[296,297] Acute abdominal hemorrhage associated with rupture of the liver may occur in some cases.

Systemic primary, immunocytic, or *idiopathic amyloidosis* is caused by the deposition of amyloid light-chain fibrils.[297] The precursor proteins in primary amyloidosis are the variable region of immunoglobulin light chains. The amyloid fibrils also stain with Congo red, but staining is retained after potassium permanganate treatment. *Local immunocytic amyloidosis,* with deposition in the upper respiratory mucosa or skin, is more common in horses than systemic primary amyloidosis. However, at least one reported case of systemic primary amyloidosis in a 14-year-old Thoroughbred mare with chronic weight loss and cutaneous nodules exists.[298] Amyloid deposits were identified in the liver, myocardium, spleen, gastrointestinal mucosa, pulmonary interstitium, pancreas, and arterial walls.

Chronic Hypoxemia

Right-sided heart failure causes the pressure in the caudal vena cava to rise. Retrograde pressure increases in the hepatic central veins, causing hypoxemia and pressure necrosis of the adjacent hepatocytes. Chronic passive congestion may cause fatty change, atrophy, and fibrosis.

Miscellaneous Vascular or Congenital Abnormalities

Portosystemic Shunt

Portosystemic shunts (PSSs) may be intrahepatic or extrahepatic, congenital or acquired. Few reports have documented congenital extrahepatic PSSs in foals.[87,194] The vascular shunts allow blood within the portal system to bypass the liver and drain into the systemic circulation, directly or indirectly, via the caudal vena cava or the azygous vein. In the reported cases, age at presentation varied between 2 and 6 months. This relatively late clinical detection could be because hindgut development in young foals is necessary to produce enough enteric ammonia to cause sufficient elevations in blood ammonia. Vague intermittent neurologic signs of blindness, ataxia, and severe depression were consistent with HE. Growth appeared to be stunted. These clinical signs are caused by the altered hepatic blood flow and hepatic insufficiency secondary to hepatocellular atrophy.

Laboratory abnormalities in the reported cases varied, but the most consistent findings included a decreased BUN, prolonged BSP half-life, and increased blood ammonia concentration. Liver biopsies revealed hepatocellular atrophy and necrosis, fibrosis, and biliary hyperplasia.[126] Antemortem diagnosis can be confirmed by liver ultrasonography (see Diagnostic Imaging of the Liver), computed tomography, ultrasound-guided percutaneous transsplenic injection of 10 mL of agitated saline into the spleen with simultaneous echocardiography of the right side of the heart ("bubble gram"), or by transrectal hepatic scintigraphy.[127,299,300] The bubble gram may have higher sensitivity because air bubbles will appear in the right side of the heart almost immediately after splenic injection if a PSS is present.[300] Theoretically, if the portal circulation is normal the liver will filter the bubbles and the bubbles will not reach the heart. Transrectal scintigraphy for the diagnosis of PSS is performed by placing a soft rubber catheter as

far into the rectum as safely possible and administering 30 mC of technetium pertechnetate, followed immediately by radioisotope scanning of both the heart and liver.[127] If the majority of technetium is detected first in the liver, portosystemic shunt can be ruled out. Once the diagnosis of PSS is made an operative mesenteric portography or CT with contrast will be needed to confirm location of the shunts(s).[299] If a liver biopsy is performed (usually unnecessary), lobular atrophy characterized by decreased distance between the central veins and portal areas and arteriolar proliferation in the portal tract with mild proliferation of interlobular arteries are usually seen. The number and size of portal veins may be subjectively less than normal.[300] The location of the shunt (or shunts) in reported cases varied, but the majority were extrahepatic, often involving a direct connection between the portal vein and the caudal vena cava. Shunts may be singular or multiple, with shunting to the caudal vena cava, azygous vein, and virtually any gastric, splenic, or mesenteric vessel.[299] Alzheimer type II astrocytes are visible in the brain, consistent with HE.[299,301] Successful treatments have included routine surgical ligation or cellophane banding.[299,300] Prior to surgery the foal should be managed to prevent HE as discussed previously. Foals with PSS may have remarkably high blood ammonia, sometimes > 200 umol/L, without obvious signs of HE.

Portal Vein Thrombosis

Acquired PSSs are rare in horses. One report describes an 11-year-old Thoroughbred with HE that subsequently was determined to have a functional PSS secondary to vascular thrombosis of the portal vein.[302] In older animals, hepatic neoplasia may predispose to thrombosis.[303] Although rare, horses with cirrhosis may occasionally develop portal vein thrombosis.

Portal vein thrombosis occurs rarely in foals following enteritis or in association with *Rhodococcus equi* infection.[304] Portal vein thrombosis has been reported in other species as a sequela to sepsis, hypercoagulability, and inflammation.

Clinical signs in foals attributed to complete portal vein thrombosis include diarrhea and HE signs.[127,304] Diarrhea may occur from increased mesenteric venous pressure and intestinal wall edema if the thrombosis is acute and completely obstructs the portal vein. Diarrhea may be a predisposing cause of or a result of the portal vein thrombosis. The neurologic signs are secondary to hyperammonemia, caused by the collateral flow of the portal blood into the vena cava and elsewhere, thus bypassing the liver. If the obstruction is not complete or portoportal collateral compensatory circulation develops, clinical signs may be absent. One foal with abdominal lymphadenitis, septic tarsitis, and hepatitis caused by *R. equi* had a large but incomplete obstruction of the portal vein, and with long-term antimicrobial therapy the patient recovered.[127] Treatment to remove portal vein thrombosis in horses has not, to the authors' knowledge, been attempted.

Biliary Atresia

Extrahepatic biliary atresia in foals has been documented.[305] An antemortem diagnosis was not possible; however, veterinary attention was sought at 4 weeks of age in both foals for anorexia, depression, lethargy, poor weight gain, colic, polydipsia, polyuria, pyrexia, and icterus. Laboratory evaluation of one of the foals was consistent with biliary obstruction, as indicated by a mildly increased serum activity of SDH and markedly increased activity of GGT and conjugated bilirubin.[305] Necropsy of both foals revealed a large, firm liver. Although not specifically documented in one case, both the entrance to the bile duct and the main bile duct were absent in the other foal.[305] Histologically, both livers appeared similar and consistent with extrahepatic biliary atresia. Bile canaliculi were present and distended, with associated degenerative hepatocytes. Biliary proliferation was extensive and surrounded by fibrous tissue with interpersed islands of hepatocytes. No bile was found in the proliferative bile ducts, and the portal triad ducts were absent.

In horses, extrahepatic biliary atresia is believed to be congenital. In human beings, other possible causes include neonatal sclerosing cholangiohepatitis, excretion of a biliary toxin, deficit of bile flow in utero, or lumen destruction because of ductal vascular insufficiency.[306] Despite the cause, extrahepatic biliary atresia induces intrahepatic biliary hypertrophy, an abortive attempt to establish continuity. The biliary hypertrophy displaces hepatocytes, causing periportal and perilobular hepatocellular degeneration, fibrous replacement, and ultimately loss of normal hepatic architecture. Although an antemortem diagnosis was not possible in either equine case, hepatobiliary scintigraphy (see Diagnostic Imaging of the Liver) successfully detected total biliary obstruction in a neonatal lamb with biliary atresia.[128]

Serous Cysts

Serous hepatic cysts have been reported and usually are an incidental finding at necropsy.[23]

Glycogen Branching Enzyme Deficiency

Autosomal recessive inheritance of glycogen branching enzyme deficiency has been reported in Quarter Horse foals (see Chapter 10 for a detailed discussion). The nonsense mutation of the affected gene, glycogen branching enzyme 1, prevents synthesis of functional enzyme. Affected foals died before 2 months of age. Clinical signs vary from stillbirth, seizures, and persistent recumbency to cardiac or respiratory failure. Leukopenia, intermittent hypoglycemia, and increased creatine kinase, GGT, and AST are common laboratory findings. Histopathology of the liver demonstrates abnormal periodic acid–Schiff (PAS)-positive globular or crystalline intracellular inclusions and reduced glycogen branching enzyme activity.[307]

Liver Lobe Torsion

Liver lobe torsion is an uncommon disorder in horses. Based on the small number of cases reported, it would appear that the left medial or accessory lobe is most commonly affected, although the entire left lobe was believed to be involved in two horses.[308-310] Predisposing causes were rarely, if ever, identified. Of the eight cases reported, only three were presented for colic. Clinical signs are most commonly anorexia of 1 or more days' duration, tachycardia, and clinical and laboratory signs associated with systemic inflammation resulting from necrosis of the twisted liver lobe and peritonitis. Peritonitis appears to be present in all cases, and peritoneal fluid is often serosanguineous. Serum levels of hepatic-derived enzymes are usually unremarkable although SDH and GLDH may be increased in association with the systemic inflammatory response. Ultrasound examination is generally unremarkable as the affected lobe may be obscured from imaging by the gastrointestinal gas. If the entire left lobe is "torsed," the affected portion may appear as a mixed echogenic mass. Surgical repair is via stapled resection of the affected lobe, and this has been successful in five cases.[308,310]

CHAPTER 14

Disorders of the Urinary System

Harold C. Schott II, Bryan Waldridge, and Warwick M. Bayly*

Anatomy and Development

Harold C. Schott II

ANATOMY

The urinary system of the horse, like that of most mammals, consists of paired kidneys and ureters, the bladder, and the urethra. With the exception of the abdominal portion of the urinary bladder, the entire urinary tract is located in the retroperitoneal space. In a newborn foal, each kidney weighs about 175 g. In an adult horse, the left kidney weighs between 600 and 700 g, and the right kidney is usually 25 to 50 g heavier, although this is not a consistent finding and one may observe the reverse relationship.[1,2] Thus the kidneys account for approximately 0.65% to 0.75% and 0.27% to 0.37% of the total body mass of the foal and adult horse, respectively.[1,3] The right kidney is located immediately below the dorsal extent of the last two or three ribs and the first lumbar transverse process, is shaped like a horseshoe, and measures about 15 cm long, 15 cm wide, and 5 to 6 cm high (dorsal to ventral). Craniolaterally, the right kidney is embedded into the liver, and its more craniad position compared with the left kidney prevents it from being accessible on rectal palpation. Although not the classically bean-shaped organ found in human beings and small animals, the left kidney in the adult horse is more elongated than the right kidney, with the cranial pole at the level of the hilus of the right kidney. In equids, the left kidney is about 18 cm long, 10 to 12 cm wide, and 5 to 6 cm high. Because of its more caudal location, one routinely can palpate the caudoventral aspect of the left kidney during rectal examination. The blood supply to the kidneys comes from one or more renal arteries branching from the aorta. Accessory renal arteries (which generally enter caudally) may arise from the caudal mesenteric, testicular, ovarian, or deep circumflex iliac arteries.[1,2]

The ureters are 6 to 8 mm in diameter and travel about 70 cm to their insertions in the dorsal bladder neck or trigone, close to the urethra. The distal 5 to 7 cm of each ureter courses within the bladder wall. This intramural segment of the ureter functions as a one-way valve to prevent vesicoureteral reflux with progressive bladder distention. The urinary bladder lies on the pelvic floor when empty but can increase in size and drop forward over the pelvic brim when filled with urine. The bladder can accommodate up to 3 to 4 L of urine before stimulation of micturition. In the foal, the bladder is attached to the ventral abdominal wall by the urachus and remnants of the paired umbilical arteries. Consequently, when empty, the bladder is commonly a band-shaped structure in a neonatal foal. During the first few months of life, this ventral attachment loosens as the urachal remnant becomes the middle ligament and the umbilical arterial remnants become the round ligaments of the free border of the paired lateral ligaments of the bladder.[1]

The urethra is about 2 to 3 cm long in a mare and 75 to 90 cm long in a male. In the intact male, the pelvic urethra, which is 10 to 12 cm long, widens in an elliptic pattern to a diameter of 5 cm across and 2 to 3 cm from dorsal to ventral. A rounded dorsal prominence, the colliculus seminalis, is located immediately caudal to the urethral orifice and is the site of the common openings of the ductus deferens and ducts of the seminal vesicles. The openings of the prostatic ducts are two groups of small papillae lateral to the colliculus seminalis. Between 2 and 3 cm farther caudad, the ducts of the bulbourethral glands open in paired dorsal lines. The smaller openings of the ducts of the lateral urethral glands open at the same level on the lateral aspect of the urethra.[1]

A fibrous capsule that peels easily from the normal kidney covers the surface of each kidney. The equine kidney consists of an outer cortex slightly wider than the inner medulla. The cortex is dotted with dark spots—renal corpuscles or glomeruli within Bowman's capsules. In horses, the corticomedullary junction is less distinct than in other species and is typically a deep red that contrasts well against the paler medulla and red-brown cortex. This region undulates along renal pyramids (cortex) and renal columns (medulla). The pyramids are subdivisions of the renal parenchyma, which are separated by arcuate arteries at the level of the corticomedullary junction. The equine kidney contains a total of 40 to 60 pyramids arranged in four parallel rows. The renal pelvis is the dilated proximal portion of the ureter. Microscopic examination reveals numerous small openings of the collecting ducts (ducts of Bellini). Additionally, the renal pelvis and proximal ureter are lined with compound tubular mucous glands and goblet cells that secrete the thick, viscid mucus normally found in the renal pelvis and urine of normal horses.[1,4]

*The editors and authors acknowledge and appreciate the contributions of Dr. Jennifer Taintor who assisted with updating of references for some sections.

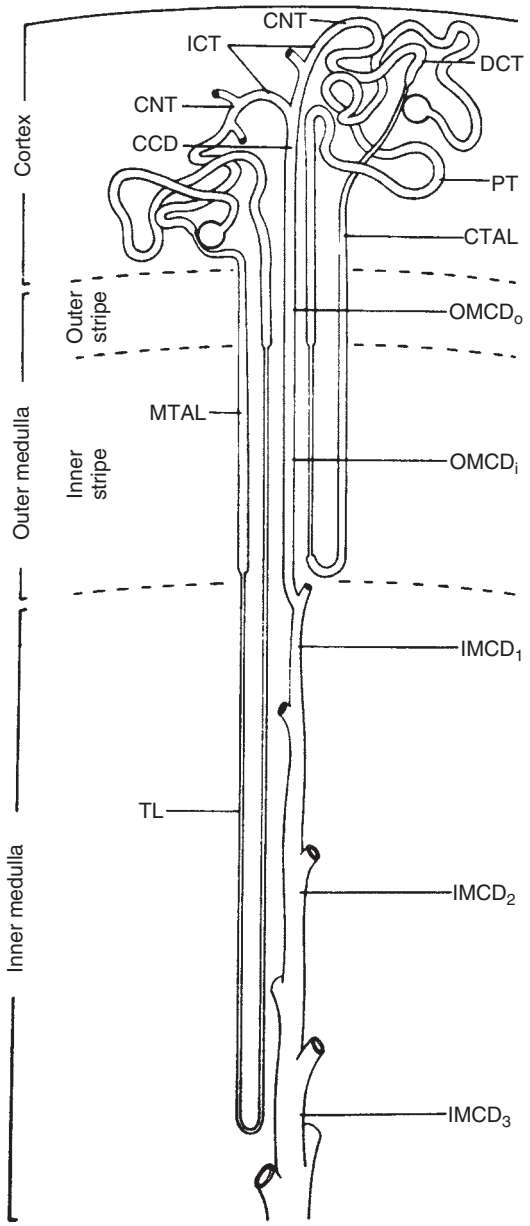

FIG. **14.1** Diagram of a superficial and juxtamedullary nephron. *TL,* Thin limb of the loop of Henle; *MTAL,* medullary thick ascending limb (mTAL) of the loop of Henle; *CCD,* cortical collecting duct; *CNT,* connecting segment; *ICT,* initial collecting tubule; *DCT,* distal convoluted tubule; *PT,* proximal tubule; *CTAL,* cortical thick ascending limb of the loop of Henle; *$OMCD_o$,* collecting duct in outer stripe of outer medulla; *$OMCD_i$,* collecting duct in inner stripe of outer medulla; *$IMCD_1$,* outer third of inner medullary collecting duct; *$IMCD_2$,* middle third of inner medullary collecting duct; *$IMCD_3$,* inner third of inner medullary collecting duct. (From Brenner BM, Rector FC, editors: *The kidney,* ed 8, Philadelphia, 2008, WB Saunders.)

The functional unit of the kidney is the nephron. Each nephron is composed of a renal corpuscle (glomerulus within Bowman's capsule), a proximal tubule (convoluted and straight components), an intermediate tubule (loop of Henle), a distal convoluted tubule, a connecting tubule, and cortical, outer medullary, and inner medullary collecting ducts (Fig. 14.1). The two populations of nephrons are (1) the superficial (or cortical) nephrons possessing short loops of Henle and (2) the juxtamedullary nephrons with long loops of Henle. Gradations exist between these two general categories of nephrons, as well as species variation in the ratio of short- to long-looped nephrons. For example, human beings have 7 times more short- than long-looped nephrons, whereas essentially 100% of nephrons in dogs and cats have long loops.[5] An early anatomic study found approximately 4 million glomeruli (nephrons) in the adult bovine kidney[6]; however, a study of kidney organogenesis using unbiased stereologic techniques to examine 45 equine left kidneys indicated that the left kidney of the horse may contain closer to 10 million glomeruli (for a total of 20 million in both kidneys).[7] The latter study also confirmed that the total number of glomeruli does not increase after birth despite continued growth of the kidney until about 1 year of age. At present, little information is available on the ratio of short- to long-looped nephrons in horses. Histologically, equine nephrons are similar to those of other mammalian species; however, the diameter and epithelial height of the tubule and collecting duct segments are comparatively larger. In addition, the equine macula densa (segment of the ascending loop of Henle that lies in close association with the juxtaglomerular apparatus of the afferent arteriole) appears more prominent than that of other mammals.[8] Whether or not these subtle histologic differences are accompanied by functional differences has not been investigated.

Relative to its size, the mammalian kidney has a richer innervation than almost any other organ.[9] Although the neuroanatomy of the equine kidney has not been well studied, autonomic nerves course from the aorticorenal and renal ganglia along the major renal vessels into the kidneys.[1] These nerves are predominantly sympathetic, because the kidneys appear to be poorly supplied by cholinergic nerves. Although the best-recognized effect of renal nerves is control of renal vascular resistance (for regulation of renal blood flow over a wide range of perfusion pressures), the nerves also act directly on renal tubules and juxtaglomerular cells. For example, low-frequency stimulation of renal nerves (below the threshold for vasoconstriction) increases proximal tubular sodium reabsorption and renin release by activation of α_1-adrenoceptors.[10] In addition to α- and β-adrenoceptors, renal vasculature is rich in dopaminergic adrenoceptors, and activation of the latter, specifically dopamine type 1 receptors, leads to increased perfusion of the outer renal medulla. Presence of these receptors is the basis for use of dopamine and the DA-1 receptor agonist fenoldopam, to improve renal blood flow in acute renal failure or decrease the risk of radiocontrast nephropathy.[11-13] Drugs also may activate renal adrenoceptors unintentionally. A common clinical example is the diuresis induced by administration of the α_2-agonists xylazine and detomidine. Although the diuresis has been attributed to a transient hyperglycemia and glucosuria, the latter is often absent.[14,15] An alternative explanation may be drug binding to α_2-adrenoceptors located on collecting duct epithelium. Activation of these receptors can lead to antagonism of the effects of antidiuretic hormone on cortical collecting ducts, which results in diuresis.[16] Renal afferent nerves appear to play a role in the pathogenesis of hypertension in species affected by this disorder.[9]

Autonomic innervation of the ureters, bladder, and urethra is important for ureteral peristalsis and micturition. The equine ureteral smooth muscle contains α_1- and β_2-adrenoceptors, which induce contraction and relaxation, respectively, when activated by norepinephrine.[17] Studies of the innervation of the equine ureter demonstrated greater densities of adrenergic neurons in the proximal (renal pelvis) and intravesicular (bladder wall) portions of the ureter.[18] Increased densities in these regions are consistent with the suspected pacemaker activity of the renal pelvis, which

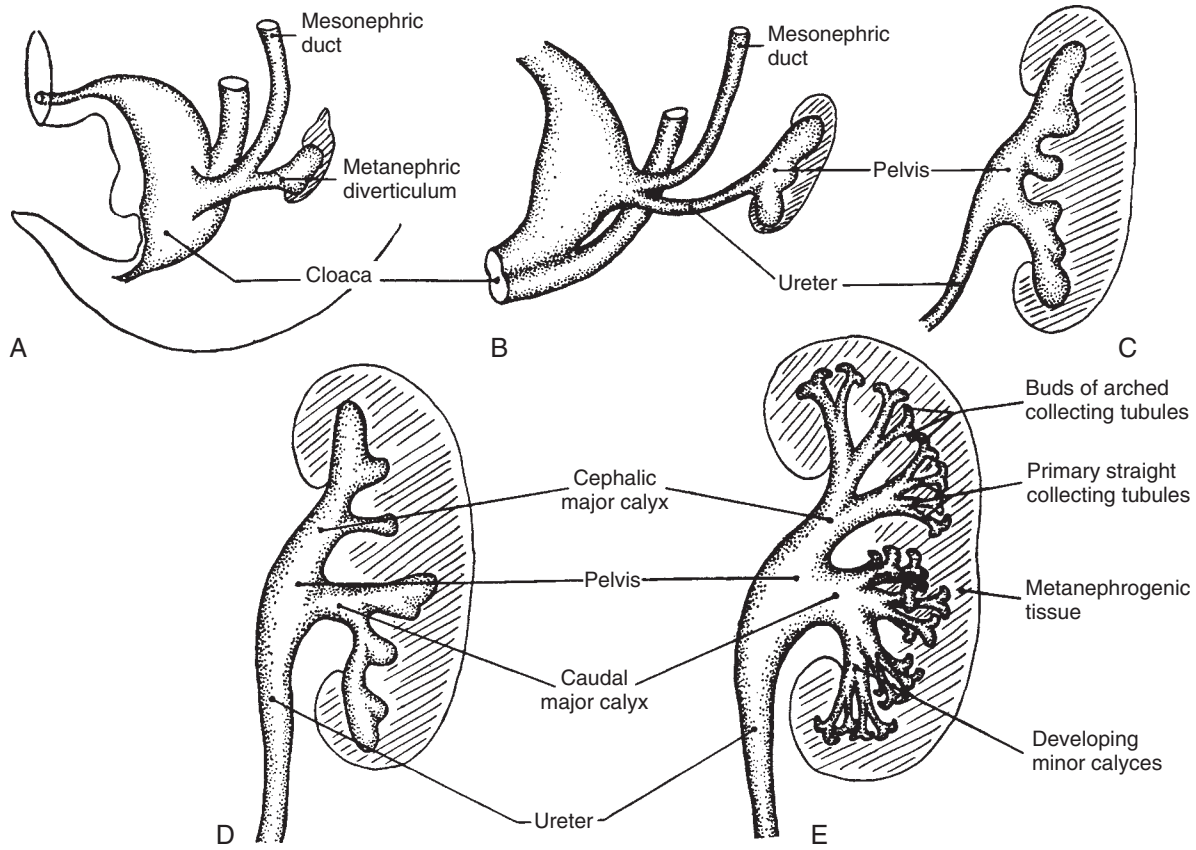

FIG. **14.2** Progression of the differentiation and development of the metanephric diverticulum into the collecting system of the mature kidney. **A,** Metanephric diverticulum originates from the caudal end of the mesonephric duct. **B,** Metanephric diverticulum develops craniad, and intermediate mesoderm (metanephrogenic tissue, hatched lines) collects about its cranial end. **C** to **E,** The metanephric diverticulum becomes the ureter and renal pelvis, and the metanephrogenic tissue becomes the collecting system and parenchyma of the mature kidney. (From Carlson BM: *Patten's foundations of embryology,* ed 6, New York, 2003, McGraw-Hill.)

initiates ureteral peristalsis and the sphincter-like function of the distal segment of the ureter. The sympathetic nerve supply to the urinary bladder is provided via the hypogastric nerve, with preganglionic fibers arriving from spinal segments L1–L4 to synapse in the caudal mesenteric ganglion. Postganglionic fibers supply the bladder (β_2-adrenergic receptors) and proximal urethra (primarily α_1- and some α_2-adrenergic receptors).[19,20] In addition to adrenergic innervation, cholinergic and peptidergic nerve fibers also innervate the equine bladder.[21] Parasympathetic innervation originates in the sacral segments of the spinal cord, with neurons joining to form the pelvic nerve.[19,20] Many complex interneuronal connections exist between sympathetic and parasympathetic nerves in the wall of the bladder, along with small adrenergic cells that facilitate interaction between sympathetic and parasympathetic pathways.[22] As a result, complete denervation of the bladder is virtually impossible. Somatic innervation of the lower urinary tract is primarily to the striated muscle of the external urethral sphincter via a branch of the pudendal nerve, which originates from the sacral cord segments (S1–S2).[1]

DEVELOPMENT

The embryonic upper urinary tract arises from bilateral primordial mesonephric ducts and intermediate mesoderm. The metanephric diverticulum originates from the caudal end of each mesonephric duct and develops craniad to become the ureter and renal pelvis. The advancing metanephric diverticuli collect about their ends intermediate mesoderm (metanephrogenic tissue), which becomes the collecting system and parenchyma of the mature kidney (Fig. 14.2). The vascular supply is derived from a branch of the aorta (renal artery) that invades the metanephrogenic tissue. The urinary bladder develops as a dilated proximal portion of the allantois. The bladder is separated from the hindgut by the craniocaudad growth of the urorectal fold, which divides the rectum from the urogenital sinus. The latter structure gives rise to the urethra (Fig. 14.3). The mesonephric and metanephric ducts initially open into the urogenital sinus, but as development continues, the distal segments of the mesonephric ducts are absorbed into the bladder wall, and the openings of the metanephric ducts are pulled craniad to their final site in the dorsal bladder neck.[23]

The fate of the mesonephric tubules (mesonephros) and mesonephric ducts varies with gender. Paired paramesonephric ducts (Müllerian ducts) arise parallel to the mesonephric ducts in both sexes. In the female, the ducts fuse distally to become the vagina and uterine body, whereas proximally they remain separate to give rise to uterine horns and oviducts. The mesonephric ducts regress into vestigial remnants termed the *epoöphoron* proximally (near the ovaries) and *Gartner's canals* distally (near the vagina and uterus; Fig. 14.4). In the

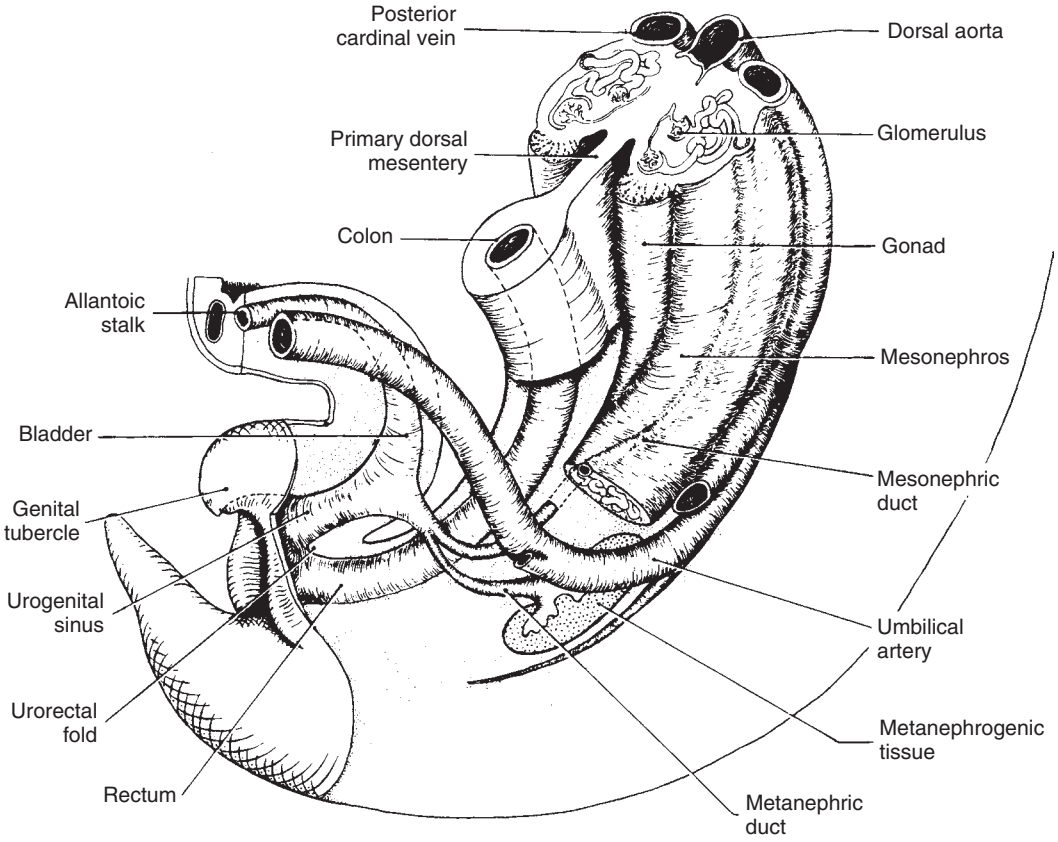

FIG. **14.3** Developing urogenital tract of the young mammalian embryo. (From Carlson BM: *Patten's foundations of embryology,* ed 6, New York, 2003, McGraw-Hill.)

male, sexual differentiation of the gonads and production of androgenic steroid hormones lead to regression of the müllerian ducts. The duct system of the male reproductive tract is appropriated from the mesonephros and mesonephric ducts (also termed *wolffian ducts*). Androgenic steroid hormones also stimulate these structures to develop into the seminiferous tubules, epididymis, and ductus deferens. The distal portion of the mesonephric duct becomes the ejaculatory duct, the terminal portion of the ductus deferens.[23]

DEVELOPMENTAL MALFORMATIONS OF THE URINARY TRACT

Anomalies of the urinary tract are uncommon in horses. A survey by Höflinger[24] revealed a similar frequency of unilateral renal agenesis (0.07%) in horses and human beings (0.10%).[5] In contrast, horseshoe kidneys (attached at the cranial or caudal poles) are the most common anomaly in human beings (0.25%) but rarely have been described in horses.[5,25]

Renal Agenesis, Hypoplasia, and Dysplasia

Renal agenesis, which may be unilateral or bilateral, results from failure of the metanephric duct to fuse with the metanephrogenic mesodermal tissue. Although unilateral anomalies have been described more frequently, this simply may reflect the incompatibility of bilateral agenesis with postnatal life.[24,26-28] Brown and colleagues[28] described a foal with bilateral renal agenesis in which severe azotemia was detected shortly after birth. Bilateral ureteral dysgenesis and cryptorchidism, agenesis of the right adrenal gland, and atresia ani accompanied renal agenesis in this foal. Unilateral defects may be incidental findings in otherwise healthy horses[29] or may be detectable during reproductive examination because many affected horses also have associated anomalies of the reproductive system. Occasionally, unilateral agenesis may result in clinical renal disease if a problem arises in the contralateral kidney. Johnson and colleagues[27] described a 4-year-old Quarter Horse with unilateral renal agenesis and a ureterolith causing contralateral hydronephrosis. The gelding was presented for weight loss, pollakiuria, and stranguria. In addition to the renal anomaly, unilateral agenesis of the ipsilateral testicle also was found on necropsy. A 9-month-old Tennessee Walking Horse colt with chronic kidney disease, unilateral renal agenesis, severe contralateral ureterolithiasis with hydronephrosis, bilateral cryptorchidism, and segmental aplasia of the ductus deferens was reported by Waldridge and colleagues.[30] Renal agenesis may be a familial disorder in several species.[25,31] Although no information is available to suggest a hereditary basis in horses, one probably should discourage repeat matings after detecting such an anomaly because congenital lesions of the urinary system are often accompanied by segmental abnormalities of the reproductive tract.

One diagnoses renal hypoplasia when one kidney is at least 50% smaller than normal or when the total renal mass is decreased by more than one third.[25] Renal hypoplasia is a quantitative defect caused by a reduced mass of metanephrogenic tissue or by incomplete induction of nephron formation by the metanephric duct. This condition may be confused with renal dysplasia. Unilateral renal hypoplasia usually is associated

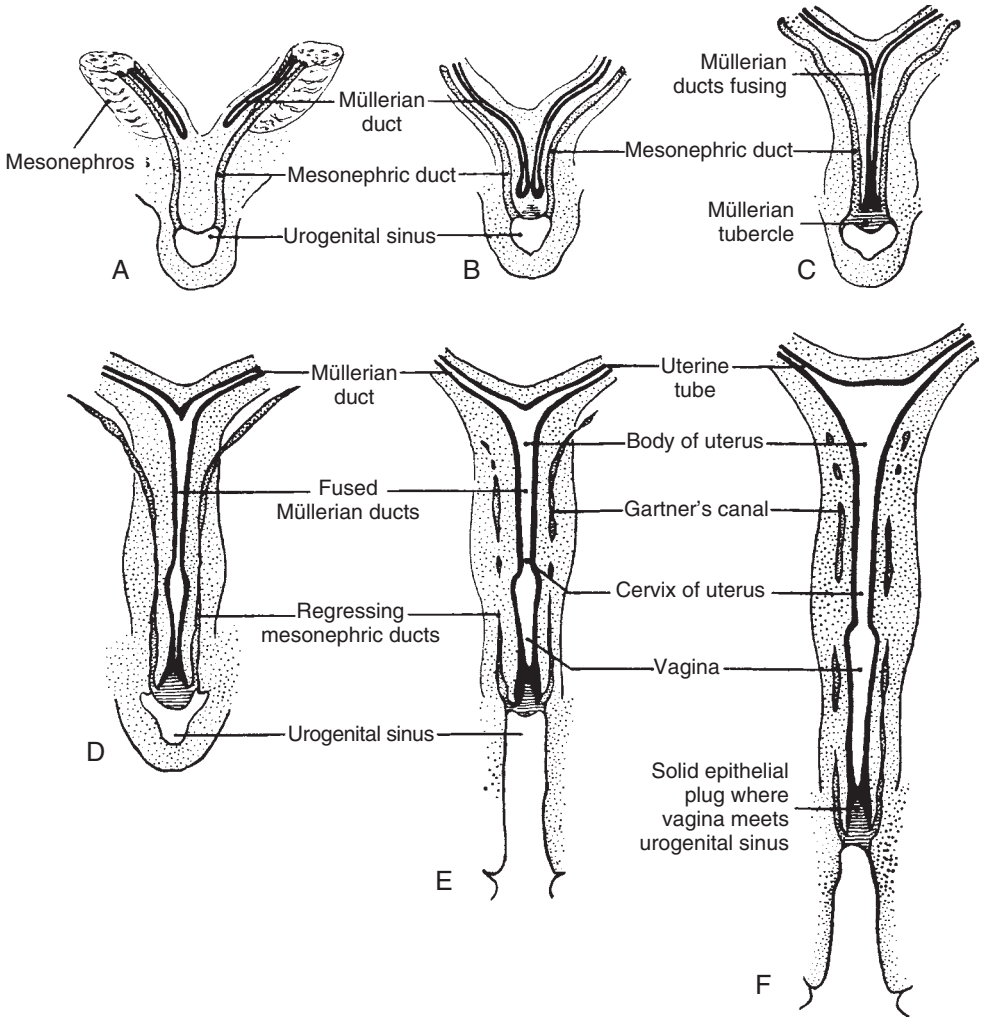

FIG. **14.4** Development of the mesonephric tubules (mesonephros) and mesonephric ducts into the female reproductive tract. **A** and **B,** Paired paramesonephric ducts (müllerian ducts) arise parallel to the mesonephric ducts in both sexes. **C** to **E,** In females, the paramesonephric ducts fuse distally to become the vagina and uterine body but remain separate proximally to give rise to uterine horns. **D** and **E,** The mesonephric ducts regress into vestigial remnants termed *Gartner's canals.* (From Carlson BM: *Patten's foundations of embryology,* ed 6, New York, 2003, McGraw-Hill.)

with contralateral hypertrophy and normal renal function, whereas bilateral hypoplasia generally leads to chronic kidney disease.[25,31] Andrews and colleagues[32] described bilateral renal hypoplasia in a foal presented after death and in three young horses with chronic kidney disease that had poor growth from birth. Anomalies in these four horses were limited to the upper urinary tract.

Renal dysplasia is disorganized development of renal tissue caused by anomalous differentiation, intrauterine ureteral obstruction, in utero viral infection, or teratogens.[25,33] Bilateral dysplasia usually leads to renal failure. In general, dysplastic kidneys are normal in size unless concurrent hypoplasia exists or the animal lives for months to years before developing renal failure. Roberts and Kelly[34] reported a case of bilateral renal dysplasia in a 19-month-old pony gelding. The pony was presented for weight loss over a 3-month period, and clinicopathologic assessment revealed chronic kidney disease. A small, firm, and nodular left kidney was palpable per rectum. At necropsy, the kidneys weighed 280 g each (33% smaller than normal for body weight) and were nodular. Renal dysplasia was suspected because glomeruli in the collapsed areas of the kidneys were small, tubules were immature, and inflammatory cells were scant. Six similar cases of bilateral renal dysplasia resulted in chronic kidney disease in horses from 2 months to 7 years of age.[35-39] Small kidneys with increased echogenicity and an indistinct corticomedullary junction were typical ultrasonographic findings,[37-39] and these findings were corroborated by computed tomography in one Miniature Horse foal.[39] At necropsy, kidneys were typically small and irregular, the cortex and medulla were not well delineated, and immature glomeruli and primitive tubules were found on histologic examination (Fig. 14.5). Renal dysplasia also may cause renal failure in neonates. For example, Zicker and colleagues[40] reported a case of renal dysplasia in a 2-day-old Quarter Horse foal presented for diarrhea and depression. Clinicopathologic assessment revealed azotemia, hyponatremia, hypochloremia, and urinary sodium wastage. At necropsy, the kidneys were normal in size (380 g), but histologic examination revealed immature glomeruli, hypoplastic tubules and vasa recta, and extensive myxomatous connective tissue occupying 90% of the

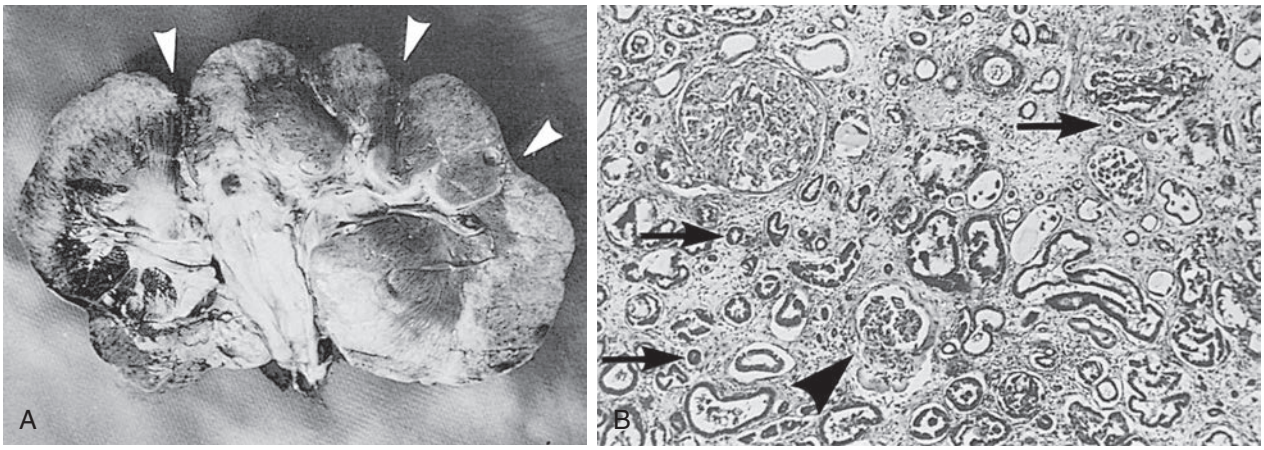

FIG. **14.5** **A,** Longitudinal section of the right kidney from a 7-year-old Arabian gelding with renal dysplasia shows focal, irregular thinning of the cortex *(arrowheads)* resulting in a nodular surface and poor delineation of the corticomedullary junction. **B,** Histologic section of same kidney (Masson trichrome stain; original magnification ×35) reveals an immature glomerulus *(large arrowhead)* and primitive tubules *(arrows)* surrounded by persistent mesenchyme. total medullary volume. Finally, renal dysplasia also may be a unilateral problem that does not result in renal failure. Jones and colleagues[41] found ureteropelvic polyps to be the cause of unilateral hydronephrosis and renal dysplasia in a Trakehner colt. Poor growth and hematuria for several weeks were the presenting complaints. Renal function remained normal for 8 months after nephrectomy until the colt developed a severe bout of colic, prompting euthanasia. Ureteral obstruction by the polyps was the suggested cause of renal dysplasia, because urinary tract obstruction has been found in a large percentage of cases of human renal dysplasia.[33]

Renal Cysts

One or more renal cysts occasionally are discovered as incidental findings on necropsy examination. The cysts may arise from any portion of the nephron but more often occur in the renal cortex than in the medulla. The pathogenesis is not known, but a defect in the basement membrane that allows tubular dilation is suspected. Renal cysts vary in size from microscopic to as large as the organ itself and routinely have a clear to slightly opaque wall and contain a thin, clear fluid. Congenital cysts are differentiated easily from acquired cysts (after obstruction) by the extensive scarring that accompanies the latter. Renal cysts also may develop as a consequence of drug therapy (i.e., long-acting corticosteroids) or exposure to certain chemicals.[25,31]

Polycystic Kidney Disease, Glomerulocystic Disease, and Other Hereditary Nephropathies

Polycystic kidney disease (PKD) is a disorder in which numerous, variably sized cysts are found throughout the cortex and medulla. With glomerulocystic disease, cysts are microscopic and limited to Bowman's spaces. Cysts of the bile duct and pancreas also may occur with PKD, and both conditions have been described in stillborn offspring in many species, including foals.[25] The two major types of human PKDs are (1) a rare congenital or infantile form inherited as an autosomal recessive trait (which may be found in stillbirths) and (2) a more common adult form inherited as an autosomal dominant trait that leads to renal insufficiency in later life in association with dramatically enlarged, cystic kidneys.[42,43] The latter form of PKD develops because of mutations in genes encoding for polycystins, integral membrane proteins responsible for cell-to-cell interaction.[44] Autosomal dominant PKD also has been documented in Persian cats and related breeds and in bull terriers.[45-47] The genetic defect in Persian cats is thought to be similar to the most common defect in human beings (PKD1 gene) and leads to end-stage renal disease by 3 to 10 years of age.[46] As in human beings, the disorder is detectable by renal ultrasonographic screening of juvenile cats and preventable by avoiding subsequent mating of affected animals. Nevertheless, because of heavy inbreeding, the prevalence of PKD in Persian cats and related breeds is between 40% and 50%.[45,46]

Ramsey and colleagues[48] described polycystic kidneys in a 9-year-old Thoroughbred mare that exhibited anorexia and weight loss. Clinicopathologic assessment revealed chronic kidney disease, and euthanasia was performed. At necropsy, the kidneys were grossly enlarged, and each weighed 12 kg (Fig. 14.6). A similar case of bilateral PKD was described in a 15-year-old pony with a 4-week history of hematuria and moderate weight loss. Evaluation revealed azotemia and presence of large masses near both kidneys on rectal examination and dramatically enlarged polycystic kidneys weighing 11.4 and 9.1 kg, respectively, were found at necropsy.[49] Bertone and colleagues[50] reported a third case of adult PKD in a 10-year-old Paint gelding with weight loss. The horse was mildly azotemic, and several 2- to 15-cm-diameter cysts were imaged in both kidneys during ultrasonographic examination. In human beings, polycystic kidneys are believed to result in renal failure as cysts expand (sometimes under pressure) and compress adjacent normal renal tissue. Altered compliance of tubular basement membranes and proliferation of renal tubular epithelium result in outflow obstruction and proximal ballooning, leading to renal cyst formation.[43] In some human cases, pressure within cysts may be 5 to 10 times higher than surrounding interstitial tissue pressures. Bertone and colleagues[50] did not find increased pressure in several cysts catheterized

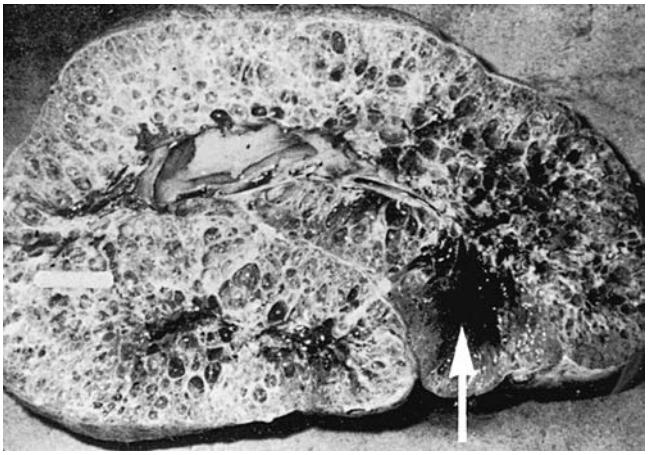

FIG. **14.6** Longitudinal section of the left kidney (35 cm long, 25 cm wide, 20 cm deep, and weighing 12 kg) from a 9-year-old Thoroughbred mare with polycystic kidneys. A calculus is located in the renal pelvis, and the arrow demonstrates the only grossly normal-looking renal parenchyma. (From Ramsey G, Rothwell TLW, Gibson KT, et al.: Polycystic kidneys in an adult horse, *Equine Vet J.* 19:243, 1987.)

percutaneously in a gelding with PKD, but differences in sodium concentrations suggested that the sampled cysts had arisen from different segments of the renal tubule. Euthanasia was performed after a prolonged hospitalization (235 days), and the kidneys were not grossly enlarged except where distorted by large cysts. Although not well documented, PKD has been described anecdotally in two additional Paint Horses, suggesting that an inherited form of PKD may occur in that breed. Another report also documented PKD in an 11-year-old Andalusian gelding.[51]

In addition to PKD, a variety of other hereditary nephropathies have been described in humans.[49] Similar disorders are starting to be recognized in domestic animals, including hereditary nephritis in bull terriers, Samoyeds, and English cocker spaniels. Analogous to Alport syndrome in human beings, a defective molecular structure of type IV collagen, an important component of the glomerular basement membrane, appears to be the cause of hereditary nephritis in these dog breeds.[47] Similarly, a syndrome of renal tubular dysplasia with autosomal recessive pattern of inheritance has been described in a population of highly inbred Japanese black cattle,[52-54] as has a syndrome of suspected hereditary renal oxalosis in Beefmaster calves.[55] Similar hereditary nephropathies are likely to occur in horses; however, to date the only one documented is a syndrome of nephrogenic diabetes insipidus in Thoroughbreds.[56]

Vascular Anomalies

Anomalies of the vascular supply to the equine urinary tract are rare but may result in hematuria, hemoglobinuria, partial ureteral obstruction, or hydronephrosis.[31,57] Latimer and colleagues[58] described a distal aortic aneurysm and associated extrarenal arteriioureteral fistula in a 5-month-old colt presented for intermittent hematuria, colic, and lameness. Partial ureteral obstruction and hydronephrosis were observed on the affected side. Intrarenal vascular anomalies, termed *renal arteriovenous malformations,* are similarly rare (reported frequency of 0.04% in humans).[59] Interestingly, vascular malformations may be silent until later in life, when varying degrees of hematuria and flank pain may ensue. The anomalous vessels are often tortuous and may be enlarged focally and devoid of elastic tissue. Hematuria and hemoglobinuria are thought to arise from areas where the anomalous vessels lie close to the collecting system.[59,60] With vascular anomalies, one should attempt to determine the extent of the defect (unilateral or bilateral) via ultrasonographic examination, contrast radiographic studies, or cystoscopy (visualization that hematuria is coming from one or both ureteral orifices). When a unilateral defect is documented in the absence of azotemia, unilateral nephrectomy or selective renal embolization has been recommended to prevent possible fatal exsanguination through the urinary tract[57,58]; however, one may consider conservative treatment if the urinary tract bleeding is minor and has not resulted in anemia.

A large vascular anomaly resulting in transient hemoglobinuria has been reported in a Quarter Horse colt.[61] Over several weeks, the large anomalous vascular structure (Fig. 14.7) spontaneously filled with a thrombus so that specific treatment (a nephrectomy) was not pursued. Severe adult-onset, idiopathic renal hemorrhage also has been described in horses.[62] Whether this latter syndrome may have been a consequence of congenital renal vascular malformations has not been determined (see Hematuria later in this chapter). Occasionally, gross hematuria with passage of blood clots can accompany omphalitis or bladder rupture.[63] One usually can detect these problems during ultrasonographic examination of the umbilical structures and sometimes can image tissue echogenicity within the bladder that is attributable to a blood clot.

Pendulant Kidney

A pendulant kidney is a rare anomaly in the horse.[64] Rectal examination reveals an extremely mobile kidney attached to the dorsal body wall by a thin band of tissue. Although a pendulous kidney could result from extreme weight loss, hydronephrosis, or perirenal trauma, the condition is usually thought to be congenital. The abnormality is an incidental finding unless displacement or rotation leads to partial or complete ureteral obstruction. As an example, the author has palpated the entire right kidney of one mare immediately craniad of the pelvic canal, and ultrasonographic imaging revealed normal size and structure of the anomalously located kidney.

Ectopic Ureter

Although ureteral ectopia occurs rarely in the horse,[65] it is the most commonly reported developmental anomaly of the equine urinary tract.[65-83] Ectopic ureters may develop when (1) the ureteric bud (metanephric duct) fails to be incorporated into the urogenital sinus or fails to migrate craniad to the bladder neck or (2) the mesonephric duct fails to regress. In the former case, the ectopic ureter opens near the urethral papilla in females or into the pelvic urethra near the colliculus seminalis in males, whereas in the latter, the ureter may open anywhere along the vagina, cervix, or uterus (but only in females because this portion of the mesonephric duct becomes the Wolffian duct system in males). In 118 reported cases of ectopic ureter in horses, 105 (89%) were females[66-69,73-78,80-83]; however, this sex distribution may reflect easier recognition of the presenting complaint of urinary incontinence in females rather than a true sex predilection. Incontinence is recognized more often in females because urine entering the pelvic urethra in males may pass retrograde into the bladder. Although a genetic predisposition for ectopic ureter exists for

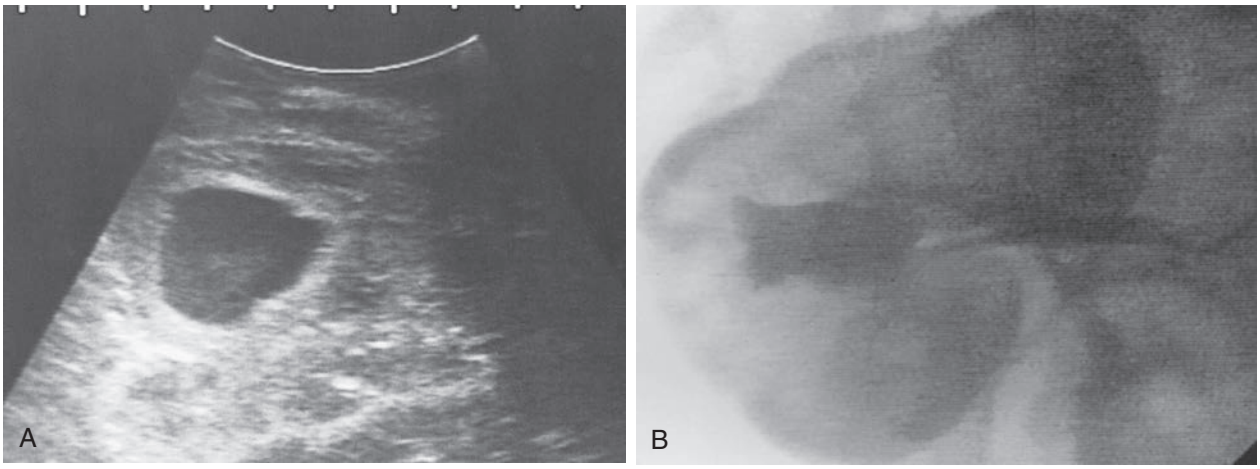

FIG. **14.7** Ultrasonographic image of the right kidney of a 9-day-old Quarter Horse colt shows a 2 × 3–cm hypoechoic cavity on a dorsal oblique view. **A,** A swirling pattern, similar in appearance to blood in the ventricles of the heart, was consistent with an arteriovenous malformation. **B,** In a selective nephrogram of the right kidney of the same colt at 20 days of age, immediately after injection of contrast, a dilated vascular space was demonstrated (contrast appears dark because of reverse gray scale) and the renal cortical tissue abaxial to this structure appeared to have reduced capillary phase contrast. (From Schott HC, Barbee DD, Hines MT, et al.: Renal arteriovenous malformation in a Quarter horse foal, *J Vet Intern Med.* 10:204, 1996.)

several dog breeds,[84] no breed predilection has been established in horses. However, Quarter Horses may be at greater risk because the condition has been reported in five Quarter Horses, three Standardbreds, two Thoroughbreds, two Appaloosas, an Arabian, a Clydesdale, a Shire, a Friesian, a Foxtrotter, and a Warmblood. The author also has seen the condition in two Quarter Horse fillies (one unilateral and one bilateral), yielding a total of 20 cases.

In horses with ureteral ectopia, urinary incontinence is generally apparent from birth, and affected animals are presented for extensive scalding of the hindlimbs. With unilateral ectopia, horses also void normally, because the other ureter enters the bladder in the appropriate location. Renal function is usually normal, but the affected ureter may be greatly dilated. Urine pooling in the vagina and uterus was a complicating factor in one case.[74] To determine the site of the ectopic ureteral orifice (or orifices), one initially visually examines the vestibule and vagina (using a blade speculum) to look for intermittent urine flow from the area of the urethral papilla. Ectopic ureteral openings usually are not apparent unless urine flow is visible. Endoscopy may be helpful in females (while inflating the vestibule and vagina with air and using a hand to form a seal at the vulva) and is required in males to visualize the ectopic ureteral opening. Intravesical placement of methylene blue dye was performed in one filly to provide evidence for ureteral ectopia. Continued dribbling of clear urine (from the ectopic ureter) followed by passage of blue, discolored urine indicated that only one ureter emptied into the bladder but provided no information on the location of the opening of the ectopic ureter.[67] Intravenous administration of dyes—including sodium fluorescein (10 mg/kg intravenously [IV]; yellow-green), indigotindisulfonate (indigo carmine, 0.25 mg/kg IV; blue-purple), azosulfamide (2.0 mg/kg IV; red), or phenolsulfonphthalein (1.0 mg/kg IV; red)—to discolor the urine may help locate ectopic ureteral openings.[85] Contrast radiography (excretory urography or retrograde contrast studies via catheterization of the bladder and ureters) has been used to detail renal architecture and the course of the ureters in some affected animals; however, results of intravenous urograms are frequently inconclusive and difficult to interpret in foals weighing more than 50 kg (contrast agent is poorly imaged). Ultrasound-guided pyelography, in which contrast agent was injected directly into the renal pelvis using a spinal needle, proved to be a more effective technique than intravenous administration of contrast agent to detail the course of an ectopic ureter, and one should consider this technique in future cases.[83]

Treatment has included ureterocystostomy (surgical reimplantation of the ectopic ureter or ureters into the bladder) or unilateral nephrectomy. Before surgery, one must determine whether the condition is unilateral or bilateral, which side is affected if unilateral, and whether urinary tract infection is present. Further, one should attempt to rule out other anomalies, especially of the reproductive tract. If the problem is bilateral (8 of 20 cases), one should establish the presence of a normal micturition response by measuring the intravesicular pressure response to progressive distention until the fluid infused is voided spontaneously. This procedure provides an estimate of bladder volume and ensures competency of the urethral sphincter before reimplantation. Among 14 cases in which surgical correction was pursued, ureterocystostomy was successful in establishing a functional urinary system in nine published cases and one foal seen by the author, but four died of postoperative complications.[69,76,83] In contrast, all four cases treated by unilateral nephrectomy had a favorable outcome.[73,74,80] Because affected ureters often are dilated and tortuous, surgical reimplantation can be difficult and may not result in a functional ureteral orifice. Consequently, when the problem is unilateral, nephrectomy of the affected side may be the preferred treatment option.[86,87]

Ureteral Defects or Tears (Ureterorrhexis)

Retroperitoneal accumulation of urine and uroperitoneum has been described in seven foals with unilateral or bilateral ureteral defects[88-94] and has been observed in three additional foals by the author. These included seven male and three female foals

of several breeds (five Standardbreds, two Thoroughbreds, one Belgian, one Oldenburg, and one Appaloosa). Clinical signs (decreased nursing, depression, abdominal distention, diarrhea, and muscle twitching or other signs of neuromuscular irritability) and clinicopathologic abnormalities (hyponatremia, hyperkalemia, hypochloremia, and azotemia) are similar to those in horses with bladder rupture but may have a slightly later onset (4–16 days of age). Mild protrusion of the vagina may occur in fillies if the peritoneum has remained intact.[95] In affected foals, ultrasonographic examination may reveal dilation of the renal pelvis and affected ureter, as well as fluid accumulation around the kidneys or farther caudad within the retroperitoneal space. As with ectopic ureters, excretory urography generally has been an unrewarding diagnostic procedure, but contrast pyelography was used successfully to image leakage of contrast agent from a proximal ureteral defect.[94] Contrast radiography has not been pursued routinely because exploratory celiotomy generally was performed shortly after a diagnosis of uroperitoneum. Catheterization of the ureters via a cystotomy and retrograde injection of methylene blue allowed localization of the defect (or defects), and surgical correction was performed successfully in four cases by suturing the defect around an indwelling catheter.[90,91,94] Although ascending urinary tract infection should be an expected complication with a stent, repair of a defect in one foal without use of an indwelling catheter resulted in further urine leakage from the ureter, prompting a nephrectomy 4 days after the initial surgery.[92] Of the remaining five foals, one died after three unsuccessful attempts at surgical repair,[89] and euthanasia was performed in four cases without attempting repair.[88,93]

At surgery or necropsy, a single defect was found in six foals, whereas bilateral defects were found in four foals and multiple defects were apparent in one ureter. In most cases the defects have been located in the proximal third of the ureter near the kidney. Interestingly, distended, tortuous ureters, occasionally accompanied by hydronephrosis, also were described in three affected foals,[89,92,94] and distal obstruction of the ureters at the bladder was suspected in two of these cases, prompting ureteroneocystostomy. Although several reports suggest that ureteral defects may be anomalies of development, the actual cause of these ureteral defects is not known. Traumatic disruption was suggested in the initial report in which histologic examination of the margins of the defect revealed hemorrhage and proliferation of immature connective tissue.[88] A traumatic cause was further supported by a subsequent report in which histologic examination of the defects revealed absence of transitional epithelium and inflammation in a foal that had been attacked by dogs.[93] Inflammation and granulation tissue also were visible in the apparently obstructed distal ureter in one of the foals with ureteral distention, again suggesting an acquired lesion. Blunt abdominal trauma, often sustained during automobile accidents, can cause retroperitoneal accumulation of urine and uroperitoneum in humans.[96] Disruption of the ureter is usually near the kidney, and this complication of trauma may not be recognized for several days after injury. In one foal evaluated by the author, multiple rib fractures found at necropsy suggested that these ureteral tears actually could be a complication of foaling trauma.

Rectourethral and Rectovaginal Fistulae

If the urorectal fold fails to separate completely the primitive hindgut from the urogenital sinus, a rectourethral fistula may be found in a colt or a rectovaginal fistula or persistent cloaca may be found in a filly.[97] These anomalies are rare in horses and when present are usually associated with atresia ani and other anomalies, including agenesis of the coccygeal vertebrae and tail, scoliosis, adherence of the tail to the anal sphincter area, angular limb deformities, and microphthalmia.[71,72,98-103] Affected foals are usually examined for atresia ani, although one also may observe signs of colic and straining. Evidence for a fistula is passage of fecal material from the vulva or urethra. In fillies, one may detect rectovaginal fistulae by digital palpation of the dorsal vestibule and vagina, but in colts a definitive diagnosis usually requires contrast radiographic procedures such as a barium enema or a retrograde urethrogram (Fig. 14.8). Surgical correction of atresia ani and fistulae has been performed successfully in several foals, but multiple surgical procedures may be required. Because ascending urinary tract infection may be a complication, one should submit a sample of urine collected via bladder catheterization (preferably during surgery) for bacterial culture.[97] In humans, evidence suggests that these anomalies are hereditary, and in one report, several foals born with atresia ani were sired by the same stallion.[98] Consequently, affected horses should not be used for breeding after surgical correction of the anomalies.

FIG. **14.8** A positive contrast urethrogram in a 3-day-old burro that had atresia ani and intermittent passage of fecal material from the urethra. A catheter passed via the urethra and contrast agent injected into the catheter resulted in accumulation of a large amount of contrast agent in the rectum and a lesser amount in the intrapelvic portion of the urethra. A small amount of contrast agent is visible in the urethrorectal fistula *(arrow)*.

A urethrorectal fistula resulting in passage of urine from the anus also has been described in a 3-year-old Thoroughbred gelding.[104] The fistula in this gelding was thought to be acquired after trauma or straining because no other developmental problems were detected, and the edges of the defect were irregular and inflamed when examined with a speculum inserted into the rectum.

Bladder Defects

Uroperitoneum may result from bladder rupture during parturition in foals (most commonly males)[105] or as a consequence of urachal leakage after infection of the umbilical structures.[106,107] In addition, Wellington described uroperitoneum in two foals that were full brothers.[108] Urine entered the abdomen from a dorsal defect in both colts, and smooth margins to the defects combined with a lack of appreciable inflammation

provided evidence in favor of anomalous development rather than trauma. Other authors have suggested that some cases of uroperitoneum likely are associated with anomalous bladder defects because of the size, location, or lack of apparent inflammation of the margins of the defects.[71,109-112] For example, Bain[109] described uroperitoneum in a foal in which the ventral portion of the bladder was absent between the lateral ligaments (umbilical artery remnants) from the umbilicus to the urethra.

Anomalous fusion of the bladder to the inner umbilical ring (absence of the urachus) has been described in one foal.[113] The malformation precluded normal contraction and evacuation of the bladder, and a megavesica (a greatly enlarged bladder) developed. The clinical appearance was similar to uroperitoneum and surgical separation of the bladder from the umbilical ring restored normal anatomic and functional integrity of the bladder. A similar case with a greatly distended bladder was reported in a foal evaluated for abdominal distention[71] that was attributed to an adhesion of the bladder to the urachus or umbilical remnant. An enlarged, flaccid bladder also was described in a foal undergoing exploratory celiotomy for suspected urinary tract disruption.[106] Adhesions to the abdominal wall were not reported, and the foal survived after the surgery, during which 50% of the distended bladder was resected. In addition to bladder distention, persistent attachment of the bladder to the area of the umbilicus via a urachal remnant was reported to cause pollakiuria and dysuria in a 15-month-old Thoroughbred filly.[114] The author also has seen postpartum bladder rupture in a mare in which a persistent urachal attachment was suspected to be a contributing factor.

Excessive bladder distention or megavesica has been described further in four stillborn foals[115] and one neonatal foal.[116] In the latter foal and in another report,[117] chronic bladder distention appeared to lead to loss of smooth muscle in the dorsal bladder wall and its replacement with collagen. The result was bladder rupture during parturition. Although these reports are similar to an early report by Rooney[105] describing the dorsal bladder wall as the anatomic weak link and likely area for rupture, they differ in that chronic distention of the bladder in utero with smooth muscle loss is not recognized in more typical bladder ruptures in neonatal foals. Why bladder distention should occur in utero without obstruction of the lower tract (not found in these cases) is not clear. Although an excessively long umbilical cord (longer than 85 cm) may lead to urachal obstruction,[115,118] urine produced in utero alternatively could drain into the amniotic cavity via the urethra. Thus megavesica remains poorly characterized and poorly understood.

Bladder distention also is recognized in some foals with hypoxic-ischemic encephalopathy. Affected foals may posture to urinate frequently, and ultrasonographic examination may reveal an enlarged bladder or incomplete bladder emptying. In recumbent foals, one may note abdominal distention, and temporary use of an indwelling bladder catheter to keep the bladder empty is helpful; however, ascending urinary tract infection may be a complication. Cystometrography would be useful to assess detrusor function in affected foals, but no reports describe this diagnostic test in equine neonates. Although administration of cholinergic drugs (e.g., bethanechol) to improve detrusor function or α-adrenergic blockers (e.g., phenoxybenzamine, acepromazine) to decrease urethral sphincter tone has been described anecdotally to be of benefit, no reports describe the efficacy of these medications in foals with this problem.

Some neonatal foals examined for abdominal pain are apparently unable to urinate normally. Ultrasound examination will reveal a normal gastrointestinal tract and a greatly enlarged but intact urinary bladder. These foals can be treated with indwelling urinary catheters for 2 to 3 days along with phenazopyridine (4 mg/kg orally [PO] every 8–12 hours) for 5 to 7 days.[119] Phenazopyridine acts as a local analgesic on the lower urinary tract and may relieve spasm or allow better relaxation of the bladder sphincters and promote normal micturition.

Patent Urachus

The urachus is the conduit through which fetal urine passes from the bladder into the allantoic cavity. Normally, the urachus closes at the time of parturition, but incomplete closure is the most common malformation of the equine urinary tract. Patent urachus occurs more commonly in foals than in other domestic species.[31] Greater than average length or partial torsion of the umbilical cord has been suggested to cause tension on the attachment of the umbilical cord to the body wall. The result is dilation of the urachus and subsequent failure to close at birth.[71,72,115,118,120] Patent urachus results in a persistently moist umbilicus after birth, from which urine may leak as drips or as a stream during micturition. One must distinguish this malformation from septic omphalitis, which also can result in urine leakage from the umbilicus within a few hours to days after birth. Ultrasound examination of the umbilical remnants is indicated to rule out or monitor for concurrent omphalophlebitis. Patent urachus has been referred to as a *congenital problem* and the latter as an *acquired problem,* but both may result in urine leakage from the urachus from birth. Neither is life threatening, but local sepsis often is accompanied by more severe illness, including septicemia or localized infection, particularly in joints.

The congenital patent urachus traditionally has been treated with frequent (two to four times daily) chemical cauterization of the urachus with swabs dipped in a concentrated phenol or 7% iodine solution or with silver nitrate applicators.[70] Because the urachus may close spontaneously in a number of cases and because these agents desiccate and irritate tissue (and may predispose to infection), the rationale for this approach is questionable.[120] In a study comparing the effects of disinfectant solutions on the bacterial flora of the umbilicus of normal foals, use of a 7% iodine solution was observed to cause rapid desiccation of the umbilical tissue and subsequent development of a patent urachus when the stump fell off a few days later.[121] Chlorhexidine diacetate (0.5%) appears to be more effective than 1% to 2% iodine solutions in reducing umbilical bacterial counts. Chlorhexidine is less irritating to tissue, binds to the stratum corneum, and has prolonged antiseptic effects.[121] The use of caustic or irritating solutions for routine umbilical dipping or treatment of patent urachus should probably be avoided because it may lead to localized necrosis and infection that may actually result in umbilical infections.

Consequently, in the absence of apparent infection, no local treatment may be indicated specifically, but affected foals frequently are given antibiotics prophylactically. For acquired patency (which may be associated with local infection, cachexia, or septicemia), broad-spectrum antibiotic therapy is indicated, and resolution of the systemic disease may be accompanied by elimination of the umbilical infection and closure of the urachus. Most cases of patent urachus without septic omphalophlebitis will resolve with supportive care, routine umbilical disinfection,

and antibiotic therapy. Empiric antibiotic therapy with antibiotics that are eliminated (and concentrated) in urine, such as potentiated sulfonamides, cephalosporins, aminoglycosides, or penicillins, usually provides adequate antimicrobial protection with uncomplicated patent urachus in otherwise healthy foals. Chemical cauterization is contraindicated with local sepsis because it may increase the risk of urachal rupture and development of uroperitoneum.[122] If one observes no decrease in urine leakage after 5 to 7 days of medical therapy, or if ultrasonography reveals abnormalities of multiple structures in the umbilicus,[123,124] surgical exploration and resection of the urachus and umbilical vessels may be indicated. In a retrospective study of 16 foals treated for sepsis of umbilical cord remnants, six of nine (67%) survived after surgical resection and antibiotic treatment, whereas only three of seven (43%) survived after antibiotic treatment alone.[125] Although this series of 16 foals often is cited in support of surgical intervention, one should note that the series studied a small number of foals and the cases were evaluated over 10 years (1975–1985), during which time many aspects of neonatal care improved. In a subsequent retrospective report of 33 foals with umbilical remnant infections, no difference in survival was observed between foals treated with antibiotics combined with surgical resection or with antibiotic therapy alone.[124] Further, emphasis was placed on the insensitivity of palpation of the umbilicus in detection of umbilical remnant infection (compared with ultrasonographic examination) and the poor outcome of cases in which the umbilical vein was involved. In addition to the possibility of omphalitis leading to urachal rupture and development of uroperitoneum, urachal leakage also may occur into the abdominal musculature and subcutaneous tissues and lead to progressive swelling and cellulitis of the ventral abdominal wall and/or prepuce.[126] Both instances require surgical intervention. Finally, trauma or tearing of the urachus also can lead to umbilical evagination of the urinary bladder,[127] which can result in partial or complete obstruction of urine flow, and surgical correction is indicated.

Renal Physiology

Harold C. Schott II

The kidneys perform two essential functions in the maintenance of homeostasis: (1) elimination of nitrogenous and organic waste products and (2) control of body water content and ion composition. In addition, the kidneys are important endocrine organs that produce renin, erythropoietin, and the active form of vitamin D; they also play an important role in the degradation and excretion of a number of other hormones, including gastrin and parathormone. To gain an understanding of the pathophysiologic alterations associated with renal disorders in horses, one must first review some aspects of normal renal physiology in this species.

PRODUCTION AND ELIMINATION OF NITROGENOUS AND ORGANIC WASTES

The two most commonly recognized waste products excreted in urine are urea and creatinine (Cr), but many other nitrogenous or organic wastes are produced each day and subsequently are eliminated by the kidneys (Box 14.1).[128]

BOX 14.1 Compounds Excreted by the Kidneys

- Urea
- Phenols
- Indoles
- Skatoles
- Hormones
- Polyamines
- Trace elements
- Serum proteases
- Creatinine (Cr)
- Pyridine derivatives
- Guanidino compounds
- β_2-Microglobulin
- Hippurate esters
- Aliphatic amines
- Aromatic amines
- Middle molecules

Urea Metabolism

A molecule of urea is produced in the liver from two ammonium ions that are liberated during catabolism of amino acids. For each urea molecule, the carbon atom is derived from bicarbonate. One ammonium ion is cleaved from an amino acid via an α-ketoglutarate–dependent transamination coupled to oxidative deamination of glutamate. The second ammonium ion is derived from aspartate in the urea cycle.[129] Urea synthesized in the liver is released into the blood, and clearance by the kidneys represents the major pathway (75%–100%) of excretion. Extrarenal urea excretion includes losses in sweat and through the gastrointestinal tract. With normal intestinal function, enteric excretion is minimal because of enterohepatic recirculation (reabsorption of ammonia from the degradation of urea by bacterial ureases and subsequent reformation of urea in the liver).[130]

In human beings, inborn errors of metabolism leading to deficiency of a specific transaminase or of one of the five enzymes of the urea cycle can result in accumulation of ammonia and other intermediates of amino acid catabolism. These disorders typically are inherited as autosomal recessive traits, and their consequence is moderate to severe mental dysfunction because the accumulated intermediates can be toxic to the central nervous system (CNS; i.e., ammonia) or can act as false neurotransmitters (i.e., aromatic amines).[128] Because urea production is limited in these disorders, blood urea nitrogen (BUN) concentration is often low.[129] Although such defects in metabolism appear to be rare in domestic animals,[131] development of encephalopathy in association with hyperammonemia has been recognized in horses.[132,133] Furthermore, in one report of two related Morgan weanling fillies, persistent hyperammonemia was suspected to be caused by a defect in a mitochondrial ornithine transporter similar to an autosomal recessive syndrome of hyperornithinemia, hyperammonemia, and homocitrullinuria in human beings.[134]

BUN concentration depends on age, diet, rate of urea production, and renal function. For example, a low BUN typically is found in neonatal foals because of an anabolic demand for amino acids.[135] Investigations of nitrogen use in ponies have demonstrated that urea production is proportional to dietary protein content. Similarly, urinary urea excretion increases in proportion with urea production.[136,137] As a result, with

increased levels of dietary protein or when urea is supplemented in the diet, BUN may increase twofold or greater.[138-140]

In human beings and small animals, BUN is routinely higher in samples collected postprandially because diets are typically high in protein.[130] Postprandial elevation of BUN has not been described in horses or other herbivores. However, fasting leads to enhanced protein catabolism to meet energy demands and increased BUN in horses.[141,142] In ponies, however, BUN decreases with fasting.[143] This opposite response suggests differences in the metabolic responses of horses and ponies to anorexia, consistent with a greater capacity of ponies to mobilize and use fat during starvation. Other causes of protein catabolism, including fever, infection, trauma, myositis, burns, and corticosteroid therapy, also can produce an increase in BUN.[130] Finally, a decrease in renal blood flow or function increases BUN. The former may occur with dehydration or during periods of anesthesia or exercise; the latter is a reflection of renal disease.[130] With short bouts of moderate to intensive exercise, BUN often does not change[140,144]; however, during prolonged exercise BUN can increase by 50% or more because of the combined effects of decreased renal blood flow and protein catabolism.[145,146]

Most renal nitrogen excretion occurs in the form of urea in urine. One must recognize that urea excretion is completely passive and that the high concentrations achieved in urine are merely a consequence of medullary tonicity produced by the countercurrent-multiplier function of the loop of Henle. Thus although variations in dietary protein intake lead to parallel changes in urea excretion, the idea that low-protein diets decrease the workload on the kidney is a fallacy.[130] Urinary urea nitrogen concentrations can vary from as low as 50 mg/dL in neonatal foals or horses with primary polydipsia to greater than 2500 mg/dL in normal horses on high-protein diets. Total daily urea excretion usually ranges between 100 and 300 g/day in horses with normal renal function.

Creatinine Metabolism

Cr is produced by the nonenzymatic, irreversible cyclization and dehydration of creatine. Three amino acids in the kidney, liver, and pancreas are indirectly responsible for its production; subsequently Cr is transported to other organs such as muscle and brain, where it is phosphorylated to store energy in the form of phosphocreatine.[130,147] In human beings, 1.5% to 2.0% of the creatine pool is converted to Cr daily and results in a fairly constant excretion of Cr within a given individual.[130] With normal renal function, a direct relationship exists between daily Cr production, serum Cr concentration, and Cr excretion, all three being proportional to total muscle mass. The fact that Cr is 30% higher in male humans than in females and urinary Cr excretion is correlated to body size across a wide range of animal species supports this relationship.[130,148] Cr is excreted principally in urine, but sweat and the gastrointestinal tract are secondary routes of excretion.[130] In contrast to urea, enterohepatic recycling of Cr does not occur, and the gastrointestinal tract may represent a major route of excretion when renal function is compromised. For example, in a group of azotemic human patients, between 15% and 65% of radiolabeled Cr was found to be excreted through the intestine.[149] Cr excreted by this route is degraded rapidly by bacteria so that little is found in feces.

Like BUN, Cr can vary with age, activity level, and renal function. In contrast, dietary protein intake has little influence on Cr in horses.[138] Newborn foals routinely have Cr values 30% to 50% higher than those measured in the mare, and values as high as 20 to 30 mg/dL have been measured in some premature or asphyxiated foals.[135] These high values may result from limited diffusion of Cr across the placenta. For example, the Cr concentration in equine amniotic fluid at term is proportionately much greater than urea nitrogen concentration (Cr, 10.1 mg/dL; urea nitrogen, 38.8 mg/dL).[150] If the foal appears healthy and all other laboratory values are within reference ranges, a Cr value in the range of 5 to 15 mg/dL should not cause alarm. In most healthy foals with normal renal function, Cr decreases to values below 3.0 mg/dL within the first 3 to 5 days of life.[149] After the first few days of life, Cr is usually lower in foals than in adults[139] because of the combined effect of rapid growth and the fact that skeletal muscle comprises a smaller percentage of body weight in foals than in adult horses. Other nonrenal factors that may influence Cr include fasting, rhabdomyolysis or muscle wasting caused by disease, and exercise. Although fasting can increase the measured value for Cr, a substantial portion of this increase actually is due to other compounds (possibly ketones) that increase during fasting and are measured as non-Cr chromagens in the commonly used Jaffe's colorimetric assay for Cr determination (see Examination of the Urinary System).[139,141,151] In contrast, the increase in Cr (up to 80% in some reports) associated with various types of exercise is likely the combined result of increased release of creatine from muscle and decreased urinary Cr excretion during exercise.[139,141,144-146]

Cr is filtered freely at the glomerulus and is concentrated to values of 100 to 300 mg/dL in equine urine, which results in a total daily urine excretion of 15 to 25 g of Cr.[152,153] In comparison to urea, Cr excretion is responsible for only one tenth as much urinary nitrogen excretion. Minor species and sex differences have been reported for renal tubular handling of Cr, with a weak proximal tubular secretory mechanism in humans and male dogs (accounting for 7%–10% of total urinary Cr excretion).[130,147] To determine whether tubular secretion of Cr occurs in equine kidneys, Finco and Groves[154] fitted anesthetized ponies with ureteral catheters and performed simultaneous inulin and exogenous Cr clearance studies. Because inulin is filtered freely at the glomerulus and is neither secreted nor reabsorbed by renal tubules, inulin clearance (Cl_{In}) provides a standard of comparison for Cr clearance (Cl_{Cr}). Tubular secretion of Cr should result in a greater value for Cl_{Cr} than for Cl_{In}, whereas the opposite should occur with tubular reabsorption of Cr. To magnify any minor tubular secretion of Cr, stop-flow studies were performed by temporarily occluding the ureteral catheters. During obstruction, tubular lumen pressure increased and tubular flow decreased. As a consequence, fluid remained in contact with tubular epithelium for a prolonged period, enhancing local tubular secretory or resorptive processes. Analysis of a series of urine samples collected after release of ureteral occlusion revealed no differences in tubular handling of inulin or Cr, leading to the conclusion that Cr neither was reabsorbed nor secreted by equine kidneys. In contrast, simultaneous measurement of endogenous Cl_{Cr} and Cl_{In} in several horses with chronic kidney disease (author's unpublished observations) has revealed higher values for Cl_{Cr}, indicating that tubular secretion of Cr may develop in horses as renal function declines (see Chronic Renal Failure). Whether significant excretion of Cr occurs in sweat or through the gastrointestinal tract has not been investigated in horses.

Metabolism of Other Nitrogenous and Organic Compounds

Although the kidneys excrete a number of nitrogenous and organic wastes in addition to urea and Cr (see Box 14.1), these compounds are quantitatively unimportant in terms of nitrogen balance.[128] Two of the more commonly recognized molecules are ammonia and uric acid. In proximal tubular epithelial cells, ammonium ions and α-ketoglutarate are produced from glutamine. Subsequent metabolism of α-ketoglutarate results in generation of two bicarbonate molecules that are returned to the systemic circulation. Ammonium ions are secreted in exchange for sodium into the tubule lumen, where they remain trapped, because tubules are relatively impermeable to ammonium ions. Furthermore, because the pK_a for ammonia is greater than 9.0, most of the tubular ammonia remains in the form of ammonium ions, even in alkaline equine urine. Although ammonium ion excretion is of little significance in overall nitrogen excretion, it plays an important role in acid (hydrogen ion) excretion. In fact, glutamine metabolism and ammonium ion excretion can increase several-fold in response to metabolic acidosis.[155] Although urinary ammonium concentration is not measured routinely, one can estimate it because it is directly related to the urinary anion gap ($[Na^+ + K^+] - Cl^-$) in human patients with normal anion gap metabolic acidosis.[156] More important, impairment of this proximal tubular acid secretion pathway contributes to the development of metabolic acidosis in patients with renal insufficiency.

Uric acid is a product of purine nucleotide degradation and is the major nitrogenous waste product formed in amphibians and reptiles. In mammals, however, uric acid excretion (mostly in the ionic form of urate) is unimportant in terms of overall nitrogen excretion.[128] Uric acid metabolism has received little attention in veterinary species with the exception of Dalmatian dogs. This breed exhibits high urate excretion rates and is predisposed to uric acid stone formation; however, this problem results from decreased hepatic uricase activity rather than any abnormality in renal urate handling.[157] Finally, hyperuricemia (leading to gout in humans) also can be attributed to a lack of uricase activity in human tissues and greater renal reabsorption of urate compared with other mammalian species. Thus crystallization of urate in tissues appears to be limited to humans.[128] Urate metabolism has been studied little in horses, although Keenan[144] observed that plasma concentrations increased dramatically in response to exercise (from less than 1 μmol/L at rest to 150–200 μmol/L 1 hour after racing) and that these increases were accompanied by a transient increase in urinary urate excretion (from less than 40 μmol/L at rest to 250–1270 μmol/L after racing).

The proximal tubule is also the major site of excretion (by tubular secretion) of a number of endogenous organic anions and cations.[128] The anions share the common pathway measured by p-aminohippurate clearance, the substance traditionally used to measure effective renal plasma flow (because more than 90% is excreted via this pathway). A number of exogenous compounds also are excreted via these pathways—acetazolamide, furosemide, probenecid, penicillin G, sulfadiazine, salicylate, atropine, cimetidine, and neostigmine. Thus administration of these compounds can interfere with tubular secretion of endogenous organic wastes or other exogenous products by healthy kidneys.[158] More important, the pharmacokinetic effects of these products vary widely in patients with renal insufficiency. Combined with the fact that anion binding to plasma proteins is decreased with azotemia, dosing protocols of many medications may need to be readjusted for patients with renal failure.

BODY WATER AND ELECTROLYTE BALANCE

Body Fluids: Volume and Composition

Water accounts for at least 60% of total body mass, equivalent to 300 L in a 500-kg horse.[128,156-161] About 200 L of total body water is intracellular fluid, and the remaining 100 L is extracellular fluid. Extracellular fluid is divided between plasma (4%–6% of body mass, approximately 25 L), interstitial fluid and lymph (10%–12% of body mass, approximately 45 L), and transcellular fluid (6%–10% of body mass, approximately 30 L, most of which is in the lumen of the gastrointestinal tract). Despite significant differences in ion composition (Table 14.1), the extracellular fluid and intracellular fluid compartments exchange water freely to maintain osmotic equilibrium.[155]

From the values in Table 14.1, one can estimate the total amount of exchangeable sodium, potassium, and chloride in the body fluids of a 500-kg horse: approximately 16,000 mEq, 28,800 mEq, and 10,800 mEq, respectively (including gastrointestinal fluid ion contents). These values are accurate except for that of sodium, which may be twice as great; however, 40% to 50% is sequestered in bone and is not readily available to buffer sodium alterations in body fluids.[159-161] Thus the 16,000-mEq estimate is accurate for the exchangeable sodium content in body fluids. Similarly, one can estimate body fluid contents of calcium, magnesium, and phosphorus at approximately 1000 mEq (20 g), 6875 mEq (84 g), and 8150 mEq (140 g), respectively (excluding gastrointestinal fluid ion contents, because these vary with the amount and solubility of the dietary source). As for sodium, the values underestimate the total body content of calcium, magnesium, and phosphorus, because more than 99%, 70%, and 85% of these elements, respectively, are contained in the skeleton.[130]

TABLE **14.1 Approximate Ionic Compositions (mEq/L) of Plasma, Interstitial Fluid, and Intracellular Fluid (Skeletal Muscle)**

Electrolyte Cations	Plasma	Interstitial Fluid	Skeletal Muscle Cell
Na^+	140	143	10

Water Balance

Appropriate water balance maintains plasma osmolality in a narrow range (270–300 mOsm/kg) and is achieved by matching daily water intake with water loss.[162-164] Water is provided from three sources: (1) free water intake (drinking), (2) water in feed, and (3) metabolic water (Table 14.2). Horses consume most of their water by drinking (about 85%), but feed and metabolic water provide about 5% and 10% of daily water, respectively. Water can be lost by three routes: (1) in urine, (2) in feces, and (3) as insensible losses (evaporation) across the skin and respiratory tract (Table 14.3). Investigations of water balance have revealed a maintenance water requirement of 60 to 65 mL/kg/day or 27 to 30 L/day for a 500-kg horse.[162,165] These values are consistent with traditional recommendations that 5 to 10 gallons/day of fresh water be provided to a stabled horse under mild environmental conditions.[166] Urinary and fecal water losses range between 20% to 55% and 30% to 55%, respectively, of the total daily water loss.[162,165,167,168] The remaining (insensible) loss accounted for up to 15% to 40% of daily water loss, despite mild ambient conditions and the lack of observed sweating in most studies of water balance.

Water drinking and urine production are the mechanisms by which water balance is finely tuned; however, they can vary widely among individual horses and also are affected by age, environmental conditions, level of exercise, and diet. Often, for example, neonatal foals consume milk in excess of 20% of their body mass daily,[169] which equates to fluid intake approaching 250 mL/kg/day. Water intake by horses increased 15% to 20% when ambient temperature increased from 13°C to 25°C.[170] Under conditions of high ambient temperature and humidity, urine concentration also may increase to conserve water, whereas fecal water content tends to remain fairly stable, at about 75% of fecal weight. Exercising horses, especially endurance horses and racing horses treated with furosemide, can increase water consumption by 100% to 200% to replace body water lost in sweat (and urine). Horses and ponies on all-roughage diets also drink more and have greater daily fecal water loss (because of greater daily fecal volume) than animals fed a large amount of concentrate or complete pelleted diets.[167,168] Diets high in nitrogen (protein) and calcium, such as legume hays, typically increase urine volume by 50% or more and are associated with a similar increase in urinary nitrogen excretion. These diets are also more digestible so that fecal water excretion generally decreases because of a decrease in total fecal material.[136,141,167,168] Although high dietary levels of salt have been suggested to increase drinking and promote diuresis, no increase in water consumption or urine volume was observed in ponies fed 5 to 10 times the daily salt requirement (equivalent to about 350 g of sodium chloride [NaCl] for a 500-kg horse).[171] The effects of water access, continuous versus intermittent, have received less attention, although a study reported in 1999 showed no difference in water balance in horses provided water three times daily compared with horses that had continuous access to water.[172] Furthermore, horses drink the most water within the hour after feeding,[173] and feral horses and ponies often drink only once or twice daily.[174] Thus horses are unlikely to require continuous access to water. An obvious exception is a patient with renal insufficiency that should have access to fresh water at all times.

Two main stimuli for thirst are (1) increased plasma osmolality and (2) hypovolemia or hypotension.[175] The former is mediated through osmoreceptors in the hypothalamus that have a high threshold for activation (about 295 mOsm/kg) in humans. Hemodynamic stimuli are mediated by low- and high-pressure baroreceptors. Osmotic and hemodynamic stimuli can produce their dipsogenic effect in part by activating a local renin-angiotensin-aldosterone system in the central nervous system.[176,177]

Renal water reabsorption is controlled principally by the action of arginine vasopressin (antidiuretic hormone) on the collecting ducts.[178] Vasopressin is produced in the neurosecretory neurons of the supraoptic nuclei, packaged in granules, and transported down axons for storage in the neurohypophysis (pars nervosa or posterior pituitary). As for thirst, increases in plasma osmolality and hypovolemia or hypotension are the stimuli for vasopressin release. Osmoreceptors for vasopressin release also are located in the hypothalamus, adjacent to the osmoreceptors mediating thirst. Activation of these receptors is the signal for vasopressin release from the neurohypophysis. Furthermore, these osmoreceptors are not equally sensitive to all plasma solutes. For example, increases in plasma sodium concentration and infusion of mannitol are potent stimuli, whereas increases in plasma glucose and urea concentrations are weak stimuli. These differences have led to the suggestion that osmoreceptor activation is caused by an osmotic water shift that produces cell shrinkage (which would be greater for sodium and mannitol than for glucose or urea). Activation of osmoreceptors signaling vasopressin release also appears to have a threshold value; however, this threshold appears to vary

TABLE **14.2 Water Balance in Hay-Fed Horses in a Cool Climate**

Water Intake (L)	Water Loss (L)
Consumption 23.6	Feces 14.0
Hay 1.1	Urine 4.9
Metabolic 2.7	Insensible 8.5
Total 27.4	Total 27.4

[d]Water intake includes imbibed water (23.6 L), water in feed (1.1 L), and metabolic water (2.9 L).

highly among individuals. In addition, the threshold for vasopressin release in human beings is significantly lower (270–285 mOsm/kg) than that for thirst. Thus vasopressin release can be thought of as the initial line of defense against a mild increase in plasma osmolality, whereas thirst and drinking are secondary responses to even greater increases.

Studies in horses, ponies, and donkeys have demonstrated that increased plasma osmolality (induced by water deprivation or infusion of hypertonic saline) and hypovolemia (induced by furosemide administration) are stimuli for thirst.[172,178-182] Furthermore, after a period of water deprivation, dehydrated ponies, horses, and donkeys appear to be able to replace water deficits within 15 to 30 minutes of gaining access to water. The increases in plasma osmolality and vasopressin concentration associated with water deprivation also are corrected in this same period of time, indicating that imbibed water is absorbed rapidly from the gastrointestinal tract.[179] Although increases in plasma vasopressin concentration have been measured in horses and ponies during water deprivation,[179,183] vasopressin also appears to be a "stress hormone" in equids, because substantially greater concentrations (tenfold greater than those induced by water deprivation) have been measured after application of a nose twitch, nasogastric intubation, or exercise.[184,185] Thus increases in plasma vasopressin concentration after water deprivation would be expected to vary in horses, and separating osmotic effects from stress effects may be difficult sometimes.

Once released, vasopressin acts on V_2-receptors on the basolateral membrane of collecting duct epithelial cells, leading to insertion of water channels (transmembrane proteins) in the apical membrane.[175] These channels increase the water permeability of the apical membranes and lead to increased water reabsorption. Action of V_2-receptors is mediated by activation of adenylyl cyclase and a stimulatory transmembrane G protein. Interestingly, V_2-receptor activation can be antagonized by activation of adjacent α_2-adrenoceptors and by a prostaglandin E_2–mediated effect on an inhibitory G protein.[16,186] Although effects of these antagonists vary with species and have not yet been studied in horses, the diuresis associated with administration of α_2-agonists to horses[14,15] likely may be attributable to vasopressin antagonism at the collecting duct.

As mentioned previously, most water drinking in equids occurs periprandially; thus feeding practices affect timing of water intake.[173] If a horse eats a large meal once or twice daily, both increased plasma sodium concentration and decreased plasma volume (because of a shift of fluid into the bowel) stimulate thirst and vasopressin release. The result is a simultaneous increase in water intake and a decrease in urine output.[187] In addition, hypovolemia further stimulates activation of the renin-angiotensin-aldosterone system, which leads to enhanced renal sodium conservation as an additional means of restoring plasma volume. Although the increase in plasma sodium concentration with meal feeding is rather small (1%–3%), the decrease in plasma volume is much greater (5%–25%). The magnitude of this fluid shift (and the degree of activation of the renin-angiotensin-aldosterone system) can be attenuated largely by feeding small meals four to six times throughout the day.[188,189] Thus more frequent feeding causes less perturbation of body fluids and likely has a protective effect against development of some forms of colic.

Although balance of daily water intake and output is critical for maintenance of homeostasis, it warrants mention that equids tolerate water deprivation well.[190-196] For example, after horses were deprived of water for 72 hours (which resulted in body weight loss in excess of 10%), most of the weight lost (90% of which was assumed to be water) was recovered within the first hour after being provided access to water.[193] Similarly, even greater body weight losses (approaching 20%) induced by water deprivation and desert walking in donkeys and burros were replaced largely within the first few minutes after water was provided.[191,192] Thus in terms of water balance, equids (especially donkeys and burros) truly can be considered desert-adapted animals.[196,197] An important reason for their ability to tolerate water deprivation appears to be a substantial intestinal reserve of water and electrolytes that they call on during periods of dehydration for the maintenance of plasma volume.[3,198] Despite rapid fluid replacement by equids that have been dehydrated by water deprivation, horses that become dehydrated because of prolonged exercise or diarrheal disease (colitis) often do not drink. This behavior can be attributed to the fact that these conditions produce loss of body water and osmoles in the form of sweat or diarrhea. As a result, plasma osmolality does not increase, and osmotic thirst stimulus is not produced. In human endurance athletes, this state of mild to moderate dehydration that does not induce thirst has been called *voluntary* and *involuntary* dehydration,[199,200] and although less well documented, a similar response appears to occur in endurance horses.[201] Another form of involuntary dehydration, which may be accompanied by increases in plasma osmolality and protein concentration, also has been described anecdotally in mares after foaling.

Electrolyte Balance

Intake and loss of electrolytes also must be matched appropriately to maintain body content of electrolytes within narrow ranges. This balance is most important for the exchangeable ions (Na^+, K^+, and Cl^-) because these have minimal tissue (skeletal) reserves that can be called on during times of need. An exception is the fluid and electrolyte reserve in the lumen of the gastrointestinal tract, which may be able to provide replacement of 10% or more of the body content of these electrolytes.[198] Three sources provide electrolytes: (1) feed, (2) water (usually minimal amounts), and (3) a number of dietary supplements. Electrolytes also can be lost by three routes: (1) in urine, (2) in feces, and (3) in sweat (insensible losses; see Table 14.3). Investigations of electrolyte balance have revealed that most horses eating predominantly hay or pasture grass ingest excess potassium and chloride. In contrast, sodium intake varies and with some diets may be marginal.[162,164,165] A maintenance requirement for sodium of 0.4 to 0.8 mEq/kg/day or 200 to 400 mEq/day (6–12 g/day) for a 500-kg horse has been suggested.[165,181] However, exercising horses that may lose 500 to 1000 mEq of sodium per hour in sweat or are treated with furosemide have greater dietary requirements to replace such losses.[164] Thus addition of 50 to 75 g of common table salt (which provides 850–1275 mEq, because 1 g of NaCl provides approximately 17 mEq sodium) is a safe and economical method of providing daily supplemental sodium and chloride to athletic horses.

Data from the water and electrolyte balance studies performed by Tasker[162] and by Groenendyk, English, and Abetz[165] (see Table 14.3) provide a good illustration of the capacity of the equine kidneys to conserve sodium when dietary intake is low (see Tasker's data[162] at top) compared with when intake is unlimited (see Groenendyk and colleagues' data[165] at bottom).

Furthermore, these studies demonstrate that urinary excretion is the major route for loss of potassium and chloride. Although dietary intake of potassium is usually excessive, equine kidneys do not appear to have a great capacity to conserve potassium during periods of food and water deprivation or with anorexia associated with disease.[162,164,200] Thus urinary potassium concentration and total excretion can remain substantial in the face of decreased intake. Consequently, with decreased feed intake horses can develop significant total body potassium depletion and often benefit from supplemental dietary potassium (25–50 g/day of potassium chloride [KCl] provides 375–750 mEq, because 1 g KCl provides approximately 15 mEq of potassium).

In horses the stimuli for electrolyte intake (salt appetite) have received much less attention than stimuli for drinking. Houpt and colleagues[181] found that horses that had marginal sodium intake (250 mEq/day) and that were treated with furosemide ate more salt in the hours after treatment than did placebo-treated horses on the same diet; however, salt intake (which was comparable for eating salt from a block or drinking a 0.9% NaCl solution) was excessive in both treatment groups (in excess of 100 g). Thus salt appetite, unlike water intake, is less closely regulated to balance intake with losses. In fact, when salt is available ad libitum, horses appear to consume more than their maintenance needs. The excess is eliminated by increased urinary sodium excretion. Although this apparently excessive salt appetite may seem inappropriate, one could consider it advantageous for exercising horses, which have a much greater daily salt requirement.[202]

RENAL REGULATION OF BODY WATER CONTENT AND ION COMPOSITION

The kidneys are the organs responsible for fine-tuning body water content and ion composition within narrow ranges. The important components of renal regulation of water and ion content include renal blood flow, glomerular filtration, and tubular modification of glomerular filtrate to produce the final urine.

Renal Blood Flow

At rest, the kidneys receive about 15% to 20% of the cardiac output, or about 7.5 to 10.0 L/min for an average-size horse.[203,204] This high tissue perfusion, 500 to 600 mL/min per 100 g of kidney compared with 50 to 100 mL/min per 100 g of brain tissue, is necessary for the kidney to function as an effective filter and regulator of extracellular fluid composition. Furthermore, tubular reabsorption of glomerular filtrate requires energy. Because more than 99% of the filtrate is reabsorbed, the metabolic rate of the kidney is high (second only to that of the heart), and despite the fact that the kidneys account for less than 1% of body weight, they are responsible for about 10% of whole body oxygen use.[128] Next, renal blood flow is distributed preferentially to the renal cortex. In fact, renal medullary blood flow, which is derived largely via the vasa recta that arise from the efferent arterioles of juxtamedullary glomeruli, accounts for less than 20% of total renal blood flow.[204] Consequently, the renal medullary tissue normally functions in a hypoxic environment. Medullary hypoxia has been described as "an inevitable accompaniment of efficient urinary concentration" as a consequence of countercurrent exchange.[205] Although the latter mechanism would suggest that oxygen tension should decrease progressively toward the inner medulla, the lowest values, often no greater than 10 mm Hg, are found in the inner portion of the outer medulla, termed the *inner stripe* (Fig. 14.9).[206] This finding can be explained by the substantial metabolic activity of epithelial cells lining the medullary thick ascending limb (mTAL) of the loop of Henle in the inner stripe. The sodium-potassium-adenosine triphosphatase pumps (Na^+,K^+-ATPase) in the basal membrane of these cells are responsible for the greatest ATP use (and thereby oxygen consumption) in the medulla.[207] The combined effects of low oxygen delivery and a high rate of use produce the lowest oxygen tension in the inner stripe. Fortunately, several "protective" mechanisms exist to preserve medullary blood flow and tissue oxygenation during periods of renal hypoperfusion and include a preferential reduction in cortical blood flow along with redistribution of renal blood flow to the corticomedullary region, accumulation of adenosine with depletion of ATP, and production of prostaglandin E_2 (PGE_2) and prostaglandin I_2 (PGI_2) and nitric oxide.[205-207] Of clinical importance is that the use of nonsteroidal antiinflammatory drugs (NSAIDs) in patients with poor renal perfusion can exacerbate tissue hypoxia because PGE_2 acts as a vasodilator and an inhibitor of Na^+,K^+-ATPase. In fact, the earliest lesions of analgesic nephropathy include degeneration and necrosis of mTAL cells before development of overt papillary necrosis.[207]

Renal blood flow of horses has been measured by a variety of techniques including p-aminohippurate clearance (Cl_{PAH}) by classic clearance techniques involving timed urine

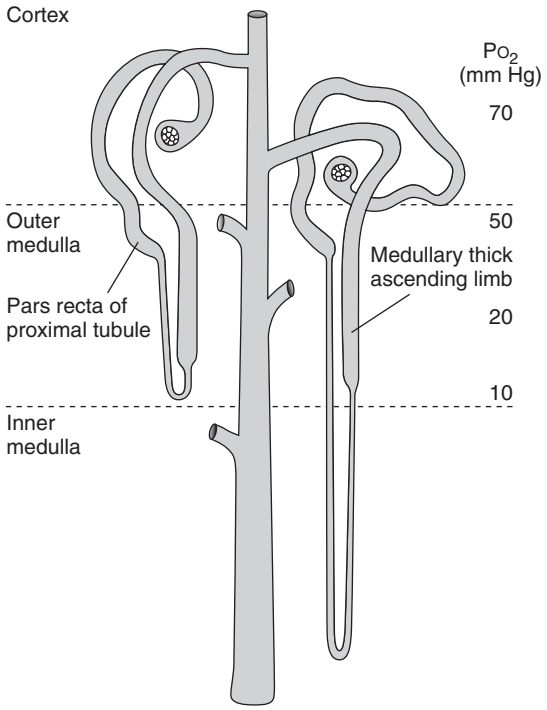

FIG. **14.9** Schematic drawing of a nephron. In the outer medulla is the site of lowest intrarenal oxygen tension (Po_2), in the final (straight) portion of the proximal tubule and the medullary thick ascending limb (mTAL) of the loop of Henle. Limited medullary blood flow and high metabolic rates make these outer medullary nephron segments the most susceptible to damage during periods of renal hypoperfusion.

collections and by plasma disappearance curves, as well as clearance of radionuclides, microsphere injection, and use of ultrasonic Doppler flow probes placed around the renal artery (Table 14.4).[11,203,204,208-223] The latter technique does not provide absolute blood flow values but rather measures changes in renal blood flow from a baseline value.[11] Plasma disappearance curves for ^{131}I-orthoiodohippuric acid and 99mTc-mercaptoacetyltriglycine have been validated in normal horses in an attempt to establish radionuclide techniques for rapid and noninvasive measurement of renal blood flow in hospitalized horses.[219,223] Although values for renal blood flow determined by these radionuclide techniques compared well with previous data (Table 14.5),[224-234] their future use in a clinical setting likely will remain limited because of moderate expense and the need to perform serial measurements to provide clinically relevant information in patients with reduced renal function.[235]

Intrinsic and extrinsic factors play a role in the control of renal blood flow. The former include autoregulation and action of renal nerves; the latter include vasoconstrictors (catecholamines, renin-angiotensin system, arginine vasopressin) and vasodilators (prostaglandins, dopamine, atrial peptides, bradykinin, adenosine, and nitric oxide).[128]

TABLE **14.4 Reported Values for Effective Renal Plasma Flow and Renal Blood Flow in Horses and Ponies**

Number of Animals	Method[a]	Effective Renal Plasma Flow (Mean ± SD/SE mL/min/kg [Range])	Renal Blood Flow (RBF) (mL/min/kg)[b]	Reference
One female horse	$Cl_{Diodrast}$	6.91 ± 0.81	13.2 ± 1.6	208
One female pony	$Cl131_{I\text{-}o\text{-}HA}$	Bolus injection: 12.85 ± 1.81	21.7 ± 3.1	209[c]
		Constant infusion: 11.45 ± 1.25	19.4 ± 2.1	
Three female horses	$Cl131_{I\text{-}o\text{-}HA}$	Bolus injection: 11.97 ± 2.63	20.2 ± 4.4	
		Constant infusion: 9.56 ± 1.84	16.2 ± 3.1	
Six female ponies	Cl_{PAH}	12.09 ± 0.34 (7.86–21.62)	20.4 ± 0.6	210
Two female horses		9.59 ± 0.86 (4.75–19.78)	16.2 ± 1.4	
Five female/gelding horses	$Cl131_{I\text{-}o\text{-}HA}$	8.24 ± 2.88 (5.66–12.89)	13.9 ± 4.9	211
Eight female horses	Cl_{PAH}	Bolus injection: 12.0 ± 1.7	20.3 ± 2.9	214
Four-day-old foals		Bolus injection: 15.2 ± 1.5	25.7 ± 2.7	
Five horses (three male, two female)		Infusion (Cl-plasma): 18.2 ± 2.0	30.8 ± 3.4	
Three ponies (one male, two female)		Infusion (Cl-urine): 11.9 ± 1.9	20.1 ± 3.2	
Six female horses	Cl_{PAH}	8.5–10.8[d]	14.4–18.3	215
Six female horses	Cl_{PAH}	11.9 ± 1.0	20.0 ± 1.7	216
Six horses[e]	$Cl131_{I\text{-}o\text{-}HA}$	6.26 (4.33–6.80)	10.58 (7.32–11.50)	217
Eight female horses	Cl_{PAH}	9.65 ± 0.84 (5.60–12.54)	16.31 ± 1.42	219
	$Cl131_{I\text{-}o\text{-}HA}$	11.32 ± 1.03 (7.82–15.71)	19.14 ± 1.74	
Six pony foals (three female, three male)	Cl_{PAH}	16.63 (15.61–17.26)	28.11	221
Ten horses (four female, six gelding)	$Cl99_{mTc\text{-}MAG\text{-}3}$	7.92 ± 1.51 (5.58–10.62)	13.39 ± 2.55	222
Four ponies[e]	Microspheres	—	208 ± 58[f,g]	204
Eleven ponies[e]	Microspheres	—	548 ± 87[f]	203
Eight ponies[e]	Microspheres	—	483 ± 79[f]	212
Eleven ponies[e]	Microspheres	—	670 ± 50[d,f]	213
Three horses (female, male, and gelding)	Microspheres	—	535 ± 93[f]	218
Nine horses[e]	Microspheres	—	589 ± 50[f]	220
Four gelding ponies	Microspheres	—	428 ± 49[f]	223

[a]$Cl_{Diodrast}$, Clearance of 3,5-diiodo-4-pyridine-*N*-acetic acid; $Cl131_{I\text{-}o\text{-}HA}$, clearance of ^{131}I-*o*-iodohippurate; Cl_{PAH}, clearance of *p*-aminohippurate; $Cl99_{Tc\text{-}MAG3}$, clearance of 99mTc-mercaptoacetyltriglycine.
[b]RBF values presented have been calculated from effective renal plasma flow (ERPF) data using extraction ratios (ERs) of 0.80 for diodrast and 0.91 for ^{131}I-*o*-iodohippurate and *p*-aminohippurate: RBF = (ERPF/ER)/(1 – hematocrit); hematocrit was assumed to be 0.35.
[c]Other horses and ponies also were studied after bolus injection of ^{131}I-*o*-iodohippurate and yielded ERPF values of 16.93 ± 6.05 and 10.65 ± 2.73 mL/min/kg for ponies and horses, respectively; these values corresponded to a RBF of 8.6 ± 10.2 mL/min/kg in ponies and 18.0 ± 4.6 mL/min/kg in horses.
[d]Values estimated from figure.
[e]Sex not reported.
[f]RBF values for microsphere studies are expressed in units of milliliters per minute per 100 g of kidney tissue; a value of 500 mL/min/100 g would correlate to an RBF value of 18 mL/min/kg (or 3.6 and 9 L/min for a 200-kg pony and a 500-kg horse, respectively).
[g]Values reported are for ponies under general anesthesia (halothane in oxygen); these authors also reported that renal medullary blood flow was 2.6% to 18.8% of total RBF in two ponies.

Although not unique to the kidney, autoregulation of blood flow is a physiologic response that maintains cortical renal blood flow in the normal range through a rather wide range of perfusion pressures (75–180 mm Hg in humans). This response is thought to be independent of neural or hormonal mechanisms and is attributed to a myogenic response to changes in arterial wall tension. The local action of renal nerves or release of vasoconstrictor substances leads to an increase in renal vascular resistance that may occur in response to disease states (hypovolemic or endotoxic shock), drugs (particularly anesthetic agents), or physical stress (exercise). Renal blood flow may or may not decrease, depending on the degree of vasoconstriction. For example, renal vascular resistance increases during low-intensity exercise to divert a greater portion of the cardiac output to the working muscles. Thus the fraction of cardiac output delivered to the kidneys decreases; however, because cardiac output also increases in response to exercise, total renal blood flow remains unchanged.[216] In contrast, during halothane anesthesia in ponies, redistribution of cardiac output occurs without an increase in cardiac output. Under these circumstances, renal vasoconstriction is accompanied by a decrease in renal blood flow to about 60% of the awake value at 1.0 to 1.5 minimal alveolar concentration of halothane. As the plane of anesthesia deepens (to 2.0 minimal alveolar concentration), a greater increase in renal vascular resistance (or degree of vasoconstriction) further decreases renal blood flow to about 25% of the awake value, likely because of further vasodilatation of other vascular beds and a mild decrease in cardiac output.[212] Although renal blood flow was not measured, results of a study of prolonged (18 hours) anesthesia with sevoflurane are of interest in terms of probable renal hypoperfusion and damage.[236] After 10 hours of anesthesia, an increase in urine production was accompanied by evidence of tubular dysfunction (e.g., glucosuria, enzymuria). Furthermore, microscopic lesions after anesthesia were limited to the more distal nephron (mTAL and distal tubule), providing support that these normally hypoxic nephron segments may be the first to succumb to prolonged hypoperfusion.

When renal blood flow decreases, counteracting vasodilatory mediators usually are released in an attempt to ameliorate the decrease in renal blood flow. The best studied of these vasodilatory mediators include renal prostaglandins (PGE_2 and PGI_2) and dopamine. Although the role of renal prostaglandins in the control of basal or resting renal blood flow is thought to be insignificant, renal prostaglandins are important mediators of vasodilation in response to a number of vasoconstrictive stimuli.[237] Furthermore, production of renal prostaglandins is several times greater in medullary tissue so that action of these mediators leads to a greater increase in inner cortical (region of juxtamedullary glomeruli) and medullary blood flow. As mentioned previously, one should not be surprised that the lesion associated with antagonism of prostanoid production by use of NSAIDs is medullary or papillary necrosis.[238,239] With or without renal vasoconstriction, activation of dopamine receptors (DA_1 type) leads to renal vasodilation. Because the receptors are located on most renal arterioles, blood flow increases in the renal cortex and the medulla. For this reason, dopamine infusions are touted to be of benefit in treating acute renal failure because this catecholamine has been shown to increase renal blood flow and urine output by 30% to 190% in normal horses.[11]

Glomerular Filtration

Approximately 20% of the blood entering the glomeruli passes through small pores in the filtration barrier into Bowman's capsule. The primary force driving filtration is glomerular capillary transmural hydraulic pressure. A relatively constant pressure across the glomerular capillary wall is maintained by greater resistance in the arteriole leaving the glomerulus (efferent arteriole) than in the arteriole entering the glomerulus (afferent arteriole). This difference in vascular resistance generates the hydraulic pressure that forces plasma water out of the glomerular capillaries.[128] The filtration barrier is made up of three layers: (1) endothelium of the glomerular capillaries, (2) basement membrane, and (3) foot processes of the epithelial cells (podocytes) lining Bowman's capsule. The pore size of the filtration barrier, about 8 to 10 nm in diameter, prevents filtration of cells and larger proteins. As a result, the fluid that enters Bowman's capsule is an ultrafiltrate that is essentially identical to plasma except that it has less than 0.05% of the protein content of plasma. Interestingly, the diameter of albumin is about 6 nm, so its size should not prevent filtration. Glycosaminoglycans containing heparan sulfate and sialic acid residues impart a significant negative charge to the filtration barrier. Thus charge repulsion of albumin (which is similarly negatively charged) may be more important than molecular size in preventing significant loss of albumin into the filtrate; however, metabolic disturbances (metabolic acidosis) can neutralize the glomerular charge barrier, and one can observe transient proteinuria in the absence of structural damage to the glomerular barrier.[240]

By definition, glomerular filtration rate (GFR) is the volume of plasma filtered per unit of time and commonly is described in milliliters per minute per kilogram of body mass. The GFR of horses and ponies ranges between 1.6 and 2.0 mL/kg/min, with some authors reporting slightly higher values for ponies. This range is similar to those of other animals and humans. For a 500-kg horse, this value equals 800 to 1000 mL/min or about 1200 to 1400 L/day. This value represents filtration of the total plasma volume 60 to 70 times per day. Because urine production is about 10 L/day, more than 99% of the glomerular filtrate is reabsorbed.

Like renal blood flow, GFR has been measured in horses by a variety of techniques, including Cl_{In} by classic clearance techniques, Cl_{Cr}, and clearance or plasma disappearance of radionuclides (see Table 14.5). Plasma disappearance curves for 99mTc-diethylenetriamine pentaacetic acid (99mTc-DTPA) compare well in normal horses with Cl_{In} (the gold standard).[219] Although this technique is less expensive than ^{131}I-orthoiodohippuric acid clearance for estimating renal blood flow,[235] clinical use is limited by availability of nuclear medicine capabilities and expense (because one must take multiple measurements to assess disease progression or response to treatment). Gleadhill and colleagues[241] described use of a three blood sample technique to estimate GFR by plasma disappearance of 99mTc-DTPA. Interestingly, rather than expressing GFR on the basis of per kilogram of body mass or a body surface area, they suggested that GFR should be compared with extracellular fluid volume. Because plasma activity of 99mTc-DTPA also can be used to estimate extracellular fluid volume, one can make this estimate of GFR using 99mTc-DTPA alone. Standardization of GFR based on extracellular fluid volume is attractive and warrants further consideration because it eliminates the effect of variable body composition (e.g., specifically differences in body fat) when expressing GFR based on body mass. The authors subsequently used this method to estimate the decrease in GFR accompanying exercise.[233]

TABLE **14.5** **Reported Values for Glomerular Filtration Rate in Horses and Ponies**

Number of Animals	Method[a]	Glomerular Filtration Rate (GFR) (Mean ± SD/SE mL/min/kg [Range])	Cl_{CRend}/Cl_{In} Ratio[a]	Reference
Not reported[b]	Cl_{In}	0.83 ± 0.13[c,d]	1.02	208[b]
	Cl_{CRend}	0.85 ± 0.22[c,d]		
One horse[e]	Cl_{In}	1.4	—	208[b]
Twelve female horses	Cl_{In}	1.66 ± 0.33[c] (1.17–2.28)	0.88 ± 0.11	208
	Cl_{CRend}	1.46 ± 0.24[c] (1.10–1.65)		
One female pony	$Cl125_{\text{I-iothalamate}}$	Bolus injection: 5.43 (one study)	—	209[f]
		Constant infusion: 6.10 ± 1.27	—	
Three female horses	$Cl125_{\text{I-iothalamate}}$	Bolus injection: 4.20 ± 1.13		
		Constant infusion: 3.14 ± 0.53		
Thirteen ponies[e]	Cl_{CRend}	1.93 ± 0.37[c] (1.36–2.70)	—	224
Nine (no NaCl supplement)		2.06 ± 0.34[c] (1.64–2.70)		
Four (NaCl supplement)		1.63 ± 0.27[c] (1.36–1.99)		
Seven female horses	Cl_{CRend}	3.68 ± 1.18[c] (2.07–4.99)	—	225

TABLE **14.5 Reported Values for Glomerular Filtration Rate in Horses and Ponies—cont'd**

Number of Animals	Method[a]	Glomerular Filtration Rate (GFR) (Mean ± SD/SE mL/min/kg [Range])	Cl_{CRend}/Cl_{In} Ratio[a]	Reference
Thirty horses (7 male, 23 female)	Cl_{In}	1.73	1.03[c]	232
	Cl_{CRend}	1.79		
Six pony foals (three female, three male)	Cl_{In}	3.21 ± 0.36 (2.73–3.64)	0.60[c]	221
	Cl_{CRend}	1.92 ± 0.14 (1.60–2.14)		
Five horses	$Cl99m_{Tc\text{-}DTPA}$	3.3 ± 0.4	—	233
Six female horses	Cl_{CRend}	1.20–1.87	—	234[a]

[a]Cl_{In}, Inulin clearance; Cl_{CRend}, endogenous creatinine clearance; $Cl125_{I\text{-}iothalamate}$, clearance of ^{125}I-iothalamate; $Cl99m_{Tc\text{-}DTPA}$, clearance of 99mTc-diethylenetriamine pentaacetic acid (99mTc-DTPA); $Cl14_{C\text{-}In}$, clearance of ^{14}C-inulin; Cl_{CRex}, exogenous creatinine clearance; $Cl99m_{Tc\text{-}DTPA(cam)}$, clearance of 99mTc-DTPA determined by serial imaging at the body surface with a gamma camera.
[b]Values taken from Knudsen.[208]
[c]Values presented have been calculated from original data.
[d]Low GFR values were attributed to rapidly declining plasma inulin concentrations (non–steady-state conditions) during the urine collection periods.
[e]Sex not reported.
[f]Other horses and ponies also were studied after bolus injection of ^{125}I-iothalamate and yielded GFR values of 5.39 ± 1.79 and 3.44 ± 1.11 mL/min/kg for ponies and horses, respectively.
[g]Attempts at measuring GFR by plasma disappearance after bolus injection of inulin were unsuccessful.
[h]Value presented is for control group; GFR was not different after phenylbutazone administration (1.36 ± 0.04 mL/min/kg) or phenylbutazone and furosemide administration (1.44 ± 0.12 mL/min/kg) but was reported to increase to 1.75 ± 0.16 mL/min/kg after water loading (25 L) and to 1.77 ± 0.18 mL/min/kg after water loading and phenylbutazone administration.
[i]Ponies were anesthetized during the studies.
[j]Mares studied before, during, and after 1.2 minimum alveolar concentration halothane anesthesia.
[k]Value calculated from urinary clearance values for inulin and creatinine (Cr).
[l]Despite correction for differences in depth (right kidney closer to lateral body surface than left kidney), the clearance of 99mTc-DTPA determined by serial imaging at the body surface with a gamma camera showed a greater (–60% of total) GFR by the right kidney compared with the left kidney (–40% of total). Because similar differences have not been demonstrated in microsphere studies of renal blood flow (RBF) (in which both kidneys receive equal blood flow), this technique requires further refinement before it can be used to provide accurate measures of GFR in horses.

The mechanisms responsible for control of renal blood flow (autoregulation, neural input, hormonal factors) also play a role in control of GFR. In addition, GFR is affected further by factors such as plasma protein concentration (oncotic pressure) and alterations in the filtration barrier. As discussed previously, a balance exists between that action of vasoconstrictor and vasodilator substances during periods of decreased renal blood flow. Interestingly, GFR decreases less than renal blood flow with moderate to severe renal vasoconstriction. This sparing effect on GFR has long been attributed to greater vasoconstrictive effects of angiotensin II on efferent arterioles compared with afferent arterioles.[242] Such a response could increase the glomerular capillary transmural hydraulic pressure driving filtration and would be manifested by an increase in filtration fraction. In fact, the latter response has been documented in exercising horses.[216] However, other vasoconstrictors (endothelins) and vasodilators (endothelium-derived relaxing factors, nitric oxide) have been shown to play a role in the control of glomerular capillary hemodynamics and filtration so that a singular role for angiotensin II is likely an oversimplified explanation for the sparing effect on GFR.[243]

Renal Tubular Function

Once the glomerular filtrate enters the renal tubule, it is modified extensively in the process of becoming the final product excreted into the renal pelvis. A complete review of renal tubular function is beyond the scope of this text; however, a few general concepts warrant mention, and a number of specific aspects are addressed elsewhere in this chapter. First, most glucose, amino acid, electrolyte, and water reabsorption occurs across epithelial cells lining the proximal tubule; however, these substances are not all reabsorbed to the same extent. For example, this tubule segment is responsible for reabsorption of essentially all filtered glucose and amino acids, about 90% of bicarbonate, 70% of sodium, and 60% of chloride.[155] Furthermore, at the end of the proximal tubule, fluid is no more concentrated than it was in Bowman's space. Tubular sodium concentration is unchanged, whereas tubular chloride concentration actually has increased (because of preferential bicarbonate reabsorption). Despite limited modification of these tubular fluid components, net reabsorption of between 60% and 80% of the total filtered load of sodium, chloride, and water occurs within the proximal tubule. Proximal tubular epithelial cells are also responsible for secretion of ammonium ions and a number of organic anions and cations, as described previously.

Tubular fluid passing into the loop of Henle becomes progressively more concentrated (hypertonic) as it travels to the inner medulla because the descending limb is permeable to water, urea, and electrolytes (the latter to a lesser degree).[155] In contrast, the ascending limb is relatively impermeable to water but actively reabsorbs sodium, chloride, and potassium via the apical $Na^+/K^+/2Cl^-$ cotransporter (blocked by furosemide), which is coupled to Na^+,K^+-ATPase on the basolateral membrane. As a result, fluid leaving this nephron segment is actually less concentrated (hypotonic) than the original filtrate. The loop of Henle is responsible for reabsorption of an additional 15% to 20% of filtered sodium and chloride, along with addition of urea to the tubular fluid. More important, the loop of Henle is responsible for generation of the medullary osmotic gradient via countercurrent multiplication. This function results from the combined effects of different permeability

characteristics of the descending and ascending limbs of the loop of Henle and active removal of sodium and chloride in the ascending limb.

The distal tubule is quantitatively less important in reabsorption of electrolytes and water; however, the distal tubule is the nephron segment in which the final qualitative changes in urine occur.[155] For example, the distal tubule is an important site of calcium, potassium, and acid excretion. The latter two typically are exchanged for sodium under the influence of aldosterone. Tubule fluid passes from the distal tubule into the outer or cortical collecting ducts, which are impermeable to urea. In addition to further modification of fluid in the cortical collecting ducts, tubular urea concentration increases steadily as water is removed (under the influence of vasopressin) as fluid travels to the inner medulla. In contrast, in the absence of vasopressin (as with diabetes insipidus), the collecting ducts are impermeable to water and produce hypotonic urine. The collecting ducts remain impermeable to urea (which accounts for up to 50% of the osmoles in urine) except for the innermost medullary segments, which allow urea to be recycled into the interstitium for maintenance of the medullary osmotic gradient.

Reabsorption of glomerular filtrate by renal tubules requires a close association with the vascular system that carries reabsorbed solute and water to the circulation. Proximal tubules are adjacent to peritubular capillaries, which have a tremendous capacity to accommodate the massive flux of solute and water across proximal tubule epithelial cells. Equally important in maintenance of the medullary osmotic gradient are the vasa recta, hairpin capillaries that travel deep into the renal medulla in association with loops of Henle derived from the population of juxtamedullary nephrons. Blood flow through these capillaries is typically slow, allowing for countercurrent exchange of solute in the medullary interstitium, which is necessary for generation and maintenance of medullary hypertonicity. Urea leaving the descending limb of Henle and being recycled across the innermost portion of the medullary collecting duct is responsible for about half of this medullary hypertonicity.

These basic aspects of tubular function have a number of important clinical implications. First, proximal tubule epithelial cells have a high metabolic rate. Although most of the proximal tubule is in the more highly perfused renal cortex, renal hypoperfusion leads to a relative hypoxia surrounding these cells because of ongoing metabolic activity. Consequently, the proximal tubule is highly susceptible to injury when cortical blood flow is reduced (e.g., with hypovolemia or other states accompanied by a decrease in renal blood flow). Second, as discussed previously, the renal medulla receives only a small fraction of the total renal blood flow, leading to a normally hypoxic local environment. Thus any degree of renal hypoperfusion also is accompanied by exacerbation of medullary hypoxia, especially in the inner stripe because of the metabolic activity of epithelial cells lining the mTAL. In fact, in cases of acute renal failure in humans, histologic examination of renal tissue actually may show more severe lesions in the more distal nephron (mTAL) rather than in the proximal tubule.[244] Recognition of this more distal tubular damage has also led to consideration of therapeutic interventions to reduce damage to this nephron segment during periods of poor renal perfusion (e.g., continuous infusion of furosemide to decrease the metabolic activity of the mTAL). Third, despite the fact that the distal tubule and collecting ducts are responsible for reabsorption of less than 5% of the total glomerular filtrate, a decrease in reabsorption of only 1% to 2% can be quantitatively significant and can lead to dramatic polyuria (see Polyuria and Polydipsia later in this chapter). Next, generation of a maximal medullary concentration gradient requires slow flow of tubular fluid for countercurrent multiplication and slow flow of blood through the vasa recta to maximize countercurrent exchange. Thus conditions that increase tubular flow rates (high-volume intravenous fluids) or increase vasa recta blood flow (endogenous PGE_2 and PGI_2 production consequent to renal hypoperfusion) compromise the medullary concentration gradient (partial medullary washout) and lead to production of more dilute urine with increased urinary sodium concentration (and excretion).

A final aspect of tubular function that appears to be unique to horses among the domestic species is excretion of calcium. Equine urine is well recognized as being cloudy and viscid. These qualities can be attributed to the large amount of calcium excreted in normal equine urine, largely in the form of calcium carbonate ($CaCO_3$) crystals, and mucus secreted by glands in the renal pelvis and proximal ureter that acts to "lubricate" the lower urinary tract to minimize adherence of crystal to the epithelium lining the ureters, bladder, and urethra. Although the nature of this unique tubular calcium excretion has been studied little in horses, one report of the role of vitamin D in calcium and phosphorus homeostasis in horses suggested that this vitamin-hormone was less important in horses than in other species.[245] This fascinating difference between horses and other species evaluated by large animal internists clearly warrants further investigation.

Excretion of Solute and Water

Renal function traditionally is thought of in terms of glomerular filtration, tubular modification of the filtered fluid, and excretion of the final urine. This concept accommodates excretion of nitrogenous and organic wastes and the major aspects of regulation of body water content and ionic balance. Urine concentration and volume also are affected by solute excretion, and another way to think about renal function is in terms of total solute and water excretion. For example, a horse could produce 6 L of urine daily with an osmolality of 900 mOsm/kg to excrete 5400 mOsm of solute or, if the solute load were doubled to 10,800 mOsm, the horse could produce 12 L of urine with an osmolality of 900 mOsm/kg to eliminate the additional solute. Thus urine osmolality reflects the ability of the kidney to dilute or concentrate the final urine but does not necessarily provide an accurate estimate of the "quantitative ability" to excrete solute or retain water. One assesses these functions by calculating osmolal clearance (C_{osm}) and free water clearance (C_{H_2O}).[155] Like other clearances, these calculations require measurement of urine flow (via timed urine collection) and measurement of plasma and urine osmolality.

These measures of renal solute and water handling are conceptualized by considering urine to have two components: (1) that which contains all the urinary solute in a solution that is isosmotic to plasma (C_{osm}, usually expressed in milliliters per minute or liters per day), and (2) that which contains free water without any solute (C_{H_2O}, also expressed in milliliters per minute or liters per day). The sum of these two components is the actual urine flow rate in milliliters per minute or liters per day. Because urine is typically more concentrated than plasma, C_{H_2O} typically has a negative value, indicating water conservation. In fact, the inverse of free water clearance

is termed *renal water reabsorption*. Returning to the foregoing example, excretion of the 5400 mOsm would require production of 18 L of urine that is isosmotic with plasma (using a value of 300 mOsm/kg for plasma). However, because 6 L of concentrated urine actually was produced during the period measured, the kidneys quantitatively have reabsorbed 12 L of free water per day. In contrast, despite production of urine with an identical urine osmolality (900 mOsm/kg), excretion of 10,800 mOsm would require production of 36 L of urine isosmotic with plasma. Free water clearance would be 30 L/day (i.e., 30 L/day of free water would be reabsorbed by the kidneys). Thus although concentrated urine always will have a negative C_{H_2O} value, indicating renal water reabsorption, and dilute urine always will have a positive value for C_{H_2O}, indicating renal water excretion, quantitative assessment of renal solute and water handling requires measurement of osmolal and free water clearances.

Excretion of free water by the kidney occurs by generation of hypotonic tubule fluid in the ascending limb of the loop of Henle, and the amount or volume of free water produced depends on the amount of tubule fluid presented to that segment. Free water consequently is excreted by keeping the collecting ducts relatively impermeable to water (lack of vasopressin). Assessment of C_{H_2O} is most helpful in patients with hyponatremia and hypo-osmolality that cannot be attributed to another primary disease process (diarrhea or bladder rupture). For hyponatremia to develop, water excretion must be defective. For example, hyponatremia can develop with prerenal failure (hypovolemia) or with oliguric renal failure after a reduction in GFR and the amount of filtrate presented to the loop of Henle. Hyponatremia and hypo-osmolality may also develop with use of loop diuretics, because less free water is generated in the ascending limb of the loop of Henle because of blockade of the apical $Na^+/K^+/2Cl^-$ cotransporter (smaller amounts of solute are removed). A final cause of true hyponatremia may be the syndrome of inappropriate vasopressin secretion or syndrome of inappropriate antidiuretic hormone secretion. Although the latter condition has not been documented in horses, occasionally it may play a role in the development of hyponatremia in a foal.[246]

Examination of the Urinary System

Harold C. Schott II

HISTORY AND PHYSICAL EXAMINATION

To begin the evaluation of a horse with urinary tract disease, one should collect a complete history and perform a thorough physical examination. Important historical information includes duration and clinical signs, number of horses affected, diet, medications administered, and response to treatment. One also should assess water intake and urine output. For example, owners may mistake pollakiuria (frequent urination) for polyuria (increased urine production), and distinguishing between the two is helpful for forming a diagnostic plan. Pollakiuria frequently occurs in females during estrus or in either sex of horse with cystic calculi or cystitis. In contrast, polyuria more often accompanies renal disease, pituitary pars intermedia dysfunction (PPID), behavior problems (primary polydipsia), diabetes insipidus, or diabetes mellitus. Astute owners may note increased thirst after exercise or a change in urine character, such as a clearer stream, to support polydipsia and polyuria.

One can determine water intake over 24 hours by turning off any automatic-watering devices and providing a known volume of water to the horse.[247] Water intake can vary widely with environmental conditions, level of activity, and diet (see Renal Physiology) so that repeated measurements over several 24-hour periods may be more rewarding in documenting average daily water consumption. Urine output, which should range between 5 and 15 L in a horse with normal renal function, is more difficult to determine. One can apply a urine collection harness for 24-hour urine collections[248-251]; alternatively, one can use an indwelling Foley catheter attached to a collection apparatus to quantify urine output in mares. Although horses used for research tolerate these devices fairly well, they have limited application to clinical patients. One can construct a practical collection device for geldings and stallions by cutting off the bottom of a large plastic bottle, padding it, and fitting it over the prepuce. One covers the opening of the bottle with a rubber tube and clip, and urine can be removed every few hours.[252] During the collection period, horses usually are tied or restrained in stocks to minimize interference with the collection device.

The most common presenting complaints for horses with urinary tract disease are weight loss and abnormal urination. Other clinical signs vary with the cause and site of the problem and may include fever, anorexia, depression, ventral edema, oral ulceration, excessive dental tartar, colic, or scalding or blood staining of the perineum or hindlimbs. Although lumbar pain and hindlimb lameness have been attributed to urinary tract disease, a musculoskeletal problem is the usual cause of these clinical signs. Decreased performance may be an early presenting complaint for renal disease, but poor performance likely results from changes associated with uremia (mild anemia and lethargy) rather than from renal pain. Occasionally a horse with urolithiasis or renal neoplasia may have a history of recurrent colic or "kidney colic," but renal disease is an uncommon cause of abdominal pain. Prolonged or repeated posturing to urinate and dysuria or hematuria would be important findings to implicate the urinary tract as the probable source of abdominal pain in such patients.

In addition to a thorough physical examination, one should include rectal palpation in the evaluation of all horses with suspected urinary tract disease. One should palpate the bladder to determine size, wall thickness, and presence of cystic calculi or mural masses. If the bladder is full, one should palpate the bladder again after bladder catheterization or urination. One can palpate the caudal pole of the left kidney for size and texture. The ureters generally are not palpable unless enlarged or obstructed by disease, but one should palpate the dorsal abdomen (retroperitoneal course of ureters) and trigone to determine whether they are detectable. Dilation of a ureter may occur with pyelonephritis or ureterolithiasis; in mares, palpation of the distal ureters through the vaginal wall may be more rewarding. One also should palpate the reproductive tract to assess whether a reproductive problem could be causing the clinical signs.

HEMATOLOGY AND SERUM BIOCHEMISTRY

A complete blood count (CBC) that reveals an elevated white blood cell count and total protein or fibrinogen concentration

would support an inflammatory or infectious disease process. One may observe mild anemia (packed cell volume [PCV], 20%–30%) consequent to decreased renal erythropoietin production and a shortened red blood cell life span in horses with chronic renal disease.

BUN and Cr concentrations are the most commonly used indices of renal function, specifically the GFR.[5,130,253] One must remember that BUN and Cr do not increase until the majority of nephrons (generally considered about 75%) become nonfunctional.[254] Although this commonly used percentage is based on studies of partially nephrectomized laboratory animals, several clinical reports in which unilateral nephrectomy was used successfully to manage disorders of the upper urinary tract support a similar renal reserve capacity in horses.[41,74,255-257] In addition, renal function remained within normal ranges, and animals maintained body weight after experimental unilateral nephrectomy in ponies[258] and in horses.[259] Thus measurement of BUN and Cr is of little use in evaluating early or minor changes in GFR. Once elevated, however, small increases in BUN and Cr are more sensitive indicators of further deterioration in GFR, because one can interpret doubling of BUN or Cr as a 50% decline in remaining renal function (Fig. 14.10).

Urea can be measured by a variety of methods, categorized broadly as direct or indirect analyses.[5,130] The direct method is the diacetyl monoxime reaction, in which urea reacts with diacetyl after hydrolysis of diacetyl monoxime to diacetyl and hydroxylamine. One determines urea concentration spectrophotometrically by measuring the yield of the yellow diazine reaction product. Indirect analysis is based on enzymatic conversion of urea to ammonia and carbonic acid by urease. Several methods exist for subsequently determining ammonia concentration, and the one used most often is the enzyme-coupled reaction with glutamate dehydrogenase. Although the term *blood urea nitrogen* is widely accepted, one must remember that the actual measurement reported is the urea concentration in serum or plasma.

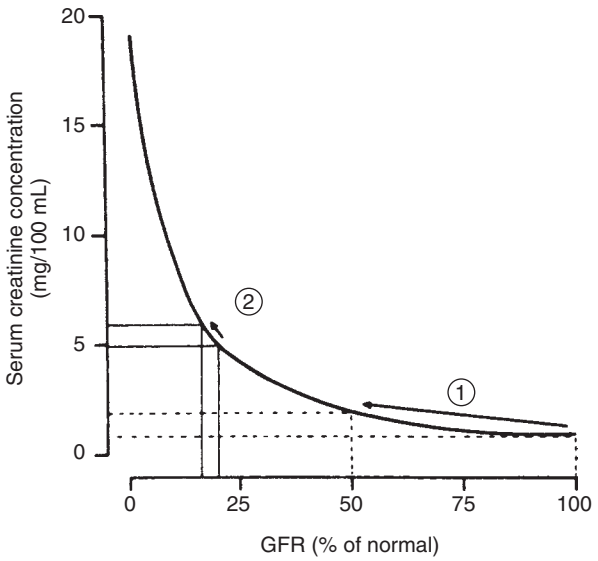

FIG. **14.10** Relationship between glomerular filtration rate (GFR) and serum creatinine (Cr). When renal function is normal, a large decrease in GFR (as with acute renal failure) results in a minor increase in Cr *(arrow 1).* In contrast, when renal function is decreased (as with chronic renal failure [CRF]), a much smaller decrease in GFR results in a similar increase in Cr *(arrow 2).* (From Brenner BM, editor: *Brenner and Rector's the kidney,* ed 8, Philadelphia, 2008, WB Saunders.)

Cr can also be assayed by several methods, but the one used most often is the Jaffe's reaction, which is a colorimetric assay based on the formation of a complex between Cr and alkaline picrate.[5,130,253] Unfortunately, a number of other substances in plasma or serum contribute to the yellow color, which leads to a 20% overestimation of actual Cr in human beings and in horses.[139] These non-Cr chromagens include glucose, pyruvate, acetoacetate, fructose, uric acid, ascorbic acid, and some drugs. Interference by non-Cr chromagens is greatest when Cr is in the normal range, which leads to a high coefficient of variation in repeated measurements of the same sample. With azotemia, Cr measurement by the Jaffe's reaction becomes more accurate because the contribution from non-Cr chromagens does not increase significantly (non-Cr chromagens are responsible for less than 5% of the color development when Cr is greater than 5.0 mg/dL). Non-Cr chromagens do not interfere significantly with urine Cr measurement.

In addition to the factors discussed in the preceding section that influence urea and Cr metabolism (see Renal Physiology), spurious increases in Cr may be reported in various metabolic disorders or after administration of certain cephalosporin antibiotics.[5] When such increases in Cr are thought to be spurious, one can measure true Cr by several methods, which include use of an automated analyzer that distinguishes Cr and non-Cr chromagens by their different rates of color development or performance of the Cr imidohydrolase enzyme assay. The latter yields ammonia, which can be quantified by colorimetric methods. As an example, Cr measured by the Jaffe's reaction increased 16% after horses were fasted for 3 days; however, when serum was analyzed by the enzymatic method, no increase in Cr was detected.[139] In addition to spurious increases in Cr, other substances can cause spurious decreases in serum Cr. The most common one is bilirubin, which, when greater than 5.0 mg/dL, may decrease measured Cr by 0.1 to 0.5 mg/dL.[5]

The reporting of serum or plasma urea and Cr concentrations also varies among different countries. In the United States BUN and Cr are reported in milligrams per deciliter, whereas in other parts of the world they are reported in standard international units of millimoles per liter and micromoles per liter, respectively. One can convert BUN from milligrams per deciliter to millimoles per liter and Cr from milligrams per deciliter to micromoles per liter by multiplying by 0.357 and 88, respectively.[5]

Azotemia is the term used to describe an elevation in BUN and Cr concentrations; thus it is strictly a laboratory abnormality. Azotemia can be prerenal in origin because of decreased renal perfusion. It may be attributable to primary renal disease or may accompany obstructive diseases or disruption of the urinary tract (postrenal azotemia).[254,260] Thus one should interpret BUN and Cr considering hydration status of the patient, presenting complaint, and physical findings. In general, animals with prerenal azotemia tend to have smaller increases in BUN and Cr than animals with intrinsic renal failure, whereas animals with postrenal failure may have the greatest degree of azotemia.[261] Unfortunately, BUN and Cr can cover a wide range of values for all three categories of azotemia; thus specific ranges do not identify the type of azotemia.[261-264] In an attempt to characterize azotemia better, use of the BUN-to-Cr ratio also has been examined. In theory,

the ratio should be higher for prerenal azotemia (because of increased reabsorption of urea with low tubule flow rates) and postrenal azotemia (because of preferential diffusion of urea across peritoneal membranes in cases of uroperitoneum) than for azotemia associated with intrinsic renal failure. As for categoric values for BUN and Cr, BUN-to-Cr ratios measured in azotemic dogs with naturally occurring diseases were distributed over wide, nondiscriminatory ranges for all three types of azotemia.[261,262] In horses, the BUN-to-Cr ratio more often has been used to separate acute renal failure from chronic kidney disease. In the acute renal failure, Cr tends to increase proportionately more than BUN, leading to a BUN-to-Cr ratio of less than 10:1.[265] In contrast, with chronic kidney disease, the BUN-to-Cr ratio often exceeds 10:1. Although a clear explanation for this difference has not been established, the difference may be related to different volumes of distribution for urea and Cr. Urea, a nonpolar molecule, diffuses freely into all body fluids, whereas Cr, a charged molecule, likely requires longer to diffuse out of the extracellular fluid space. Thus a sudden decrease in renal perfusion leads to a greater increase in Cr than in BUN. Muscle breakdown or damage, as with rhabdomyolysis, may be an additional factor contributing to the rapid increase in serum Cr concentration. Furthermore, the BUN-to-Cr ratio value provides only a suggestion of the duration of azotemia in horses, because one can find exceptions for acute and chronic renal failure. Finally, the BUN-to-Cr ratio also may be useful in assessing adequacy of dietary protein intake in cases of chronic kidney disease (see Chronic Kidney Disease).[266]

The terms *prerenal azotemia* and *prerenal failure* describe the reversible increase in BUN and Cr associated with renal hypoperfusion.[254,260,264,267] Although these terms are entrenched firmly in human and veterinary medical literature, they likely contribute to the failure to recognize the renal damage that accompanies several medical and surgical conditions. Lack of recognition is attributable to the large renal functional reserve. In fact, in many cases of prerenal failure, one can demonstrate altered glomerular and tubule function by proteinuria and cast formation, impaired concentrating ability, and changes in electrolyte excretion.[268,269] Although such functional alterations are usually reversible, a degree of permanent nephron loss can occur and could explain microscopic evidence of renal disease in as many as one third of equine kidneys examined.[270] Thus considering prerenal failure as a transient and reversible period of compromised renal function that can lead to permanent but clinically silent decreased renal functional mass may be more appropriate. Furthermore, periods of decreased renal blood flow or prerenal failure are accompanied by a number of compensatory renal responses that are mobilized to preserve renal blood flow (autoregulatory response of the afferent arterioles) and GFR (increase in filtration fraction because of angiotensin II–mediated efferent arteriolar constriction). In addition, increased intrarenal production of vasodilatory prostaglandins (PGE_2 and PGI_2) is an important response to renal ischemia that maintains or even increases medullary blood flow (see Renal Physiology). Thus one also can consider prerenal failure as a period of decompensation from the numerous renal compensatory responses to hypoperfusion.[271]

Prerenal azotemia traditionally is differentiated from intrinsic renal failure by assessing urinary concentrating ability. With prerenal azotemia, maintenance of urinary concentrating ability is demonstrated by a urine specific gravity greater than 1.020 and urine osmolality exceeding 500 mOsm/kg. In contrast, urinary concentrating ability typically is lost with intrinsic renal failure, and urine specific gravity and osmolality are less than 1.020 and 500 mOsm/kg, respectively, in the face of dehydration.[272] Such assessment is challenging, however, because it is valid only when performed on urine collected before initiation of fluid therapy or administration of any medications (α_2-receptor agonists, furosemide) that can affect urine flow and concentration.[14-16,273] In addition to these measures of urinary concentrating ability, urine-to-serum ratios of osmolality, urea nitrogen and Cr concentrations, and fractional sodium clearance may provide useful information to differentiate prerenal azotemia from intrinsic renal failure (Table 14.6).[272,273] For example, urine-to-serum Cr ratios exceeding 50:1 (reflecting concentrated urine) and fractional sodium clearance values less than 1% (indicating adequate tubule function) would be expected in horses with prerenal azotemia, whereas ratios less than 37:1 and clearance values greater than 0.8% were reported in a group of horses determined to have primary renal disease.[272] Although these values can be helpful, the data in Table 14.6 illustrate that renal hypoperfusion is accompanied by a progressive loss of concentrating ability because the ranges of these ratios tend to be lower for horses with prerenal azotemia than for clinically normal horses. Thus these data also support the concept that the progression from prerenal failure to intrinsic renal failure is associated with decompensation of the intrarenal responses to hypoperfusion.[271] Clinically, this decompensation is recognized as persistence of azotemia, whereas prerenal azotemia rapidly improves (by 30%–50% within 24 hours and completely by 72 hours) in response to fluid therapy and other supportive treatments.

In patients at risk for developing acute renal failure, including horses with serious gastrointestinal disorders or rhabdomyolysis and those receiving nephrotoxic medications, serial assessment of urine specific gravity or osmolality, sodium concentration, and fractional sodium clearance may be useful in identifying significant changes in renal function before the onset of azotemia. Similarly, if one determines urine flow rate during a timed urine collection period, assessment of renal water reabsorption (C_{H_2O}; see Renal Physiology) can be a sensitive predictor of impending renal failure.[274-276] Unfortunately, monitoring of these parameters often is complicated by use of intravenous fluid support in such patients. Although

TABLE **14.6 Diagnostic Indices That May Be Useful for Separating Prerenal from Renal Azotemia in Horses**

Diagnostic Index	Normal Horses	Prerenal Azotemia	Renal Azotemia
Urine osmolality (mOsm/kg)	727–145	458–961	226–495
Uosm/Posm	2.5–5.2	1.7–3.4	0.8–1.7
UUN/PUN	34.2–100.8	15.2–43.7	2.1–14.3
UCr/PCr	2.0–344.4	51.2–241.5	2.6–37.0
FCl_{Na}	0.01–0.70	0.02–0.50	0.80–10.10

Modified from Grossman BS, Brobst DF, Kramer JW, et al.: Urinary indices for differentiation of prerenal azotemia and renal azotemia in horses, *J Am Vet Med Assoc.* 180:284, 1982.
Uosm, Urine osmolality; *Posm,* plasma osmolality; *UUN,* urine urea nitrogen; *PUN,* plasma urea nitrogen; *UCr,* urine creatinine; *PCr,* plasma creatinine; *FCl_{Na},* fractional sodium clearance.

intravenous fluids can complicate interpretation of many of these indexes of renal function, Roussel and colleagues[273] found that the urine-to-plasma osmolality ratio remained greater than 1.7:1 in healthy horses receiving 20 L of an intravenous polyionic solution over 4 hours. Thus serial measurement of urine specific gravity or osmolality may provide useful information for patients at high risk for acute renal failure.

One usually considers a diagnosis of postrenal azotemia resulting from obstruction or disruption of the urinary tract based on clinical signs, including dysuria and renal colic. With bladder rupture, however, some affected foals and adult horses continue to void urine, although progressive abdominal distention usually accompanies development of uroperitoneum. One most often confirms urinary tract disruption by measuring a twofold or greater value for peritoneal fluid Cr concentration compared with serum Cr concentration. Occasionally in a foal with a urachal problem or a gelding with a disrupted urethra, postrenal azotemia may be accompanied by considerable swelling in the abdominal wall or in the prepuce, respectively.

In addition to screening for azotemia and concentrating ability, the laboratory database should include serum electrolyte, protein (albumin and globulin), and glucose concentrations, as well as muscle enzyme activity.[5,260,263-267] Hyponatremia and hypochloremia are common in horses with renal disease. Serum potassium concentration may be normal or may be elevated in cases of acute or chronic kidney disease. Hyperkalemia is often most extreme and most serious with urinary tract disruption and uroperitoneum. Calcium and phosphorus concentrations vary in horses with renal disease. Hypercalcemia and hypophosphatemia often occur in horses with chronic kidney disease, especially when they are fed alfalfa hay (see Chronic Kidney Disease), whereas hypocalcemia and hyperphosphatemia are more common with acute renal failure. With protein-losing glomerulopathies, albumin tends to be lost to a greater extent than the higher molecular weight globulins. One can find low total protein and albumin concentrations in severe cases of chronic renal disease, whereas other horses may have an increased globulin concentration consistent with a chronic inflammatory response. Hyperglycemia (values greater than 150–175 mg/dL) after stress, exercise, sepsis, PPID, α_2-agonist administration, or diabetes mellitus can result in glucosuria.[277,278] Finally, when pigmenturia is a complaint, muscle enzyme activity measurements and urine sediment examination are helpful in differentiating myoglobinuria from hematuria or hemoglobinuria.

URINALYSIS

One should perform urinalysis whenever one suspects urinary tract disease. One can collect urine as a midstream catch during voiding, via urethral catheterization, or via cystocentesis in foals. Unlike cows, horses cannot be stimulated easily to urinate, but they often urinate within a few minutes after being placed in a freshly bedded stall. Manual compression of the bladder during rectal palpation may stimulate urination after the rectal examination is completed. One should evaluate color, clarity, odor, viscosity, and specific gravity at the time of collection.[279,280] Normal equine urine is pale yellow to deep tan and often is turbid because of the large amounts of $CaCO_3$ crystals and mucus. Urine appearance commonly changes during urination, especially toward the end of micturition, when more crystals tend to be voided. If pigmenturia or hematuria is present, then noting the timing and duration of passage of discolored urine may help localize the source. Pigmenturia throughout urination is most consistent with myonecrosis or a bladder or kidney lesion, whereas passage of discolored urine at the start or end of urination more often occurs with lesions of the urethra or accessory sex glands (see Hematuria).

Assessment of Urine Concentration

Urine specific gravity is a measure of the number of particles in urine and is a useful estimate of urine concentration. Although determination of specific gravity with a refractometer is quick and easy (reagent strips should not be used to measure specific gravity in horses),[279] one must recognize that urine concentration is determined most accurately by measurement of urine osmolality, because the presence of larger molecules in urine, such as glucose or proteins, leads to overestimation of urine concentration by assessment of specific gravity. Clinically, overestimation is a problem in patients with diabetes or heavy proteinuria.[155] Urine specific gravity is used to separate urine concentration into three categories: (1) urine that is more dilute than serum (hyposthenuria or specific gravity less than 1.008 and osmolality less than 260 mOsm/kg); (2) urine and serum of similar osmolality (isosthenuria or specific gravity of 1.008–1.014 and osmolality of 260–300 mOsm/kg); and (3) urine that is more concentrated than serum (specific gravity greater than 1.014 and osmolality greater than 300 mOsm/kg). Although urine of most normal horses is concentrated (3 to 4 times more concentrated than serum with specific gravity of 1.025–1.050 and an osmolality of 900–1200 mOsm/kg), occasionally a normal horse produces dilute or highly concentrated urine. For example, in response to water deprivation for 24 to 72 hours, horses with normal renal function often produce urine with a specific gravity greater than 1.045 and an osmolality greater than 1500 mOsm/kg.[194,195,200] In contrast, foals typically have hyposthenuric urine consequent to their mostly milk diet.[169] Although constant polyuria decreases the ability of the neonate to generate a large osmotic gradient in the medullary interstitium, dehydrated foals still can produce urine with a specific gravity greater than 1.030. With chronic renal insufficiency, the ability to produce concentrated (specific gravity greater than 1.025) or dilute (specific gravity less than 1.008) urine is lost. Thus horses with chronic kidney disease typically manifest isosthenuria. As discussed previously, urine specific gravity is helpful in differentiating prerenal from renal azotemia in horses that exhibit dehydration or shock with many disorders.

Reagent Strip Analysis

The pH of equine urine is usually alkaline (7.0–9.0 pH).[279,280,281] Vigorous exercise or bacteriuria can result in acidic pH. Bacteriuria can impart an ammonia odor to the urine secondary to breakdown of urea by bacteria with urease activity. Concentrate feeding generally decreases urine pH toward the neutral value.[281] Similarly, the more dilute the urine sample is, the closer the pH is to 7.0. The dilute urine produced by foals typically is neutral to mildly acidic and is relatively free of crystalline material. Interestingly, calcium oxalate crystals are more prevalent in urine of foals than in that of adults.[282] Occasionally, one detects aciduria in a dehydrated or anorectic horse. Although aciduria typically has been attributed to metabolic acidosis, many patients actually may have hypochloremic metabolic alkalosis accompanied

by paradoxic aciduria. The mechanism for paradoxic aciduria is likely similar to that described in ruminants with abomasal outflow obstruction.[283] Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus paradoxic aciduria is most likely to occur with concomitant hypokalemia or whole-body potassium depletion.

Commercially available urine reagent strips can yield false-positive results for protein with alkaline samples. Thus proteinuria can be assessed better by performing the semiquantitative sulfosalicylic acid precipitation test or by specific quantification with a colorimetric assay (e.g., the Coomassie brilliant blue dye method[284] or other assays that are used routinely on cerebrospinal fluid [CSF]). In normal mares, a mean value of 3.2 mg/kg (1.6 g) per day and a range of 3.6 to 22.3 mg/kg (1.8–11.2 g) per day for urinary protein excretion have been reported by Schott and colleagues[285] and Kohn and Strasser,[153] respectively. These values translate into urinary protein concentrations of less than 100 mg/dL in most normal horses. Comparison of the quantitative protein result (milligrams per deciliter) to urine Cr concentration (milligrams per deciliter) in the form of a urine protein-to-Cr ratio also is recommended. This technique is more practical because it obviates timed urine collection. Although a normal range has not yet been reported for horses, values exceeding 1.0:1.0 and 3.5:1.0, respectively, are considered above normal for dogs[286] and indicate nephrotic range proteinuria in human beings.[5] Thus a urine protein-to-Cr ratio greater than 2:1 likely supports significant proteinuria in an equine patient. Proteinuria may occur with glomerular disease, bacteriuria, or pyuria or may transiently follow exercise.[285]

Normal equine urine should not contain glucose. Although the renal threshold for glucose has not been evaluated thoroughly in horses, an early study by Link[287] suggested that the threshold may be lower (about 150 mg/dL) than that of small animals and human beings. Thus glucosuria can accompany hyperglycemia associated with the causes described previously or with administration of dextrose-containing fluids or parenteral nutrition.[277,278] In addition, glucosuria may accompany sedation with α_2-agonists or exogenous corticosteroid administration.[14,15] When one detects glucosuria in the absence of hyperglycemia, one should suspect primary tubule dysfunction (Fanconi syndrome). Glucosuria more often has been detected in horses with acute renal failure (mostly in experimental models of nephrotoxicity) than in those with chronic renal disease. Unlike ruminants, ketones rarely are detected in equine urine, even in advanced catabolic states or with diabetes mellitus. A positive result for blood on a urine reagent strip can reflect the presence of hemoglobin, myoglobin, or intact erythrocytes in the urine sample. Evaluation of serum for hemolysis and of urine sediment for red blood cells, combined with an ammonium sulfate precipitation test to detect myoglobin,[288] can be rewarding in differentiating among these pigments (see Hematuria). Finally, occasionally one detects bilirubinuria on reagent strip analysis of equine urine. Bilirubinuria is associated with intravascular hemolysis, hepatic necrosis, and obstructive hepatopathies. In most instances, one more commonly detects hemolysis and hepatic disease by abnormal biochemical data such as elevated serum bilirubin concentration and increased hepatic enzyme activity.

Sediment Examination

Sediment examination is probably the most underused diagnostic technique available for evaluation of urinary tract disorders in horses. In humans, sediment examination has been demonstrated to be a useful predictor for occurrence and severity of acute renal failure.[289] Unfortunately, a major limitation is that sediment should be examined within 30 to 60 minutes after collection. To perform sediment examination, 10 mL of fresh urine is centrifuged (usually in a conical plastic tube) at 1000 rpm for 3 to 5 minutes. The supernatant urine is discarded (or used for quantitative protein determination), and the pellet is resuspended in the few drops of urine remaining in the tube. A drop of sediment is transferred to a glass slide, and a coverslip is applied. One first examines the sediment at low power to evaluate for casts and subsequently at high power to quantify erythrocytes, leukocytes, and epithelial cells, as well as to determine whether bacteria are present. Casts are molds of Tamm-Horsfall glycoprotein and cells that form in tubules and subsequently pass into the bladder. Casts are rare in normal equine urine but may be associated with inflammatory or infectious processes. Casts are unstable in alkaline urine; thus, one should evaluate sediment as soon as possible after collection to ensure accurate assessment. Fewer than five erythrocytes per high-power field should be seen in an atraumatically collected urine sample. Increased numbers of urinary red blood cells can result from inflammation, infection, toxemia, neoplasia, or exercise (see Hematuria). Pyuria (more than 10 white blood cells per high-power field) most often is associated with infectious or inflammatory disorders. Normal equine urine should have few bacteria, if any. The absence of bacteria on sediment examination does not rule out their presence, however, and bacterial culture of urine collected by catheterization or cystocentesis (foals) should be performed when one suspects cystitis or pyelonephritis. Finally, equine urine is rich in crystals. Most of these are $CaCO_3$ crystals of variable size, but calcium phosphate crystals and occasionally calcium oxalate crystals also are visible in normal equine urine (Fig. 14.11).[279,280,290] Addition of a few drops of 10% acetic acid solution may be necessary to dissolve crystals for accurate assessment of urine sediment.[279]

Enzymuria

Renal tubules are metabolically active, being responsible for absorption or excretion of a wide range of substances. Transport of these compounds is facilitated by several enzymes, which are found in large amounts in lysosomes within or in the brush borders of tubular epithelial cells. Regular turnover of these cells and release of endocytotic vesicles and lysosomes into the tubular lumen results in activity of enzymes in urine (enzymuria).[291] A number of substances that are filtered at the glomerulus (including bile acids, aminoglycoside and cephalosporin antibiotics, mannitol, dextrans, radiographic contrast media, and heavy metals) are taken up via endocytosis into proximal tubular epithelial cells. Endocytotic vesicles combine with lysosomes and substances that are not broken down by lysosomal enzymes subsequently are extruded into the tubule lumen through evacuation of residual bodies.

Inflammation or necrosis of tubular epithelial cells results in elevated urinary activity of lysosomal and brush border enzymes. Because proximal tubular epithelial cells are the most metabolically active of all kidney cells, they are particularly susceptible to ischemic injury. Furthermore, they can be injured similarly by exposure to large quantities of

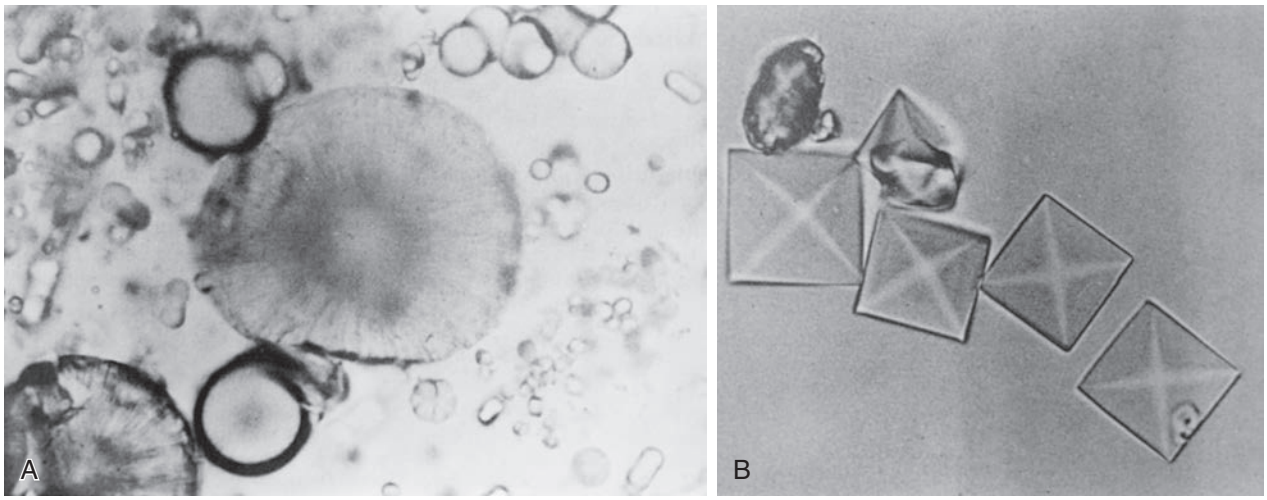

FIG. **14.11** Crystals commonly observed in equine urine sediment (original magnification, ×160). **A,** Large, round calcium carbonate ($CaCO_3$) crystals (center and lower left) and smaller calcium phosphate crystals (oblong). **B,** Calcium oxalate dihydrate crystals. nephrotoxins in glomerular filtrate. As a result, determination of the activities of certain urinary enzymes can provide evidence of tubular damage several days before azotemia may develop.[292-295] Additional contributors to increased urinary enzyme activity include (1) low-molecular-weight enzymes such as amylase that normally are filtered by glomeruli and reabsorbed in the proximal tubules, (2) postrenal genitourinary tract epithelia that usually contribute a negligible amount to the overall urinary enzyme activity (unless they become neoplastic), and (3) secretions from accessory sex glands. Contributions from the latter explain why intact males tend to have higher urinary activities of lactate dehydrogenase (LDH) and *N*-acetyl-β-D-glucosaminidase (NAG).

Although more than 40 enzymes have been detected in urine of different species, only a few appear to be of diagnostic relevance. To be of clinical use, a urinary enzyme must have measurable activity in the kidney; its activity must lie within a narrow range in urine of healthy animals; it must be sufficiently large (molecular weight greater than 60,000) so as not to be filtered freely across the glomerulus; and its activity must increase early enough during renal injury to permit institution of corrective treatment. Finally, the activity of the urinary enzyme should remain fairly stable in urine for several days without the need for special processing. In human beings and dogs, a number of enzymes, including NAG, LDH, β-glucuronidase, alanine aminopeptidase, alkaline phosphatase (ALP), leucine aminopeptidase, γ-glutamyltransferase (GGT), and kallikrein have been demonstrated to be sensitive indicators of renal damage.[292-294,296,297] With respect to horses, normal values have been established for activities of GGT, ALP, NAG, LDH, and kallikrein.[298-302] Attempts to assay aspartate aminotransferase and alanine aminotransferase activities were unsuccessful in normal horse urine.[299]

ALP and GGT are membrane-associated enzymes found primarily in the brush border of the proximal tubular epithelium.[293-297,303] Their activity in distal tubular epithelium is negligible.[257] These enzymes have activity in other tissues, but because they are not filtered by the glomerulus, elevated activity in urine in the absence of significant proteinuria is presumed to originate from the kidneys. Measurable activity in normal urine is attributed to cell turnover.[293] LDH is a more ubiquitous tubular epithelial enzyme, being as active in the distal tubules and medullary papillae as in proximal tubular epithelium.[296-303] NAG is a proximal tubular lysosomal enzyme.[293-303] Only GGT, ALP, LDH, and NAG have been assayed in the urine of horses known to have, or thought to have, some form of renal dysfunction. Determination of NAG activity can be difficult in normal equine urine because of its alkalinity, and normal values may be less than detectable assay limits when one uses a spectrophotometric, rather than a fluorometric, method.[304-307] Published normal activities (expressed per gram of Cr) for these enzymes in equine urine are GGT: 0 to 25 IU/g Cr; ALP: 0 to 28 IU/g Cr; LDH: 0 to 12 IU/g Cr; and NAG: less than 1 IU/g Cr (less than 2 IU/L urine). Comparison with Cr concentration, which is relatively constant, results in less volume-related variation and allows interpretation of a randomly collected specimen (compared with a urine sample obtained during a timed collection period).[298,308,309]

Factors one must consider when measuring urinary enzyme activities include conditions under which the urine sample has been stored, urinary pH, diurnal variation, gender- and age-related variations, and other naturally occurring inhibitors or promoters of enzyme activity in urine (albumin, mucoproteins, proteolytic agents, amino acids, and ammonia). Although these factors have received limited study respecting equine urine, it has been documented that freezing can decrease activity of all enzymes, especially GGT. Furthermore, the colder the temperature, the more rapid the loss of enzyme activity.[298] To obtain the most accurate results, one should refrigerate samples (4°C) and assay them within 72 hours of collection. In species that have a slightly acidic or neutral urinary pH, assay of NAG is considered one of the most valuable diagnostic tests available. However, its activity appears to be susceptible to pH changes. In human beings receiving nephrotoxic medications, NAG activity in urine became undetectable at pH values greater than 8.[310] Similarly, NAG activities were undetectable (less than 2 IU/L) in urine

of normal horses.[311] In a study of monensin toxicosis in horses, NAG activity increased as urinary pH decreased.[300] Certain amino acids and ammonia further act as inhibitors of lysosomal enzymes such as ALP and NAG in the urine of humans, dogs, and rats,[312,313] and techniques have been developed to remove these agents from the urine by gel filtration before assay of their activity.[314]

Theoretically, assessment of changes in the urinary activity of selected enzymes may assist the clinician in identifying the segment of the nephron suffering the greatest dysfunction or damage. Although NAG, GGT, and ALP are associated primarily with proximal tubular epithelium, LDH usually is associated with distal tubular epithelial cells. Increases in urinary GGT and ALP activity have been induced experimentally in horses receiving gentamicin and neomycin for 5 to 10 days.[315,316] Increases also have been measured in horses with diarrhea, acute abdominal crises, and endotoxic shock. In the latter instances, enzymuria was assumed to indicate tubular damage after ischemia. Five consecutive days of furosemide administration also produced moderate increases in GGT and ALP activity, with ALP increasing more rapidly.[311] However, 48 hours of water deprivation failed to induce any changes in GGT, ALP, or LDH activity.[302] Similarly, no change in urinary LDH activity was observed in horses administered phenylbutazone (8.8 mg/kg PO) daily for 6 days.[302]

Although increases in urinary enzyme activities generally indicate acute tubular damage, one must interpret urine enzyme-to-Cr ratios carefully. Threshold values above which elevations are significant have not been well documented, although one study reported that a GGT/Cr value greater than 25 IU/g indicated tubular damage.[298] In contrast, in a study of gentamicin-induced nephrotoxicity in pony mares, Hinchcliff and colleagues[315] measured GGT/Cr values exceeding 100 IU/g several days before measuring an increase in Cr concentration. Furthermore, one frequently may measure GGT/Cr values between 25 and 100 IU/g in horses receiving gentamicin at recommended doses. Similar to gentamicin pharmacokinetics, enzymuria in these horses has been highly variable; these horses have not been recognized to be at risk of developing acute renal failure. Although enzymuria likely reflects a degree of tubular damage in these patients, one should interpret increases in GGT/Cr values between 25 and 100 IU/g with caution, whereas increases greater than 100 IU/g are more likely to be clinically significant.

Horses with chronic renal disease may have normal or reduced enzyme activities that reflect cellular changes that occur in the nephron in response to chronic inflammation. Just as BUN and Cr concentrations may be normal during the early stages of renal disease; urinary enzyme activities may not accurately reflect renal dysfunction later in the disease course when results of blood tests and urinalysis are more likely to be abnormal. A possible reason for this phenomenon is that substantial destruction of tubular epithelium occurring early in the disease leaves fewer epithelial cells to be an ongoing source of elevated enzyme activities. Alternatively, regenerating tubular epithelial cells may be more refractory to the effects of the toxin.

All in all, determination of urinary enzyme activities has failed to gain acceptance as a routine measure of renal tubular damage in most equine hospitals. This lack of acceptance can be attributed to the high sensitivity for detection of subclinical renal tubular damage. For example, although a urine GGT/Cr ratio elevated to a value of 75 supports tubular damage, it does not provide the clinician a quantifiable risk for development of acute renal failure. Thus, as a single measurement, the ratio is of limited use in deciding whether one should discontinue use of a nephrotoxic medication (e.g., gentamicin). In contrast, more dramatic elevations of the GGT/Cr ratio may precede development of azotemia and could be a useful warning that one may need to discontinue a medication or, at a minimum, prolong the dosing interval. Until values for urinary enzyme activities are reported for a larger number of equine patients with various diseases, the true value of assessing urinary enzyme activity will remain unclear.

Fractional Clearance of Electrolytes

Urinary electrolyte losses, which reflect tubular function, can be expressed as excretion rates (total amount of electrolyte excreted during a given time period, expressed as milliequivalents per minute) or as clearance rates. Determination of clearance rates uses the same clearance concept to measure GFR. In brief, a clearance rate (Cl_A) is a measure of the volume of plasma that is cleared completely of the substance in question (A) during a given time period. One calculates the Cl_A by performing a timed urine collection (to determine urine flow in milliliters per minute) and measuring the concentration of the desired substance in plasma and urine (Cr or inulin for determination of GFR)[5]:

$$Cl_A = (\text{urine [A]/plasma [A]}) \times \text{urine flow}$$

As with protein, urinary clearance of many substances, including electrolytes, often is compared with that of Cr.[5] Basically, a substance that is filtered mostly across the glomerulus but is neither reabsorbed nor secreted by renal tubules (inulin) will have a clearance rate similar to that of Cr. In contrast, a substance that is poorly filtered (larger molecule) or reabsorbed to a great extent by renal tubules (sodium or chloride) will have a lower clearance value than that of Cr. Similarly, clearance values for substances that are eliminated by filtration and tubular secretion (potassium) may exceed that measured for Cr. An advantage of comparing the clearance of a substance (A) to Cl_{Cr} (expressed as a fraction of Cl_{Cr}) is that it obviates the need to perform a timed urine collection, because the urine flow factor is cancelled out in the calculation:

$$\frac{Cl_A}{Cl_{Cr}} = \frac{(\text{Urine [A]/Plasma [A]}) \times \text{Urine flow}}{(\text{Urine [Cr]/Plasma [Cr]}) \times \text{Urine flow}}$$

that, by rearrangement and expression as a percentage, becomes

$$\frac{Cl_A}{Cl_{Cr}} = \frac{\text{Urine [A]}}{\text{Plasma [A]}} \times \frac{\text{Plasma [Cr]}}{\text{Urine [Cr]}} \times 100$$

This calculation is called the *fractional Cr clearance value*.[5,317] More often, however, the term *fractional excretion* has been used to describe this value. Although most sources recommend that blood and urine samples be collected at the same time for determination of fractional clearance values, serum electrolyte and Cr concentrations are usually stable (except in patients with prerenal azotemia or acute renal failure), so one can use blood values measured within a few days of the urine sample in the clearance calculations. Consequently, leaving a specimen cup for the client to use to collect a voided sample is acceptable and obviates bladder catheterization in many cases.

As previously discussed (see Renal Physiology), the equine kidneys function to conserve more than 99% of filtered sodium and chloride ions. In contrast, potassium ions are conserved poorly except during periods of whole body potassium depletion (anorexia, prolonged exercise). Thus normal fractional clearance values are less than 1% for sodium but are considerably higher for potassium (Table 14.7).[318-325] Increases in fractional sodium and chloride clearance values may reflect an appropriate renal regulatory response to dietary excess, as with psychogenic salt consumption.[265] Alternatively, increases in fractional clearance values specifically for sodium and phosphorus also can be early indicators of renal tubule damage[272,295,315,324,326]; however, one must interpret results of these calculations in light of fluid therapy because fractional clearance values can be increased artifactually in horses receiving intravenous polyionic solutions.[272] Similarly, medication (furosemide) or light exercise also can result in increased urine flow and fractional sodium and chloride clearance values.[327]

The kidneys play an important role in equine calcium and phosphorus homeostasis, and renal loss varies with dietary intake. Thus fractional clearances of calcium and phosphorus also have been used to assess adequacy of dietary intake. Although diet is evaluated more appropriately on a herd basis by analyses of hay and concentrates, fractional clearances may be useful in individual animals or when feed analysis is impractical (e.g., forage consists of pasture). Determination of fractional calcium and phosphorus clearances has received limited study with a focus on young racing horses.[227,320,321,328-330] For example, excessive dietary phosphorus intake (which can lead to nutritional secondary hyperparathyroidism) leads to increased fractional clearance of phosphorus. Evaluation of fractional calcium clearance is hampered by the fact that most of the calcium in equine urine is in the form of $CaCO_3$ crystals. To measure the urinary calcium concentration reliably, one must collect the entire contents of the bladder during voiding or via catheterization to ensure collection of the initial crystal-poor and final crystal-rich fractions. Subsequently, one treats a well-mixed aliquot of urine with acetic acid or nitric acid to solubilize the crystals.[324] In one report, fractional calcium and phosphorus clearance values greater than 2.5% and less than 4% were considered consistent with adequate dietary intake (adequate calcium intake with phosphorus intake that was not excessive).[320] Unfortunately, because the ranges for fractional calcium and phosphorus clearances can be wide in normal horses (see Table 14.7), measurement of these clearances may not be sensitive enough to detect minor dietary imbalances. Like potassium, the fractional clearance of magnesium is high (29%± 8%) in horses fed a diet adequate in magnesium. Horses fed a low-magnesium diet reduced fractional clearance to 6%± 3%.[331]

Determination of fractional electrolyte clearance values also has been advocated in the evaluation of horses with recurrent rhabdomyolysis.[319,332,333] Low sodium and potassium clearances have been reported in some affected horses. Whether these low fractional clearance values reflected total body electrolyte depletion (as a consequence of repeated bouts of exercise in hot weather or repeated furosemide administration) or a true physiologic predisposition to rhabdomyolysis was not determined. Nevertheless, low fractional clearance values document the need for electrolyte supplementation in equine athletes. Harris and Snow[332] also described another population of horses that exhibited recurrent rhabdomyolysis that had increased fractional phosphorus clearance and was reported to respond to dietary supplementation with ground limestone. Thus although

NR, Not reported.
[a]Values calculated from data provided.
[b]Fractional clearance of potassium may exceed upper limit on high potassium diets; a fractional clearance of phosphorus exceeding 4% suggests excessive dietary intake; a fractional clearance for calcium should exceed 2.5% with adequate intake.
[c]Low range attributed to low urine potassium concentrations determined by ion-specific electrodes.
[d]Fractional clearance value for magnesium reported at 7 to 30.

determination of fractional electrolyte clearances may be helpful in the evaluation of horses with recurrent rhabdomyolysis, only a small portion of affected horses are likely to show significant clinical improvement in response to dietary electrolyte supplementation alone.

Finally, the methodology used to determine fractional electrolyte clearances should be standardized because several factors may lead to erroneous results. For example, a note of caution is warranted when ion-specific electrodes (instead of a flame photometer) are used to measure urinary potassium concentration, because components of animal urine can interfere with the ion-specific electrode and lead to spurious low values. One usually can avoid this problem by performing the analysis on urine diluted with water.[334] As mentioned previously, light exercise may increase urine flow rate and sodium excretion.[327] Thus "spot" urine samples are best collected in the morning before feeding and exercise. McKenzie and colleagues[234] compared fractional electrolyte clearance values between single-sample spot urine collections to 24-hour volumetric urine collections over 3 days in horses receiving diets varying in cation-anion balance. They found substantial variation in fractional clearance values within individual horses over the 3-day study, despite feeding of a consistent diet. When they assessed the effect of the differing diets, fractional clearance values for sodium, potassium, and chloride were generally similar when calculated using urine electrolyte concentrations determined in spot urine samples or well-mixed 24-hour collection samples. However, they found greater variability with fractional clearance values for calcium and magnesium. The fact that they detected considerable variability should not be surprising when one remembers that fractional clearance values are a calculation using four measurements (Cr and electrolyte concentrations in plasma serum and urine). Thus small variations in each measured value have the potential to magnify error in the final calculation. All in all, this study should serve as a reminder that determination of fractional electrolyte clearances is only one of the diagnostic tools one should use to evaluate patients with renal disease or recurrent rhabdomyolysis or to assess diet in a group of horses.

IMAGING TECHNIQUES

Ultrasonography

One can perform ultrasonographic examination of the urinary tract transrectally or transabdominally.[335-342] Bladder imaging is performed best transrectally using a 5-MHz probe. One must remember the character of equine urine while imaging the bladder; the urine will be an inhomogeneous, swirling, echogenic fluid because of the presence of mucus and crystals. The latter can appear as echogenic sediment in the ventral aspect of the bladder, and balloting the bladder may cause this echogenic material to swirl. One also can confirm the presence of a cystic calculus because calculi have a highly echogenic surface and produce an acoustic shadow (Fig. 14.12). Similarly, one may image and palpate masses in the bladder wall during the examination.

The right kidney is triangular or horseshoe shaped and is imaged best transabdominally via the dorsolateral aspect of the last two or three intercostal spaces (Fig. 14.13A). The left kidney is somewhat a more typical bean shape, lies deep to the spleen, and can be imaged via the last two intercostal spaces or via the paralumbar fossa. Because the left kidney is deeper than the right kidney, it can be difficult to image completely and is

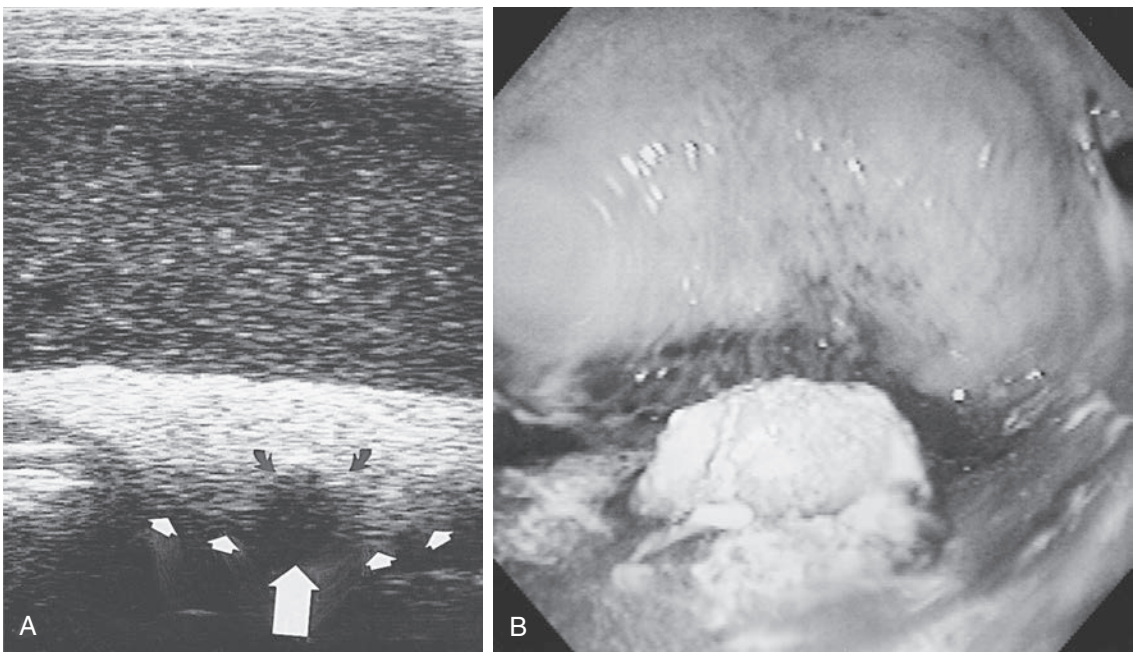

FIG. **14.12** Transrectal ultrasonographic and cystoscopic images of the bladder of a Miniature Horse mare with recurrent cystitis and urolithiasis. **A,** The ultrasonographic image shows a layer of echogenic crystalline material in the ventral aspect of the bladder (*small, white arrows* outline ventral bladder wall) and presence of a small cystolith (outlined by *small black arrows* and *large white arrow*). **B,** After lavage of the urine sediment, cystoscopy confirmed the presence of a small urolith, which was amenable to removal by digital manipulation.

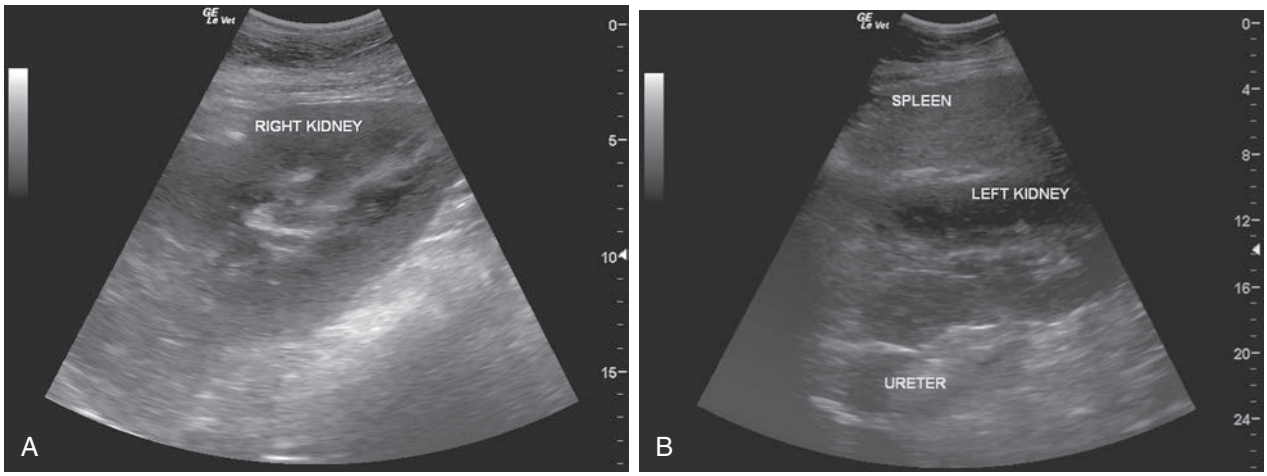

FIG. **14.13** Transabdominal ultrasonographic image of a normal **(A)** right kidney **(B)** and left kidney. The renal medulla is more hypoechoic than the renal cortex, except for the renal pelvis, which varies in echogenicity. The left kidney is imaged deep to the spleen.

examined best with a 2.5- or 3-MHz probe (Fig. 14.13B). One should assess systematically the size and shape of both kidneys, architecture, and echogenicity of the parenchyma, including imaging the kidneys in dorsal, sagittal, transverse, and transverse oblique anatomic planes.[340] In a full-size horse, the right kidney should not measure more than 15 cm in the longest axis, whereas the left kidney may measure up to 18 cm if imaged longitudinally.

In acute renal failure the kidneys may be normal or enlarged, and abnormalities of parenchymal detail are not often detected. When present, abnormal findings may include perirenal edema, widening of the renal cortex, and loss of a distinct corticomedullary junction.[336,337,339,341-343] Chronic kidney disease can result in decreased kidney size, irregular surfaces, and increased echogenicity because of renal fibrosis. Cystic or mineralized areas in renal parenchyma can be associated with chronic renal disease or congenital anomalies. Although uncommonly recognized, distinct curvilinear hyperechoic bands in the outer renal medulla parallel to the corticomedullary junction have been imaged in foals and adults horses with renal disease attributable to acute or chronic phenylbutazone toxicity.[342,344,345] This finding, termed the *medullary rim sign,* is thought to result from damage (and possible secondary mineralization) to the inner stripe of the outer medulla, the location of highly metabolically active nephron segments including the distal extent of the proximal tubule and the thick ascending limb of the loop of Henle. Calculi in the renal pelvis generally cast an acoustic shadow and can result in hydronephrosis of the affected kidney (Fig. 14.14).[336,337,339] Occasionally, one cannot image one or both kidneys because of a gas-filled bowel between the kidney and abdominal wall. Reexamination at a later time generally is required for successful imaging in such cases. In addition, administration of high rates of fluid therapy, especially in foals, can lead to iatrogenic pyelectasia (fluid distention of the renal pelvis).[342,346] One should use caution so as not to interpret this mild distention of the renal pelvis falsely as evidence of ureteral or lower urinary tract obstruction.

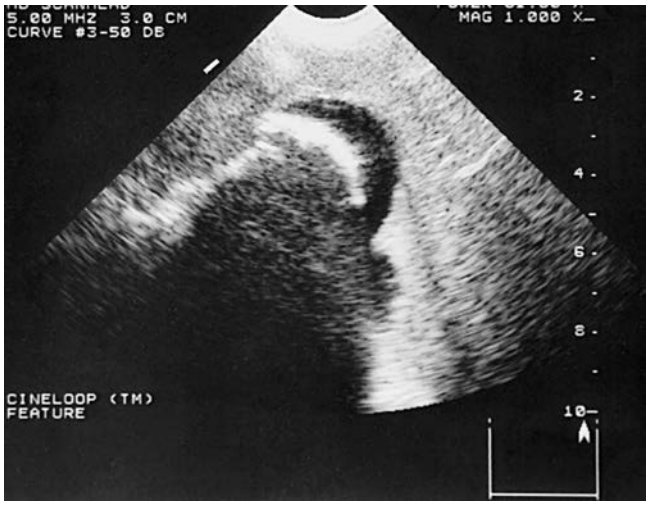

FIG. **14.14** Transrectal ultrasonographic image of the left kidney of a mare with nephrolithiasis and hydronephrosis. The nephrolith has an echogenic surface and produces an acoustic shadow. The echolucent crescent moon-shaped structure is a fluid-filled remnant of the renal parenchyma, consistent with hydronephrosis.

Radiography

Radiography rarely is used to evaluate urinary tract disease in adult horses. One usually can obtain diagnostic radiographs of the urinary tract only in foals or Miniature Horses. Excretory urography using intravenous contrast material or pyelography using contrast agent delivered into the renal pelvis under ultrasonographic guidance may be useful to identify a nonfunctional or hypoplastic kidney or an ectopic or torn ureter.[78,83] The latter procedure may be more rewarding, but both require general anesthesia to be performed safely, and these radiographs can be very difficult to interpret due to extensive superimposition and poor image quality. One also can use retrograde contrast studies to evaluate the ureters in mares[347]; however, they have been used most often in foals suspected of having an ectopic ureter or a ruptured bladder. Contrast radiographic studies also can help to identify strictures or masses in the urethra or bladder, but endoscopy is generally more useful for these problems. In small animals, abdominal survey radiographs are most useful for assessing

kidney size and shape, whereas ultrasonography provides more information about parenchymal changes associated with renal disease.[348] Thus use of a standardized protocol for ultrasonographic evaluation of the equine kidneys should provide essentially the same amount of information as the combined use of survey radiography and ultrasonography in small animal patients.[340]

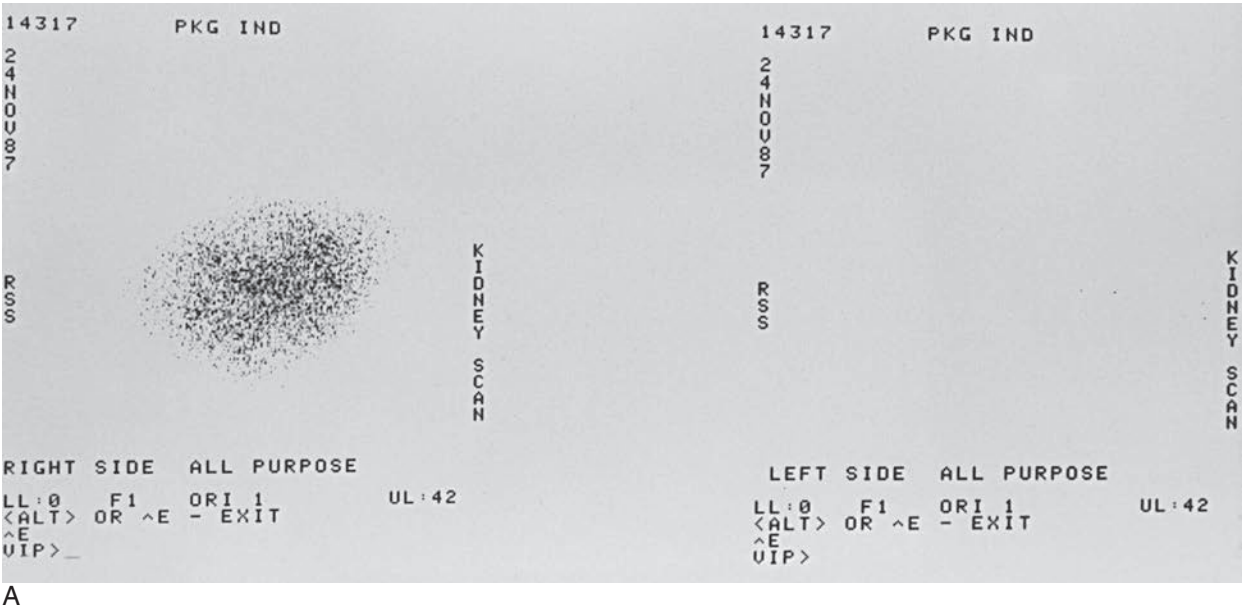
Nuclear Scintigraphy

Nuclear scintigraphy is an additional imaging modality often used to assess renal anatomy and function in human beings and small animals. One can use various radionuclides and pharmaceuticals, depending on the type of scintigraphic examination being pursued.[349-351] In fact, scintigraphy is used routinely for quantitative measurement of GFR in these species. Walsh and Royal[231] compared use of renal scintigraphy (using 99mTc-DTPA, which is similar to inulin in that it is neither secreted nor reabsorbed after filtration) for measurement of GFR in horses but found greater variability compared with GFR values measured by plasma disappearance of inulin or the same radionuclide (99mTc-DTPA). Nevertheless, renal scintigraphy using 99mTc-DTPA can provide qualitative information about renal function and is the only method currently available for assessing split renal function (assessing individual kidney function) in horses. Renal scintigraphy also has been performed with 99mTc tagged to glucoheptonate (taken up by the proximal tubule epithelial cells to provide anatomic detail) or mercaptoacetyltriglycine (MAG_3, which is similar to p-aminohippurate because it is eliminated by proximal tubular secretion) to provide qualitative information about renal anatomy and function (Fig. 14.15).[352,353] Thus one may use renal scintigraphy to document the presence of a functional kidney in horses when multiple ultrasonographic examinations have been complicated by interfering bowel or when one desires information about individual kidney function.

Endoscopy

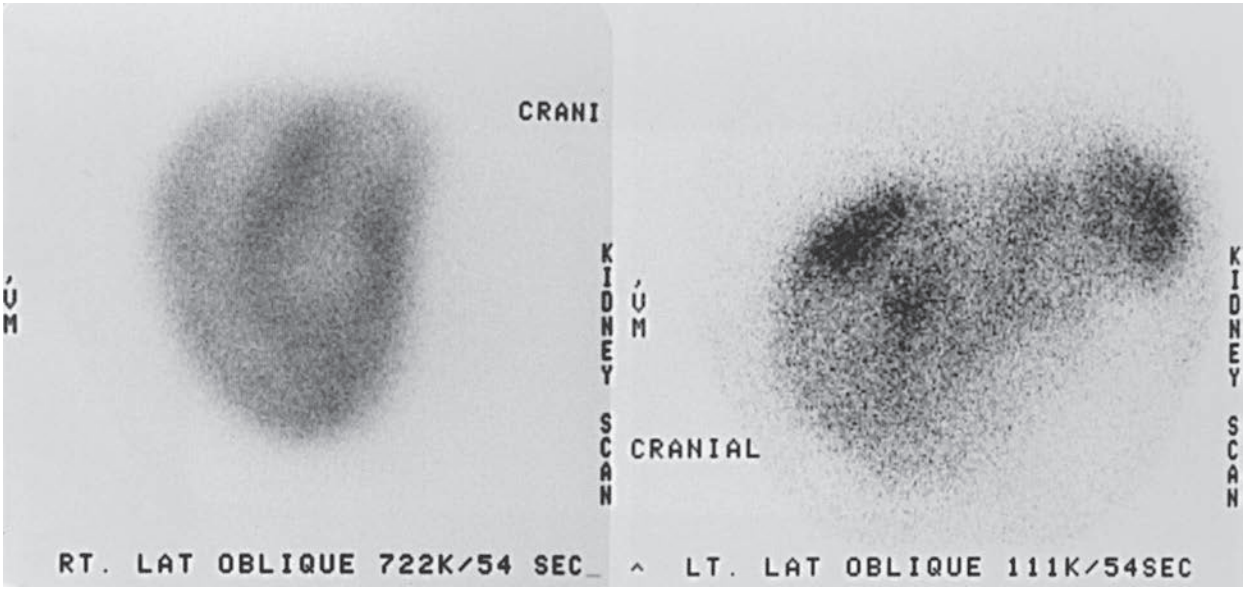
Endoscopy of the urinary tract is a useful diagnostic aid when the complaint is abnormal urination.[279,354-356] A flexible endoscope with an outside diameter of 12 mm or less and a minimum length of 1 m is adequate for examination of the urethra and bladder of an adult horse of either sex. One should sterilize the endoscope before endoscopy of the lower urinary tract. Tranquilization of the patient is recommended, and one should clean the distal end of the penis or the vulva thoroughly. The endoscope is passed as one passes a urinary catheter, using the air control intermittently to inflate the urethra or bladder. It is important to not insufflate with air excessively while the endoscope is underneath urine in the bladder because the mucus will bubble and prevent complete visualization. Normal urethral mucosa is pale pink with longitudinal folds. When dilated with air the mucosa flattens and may appear redder than normal, and a prominent submucosal vascular pattern may be apparent. Passage of a catheter before endoscopy (for sample collection or to empty the bladder) can produce mild irritation and erythema of the urethral mucosa; therefore, one should not mistake this for abnormal findings. The regions of the ischial arch (where the urethra begins to widen into the ampullar portion) and of the colliculus seminalis (in the roof of the pelvic urethra just distal to the urethral sphincter) should be examined closely, because these are common sites of posturination or postbreeding hemorrhage in geldings or stallions (see Hematuria). Subsequent passage of the endoscope through the urethral sphincter and air distention allows evaluation of the bladder for calculi, inflammation, and masses (see Fig. 14.12). Viewing the ureteral openings in the dorsal aspect of the trigone can help determine the source of hematuria or pyuria (see Hematuria). A small volume of urine should pass from each ureteral opening approximately once each minute or more frequently if the horse is well hydrated or has been sedated with an α_2-agonist. One can perform individual ureteral catheterization to obtain urine samples from each kidney by passing sterile polyethylene tubing via the biopsy channel of the endoscope. Additionally, one can take biopsies of masses in the bladder or urethra.

SPECIALIZED DIAGNOSTIC TECHNIQUES



Ureteral Catheterization

With the development of high-resolution videoendoscopic equipment, retrograde instrumentation of the bladder, ureter, and renal pelvis rapidly is replacing surgical exploration for diagnostic evaluation and therapeutic management of urinary tract disorders in human beings and dogs.[349,357-359] Similarly, retrograde ureteral catheterization and instrumentation can be a valuable technique for evaluation and treatment of horses with unilateral disorders of the upper urinary tract.[29,360,361] In addition to localization of unilateral renal hemorrhage, pyelonephritis, and neoplasia, ureteral catheterization further enables retrograde pyelography.[347] As mentioned previously, one may perform this technique successfully in male and female horses during cystoscopic examination.[279,354-356]



In mares, one also can catheterize the ureters manually without endoscopic guidance.[362] After preparation of the vulva, one catheterizes the bladder and drains the urine. One removes the bladder catheter and dilates the urethra manually until two fingers can be passed into the bladder. One can palpate the ureteral orifices dorsally as small, soft projections. When this is done, a catheter is placed between the fingertips, passed through the urethra, and directed into the ureter (Fig. 14.16). A relatively rigid catheter with a rounded end (no. 8–10 Fr polypropylene catheter) facilitates passage into the ureter. After advancing the catheter 5 to 10 cm into the ureter, one attaches a syringe to the other end of the catheter and collects a urine sample. During sampling, the catheter is held in place, and the ureteral opening is occluded with the fingertips to minimize loss of urine around the catheter.

Water Deprivation and the Antidiuretic Hormone Challenge Test

Water deprivation is a simple test to determine whether hyposthenuric polyuria is caused by a behavior problem such as primary (psychogenic) polydipsia or results from central or nephrogenic diabetes insipidus.[252] One should not perform a water deprivation test in an animal that is clinically dehydrated or azotemic. A baseline urinalysis should be performed (sample collected by catheterization to empty the bladder at the start of the test), and serum concentrations BUN and Cr and body weight should be measured before removal of water (food does not necessarily need to be removed, but this may help prevent gastrointestinal complications of water deprivation). One measures urine specific gravity and weight loss after 12 (usually overnight) and 24 hours. Horses with normal renal function

B

FIG. **14.15** Renal scintigraphic images of horses with renal disease. **A,** Renal scintigraphic image using 99mTc-diethylenetriamine pentaacetic acid (99mTc-DTPA) revealed absence of functional left renal tissue, compared with an image of the right kidney, in a stallion with chronic renal failure (CRF). A nonfunctional hypoplastic left kidney was found on necropsy examination. **B,** Renal scintigraphic image using technetium-99m-glucoheptonate (99mTc-GH) in a gelding with unilateral left-sided pyelonephritis revealed inhomogeneous uptake of the radionuclide and lesser count emission over the same time compared with the normal right kidney. The scintigraphic study, which provided anatomic and functional information, supported pursuit of unilateral nephrectomy, rather than prolonged antibiotic administration, as the treatment of choice for this horse.

typically produce urine with a specific gravity greater than 1.045 and an osmolality greater than 1500 mOsm/kg in response to water deprivation within 24 to 72 hours.[194,195,200] Practically, one can stop the test when urine specific gravity reaches 1.025 or greater. Furthermore, the test should be stopped if more than 5% of body weight is lost or clinical evidence of dehydration becomes apparent. With long-standing primary polydipsia, affected horses may not be able to concentrate urine fully (to a specific gravity greater than 1.025) because of partial washout of the medullary interstitial osmotic gradient. Extending the test period beyond 24 hours for such patients offers little benefit; however, affected horses should respond more favorably to water deprivation (producing urine with a higher specific gravity) after a period of partial water deprivation (termed a *modified water deprivation test*) during which daily water intake is restricted to 40 mL/kg for several days, which should allow time for restoration of the medullary interstitial osmotic gradient.[252] Horses with central or nephrogenic diabetes insipidus

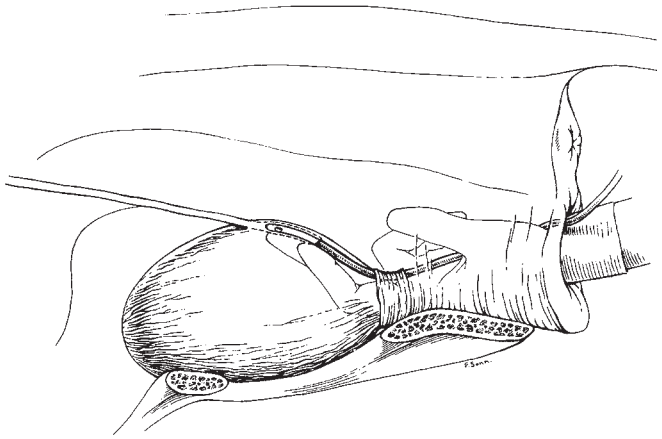

FIG. **14.16** Manual placement of a polypropylene catheter into the ureter of a mare. (From Schott HC, Hodgson DR, Bayly WM: Ureteral catheterization in the horse, *Equine Vet Educ.* 2:140, 1990.)

cannot concentrate urine in response to a water deprivation test.[56,252,363,364] When one suspects these problems, patients should be monitored every few hours because significant dehydration may ensue within 6 hours of water deprivation.

In the absence of azotemia or clinical signs of early renal failure, inability to concentrate urine in response to water deprivation supports a diagnosis of diabetes insipidus; however, the test does not distinguish between the neurogenic and nephrogenic forms of the disorder. One can differentiate these by exogenous administration of vasopressin (antidiuretic hormone).[56,363,364] Currently, two approaches exist for performing an antidiuretic hormone challenge test. First, one can administer aqueous synthetic vasopressin (20 U/mL for intramuscular or subcutaneous injection) as an intravenous infusion (5 U [0.25 mL] added to 1 L of a 5% dextrose solution and administered IV at a rate of 2.5 mU/kg over 60 minutes [250 mL to a 500-kg horse]) or an intramuscular injection (0.5 U/kg). An increase in urine specific gravity to 1.020 or greater after 60 to 90 minutes would be the expected response, whereas failure to increase urine concentration would support nephrogenic diabetes insipidus. Second, one can use desmopressin acetate (DDAVP), a synthetic analog of arginine vasopressin. Administration of DDAVP is considered the safer diagnostic technique in small animals because the change in structure of this vasopressin analog has decreased pressor actions and less effect on visceral smooth muscle compared with an enhanced antidiuretic effect. One microgram of DDAVP has an antidiuretic activity of 4 U of arginine vasopressin. The author and coworkers have validated the use of DDAVP as a replacement for the antidiuretic hormone challenge test in normal horses. In this study, the nasal spray form of DDAVP (0.1 mg/mL DDAVP) was diluted in sterile water, and 0.05 μg/kg was administered intravenously (25 μg, equal to 100 U of antidiuretic activity, to a 500-kg horse) to horses that had polyuria induced by repeated nasogastric intubation with water for 3 days preceding DDAVP challenge. Urine was collected for 8 hours after DDAVP administration, and an increase in urine specific gravity to values greater than 1.020 was observed from 2 to 7 hours after DDAVP administration (Fig. 14.17).[365] Furthermore, DDAVP administration had no effect on heart rate or systemic blood pressures. These data demonstrate that intravenous administration of DDAVP is a safe and useful diagnostic tool for evaluation of horses with diabetes insipidus.

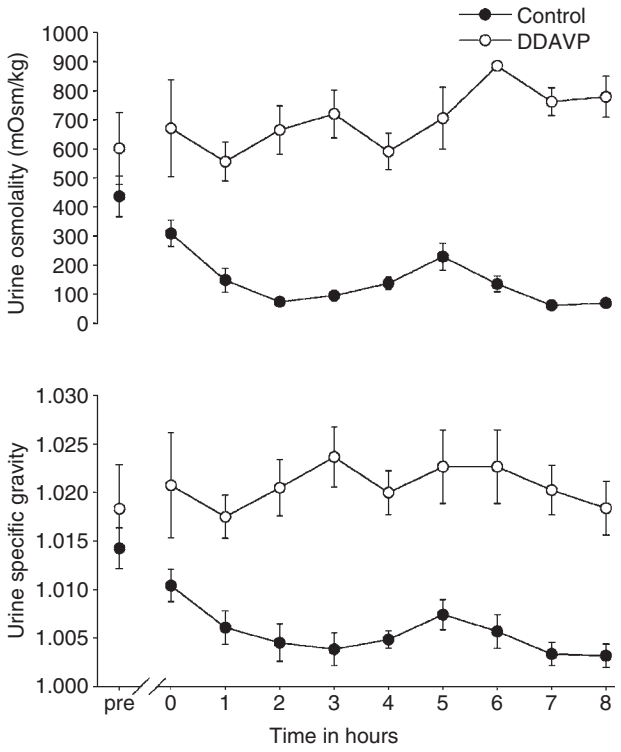

FIG. **14.17** Urine osmolality and specific gravity in six horses administered 0.05 μg/kg desmopressin acetate (DDAVP) *(open circles)* or placebo *(filled circles)* intravenously at time 0. The horses had polyuria induced by repeated nasogastric intubation with water (40 mL/kg) twice daily for 3 days preceding DDAVP challenge and again 4 hours after administration of DDAVP. Urine was collected for 8 hours after treatment, and an increase in urine specific gravity to values greater than 1.020 was observed from 2 to 7 hours after DDAVP administration.[365]

A final test for evaluating polyuria and polydipsia is an intravenous challenge with hypertonic saline (Hickey-Hare test).[182] The goal is to produce an increase in plasma osmolality, which should trigger release of endogenous vasopressin. One protocol for the test would be to measure plasma osmolality and endogenous vasopressin concentrations before and within 30 minutes after administration of 1 to 2 mL/kg of a 7.5% NaCl solution. A normal response, expected in horses with primary polydipsia, would be concurrent increases in plasma vasopressin concentration and urine specific gravity. Horses with nephrogenic diabetes insipidus also would respond with an increased plasma vasopressin concentration; those with neurogenic diabetes insipidus would not. Urine specific gravity would not be expected to increase in response to hypertonic saline administration with either form of diabetes insipidus. One could evaluate plasma vasopressin concentrations similarly before and at the end of a water deprivation test.[179,183] Unfortunately, however, assays for plasma vasopressin concentration are not currently available at commercial laboratories. Thus pursuit of this diagnostic test requires cooperation of a research laboratory.

Quantitative Measures of Renal Function

As mentioned previously, azotemia does not develop until more than 75% of nephrons cease to function; therefore measurement of BUN and Cr, although readily available, provides a poor reflection of smaller declines in renal function.

A number of methods are available to quantitate renal function in horses.[279,235] Basically, these tests can be separated into plasma disappearance curves or clearance studies involving use of timed urine collections. Generation of plasma disappearance curves requires collection of an initial blood sample, intravenous administration of one of a number of compounds (inulin, Cr, sodium sulfanilate, phenolsulfonphthalein [phenol red], or radionuclides), and collection of another series of blood samples over the subsequent 60 to 90 minutes.* One can express results in terms of an elimination half-life in minutes or as clearance values in milliliters per kilogram per minute. Mean elimination half-lives of 39.5 ± 4.4, 32.8 ± 4.1, and 16.4 ± 2.3 minutes have been reported for sodium sulfanilate, 99mTc-MAG_3, and phenolsulfonphthalein, respectively, in healthy horses.[222,366,367] The difference in these values can be explained in part by the fact that 99mTc-MAG_3 and phenolsulfonphthalein are eliminated mostly by tubular secretion and consequently are cleared more rapidly from plasma than is sodium sulfanilate (eliminated mostly by glomerular filtration). Plasma elimination half-times are most useful when measured sequentially throughout the course of renal disease; for example, Bertone and colleagues[50] reported a progressive increase in the sodium sulfanilate elimination half-time from 90 to 150 minutes during a 240-day course of chronic kidney disease in a horse with PKD.

When one uses plasma disappearance curves of a substance to estimate GFR, the compound being used must meet all the requirements of a filtration agent[211,214,219]: (1) no significant binding to plasma proteins, (2) ability to be filtered freely across the glomerulus, and (3) absence of tubular reabsorption or secretion. The gold standard compound is inulin. More traditionally, GFR has been measured by timed urine collection periods (to measure urine flow rate) and measurement of plasma and urine concentrations of a test compound that meets the listed requirements.[5,235] Several protocols exist for performing urine clearance studies. Ideally, the urine collection period should span 24 hours, although for practicality, one may use shorter collection periods.[252,235] For all protocols, one documents the bladder as being empty at the start of the collection period by catheterization or observation of voiding. All urine produced during the study period is collected and pooled into one sample. At the end of the collection period, the bladder should be emptied again via catheterization, the total volume of urine produced should be recorded, and an aliquot of the pooled urine sample should be assayed for the test substance. Similarly, one measures the concentration of the test substance in a blood sample collected near the midpoint of the urine collection period. For urine collections of 12 to 24 hours, endogenous Cr is the test substance used because it is the only one that does not have to be given by steady intravenous infusion during the collection period. GFR is calculated as the Cl_{Cr},

$$\text{GFR} = (\text{Urine [Cr]}/\text{Plasma [Cr]}) \times \text{Urine flow}$$

with the modification that the result usually is divided by body mass (in kilograms) to express GFR in term of milliliters per minute per kilogram. Although endogenous Cr is a convenient test substance, its use typically underestimates GFR because non-Cr chromagens in serum artifactually increase the value in the denominator.[235] Similarly, significant tubular secretion of Cr can be one of the compensatory responses to renal failure. This can lead to overestimation of GFR calculated using endogenous Cl_{Cr}. Despite these limitations, the endogenous Cl_{Cr} technique for measurement of GFR can provide useful information, especially when it is performed on several occasions during the course of renal failure (see Chronic Kidney Disease).

To avoid the limitations of endogenous Cl_{Cr} as a measure of GFR, one can administer a number of filtration markers (inulin, Cr, radionuclides) as an intravenous infusion throughout the urine collection period.* One starts the infusion as a bolus to increase the plasma concentration of the test substance to the desired level (e.g., the desired plasma concentration for exogenous Cr is 5–10 mg/dL, to minimize the influence of non-Cr chromagens) and subsequently continues a steady infusion throughout the remainder of the collection period. One usually performs this type of study for a shorter period with the horse restrained in stocks. One should empty the bladder of the horse at the start of the study and collect urine after two or three 30-minute intervals. One should pass a catheter and empty the bladder completely at the end of each 30-minute period. Alternatively, an indwelling bladder catheter can be used for the entire collection. After urine volumes are measured, an aliquot of each urine sample is assayed, and a blood sample is collected at the midpoint of each urine collection period for the test substance; then the GFR is calculated as the mean value for the two or three collection periods. For all practical purposes, these types of GFR measurements (with the exception of exogenous Cl_{Cr}) usually are limited to research studies, because commercial laboratories do not offer inulin assays. One also can use this shorter protocol for GFR determination using endogenous Cr as the test substance, without the need for an intravenous infusion. (The results of several studies measuring GFR in normal horses are presented in a previous section of this chapter; see Renal Physiology.)

Renal Biopsy

Renal biopsy is a useful diagnostic technique for identifying the affected region of the nephron, the type of lesion, and the chronicity and severity of disease.[5,368-371] Although biopsy is a safe procedure when performed with ultrasonographic guidance, it has risks, including perirenal hemorrhage or hematuria and, less commonly, penetration of bowel. In human beings, perinephric hematomas are common and have been detected in 57% to 85% of patients the day after biopsy. Microscopic hematuria occurs in virtually all patients for the first couple of days after biopsy, and gross hematuria occurs in 5% to 10% of patients. Most of these complications are inconsequential, but in 1% to 3% of patients the complications have resulted in the need for postbiopsy transfusions.[5] Similarly, in a group of seven normal horses subjected to renal biopsy, postbiopsy macroscopic and microscopic hematuria occurred in five animals. Furthermore, perirenal hemorrhage was a prominent finding during necropsy examination of five of these animals (including one examined 27 days after biopsy tissue was collected).[371] Thus renal biopsies remain controversial in human and equine renal failure patients.[372-374] Renal biopsies should be approached with caution and are indicated only when the results would alter the therapeutic plan or prognosis. Information about the effect of renal biopsy results on therapy and outcome of renal disease in human beings is limited; however, in one prospective study, biopsy results were found to influence

* References 211, 214, 219, 222, 231, 366, 367.

* References 154, 208, 210, 214, 216, 219, 226, 230.

physicians' decisions on about half of cases when the technique was performed.[375] In general, renal biopsy is pursued more aggressively in human beings with acute renal insufficiency than in those with chronic renal insufficiency, especially when it is difficult to determine the type of renal disease based on results of urinalysis and sediment examination.[5] In the equine patient, one performs a renal biopsy with the horse sedated and restrained in a stocks. Penetration of the needle (a Tru-Cut™–type biopsy needle or, preferably, a triggered biopsy device) into the renal parenchyma is imaged sonographically by triangulating the ultrasound beam with the biopsy instrument and the kidney or by determination of the site and depth of biopsy needle placement via ultrasonographic imaging immediately before biopsy. One should place the tissue collected in formalin for histopathologic and possibly electron microscopic evaluation. Additional samples can be collected for bacterial culture and for immunofluorescence testing (placed in Michel's transport medium or quick-frozen after coating with a preservative such as Tissue-Tek). One should determine appropriate sample processing beforehand by contacting the pathologist who will examine the biopsy samples.

Although renal biopsy results could provide useful diagnostic and prognostic information about the type of renal disease in horses with acute renal failure (e.g., glomerulonephritis, tubular necrosis, interstitial nephritis), they have been used more often to document pathology in horses with chronic kidney disease. In most cases of chronic kidney disease, one cannot detect the inciting cause unless it can be associated with a historical event or immunofluorescence testing is pursued. This limitation can be attributed to the fact that significant renal disease develops before onset of azotemia. Pathologic lesions are widespread at this point, and involvement of all nephron segments and the interstitium often leads to the interpretation of end-stage kidney disease. In occasional cases, the results may help separate infectious (pyelonephritis) or congenital (renal dysplasia) causes from nonspecific causes of renal failure. Although such results could be useful in the therapeutic approach to these patients, one should consider the limitations and risks of renal biopsy before performing this technique in horses with chronic kidney disease.

Urodynamic Procedures

Cystometrography and urethral pressure profiles are used to evaluate detrusor and urethral muscle function, respectively. Both techniques involve measurement of intraluminal pressure during inflation of the bladder or urethra. These techniques have been useful for diagnosis of myogenic and neurogenic disorders of the bladder and urethra in dogs and human beings.[376] The procedures have been performed experimentally in normal horses and ponies,[377-379] but little information is available about the use of these techniques in clinical cases (see Urinary Incontinence and Bladder Dysfunction).

Acute Renal Failure

Warwick M. Bayly

Acute renal failure (ARF) is a clinical syndrome associated with abrupt reduction in GFR. Sustained reduction in GFR is associated with failure of the kidneys to excrete nitrogenous wastes causing azotemia and with disturbances in fluid, electrolyte, and acid-base homeostasis. The human medical literature is full of various terms and definitions for different forms of ARF. Veterinary medical definitions are simpler. Basically, ARF can result from decreased renal perfusion without associated cell injury, as with dehydration (prerenal failure); obstruction or disruption of the urinary outflow tract (postrenal failure); or ischemic or toxic damage to the tubules, tubular obstruction, acute glomerulonephritis leading to a primary reduction in the filtering capacity of the glomeruli, or tubulointerstitial inflammation and edema. Any of these intrarenal causes can be associated with intrinsic renal failure. Prerenal azotemia, dehydration, and ischemic tubular insults or necrosis represent a continuum, the former resulting in the latter when perfusion is compromised sufficiently to result in death of tubule cells.[380] Classically, ARF has been associated with oliguria and occasionally with anuria, and these are certainly the most commonly noted clinical signs associated with this disease in horses. However, nonoliguric forms of ARF, particularly intrinsic renal failure, exist and are characterized by slower development of azotemia, lower peaks in creatinine concentrations, subtler increases in urinary sodium clearance, and a more rapid recovery of renal function in response to treatment. Nonoliguric renal failure seems to be diagnosed less commonly in horses, although it is not uncommon to recognize mildly azotemic horses that have apparently normal urine output. In some cases, localized proximal tubule damage and reduced solute reabsorption actually may lead to enhanced distal delivery of filtrate, which may result in polyuric ARF.

In horses, ARF is usually prerenal or renal in origin and most often is caused by dehydration, hemodynamic, or nephrotoxic insults.[70] With the exception of bladder rupture or ureteral or urachal rents in neonates, postrenal failure is uncommon in horses. Identification and correction of the cause of ARF are important because, in the early stages, renal dysfunction is frequently reversible, whereas established ARF often requires extensive supportive care and carries a guarded prognosis. By identifying patients at increased risk and attempting to interrupt the cycle of events leading to ARF, one possibly may reduce the incidence of this condition.

CAUSES

Prerenal failure is associated with conditions that result in decreased cardiac output or increased renal vascular resistance (or in both) and is the most common cause of reversible azotemia. In horses, the most common causes of dehydration, reduced cardiac output, and therefore reduced renal perfusion are associated with diarrhea, endotoxemia, acute blood loss, septic shock, and prolonged exercise. The resultant reductions in renal blood flow, GFR, and urine production usually cause azotemia and retention of water and electrolytes. Anesthesia and decreased mean arterial pressure also may decrease cardiac output and urine production enough to result in a degree of prerenal azotemia. NSAIDs also can precipitate prerenal azotemia in patients with decreased renal blood flow.[381] Although prostaglandins play only a minor role in maintenance of renal blood flow in the normal state, PGE_2 and PGI_2 are important vasodilatory mediators of renal blood flow under conditions of reduced renal perfusion. Thus administration of NSAIDs to dehydrated or toxemic patients may contribute further to renal hypoperfusion by exacerbating a decrease in renal blood flow. In some cases, this may be sufficient to produce ischemic renal parenchymal damage, thus causing intrinsic renal

failure. Generally, the parenchymal lesion associated with NSAID toxicity is medullary crest or papillary necrosis. Such lesions develop because the renal medulla normally receives much less blood flow than the renal cortex and consequently is much more susceptible to NSAID-induced changes in renal blood flow.

In human beings, intrinsic renal diseases that lead to ARF generally are categorized according to the primary site of injury: tubules, interstitium, glomeruli, or vessels.[380] Acute tubular necrosis (ATN) is the intrinsic renal failure recognized most often in horses (interstitial and primary glomerular disease being recognized occasionally and vascular disease almost never). Ischemia, especially when associated with microvascular coagulation (which often leads to irreversible cortical necrosis[265]), and nephrotoxins probably are the most common causes of equine ATN. Important nephrotoxins include aminoglycoside antibiotics and NSAIDs. Less commonly, ATN develops after exposure to endogenous pigments (myoglobin or hemoglobin), heavy metals such as mercury (contained in some counterirritants), or vitamins D or K_3 (menadione).[382-385] Use of aminoglycosides, particularly gentamicin, is a common cause of equine ATN.[386] Aminoglycoside toxicity is a result of damage to proximal tubular epithelial cells that is mediated by impaired cell organelle function. Administration of potentially nephrotoxic agents such as NSAIDs, polymyxin B, or furosemide (which can exacerbate hypovolemia) can increase the risk of aminoglycoside nephrotoxicity.

Myoglobinuria and hemoglobinuria have been associated with the development of ARF in horses (pigmentary nephropathy).[387] Myoglobinuric nephrosis can follow exertional rhabdomyolysis, heat stroke, or extensive crush injuries. Causes of intravascular hemolysis and hemoglobinuria include incompatible blood transfusions, immune-mediated hemolytic anemia, fulminant hepatic failure, and toxicosis from ingesting onions (*Allium* spp.) or withered red maple leaves *(Acer rubrum)*. Although the mechanism of pigment-induced renal injury is still not well understood, increased hydroxyl radical formation associated with reduction of ferrous iron compounds and tubular obstruction by casts of heme proteins are likely contributing factors. The fact that pigmentary nephropathy is uncommon in well-hydrated horses suggests a possible link to renal perfusion. Myoglobin and hemoglobin have also been suggested to induce renal vasoconstriction.

Acute interstitial nephritis often is not recognized but is believed usually to result from an allergic reaction to drugs such as β-lactam and sulfonamide antibiotics. Immune-mediated and embolic or ascending bacterial infections also may be associated with the condition, which is characterized by edema and inflammatory cell infiltration of the interstitium. Tubules frequently contain leukocytes and erythrocytes, which pass into the lumen through the disrupted tubular basement membrane.

Glomerulonephritis often is identified postmortem in aged horses[70,270] and apparently is most often immune mediated. Glomerulonephritis often results in subacute or nonoliguric renal failure. Although the condition is theoretically reversible with immunosuppressive agents, in horses such undertakings are usually impractical and rarely are tried for long.

Postrenal obstructive failure can develop with disease of the renal pelves, ureters, bladder, or urethra. The severity of renal failure depends on the extent of the obstruction. Frequently, problems are not recognized in horses until urine output is obviously reduced or renal function is impaired to the point that systemic problems are manifested. Although a neurogenic bladder can cause a functional obstruction, postrenal failure in horses most often results from intraluminal blockage by uroliths, which can cause obstruction anywhere in the urinary outflow tract.[388,389] Other possible intraluminal causes include neoplasia or stricture formation. Extraluminal obstructive lesions such as retroperitoneal tumors, adhesions, or bladder displacements also occasionally are associated with the development of postrenal failure.

PATHOPHYSIOLOGY

The pathophysiology of equine ARF has received little study, and the mechanisms at work are assumed essentially to be the same as those identified in experimental studies of other animal species. Several mechanisms have been demonstrated to be involved in the development of ARF, the actual pathogenesis being complex and depending somewhat on the cause of the disease, hydration status, and exposure to potential nephrotoxins. Multiple factors probably operate in different combinations at different times and in different nephrons. These different mechanisms are discussed next in relation to the type of failure with which they are associated (i.e., prerenal, intrinsic, and postrenal failure).

The pathophysiology of prerenal failure and ischemic ARF tends to involve the same processes. Toxins that cause ATN also share many pathophysiologic features with ischemic ARF.[205] The heterogeneity of intrarenal blood flow is an important factor in the development of this condition. The kidneys are particularly susceptible to ischemic and toxic injury because of their unique anatomic and physiologic features. Although they receive approximately 20% of the cardiac output, only about 10% to 20% of total renal blood flow reaches the medulla via the vasa recta. This low medullary blood flow is necessary to ensure a functional countercurrent mechanism in this region of the kidney; however, low blood flow also creates a large corticomedullary oxygen gradient and renders the renal medulla hypoxic and highly susceptible to ischemic injury. Conversely, the renal cortex receives 80% to 90% of total renal blood flow and is particularly susceptible to toxins.

Hypovolemia and dehydration trigger compensatory systemic and renal responses. The systemic responses include activation of the autonomic nervous system and renin-angiotensin system and release of antidiuretic hormone. Peripheral vasoconstriction is one of the effects of these responses. Renal responses to decreases in circulating blood volume have several phases. Initially, tubular reabsorption of sodium and water increases and is mediated by nerves and hormones. Reabsorption usually is associated with reduced clearance of urea and an associated increase in serum urea nitrogen concentration in the face of preservation of GFR, which in turn maintains plasma creatinine concentration in the normal range. More severe hypovolemia overcomes renal autoregulation responses, with renal blood flow being redistributed from the cortex to the medulla and GFR thus declining. The renal circulatory changes further enhance tubule solute reabsorption in the face of the decreased GFR. The net effect is production of small amounts of concentrated urine, a high urine-to-plasma creatinine ratio, and low fractional sodium clearance.[272]

A further reduction in renal blood flow results in a syndrome considered intermediate between the prerenal and intrinsic ischemic forms of ARF. Urine concentrating ability apparently is disrupted earlier than is sodium reabsorptive

capability, with the result that urine osmolality decreases and output increases, but fractional sodium clearance stays low. Patients may appear to be mildly polyuric.[390] With more severe or prolonged renal hypoperfusion and ischemic insult, urinary sodium and fractional sodium clearance start to increase, and the animal develops nonoliguric, and then oliguric, ARF. These changes are associated with progressively more severe tubular necrosis as the ARF progresses from prerenal to renal. The more severe the insult, the poorer is the prognosis.

Intrarenal vasoconstriction is caused by an imbalance between vasoconstrictive and vasodilating factors (systemic or local) that act on small renal vessels in particular. These potent vascular mediators include the vasodilator nitric oxide and the vasoconstrictor endothelin. Hypercalcemia is associated with increases in free calcium in the vascular smooth muscle and leads to enhanced vascular tone. Vasopressin and angiotensin II also have been shown to induce significant vasoconstriction under certain experimental conditions, as well as endotoxin and myoglobin. Some nephrotoxins (e.g., gentamicin, heavy metals, and radiographic contrast agents) can cause renal vasoconstriction in addition to direct toxic effects on the proximal tubules.[391-393]

Prostaglandins E_2 and I_2 are potent mediators that are responsible for a critical vasodilatory response in the face of reduced renal blood flow when activation of the renin-angiotensin system alone would result in further vasoconstriction. Increases in circulatory concentrations of angiotensin II stimulate synthesis of renal prostaglandins. Consequently, the vasoconstrictive effects of stimulating the renin-angiotensin system usually are blunted somewhat by concomitant increases in PGE_2 and PGI_2; however, in the face of increased angiotensin II and simultaneous inhibition of prostaglandin synthesis (e.g., because of NSAID administration), a significant increase in renal vascular resistance results.[394]

The reduction in GFR associated with reduced renal perfusion is associated with a number of mechanisms involving the glomeruli, vasculature, and tubules. In the initial phases, a reduction in glomerular capillary hydrostatic pressure is associated with a net drop in renal blood flow and a rise in renal vascular resistance. The latter phenomenon usually is associated with afferent arteriolar vasoconstriction and efferent arteriolar vasodilation and initially is reversible with volume expansion. Later (2 days or more), restoration of renal blood flow does not necessarily improve GFR, and a drop in renal blood flow is associated with a disproportionately greater drop in GFR.[395] Even when vasoconstriction is reversed, GFR may not improve; this reflects loss of renal blood flow autoregulation. This disproportionate reduction in GFR suggests a fall in the ultrafiltration coefficient of the glomeruli after a reduction in total filtering area. The mechanism for this is unclear but may be associated with increases in angiotensin II concentration because it is known to induce mesangial contraction and a drop in the ultrafiltration coefficient.[396]

In addition to the aforementioned vascular changes that can affect GFR, the possible effects on GFR in the juxtamedullary region of even mild changes in renal blood flow warrant specific mention. The glomeruli and adjacent straight portion of the proximal tubule and thick ascending limbs of the loops of Henle in this region are apparently particularly susceptible to hypoxia (i.e., ischemia) because of their high oxygen requirements. Swelling of endothelial and tubule cells after prolonged ischemia in this region results in increased vascular resistance and continued compromise of the medullary circulation, even when cortical renal blood flow has been restored.[205,397]

GFR also can be compromised significantly by obstruction of tubular lumina by casts of cellular debris, inflammatory cells, and endogenous pigments. Increased intratubular pressure decreases the net driving pressure for glomerular filtration in the same way that obstruction of the urinary outflow tract ultimately can lead to a lower GFR. One of the reasons that treatments to accelerate the solute excretion rate (e.g., furosemide, mannitol) may be therapeutic adjuncts is that they are believed to help disperse these luminal blockages.

Tubuloglomerular feedback is a regulatory mechanism that lowers GFR whenever solute (most notably NaCl) concentrations at the macula densa are increased. In ARF, impaired transport in the thick ascending limb of the loop of Henle in the context of preserved glomerular response to signals from the macula densa results in decreased GFR. This feedback is a normal protective mechanism mediated principally by the renin-angiotensin system, although prostaglandin, intracellular calcium, and adenosine may play a role in signal transmission or regulation. In essence, the mechanism serves to prevent massive fluid losses associated with a reduction of tubular reabsorptive capacity; however, in cases of renal hypoperfusion and ischemia, the effect is the opposite, because basically the feedback mechanism exacerbates the effects of already reduced renal blood flow.

Proximal tubule cells undergo morphologic changes early in cases of ischemia. They lose their brush borders and polarity and the integrity of their tight junctions is disrupted, probably after alterations in the actin and microtubular cytoskeletons.[398,399] Under these conditions, the glomerular filtrate is able to leap back to the peritubular circulation, thus reducing the net (or effective) GFR. This mechanism is thought to be an important source of GFR reduction only in more severe cases of ischemia or nephrotoxin exposure.

Tubule cells involved in solute reabsorption have a high metabolic rate and a high demand for oxygen. The corticomedullary oxygen gradient makes these cells vulnerable to the effects of hypoxia and ischemia, the thick ascending limb of the loop of Henle in the outer medulla being most susceptible.[400] Early in ischemic and toxic ARF, decreases in ATP and adenosine diphosphate tissue levels occur with associated elevations in adenosine monophosphate and inorganic phosphate concentrations. Much of the adenosine monophosphate is broken down further to adenosine and then to xanthine. Adenosine is a potent constrictor of cortical blood flow and probably enhances the effect of the tubuloglomerular feedback system. Depletion of ATP in tubular cells inhibits cell volume regulation, and the resultant swelling probably contributes to luminal obstruction and increased vascular resistance. Redistribution of Na^+-K^+-ATPase from the basolateral to the apical membrane of the tubule cells reduces the ability of the cells to extrude sodium into the peritubular fluid and circulation.[401] Redistribution of integrins to the apical surface contributes to the breakdown of tight junctions.[402] Depletion of ATP in tubule cells also leads to an increase in cytosolic calcium concentration. In addition to being a vasoconstrictor, calcium activates proteases and phospholipases, interferes with mitochondrial energy metabolism, and can break down the cytoskeleton.[380,403] Administration of calcium channel blockers has helped ameliorate ARF in some experimental situations.[404]

Reperfusion of renal tissue after a period of ischemia is associated with rapid production of oxygen free radicals and with significant tissue damage. Xanthines, neutrophils, phospholipase A_2, mixed-function oxidases, and mitochondrial

electron transport are associated with the production of these oxidants.[405] Phospholipase A_2 hydrolyzes phospholipids in cell and mitochondrial membranes to free fatty acids and lysophospholipids and produces arachidonic acid. Arachidonate in turn is converted to eicosanoids that are vasoconstricting and chemotactic for neutrophils.[406] Cell membranes are particularly susceptible to phospholipase activity after reperfusion. Reperfusion injury is a major consideration in transplant surgery; however, the role it plays in the pathogenesis of prerenal and ischemic ARF is not clear.

Many of the cellular biochemical and structural changes that occur with ischemic ARF are also important parts of the pathogenesis of ATN associated with exposure to nephrotoxins. Toxin-associated dysfunction and necrosis of cells result in increased tubular pressure and a decreased glomerular capillary hydrostatic pressure gradient. Loss of reabsorptive capability triggers tubuloglomerular feedback and further reduces GFR by lowering renal blood flow after vasoconstriction and a decrease in the glomerular ultrafiltration coefficient. Transepithelial back leak of solutes into the circulation further interferes with the excretory function of the kidneys.

Acute Tubular Necrosis

Many agents are recognized to have potential nephrotoxic effects. Aminoglycoside-induced renal toxicity results from accumulation of these antibiotics within the renal cortex. Streptomycin is the least nephrotoxic of the aminoglycosides, whereas gentamicin and kanamycin are intermediate nephrotoxins. Neomycin is the most nephrotoxic. Most cases of aminoglycoside toxicity are associated with conditions that cause reduced renal perfusion because the healthy kidney usually can tolerate some degree of aminoglycoside overdosing, especially with every-24-hour administration, which allows tubule cells time to recover as concentrations decrease. After being freely filtered at the glomerulus, aminoglycosides bind to polyphosphoinositides on the brush border of proximal tubules and subsequently are reabsorbed by pinocytosis. Accumulation of these antibiotics interferes with lysosomal, mitochondrial, and Na^+-K^+-ATPase function by inhibiting phospholipase A activity. Binding to the brush border is saturable, with the result that sustained exposure of the proximal cells to the drug over time (as with more frequent dosing) results in greater accumulation of the drug and increased nephrotoxicity. High trough concentrations are more nephrotoxic than high peak concentrations because tubule cells are exposed to higher aminoglycoside concentrations over a longer period of time. As a result, once-daily dosing may attenuate the risk of nephrotoxicosis while maintaining or improving therapeutic efficacy (because it results in higher peak concentrations and postantibiotic effect).[407,408] Calcium in the glomerular filtrate competitively inhibits aminoglycoside binding in the proximal convoluted tubule. Experimentally, it has been demonstrated that both intravenous calcium supplementation (calcium gluconate 20 mg/kg q 12 h)[409] and increased dietary calcium intake through alfalfa hay[410] had a protective effect against experimental gentamicin toxicity. Many mild cases of aminoglycoside toxicity notably are associated with nonoliguric ARF and therefore may go unrecognized in horses.

Some cephalosporins, such as cephaloridine, have considerable nephrotoxic potential. These agents cause necrosis because of mitochondrial toxicity after intracellular accumulation of the antibiotic.[411]

Polymyxin B is a polypeptide antibiotic that can bind endotoxin. It is often administered to horses at risk for ARF with colitis, endotoxemia, NSAID administration, and dehydration. In rats, renal histopathologic lesions of experimental polymyxin B toxicity include proximal tubular epithelial cell cytoplasmic vacuolization and focal necrosis, tubular dilation, and interstitial edema.[412] More frequent administration resulted in a quicker onset of renal toxicity and higher renal concentrations than once-daily dosing, which suggested an active uptake mechanism for polymyxin B in proximal tubule cells. Polymyxin B (6000 IU/kg IV q 8 h) did not significantly affect the urinary GGT/Cr ratio and appeared safe in healthy horses.[413]

Bisphosphonates may be administered to horses with osteopenic disease or other orthopedic conditions, and these drugs may sometimes cause acute tubular necrosis. Renal function should be evaluated in horses treated with bisphosphonates that develop clinical signs of ARF after treatment, and perhaps renal function should be routinely assessed before and after treatment. Higher doses and rapid intravenous administration or concurrent treatment with NSAIDs have been associated with a higher risk for ARF.[414]

Not all cases of ATN are caused by direct toxic changes in tubule cells. For instance, whether myoglobin and hemoglobin are truly nephrotoxic is still debatable. The principal characteristics of pigmentary nephropathy caused by these agents are tubule obstruction and reduced renal blood flow (caused by direct vasoconstrictor effects). Whether obstruction is physical, caused by pigment accumulation, or the aggregation of sloughed cells is not clear. Myoglobin tends to be associated with nephropathy more frequently than hemoglobin. Patients often quickly become oliguric, presumably because of the widespread tubule obstruction.

Acute Interstitial Nephritis

Distinguishing between drug-induced ATN and acute interstitial nephritis can be difficult, and the latter rarely is diagnosed in horses. Making a distinction may be a particular problem when continued use of antibiotics is indicated. With ATN, one may alter the dosing regimen by reducing the dose or prolonging the treatment interval, whereas with interstitial nephritis, short-term corticosteroid therapy is often of benefit in human beings. Interstitial nephritis often is marked by eosinophiluria and eosinophilia and is more likely to be associated with the presence of red blood cells than is ATN. The exact immune mechanism by which interstitial nephritis develops is unclear, although it is thought most likely to be caused by delayed cell-mediated hypersensitivity or the presence of antitubule basement membrane antibodies.[415] The prognosis is usually grave in horses with acute interstitial nephritis.

Acute Glomerulonephritis

Acute glomerular nephropathy is rare in horses; however, when it occurs, it usually is manifested by nephrotic syndrome, although hematuria and oliguria sometimes are apparent. Deposits of γ-globulin and complement are found along the basement membrane (global form) or in the mesangial area (mesangioproliferative form).[416] Group C streptococcal antigens have been identified along with equine glomerulonephritis, and equine infectious anemia (EIA) viral antigen-antibody complexes have been recognized in the glomeruli of horses that were not in renal failure.[270,417] Deposition of immune complexes activates the complement cascade. Formation of

C_3b and C_5a causes platelet aggregation and attracts neutrophils. Tissue damage results from deposition of complement per se and from inflammation associated with neutrophil activation and release of reactive oxygen radicals, proteases, elastases, and other lysozymes. These enzymes, plus platelet-activating factor and leukotriene B_4, increase vascular permeability and upregulate expression of adhesion molecules, thus promoting further inflammation.[406] Severe reduction in GFR results from large drops in the glomerular permeability coefficient, which is associated with widening of Bowman's spaces after inflammation and deposition of immune complexes.

Basically, increases in ureteral pressure for any reason result in GFR reduction because of a drop in the glomerular capillary hydrostatic pressure gradient, some tubular backleaking, a decrease in the glomerular permeability coefficient, and ultimately, a reduction in renal blood flow. (See previous discussion of the pathophysiology of postrenal ARF.)

CLINICAL SIGNS

In most horses with hemodynamically mediated (i.e., prerenal, ischemic, dehydration) ARF, clinical signs are usually more pronounced from the primary problem, such as acute colic or enterocolitis, sepsis, coagulopathies, rhabdomyolysis, or heavy metal poisoning, rather than renal dysfunction. Therefore the predominant clinical signs are often dehydration (with or without diarrhea), depression, and anorexia. Other signs can include tachycardia, hyperemic mucous membranes, pyrexia, mild abdominal pain, and laminitis. Because clinical signs usually relate to the inciting problem, ARF may not be suspected or detected unless the veterinarian specifically evaluates renal function as part of the workup for a more obvious disease. In general, the clinical manifestations of ARF reflect the systemic effects of toxic substances usually excreted in the urine (i.e., azotemia generally is reflected by anorexia and depression), urinary tract dysfunction, and derangements of fluid, electrolyte, and acid-base balance. One may observe signs of encephalopathy or hyperlipemia in horses with severe azotemia.

Although oliguria is considered the hallmark of ARF, urine production in horses varies. Oliguria frequently occurs in the early stages of hemodynamically mediated ARF and is the most frequently reported clinical sign that is related directly to urinary tract dysfunction. As outlined in the section on pathophysiology, however, nonoliguric and polyuric stages of prerenal and intrinsic ARF also can be associated with renal hypoperfusion. Anuria is rare. Nonoliguric or polyuric ARF also can be associated with exposure to nephrotoxins (ATN), and polyuria is common during the recovery phase of ARF, regardless of its cause. The magnitude of azotemia tends to be lower in nonoliguric than in oliguric ARF, possibly indicating less severe damage in the former condition. Similarly, nonoliguric ARF is associated with a more favorable prognosis.

Patients with ARF often are treated initially with large volumes of intravenous or oral fluids for the primary disease to restore plasma volume. In these cases, oliguria may progress to polyuria. When significant renal damage has been sustained, persistence of oliguria in the face of fluid administration usually is manifested as failure to produce a significant volume of urine in response to fluid therapy. The degree of change of azotemia also is minimal in the initial 24 to 36 hours of treatment. If one does not monitor these patients carefully, then fluid retention may lead to development of subcutaneous and pulmonary edema. Hematocrit, total protein concentration, and renal indices should be frequently measured to objectively assess response to fluid therapy and renal function. Soft feces caused by fluid retention also may be apparent in patients with oliguric ARF.

Postrenal or obstructive uropathy usually is characterized by mild to severe abdominal pain and pollakiuria and stranguria (see Obstructive Disease of the Urinary Tract).

DIAGNOSIS

Increases in plasma urea nitrogen and creatinine concentrations (i.e., azotemia) are frequently the initial findings that suggest compromised renal function. Azotemia simply reflects a reduction in GFR; it has almost no differential diagnostic value. After establishing recent development of azotemia, the equine internist must proceed systematically to differentiate among six possible syndromes associated with ARF: (1) prerenal ARF, (2) ischemic ARF, (3) ATN, (4) acute interstitial nephritis, (5) acute glomerulonephritis, and (6) obstructive (postrenal) ARF. A useful way to go about this is first to try to rule out prerenal and postrenal ARF. If this is possible, then the patient must have a type of intrinsic ARF; therefore one can direct further diagnostic efforts to identifying the disease subtypes.

As described in greater detail later (see Urolithiasis), the diagnosis of postrenal obstructive disease usually is based on a combination of clinical signs, history, and the results of rectal palpation, ultrasonography, and urinary tract endoscopy. The frequency and volume of urination can vary with these cases, and total obstruction causes anuria. Salt and water reabsorption often are impaired as the problem persists, which results in hyponatremia (i.e., plasma sodium concentration in the low-normal range). Although the mechanisms for this sodium wasting are not completely clear, it apparently is related to impaired function of the ascending limb of the loop of Henle and an increased medullary blood flow after prostaglandin release. Both of these events greatly diminish the magnitude and effect of the medullary countercurrent concentrating mechanisms. Prostaglandin also directly inhibits the effect of antidiuretic hormone.[418]

Measurement of urine specific gravity in the azotemic horse is a commonly practiced means of detecting prerenal ARF. In these cases, urine specific gravity is usually greater than 1.025 and often as high as 1.055. In human beings, one can use a number of reliable indexes to differentiate renal azotemia from prerenal azotemia[419-421] that are based on urine osmolality and the ratio of urine-to-plasma osmolality (U/P_{osm}), urine sodium concentration, and fractional sodium clearance and ratios of urine-to-plasma urea concentrations (U/P_{UN}) and urine-to-plasma Cr concentrations (U/P_{Cr}). Fractional sodium clearance in particular is a good indicator of solute reabsorption and proximal tubule function, whereas U/P_{Cr}, and to a lesser extent U/P_{UN}, are useful indexes of the ability of the tubules to reabsorb water. The utility of these indexes in horses also has been investigated and has been shown to have considerable differential diagnostic value.[272] Although these tests are discriminatory, some degree of overlap occurs between them respecting prerenal and parenchymal or intrinsic problems. One also must bear in mind that these indexes do not allow differentiation between intrinsic and postrenal disease. A number of horses with prerenal (nonoliguric) ARF have urine osmolality less than 360 mOsm. A small percentage

of horses in prerenal ARF have U/P_{Cr} less than 30 (usually greater than 50) and fractional sodium clearance greater than 0.80% (usually less than 0.50%), most likely because of the unrecognized existence of tubule damage before volume depletion or because of a natriuretic effect of some treatments such as diuretics or intravenous fluids. Natriuresis is particularly likely to be induced with bicarbonate administration because sodium cations are lost with unreabsorbed bicarbonate anions. In these cases, the determination of the fractional chloride clearance may be a better indicator of the response of the kidney to hypoperfusion.

No parameter reliably differentiates between prerenal and ischemic ARF because of the pathophysiologic continuum between these diseases. At one end is reduced GFR with preserved tubule function and concentrating mechanisms. This form is readily reversible with appropriate therapy. Additional or more prolonged decreases in GFR lead to disturbances in tubule function and slower reversal of damage until the other end of the spectrum is reached, in which complete and irreversible loss of renal function occurs. Assessment of urine specific gravity before initiation of fluid therapy is helpful in differentiating prerenal failure from renal failure. As normally functioning kidneys would preserve salt and water maximally in response to a transient decrease in renal blood flow with prerenal failure, so urine specific gravity and osmolality are greater than the values associated with serum, whereas the urine produced by horses with intrinsic ARF is often isosthenuric (specific gravity less than 1.020). In a clinical situation, assessment of the response to fluid therapy is the most practical way to differentiate prerenal failure from intrinsic forms of ARF. Azotemia caused by prerenal problems should resolve quickly with replacement of fluid deficits and restoration of renal perfusion. In prerenal failure, volume repletion also should restore renal function, with the result that the magnitude of azotemia should decrease by 50% or more during the first day of therapy. In contrast, fluid therapy usually does not lead to prompt resolution of azotemia associated with intrinsic problems. Application of the measurement of U/P_{Cr} and U/P_{UN} ratios is limited to use on urine samples collected before initiation of fluid therapy or the first urine sample voided after fluid therapy has been started.

In prerenal ARF, electrolyte and acid-base abnormalities generally reflect problems caused by a primary disease (e.g., enterocolitis, colic, blood loss). Most frequently, horses are mildly acidotic, hyponatremic, and hypochloremic. Plasma concentrations of potassium and calcium vary according to what disease is causing renal hypoperfusion. Potassium concentration also is affected to some extent by urine output and feed intake, hyperkalemia being most common in association with oliguria and anuria.

The technique for biopsy of the left kidney has been well described.[369] The main indication of kidney biopsy is to help differentiate between types of intrinsic renal diseases when one thinks that this distinction will have therapeutic and prognostic relevance. One often can diagnose ischemic failure and ATN without biopsy. The primary complication associated with the biopsy procedure is renal hemorrhage, which can be severe. Ultrasonographic guidance and use of a spring-loaded biopsy instrument may reduce the risk of complications. Ultrasonography also allows biopsy of the right kidney. As the knowledge of equine renal physiology and pathology improves and advances in molecular genetics lead to techniques that supplant or supplement standard histopathologic methods, the diagnostic usefulness of renal biopsy may increase. For example, biopsy results may dictate the use of immunosuppressive agents in the treatment of some forms of renal parenchymal diseases (e.g., interstitial nephritis).

Identification of subtypes of intrinsic ARF often depends on analysis of urine and urine sediment. The history of exposure to ischemic insults or potential nephrotoxins such as aminoglycosides certainly helps in this regard, but determination of the severity of the condition and its prognosis still generally relies on the analysis of urine. Ischemic tubule disease is similar to ATN. In both cases a slight to moderate proteinuria with specific gravities usually less than 1.020 and urine osmolality less than 350 mOsm occur. Fractional sodium clearance is nearly always greater than 1.0, regardless of urine output. Granular casts frequently are visible, particularly with ATN. Enzymuria and phosphaturia are frequently prominent early in the course of ATN.[295,422] Plasma sodium and chloride concentrations are usually low. Plasma concentrations of calcium and inorganic phosphate vary greatly: increases, decreases, and normal values are possible, depending on the diet of the horse, the nephrotoxin, and the location and severity of damage to the nephron.[295,417,422]

One must remember that GFR is reduced in cases of ATN and is most likely caused by the increase in presentation of sodium and chloride at the macula densa after dysfunction of proximal sodium reabsorption. Stimulation of the macula densa results in release of renin and local production of angiotensin II, thus increasing renal vascular resistance and lowering renal blood flow. The low GFR may mask the absolute magnitude of the damage in tubule function; however, if one studies renal sodium reabsorption carefully over time in cases of ATN, this defect appears to improve more rapidly than that of GFR.[423]

Acute interstitial nephritis often is not recognized in horses; however, in a study conducted about 40 years ago, the condition was diagnosed in approximately one eighth of all human patients who needed renal biopsy for diagnosis of unexplained ARF.[424]

Edema and diffuse or focal patches of interstitial inflammation characterize the disease. In human medicine, the numbers of drugs, toxins, and infectious agents known to induce this disease are growing. No reason exists to believe that similar agents are not capable of causing the same disease in equids. Inflammatory cells surround the tubules and can move between epithelial cells into the tubule lumina. As a result, white blood cell casts are common. The leukocytes are also capable of disrupting the tubule basement membrane, making cell repair much less likely; this is an important distinguishing feature between ATN and interstitial nephritis. With the former disease the basement membrane usually stays intact. Reduction of GFR and azotemia probably result from the interstitial edema, intratubular obstruction, and release of vasoactive agents.

Acute interstitial nephritis and ATN have similar fractional sodium clearance, U/P_{Cr}, and U/P_{osm} values; however, the urine sediment may be different for each disease. Sterile pyuria and microscopic hematuria commonly occur with interstitial nephritis, although red blood cell casts are rare. Mild proteinuria and eosinophiluria are also common. Eosinophiluria generally seems to be limited to renal interstitial disease, mainly drug-induced interstitial nephritis but also chronic pyelonephritis and systemic lupus erythematosus.[425,426] Eosinophiluria may or may not be accompanied by

eosinophilia. Eosinophils in equine urine should be easy to observe using Wright's stain, given the alkaline nature of the fluid. Occasionally, fevers are believed to be associated with the development of interstitial nephritis. This clinical sign is relatively nonspecific and might be misleading if the animal is being treated with antibiotics for an infection. What one might see with close monitoring of the patient is an initial reduction or resolution of the fever after the onset of antimicrobial therapy followed by recurrence of the fever and development of azotemia. If this happens, then acute interstitial nephritis should be on the rule-out list.

The nephrotic syndrome usually characterizes acute glomerulonephritis. Proteinuria is moderate to severe, and the urine usually is concentrated. Urine osmolality and U/P_{osm} are comparable with the values with prerenal ARF and are higher than those values normally seen in ATN. Urinary sodium concentration and fractional sodium clearance tend to be much lower than with other intrinsic renal and postrenal causes of ARF. The ratios of U/P_{UN} and U/P_{Cr} are often similar to those associated with prerenal failure and higher than those in ischemic, tubular, interstitial, or postrenal disease. Renal tubular secretion of creatinine is increased in glomerulonephritis, with the result that creatinine concentrations may not rise quickly and urea nitrogen-to-creatinine ratios stay high, as they frequently do with prerenal problems. Therefore although urinary indexes should make possible differentiation of acute glomerulonephritis from other parenchymal and postrenal diseases, they overlap much with those associated with prerenal ARF. One is going to differentiate ARF caused by acute glomerulonephritis from that caused by hypoperfusion based on the significant proteinuria and red blood cell numbers usually associated with the former disease. Erythrocyte casts are more common with glomerulonephritis than with other intrinsic causes of ARF. Some causes of postrenal ARF also may manifest red blood cell casts, but the proteinuria is not normally as great in those situations.

TREATMENT

Initially, treatment of horses with ARF should focus on reversing the inciting or underlying cause and correcting fluid and electrolyte imbalances. Early identification of patients at risk and prevention of problems by rapid restoration and accurate maintenance of intravascular fluid volume, glomerular filtration, and urine production (with fluids and possibly diuretics) is obviously preferable to treatment. The importance of prevention cannot be overstated. One should correct initial fluid deficits over the first 6 to 12 hours of treatment. Physiologic saline or a balanced electrolyte solution is the fluid of choice unless the patient is hypernatremic, as may be the case in prerenal ARF or acute glomerulonephritis. In the event of hypernatremia, solutions of 0.45% NaCl and 2.5% dextrose are recommended. The addition of 50 to 100 g of dextrose per liter of fluid to saline or polyionic fluids helps address the caloric needs of anorectic horses. If fluid administration is begun early in the course of the disease or if the problem is not severe, then diuresis should result. When this occurs, one should maintain intravenous fluid therapy at least at twice maintenance level (up to 100 mL/kg/day or more) until serum creatinine concentration decreases dramatically. One then reduces the rate of fluid administration to 40 to 50 mL/kg/day until the creatinine concentration is normal or the horse is eating and drinking adequately. The horse must be carefully observed to ensure that it urinates appropriately in response to fluid therapy and does not develop edema and renal indices decrease as desired.

In the event that the horse remains oliguric 10 to 12 hours after starting fluid therapy, administration of dopamine in 5% dextrose slowly (3–5 μg/kg/min) may improve renal blood flow and urine output. One should monitor blood pressure during dopamine infusion because the drug can induce significant hypertension. Administration of dopamine should be discontinued if blood pressure starts to rise. The infusion can be restarted at a lower rate when blood pressure has returned to normal. Blood pressure also may increase because of overhydration of oliguric patients. Regular monitoring of body weight, hematocrit, and serum total protein concentration, central venous pressure, and lung sounds is important to prevent problems caused by overhydration.

The use of diuretic agents such as mannitol and loop diuretics to treat ARF is controversial. Furosemide and ethacrynic acid are the loop diuretics most commonly used. Furosemide is a particularly potent short-acting agent that acts by blocking the $Na/K/2Cl^-$ cotransporter in the ascending limb of the loop of Henle. In addition to promoting diuresis, cotransporter inhibition also may protect these tubule cells by reducing their metabolic rate and thus oxygen demand in the face of limited oxygen availability after hypoperfusion. To be effective, loop diuretics must gain access to the tubule lumina. Therefore loop diuretics may be of limited value in prerenal or ischemic problems, although the potential protective effect of furosemide on the especially vulnerable cells of the thick ascending limb may warrant its administration. Loop diuretic administration also may exacerbate or induce volume depletion in cases of ARF that are characterized by isosthenuria or polyuria (e.g., early ATN), thus making the condition worse and rendering the patient more susceptible to the effects of nephrotoxins such as gentamicin. Loop diuretics appear to be most beneficial when used in cases characterized by tubule obstruction (e.g., pigmenturia) because the diuretic-induced increase in solute retention apparently helps flush these blockages and casts from the tubules. In any case, urine production should first be stimulated with volume replacement rather than diuretic administration.

Although loop diuretics have no direct effect on GFR, 20% mannitol (0.25–1.0 g/kg) given over 15 to 20 minutes may help combat oliguria by increasing renal blood flow and GFR. The increase occurs after reductions in plasma protein concentration and oncotic pressure. These changes in turn result from the systemic effects of the increase in intravascular osmolality induced by mannitol. Mannitol also may induce synthesis of the vasodilator PGE_2 and release of atrial natriuretic peptide, which also would increase renal blood flow and GFR. Once filtered, it also acts as an osmotic diuretic, thus decreasing urine solute concentration and increasing urine volume. Consequently, mannitol also can be effective in treating conditions characterized by tubular obstruction and swelling of tubule cells.

Hyperkalemia is uncommon in equine ARF, except in some postrenal cases. When present, hyperkalemia is usually mild and responds to administration of potassium-free intravenous fluids. When hyperkalemia (greater than 6.5 mEq/L) persists, correction of any associated acidosis with sodium bicarbonate or administration of glucose (up to 10% solution), or both, usually helps. In the worst or most refractory cases, insulin may be necessary. Potassium supplementation (KCl 20–40

mEq/L IV) may be necessary during the polyuric phase of recovery from ARF.

Calcium metabolism often is disrupted in cases of equine ARF, with hypocalcemia and hyperphosphatemia or hypercalcemia and hypophosphatemia having been reported variously. Hypercalcemia usually resolves with a switch to a grass or grass-hay die (avoid legumes) and time. Hypocalcemia probably occurs for a number of reasons, including skeletal resistance to parathyroid hormone during the early stages of ARF and deficiency of 1,25-dihydroxycholecalciferol, which results from downregulation of renal 1,25-hydroxylase with hyperphosphatemia, dysfunction of this enzyme after renal parenchymal damage, or both.[422,427] Hypoalbuminemia and enhanced deposition of calcium in injured tissues, as can occur in cases of rhabdomyolysis, are other factors to consider. Administration of a calcium salt with intravenous fluid therapy protocol and feeding legumes such as alfalfa are usually sufficient to correct hypocalcemia.

Severe uremia often decreases erythrocyte life span and induces platelet dysfunction. Consequently, anemia (possibly also caused by decreased production of erythropoietin) and bleeding tendencies may be associated with ARF. These conditions may require symptomatic treatment with whole blood transfusions.

Because aminoglycoside toxicity is one of the more commonly recognized causes of equine ARF,[265,386,428] continued aminoglycoside use in horses with ARF warrants specific attention. Gentamicin and amikacin are the aminoglycoside antibiotics most often used in equine practice, and their pharmacokinetics have been well studied in healthy animals. Large interindividual and age variations occur in the volume of distribution and clearance of these drugs in normal horses, and this variability is even greater in diseased horses. Therefore when a patient with ARF requires aminoglycoside antibiotics, monitoring serum trough concentrations of the drug to adjust the dosing interval or dose is strongly indicated, because it provides the best protection against exacerbating renal damage. Therapeutic drug monitoring of aminoglycoside concentration can be helpful to maintain desired concentration, prevent toxicity, and assess GFR. Increased trough concentration of aminoglycosides can indicate reduced GFR because their excretion is dependent on glomerular filtration. Renal dysfunction associated with aminoglycoside toxicity usually is indicated by an increase of at least 0.3 mg/dL in creatinine concentration. When this occurs, discontinuing therapy until renal indices have normalized, prolonging the dosing interval, or reducing the dose should be considered. One must remember that changes in urine sediment (casts) and development of enzymuria, mild proteinuria, glucosuria, and decreased urine-concentrating ability develop a number of days before creatinine concentration increases and are good indicators of the development of aminoglycoside nephrotoxicity. One usually can address the problem successfully by maintaining or increasing intravenous fluid therapy to guard against renal hypoperfusion and by appropriately adjusting the dosing interval with the antibiotic.

Intermittent hemodialysis has been used to successfully treat oxytetracycline toxicosis and ARF in a 4-day-old foal.[429] Oxytetracycline can be directly nephrotoxic at high doses (as for contracted tendons in neonates), and oxidation of oxytetracycline can result in the formation of nephrotoxic compounds. Hemodialysis is an excellent ancillary therapy in cases of toxin-induced ARF, if feasible. In 2013 Wong and colleagues[430] reported a technique of renal replacement therapy in healthy adult horses using a commercially available machine for humans. Another dialysis technique that may be more practical is continuous-flow peritoneal dialysis.[431] Continuous-flow peritoneal dialysis involves the placement of two indwelling catheters in the flank (ingress) and ventral abdomen (egress) and continuous infusion of dialysate solution. The use of two catheters and continuous flow of the dialysate solution, rather than a single ventral abdominal catheter and intermittent infusion, may both increase the surface area of the peritoneum for dialysis and have fewer complications.

PROGNOSIS

The prognosis for equine ARF depends on the underlying cause, the duration of renal failure, the response to initial treatment, and the development of secondary complications such as diarrhea, thrombophlebitis, and laminitis. Generally speaking, the duration of ARF before beginning therapy is the most important determinant of prognosis. Of the primary causes of ARF, severe ischemic failure and acute interstitial nephritis probably carry the worst prognosis in horses. ARF of any cause, however, should be associated with a reduced or poor prognosis in the event that early interruption of the pathophysiologic events leading to ARF is not achieved or that the animal displays prolonged oliguria or anuria (longer than 12 hours) after institution of vigorous therapy. Most cases of postrenal ARF carry a favorable prognosis and are reversible, provided the initiating disease is treated successfully. When discussing prognosis with horse owners, practitioners always must bear in mind that a successful outcome is not always associated with complete return of normal function. Many horses live long after a bout of ARF but never fully regain the ability to concentrate urine as well as they did before the disease; in other cases, they remain constantly polyuric. ATN, after nephrotoxicity in particular, carries a favorable prognosis when tubule basement membranes remain intact.

Chronic Kidney Disease

Harold C. Schott II

PREDISPOSING CONDITIONS

Chronic kidney disease (CKD or chronic renal failure) is recognized infrequently in horses. In dogs and cats, the prevalence of CKD has been reported to be 0.9% and 1.6%, respectively,[432] whereas the Veterinary Medical Database at Purdue University reported that only 515 of 442,535 horses admitted to participating veterinary teaching hospitals during the years 1964 to 1996 had CKD (prevalence of 0.12%). In actuality, this may be an underestimate, because when a diagnosis of CKD is established for a horse, it likely may be destroyed without presentation to a veterinary teaching hospital. As in dogs and cats, CKD appears to be a greater problem in older horses (the prevalence increased to 0.23% in horses older than 15 years). A 0.51% prevalence in intact males older than 15 years of age also suggests that stallions may be at greater risk.

Although the clinical syndrome of CKD is uncommon, one widely cited abattoir study revealed that 16% of 45 horses examined had glomerular lesions on light microscopic

examination and 42% (22 of 53 horses examined) exhibited deposits of immunoglobulin or complement with immunofluorescence staining of tissue samples.[270] Although these findings suggest that as many as one third of horses may have microscopic evidence of renal disease, only one of the horses in this survey exhibited signs of CKD. This disparity can be attributed to the large renal reserve capacity, because clinical signs of renal failure do not become apparent until two thirds to three fourths of functional nephrons have been lost.[254] Although this rule of thumb is based on studies of partially nephrectomized laboratory animals, support for a similar renal reserve capacity in horses is found in several clinical reports of unilateral nephrectomy used successfully to manage disorders of the upper urinary tract.[41,74,255-257] In addition, after experimental unilateral nephrectomy in ponies[258] and horses,[259] renal function remained within normal ranges, and the animals maintained body weight.

Renal disorders leading to CKD may be congenital or acquired. In horses younger than 5 years of age with a history that does not include an event that might have been complicated by ARF, one should suspect a congenital renal disorder: renal agenesis, hypoplasia, dysplasia, or polycystic kidney disease.[27,28,32,34-40,48-51] Although each of these congenital abnormalities is occasionally recognized, acquired disease consequent to glomerular or tubular injury is more often the cause of CKD in horses.[70,95,260,266,433,434] Acquired disease is usually insidious in onset, and renal injury may have started years earlier. Thus identifying the cause of CKD is challenging because many horses have evidence of advanced glomerular and tubular disease, termed *end-stage kidney disease (ESKD),* by the time clinical signs of CKD develop. Nevertheless, knowing the various causes of CKD affords a better overall understanding of CKD in horses.

Glomerulonephritis

Glomerular injury is a common precipitant of renal insufficiency and CKD in horses. Although immune-mediated glomerular injury is implicated most often in glomerulonephritis, glomerular integrity can be disrupted by a number of unrelated disease processes, including ischemia, toxic insults, and infection.[435] These mechanisms usually lead to significant vascular and tubulointerstitial changes in addition to glomerular injury. Thus the designation glomerulonephritis typically is reserved to denote renal disease of which immune-mediated glomerular damage is suspected to be the initiating factor in the development of renal failure. Until the past decade, glomerulonephritis was considered a rare cause of CKD in domestic animals, and interstitial nephritis was implicated more often.[436-438] Refinement of histologic examination techniques with immunofluorescence staining and electron microscopy examination of renal tissues has led to increased recognition of subclinical and clinically significant glomerulonephritis.[438]

A brief review of the subgross anatomy of the glomerulus sheds light on the pathophysiology of glomerulonephritis. The renal corpuscle, or glomerulus, is comprised of a tuft of glomerular capillaries surrounded by epithelial cells that line Bowman's capsule. The root that supports the pedicle of the glomerular capillary network is similar to the mesenteric root that supports the intestinal tract, and Bowman's capsule is analogous to the peritoneum (Fig. 14.18A). On a microscopic level, components of the glomerulus include capillary endothelial cells, mesangium (cells and matrix), glomerular basement membrane (GBM), and visceral epithelial cells. At the vascular

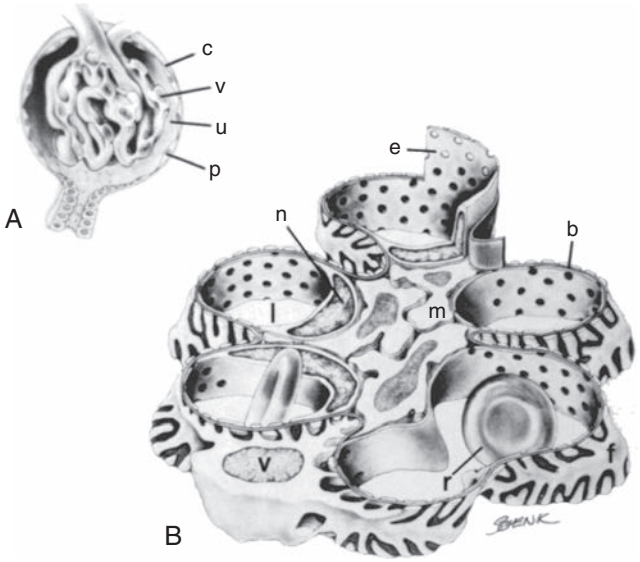

FIG. **14.18** Subgross anatomy of a renal corpuscle. **A,** A renal corpuscle with a tuft of glomerular capillaries surrounded by Bowman's capsule *(**c**)* shows visceral *(**v**)* and parietal *(**p**)* epithelial cells separated by the urinary space *(**u**)*. **B,** Cross-section of a portion of a glomerulus shows the nucleus *(**n**)* and fenestrations *(**e**)* of capillary endothelial cells, the glomerular basement membrane (GBM) *(**b**)*, mesangial cells *(**m**)* separated by mesangial matrix, and the nucleus *(**v**)* of a visceral epithelial cell. A red blood cell (RBC) *(**r**)* is in the lumen *(**l**)* of one of the glomerular capillaries. (From Osborne CA, Hammer RF, Stevens JB, et al.: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med.* 21:207, 1977.)

pedicle, the latter become contiguous with parietal epithelial cells that line Bowman's space, much as mesothelial cells covering bowel serosa and mesentery become contiguous with the peritoneum at the mesenteric root.[435] Glomerular capillary endothelial cells are unique in that they are fenestrated with pores that are the initial barrier for passage of blood components into the urinary space (Fig. 14.18B). The mesangium, which lies between endothelial and epithelial cells, is the support structure of the glomerular capillaries and is analogous to the mesenteric tissue supporting bowel. Mesangial cells are a component of the reticuloendothelial system and phagocytize macromolecular substances, including fragments of old GBM or larger molecules that pass through endothelial cell pores but cannot pass subsequently through the GBM. In addition, mesangial cells have contractile elements that allow them to participate in regulation of glomerular hemodynamics. Furthermore, these cells proliferate in response to glomerular injury and can release a number of cytokines that modulate the glomerular inflammatory response.[5] The GBM lies between endothelial and epithelial cells and surrounds glomerular capillaries, except where mesangium is present (Fig. 14.19A). Returning to the abdominal cavity analogy, the GBM would lie beneath bowel serosa except in the area of mesenteric attachment, which would contain mesangial cells and matrix. The GBM consists of a central electron-dense layer, the lamina densa, and two thinner, more electron-lucent layers, the lamina rara externa and the lamina rara interna (Fig. 14.19B).[5,435] The main components of the GBM are collagen-like molecules and matrix glycoproteins that are produced principally by visceral epithelial cells. Normal GBM undergoes steady turnover

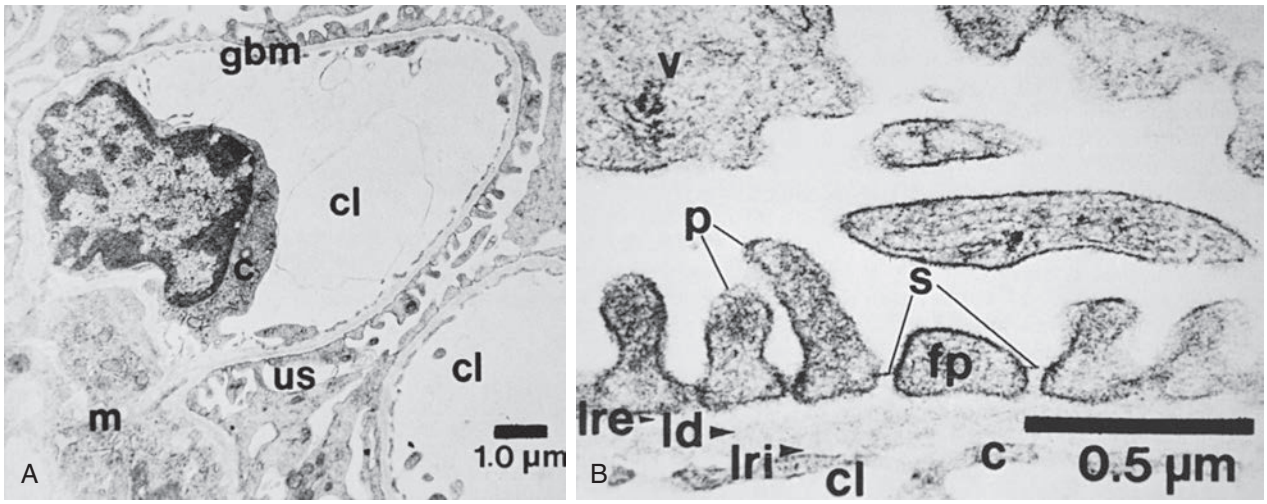

FIG. **14.19** Electron micrograph of a normal glomerulus. **A,** Low-power magnification illustrates patent capillary lumens *(**cl**)* separated from the urinary space *(**us**)* by fenestrated endothelial cell cytoplasm *(**c**)*, the glomerular basement membrane (GBM) *(**gbm**)*, and foot processes of visceral epithelial cells. Mesangial cells and matrix *(**m**)* are also apparent (bar = 1.0 μm). **B,** Higher power magnification reveals the ultrastructural features of the filtration barrier including, from bottom to top, the capillary lumen *(**cl**)* and endothelial cell cytoplasm *(**c**)*; the lamina rara interna *(**lri**)*, lamina densa *(**ld**)*, and lamina rara externa *(**lre**)* of the GBM; and cytoplasm *(**v**)*, foot processes *(**fp**)*, and slit diaphragms *(**s**)* of the visceral epithelial cells. Deposits of glomerular polyanion or glycosaminoglycans *(**p**)* are visible on the foot processes (bar = 0.5 μm). (From Osborne CA, Hammer RF, Stevens JB, et al.: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med.* 21:207, 1977.)

with removal of debris by mesangial cells. The visceral epithelial cells, also called *podocytes,* cover the uriniferous duct side of the GBM and have many cytoplasmic extensions called *foot processes* that form extensive interdigitations with foot processes of adjacent epithelial cells. The narrow gap between foot processes—the filtration slit or slit pore—is bridged by a thin membrane, the slit pore diaphragm.[5,435]

The filtration barrier of the glomerulus consists of fenestrated endothelial cells, GBM, and slit pores between epithelial cell foot processes. These structures constitute a size and charge selective filtration barrier. Although all components of this barrier are anionic (i.e., they repel anionic macromolecules), the GBM is thought to be the principal agent for the permeability characteristics of the filtration barrier. The GBM is rich in glycosaminoglycans, containing heparin sulfate and sialic acid residues. These strongly anionic molecules are responsible for its negative charge barrier, which limits filtration of anionic macromolecules, predominantly albumin.[5,432]

Glomerulonephritis is initiated by deposition of circulating immune complexes along the GBM and in the mesangium, leading to complement activation and leukocyte infiltration and adherence. Release of oxidants and proteinases by neutrophils and macrophages; production of eicosanoids, cytokines, and growth factors by macrophages and mesangial cells; and platelet aggregation and activation of coagulation factors lead to endothelial and epithelial cell swelling (with fusion of foot processes), formation of microthrombi in glomerular capillaries, and mesangial cell proliferation.[432,435,439] Immune complexes can be deposited in a subendothelial, intra-GBM, or subepithelial site, depending on their size and charge properties, but most tend to be found in the subendothelial space. On electron microscopic examination, these immune complexes appear as electron-dense granular deposits (Fig. 14.20A), and staining with antiimmunoglobulin G and anticomplement (C3) antibodies reveals an irregular (granular or "lumpy bumpy") immunofluorescence staining pattern (Fig. 14.20B).[270,432,435] The GBM proliferates to surround the immune deposits, leading to irregular thickening of the filtration barrier. Despite widening of the filtration barrier, the size and charge selective filtration properties are compromised, and microscopic hematuria and proteinuria result. In rare instances, glomerulonephritis may be attributed to a true autoimmune disorder in which autoantibodies directed against GBM components (e.g., type IV collagen) are produced. Electron microscopic examination in these cases also reveals GBM thickening with predominantly subepithelial electron-dense deposits (Fig. 14.21A), and immunofluorescence staining shows a more regular or smooth linear pattern of immunofluorescence (Fig. 14.21B).[435,440,441] Immune-mediated glomerulonephritis, accompanied by proteinuria, also has been described as one of the manifestations of systemic lupus erythematosus in horses.[442] Another immune mechanism of glomerulonephritis in horses is production of mixed or monoclonal cryoglobulins and deposition of antibody-antibody immune complexes along the glomerular GBM.[443,444] Cryoglobulinemia is associated with a number of diseases in human beings[5,443] but has been described in only a few horses.[444,445] Deposition of antibody-antibody immune complexes along the GBM may be a more important precipitant of glomerulonephritis than was recognized previously because electron microscopic examination is required to demonstrate characteristic fibrillar or crystalline intracapillary and subendothelial deposits associated with the condition.[443] Regardless of what immune mechanism leads to glomerular injury, the end result is thickening of the filtration barrier, retarded GFR, and development of CKD in severe cases.

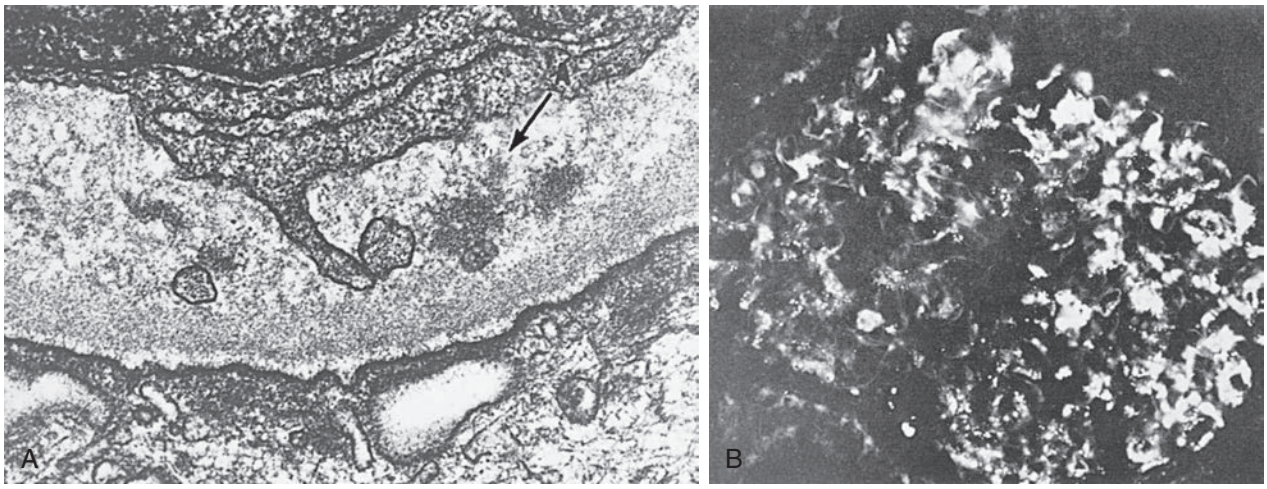

FIG. **14.20** Immune-mediated glomerulonephritis in a horse 165 days after experimental infection with equine infectious anemia virus (EIAV). **A,** An electron micrograph (×32,500) shows endothelial cell swelling *(top),* thickening of the glomerular basement membrane (GBM) with electron-dense immune deposits in a predominantly subendothelial location *(arrow),* and fusion of foot processes of the visceral epithelial cells. **B,** Immunofluorescent staining with fluorescein-tagged antiequine immunoglobulin G antibody (×100) demonstrates granular or "lumpy bumpy" deposits of immunoglobulin G along the GBM and in the mesangium. FIG. **14.21** Spontaneous immune-mediated glomerulonephritis in a horse. **A,** An electron micrograph (×22,750) shows a red blood cell (RBC) in the capillary lumen *(top),* relatively normal fenestrated endothelial cytoplasm, thickening of the glomerular basement membrane (GBM) with electron-dense immune deposits in a predominantly subepithelial location, and fusion of foot processes of the visceral epithelial cells. **B,** Immunofluorescent staining with fluorescein-tagged antiequine immunoglobulin G antibody (×160) demonstrates smooth, linear deposits of immunoglobulin G. (From Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 2. Antiglomerular basement membrane antibody and other mechanisms of spontaneous disease, *Lab Invest.* 26:708, 1972.)

Although a number of terms are used to describe the specific morphologic changes associated with glomerular injury, glomerulonephritis is categorized most broadly histologically as *proliferative* or *membranous.*[432,435,438] Proliferative (or mesangioproliferative) glomerulonephritis describes glomerular injury associated with influx of inflammatory cells and proliferation of mesangial cells. The predominant histologic finding is increased cellularity in glomeruli (Fig. 14.22A–B). This lesion tends to be associated with the more acute stages of glomerulonephritis during which immune complexes are being deposited in a predominantly subendothelial site. Membranous glomerulonephritis describes glomerular injury accompanied by significant thickening of the capillary wall and GBM; with periodic acid–Schiff (PAS) staining, the predominant histologic finding is increased in the mesangial area and on the GBM (Fig. 14.22C). Methenamine silver stain further

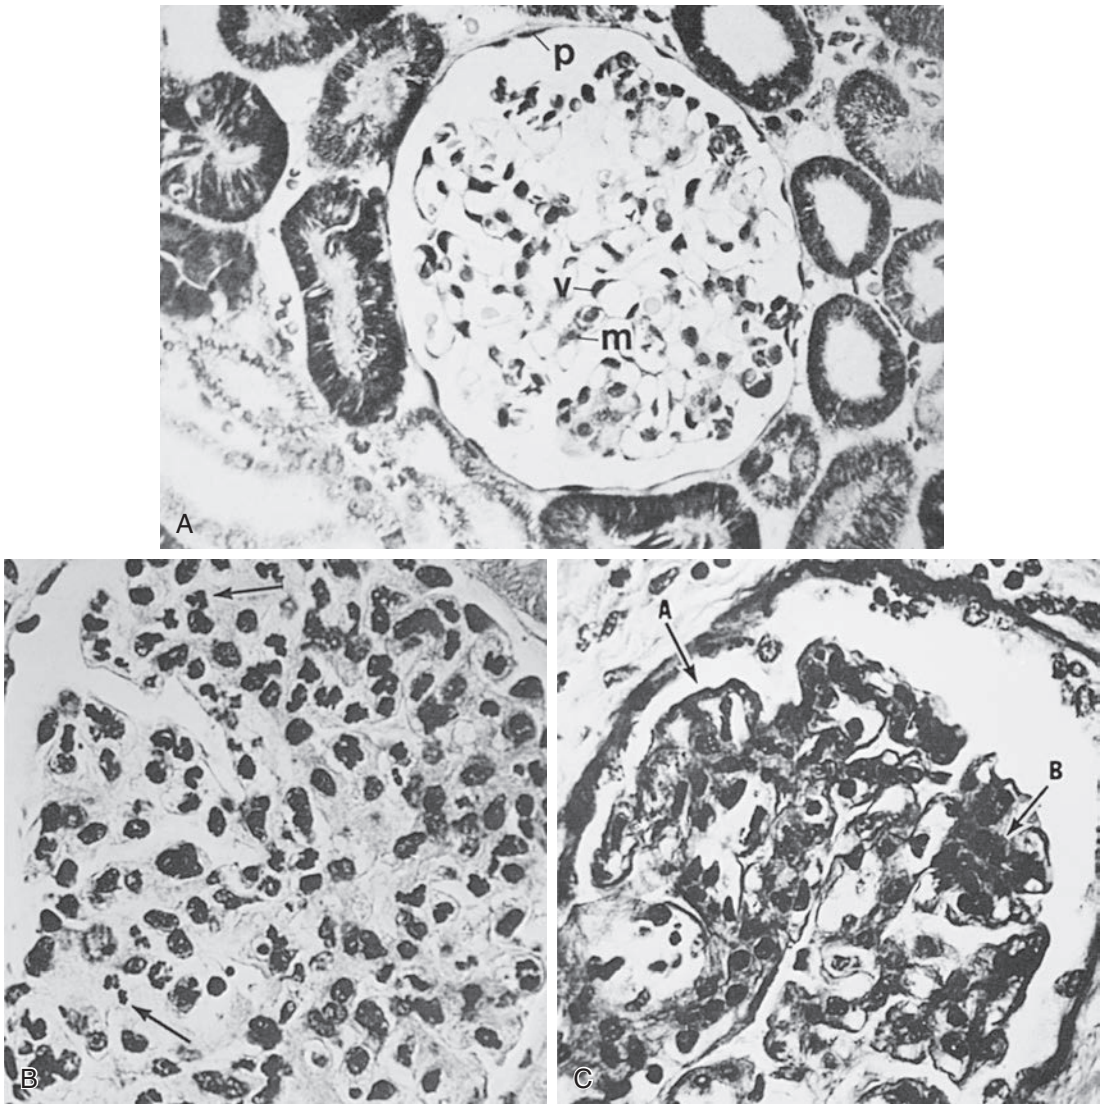

FIG. **14.22** Histologic changes in equine glomerulonephritis. ***A,*** Photomicrograph of a normal glomerulus. Bowman's capsule is lined by flattened parietal epithelial cells *(**p**)*. Visceral epithelial cells *(**v**)* are adjacent to the glomerular basement membrane (GBM), which is of uniform thickness. Mesangial cells *(**m**)* are surrounded entirely by glomerular capillaries (periodic acid–Schiff [PAS] stain, ×100). ***B,*** Photomicrograph demonstrates proliferative glomerulonephritis in a horse after experimental infection with equine infectious anemia virus (EIAV). A combination of neutrophil infiltration *(arrows)* and mesangial cell proliferation is apparent (hematoxylin–eosin stain, ×160). ***C,*** Photomicrograph demonstrates membranous glomerulonephritis in a horse after experimental infection with EIAV. The GBMs are thickened **(A),** and mesangial areas contain PAS-positive material **(B)** (PAS stain, ×160). (**A** from Osborne CA, Hammer RF, Stevens JB, et al.: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med.* 21:207, 1977; **B** and **C** from Banks KL, Henson JB, McGuire TC: Immunologically mediated glomerulitis of horses. 1. Pathogenesis in persistent infection by equine infectious anemia virus, *Lab Invest.* 26:701, 1972.)

enhances visibility of the thickening of the GBM.[435,438] Membranous glomerulonephritis tends to be associated with more soluble immune complexes or autoantibodies that can pass through the GBM and localize in a predominantly subepithelial site, resulting in less infiltration of inflammatory cells. As would be expected, a spectrum of lesions is visible in naturally occurring glomerulonephritis, leading to varying histologic descriptions of the disease (membranoproliferative glomerulonephritis). As glomerular injury progresses, proliferation of the parietal epithelium also occurs, likely in response to filtration of macromolecules and cellular debris. Lesions associated with parietal cell proliferation can include layering of epithelial cells (termed *crescents*) on the inner aspect of Bowman's capsule (Fig. 14.23A), adhesion formation between the glomerular tuft and Bowman's capsule (Fig. 14.23B), and tuft collapse. Glomerulosclerosis describes the end stage of progressive, irreversible glomerular injury in which replacement of glomerular components with hyaline material is visible on histologic examination (Fig. 14.23C).[435]

Specific histologic categorization of glomerulonephritis provides causative and prognostic information for human beings with renal failure attributable to glomerular disease.[5] Subcategorization

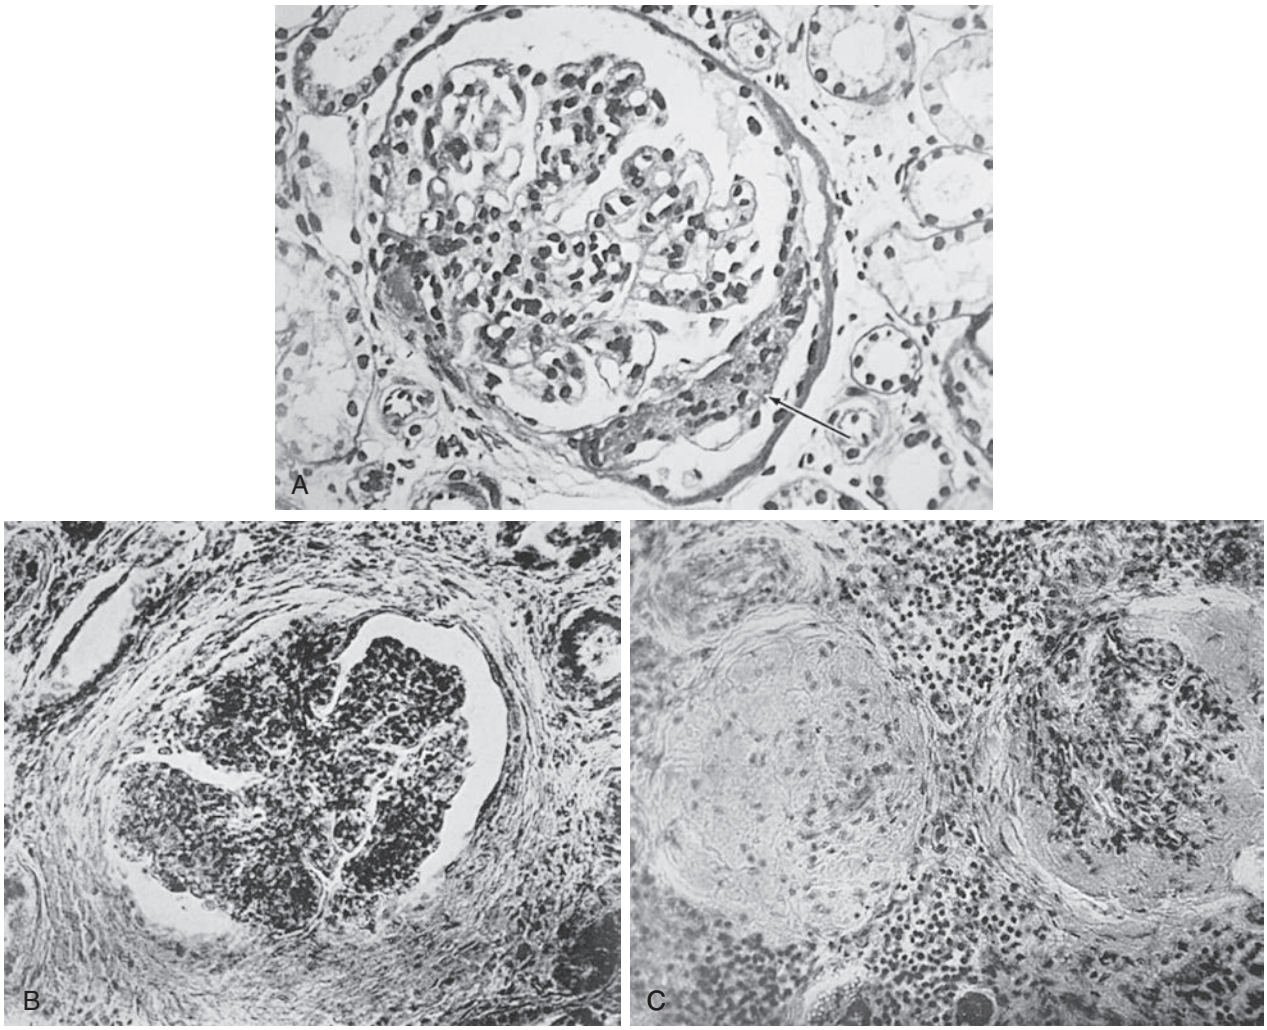

FIG. **14.23** Progressive histologic changes in equine glomerulonephritis. **A,** Photomicrograph of a renal biopsy specimen illustrates membranoproliferative glomerulonephritis (an increase in cell numbers and thickening of the glomerular basement membrane [GBM]) and parietal epithelial cell proliferation resulting in crescent formation (*arrow;* periodic acid–Schiff stain [PAS], ×100). **B,** Photomicrograph demonstrates progressive glomerulonephritis resulting in adhesion formation between the capillary tuft and proliferating parietal epithelial cells. **C,** Photomicrograph of end-stage glomerulosclerosis shows replacement of glomerular components with hyaline material (more complete in glomerulus on the left). (**A** from Osborne CA, Hammer RF, Stevens JB, et al.: The glomerulus in health and disease: a comparative review of domestic animals and man, *Adv Vet Sci Comp Med.* 21:207, 1977; **B** and **C** from Fincher MG, Olafson P: Chronic diffuse glomerulonephritis in a horse, *Cornell Vet.* 24:356, 1934.)

of glomerulopathies also has been done in a prospective study of naturally occurring chronic renal disease in canines. Although classifications—including focal glomerulonephritis, mesangioproliferative glomerulonephritis, endocapillary proliferative glomerulonephritis, crescentic glomerulonephritis, and sclerosing glomerulonephritis—could be made, histologic findings were not prognostically useful.[446] This study also revealed that glomerular disease was responsible for 52% of canine CKD; however, an inciting disease could be identified in only one of 31 dogs with glomerulonephritis (vegetative endocarditis).

Glomerulonephritis also appears to be an important cause of CKD in horses.[266] Of 60 reported cases of CKD attributable to acquired disease, glomerulonephritis was identified as the inciting cause of CKD in 32 (53%) (Table 14.8).*

Glomerulonephritis also may be the initiating disease process in cases of ESKD for which gross and histopathologic changes are so extensive that a primary mechanism of renal injury cannot be identified. A number of systemic inflammatory and infectious disease processes in horses may be accompanied by glomerulonephritis, but progression to CKD appears to be a rare sequela. For example, experimental *Leptospira pomona* infection produced subacute glomerulonephritis characterized by hypercellularity and edema of capillary tufts,[472] but leptospirosis appears to be a rare cause of clinical renal disease in horses.[473-475] Similarly, experimental infection with equine infectious anemia virus (EIAV) produced histologic and immunofluorescent evidence of glomerulonephritis in 75% and 87% of infected horses, respectively.[440] Immunoglobulins with anti-EIA activity were eluted from glomeruli collected from experimentally infected horses, but none of the

[a]In many reports of acquired renal disease leading to chronic renal failure, histopathologic changes involve glomeruli and interstitium. Categorization in this table is based on the authors' conclusions in these reports. When severe lesions involved glomeruli and interstitium, a categorization of ESKD was made.
[b]ESKD and reports of oxalate nephropathy.

horses showed clinical signs of renal disease. Poststreptococcal glomerulonephritis is a well-recognized cause of renal disease in human beings,[5,476] and Roberts and Kelly[477] speculated that glomerulonephritis in a horse with chronic pleuritis and purpura hemorrhagica likely resulted from circulating immune complexes involving streptococcal antigens. Divers and colleagues[417] provided support for this hypothesis by eluting group C streptococcal antigens from immune complex deposits in glomeruli collected from a horse with CKD. Finally, an occasional case of equine glomerulonephritis may result from true autoimmune disease, and in one instance, anti-GBM antibody was eluted from glomeruli with linear GBM immunofluorescent staining pattern isolated from a horse.[270] Little information is available about histopathologic subcategories of glomerulonephritis in horses, although several reports have attempted to make comparisons with glomerular lesions that have been better characterized in other species.[443,455,478] No reports have attempted to correlate histologic changes with the degree of renal failure in horses. Thus assessment of the severity of renal disease associated with glomerulonephritis in horses currently is based more on clinical findings (e.g., body condition, magnitude of azotemia) than on histologic changes in a renal biopsy sample.

Chronic Interstitial Nephritis

Tubulointerstitial disease usually results from ATN after ischemia, endotoxemia, sepsis, or exposure to nephrotoxic compounds. Hypovolemia associated with acute blood loss, colic, diarrhea, endotoxemia, or sepsis can lead to renal hypoperfusion and ischemic damage.[265] Severe localized infection (e.g., pleuritis, peritonitis) or septicemia also may be accompanied by tubule damage. Aminoglycoside antibiotics, NSAIDs, vitamin D, vitamin $K_{3\,(menadione)}$, acorns, and heavy metals such as mercury are potentially nephrotoxic.[382] Intravascular hemolysis or rhabdomyolysis also can lead to acute tubular damage after the nephrotoxic effects of hemoglobin and myoglobin (see Acute Renal Failure). In horses, tubulointerstitial disease culminating in CKD also can be caused by ascending urinary tract infections resulting in pyelonephritis[266,433,453,463-467,479] or bilateral obstructive disease caused by ureteroliths or nephroliths.[38,266,388,459-462,480] In other cases, a cause of the tubular disease may not be identified.[457,458] Finally, although this has not yet been described in horses, immune mechanisms, including antitubular basement membrane disease, can lead to chronic interstitial nephritis (CIN) in human beings.[5]

CIN is defined most strictly by clinical signs of renal disease associated with histologic changes of tubular damage and an interstitial inflammatory cell infiltrate (Fig. 14.24). Inflammatory cells include lymphocytes, monocytes, and occasionally plasma cells. Neutrophils are uncommon; however, eosinophilic infiltrates suggest drug reactions in human patients.[5] Major glomerular and vascular lesions are not apparent. The hallmark that distinguishes CIN from acute tubular and interstitial disease is interstitial fibrosis.

Although CIN has a fairly strict histologic definition, a number of disease processes can lead to tubular damage. For all practical purposes, *CIN* is a catchall term for extraglomerular causes of CKD in horses. As a consequence, gross findings in horses with CIN can vary dramatically. For example, NSAID toxicity, of which phenylbutazone has the greatest nephrotoxic potential,[481] can produce papillary necrosis[238,239] manifested by hematuria[482] in the early stages of disease, whereas chronic disease may be associated with nephrolithiasis and hydronephrosis. An area of papillary necrosis serves as a nidus for stone formation, and subsequent obstructive disease leads to hydronephrosis.[388,480] Similarly, upper urinary tract infection can lead to minor or major changes in the architecture of the kidneys and to variable histologic changes.

Using CIN as a broad category for nonglomerulonephritic causes of CKD in horses, this group of tubulointerstitial diseases was responsible for 38% (23 of 60) of the previously reported cases of CKD in horses (see Table 14.8). Although in

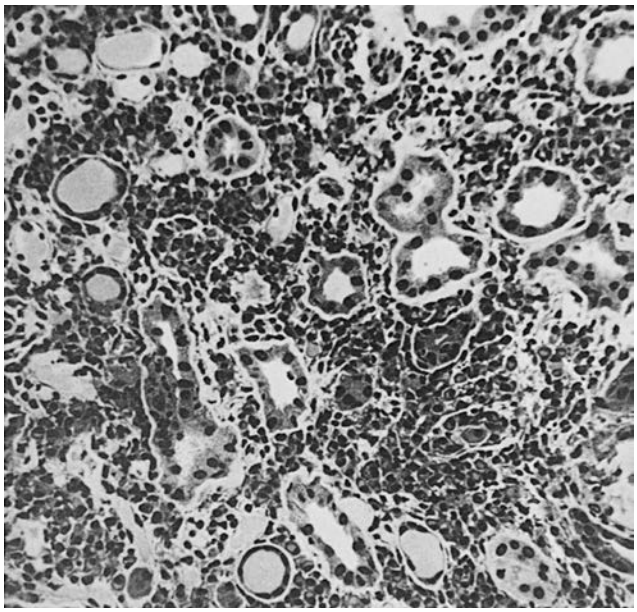

FIG. **14.24** Histologic changes in interstitial nephritis. The interstitium contains dense infiltrates of lymphocytes and plasma cells superimposed on moderate interstitial fibrosis and tubular atrophy (hematoxylin–eosin stain, ×275). (From Brenner BM, editor: *Brenner and Rector's the kidney,* ed 8, 2008, Philadelphia, WB Saunders.)

theory one would expect CIN to be accompanied by greater evidence of tubular dysfunction (e.g., enzymuria, glucosuria, increased fractional clearance of sodium), abnormal measures of tubular function have not been detected regularly. Similarly, microscopic hematuria and proteinuria, the hallmarks of glomerular disease, would not be expected.

End-Stage Kidney Disease

End-stage kidney disease describes the severe gross and histologic changes in kidneys collected from animals in the final stages of CKD. Grossly, the kidneys typically are pale, shrunken, and firm, and they may have an irregular surface and an adherent capsule. Histologically, severe glomerulosclerosis occurs along with hyalinization and extensive interstitial fibrosis. The end-stage lesions make determining the initiating cause of renal disease virtually impossible. In several cases with a pathologic description consistent with ESKD, the underlying cause of renal injury could not be established.[458,468-471]

Chronic Kidney Disease of Other Causes

Several early cases of CKD in horses were attributed to oxalate poisoning because oxalate crystals were observed in renal tubules.[457,468] Horses appear to be more resistant than other domestic species to oxalate-induced renal damage[25]; however, experimental administration of various forms of oxalate (in large doses) produced hypocalcemia and gastrointestinal signs rather than renal failure.[483] In fact, the early reports of oxalate nephropathy in horses failed to demonstrate that the affected horses had been exposed to oxalates.[457,468] Furthermore, long-term ingestion of plants containing oxalate produces fibrous osteodystrophy (oxalates bind calcium in the intestinal tract, decreasing intestinal calcium absorption), but renal damage in affected horses is minimal.[484] Formation of oxalate crystals in diseased equine kidneys now is recognized as a secondary change likely related to stasis of urine in damaged renal tubules.[451]

Amyloidosis is an unusual cause of CKD in horses.[25,485] Amyloid deposits associated with systemic disease typically are composed of aggregates of the amino-terminal fragment of serum amyloid A protein, an acute phase protein.[486-489] Concentrations of serum amyloid A increase with many inflammatory disease processes, and chronic elevations can result in amyloid deposition (AA type) in a variety of tissues, a condition termed *systemic reactive amyloidosis.*[490,491] Incidence and tissue localization of amyloid exhibit considerable species variation. Dogs appears to be affected most often, but the fact that the disease is familial in Abyssinian cats implies a genetic basis for the disease.[491] Amyloid deposits accumulate as stacks of protein in a β-pleated sheet conformation and are identified in tissue samples by their extracellular location and homogeneous, eosinophilic appearance when stained with hematoxylin and eosin. They are birefringent when viewed under polarized light, and staining with alkaline Congo red solution imparts a characteristic green color.[490,491] Amyloid deposition in the kidney is most common in dogs and cattle, and renal amyloidosis is a significant cause of CKD in dogs.[491] In horses, localized amyloidosis of the upper airway (around the nares or nasal septum) or skin is more common than systemic amyloidosis.[490] In the localized form, amyloid deposits are composed of immunoglobulin light chains (AL type). Although reports describe systemic reactive amyloidosis consequent to heavy parasite infestation in horses, renal involvement was minimal or not apparent.[492,493] Systemic amyloidosis has been recognized most often in horses hyperimmunized for antiserum production, and hepatic and splenic involvement may be more common than renal involvement in these horses.[25,485,487]

A final acquired cause of CKD, renal neoplasia, is discussed in greater detail elsewhere in this chapter. Although horses with renal neoplasia may have weight loss, tumors are usually unilateral and development of CKD is uncommon.

UREMIC TOXINS AND THE UREMIC SYNDROME

Regardless of the underlying cause of nephron loss, the ensuing renal insufficiency leads to development of azotemia and its clinical manifestation, the uremic syndrome.[5,486-488,494] The uremic syndrome is a multisystemic disorder that develops as a result of the effects of uremic toxins on cell metabolism and function. Although the uremic syndrome originally was attributed to the effects of increased BUN concentration, a number of nitrogenous compounds now are known to accumulate in CKD and contribute to alterations of cell metabolism and function. In fact, the correlation between the severity of the uremic syndrome and the magnitude of azotemia is poor. For example, urea administered to human beings with normal renal function results simply in fluid shifts, osmotic diuresis, and increased thirst.[495] Urea toxicity also has been studied in nephrectomized dogs and in human patients with CKD sustained by dialysis. Increasing the urea concentrations of the dialysate to maintain BUN at artificially higher values has produced variable results. For example, BUN values up to about 150 mg/dL were associated with few clinical signs, whereas lethargy, weakness, anorexia, vomiting, and bleeding diathesis (caused by platelet dysfunction) were produced when BUN was increased to values exceeding 175 to 200 mg/dL. Excess circulating urea also can degrade spontaneously to ammonia, carbonate, or cyanate. Cyanate can react with

N-terminal amino groups on a number of proteins and, by altering tertiary structure, can interfere with enzyme activity and structural integrity of cell membranes.[5] Thus accumulation of urea is likely responsible for some of the signs of uremic syndrome.

Creatinine and other guanidino compounds also accumulate in renal failure. These compounds are strong organic bases that contain an amidino group (N–C = NH).[5] With CKD, urinary excretion of creatinine and other guanidino compounds actually may increase (because of tubular secretion) but not enough to prevent increases in blood concentrations. For example, the author has found that in naturally occurring cases of equine CKD (author's unpublished data), endogenous Cl_{Cr}, when measured simultaneously with Cl_{In}, overestimates GFR by 50% to 100%. These data indicate that tubular secretion of creatinine, which Finco and Groves were unable to document in healthy ponies,[154] is initiated by or is quantitatively much greater with CKD. Although metabolic pathways have not been elucidated fully, guanidino compounds appear to be produced predominantly in the liver, and their concentration in blood and tissues increases with decreased renal function or increased dietary protein intake.[495] The relationship between guanidino compounds and the syndrome of uremia is also unclear. For example, administration of methylguanidine to healthy dogs resulted in weight loss, neurologic signs, and anemia but only when blood concentrations were an order of magnitude greater than those in spontaneous cases of CKD.[5] In contrast, administration of another guanidino compound, guanidinopropionic acid, led to hemolysis by depleting erythrocyte glutathione concentrations (supporting a role for this uremic toxin in the anemia of CKD).

Products of intestinal bacterial metabolism—including secondary methylamines (from metabolism of choline and lecithin), aromatic amines (from metabolism of tyrosine and phenylalanine), polyamines (from metabolism of lysine and ornithine), and tryptophan breakdown products (indole, skatole, indoleacetic acid, and others)—can contribute to the clinical signs associated with the uremic syndrome and neurologic disease. Some of these compounds have been studied thoroughly (e.g., the inhibitory effect of the polyamine, spermine, on erythropoiesis), whereas others are ill understood but likely contribute to altered neuromuscular and neurologic function.[5,494,495]

Another group of larger uremic toxins have been termed *middle molecules*.[5,495] These compounds are higher molecular weight compounds (500–3000 D) that are removed more readily from uremic patients by peritoneal dialysis than by hemodialysis. These compounds are not well characterized, and their existence is supported more by the difference in clinical response to peritoneal dialysis and hemodialysis in uremic human patients awaiting renal transplantation.

In addition to nitrogenous compounds, abnormal metabolism of hormones and trace minerals also accompanies the decline in renal function associated with acute and CKD. Secondary hyperparathyroidism (leading to osteodystrophy) and insulin insensitivity are well-recognized endocrine contributions to the uremic syndrome in human and small animal patients.[5,495-497] Endocrine dysfunction can be attributed to several factors: (1) decreased production of renal hormones (erythropoietin, vitamin D_3), (2) decreased hormone clearance prolonging plasma half-life (parathormone, gastrin), (3) decreased hormone production (testosterone), (4) tissue insensitivity (insulin, parathormone), and (5) hypersecretion to reestablish homeostasis (parathormone).[5] Regarding trace minerals, uremia may be accompanied by aluminum toxicity and zinc deficiency. Aluminum may contribute to some of the neurologic signs associated with azotemia (especially with ARF), whereas zinc has been implicated in testicular atrophy and abnormal taste in uremic human patients.[5,495] Presumed uremic encephalopathy has been reported in horses with CKD when neurologic dysfunction could not be attributed to other causes.[498] All five reported cases died or were euthanized. Swollen astrocytes were observed histologically in all horses that were necropsied.

Clearly, because so many potential uremic toxins exert their effects as renal function declines, it is unlikely that a single compound or even a few compounds will ever be identified as the primary cause of the uremic syndrome in patients with CKD. Furthermore, these compounds together are more likely to impair basic cell function in a number of tissues, and the signs of uremia are more likely to reflect multisystemic organ dysfunction. Methylation of membrane proteins has been identified as one of the common mechanisms of cell dysfunction.[499] What is truly remarkable, however, is the tremendous adaptive capacity of the failing kidneys to maintain sodium and water balance within narrow ranges until GFR declines to 20% of the normal value or less.[500]

CLINICAL SIGNS

Horses with CKD present relatively late in the disease course, when their owners note lethargy, anorexia, and weight loss. A history of months to years of polydipsia and polyuria in some cases supports renal disease of long duration. In other animals, preexisting disease (e.g., colic, colitis, pleuropneumonia) or prolonged medication (e.g., aminoglycoside antibiotics, NSAIDs) may provide important information about the initiation and duration of renal failure. In most cases, however, the onset is insidious, and identifying a precipitating event or gauging the duration of renal disease is not possible.

Chronic weight loss is the most common presenting complaint for horses with CKD.[70,95,260,266,433,434] Partial anorexia, ventral edema, polydipsia and polyuria, rough hair coat, lethargy, and poor athletic performance are other owner concerns. In addition, horses with advanced CKD may have a characteristic odor that likely reflects the combined effects of uremic halitosis and increased urea excretion in sweat. For the horses presented in Table 14.8, weight loss, ventral and peripheral edema, and polydipsia and polyuria were reported in 53 of 63 (84%), 24 of 56 (43%), and 21 of 48 (44%), respectively, of the cases. Lethargy and weight loss can be attributed to several factors. An increase in the concentration of nitrogenous wastes in blood can have a direct central appetite suppressant effect that can lead to partial or complete anorexia.[5,495] Next, as azotemia develops, excess urea diffuses across gastrointestinal epithelium and is metabolized to ammonia and carbon dioxide by bacterial urease. Also, when blood urea concentration is high, urea is excreted in saliva. In the oral cavity, excess ammonia can lead to excessive dental tartar formation (Fig. 14.25), gingivitis, and oral ulcers. In the gastrointestinal tract, excess urea and ammonia can lead to ulceration and mild to moderate protein-losing enteropathy, and severely uremic animals may produce soft feces.[5,432,495] The prolonged half-life of gastrin (eliminated

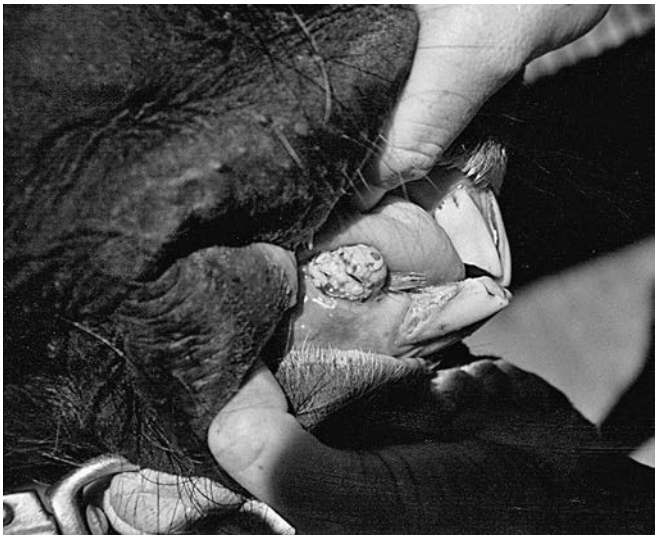

FIG. **14.25** Excessive dental tartar on the canine tooth and lower corner incisor of a horse with chronic renal failure (CRF).

through the kidneys) may contribute further to gastric ulcer formation because of increased acid secretion.[35] Finally, as the combined effects of uremic toxins render the affected patient catabolic, body mass declines as body reserves are tapped to meet basal energy requirements.[5,495]

Mild ventral edema with CKD may be attributable to three factors: (1) decreased oncotic pressure, (2) increased vascular permeability, and (3) increased hydrostatic pressure. Because albumin accounts for approximately 75% of plasma colloid oncotic pressure, decreases in albumin concentration (less than 2 g/dL) can decrease plasma oncotic pressure despite a normal total plasma protein concentration.[155,501] The effects of uremic toxins on endothelial cell membranes can alter vascular permeability, which contributes to edema.[5,495] Chronic renal insufficiency can lead to renal hypoxia and hypoperfusion, which stimulate renal juxtaglomerular cells to release renin. Activation of the renin-angiotensin system tends to elevate blood (and capillary hydrostatic) pressure and contributes to edema. Activation of the renin-angiotensin system also leads to increased sodium reabsorption in the proximal (direct effect of angiotensin II) and distal (effect of aldosterone) tubules.[155] Sodium retention leads to expansion of circulating volume, which is another factor in edema formation. Alterations in blood pressure in horses with CKD have not been evaluated routinely (as they have in small animal and human patients), and increased circulating concentrations of angiotensin II or aldosterone in horses have not been documented extensively. The nephrotic syndrome (characterized by edema, hypoalbuminemia, and heavy proteinuria) is not as well documented in horses as in small animals and human beings with CKD. However, horses with CKD appear less at risk for the significant pleural effusion or ascites that can accompany the nephrotic syndrome in small animals.[432]

Polydipsia and polyuria are variable findings in horses with CKD. The magnitude of polydipsia and polyuria theoretically is related to the degree of tubulointerstitial damage; however, the degree of polyuria does not appear to correlate with the magnitude of azotemia in clinical cases. Typically, polyuria is not as severe with CKD as with diabetes insipidus or psychogenic water drinking and may not be noticed by an owner (see the Polyuria and Polydipsia section of this chapter). The wide variation in water intake in normal horses and common use of automatic waterers and large stock tanks also make observation of polydipsia more difficult. The mechanisms of polyuria with CKD can include (1) increased tubular flow rate in surviving nephrons, (2) decreased medullary hypertonicity, and (3) impaired response of collecting ducts to vasopressin (acquired nephrogenic diabetes insipidus). Although these mechanisms may contribute to the polyuria of CKD, which of them may be most important is not known.[432,502]

An early complaint for horses with CKD is poor performance, which may be related to mild anemia (PCV 25%–30%) and lethargy. Although the anemia of CKD has been attributed to several factors—including blood loss, decreased erythrocyte survival time, nutritional deficiencies, and decreased erythropoietin production—the latter clearly has emerged as the principal cause of anemia in human beings and small animals with CKD.[5,432,503] In fact, administration of recombinant human erythropoietin (rhEPO) to human patients awaiting kidney transplant has been one of the most significant advances in management of CKD because it has eliminated the need for blood transfusions, improved exercise capacity, and decreased morbidity associated with the uremic syndrome.[5,503] Administration of rhEPO has also benefited anemic dogs and cats with CRF, although both species may need iron supplementation to support erythropoiesis.[5,432] The response often has been only temporary because many small animal patients develop refractory anemia after production of antirhEPO antibodies within a few weeks to months after initiation of treatment.[432] Plasma concentrations of erythropoietin have been determined in normal horses,[504] and rhEPO administration (15 IU/kg IV, three doses per week for 3 weeks) has been reported to increase the hematocrit in splenectomized horses[505]; however, no reports describe rhEPO administration to horses with CKD. Furthermore, moderate to severe anemia that may be fatal has been reported to develop after repeated rhEPO administration to racehorses.[506-508] The risks of adverse reactions far outweigh the potential benefits of rhEPO, and its use in horses should be avoided.

DIAGNOSIS AND LABORATORY EVALUATION

One establishes a diagnosis of CKD when persistent isosthenuria (specific gravity of 1.008–1.014) accompanies azotemia and typical clinical signs.[70,95,260,264,266] Rectal palpation of the left kidney may be normal or may reveal a kidney that is small or firm with an irregular surface. Less often, the kidneys and ureters may be enlarged if obstructed by uroliths or if infection or neoplasia is present. The ratio of BUN-to-creatinine concentration (BUN-to-Cr ratio) in horses with CKD is typically greater than 10:1 (Table 14.9); that for horses with prerenal azotemia or ARF is often less than 10:1.[266] This difference can be attributed in part to different volumes of distribution for urea (all body fluids) and creatinine (primarily the extracellular fluid space). As a consequence, with acute reductions in renal blood flow, the increase in creatinine concentration is usually greater, on a relative or percentage basis, than the increase in BUN. The point deserves emphasis, however, that BUN is influenced by dietary protein intake so that BUN-to-Cr values do not always distinguish ARF from CKD. In fact, one also can use the BUN-to-Cr ratio to assess adequacy of

TABLE **14.9 Abnormal Laboratory Values Reported for Horses with Chronic Renal Failure**

Parameter	Number[a]	Percentage
Blood urea nitrogen/serum creatinine concentrations (BUN/Cr) >10	29/34	85%
BUN/Cr >15	17/34	50%
Anemia (packed cell volume [PCV] <30%)	12/30	40%
Hypoalbuminemia (<2.5 g/dL)	12/14	86%
Hypoalbuminemia (<2.0 g/dL)	7/14	50%
Hyponatremia (Na^+ <135 mEq/L)	26/40	65%
Hyperkalemia (K^+ >5.0 mEq/L)	23/41	56%
Hypochloremia (Cl^- <95 mEq/L)	19/41	46%
Hypercalcemia (Ca^{2+} >13.5 mg/dL)	26/39	67%
Hypophosphatemia (P <1.5 mg/dL)	17/36	47%
Acidosis (pH <7.35)	3/5	60%

[a]Number of reports with this laboratory finding/total number of reports in which this laboratory parameter was reported.

dietary protein intake in the management of horses with CKD because a value greater than 15:1 can reflect excessive protein intake.[95]

In addition to azotemia, further abnormal laboratory data accompanying CKD can include mild anemia, hypoalbuminemia, hyponatremia, hyperkalemia, hypochloremia, hypercalcemia, hypophosphatemia, and metabolic acidosis (see Table 14.9). A nonregenerative anemia is related largely to a deficient supply of the renally secreted glycoprotein, erythropoietin; however, reduced erythrocyte life span may be another significant contributor to anemia. Normally, equine erythrocytes have a life span of 140 to 155 days.[507] With uremia, erythrocyte life span is shortened because excessive nitrogenous waste products alter the integrity of erythrocyte membranes and the function of ion channels, which regulate erythrocyte volume.[154] These less resilient erythrocytes are more likely to be removed from the circulation by the reticuloendothelial system.

The electrolyte alterations associated with CKD reflect loss of tubule function. Because sodium, chloride, bicarbonate, and phosphate are conserved by renal tubules, excessive urinary loss of these electrolytes accompanies CKD. Although fractional electrolyte clearance values (see Examination of the Urinary System) may remain within normal ranges or increase only slightly in horses with CKD, significant daily urinary loss of electrolytes still may occur. As an example, if a horse with CKD and creatinine and sodium concentrations of 5 mg/dL and 130 mEq/L, respectively, is producing 20 L of urine daily with respective creatinine and sodium concentrations of 50 mg/dL and 12.5 mEq/L, the fractional clearance of sodium is 1.0% and daily urinary sodium loss is 250 mEq. An increase in urinary sodium concentration to 25 mEq/L after another decrease in tubular reabsorption would result in an increase in fractional sodium clearance to 2% but would represent an additional 250 mEq of daily sodium loss in the urine. The latter value would approach 1% to 2% of the exchangeable sodium in the body and would require an additional 15 g of salt intake daily to accommodate this loss. Hypercalcemia and hypophosphatemia (Williams-Smith syndrome) are fairly common findings in horses with CKD (see Table 14.9), and the degree of hypercalcemia appears to vary with the amount of calcium in the diet.[433,450,453,509] In human beings with ESKD, hypercalcemia is an occasional finding attributed to hyperparathyroidism, vitamin D supplementation, or use of calcium-containing dialysate solutions. Furthermore, the osteodystrophy of CKD is associated with aluminum deposition in bone, which has been speculated to reduce skeletal buffering capacity for increases in serum calcium concentration and thereby contributes to hypercalcemia.[5] Because the equine kidney is an important route of calcium excretion (via $CaCO_3$ crystals), impaired tubular function in the face of continued intestinal absorption is the most common explanation for calcium accumulation in blood. This explanation is supported by the rapid development of hypercalcemia after experimental bilateral nephrectomy in ponies fed alfalfa hay (Fig. 14.26).[258] In addition, parathormone concentrations have been found to be below the lower limit of detection in horses with CKD, indicating that hyperparathyroidism does not play a role in development of hypercalcemia.[51,458] However, parathormone clearance by the kidney also is reduced with CKD and may be associated with a change in the regulatory set point for serum calcium concentration in uremic human beings.[5] Whether hypercalcemia in horses with CKD leads to exacerbation of renal disease or tissue mineralization remains unknown. Nevertheless, one can demonstrate the effect of dietary calcium by changing the type of hay fed to horses with CKD. Horses with serum calcium concentrations exceeding 20 mg/dL on a diet of mostly alfalfa can have their serum calcium concentrations returned to the normal range within a few of days after changing the diet to grass hay.[50,266] Similarly, nephrectomized ponies fed grass hay did not become hypercalcemic.[266] The cause of hypophosphatemia in horses with CKD also remains undocumented, although it has been explained by the law of mass action, which leads to a decrease in serum phosphate concentration in association with hypercalcemia.[5,509] A similar response is not observable in horses that eat *Cestrum diurnum* (leading to a syndrome of hypervitaminosis D)—they develop hypercalcemia without hypophosphatemia.[510] Another possibility that has been suggested is that hypophosphatemia may result from long-standing anorexia associated with CKD.[458] Regardless of the cause, clinical problems associated with hypophosphatemia have not yet been recognized in horses with CKD.

A degree of metabolic acidosis accompanies CKD in human beings and small animals and is attributed to decreased ability of failing kidneys to excrete hydrogen ions and regenerate bicarbonate.[5,432] Normally, acid-base balance is maintained by reabsorption of filtered bicarbonate and excretion of hydrogen ions along with ammonia and phosphate. As renal function declines in the early stages of renal failure, hydrogen ion excretion via renal ammoniagenesis and ammonium excretion increases. As renal failure progresses, compromised renal ammoniagenesis and decreased medullary recycling of ammonia caused by structural renal damage likely contribute to impaired ammonium excretion. Because hepatic glutamine synthesis is required for renal ammoniagenesis, the earlier increase in ammonium excretion may contribute to protein malnutrition in patients with CKD.[432] Metabolic acidosis also contributes to a number of the clinical signs of the uremic syndrome and may exacerbate some of the electrolyte alterations (e.g., hyperkalemia) of CKD. Metabolic acidosis has been reported in a limited number of horses with CKD (see Table 14.9); however, in the author's experience and that of others,[260,458] most horses with CKD have normal acid-base status

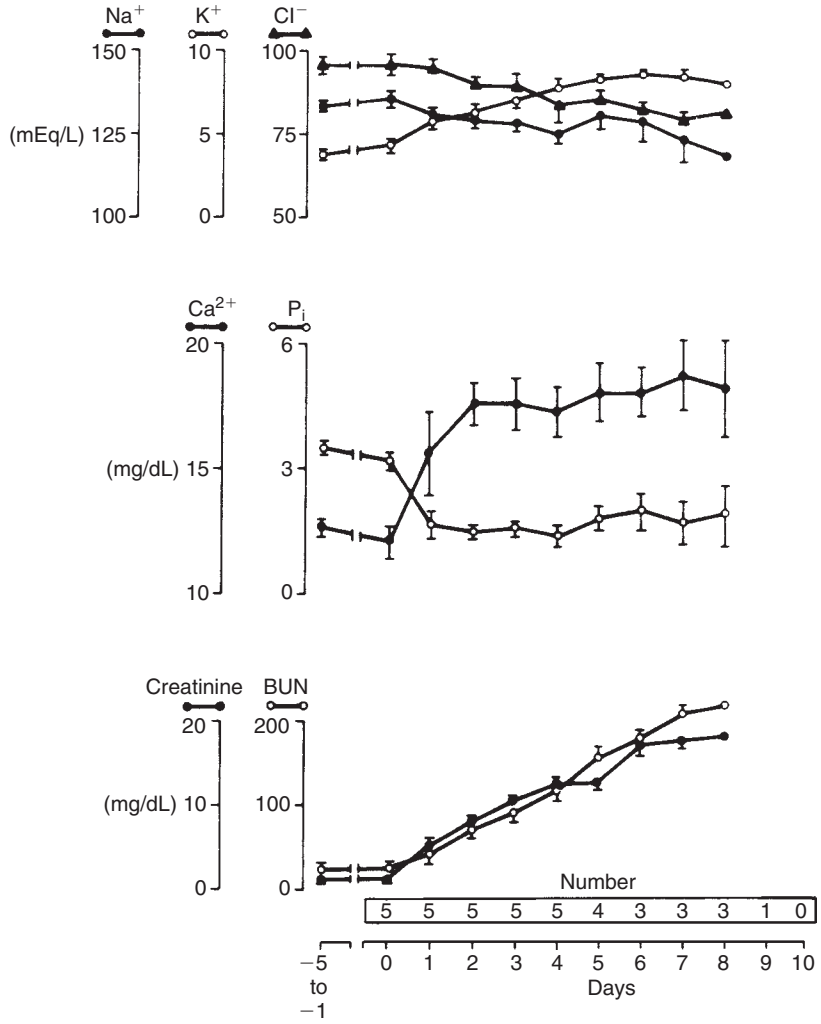

FIG. **14.26** Changes in serum electrolyte concentrations, blood urea nitrogen (BUN) concentration, and serum creatinine (Cr) concentration after bilateral nephrectomy in Shetland ponies. (From Tennant B, Lowe JE, Tasker JB: Hypercalcemia and hypophosphatemia in ponies following bilateral nephrectomy, *Proc Soc Exp Biol Med.* 167:365, 1981.)

or are alkalotic until the terminal stages of the disease, when metabolic acidosis typically develops. Metabolic alkalosis has been attributed to enhanced bicarbonate reabsorption and production, in association with hypochloremia and increased renal ammoniagenesis, respectively. In some instances, hypochloremic metabolic alkalosis may be accompanied by paradoxic aciduria.[458] The mechanism of paradoxic aciduria is likely similar to that of hypochloremic metabolic alkalosis in ruminants with abomasal outflow obstruction.[283] Briefly, after all chloride has been reabsorbed from the glomerular filtrate, further sodium reabsorption occurs by exchange with (excretion of) potassium or hydrogen ions. Thus paradoxic aciduria is most likely to occur with concomitant hypokalemia or whole body potassium depletion.

Horses with CKD also can develop hypercholesterolemia and hyperlipidemia (hypertriglyceridemia), and occasionally an animal has grossly lipemic plasma (hyperlipemia).[95,264,266] In fact, Naylor, Kronfeld, and Acland[511] reported a positive correlation between serum triglyceride and creatinine concentrations in a group of azotemic horses. Twelve of 13 cases of hypertriglyceridemia in horses reviewed by Dunkel and McKenzie[512] were azotemic. With azotemia, hyperlipidemia can develop as a result of increased synthesis, decreased degradation, or increased mobilization of triglycerides from fat stores.[5] Lipoprotein lipase, which stimulates triglyceride uptake into cells, is inhibited by azotemia.[513] Heparin treatment (40 IU/kg subcutaneously every 8 hours) has been recommended to stimulate lipoprotein lipase in an attempt to clear the serum.[95,266] Hypercholesterolemia and hyperlipidemia increase the risk of atherosclerotic cardiovascular disease in human beings with CKD.[5] Furthermore, these conditions stimulate mesangial cell proliferation and matrix production in diseased glomeruli and thus accelerate progression to glomerulosclerosis.[514]

The failing kidneys have a tremendous adaptive capacity to maintain tubular function until GFR is low.[500] In the author's experience, tubular dysfunction resulting in significant sodium or phosphorous wasting (manifested by increased fractional clearance values), glucosuria, or enzymuria is more common with ARF than with CKD. When present, however, abnormal tubule function rarely leads to values for fractional sodium clearance in excess of 5%.[272,461,471] In contrast, loss of

concentrating ability resulting in isosthenuria is a consistent feature of CKD that usually develops before azotemia. The associated polyuria may or may not be observed by the client, but the horse usually maintains water balance well through polydipsia. Polyuria typically results in urine that is clear and essentially devoid of crystals and mucus. Sediment examination is generally unremarkable, but increased numbers of red or white blood cells may occur with nephrolithiasis or ureterolithiasis or with pyelonephritis, respectively. Gross hematuria further supports urolithiasis or neoplasia. One should include a quantitative urine culture in the diagnostic plan for all horses with CKD because bacteriuria may not always be accompanied by pyuria.

Alterations in the integrity of the highly anionic glomerular filtration barrier also can lead to loss of protein, predominantly albumin, in the urine. Few quantitative data are available on urinary protein loss in horses with CKD because in most previous reports proteinuria was assessed using urine reagent strips. Reagent strip results of +++ or ++++ correlate with protein concentrations of 100 to 300 and 1000 to 2000 mg/dL, respectively, depending on which reagent strip one uses. In a proteinuric horse that is producing 20 L of urine daily, these values would yield a wide range of urinary protein loss (20–400 g daily). The latter value would approach 25% of the total protein content of plasma and so is not realistic. In human beings with CKD, urinary protein loss exceeding 3.5 g/day (50 mg/kg/day for a 70-kg person) is classified as *nephrotic-range proteinuria,* and some patients with heavy proteinuria may lose in excess of 15 g per day (more than 200 mg/kg/day).[5] The upper limit of acceptable urinary protein excretion in dogs is 20 mg/kg/day.[286] Using these values, estimates for the upper acceptable limits for urinary protein loss and nephrotic-range proteinuria in a 500-kg horse would be 10 g and in excess of 25 g/day, respectively. These values agree well with a mean value of 3.2 mg/kg (1.6 g/day) and a range of 3.6 to 22.3 mg/kg (1.8–11.2 g) per day in normal mares reported by Schott, Hodgson, and Bayly[285] and by Kohn and Strasser,[153] respectively.

Another method to document proteinuria is to determine the ratio of urinary protein to urinary creatinine (in milligrams per deciliter). This technique is more practical because it avoids a timed urine collection period. Although a normal range has not yet been reported for horses, values in excess of 1.0:1 and 3.5:1 are considered above normal and indicate nephrotic-range proteinuria in dogs[286] and human beings,[5] respectively. Thus a urine protein-to-Cr ratio greater than 2.0:1 likely supports significant proteinuria in a horse with CKD. Finally, a horse with CKD and heavy proteinuria (more than 200 mg/kg/day) could excrete as much as 100 g of protein daily (5%–7% of total plasma protein). Proteinuria of this magnitude can increase urine specific gravity to 1.020 or greater and certainly would be great enough to lead to a decline in serum albumin (and total protein) concentration, despite increased hepatic albumin production. In some horses with CKD and a normal total plasma protein concentration, increased globulin concentration offsets mild hypoalbuminemia, whereas in other cases hyperglobulinemia actually can result in an increase in total plasma protein concentration.

One can use ultrasonography to determine kidney size in horses with CKD and to evaluate for the presence of cysts or nephroliths. Horses with ESKD typically have small kidneys that are more echogenic than normal (because of sclerosis and possible tissue mineralization).[335,336,339,341,342] Cystoscopy also can be a useful diagnostic aid to assess urine production qualitatively in each kidney and is particularly useful when ultrasonographic imaging fails to identify a kidney.[335] Renal scintigraphy is another imaging option to detect functional renal tissue that may not be apparent by ultrasonography.[352] One can perform renal biopsy using ultrasonographic guidance to document renal disease. Unfortunately, because most horses are presented for evaluation in the later stages of disease, biopsy results typically reveal glomerular, tubular, and interstitial lesions consistent with ESKD. Rarely do the lesions provide information about the inciting cause of the renal disease unless immunofluorescence testing and electron microscopy are pursued. These require placing samples in special fixatives, in addition to the sample placed in formalin for routine histopathologic examination. In some cases, renal biopsy results supporting pyelonephritis or a congenital anomaly (dysplasia) as the cause of CKD are useful in developing a therapeutic plan or providing a prognosis.

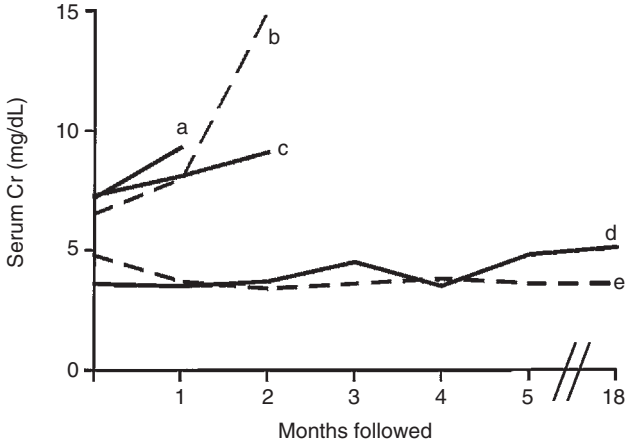

FIG. **14.27** Serum creatinine *(**Cr**)* concentrations in five horses with chronic renal failure (CRF). The three horses with an initial Cr concentration greater than 5 mg/dL *(**a** to **c**)* had rapid progression of renal disease over a 1- to 2-month period, necessitating euthanasia, whereas the two horses with an initial Cr concentration less than 5 mg/dL *(**d** and **e**)* were maintained with supportive care for longer than 18 months.

One can assess the severity of CKD in affected horses using available sophisticated techniques. The magnitude of azotemia is the most readily available and practical parameter, but it is an insensitive one.[5] Azotemia becomes apparent only after 75% or more of renal function is lost. Furthermore, the degree of azotemia can vary with nonrenal factors such as diet, body mass, and hydration. In general, creatinine concentration is a more reliable measure than BUN, and doubling of creatinine roughly correlates to a 50% decline in GFR (see Fig. 14.6). Creatinine concentrations in the range of 5 to 10 mg/dL indicate a significant decline in renal function, and values exceeding 15 mg/dL are consistent with a grave prognosis. In contrast, horses with a creatinine concentration below 5 mg/dL may exhibit few clinical signs and can be managed for months to years (Fig. 14.27). Plotting the inverse of creatinine concentration (1/Cr) over time also has been used to monitor progression of CKD in human beings[515,516] and in one horse[50] in an attempt to predict the end point of the disease process (Fig. 14.28). Unfortunately, these plots are subject to considerable variation (because of changes in tubular secretion of creatinine) and have not proved to be of any more value than monitoring creatinine over time.[515,516]

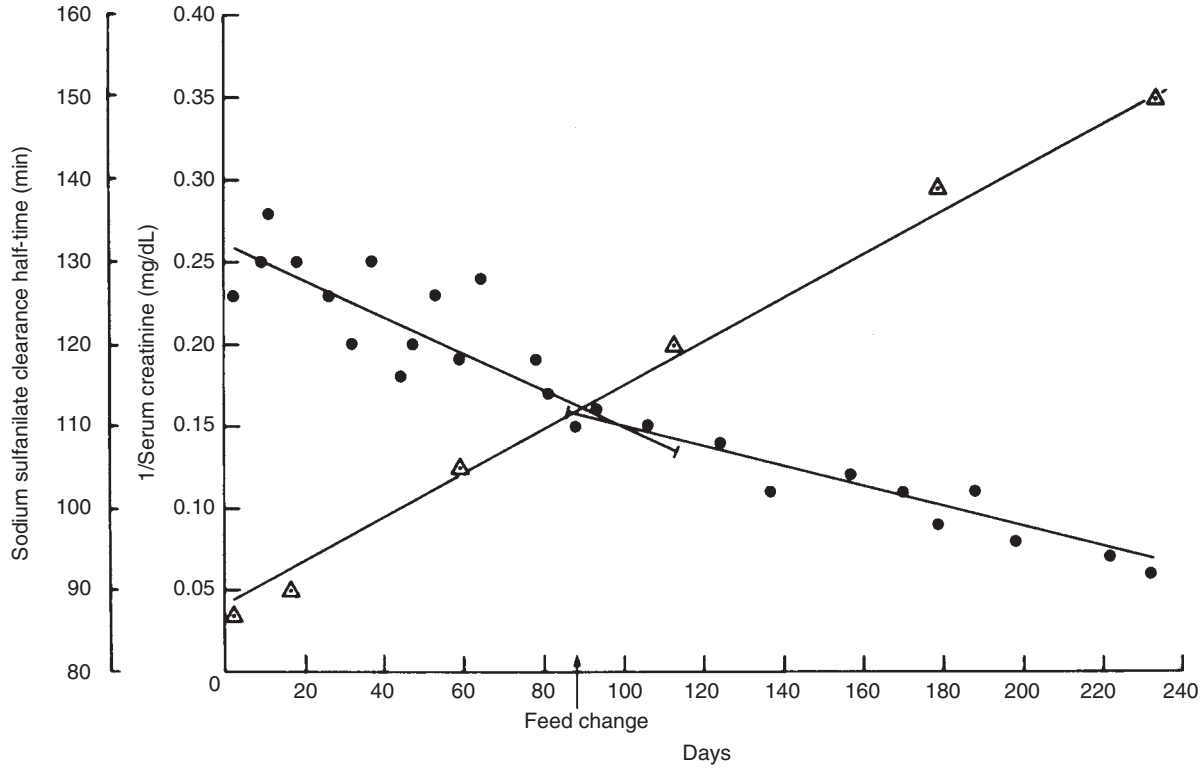

FIG. **14.28** The inverse of the serum creatinine (Cr) concentration *(filled circles)* and the whole-blood sodium sulfanilate clearance half-time in a horse with chronic renal failure (CRF) associated with polycystic kidney disease (PKD). The slope of the line describing the reciprocals of Cr concentration from day 1 to day 98 was significantly different ($P < 0.05$) from that from day 99 to 235, and the slope change was associated with a change from alfalfa to grass hay. (From Bertone JJ, Traub-Dargatz JL, Fettman MJ, et al.: Monitoring the progression of renal failure in a horse with polycystic kidney disease: use of the reciprocal of serum creatinine concentration and sodium sulfanilate clearance half-time, *J Am Vet Med Assoc.* 191:565, 1987.)

Measurement of GFR provides the most accurate quantitative assessment of renal function but is pursued rarely because it is more time consuming and technically demanding than measurement of creatinine concentration. Although a number of methods are available to measure GFR,[235] measurement of endogenous Cl_{Cr} or the plasma disappearance of exogenous creatinine, sulfanilate,[270,366] or 99mTc-DTPA[219] are the most practical methods in a clinical setting. The former requires timed urine collections, whereas the latter may require special assays or nuclear medicine capabilities (see Examination of the Urinary System). Horses in the earlier stages of CKD can develop tubular creatinine secretion, which could lead to overestimation of GFR measured by the Cl_{Cr} technique. As renal disease progresses, however, creatinine excretion decreases faster than GFR declines because of loss of compensatory secretion. Despite these limitations, repeated measurement of Cl_{Cr} in a single animal can be useful for monitoring progression of CKD over time (Fig. 14.29).

DISEASE PROGRESSION

One of the hallmarks of CKD is the progressive nature of the disease,[517-519] and progression appears to be largely independent of the inciting cause because of the final common pathways of renal injury. The response to a decrease in renal functional mass is a compensatory increase in filtration (termed *single-nephron GFR*) and tubular function (e.g., creatinine secretion, ammoniagenesis) by remaining nephrons. The increase in single-nephron GFR results from increased glomerular capillary blood flow and hydrostatic pressure leading to glomerular hyperfiltration. Hyperfiltration is associated with increased permeability of the GBM and proteinuria. Furthermore, increased filtration of macromolecules leads to activation and proliferation of mesangial and epithelial cells and eventually progression to glomerulosclerosis.[5,501,517-519] In addition to causing proteinuria, increased filtration of protein is accompanied by increased proximal tubular protein reabsorption. The latter leads to upregulation of genes encoding vasoactive and inflammatory mediators by tubular and interstitial cells and contributes substantially to injury of the renal interstitium.[519]

A number of studies investigating the mechanisms of glomerular hypertension have demonstrated that activation of the renin-angiotensin system and angiotensin II production are of considerable importance, because angiotensin II is a potent constrictor of glomerular efferent arterioles.[520-522] Activation of the intrarenal renin-angiotensin system can produce significant glomerular hypertension without producing increases in systemic angiotensin II concentration or blood pressure. In fact, administration of specific angiotensin II receptor antagonists or angiotensin-converting enzyme inhibitors has been demonstrated to decrease glomerular capillary hydrostatic pressure and the magnitude of proteinuria in experimental studies of renal disease.[520-523] Angiotensin-converting enzyme inhibitors have helped to control hypertension and proteinuria

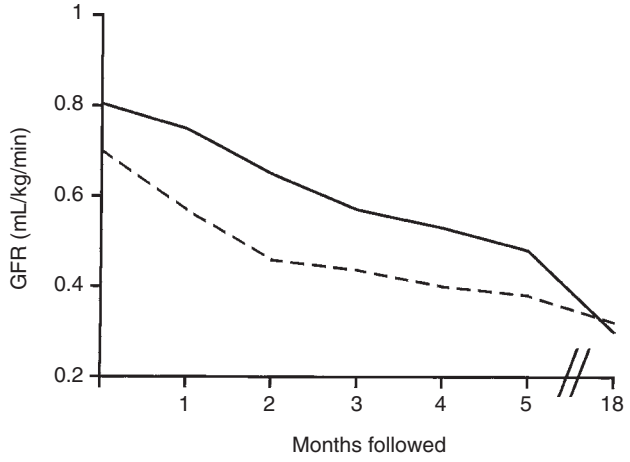

FIG. **14.29** Glomerular filtration rate (GFR) as measured by endogenous creatinine clearance (Cl_{Cr}) *(solid line)* and inulin clearance (Cl_{In}) *(dashed line)* in a mare (see horse in Fig. 14.28) with chronic renal failure (CRF). GFR declined steadily over the 18-month period, despite minimal change in serum creatinine (Cr) concentration. Compared with Cl_{In}, endogenous Cl_{Cr} overestimated GFR until the terminal stage of the disease process. This difference likely reflects tubule secretion of Cr in the earlier stages of CRF, which subsequently diminished during the final weeks of the disease course.

in small animals,[432,524] but no reports describe use of angiotensin-converting enzyme inhibitors in horses with CKD.

The role of dietary protein in the progression of CKD has been the subject of a number of investigations in human beings and small animals with a variety of renal diseases.[525-530] A well-established fact is that one can ameliorate clinical signs of uremia by decreasing dietary protein content; however, whether decreasing dietary protein slows progression of renal disease remains controversial. Increased dietary protein has been demonstrated to increase activation of the renin-angiotensin system; therefore decreasing dietary protein could be protective for the reasons discussed in the preceding paragraph. Next, a decrease in protein intake leads to production of smaller amounts of urea and other nitrogenous wastes. In theory, the workload on the kidneys is similarly decreased. Because all work (aerobic ATP production and use) is associated with a degree of free radical production, greater protein intake would generate more free radicals. Free radicals appear to be especially injurious to diseased kidneys because their scavenging mechanisms are compromised. Increased dietary protein also requires increased ammoniagenesis by renal tubules to excrete the associated proton load; however, ammoniagenesis can lead to noninflammatory, nonimmune complement activation in proximal tubule epithelial cells. One can ameliorate this proinflammatory consequence of ammoniagenesis by supplementation with sodium bicarbonate. In summary, excessive dietary protein leads to a greater degree of uremia and has the potential to exacerbate renal damage in CKD by several mechanisms.

In contrast, protein-calorie malnutrition is associated strongly with increased morbidity and mortality in human CKD patients and can be attributed to increased protein catabolism when dietary protein intake is marginal to low. In human beings a number of serum components, including prealbumin, cholesterol, and insulin-like growth factor; plasma and muscle amino acid profiles; and body composition measurements have been studied as potential indexes of nutritional status. However, serum albumin concentration is the most practical and most extensively studied nutritional index. In addition to heavy proteinuria, hypoalbuminemia also can be attributed to protein-calorie malnutrition. Furthermore, a BUN-to-Cr ratio less than 10:1 may be another indication of inadequate protein intake. Thus current dietary recommendations call for dietary protein and caloric intake at levels that meet or slightly exceed predicted requirements, which should render nitrogen balance neutral.[531] Finally, a critically important but often overlooked aspect of nutritional management of CKD patients is provision of a palatable diet.[432,531] Feeding smaller meals more frequently and varying the diet help to increase food intake in CKD patients of all species.

Experimental studies of CKD in horses are limited to reports that describe the effects of prolonged daily dosing of horses with mercurial compounds.[532-535] In these four reports, each involving a single horse, the subjects were destroyed between 85 and 191 days after mercury administration began. Anorexia, weight loss, and nonpruritic urticaria were the major clinical signs. The renal lesion was CIN, which was accompanied by a decrease in concentrating ability and an increase in water consumption. Additional tubular dysfunction included glucosuria in all four horses and a variable degree of proteinuria. Interestingly, clinical signs and tubular dysfunction preceded the development of azotemia in all horses, and excretion of sodium or chloride did not increase. The final report focused principally on the effects on renal function, and azotemia did not develop until the final week of life; GFR (assessed by endogenous Cl_{Cr}) decreased to 35% of the highest measured value on the day before euthanasia.[535] Aciduria and increased phosphate excretion, in addition to glucosuria and proteinuria, also were detected during the final week of life.

TREATMENT

At the time of presentation most horses with CKD exhibit obvious weight loss and other clinical signs. Because of the progressive and irreversible nature of the renal disease, the long-term prognosis is grave. Specific corrective treatment for CKD (renal transplantation) is not available for horses, and maintenance by peritoneal dialysis or hemodialysis would only be practical for valuable breeding animals. Pyelonephritis could be considered an exception because antibiotic treatment in theory could lead to resolution of infection and improved renal function. Unfortunately, significant renal damage usually has occurred by the time the diagnosis is established in most cases of bilateral pyelonephritis, so the prognosis for a return to normal renal function is guarded to poor. In contrast, the short-term prognosis may be more favorable. Some horses with CKD may maintain creatinine concentration of less than 5 mg/dL for months with minimal deterioration. To predict which patients will deteriorate more rapidly is difficult, but a recent history and initial ability to counteract weight loss with improved management are useful indicators. Laboratory analysis of blood samples at 2- to 4-week intervals to follow the degree of azotemia and serum electrolyte alterations may be useful in monitoring disease progression. In general, animals that are eating well and maintaining reasonable body condition carry the best short-term prognosis and may still be able to perform some limited work. Their use as breeding animals may be reduced because azotemia and eventual weight

loss would reduce the chance for normal conception and gestation. Horses with less severe to moderate CKD may do well clinically until they face a hypovolemic crisis, such as colic or colitis, and severe azotemia occurs. The goal in each case is to provide appropriate supportive care and to monitor the horse closely so as to provide humane euthanasia before the patient develops uremic decompensation.

As previously discussed, once significant renal disease is established, irreversible decline in GFR and progression of renal failure generally ensue.[5,517-519] Thus management of the equine patient afflicted with CKD involves palliative efforts to minimize further loss of renal function. The goals are to prevent complicating conditions (e.g., by providing plenty of water), to discontinue administration of nephrotoxic agents, and to provide a palatable diet to encourage appetite and minimize further weight loss.[70,95,266,434,536] Intravenous fluid therapy to promote diuresis, usually with 0.9% NaCl, is of much greater benefit in cases of acute, reversible renal failure but also may benefit patients that suffer a sudden exacerbation of CKD. One must administer intravenous fluid therapy cautiously because horses with CKD are at a higher risk to develop significant peripheral or pulmonary edema.

Supportive care also can include supplementation of sodium bicarbonate (50–150 g/day) when serum bicarbonate concentration is consistently less than 20 mEq/L.[536] One may need to add supplemental bicarbonate to a bran mash. If sodium bicarbonate supplementation aggravates ventral edema, one should limit or discontinue supplementation. Edema is not usually a significant problem, and the horse should tolerate mild edema (rather than being treated with diuretics that could be ineffective or lead to further electrolyte wastage) unless the edema interferes with ambulation. In a previous edition of this text, the author also recommended supplementation with NaCl to replace potential loss of these electrolytes in urine in horses with CKD. However, one study[537] found that supplementation with NaCl (used in an attempt to increase water intake) in cats with preexisting renal disease led to progression of renal disease that remained after salt supplementation was discontinued. Thus one should approach salt supplementation in horses with CKD with caution and should consider it only for patients with hyponatremia and hypochloremia.

Substituting high-calcium and high-protein feed sources such as alfalfa hay with good-quality grass hay and carbohydrates (corn and oats) may help control hypercalcemia and the magnitude of azotemia. Ideally, the hay and grain should contain an adequate but not excessive amount of protein (less than 10% crude protein), which should maintain the BUN-to-Cr ratio in a target range between 10:1 and 15:1.[266] Providing unlimited access to fresh water and encouraging adequate energy intake by feeding a variety of palatable feeds is important. In fact, if appetite for grass hay deteriorates, then offering less ideal feeds (e.g., alfalfa hay, increased amounts of concentrate) to meet energy requirements and reduce the rate of weight loss is preferable. Often horses continue to graze at pasture when their appetite for hay is diminished. Administration of B vitamins or anabolic steroids for their touted appetite-stimulating effects may benefit some animals. Although dietary fat is calorie dense, one must approach supplementation judiciously in patients with hyperlipidemia and hypercholesterolemia, and excessive fat supplementation can result in feed refusal.

Administration of corticosteroids or NSAIDs can limit the intrarenal inflammatory response associated with renal failure and also may attenuate renal injury. For example, administration of meclofenamate limited proteinuria in a group of human patients with severe manifestations of the nephrotic syndrome[538]; however, nonspecific blockade of prostaglandin production by corticosteroids and most available NSAIDs has the adverse effect of decreasing production of important renal vasodilating agents (prostaglandin E_2 and prostacyclin). Production of these prostanoids increases during periods of renal vasoconstriction or ischemia to maintain intrarenal blood flow, particularly to the renal medulla. With excessive or long-term NSAID administration, renal papillary necrosis develops after medullary ischemia.[238,239,388,461] Thus the negative effects of corticosteroids and NSAIDs on renal blood flow outweigh possible benefits, and they are not recommended routinely for the management of CKD in horses.

The progressive renal injury that occurs in CKD is associated with continued damage to glomerular and tubular membranes mediated by ongoing activation of the inflammatory cascade. In theory, treatment with antioxidant medications and free radical scavengers could be of benefit, but experimental data in horses do not bear this out. Similarly, interest in the role of dietary fatty acids as precursors of eicosanoids has been considerable. Specifically, dietary supplementation with sources rich in ω-3 fatty acids (linolenic acid; fish and flax oils) compared with ω-6 fatty acids (linoleic acid), appear to decrease generation of more damaging fatty acid metabolites during activation of the inflammatory cascade. In horses, dietary supplementation with ω-3 fatty acids (in the form of linseed oil) has been effective at ameliorating the effects of endotoxin in studies in vitro,[539-541] and supplementation with fish oil (another rich source of ω-3 fatty acids) slowed the progression of renal failure in laboratory animals.[542,543] Unfortunately, the effects of endotoxin in vivo were not ameliorated by feeding linseed oil in preliminary equine studies,[544] and the possible benefits of feeding ω-3 fatty acids to horses with CKD are not known at this time.

Control of hypertension and reduction of proteinuria have been recognized as the most successful interventions to limit progression of renal disease in human beings with CKD.[519] Thus monitoring the blood pressure and the level of proteinuria (urine protein-to-urine Cr ratio) in horses with CKD seems to be prudent. Treatment with angiotensin-converting enzyme inhibitors could be beneficial in horses with either of these problems but has not yet been pursued because of the expense of the available medications. Attention also has been directed to use of more specific antiinflammatory or immunosuppressant medications to limit renal injury in immune-mediated glomerulonephritis. For example, inhibition of thromboxane synthetase activity (thromboxane A_2 is a potent vasoconstricting agent and platelet activator) was demonstrated to limit renal histologic and functional changes in a canine model of immune-mediated glomerulonephritis.[545] Similarly, cyclosporine was used as an adjunct treatment in a prospective study of naturally occurring canine glomerulonephritis. Unfortunately, renal function declined in cyclosporine-treated dogs, as it did in control dogs. The lack of any beneficial effect, along with the adverse reactions to cyclosporine, led to the conclusion that cyclosporine was of no use for treating CKD.[546] As these studies demonstrate, specific manipulation of the inflammatory or immune response can limit renal injury when one can administer medications before or early in the course of renal

disease; however, with long-standing, naturally occurring disease, such treatments are much less likely to retard progression of renal failure significantly. Finally, other investigators are focusing on developing therapeutic strategies that may modulate or limit renal fibrosis. Their studies of the effects of cytokines, lymphokines, and proteoglycans on matrix synthesis and degradation by mesangial cells and on fibroblast activation in damaged glomeruli may lead to novel treatment options in the future.[547,548]

Urinary Tract Infections

Harold C. Schott II

In human beings, bacterial urinary tract infections (UTIs) are among the most common infections.[5] In contrast, bacterial UTIs are uncommon in horses.[70,95,434,549] As in other species, ascending UTIs are more common, although septic nephritis may be an occasional consequence of septicemia, especially in neonatal foals.[550] Mares are at higher risk for UTIs than geldings or stallions because of their shorter urethra.

Development of a UTI requires initial urethral colonization with pathogenic bacteria, entry of pathogens into the bladder, and subsequent multiplication in the bladder.[5,551] Urethral colonization involves adherence to uroepithelial cells, typically by enteric bacteria that possess fimbrial adhesins (pili) that bind to specific glycolipid receptors on uroepithelial cells. Not surprisingly, pathogenic *Escherichia coli* are rich in these specific surface adhesins, whereas nonpathogenic *E. coli* have few specific surface adhesins. Further characterization of human pathogenic *E. coli* strains by their somatic (O), flagellar (H), and capsular (K) antigens has revealed that a small number of *E. coli* strains are responsible for a large percentage of UTIs.[5,551,552] Normal vulvar and preputial flora protect against urethral colonization by pathogenic bacteria, but any anatomic defect leading to turbulent urine flow compromises maintenance of normal flora and may increase the likelihood of colonization by pathogens.[553,554] Although broodmares have not been proven to be at greater risk, intercourse is a well-established risk factor for the development of UTIs in women. In addition, human prostatic secretions contain a heat-stable cationic protein that has potent antibacterial activity.[5] Thus stallions may be at lower risk than geldings for UTIs.

Once a pathogen has colonized the distal urethra, rapid multiplication between micturitions allows invasion of the proximal urethra and bladder, which do not have a protective flora. Host defenses in the bladder include immunoglobulins in urine and a mucopolysaccharide layer rich in glycosaminoglycans covering the uroepithelial surface.[551,552] Production of protective glycosaminoglycans is under hormonal control by estrogen and progesterone in rabbits.[555] Thus the lack of these beneficial hormonal effects has been suggested as an explanation for the increased risk for UTIs in prepubertal and postmenopausal women and spayed dogs.[556] Furthermore, women with recurrent UTIs have been speculated to have decreased concentrations of secretory immunoglobulin A in their urine.[557] Although continued urine production dilutes proliferating bacteria, once pathogens have gained access to the bladder, the rate of replication far outweighs any dilution effect and allows the UTI to become established.[5] Although antibiotic therapy is highly effective in eliminating most UTIs, recurrent UTIs can be a challenge to manage. In addition to thorough evaluation to eliminate predisposing factors in these patients, one may consider additional approaches to prevention. For example, fimbrial vaccines are effective against experimental UTIs in monkeys.[552]

URETHRITIS

Bacterial urethritis has been described as a cause of hemospermia in stallions[558,559]; however, with the exception of traumatic, parasitic (habronemiasis), or neoplastic conditions of the penis or urethra that interfere with urine flow, the author is unaware of documented cases of primary bacterial urethritis resulting in dysuria.[87,560] Furthermore, hemospermia likely attributable to urethritis in a number of previous cases probably was caused by urethral rents at the ischial arch that involve the corpus spongiosum penis, which have become easier to identify with urethral videoendoscopy (see Hematuria).[561] Bacterial infections of accessory sex glands or the prepuce also may cause dysuria. Accessory sex gland infections generally are limited to intact males and are more likely to cause infertility or hemospermia than dysuria.[87,562] Preputial infections can occur after trauma, presence of a foreign body, habronemiasis, or neoplasia, and affected horses typically have a malodorous, swollen sheath. Examination of the sheath and penis, along with biopsy of abnormal tissue, allows diagnosis of the primary problem. Occasionally, an older gelding may develop recurrent sheath swelling or infection that cannot be attributed to a primary disease process. The pathogenesis of this problem is not known, although fat accumulation, poor hygiene, and inactivity may be contributing factors. Treatment involves repeated sheath cleaning, application of topical anti-inflammatory and antibacterial ointments, and when involvement is more severe, systemic antibiotic administration.

CYSTITIS

Primary cystitis is uncommon in horses, and predisposing causes should be ruled out whenever cystitis is suspected. Bacterial cystitis is usually a secondary problem that may accompany alterations in urine flow caused by urolithiasis, bladder neoplasia, bladder paralysis, an anatomic defect of the bladder or urethra, or entry into the urinary tract (e.g., catheterization, endoscopy).* Dysuria may be manifested by pollakiuria, stranguria, hematuria, or pyuria. One may observe scalding and accumulation of urine crystals on the perineum of affected mares or on the front of the hindlimbs of affected male horses. These findings should not be confused with normal estrous activity in the mare. Although nosocomial UTIs are a well-documented problem in hospitalized human[5] and small animal patients,[567] this complication has not been well recognized in equine patients except for ill neonatal foals.

Diagnostic evaluation includes physical and rectal examinations and collection of a urine sample for urinalysis and quantitative bacterial culture. In the absence of uroliths or other bladder masses, transrectal palpation of the bladder is usually within normal limits; however, endoscopic and ultrasonographic examination of the bladder may be helpful in assessing mucosal damage and wall thickening in horses with cystitis.[335,354] Because normal equine urine is rich in mucus and crystals, gross examination may be unrewarding, but sediment examination may reveal increased numbers of white

* References 70, 95, 389, 434, 553, 554, 563-566.

blood cells (more than 10 leukocytes per high-power field) and presence of bacteria in some cases of cystitis. Normal sediment examination results do not rule out UTI. A definitive diagnosis requires quantitative culture results exceeding 10,000 colony-forming units (CFUs) per milliliter in a urine sample collected by midstream catch or urethral catheterization.[95,279,549] For best results, one should evaluate urine sediment within 30 to 60 minutes of collection and should cool samples for culture during transport because bacterial numbers may increase in samples left at room temperature. Organisms that may be isolated on culture include *E. coli, Proteus* spp., *Klebsiella* spp., *Enterobacter* spp., *Streptococcus* spp., *Staphylococcus* spp., *Pseudomonas aeruginosa,* and rarely *Corynebacterium renale.*[70,95,434,549,564] Isolation of more than one organism is common. *Salmonella* spp. occasionally have been isolated from the urine of apparently healthy horses, and *Candida* spp. infections of the lower urinary tract also have been documented in sick neonatal foals receiving broad-spectrum antibiotics.[70,95]

Successful treatment of bacterial cystitis requires correction of predisposing problems such as urolithiasis and administration of systemic antibiotics. Ideally, selection of an antibiotic is based on the results of susceptibility testing of isolated organisms, and the initial recommended course of treatment traditionally is at least 1 week.[70,95,434,549] A trimethoprim-sulfonamide combination, ampicillin, penicillin, and an aminoglycoside or ceftiofur can be initial choices. In human beings with uncomplicated cystitis, single-dose antimicrobial therapy, which is less costly and is associated with fewer adverse effects, has a success rate comparable with that of longer term conventional therapy (75% or greater). Furthermore, relapse after single-dose therapy is not accompanied by more severe clinical signs or more extensive urinary tract involvement[5]; however, if clinical signs recur after treatment is discontinued, one should repeat urine culture along with additional diagnostic evaluation to determine a cause for altered urine flow or bacterial persistence.

Treatment of recurrent UTI usually requires long-term medication (4–6 weeks), and ease of administration and cost become additional considerations in antibiotic selection. Trimethoprim-sulfonamide combinations and β-lactams are excreted via the kidneys and concentrated in urine. Although results of in vitro susceptibility testing of isolated pathogens may reveal resistance, these drugs may have effective antimicrobial activity against the causative organisms because of their high concentrations achieved in urine.[549] Metabolism of the antibiotic is another consideration. For example, sulfamethoxazole is metabolized mostly to inactive products before urinary excretion, whereas sulfadiazine is excreted mostly unchanged in urine.[568]

Additional treatments for recurrent UTI can include supplementation with 50 to 75 g of loose salt in the diet[556] or provision of warm water during cold weather in an attempt to increase water intake and urine production. Administration of a urine-acidifying agent like ammonium chloride (20–40 mg/kg PO daily) also has been recommended in cases of cystitis and urolithiasis.[563] Use of ammonium chloride at this dose, however, has not produced a consistent decrease in urine pH. Larger oral doses of ammonium chloride (60–520 mg/kg/day),[569-571] methionine (1 g/kg every 24 hours), vitamin C (1–2 g/kg/day),[281] or ammonium sulfate (175 mg/kg/day)[572] were more successful in reducing urine pH to less than 6.0 in a limited number of horses; however, at these doses, medications were usually unpalatable and had to be administered by dose syringe or stomach tube. Adding grain to the diet is another simple way to decrease urine pH, although the decline is modest, and urine pH typically remains greater than 7.0.[281] A final treatment aid is bladder lavage. This procedure most benefits horses with accumulations of large amounts of crystalloid material in the bladder, a condition that has been termed *sabulous urolithiasis.*[572] Whenever sabulous urolithiasis is present, neurologic control of bladder function should be assessed. Incomplete emptying of the bladder can result in excessive accumulation of urinary sediment. Although one can add a number of antiseptics to the sterile polyionic lavage fluid, the most important consideration is adequate volume to flush the crystalline debris completely from the bladder. Concurrent cystoscopy is a useful tool to assess the efficacy of bladder lavage.

One report of experimental induction of cystitis in equids exists.[573] After chemical irritation of the bladder mucosa, 2.5×10^{13} CFUs of *Proteus mirabilis* were instilled into the bladders of nine female ponies. Three days later all ponies demonstrated stranguria, and culture results yielded 20,000 to 100,000 CFUs/mL of *P. mirabilis.* Sediment examination revealed increased numbers of white blood cells (more than 10 per high-power field) in seven of nine ponies, and bacteria were observed in all samples (although in low numbers of one to three per high-power field). In two untreated ponies, the cystitis resolved spontaneously between 2 and 4 weeks after inoculation; however, resolution was complete within 3 to 6 days in ponies treated with trimethoprim-sulfadiazine.

Epizootics of cystitis also have been reported in the southwestern United States[564,574] and Australia.[575] In the former reports, a syndrome of ataxia and urinary incontinence was associated with ingestion of Sudan grass and Johnson grass (hybrids of *Sorghum* spp.). Both problems were attributed to sublethal intoxication with hydrocyanic acid in the plants, which resulted in demyelination of the lower spinal cord and bladder paralysis. Pyelonephritis was often the cause of death in affected horses.[574] Another outbreak of cystitis, manifested by hematuria more than incontinence, occurred in the Northern Territories and Western Australia in 1963.[575] The kidneys and ureters were not affected, and ataxia was not observed in these horses. The problem, which resulted in loss of more than 200 horses, began shortly after the end of the wet season. Affected horses were on range pasture, and, although this was not proved, a fungal toxin was suspected because sporidesmin (a toxin produced by *Pithomyces chartarum*) was known to cause bladder lesions in sheep and cattle. An environmental cause was substantiated further when no additional cases developed in 1964, after a "dry" wet season.

PYELONEPHRITIS

Upper UTIs involving the kidneys and ureters are rare in horses.[70,95,549] The course of the distal segment of the ureters into the dorsal bladder wall creates a physical barrier or valve to prevent vesicoureteral reflux, a prerequisite for ascending pyelonephritis. Vesicoureteral reflux is more common in children because the intramural portion of the distal ureter lengthens with growth. Furthermore, congenital vesicoureteral reflux often occurs in families, which suggests a genetic tendency for the problem, which has been associated with developmental anomalies of the intramural insertion of one or both ureters.[5] More obvious problems that interfere with this barrier and increase the risk for vesicoureteral reflux

and associated upper UTIs include ectopic ureter or bladder distention, which may occur with bladder paralysis or urethral obstruction. Over time, vesicoureteral reflux leads to progressive ureteral dilation and renal scarring (Fig. 14.30). This effect explains the common finding of ureteral dilation in young horses with ectopic ureters and provides further support for unilateral nephrectomy, rather than reimplantation of the ureter as the treatment of choice for ectopic ureter.[69,76] In addition to vesicoureteral reflux, intrarenal urinary reflux also is required to initiate renal damage, predisposing the parenchyma to ascending infection. The renal papillae contain collections of papillary duct openings. These are typically conical structures that protrude into the renal pelvis. Similar to the protective nature of the intramural ureteral segment against vesicoureteral reflux, this morphology protects against intrarenal reflux; however, in human infants and young pigs, a second type of large, concave, "refluxing" papillae also have been described in the areas of the renal pelvis most often affected with renal scarring.[5] Thus vesicoureteral and intrarenal reflux are important in development of pyelonephritis.

The role of recurrent lower UTI in the development of pyelonephritis is less clear. For example, pyelonephritic scarring (without infection) can develop after high-pressure urinary tract obstruction (urethrolithiasis) and can predispose to future upper UTI. In contrast, many cases of recurrent cystitis never proceed to involve the upper urinary tract.[5] Because the kidneys are densely vascular organs, septic nephritis may develop in association with septicemia in neonatal or adult horses.[550] Unless renal involvement is extensive, upper UTI may go undetected but could lead to development of nephrolithiasis or chronic kidney disease months to years later. As in the bladder, defense mechanisms within the normal kidney act to minimize bacterial colonization and proliferation. Efficacy of renal clearance varies with the species of bacteria entering the kidney. In addition, obstruction of urine flow (unilateral ureterolithiasis or nephrolithiasis) increases, rather than decreases, the risk of bacterial proliferation in the obstructed kidney.

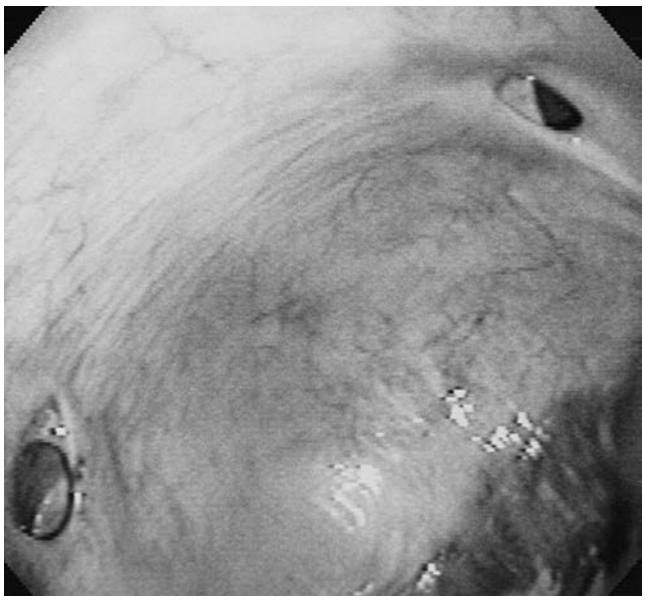

FIG. **14.30** Endoscopic image of the bladder of a pony mare with recurrent cystitis and pyelonephritis. The ureteral openings were distended easily by insufflation of the bladder with air. Ureteral dilation resulted from long-term vesicoureteral reflux.

Pyelonephritis in horses has been described in association with urolithiasis, recurrent cystitis, and bladder paralysis.[70,95,389,549,574] Other causes have included accidental amputation of the penis during castration,[576] foreign bodies in the bladder,[467] and lower urinary tract neoplasia.[465,565] With pyelonephritis, dysuria is manifested by hematuria or pyuria rather than stranguria and pollakiuria (as for cystitis). Some cases of pyelonephritis may have severe hematuria. In addition, horses with upper UTIs generally have other clinical signs, including fever, weight loss, anorexia, or depression.* Upper UTIs also can be accompanied by nephrolithiasis, ureterolithiasis, or both.[266] In such cases, whether urolithiasis or infection develops first or whether both are consequences of vesicoureteral reflux, intrarenal reflux, and renal parenchymal damage is unclear. In an occasional case, small uroliths may travel down the ureter and lead to recurrent urethral obstruction with renal colic as the presenting complaint.

As for cystitis, diagnostic evaluation includes physical and rectal examinations, urinalysis, and a quantitative urine culture. Careful palpation may allow detection of an enlarged ureter or kidney, although the kidney also may become shrunken in long-standing cases. In addition to the organisms causing cystitis, one can isolate *Actinobacillus equuli, Streptococcus equi* subsp. *equi, Rhodococcus equi,* or *Salmonella* spp. from horses with hematogenous septic nephritis.[95,550] In horses with upper UTIs, one should perform a CBC and serum biochemistry profile to assess the systemic inflammatory response and renal function. Finally, cystoscopy (including watching for urine flow from each ureteral opening) and ultrasonographic imaging of the bladder, ureters, and kidneys are helpful adjunct diagnostic procedures.[335,354] Ureteral catheterization (by passing polyethylene tubing via the biopsy channel of the endoscope or by using a no. 8–10 Fr polypropylene catheter, which can be passed blind in mares) may allow collection of urine samples from each ureter to distinguish unilateral from bilateral disease.[362]

Treatment for upper UTIs includes a prolonged course of appropriate systemic antibiotics (selected based on susceptibility testing results on isolated pathogens). In select cases with unilateral disease, one may consider surgical removal of the affected kidney and ureter.[87,255,256] Prerequisites for a nephrectomy include documentation of unilateral disease by normal laboratory results for renal function (absence of azotemia), recovery of insignificant numbers of bacteria (fewer than 10,000 CFUs/mL) from urine collected from the ureter leading to the unaffected kidney, and ultrasonographic evidence of abnormal structures (e.g., fluid-filled structures, nephrolithiasis) in the affected kidney. Alternatively, poor response to several weeks of appropriate antimicrobial therapy and recurrence of clinical signs of pyelonephritis are additional indications for nephrectomy. Unfortunately, successful treatment of bilateral pyelonephritis is rare, but the poor prognosis likely is related to failure to establish the diagnosis until late in the disease course.

PARASITIC INFECTIONS

One occasionally finds parasitic lesions associated with the nematodes *Strongylus vulgaris, Halicephalobus gingivalis*

* References 70, 95, 255, 256, 453, 463, 464, 466, 479, 549.

(previously *Micronema deletrix*), and *Dioctophyma renale* in equine kidneys.[64] Although larval migration of *S. vulgaris* in the renal artery and parenchyma is considered aberrant,[577] larval migration was found in more than 20% of horses in one abattoir survey. Passage through renal tissue may result in infarction or subcapsular or pelvic hemorrhage when parasites localize in these sites.[578] Although rare, *H. gingivalis* infection is often life threatening because of concurrent CNS involvement leading to a variety of neurologic deficits that generally require euthanasia.[579-583] *Halicephalobus gingivalis* has been suggested to be the most important cause of verminous meningoencephalomyelitis in horses.[584] Only the female parasite has been identified in equine tissues, typically in highly vascular organs. One usually finds large, granulomatous lesions that are full of the rhabditiform nematodes in the kidneys. The life cycle of *H. gingivalis* is unknown, but the apparent saprophyte appears to have worldwide distribution. The finding of gingival lesions and oral granulomata in some horses suggests that ingestion is the likely route of infection. Attempts to find nematode larvae or eggs in urine have been unsuccessful, and whether the horse is an accidental host or is important for the life cycle of the parasite is unclear.[579] The free-living form is found in decaying organic debris (e.g., tree stumps) and also has been reported to affect human beings.[583] Antemortem diagnosis has not been made, and cytologic changes in CSF from affected horses cannot differentiate between nematodiasis and protozoal encephalomyelitis.[582] Renal involvement is typically inapparent, although one affected horse demonstrated a 2-week course of stranguria and polyuria before onset of neurologic deficits.[580]

Dioctophyma renale is a large, bright-red nematode, and the female may reach 100 cm in length. The typical hosts are carnivorous species, but the parasite occasionally affects horses that ingest the intermediate host (annelid worm) while grazing or drinking from natural water sources.[585] Once localized in the kidney, the parasite may live 1 to 3 years; eggs are shed in the urine. The parasite completely destroys the renal parenchyma, and death of the parasite leads to shrinking of the host kidney into a fibrous mass. Occasionally, hydronephrosis or renal hemorrhage may be a serious complication of parasitic infection.[586,587]

In contrast to the nematodes, infection with the coccidian parasite *Klossiella equi* appears common, yet no reports describe clinical disease associated with this coccidial infection.[588-593] Although disorders accompanied by immunosuppression have been suggested to increase its likelihood, *K. equi* infection is still considered an incidental finding in affected horses. The life cycle has not been elucidated fully, but one proposal is that ingested sporocysts (or sporozoites) enter the bloodstream and undergo schizogony in endothelial cells of the glomeruli. Merozoites are released into the urinary space and undergo one or more additional rounds of schizogony in tubular epithelial cells. Eventually, a population of merozoites develop into microgametes and macrogametes. Little evidence of an inflammatory response to parasite replication in renal tissues is apparent. Sporogony follows with the subsequent release of sporocysts into the urine.[589,593] Although *K. equi* has not been associated with clinical disease, it warrants mention that the organism has been found worldwide in horses, ponies, donkeys, burros, and zebras, and a postmortem survey of 47 horses in Australia revealed that six (12.8%) were infected.[593]

Obstructive Disease of the Urinary Tract

Harold C. Schott II

Most cases of obstructive urinary tract disease in horses are caused by urolithiasis. Urinary tract displacement, trauma, and neoplasia are other causes.[70,95,434] Urinary tract obstruction can result in a variety of clinical signs depending on the site and degree of obstruction. Incomplete obstruction can result in dysuria, incontinence, and mild abdominal pain, whereas complete obstruction usually results in moderate to severe pain termed *renal* or *kidney colic*. True "kidney colic" is an uncommon cause of abdominal pain, although horses may show signs similar to those of dysuria with gastrointestinal pain. Another complication of complete obstruction is rupture of the bladder or urethra. Signs of pain subside after rupture but are replaced by depression and inappetance, which accompany postrenal acute renal failure. In some cases of disruption of the urinary tract, one also may observe progressive abdominal distention and enlargement of the ventral midline, penis, and prepuce.

EPIDEMIOLOGY OF UROLITHIASIS

The epidemiology of urolithiasis varies with species.[389,563,594,595] Lower urinary tract stones predominate in veterinary species, whereas upper urinary tract stones are more common in human beings. Historically, lower urinary tract stones were a more substantial problem in human beings as well, and they remain the more common form of urolithiasis in underdeveloped countries. The shift in prevalence from lower to upper urinary tract stones appears to have accompanied industrialization, but the reasons for this are not entirely clear.[595]

From 1970 to 1989, urolithiasis was responsible for 0.11% of equine admissions to 22 veterinary teaching hospitals and accounted for 7.8% of the diagnoses of urinary tract disease.[389] Male horses, especially geldings, are predisposed to urolithiasis (75% of all cases), and a breed predisposition has not been described. This sex predilection has been attributed to the shorter, distensible urethra of the mare, which likely permits voiding of small calculi.[563] Urolithiasis is typically an adult disease, and the mean age of affected horses is about 10 years.[389] Nevertheless, young horses can be affected, and the author has seen bilateral nephrolithiasis in a weaning foal (likely a consequence of neonatal septicemia) and dysuria in a 3-month-old colt caused by multiple cystoliths that formed on sutures used to repair a ruptured bladder as a neonate. Uroliths are most common in the urinary bladder (60%), although they also may develop in the kidneys (12%), ureters (4%), and urethra (24%).[389] Interestingly, as many as 10% of affected horses have uroliths in multiple locations.[389] Uroliths can vary greatly in size. In one mare, a cystolith weighing more than 6 kg was present as an apparently incidental finding in a horse destroyed for a limb fracture.[596]

PATHOPHYSIOLOGY OF UROLITHIASIS

In general, two steps are required for calculus formation: (1) nucleation and (2) crystal growth.[5,597-599] Factors that contribute to precipitation of urinary crystals and nucleation include

supersaturation of urine; prolonged urine retention; genetic tendencies to excrete larger amounts of calcium (hypercalciuria), uric acid (hyperuricosuria), or oxalates (hyperoxaluria); and inhibitors and promoters of crystal growth. For two or more ions in a solution to precipitate into a crystal, the product of their individual ion activities must exceed the equilibrium solubility product (K_{sp}). A supersaturated solution is one in which the ion activity product exceeds the K_{sp}. A mildly supersaturated solution is termed *metastable,* because crystals tend to precipitate and dissolve at similar rates, so that crystal growth does not occur and the solution remains clear. However, once the ion activity product exceeds a critical value (formation product ratio), precipitation outpaces dissolution, rapid crystal growth occurs, and the solution becomes cloudy.[5,597-599] Normal human urine typically is supersaturated with one or more ion activity products; however, the formation product ratios are considerably higher in urine (10 times greater than K_{sp}) than they are in an aqueous solution because of the presence of inhibitors of crystal growth.[5] This activity explains why observation of crystals in urine sediment examination is common, yet calculus formation is uncommon. Furthermore, although K_{sp} values are constant for each type of crystal, they vary with temperature and pH. Typically, cooling promotes crystal formation (as when samples are refrigerated), whereas effects of pH vary with the type of calculus (acidification leads to dissolution of calcium crystals but promotes crystallization of urate crystals).[597] Next, any problem resulting in urine retention or incomplete bladder emptying increases the chance of crystal growth. Although not described for horses, genetic variations in ion excretion rates are well-documented risk factors for human and canine urolithiasis. For example, hypercalciuria is inherited as an autosomal dominant trait in human beings and is responsible for 30% to 40% of nephroliths.[5] Similarly, dogs with cystine urolithiasis have an inherited defect in renal tubular transport of cystine, whereas Dalmatians are afflicted with urate stones because of a defect in uric acid metabolism in the breed.[594]

Normal urine is rich in a number of inhibitors of crystal growth, including pyrophosphate, citrate, magnesium ions, glycosaminoglycans, and several glycoproteins, including nephrocalcin.[5,597,599] The degree of inhibitory activity varies with crystal type; for example, pyrophosphate is responsible for 50% of the inhibitory activity against calcium phosphate stone formation in human urine but has a much less inhibiting effect on calcium oxalate stone formation.[5] Although poorly documented, inhibitors of crystal growth in equine urine, including its high mucus content, likely play an important protective role against calculus formation, which would seem especially true in light of the substantial urinary excretion of $CaCO_3$ crystals by normal horses. Similar to the risk associated with increased ion excretion, one should not be surprised that defects in inhibitor activity also have been documented in syndromes of human urolithiasis.[5,597] Other urine components may act as promoters of crystal growth. These components principally include organic matrix components of calculi: matrix substance A, uromucoid, and a number of serum proteins.[597,598] Finally, some urine components may have inhibitor and promoter activity. For example, Tamm-Horsfall glycoprotein, a protein secreted in the ascending limb of the loop of Henle that forms the backbone of urine casts, has been shown to promote struvite crystal formation in feline urine.[600] In contrast, this glycoprotein also inhibits calcium oxalate crystal aggregation, and a group of human patients with calcium oxalate urolithiasis were demonstrated to have an abnormality in Tamm-Horsfall mucoprotein.[601]

Because normal urine of most species typically is supersaturated and is in balance between crystal precipitation and dissolution, spontaneous nucleation rarely initiates calculus growth. Rather nucleation generally requires stasis of urine flow, increasing the chance of contact between crystalloid material and uroepithelium (as occurs in areas of the renal pelvis) or a damaged uroepithelial surface.[597-600] The latter results in local activation of inflammatory and clotting pathways, producing a nidus for local crystal adherence.[602] In addition, desquamated epithelial cells, leukocytes, or necrotic debris may provide a nidus for crystal growth at more distal sites in the urinary tract. Tissue damage from a variety of causes is likely the most important factor for the development of uroliths in horses. For example, after urinary tract catheterization or endoscopy, areas of traumatized uroepithelium are covered rapidly with a fine layer of crystalline material. This material usually resolves spontaneously unless infection develops. Similarly, nephroliths may form in the renal medulla or pelvis after renal papillary necrosis secondary to NSAID toxicity. Once crystal growth begins around a nidus, equine urine has the disadvantage of being highly alkaline, favoring crystallization of most urolith components, especially $CaCO_3$.

Horses develop two basic forms of uroliths, and both are composed primarily of $CaCO_3$.[563,603] More than 90% are yellow-green spiculated stones that easily fragment (type I urolith) (Fig. 14.31A). Less commonly, uroliths are gray-white smooth stones that are more resistant to fragmentation (type II urolith; Fig. 14.31B). The latter stones often contain phosphate in addition to $CaCO_3$. The crystalline composition of normal equine urine sediment ($CaCO_3$ crystals predominate, although calcium oxalate and phosphate crystals also occur) and uroliths is similar: $CaCO_3$ in the form of calcite (a hexagonal crystal form of $CaCO_3$) is most common, followed by vaterite (a metastable, hexagonal crystal form in which $CaCO_3$ is replaced partially by magnesium or to a lesser extent by manganese, strontium, and sulfur). Other less common components include aragonite (an orthorhombic crystal form of $CaCO_3$), weddellite (calcium oxalate dihydrate), struvite (magnesium ammonium phosphate hexahydrate), hydroxyapatite, and uric acid (Table 14.10).[290,603-607] Neumann and colleagues[603] examined the cut surface of a number of equine uroliths by scanning electron microscopy and described a pattern of irregular, concentric bands around the core (Fig. 14.32A) that were separated by small spherules of crystalline material (Fig. 14.32B). This pattern suggested that calculus growth occurs by accretion of preexisting microscopic spherules (the crystals already present in normal equine urine) on the surface of the growing urolith rather than de novo crystal formation at the surface of the urolith. Furthermore, banding was speculated to represent growth through incorporation of organic matrix on the surface of the urolith at times when fewer spherules were present in urine. The gaps between adjacent spherules result in porosity to the urolith. Because precipitation and dissolution occur simultaneously during growth of urinary calculi, porosity allows exposure of inner aspects of the urolith to urine, which can lead to dissolution as urine composition changes. Neumann and colleagues[603] described two types of porosities observed by electron microscopy: (1) primary porosity, consisting of the original pores or gaps between spherules, and (2) secondary porosity, which developed after dissolution of inner areas of the uroliths. Greater dissolution or secondary porosity developed preferentially in areas of the urolith with

higher magnesium content (vaterite). More extensive development of secondary porosity theoretically leads to increased urolith fragility, which has the therapeutic benefit of increasing the chance that the urolith can be crushed or fragmented before removal.

The role of UTI in the development of urolithiasis appears to vary with species.[5,594,598] Struvite urolithiasis in human beings and dogs appears to be almost exclusively a consequence of UTI, whereas most struvite uroliths in cats and sheep are not associated with infection.[598] In addition to contributing to uroepithelial injury and nidus formation, UTI with urease-positive bacteria (*Proteus* spp. and coagulase-positive staphylococci are most common) allows splitting of urea into two ammonia molecules, which are hydrolyzed rapidly to ammonium ions (a component of struvite crystals).[5,598,599] In a review of 68 horses with urolithiasis, Laverty and colleagues[389] reported positive urine culture results in only 2 of 19 horses in which urine culture was performed; however, culture of material from the centers of 30 calculi yielded positive results from 19 (63%), and a variety of different bacterial species were isolated. Only 1 of 28 calculi examined in this study contained struvite. The significance of finding bacteria in the center of equine $CaCO_3$ uroliths is not known, especially for isolates other than coagulase-positive staphylococci and *Proteus* spp.; culture of an appropriately collected sample of urine always is preferred over culture of a calculus.[389,608] Nephroliths and ureteroliths also are found in some cases of pyelonephritis.[461-463,479] Laing and colleagues[462] described a 2-year-old colt with bilateral nephrolithiasis and chronic kidney disease. *Proteus* spp. were isolated from urine, and the nephroliths were composed principally of $CaCO_3$ but also contained lesser amounts of struvite. In contrast, Ehnen and colleagues[388] found evidence of infection in only one of eight horses with nephrolithiasis or ureterolithiasis (or both) and chronic kidney disease. In the author's experience, the presence of stones in the upper urinary tract or presence of multiple uroliths warrants concurrent evaluation for UTI, because the author has seen two horses with recurrent urinary tract obstruction with ureteroliths that were determined ultimately to be sequelae of unilateral pyelonephritis. Holt and Pearson[609] described a similar case in which a renal calculus and abscess were found 5 months after removal of a cystic calculus.

NEPHROLITHIASIS AND URETEROLITHIASIS

It used to be that renal or ureteral calculi rarely were described as forms of equine urolithiasis[610]; however, since the advent of diagnostic ultrasound, nephrolithiasis and ureterolithiasis are now more commonly recognized.[257,360,361,388,389,459-462] In a review of 68 horses with urolithiasis by Laverty and colleagues,[389] 16% had uroliths in the kidneys and ureters, and a few horses with cystic calculi also had calculi in the upper urinary tract. Interestingly, 9 of 15 horses with nephroliths in this review were stallions, 3 of 15 were geldings, and 3 of 15 were mares. Whether a true increase in prevalence of nephrolithiasis and ureterolithiasis has occurred, or whether

these conditions have become easier to document with the simultaneous development of ultrasonographic imaging as a diagnostic tool for equine medicine, is not clear. An undocumented speculation is that young racehorses may be at greater risk of developing renal calculi because of the common use of NSAIDs (and increased risk for development of papillary necrosis) in these athletes.[388] The important point is that one should not overlook upper urinary tract lithiasis in horses.

Nephroliths may develop around a nidus associated with a variety of renal diseases, including polycystic kidney disease (see Fig. 14.6), pyelonephritis (Fig. 14.33A), papillary necrosis (Fig. 14.33B), or neoplasia. At present, data on upper urinary tract stones in horses are insufficient to know if they develop spontaneously (in the absence of tissue damage) as in human beings or if they differ significantly in mineral composition from cystic calculi. Although nephrolithiasis and ureterolithiasis are painful conditions in human beings, horses with nephroliths or ureteroliths often remain asymptomatic until bilateral obstructive disease leads to development of acute or chronic renal failure.

Upper urinary tract stones also may be an incidental finding at necropsy.[610] When clinical signs are present, nonspecific presenting complaints consistent with uremia (poor performance, lethargy, inappetance, and weight loss) are more common than signs of obstructive disease (colic, stranguria, hematuria). Occasionally in the horse, a stone or nidus may pass down the ureter and lead to urethral obstruction and signs of acute obstructive disease. Rectal palpation may reveal an enlarged kidney or ureter (or bladder with urethral obstruction), and ureteral calculi may be palpable in an enlarged ureter. Because normal ureters are not palpable on rectal examination, one should palpate the entire course of the ureters (retroperitoneally along the dorsal abdominal wall to the dorsolateral aspects of the pelvic canal to their insertion at the dorsal bladder neck) because an enlarged ureter is easy to overlook.

One usually diagnoses renal and ureteral calculi during rectal or ultrasonographic examination (Fig. 14.34). Although ultrasonographic imaging may provide information on the presence, number, and location of calculi, one can miss stones smaller than 1 cm in diameter despite complete examination. Other ultrasonographic findings to support upper tract lithiasis include dilation of the renal pelvis or proximal ureter and, in long-standing cases, hydronephrosis.[336,339] Although azotemia generally accompanies bilateral disease, horses with unilateral disease often maintain normal renal function. For reasons detailed previously, one should perform a quantitative urine culture in all horses with nephrolithiasis or ureterolithiasis to assess possible concurrent UTI.

Because most horses with nephrolithiasis or ureterolithiasis have chronic kidney disease by the time the diagnosis is established,[266,388,480] few cases are amenable to treatment. Thus reports of successful management of horses with renal and ureteral calculi are few. Removal of the calculus, limited to horses with unilateral disease or mild azotemia, has been the only effective means of treatment.[257,360,361] In the absence of azotemia, nephrectomy is the preferred technique for management of unilateral renal calculi.[257] Furthermore, removal of the affected kidney and ureter should eliminate any associated upper UTI or chance of recurrence. The approach involves a dorsal flank incision, rib resection, and blunt retroperitoneal dissection to expose the kidney.[87,434,611] In one horse with mild azotemia, nephrotomy (via an approach similar to nephrectomy) was performed successfully to remove obstructing calculi in the renal pelvis and proximal ureter. Unfortunately, little improvement in azotemia occurred, and the horse was destroyed a few weeks later.[388] Ureteral calculi also have been removed by ureterolithectomy via ventral celiotomy and paralumbar approaches.[360,459] A basket stone dislodger (Dormia Stone Dislodger, V Mueller Co., McGow Park, IL), introduced through a vestibulourethral approach and guided by rectal

palpation, also has been used for removal of distal ureteral calculi in the mare.[360] Medical management (antibiotics, grass hay, and salt to promote diuresis) of bilateral ureterolithiasis was attempted in a 3-year-old Thoroughbred filly with incomplete ureteral obstruction and mild azotemia.[459] After 4 weeks, deterioration of clinical signs and more severe azotemia prompted ureterolithectomy to remove stones from the left ureter. Percutaneous nephrostomy was used successfully for placement of a catheter in the right renal pelvis (to establish percutaneous urine flow) for short-term management of azotemia in the postoperative period. Unfortunately, the filly was destroyed after developing cecal impaction 6 days later, and necropsy revealed a shrunken, nonfunctional left kidney and a previously undetected nephrolith in the right kidney. This case demonstrated the feasibility and potential benefits of accessing the renal pelvis of the horse via percutaneous nephrostomy.[612,613]

Rodger and colleagues[361] described the successful use of electrohydraulic lithotripsy through a ureteroscope to disintegrate a single, unilateral ureterolith in a horse with evidence of bilateral renal disease. Electrohydraulic lithotripsy is a means of converting electric energy into mechanical energy that can be directed to fragment the urolith.[361,614,615] Basically, the device produces an electric discharge arc (a spark) between two electrodes at the tip of the instrument. The heat associated with the discharge causes a small amount of the liquid medium (urine) to burst into gas bubbles, and the associated shock wave fractures the urolith. One must keep the end of the instrument adjacent to the urolith yet away from the mucosa, which could be disrupted by the same shock waves that destroy the calculus. Although the technique has not been highly successful for treatment of canine uroliths,[616] equine uroliths may be more amenable to its use because they are commonly porous (and fragile). Although electrohydraulic lithotripsy has

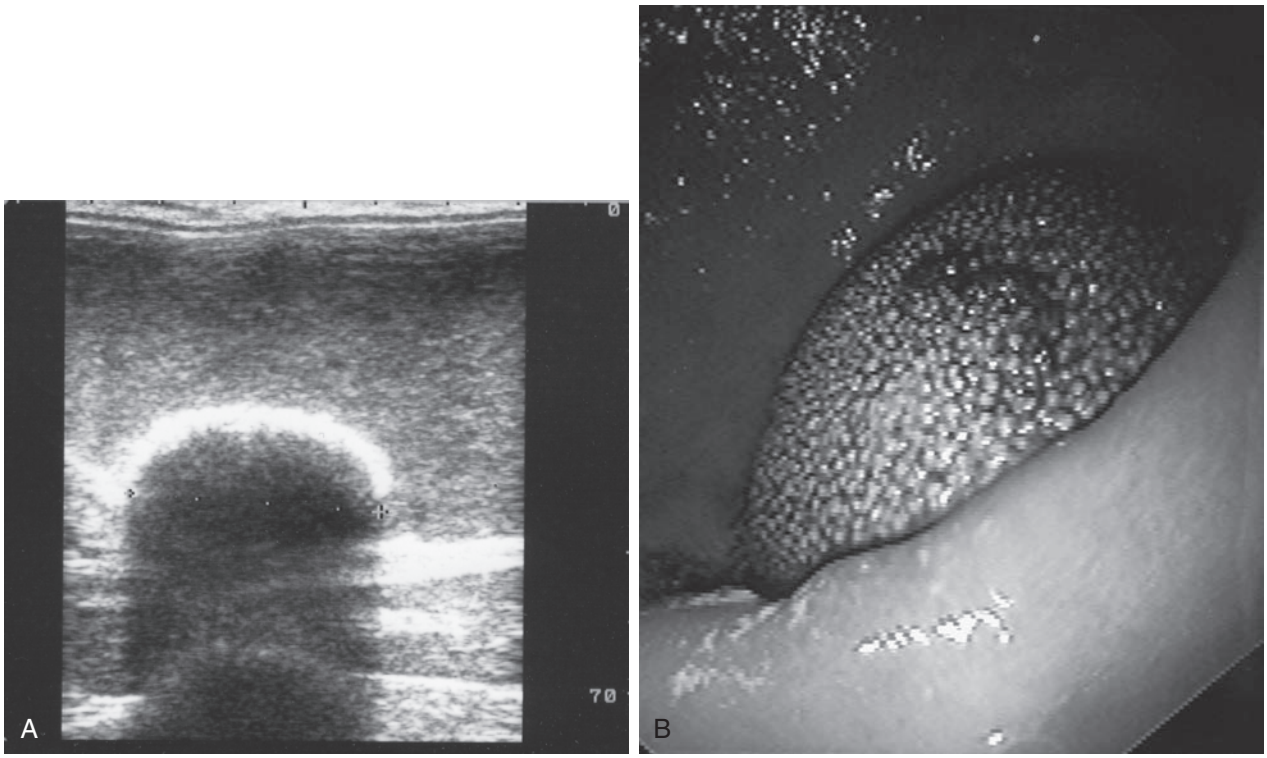

FIG. **14.35** **A,** Transrectal ultrasound examination of the bladder using a 5-mHz linear array probe. A single large calculus is present with acoustic shadowing ventral to the urolith. **B,** A type I urolith within the bladder as seen during cystoscopy.

been effective in treating selected equine cystoliths[614,615] and one ureterolith,[361] the expense of the equipment and availability of other surgical options likely will limit its use to selected cases that are not amenable to routine surgical treatments. Extracorporeal shock wave lithotripsy has been utilized for upper tract stone removal in human beings and dogs[613] and may have application in equids. This noninvasive technology uses a reflector to focus the energy from a shock wave generated outside the body on a nephrolith in situ and has proven to be an effective treatment for human nephrolithiasis.

CYSTIC CALCULI

Cystic calculi are the most commonly recognized form of equine uroliths.[70,95,389,434,563,609] Cystoliths typically are flattened, spherical stones with a spiculated or smooth surface. Dysuria resulting from cystoliths may include hematuria, stranguria, pollakiuria, pyuria, or incontinence. Hematuria is usually more apparent after exercise. An affected male horse may demonstrate stranguria by repeatedly dropping its penis and posturing to urinate but voiding little or no urine. An affected mare also may posture repeatedly to urinate and demonstrate winking, and these signs could be confused with estrous activity. Less common signs include an irritable attitude, recurrent colic, and loss of condition; one burro was presented for recurrent rectal prolapse.[617]

One usually diagnoses cystic calculi by palpation and ultrasound examination of the bladder per rectum (Fig. 14.35). Bladder uroliths are usually large enough to be detected easily; however, if the bladder is distended, one may need to empty it by passing a catheter to facilitate palpation of the stone. Bladder catheterization also allows assessment of urethral patency and collection of samples for urinalysis and quantitative culture. One should perform a CBC and serum biochemical profile to document whether anemia, inflammation, or azotemia has developed. Cystoscopic examination is helpful in assessing the size and number of cystic calculi and the severity of damage to the bladder mucosa, as well as any asymmetry in appearance or function of the ureteral openings (Fig. 14.36).[335,354] Because one may find calculi in multiple sites in the urinary tract, thorough evaluation of the upper urinary tract is warranted for all cases of cystic urolithiasis.

In contrast to upper urinary tract lithiasis, many reports[569,614,615,617-632] and several reviews detail the clinical signs and surgical options for management of cystic calculi.[570,571]

The size of the calculus, gender of the horse, and surgeon's preference play roles in treatment selection. The preferred technique in males, especially for larger stones, is laparocystotomy through a ventral midline or paramedian incision with the horse in dorsal recumbency under general anesthesia. Laparoscopic or laparoscopic-assisted cystotomy may also be used for urolith removal in geldings.[633,634] For removal of smaller cystoliths, one can perform a perineal urethrotomy in the standing male horse with the use of local or epidural anesthesia. One catheterizes the urethra to facilitate identification of the urethra and makes an incision at the level of the ischial arch. After incising the urethra, forceps are used to grasp and remove the calculus, and the bladder is lavaged to remove remaining debris. One may attempt removal of larger calculi via this approach by using a lithotrite to crush the urolith into smaller fragments. The urethral incision can be closed, but it usually is allowed to heal by second intention. Although this approach can be performed less expensively and the risks associated with general anesthesia

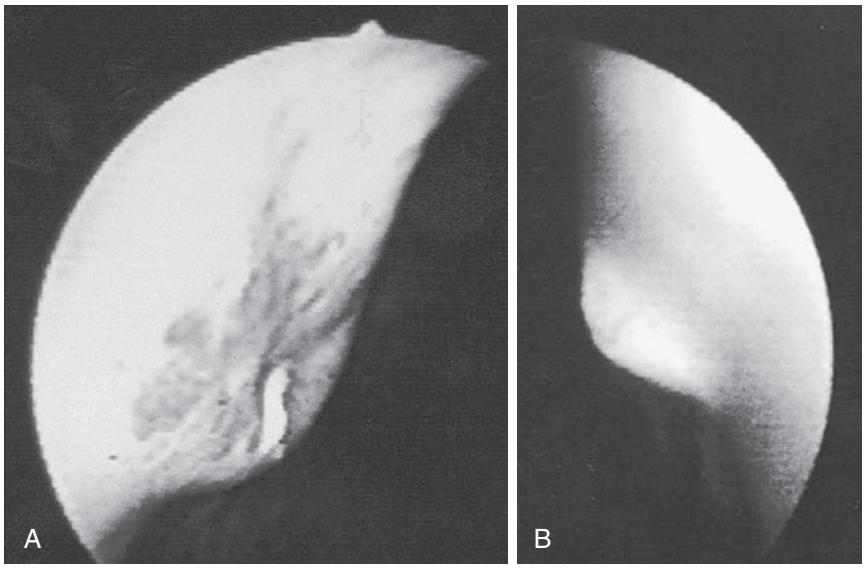

FIG. **14.36** View of the abnormal left **(A)** and normal right **(B)** ureteral openings of a horse with unilateral pyelonephritis and recurrent cystic calculi. The diagnosis was confirmed by culture of urine samples collected from each ureter.

can be avoided, doing so increases the risk of complications, including urethral trauma and stricture formation,[559,609,635] urethrolith formation at the surgical site,[389,636] development of a urethral diverticulum,[636] and persistent urine passage through a fistula at the surgical site.[635,637] The distensible urethra of the mare allows retrieval of cystic calculi via this route in many cases. Using sedation and epidural anesthesia, one can remove the stone intact with forceps or by direct grasping if the surgeon has small hands. One may crush a spiculated urolith with a lithotrite to ease removal. Spiculated stones or urolith fragments can be manipulated further into a sterile plastic bag or palpation sleeve to minimize trauma to the urethral mucosa during removal. If necessary, the urethral lumen can be enlarged by performing sphincterotomy at the dorsal aspect of the urethra.[638] A pararectal (Gökels) approach for dorsal cystotomy[611,632] and electrohydraulic lithotripsy,[614,615] as described for ureterolithiasis, also have been used in male and female horses to treat cystic calculi. Ballistic shockwave lithotripsy using an operating cystoscope via a perineal urethrostomy approach has also been used in a gelding with a cystolith.[639] Successful laser lithotripsy in horses depends on the composition of the urolith and type of laser.[640] Pulsed-dye lasers may be more efficacious for fragmentation of equine uroliths. However, reports of laser lithotripsy in horses are limited, and it appears that certain lasers cannot be assumed to be uniformly successful against all types of equine uroliths.

After surgical removal of cystoliths, one administers systemic antibiotics and an antiinflammatory drug for a minimum of 1 week. As for cystitis, antibiotic selection should be based on susceptibility testing of recovered isolates. If culture results are negative, then a sulfonamide-trimethoprim combination is an appropriate selection. An early report by Lowe[636] described excellent long-term results—and no recurrence—after removal of cystic calculi by laparocystotomy in four horses. Similar low rates of recurrence have been echoed in several reviews of equine urolithiasis.[563,571,609,611] In contrast to these favorable reports (most of which do not provide supporting data), Laverty et al.[389] reported that clinical signs of urolithiasis recurred in 12 of 29 horses (41%) for which follow-up data were available. The interval between episodes of recurrence was 1 to 32 months (mean: 13 months). As Lowe initially described in 1965,[636] Laverty and colleagues[389] also found greater recurrence of cystic calculi after treatment by perineal urethrotomy (7 of 15 horses) compared with laparocystotomy. Other complications of cystic calculi unrelated to the surgical approach have included vesiculoureteral reflux and renal failure[641] and concurrent urolithiasis at other sites.[389] A more common complication of urethral obstruction,[559] bladder rupture, also may occur after cystic urolithiasis. The author also has seen a case of squamous cell carcinoma of the bladder that was associated with a large cystic calculus and development of uroperitoneum after bladder rupture (Fig. 14.37).

Postoperative recommendations that may help prevent recurrence include control of UTI and use of urinary acidifiers, although the benefits of the latter are not well documented (see Cystitis in the Urinary Tract Infections section of this chapter).[281,563,569-571] Other considerations for decreasing recurrence include dietary modifications to decrease calcium excretion and to promote diuresis. Changing the diet from a high-calcium hay (e.g., alfalfa or clover) to grass or oat hay decreases dietary calcium and thus should decrease urinary calcium excretion because fecal calcium excretion is relatively constant in horses.[642] This dietary change should decrease total calcium excretion and may decrease urinary nitrogen excretion and daily urine volume.[168] The latter changes could enhance supersaturation of urine. In theory, the addition of 50 to 75 g of loose salt daily to the concentrate portion of the diet should promote diuresis; however, in a study of ponies fed NaCl as 1%, 3%, or 5% of the total dry matter of the diet (1% approximates 75 g of NaCl for a 500-kg horse), no differences in water intake, urine production, or calcium excretion were observed.[171] Another factor that affects urine pH and urine calcium excretion is dietary cation-anion balance (DCAB = [Na + K] − [Cl + S]). A lower DCAB has been associated with

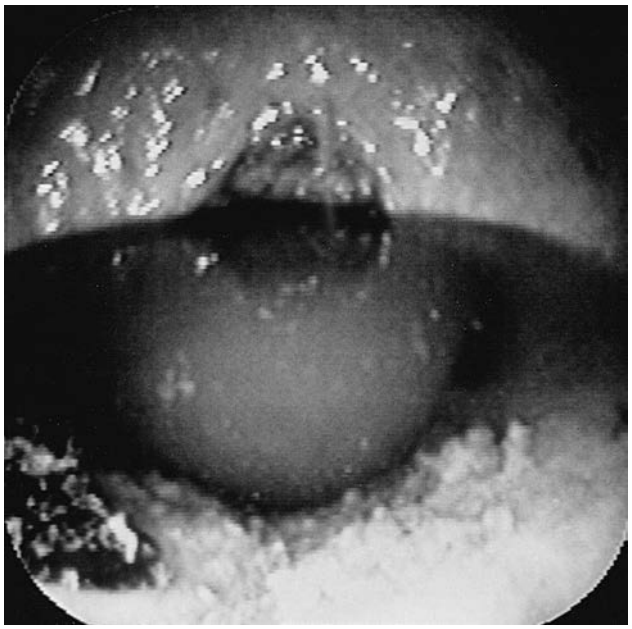

FIG. **14.37** A large urolith is present in the bladder below the surface of the pool of urine. The cystolith was accompanied by bacterial cystitis and squamous cell carcinoma of the bladder.

a decrease in urine pH and an increase in urinary calcium excretion.[643-645] Increasing the amount of grain in the diet, changing to lower quality hay, or adding one or more minerals to the diet (e.g., ammonium chloride, calcium chloride, ammonium sulfate) usually lowers DCAB. Not surprisingly, supplements that decrease DCAB are familiar as urinary acidifying agents. Because a diet low in calcium and DCAB could result in a negative calcium balance, a possible long-term effect could be decreased skeletal calcium content.

Despite the success of dietary management (low protein, phosphorous, and magnesium) for medical dissolution of canine[646] and feline[647] uroliths, dietary management is unlikely to replace surgical treatment of cystic urolithiasis in horses. This problem can be attributed to the fact that dietary management for small animals has been directed at struvite urolithiasis and these stones are not common in horses. Nevertheless, one should not overlook dietary management as one of the postoperative recommendations for urolithiasis, because it could decrease the risk of recurrence. At the least, legume hays and dietary supplements containing calcium should be avoided, and the diet could be supplemented with 50 to 75 g of loose salt daily. Remillard and colleagues[572] used these dietary manipulations effectively, along with administration of ammonium sulfate as a urine-acidifying agent, to manage one recurrent case of equine urolithiasis.

URETHRAL CALCULI

Urethral calculi are primarily a problem of male horses,* although they have been detected in a few mares.[389] In the absence of predisposing urethral damage or stricture formation, urethroliths are usually small cystoliths passed into the urethra. Thus most urethroliths initially lodge where the urethra narrows as it passes over the ischial arch. They may pass

* References 70, 95, 389, 434, 559, 563, 636, 648, 649.

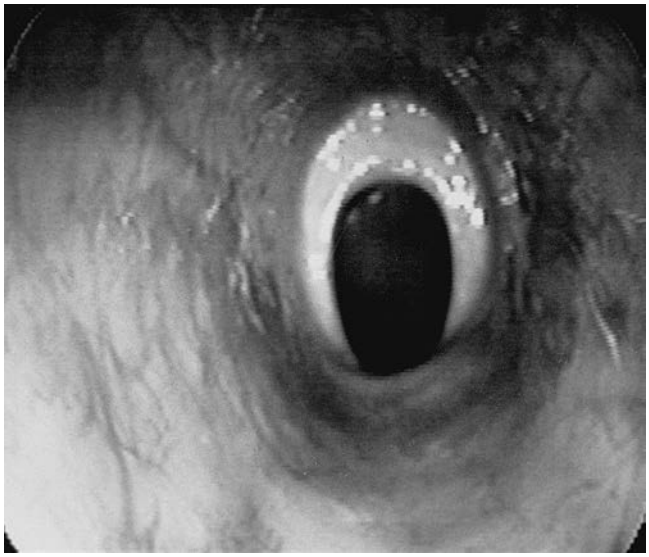

FIG. **14.38** Stricture formation in the urethra at the level of the ischial arch formed as a complication of a perineal urethrotomy.

slowly farther down the urethra, until complete obstruction produces signs of renal colic. One should consider an obstructing urethral calculus when male horses show colic signs and frequently posture to urinate. Occasionally, one may see blood on the end of the urethra. Palpation of the penis may reveal repeated urethral contractions or a firm mass in the urethra. Rectal palpation reveals a distended bladder that is turgid, unlike the flaccid bladder distention of bladder paralysis. If the bladder ruptures, colic signs are supplanted by progressive depression and anorexia after the development of postrenal acute renal failure.[389,559,648,649] The diagnosis is confirmed by passage of a urinary catheter that is then obstructed by the urolith or by endoscopic examination of the urethra. One can confirm suspected bladder rupture by measuring a twofold or greater increase in peritoneal fluid creatinine concentration compared with serum creatinine concentration.

One can remove calculi lodged at the ischial arch through a perineal urethrotomy. Passage of a catheter into the bladder, if not achieved before surgery, is necessary to ensure a patent urinary tract after stone removal. The urethrotomy is allowed to heal by second intention, and temporary use of an indwelling bladder catheter usually is not necessary. One often can remove calculi lodged in the distal urethra from a sedated horse by gentle transurethral crushing of the urolith with a hand or forceps. For a calculus lodged distal to the ischial arch and unpalpable in the distal portion of the penis, general anesthesia and positioning the horse in dorsal recumbency are generally necessary for surgical removal of the stone. One may close the urethra or allow it to heal by second intention. A commercial extracorporeal shock wave machine designed for orthopedic conditions in horses has been used to successfully break up a distally lodged urethrolith in a standing sedated horse.[650]

Follow-up endoscopic examination of the urethra allows assessment of urethral healing and possible stricture formation (Fig. 14.38). Further treatment includes administration of antibiotics and antiinflammatory agents until dysuria resolves. Although initial treatment of urinary tract obstruction caused by a urethrolith is straightforward, the prognosis for affected horses should remain guarded because a number of potential

complications of perineal urethrotomy (described previously) may occur. Furthermore, a substantial number of horses have had poor outcomes because of associated bladder rupture and peritonitis[389,559,648] or upper urinary tract lithiasis or pyelonephritis.[389,609]

SABULOUS UROLITHIASIS

Another form of equine urolithiasis termed *sabulous urolithiasis* also has been described in a limited number of horses.[609,566] Sabulous (Greek for *sand*) urolithiasis refers to the accumulation of large amounts of crystalloid urine sediment in the ventral aspect of the bladder. This condition is a secondary problem resulting from bladder paralysis or other physical or neurologic disorders interfering with complete bladder emptying.[564,574,575] Affected horses usually are presented for evaluation of urinary incontinence or hindlimb weakness and ataxia, and one may detect accumulation of urine sediment in a distended bladder during rectal palpation. A complete neurologic examination should be performed on horses with sabulous urolithiasis or bladder dysfunction. Common differential diagnoses for bladder paresis or paralysis include equine herpesvirus–1, polyneuritis equi, illicit tail block, equine protozoal myeloencephalitis, and sacral fracture or osteomyelitis. Symptomatic treatment includes repeated bladder lavage, medications that promote bladder emptying, and broad-spectrum antibiotics, but the condition carries a poor prognosis unless the primary problem resulting in bladder paralysis can be resolved (see Urinary Incontinence and Bladder Dysfunction).

BLADDER DISPLACEMENT

Displacement of the urinary bladder is a rare cause of obstruction and dysuria.[70,651-654] In mares, two types of bladder displacements can occur: (1) extrusion through a tear in the floor of the vagina or (2) true prolapse with eversion of the bladder.[655] Urethral obstruction also may occur with vaginal or uterine prolapse. In male horses scrotal herniation of the bladder has been described, but this type of bladder displacement is rare.[656] Bladder displacements typically result from repeated abdominal contractions or straining. Thus they most often are associated with parturition and to a lesser extent with colic. Perineal lacerations after trauma or foaling may lead to extrusion, whereas excessive straining without laceration leads to prolapse and eversion. Because the bladder turns inside out with the latter problem, one establishes the diagnosis by recognizing the appearance of the bladder mucosa and ureteral openings. Eversion does not always result in obstruction.

With urethral obstruction, one should pass a catheter into the bladder before correction of the displacement. In the absence of obstruction, one corrects extrusions during repair of the perineal or vaginal laceration. One should institute a course of broad-spectrum antibiotics and an antiinflammatory agent because pelvic abscess and peritonitis are potential complications. Manual reduction of bladder eversions may be successful in some cases, but more often than not, one may need to perform urethral sphincterotomy to replace the bladder.[654] In some cases, reduction via laparotomy may be necessary because the everted bladder may be filled with the pelvic flexure, complicating manual reduction.[653] A purse-string suture placed in the area of the external urethral sphincter may be of benefit to prevent recurrence of the prolapse, and medical treatment should include broad-spectrum antibiotics and an antiinflammatory agent because UTI is a potential complication.

PENILE TRAUMA

Urinary tract obstruction is an occasional complication of penile trauma or paraphimosis, and one should consider the patency of the urethra in all cases of penile injury. Causes may include blunt trauma, breeding injuries, use of stallion rings, sedation with phenothiazine tranquilizers, or laceration during castration.[70,657-659] In addition to preputial swelling, injury may result in a penile hematoma or possible paraphimosis.[660,661] In one report, hematoma formation in the corpus spongiosum penis of a Quarter Horse stallion resulted in complete obstruction and bladder rupture.[662] In addition to ensuring patency of the urinary tract, treatment includes administration of antibiotics and antiinflammatory agents until most of the swelling resolves. One may close lacerations of the urethra or leave them to heal by second intention depending on location and condition of the wound. Because stricture formation is a possible complication, some wounds may be treated better by phallectomy than by urethral repair.[658]

Hematuria

Harold C. Schott II

Hematuria can be a presenting complaint for a variety of disorders of the urinary tract, including vascular malformation, urinary tract infection, urolithiasis, and neoplasia.[663] In addition to these problems, which are discussed elsewhere in this chapter, several other specific causes of hematuria exist. These causes range from microscopic hematuria accompanying exercise to more severe conditions that can result in life-threatening urinary tract hemorrhage. In addition, normal equine urine may contain pyrocatechin, an oxidizing agent that can cause urine to turn red to brown after exposure to air, snow, or bedding (especially wood shavings).

Although values have not been determined in horses, normal human urine contains about 5000 (range: 2000–10,000) red blood cells (RBCs) per milliliter.[5] This range of RBC excretion should yield negative results on reagent strip analysis and a report of not more than five RBCs per high-power field on sediment examination. Increases in RBC excretion may lead to microscopic or macroscopic hematuria. Microscopic hematuria, which implies an increase in RBC excretion that is not visible grossly, usually is associated with increases in the range of 10,000 to 2.5 million RBCs per milliliter of urine. On sediment examination, at least 10 RBCs per high-power field should be apparent. Reagent strip analysis results can range from trace to +++. One must realize that reagent strip results, which use the peroxidase-like activity of hemoglobin and myoglobin to oxidize a chromogen in the test pad, do not differentiate between hemoglobin and myoglobin.[664] Thus positive results are not specific for hematuria and may be more appropriately termed *pigmenturia.* Despite this limitation, one can use reagent strips to differentiate hematuria from hemoglobinuria or myoglobinuria when the color change is limited to scattered spots on the test pad. This pattern implies that intact RBCs were adsorbed onto the pad, underwent lysis, and produced a localized color change caused by hemoglobin activity on the chromogenic

substrates. Ability to differentiate hematuria from excretion of the heme pigments is limited to a threshold of 250,000 to 300,000 RBCs per milliliter of urine, unless urine samples are diluted with normal saline. Other limitations of reagent strip analysis include false-positive reactions when urine samples are contaminated with oxidizing agents (e.g., disinfectants) or false-negative reactions when urine samples contain vitamin C or have been preserved with formalin.[664]

Macroscopic or gross hematuria indicates RBC excretion in excess of 2.5 to 5 million RBCs per milliliter of urine (or about 0.5 mL of blood per liter of urine).[5,285,664,665] One can differentiate macroscopic hematuria from other causes of pigmenturia by centrifuging a sample of urine to produce a red cell pellet and yellow supernatant urine. Quantification of erythrocyte numbers in macroscopic hematuria is of little clinical value. In contrast, urinary RBC numbers may provide diagnostic and prognostic information in cases of microscopic hematuria in human beings.[5] However, variations in urine concentration complicate accurate counts. In concentrated urine (specific gravity greater than 1.020), RBCs tend to become crenated because of the osmotic shift of water out of the cells. In urine with a specific gravity less than 1.010, osmotic swelling and dilution of hemoglobin lead to "ghost cell" formation.[5,666] Furthermore, many RBCs lyse in dilute urine (especially alkaline urine) so that RBC excretion is vastly underestimated. Reagent strip analysis can be useful in dilute urine samples to detect hemoglobin released from lysed erythrocytes.[665]

Microscopic examination of urine sediment in cases of hematuria is helpful in distinguishing glomerular from nonglomerular bleeding. The hallmark of glomerular bleeding is a substantial variation in RBC size, shape, and hemoglobin content (termed *dysmorphism*), whereas bleeding from other sites produces a more uniform population of urinary erythrocytes.[5,665,667] Dysmorphism is attributed to membrane deformation, which occurs as erythrocytes traverse the glomerular filtration barrier.[667] Urinary RBCs in normal persons are typically dysmorphic, indicating glomerular origin, but the excretion rate is low.[5] Thus one must interpret urinary RBC morphologic characteristics along with urinary RBC numbers to determine significance.[667,668] The volume of dysmorphic cells tends to be lower than that of erythrocytes of nonglomerular origin, so that measurement of mean corpuscular volume also has been used to separate glomerular from nonglomerular bleeding.[669] The presence of RBC or hemoglobin casts is also pathognomonic for glomerular bleeding.[5,665,667] These casts form when urinary RBCs and hemoglobin from the proximal portion of the nephron (glomerulus) combine with Tamm-Horsfall mucoprotein secreted in the ascending limb of the loop of Henle. Because urinary RBCs and casts deteriorate rapidly in urine samples, other methods of detecting glomerular hematuria, such as immunocytochemical staining for Tamm-Horsfall glycoprotein, have been developed but have not gained widespread use.[670]

Noting the timing of hematuria is usually a more practical means of initially localizing the site of urinary tract hemorrhage.[666] Hematuria throughout urination is consistent with hemorrhage from the kidneys, ureters, or bladder, whereas hematuria at the beginning of urination often is associated with lesions in the distal urethra. Hematuria at the end of urination usually results from hemorrhage from the proximal urethra or bladder neck. A thorough diagnostic evaluation, including physical examination, rectal palpation, analyses of blood and urine, endoscopy of the lower tract, and ultrasonography, usually is rewarding in establishing the source and cause of urinary tract hemorrhage.[663]

Urinary tract infection, although uncommon in horses, may result in hematuria. With infection of the upper urinary tract, partial anorexia, weight loss, and fever may be additional presenting complaints, whereas horses with cystitis generally manifest stranguria and pollakiuria; however, hematuria has been the presenting complaint in several reports of cystitis and pyelonephritis.[479,575,671-673] The presence of uroliths at any level of the urinary tract may cause mucosal irritation and hemorrhage, resulting in hematuria.[257,389,563] Typically, affected horses also show signs of renal colic or painful urination (stranguria or pollakiuria), especially with uroliths in the bladder or urethra. Finally, neoplasia of the kidneys, ureters, bladder, or urethra may result in hematuria as the presenting complaint.[565,674-676] These conditions are discussed in detail in other sections in this chapter.

TOXICITIES

Nephrotoxicity, particularly after administration of NSAIDs (especially phenylbutazone), may result in microscopic or gross hematuria.[238,239,482,677,678] Historical or current use of nephrotoxic medications supports this diagnosis, and discontinuation of the nephrotoxic agent and supportive care are the appropriate treatments. Horses that consume alfalfa hay containing blister beetles (equine cantharidiasis) may void red urine. Cantharidin is excreted in urine and is very irritating to the lower urinary tract, resulting in cystitis and hemorrhage from the urinary bladder mucosa.[679]

URETHRAL DEFECTS

Although a widely recognized cause of hemospermia in stallions, rents or tears of the proximal urethra at the level of the ischial arch can also cause hematuria in geldings.[561,663,680,681] Because the defects are difficult to detect without videoendoscopic equipment, the lesions likely may have been missed in previous reports of urethral bleeding.[558,559] Consequently, hematuria has been attributed to urethritis or hemorrhage from "varicosities" of the urethral vasculature.[559,680] Because the vasculature underlying the urethral mucosa becomes prominent when the urethra is distended with air during endoscopic examination, especially in the proximal urethra (to the point that blood can be seen flowing in the submucosal vasculature), one easily would suspect that hemorrhage could arise from apparent urethritis or urethral varicosity.

Urethral rents or tears in geldings typically occur at the ischial arch and involve the corpus spongiosum penis (CSP). The urethral rent into the vascular space of the penis results in hematuria at the end of urination in association with urethral contraction.[561,663,680] Affected geldings generally void a normal volume of urine that is not discolored. At the end of urination, a series of urethral contractions results in squirts of bright-red blood. Occasionally, the horse may pass a smaller amount of darker blood at the start of urination. In most instances the condition does not appear painful or result in pollakiuria. Interestingly, most affected stallions with hemospermia and geldings with hematuria have been Quarter Horses or Quarter Horse crosses that have been free of other complaints.[559,561] Treatment with antibiotics for suspected cystitis or urethritis routinely has been unsuccessful, although hematuria has resolved spontaneously in approximately half of the cases seen by the author.

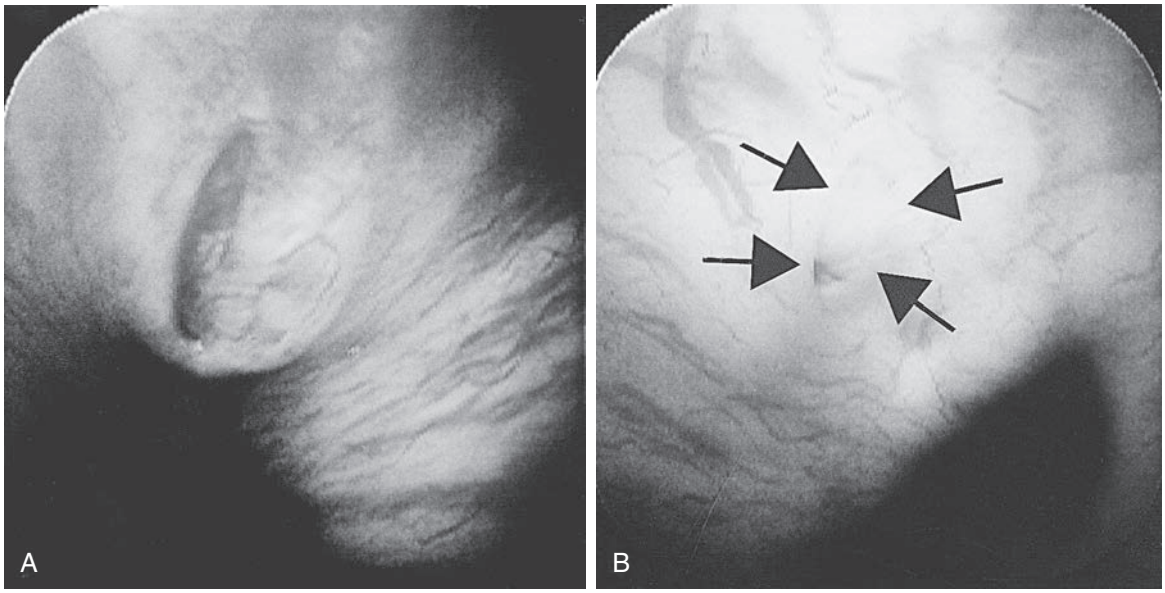

FIG. **14.39** Endoscopic images of urethral defects or tears at the level of the ischial arch. **A,** A more acute lesion (hematuria for 2 weeks) is surrounded by a raised rim of tissue. **B,** A chronic lesion (hematuria for 6 months) is flat to recessed *(between arrows).* Evidence of inflammation around both lesions is minimal.

Examination of affected horses is often unremarkable. In comparison, horses with hematuria caused by neoplasms involving the distal urethra or penis usually have additional complaints such as pollakiuria, a foul odor to the sheath, or presence of a mass in the sheath or on the penis.[682] With urethral rents, laboratory analysis of blood reveals normal renal function, although mild anemia can be an occasional finding. Urine samples collected midstream or by bladder catheterization appear grossly normal. Urinalysis may have normal results, or the number of RBCs may be increased on sediment examination (a finding that also would result in a positive reagent strip result for blood). Bacterial culture of urine yields negative results.

One makes the diagnosis via endoscopic examination of the urethra, during which one typically sees a lesion along the dorsocaudal aspect of the urethra at the level of the ischial arch (Fig. 14.39A). With hematuria lasting several weeks, the lesion appears as a fistula communicating with the vasculature of the CSP (Fig. 14.39B). External palpation of the urethra in this area is usually unremarkable but can help localize the lesion, because external digital palpation is visible via the endoscope as movements of the urethra.

Although the complete pathophysiology of this condition remains unclear, the defect has been speculated to result from a "blowout" of the CSP into the urethral lumen (Fig. 14.40).[561] Hemorrhage from urethral rents occurs with higher pressure within the CSP during urination in geldings and ejaculation in stallions.[681] Pressure in the CSP during urination is higher in geldings because of their smaller CSP diameter compared with stallions. Hematuria at the end of urination in geldings with urethral rents is speculated to occur when a sudden decrease in intraluminal urethral pressure occurs while pressure in the CSP is still high. Once created, the lesion is maintained by bleeding at the end of each urination, and the surrounding mucosa heals by formation of a fistula into the overlying vascular tissue.[561] An explanation for the consistent location along the dorsocaudal aspect of the urethra at the level of the

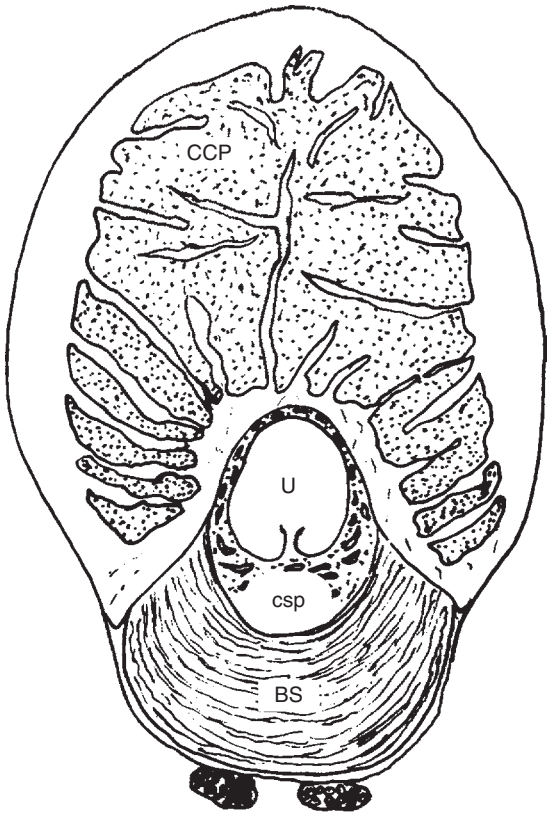

FIG. **14.40** Cross-sectional diagram of the equine penis at the level of the ischial arch shows a defect between the corpus spongiosum penis (CSP) ***(csp)*** and the urethral lumen ***(U)***. The CSP is a cavernous tissue surrounding the urethra that is distinct from the corpus cavernosum penis ***(CCP)***; the CSP is also adjacent to the bulbospongiosus muscle ***(BS)*** caudally. (From Schumacher J, Varner DD, Schmitz DG, et al.: Urethral defects in geldings with hematuria and stallions with hemospermia, *Vet Surg.* 24:250, 1995.)

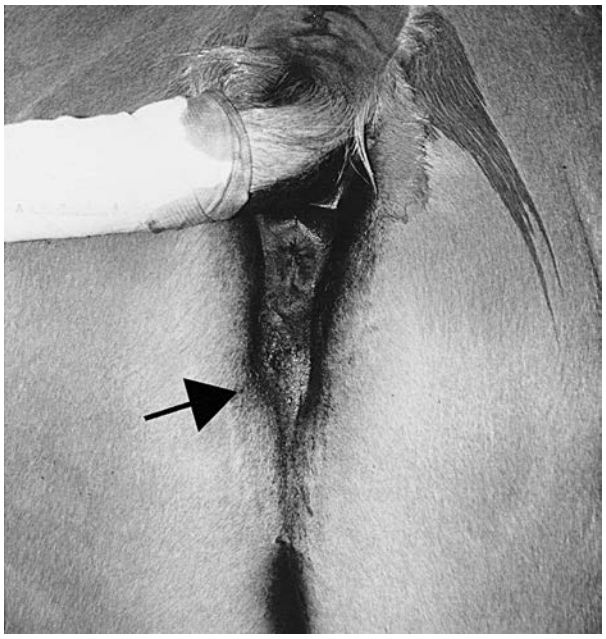

FIG. **14.41** Perineum of Paint gelding with hematuria associated with a proximal urethral defect. The asymmetry of the perineal musculature is visible at the level of the ischial arch. (*Arrow* shows where asymmetry is more prominent on left side.)

ischial arch has not been documented but may be related to the anatomy of the musculature supporting the base of the penis and an enlargement of the CSP in this area. Furthermore, a narrowing of the lumen of the urethra at the distal extent of the ampullar portion of the urethra occurs that also may contribute to the location of the defects. However, histologic studies in both geldings and stallions have shown that no differences exist in the urethral mucosa, lamina propria, or CSP between the ischial arch and other sites in the penis.[681] An anatomic predisposition in Quarter Horses has not been documented but could be speculated to be based on an apparently increased risk in this breed. In addition, some of the affected horses have asymmetry to the musculature under the tail in this area, supporting a possible developmental defect (Fig. 14.41).

Because hematuria may resolve spontaneously, no treatment may be required initially. If hematuria persists longer than 1 month or if significant anemia develops, then a temporary subischial urethrotomy has been successful in a number of affected geldings. With sedation and epidural or local anesthesia, one makes a vertical incision down to a catheter placed in the urethra. The surgical wound requires several weeks to heal, and moderate hemorrhage from the CSP is apparent for the first few days after surgery. Additional treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for 7 to 10 days. Hematuria should resolve within 1 week after this procedure. Limiting the incision into the CSP but not extended into the urethral lumen also has been a successful treatment and is now the preferred surgical treatment.[561] This treatment option provides support for the vascular blowout theory and lessens the risk of urethral stricture formation. Furthermore, the treatment decreases the chance of a permanent fistula forming at the site, a surgical complication that has occurred in geldings.

IDIOPATHIC RENAL HEMATURIA

Idiopathic renal hematuria is a syndrome characterized by sudden onset of gross, often life-threatening hematuria.[62,683] Hemorrhage arises from one or both kidneys and is manifested by passage of blood clots in urine. Endoscopic examination of the urethra and bladder usually reveals no abnormalities of these structures, but one may see blood clots exiting one or both ureteral orifices. Although a definitive cause of renal hemorrhage may be established in some horses (e.g., renal adenocarcinoma, arteriovenous or arterioureteral fistula),[58,61] the disorder is termed *idiopathic* when a primary disease process cannot be determined. Both sexes, a wide age range, and several breeds of horses (including a mammoth donkey and a mule) have been affected. However, more than 50% of animals with idiopathic renal hematuria have been Arabians.

Use of the term *idiopathic renal hematuria* to describe this syndrome of horses was adopted from its use in human patients and dogs with severe renal hemorrhage.[5,61,684-690] *Benign essential hematuria* and *benign primary hematuria* are other terms that describe less severe hematuria that is not associated with trauma or other obvious causes of hematuria. In the latter species, hematuria is more commonly a unilateral than a bilateral problem, similar to what has been observed in the few affected horses. The pathophysiology remains poorly understood, but macroscopic hematuria has been associated with immune-mediated glomerular damage (e.g., acute postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, immunoglobulin A nephropathy, Berger's disease), thin basement membrane nephropathy, and the loin pain–hematuria syndrome in human patients.

Although hematuria and pigmenturia can accompany a number of systemic diseases in horses,[477,691,692] patients affected with idiopathic renal hematuria have spontaneous, severe hematuria in the absence of other signs of disease. Although one report suggested that severe renal hemorrhage resulted from pyelonephritis,[673] supportive data were lacking. In cases managed by the author, neither urinary tract infection nor urolithiasis has been detected; the magnitude of hematuria often resulted in the need for repeated blood transfusions. As with guttural pouch mycosis, the syndrome may produce episodic hemorrhage. Initially, one notes hemorrhage by finding a large amount of clotted blood in stall bedding or in the pasture. However, other clinical signs (e.g., depression, anorexia, weight loss) are typically absent. Examination may reveal dried blood at the end of the penis or in the sheath of males or on the vulvar lips and between the hindlimbs of mares. In both sexes, neoplasia of the external genitalia or urinary tract is an important differential diagnosis, whereas in mares, one also must consider varicosities in the area of the vestibulovaginal sphincter, especially in multiparous mares. When blood is not detected in the sheath or vulvar areas, further evaluation may be unrewarding because the renal bleeding may cease spontaneously. Bleeding has been attributed anecdotally to cystitis and pyelonephritis in the absence of positive urine culture results, because hemorrhage stops during a course of antimicrobial therapy. More likely, spontaneous resolution has occurred. Furthermore, the magnitude of hematuria is considerably greater with idiopathic renal hematuria than with most urinary tract infections, pyuria is absent, and urine culture results are negative. In the author's experience, one or two initial episodes of hemorrhage are followed by a more severe hemorrhagic crisis within months to several years after

observation of the initial bleeding episode. Interestingly, renal colic has been notably absent in the history of affected horses.

One diagnoses idiopathic renal hematuria by exclusion of systemic disease, other causes of hematuria, and alterations in hemostasis. Physical examination may reveal tachycardia, tachypnea, and pale mucous membranes consistent with acute blood loss. Rectal palpation may reveal an enlarged, irregular bladder because of the presence of blood clots. Azotemia is inconsistent. Endoscopic examination is important to document that hematuria is originating from the upper urinary tract and to determine whether hemorrhage is unilateral or bilateral (Fig. 14.42). Repeated examinations may be required to answer the latter question. Ultrasonographic imaging is necessary to rule out nephrolithiasis or ureterolithiasis and occasionally may reveal a distended vascular space or renal vascular anomaly as the cause of hematuria. Renal scintigraphy can be a useful technique in affected horses because it may provide semiquantitative information about renal function when a nephrectomy is being considered. Renal biopsy and immunofluorescent staining may assist in documenting immune-mediated glomerular injury, but the significance of such results is not well understood at this time.

Treatment for idiopathic renal hematuria consists of supportive care for acute blood loss, including blood transfusions. Medications intended to promote hemostasis (e.g., aminocaproic acid, formalin) also have been administered, but their efficacy has not been validated. Treatment with corticosteroids may be useful in cases with potential immune-mediated mechanisms as the cause of bleeding. Because the condition may be self-limiting in some patients, supportive care is warranted. With severe and recurrent unilateral hematuria, a nephrectomy may be indicated, but one should warn owners of the risk of hematuria developing in the contralateral kidney. In the author's experience, risk of contralateral renal bleeding appears to be greater in the Arabian breed.

FIG. **14.42** Endoscopic image of a large blood clot exiting the right ureteral opening of a gelding with idiopathic renal hematuria.

EXERCISE-ASSOCIATED HEMATURIA

Exercise is accompanied by increased filtration of RBCs and protein across the glomerular barrier in a large percentage of human and equine athletes.[285,693] Typically the hematuria is microscopic, but occasionally one may observe gross discoloration of urine. Gross hematuria more often may result from bladder erosions, which may be induced traumatically by the abdominal contents pounding the bladder against the pelvis during exercise.[356] Detection of focal bladder erosions or ulcers with a contrecoup distribution and a history of emptying the bladder immediately before the exercise bout are characteristic for this problem. A diagnosis of exercise-associated hematuria should be one of exclusion after diagnostic evaluation has ruled out other causes of hematuria such as presence of a cystolith.

PIGMENTURIA ASSOCIATED WITH SYSTEMIC DISEASE

With any systemic disease that may lead to hemolysis, thrombocytopenia, coagulopathy, or alterations in vascular permeability, hematuria or hemoglobinuria may develop. Discolored urine has the potential to be accompanied by a degree of nephrotoxicity because of the interaction of iron ions of heme molecules with surface molecules on proximal tubular epithelial cells. With transient pigmenturia (as with exercise-associated hematuria), changes in renal function may not be apparent, but with more severe disease processes, acute renal failure may develop. In human beings, a syndrome of hemolytic anemia and thrombocytopenia leading to development of acute renal failure has been termed the *hemolytic-uremic syndrome*.[694] The syndrome is recognized more commonly in children than in adults and is the most common cause of acute renal failure in children. Similar syndromes have been described in a limited number of horses.[477,691,692] Furthermore, hemolysis and hemoglobinuria may be recognized with liver disease, medications (e.g., penicillin-induced immune-mediated hemolytic anemia, concentrated intravenous DMSO solutions), or intoxications (e.g., ingestion of red maple leaves). Finally, conditions accompanied by extensive rhabdomyolysis also may result in pigmenturia and acute renal failure.[695] Assessment of muscle enzyme activities in these cases usually is rewarding in establishing myoglobin as the most likely cause of pigmenturia. In addition, one can use the Blondheim test (ammonium sulfate precipitation) to differentiate myoglobinuria from hemoglobinuria.[288] Furthermore, serum is discolored with intravascular hemolysis, whereas serum appears normal if hematuria or myoglobinuria is present. Centrifugation of urine and sediment analysis will differentiate if pigmenturia or hematuria is the cause of discolored urine.

Polyuria and Polydipsia

Harold C. Schott II

For small animals, polyuria and polydipsia have been defined as urine output exceeding 50 mL/kg/day and fluid intake of more than 100 mL/kg/day.[696,697] These values would equate to 25 L of urine production and 50 L of water consumption for a 500-kg horse. Compared with normal values for daily urine production and water consumption of 5 to 15 L and 20

TABLE **14.11 Relationship of the Percentage of Water Filtered That Is Reabsorbed to Daily Urine Output and Renal Water Absorption**

Glomerular Filtration Rate (GFR) (L/day)	Percentage of Filtered Water Reabsorbed	Urine Production (L/day)	Urine Osmole Excretion (mOsm)	Urine Osmolality (mOsm/kg)	Renal Water Reabsorption[a] (L/day)
1000	99%	10	10,000	1000	23.3
1000	98%	20	10,000	500	13.3
1000	96%	40	10,000	250	6.7

[a]Renal water reabsorption (the inverse of free water clearance) is a calculated volume of water that is retained or lost by the kidney. Renal water reabsorption is calculated from actual urine volume and the calculated volume of urine required to excrete all osmoles in urine that is isosmotic with plasma. In this table a urine osmolality value of 300 mOsm/kg is assumed to be isosmotic to plasma, 1 kg of water is assumed to equal 1 L of water, and a total of 10,000 Osm is assumed to be excreted daily. Thus when 98% of filtered water is reabsorbed, the 20 L of urine produced (if isosmotic) would contain 6000 mOsm. Because an additional 13.3 L of water would be needed to excrete the remaining 4000 mOsm (as isosmotic urine), the kidneys are considered to be actively reabsorbing 13.3 L of water.

to 30 L, respectively,* these definitions of polyuria and polydipsia appear applicable to horses as well. One must remember that urine production and water consumption vary with age, diet, workload, environmental temperature, and gastrointestinal water absorption. For example, urine production increases by 50% to 100% when the diet is changed from a grass to a legume hay.[168] Although this increase in urine production has been associated with higher dietary protein intake and urinary nitrogen excretion,[136] increases in calcium intake and urinary calcium excretion may be another contributing factor. Similarly, horses that are exercised heavily, are stabled in hot climates, or have chronic diarrhea may have a water intake exceeding 100 L per day yet produce normal volumes of urine.[163]

A brief review of water turnover by the equine kidneys provides insight into how a small change in renal water reabsorption can lead to a dramatic increase in urine production (polyuria). In normal horses, glomerular filtration exceeds 1000 L/day, a volume that is 10 times greater than the total extracellular fluid volume; however, approximately 99% of this water is reabsorbed in the renal tubules and collecting ducts, resulting in production of 5 to 15 L of urine daily. The result is urine that is 3 to 4 times more concentrated than plasma (urine osmolality of 900–1200 mOsm/kg and a specific gravity of 1.025–1.050). Furthermore, urea (in urine) has replaced sodium (in plasma) as the most important solute. If only 98% of water is reabsorbed, urine volume would double, and the additional water would result in more dilute urine (urine osmolality of 450–600 mOsm/kg and a specific gravity of 1.015–1.025). If water reabsorption decreased to 96% of filtered water, the horse would produce approximately 40 L of urine with a urine osmolality of 225 to 300 mOsm/kg and a specific gravity of 1.005 to 1.010 (Table 14.11). In the latter case, urine is more dilute than plasma (hyposthenuria), and the kidneys are excreting or losing water actively. Under certain conditions, active water excretion by the kidneys is important for maintenance of plasma osmolality in the normal range. The best example is a neonatal foal that may ingest a volume of milk exceeding 20% of its body weight daily.[169] This ingestion equates to a fluid intake approaching 250 mL/kg/day, and failure to produce a large volume of hyposthenuric urine could result in water retention, decreased plasma osmolality, and clinical hyponatremia (manifested by neurologic signs).

Determining that a horse is producing more urine than normal is often difficult, especially in horses kept at pasture. Owners may report that a horse is polyuric when in fact the frequency of urination has increased (pollakiuria) rather than the volume. Pollakiuria occurs with conditions such as cystitis and urolithiasis or during estrus in the mare. Horses housed in stalls bedded with straw are difficult to evaluate because excessive urine may not be obvious to the casual observer. For those bedded on shavings or sawdust, excessively wet bedding may be easier to recognize, but this is a subjective impression. Occasionally, polyuria may be so severe that urine may flow from the stall into the barn aisle. When doubt exists as to whether a horse has polyuria and polydipsia, documentation of water consumption over one or more 24-hour periods may be necessary.[247] One can quantify urine production by collecting urine over a 12- or 24-hour period. For geldings and stallions, one can construct a collection device by cutting off the bottom of a large plastic bottle, padding it, and fitting it over the prepuce. One covers the opening of the bottle with a rubber tube and clip to allow removal of urine every few hours. In mares, one can place an indwelling Foley catheter in the bladder or apply a urine collection harness.[248-252] During the collection period, horses usually are tied to minimize interference with the collection device.

The major causes of polyuria in horses include renal failure, pituitary pars intermedia dysfunction (PPID), and primary or psychogenic polydipsia.[70,252] Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus, diabetes mellitus, sepsis and endotoxemia, and iatrogenic causes (sedation with α_2-agonists, corticosteroid therapy, or diuretic administration).

RENAL FAILURE

Horses with acute renal failure usually have a transient period of anuria or oliguria. If horses survive the acute phase of renal disease, tubule damage results in a subsequent period during which impaired concentrating ability results in polyuria.[252,260] Urine is frequently hyposthenuric during this period of tubular repair. Owners should provide horses recovering from acute renal failure with adequate water, salt, and a low-nitrogen (protein) and low-calcium diet. Such a diet consists of good-quality grass hay or nonleguminous pasture. Repair of tubules and return of concentrating ability may take several weeks. Although these animals appear to have normal renal function after this recovery period, a permanent reduction in total renal function likely persists because most animals can maintain apparently normal health with only about 30% to 50% of functioning nephrons.

Chronic kidney disease may develop after damage from nephrotoxins. In addition, immune-mediated mechanisms,

* References 152, 153, 162, 165, 167, 194, 200, 247.

chronic infection, and nephrolithiasis may give rise to chronic kidney disease.[260,266,698] Horses that do not recover from the ischemic renal damage occurring with hypovolemic or endotoxic shock also may progress to chronic kidney disease. Signs vary and include polyuria and polydipsia in some cases. When present, polyuria and polydipsia are usually moderate compared with the dramatic increases in urine production observed with primary polydipsia or diabetes insipidus. Most horses with chronic kidney disease also exhibit other signs, including poor performance, weight loss, and ventral edema. A variable degree of azotemia is present, and urinalysis reveals isosthenuria (urine is isosmotic with plasma [260–300 mOsm/kg] with a specific gravity of 1.008–1.014).

The mechanisms of polyuria after acute and chronic kidney disease are not entirely clear.[158] Increased tubular flow rate in surviving nephrons is one possible mechanism that would result in less time for water removal from tubular fluid. Next, medullary hypertonicity may decrease because of diminished transport of sodium and chloride out of tubular fluid passing through the ascending limb of the loop of Henle (diluting segment of the nephron) along with increased blood flow through the remaining medullary tissue. A third possibility is impaired response of collecting ducts to vasopressin (acquired nephrogenic diabetes insipidus). Although all these mechanisms may contribute to the polyuria of renal failure, which particular mechanism may be the most influential is not known. Furthermore, because the horse can produce hyposthenuric urine during the recovery phase of acute renal failure, the mechanisms of polyuria differ somewhat for acute and chronic kidney disease.

PITUITARY PARS INTERMEDIA DYSFUNCTION

PPID is a common disorder of older horses that is often referred to as *equine Cushing's disease* because of its similarity to Cushing's disease in dogs and humans.[70,699-706] The clinical syndrome of PPID in horses is associated with hypertrichosis, laminitis, weight loss, and polydipsia and polyuria. The disorder is discussed in detail elsewhere in this text.

In one review of 17 horses with PPID, polyuria and polydipsia were found in 13 (76%)[706]; however, in another series of 21 horses with PPID, polyuria and polydipsia were not a historical complaint in any of the affected horses.[705] Thus polyuria and polydipsia associated with PPID are generally less severe than that observed with primary polydipsia or diabetes insipidus. PPID may lead to polyuria by several mechanisms. First, polyuria may result from actions of hormones derived from proopiomelanocortin, most specifically adrenocorticotropin. Hyperadrenocorticism resulting from excessive adrenocorticotropin activity on the adrenal cortex can lead to hyperglycemia, which may exceed the renal tubular threshold for reabsorption. The renal threshold for glucose in horses appears to be lower than in small animals (about 150 mg/dL).[287] When plasma glucose concentrations exceed this threshold value, the resultant glucosuria can lead to an osmotic diuresis. Although commonly implicated as the cause of polyuria in horses with PPID, glucosuria was found in only one of five affected horses in a clinical report.[705] Furthermore, horses with hyperglycemia and glucosuria still may be able to concentrate their urine in response to water deprivation.[702] A second mechanism implicated in the development of polyuria is cortisol antagonism of the action of vasopressin on the collecting ducts. Although frequently cited as the mechanism of polyuria in canine hyperadrenocorticism, experimental evidence to support this mechanism is lacking in dogs and horses. Furthermore, considerable species heterogeneity exists in the effects of corticoids on vasopressin activity, and in some species a primary dipsogenic effect may be more important. Next, growth of the pars intermedia may lead to impingement on the posterior pituitary and hypothalamic nuclei (located immediately dorsal to the pituitary gland), which are the sites of vasopressin storage and production, respectively. Decreased vasopressin production and release would result in a partial central diabetes insipidus as a third mechanism for polyuria.[699] Central diabetes insipidus, however, is not the cause of polyuria in all cases because some affected horses can concentrate their urine when deprived of water.[702] Consequently, the polyuria and polydipsia seen in many horses with PPID is likely the combined result of several mechanisms.

PRIMARY POLYDIPSIA

Although rare, primary or psychogenic polydipsia is probably the most common cause of polyuria and polydipsia in adult horses for which clients have a primary complaint of excessive water consumption and urination.[70,252] Primary polydipsia can be attributed to the fact that horses that exhibit this problem are generally in good body condition and are not azotemic. Furthermore, the magnitude of polyuria typically is much greater than that observed with renal failure or PPID. Owners may report that horses with primary polydipsia drink two to three times more water than their stablemates and their stalls often are flooded with urine. In some instances, primary polydipsia appears to be a stable vice that reflects boredom in affected horses, whereas in other cases it may develop after a change in environmental conditions, stabling, diet, or medication administration. Anecdotally, primary polydipsia is reported to be more common in southern states during periods of high temperature and humidity. In human beings, primary polydipsia can be a compulsive behavior associated with mental illness or may be caused by a primary abnormality in the osmoregulation of thirst, in which case it is referred to as *dipsogenic diabetes insipidus*.[5] The latter may be idiopathic or may occur after neurologic disease involving the hypothalamic osmoreceptors regulating thirst. Excessive water consumption causes expansion and dilution of body fluids, leading to a decrease in plasma osmolality and suppression of vasopressin release. With low plasma vasopressin concentrations, collecting ducts become impermeable to water, and hyposthenuria is induced to allow the rate of water excretion to balance intake. In human beings the magnitude of polydipsia and resultant polyuria varies considerably among affected persons, and similar variation, although undocumented, likely occurs in affected horses as well.

One diagnoses primary polydipsia by exclusion of renal failure and hyperadrenocorticism. In addition, other factors, such as excessive salt supplementation and medication administration, must be excluded. One excludes diabetes insipidus and confirms the diagnosis of primary polydipsia by demonstrating urine-concentrating ability after water deprivation.[194,200] Specific gravity should exceed 1.025 after water deprivation of sufficient duration (12–24 hours) to produce a 5% loss in body weight. In cases of long-standing polyuria, the osmotic gradient between the lumen of the collecting tubule and the medullary

interstitium may be diminished (medullary washout). In these cases, vasopressin activity may not lead to an increase in urine specific gravity to values greater than 1.020. Consequently, horses with primary polydipsia lasting several weeks that fail to concentrate their urine after 24 hours of water deprivation may be given a modified water deprivation test. One performs the test by restricting water intake to approximately 40 mL/kg/day for 3 to 4 days. By the end of this time, urine specific gravity should exceed 1.025 in a horse that has had medullary washout. If the urine specific gravity remains in the isosthenuric range (1.008–1.014), then one should evaluate the polyuric horse further for early chronic kidney disease, in which urine-concentrating ability may be compromised before the onset of significant azotemia. In theory, chronic kidney disease could occur when between two thirds and three fourths of functional nephrons have been lost. Subtle signs of decreased performance and mild weight loss also would support early renal failure. Finally, horses with primary polydipsia typically produce hyposthenuric urine. Although such dilute urine would be an unlikely finding in the early stages of chronic kidney disease, it could be found in the polyuric recovery phase after acute renal failure. In the latter instance a thorough history should reveal whether any event that may have been complicated by acute renal failure may have affected the horse recently.

Management of horses with primary polydipsia is empiric. Because the diagnosis is one of exclusion, once it is established that the horse is not suffering from significant renal disease, one may safely consider restricting water intake to meet maintenance, work, and environmental requirements of the horse. In addition, one should take steps to improve the attitude of the horse by reducing boredom. Increasing the amount of exercise and turning the horse out to pasture are possible options, as well as providing a companion or toys in the stall. Increasing the frequency of feeding or the amount of roughage in the diet also may increase the time spent eating and thus reduce the habitual drinking.

EXCESSIVE SALT CONSUMPTION

In an occasional case of apparent primary polydipsia, polyuria and polydipsia may be attributed to excessive salt consumption and are manifested by increased fractional sodium clearance. Psychogenic salt eaters appear to be less common than psychogenic water drinkers, because the former would have to consume a substantial amount of salt to develop polyuria. In fact, the authors are aware of only one well-documented report of psychogenic salt eating in which a yearling Paint filly drank in excess of 500 mL/kg/day and had excessive urination when provided free access to salt.[326] The fractional clearances of sodium (3.4%) and chloride (2.6%) were increased and supported excessive intake. Although salt intake was not quantified for this filly, it may have exceeded 10% of the dry matter intake and appeared to be associated causally with muscle fasciculations and a stilted gait. Such a high salt intake is suggested because no increases in water consumption or urine volume were detected in one study in which ponies were fed diets containing 1%, 3%, and 5% of NaCl.[171] The 5% NaCl diet contained 5 to 10 times the daily requirement of NaCl and was similar to feeding about 350 g of NaCl daily to a 500-kg horse. Similar to cases of primary polydipsia, the filly described in this report was able to concentrate urine in response to water deprivation, and the problem was managed successfully by limiting water intake to 50 mL/kg/day and preventing access to salt.

DIABETES INSIPIDUS

Diabetes insipidus results in polyuria and polydipsia because of vasopressin deficiency or insensitivity of the renal collecting duct epithelial cells to vasopressin. In human beings, vasopressin deficiency, central or neurogenic diabetes insipidus, is the more common form, with hereditary and acquired forms being described. The hereditary form appears to result from decreased numbers of neurosecretory neurons in the supraoptic nuclei of the hypothalamus and is inherited in an autosomal dominant fashion. However, polyuria and polydipsia do not develop until after the first few years of life in affected persons, suggesting progressive loss of neurosecretory tissue. The acquired form of neurogenic diabetes insipidus results from degeneration of neurons in the supraoptic nuclei after trauma, vascular abnormalities, infection, a variety of tumors, or occasionally pressure from pituitary enlargement (PPID).[5,707,708] As with the hereditary form, polyuria and polydipsia usually are not manifested until 80% to 90% of the neurosecretory neurons are destroyed.

In equids, two well-documented cases of neurogenic diabetes insipidus have been described.[363,364] Neither animal could concentrate urine in response to water deprivation, but administration of exogenous vasopressin resulted in an increase in urine concentration and a decrease in urine volume. In a Welsh pony in which the condition was considered idiopathic, the absence of an increase in plasma vasopressin concentration after water deprivation (compared with control ponies) further supported a diagnosis of neurogenic diabetes insipidus.[364] Acquired neurogenic diabetes insipidus after encephalitis was confirmed histologically in the other horse.[363] Two other reports of diabetes insipidus in horses more likely described cases of primary polydipsia because both animals demonstrated an ability to concentrate urine during water deprivation or had random urine specific gravities greater than 1.020.[709,710]

Nephrogenic diabetes insipidus results from resistance of the cortical and medullary collecting ducts to the antidiuretic action of vasopressin.[5,707,708] In the absence of systemic disease, nephrogenic diabetes insipidus is most commonly a familial disorder in human beings with an X-linked semirecessive mode of inheritance. As such, the disorder is carried by females and expressed in male offspring.[711] Nephrogenic diabetes insipidus has been reported in three colts, two of which were sibling Thoroughbreds, suggesting that an inherited form of nephrogenic diabetes insipidus also may occur in horses.[56,712] Two of the three colts were underweight for their age. Affected colts could not increase urine concentration in response to water deprivation, although they did show appropriate increases in plasma vasopressin concentration. Furthermore, minimal response to exogenous vasopressin administration in all three colts confirmed resistance of the cortical and medullary collecting ducts to the antidiuretic action of vasopressin.

Nephrogenic diabetes insipidus also may be acquired after drug therapy or a variety of metabolic, infectious, or mechanical (postobstruction) disorders. Anomalous or neoplastic disorders resulting in structural deformation of the kidneys are another potential cause of nephrogenic diabetes insipidus.[5,707,708] Necropsy and histopathology revealed no lesions in one colt and few focal interstitial aggregates of lymphocytes, plasma cells, and rare areas of interstitial fibrosis in the kidneys with focal necrosis of the renal pelvis and ureteral epithelium

in another.[56] Histopathologic lesions found in renal biopsies from one case[712] included severe vacuolization and intracytoplasmic eosinophilic granular changes in distal collecting duct epithelium and occasional slightly increased cellularity of glomeruli. However, these lesions were apparently reversible and not observed in repeat biopsies performed later, after dietary and supportive therapy for diabetes insipidus.

Neurogenic and nephrogenic forms of diabetes insipidus share some similarities in pathogenesis. Polyuria because of a lack of vasopressin activity results in net water loss and an increase in plasma osmolality. As plasma osmolality increases, stimulation of thirst results in a compensatory increase in water consumption. In normal individuals and those with nephrogenic diabetes insipidus, the osmoreceptors in the hypothalamus sense the increase in plasma osmolality and subsequently signal for vasopressin release. As little as a 1% increase in plasma osmolality (about 3 mOsm/kg) results in a 1-pg/mL increase in plasma vasopressin concentration. In normal individuals, this small change is substantial enough to increase urine osmolality and decrease urine flow. With greater increases in plasma osmolality, more vasopressin is secreted. In human beings, urine osmolality approaches a maximum after an increase in vasopressin concentration to about 5 pg/mL (from a resting value of about 1 pg/mL).[5,708]

Limited studies in ponies and horses suggest that a similar degree of vasopressin release occurs in response to minor increases in plasma osmolality[179,182,183]; however, vasopressin also appears to be a "stress hormone" in horses because substantially greater concentrations (tenfold higher than those induced by water deprivation) have been measured after application of a nose twitch, nasogastric intubation, or exercise.[185] Thus increases in plasma vasopressin concentration after water deprivation would be expected to vary in horses, and separating osmotic effects from stress effects in an individual horse may be difficult. A word of caution also is warranted about subjecting horses suspected of having diabetes insipidus to water deprivation. Because urine-concentrating ability may show minimal improvement with either form of diabetes insipidus, affected horses may continue to excrete excess water in the face of water deprivation. As a result, they may become substantially dehydrated (10%–15%) within the first 12 hours of water deprivation. Thus one should carefully monitor horses suspected of having diabetes insipidus during the period of water deprivation to decrease the risk of inducing serious hypertonic dehydration.

The Hickey-Hare test to diagnose diabetes insipidus involves infusion of hypertonic (2.5%) saline (0.25 mL/min/kg IV for 45 minutes) to stimulate vasopressin release and water retention.[712] Normal animals will respond with concentrated urine and reduced urinary volume after sodium infusion. Horses with diabetes insipidus did not concentrate urine after hypertonic saline administration.[56,712]

In addition to assessing the effects of water deprivation on urine-concentrating ability and plasma vasopressin concentrations, the final diagnostic manipulation is often administration of exogenous vasopressin (2.5 mU/kg in 5% dextrose [5 U vasopressin/L] constant rate infusion over 60 minutes or 0.5 U/kg intramuscularly [IM]).[713] In normal horses, urine specific gravity should increase to at least 1.020 at 60 to 90 minutes after vasopressin administration. Alternatively, DDAVP, a synthetic vasopressin analog, may be used. DDAVP is available as a nasal solution (0.1 mg/mL) for humans with central diabetes insipidus. The nasal spray can be diluted in sterile water and administered (0.05 μg/kg IV) for the diagnosis of diabetes insipidus in horses. Normal horses that underwent experimentally induced diuresis by repeated dosing of water via nasogastric tube increased urine specific gravity to greater than 1.020 from 2 to 7 hours after administration of DDAVP.

The medullary interstitial osmotic gradient develops as a result of countercurrent exchange, and the magnitude of the gradient is related inversely to tubular flow. Medullary washout may occur with the high tubular flow rates that can accompany renal disease. Although partial medullary washout may contribute to the concentrating defect in diabetes insipidus, the rapid response to exogenous vasopressin administration in cases of neurogenic diabetes insipidus (increase in urine osmolality to 900 mOsm/kg or greater) indicates that the medullary concentration gradient is not severely compromised.[5,714] This response further explains why in some cases of diabetes insipidus, urine osmolality can be greater than plasma osmolality after water deprivation. The mechanism for this response is thought to be a decrease in tubule flow rate that allows more time for passive water extraction from the hypoosmotic tubular fluid. With nephrogenic diabetes insipidus, one also may observe mild improvement in urine-concentrating ability (an increase in urine osmolality up to 500 mOsm/kg) in response to exogenous vasopressin administration. This response has been attributed to partial sensitivity of the collecting ducts to vasopressin and to vasopressin activity at other portions of the renal tubule.[5,707]

Treatment of diabetes insipidus should aim to manage polydipsia and polyuria. With neurogenic diabetes insipidus, recovery of vasopressin secretion is rare once the secretory neurons have degenerated to the degree that polyuria and polydipsia become apparent. Consequently, treatment consists of hormone replacement. In the past, intramuscular injection of Pitressin tannate in oil every 2 to 3 days was successful in limiting polyuria; however, development of resistance or allergic reactions was an occasional problem, and long-acting vasopressin formulations are no longer available. Vasopressin has relatively short antidiuretic effects and a short plasma half-life, which makes replacement therapy in horses difficult.[715] With the development of potent vasopressin analogs (desmopressin), effective treatment by nasal insufflation is now available.[5] Desmopressin eye drops have also been used to increase urine specific gravity in a foal with central diabetes insipidus.[716] The use of desmopressin for diagnosis and treatment of neurogenic diabetes insipidus in small animals has been described.[714,717] Largely by chance, other oral medications, including chlorpropamide and clofibrate, have been found efficacious in treating neurogenic diabetes insipidus. The mechanism of action of these drugs is uncertain, but they are thought to potentiate the effect of vasopressin on the collecting ducts.[5,714]

With nephrogenic diabetes insipidus, replacement hormone therapy is ineffective, and the only practical form of treatment for many years has been to restrict sodium and water intake or to administer thiazide diuretics. The latter treatment may reduce polyuria by 50% in many cases.[5] Thiazide diuretics inhibit sodium reabsorption in the distal tubule (diluting segment of the nephron) and increase solute delivery to the collecting duct. The mechanism by which such therapy paradoxically benefits patients with nephrogenic diabetes insipidus is poorly understood. Explanations include enhanced proximal tubular fluid reabsorption (via glomerulotubular balance) and decreased glomerular filtration and tubular flow

(via a greater osmotic stimulus to the macula densa and subsequent tubuloglomerular feedback).[5,708] Treatment with prostaglandin inhibitors or amiloride has also decreased polyuria in patients with nephrogenic diabetes insipidus. The former agents probably work by decreasing renal blood flow and glomerular filtration, whereas the latter drug, a sodium channel blocker, is thought to act in a manner similar to the thiazide diuretics.[5] One horse clinically improved with only dietary salt restriction (no additional salt other than what was contained in feed) and limited but regular access to water.[712]

DIABETES MELLITUS

Diabetes mellitus is a state of chronic hyperglycemia usually accompanied by glucosuria.[277,718] The resultant osmotic diuresis is an occasional cause of polyuria and polydipsia in horses that has been described to result in a water intake exceeding 80 L/day.[719,720] Type 1 (insulin-dependent) diabetes mellitus results from a lack of insulin that in human beings is usually attributable to viral or autoimmune disease. Those with type 2 (non–insulin-dependent) diabetes mellitus have normal to high insulin concentrations, but their tissues are insulin insensitive. Thus the response to an oral carbohydrate load or an intravenous glucose challenge is impaired, resulting in prolonged hyperglycemia.[718] The mechanism of insulin resistance is not well documented for horses but may result from insulin antagonism, decreased numbers of insulin receptors, or lack of insulin receptor activation in response to insulin binding. The most common causes of equine non–insulin-dependent diabetes mellitus are equine metabolic syndrome and PPID, both of which are discussed in detail elsewhere in this text.[700-704]

Although very uncommon, a few reports describe insulin-dependent and non–insulin-dependent diabetes mellitus that were not caused by PPID or equine metabolic syndrome and that resulted in polyuria and polydipsia as one of the presenting complaints.[719-724] Diagnostic evaluation reveals consistent hyperglycemia but negative dexamethasone suppression test results (a normal decrease of plasma cortisol to low concentrations). Treatment in most instances is supportive, although replacement insulin therapy may be helpful in cases in which measured serum insulin concentrations are low (insulin-dependent diabetes mellitus). In one case of pancreatic β-cell failure,[720] treatment with glyburide (0.02 mg/kg) and metformin (1.9 mg/kg) lowered interstitial fluid glucose concentrations to normal ranges. Insulin therapy may be of some benefit in horses with elevated serum insulin concentrations because pharmacologic doses in part may overcome the insulin insensitivity. In such cases, synthetic insulin products may be preferable over protamine zinc insulin, because one horse with PPID and secondary diabetes mellitus developed antiinsulin antibodies and had a relapse in clinical signs after 7 weeks of insulin therapy.[704]

SEPSIS AND ENDOTOXEMIA

Polyuria and polydipsia also have been reported as clinical signs in horses with sepsis or endotoxemia, although other clinical signs such as fever, abdominal pain, and weight loss predominate.[725] The mechanism is unclear but may result from endotoxin-induced prostaglandin production. Prostaglandin E_2 is a potent renal vasodilating agent in laboratory animals, and it antagonizes the effects of antidiuretic hormone on the collecting ducts.[186] Some horses with chronic gram-negative bacterial infections (e.g., peritonitis, pleuritis) may have low-grade or intermittent endotoxemia as a mechanism for polyuria, similar to the polyuria observed with canine pyometra.[726]

IATROGENIC POLYURIA

Finally, polyuria can be iatrogenic, occurring after a number of management practices or medical treatments. The most obvious iatrogenic cause is fluid therapy, for which polyuria is a desired response. Polyuria also has been observed with exogenous corticoid administration, although as for PPID the mechanism remains unclear. Human beings and dogs appear to experience a potent thirst response to exogenous corticoids; thus polydipsia may be an important cause of the polyuria observed. In horses receiving long-term dexamethasone treatment for immune-mediated disorders, one may observe profound glucosuria (2–3 g/dL) that leads to osmotic diuresis in these patients. Finally, transient diuresis or polyuria accompanies sedation with the α_2-agonists xylazine and detomidine.[14,15] Although these agents cause hyperglycemia for a few hours after administration, and occasionally glucosuria, a more likely mechanism for the transient polyuria is the existence of α_2-adrenoreceptors on collecting duct epithelial cells. Activation of these receptors is another mechanism of vasopressin antagonism.[16]

Renal Tubular Acidosis

Warwick M. Bayly

The veterinary profession recognizes well that horses with acute or chronic kidney disease are frequently acidotic. These animals are almost invariably azotemic, hypochloremic, and normokalemic or hyperkalemic and frequently have significant abnormalities on urinalysis. A less frequent renal disease associated with acidosis is renal tubular acidosis (RTA). RTA is a clinical syndrome of impaired renal acidification characterized by a hypokalemic, hyperchloremic acidosis without azotemia. Affected horses frequently have normal urinalysis. The condition has been well described in human beings,[727-729] and several case reports documenting its existence in horses have appeared since the mid-1980s.[730-738]

The causes and pathogenic mechanisms responsible for the development of RTA are ill understood. In human beings RTA may be primary (genetic or idiopathic) or secondary, occurring after a variety of conditions, including hyperglobulinemia, various autoimmune disorders, kidney disease such as polynephritis and obstructive uropathy, cirrhosis, drug- or toxin-induced nephropathies (including amphotericin B), metabolic disorders involving nephrocalcinosis, and a number of genetic diseases. All reported equine cases apparently have been idiopathic, because no signs of primary renal, hepatic, or immune-mediated disease or disturbance of calcium metabolism have been evident, and the horses have had no history of access to toxins. In some cases, however, low-grade renal tubular disease has been suspected because of mild proteinuria.

General agreement is that three types of RTA exist.[155] Type 1, also known as *distal* or *classic RTA,* arises from the inability of the cells of the distal tubule to establish a steep hydrogen ion gradient between the blood and the urine. This inability results from failure of normal H^+ excretion from the distal tubules. In many cases, this gradient may be less than 10:1. Whether

TABLE **14.12 Features Used to Differentiate Type 1 and Type 2 Renal Tubular Acidosis**

Variable	Type 1	Type 2
Acidosis	Severe	Less severe, self-limiting
Hypokalemia	Severe	Mild to moderate
Glycosuria, proteinuria	Absent	Often present
Urine pH during mild/moderate acidosis	Inappropriately high	Inappropriately high
Severe acidosis	Inappropriately high	Normal
Effect of alkali administration	Decreases or worsens hypokalemia, depending on stage of disease	Worsens hypokalemia
Amount of HCO_3^- needed to correct acidosis	Low	High
Ammonium chloride challenge	Failure to excrete acid (urine does not acidify)	Urine pH decreases
Bicarbonate loading	Filtered bicarbonate is reabsorbed	Bicarbonate is lost in the urine

or not this low ratio is caused by an insufficient number of proton-secreting pumps in the distal nephron or by H^+ diffusing back across the lumenal membrane after being secreted is not clear. Accelerated K^+ secretion occurs because of the existing electrochemical driving forces in the distal nephron and the lack of protons to offset them. In addition to having high urinary K^+ clearance, patients may be hypercalciuric and hyperphosphaturic, although in horses this may be difficult to assess. Equine urinary concentrations of K^+ and Ca^{+2} in particular are high. In human beings, about 70% of adults with distal RTA develop some form of urolithiasis.[739] This condition has not been recognized in the few reported equine cases and may not be, given the significant differences between the two species.

Type 2, or proximal, RTA is caused by a failure of HCO_3^- resorption in the proximal tubule. This part of the nephron usually reabsorbs the bulk of the filtered HCO_3^- via Na^+ and H^+ exchange and the subsequent breakdown of carbonic acid to carbon dioxide and water under the influence of carbonic anhydrase. Disruption of normal Na^+ and H^+ exchange or carbonic anhydrase activity therefore results in excess flow of HCO_3^- to the distal tubule where the ability to resorb the anion is poor. This bicarbonaturia also results in accelerated K^+ secretion and hypokalemia. In humans with this form of the disease, the suggestion is that a reduction occurs in the threshold concentration at which HCO_3^- is reabsorbed from the proximal nephron. As a result, reabsorption resumes once serum HCO_3^- concentration drops below this threshold, and a new steady state is said to develop. More likely because of the urinary HCO_3^- loss, plasma HCO_3^- concentration decreases, as does glomerular filtration of HCO_3^-. Eventually the distal tubule reaches a point at which it can handle the amount of HCO_3^- presented. Urine pH may start to decrease because of the lower amount of HCO_3^- being excreted. A new steady plasma HCO_3^- concentration is established, albeit considerably below the normal range, and acid-base homeostasis may return gradually. Consequently, type 2 RTA often appears to be self-limiting in humans.[740] This form of the disease occurs rarely by itself in humans and almost always is associated with other proximal tubule dysfunction such as defective resorption of glucose, amino acids, and phosphate (Fanconi syndrome). Type 2 RTA has been reported in two horses.[730]

Fanconi syndrome has been rarely reported in horses, either experimentally with mercuric chloride toxicity[535] or as an idiopathic transient syndrome of weight loss, glucosuria, lactic aciduria, and aminoaciduria in two adult Quarter Horses.[741] A metabolic screening test that detects carbohydrates and organic acids in urine for the diagnosis of Fanconi syndrome in dogs has also been applied to horses. Animals with Fanconi syndrome have aminoaciduria and possibly proteinuria with other indications of tubular disease such as glycosuria, bicarbonaturia, and lactic aciduria. One of the Quarter Horses reported by Ohmes and colleagues[741] had chronic kidney disease, but both horses responded within days to months with intravenous and oral supplementation of bicarbonate and potassium.

Type 4 RTA is characterized by hyperkalemic, hyperchloremic acidosis and is common in humans, but it has not been reported in horses. Type 4 RTA apparently is associated with hypoaldosteronism or resistance of the distal nephron cells to the effects of aldosterone. As a result, the renal clearance of K^+ and H^+ is reduced. The associated natriuresis ultimately may lead to a reduced ability to concentrate urine because of "washout" of the medullary concentrating gradient, if the condition becomes chronic. Another form of RTA (type 3), which formerly had been described as having characteristics of type 1 and type 2 RTA, now is considered to be a variation of type 1.[155]

Differentiating between the distal (H^+ retention) and proximal (HCO_3^- wasting) forms of RTA is theoretically important if the approach to the human form of the disease is any guide, because in human beings the two types differ with respect to clinical severity, treatment, and prognosis.[742] The ability to differentiate between the forms of RTA in horses appears to be less critical, because treatment does not seem to differ much according to the suspected type. Table 14.12 summarizes some differential characteristics of the two types of RTA. In humans with type 2 RTA, plasma HCO_3^- concentrations tend to be higher than those associated with the distal form of the disease, but this does not appear to be the case in horses, because all the horses the author has seen, plus those that have been described in the literature, have been severely acidotic (HCO_3^- concentrations 10 mmol/L or less). In horses, differentiation between the distal and proximal types of RTA has been based on measurement of urine pH. Evaluation of urine ammonium excretion, urine net charge or anion gap, and urinary P_{CO_2} have not been reported in horses, although they are regarded as critical to the specific differentiation of RTA in humans.[156,743,744] Because of the alkalinity of normal equine urine, measurement of urine P_{CO_2} is probably of little

benefit. With type 1 RTA, urine pH tends to stay high (i.e., in the normal to alkaline range). In type 2, urine pH is generally neutral or slightly acidic. A suggested way of making this differentiation is to assess the urinary response to the administration of the urine-acidifying agent ammonium chloride (0.1 g/kg). Typically, one gives this solution orally, and it should lower the urine pH to less than 7.0, which it supposedly does in normal horses and those with type 2 RTA. In cases of distal (type 1) RTA, the urine pH remains high in the face of the increased acid load. Because the administration of such acidifying agents potentially could worsen the degree of acidosis in cases of type 2 RTA (as a result of reduced buffering capacity), performance of this test is not recommended until one has attempted at least partial replacement of the HCO_3^- deficit. In the author's experience, the ammonium chloride challenge test has proved unreliable, having failed to acidify the urine of normal healthy horses even when given intravenously. The dose and rate of administration may need to be increased before the test can be considered worthwhile. A more suitable alternative may be to infuse sodium sulfate as is done sometimes in humans.[727] The author could find no reports of the use of this test in horses.

Another diagnostic option that may be worthy of investigation in horses is calculation of the urine net charge. As in any body fluid, the sum of urinary cations must equal the sum of its anions. Therefore in urine,

$$Na^+ + K^+ + Mg^{2+} + NH_4^+ = Cl^- + HPO^- + SO^- + \text{other urine buffers} + \text{organic anions}$$

In human beings, Ca^{2+} and Mg^{2+} tend to be present in urine in small constant quantities. Excretion of HPO^-, SO^-, titratable buffers, and organic anions is also constant and exceeds the Ca^{+2} and Mg^{+2} by an amount that is referred to as the *urine anion gap* (AG_u). Thus

$$Na^+ + K^+ - Cl^- = AG_u + NH_4^+$$

The expression ($Na^+ + K^+ - Cl^-$) is referred to as the *urine net charge* and reflects the excretion of NH_4^+.[156] Given the aforementioned plasma electrolyte and acid-base abnormalities, type 2 RTA has been shown likely to exist when the urine net charge is negative (i.e., Cl^- greater than [$Na^+ + K^+$]) because NH_4^+ is greater than AG_u. In other words, H^+ continues to be secreted normally from the distal tubule and plenty of NH_4^+ is being produced. When ($Na^+ + K^+$) is greater than Cl^-, the net charge is positive, indicating that NH_4^+ excretion is low because of failure to excrete H^+ (i.e., type 1 or distal RTA exists).

No breed or sex predilection exists for RTA in horses, and the average age for 16 affected horses was 7 years.[737] The most common clinical signs in affected horses are depression, poor performance, weight loss, and anorexia. Various other signs such as chronic weight loss, ataxia, dysphagia, and periodic collapse also have been reported. The latter three signs may be manifestations of severe weakness, which probably is caused by the severe hypokalemia. The reduced K^+ concentration also may be associated with bradycardia.

On clinical examination, affected horses are usually afebrile. Mild icterus is common, presumably because of anorexia, although significant indirect hyperbilirubinemia and increases in serum activities of GGT and ALP have been observed. Although cirrhosis of the liver has been associated with the development of RTA in human beings, equine cases that the author is aware have demonstrated no clinicopathologic changes compatible with severe liver disease. Sulfobromophthalein clearance half-time was normal in the one case in which it was measured.[731]

One should suspect RTA whenever a horse has a severe hyperchloremic metabolic acidosis in the absence of any obvious cause of extrarenal hypovolemia such as diarrhea or small intestinal ileus. In such cases, the plasma anion gap usually is widened, whereas with RTA it remains normal. However, hypoalbuminemia may mask widening of the anion gap because albumin is normally responsible for much of the normal anion gap.[745] Therefore the anion gap value should be smaller in hypoalbuminemic horses. Azotemia has not been recognized in horses with RTA, although signs of tubular dysfunction, such as mild proteinuria and increases in fractional K^+ clearance and urine GGT activity, have been observed. Renal biopsy and ultrasonic examination of the kidneys are normal.

Definitive diagnosis of RTA is based on the demonstration of severe hypokalemia (2.3 mmol/L or less) and a urine pH that is generally neutral or alkaline in the face of a severe acidosis (venous blood pH less than 7.15), although theoretically one could observe a slight aciduria with type 2 RTA. Hypokalemia in the face of severe acidosis is uncommon. Classically, the reverse is expected because of intracellular buffering of H^+ and the reciprocal role of H^+ and K^+ in maintaining electroneutrality of the extracellular fluid. Occasionally, serum chloride concentrations are in the high normal range rather than being elevated. Blood gas measurement usually reveals some degree of compensatory respiratory alkalosis ($Paco_2$ = 25–35 mm Hg).

The differential diagnosis of RTA should be included for any animal that has sudden weakness, depression, and possible collapse: cardiovascular failure, neurologic disease (including rabies), hypoglycemia, and peracute toxemia or endotoxemia. One usually can rule out all of these based on a thorough physical examination. These findings, plus demonstration of the aforementioned electrolyte and acid-base abnormalities, suggest RTA. Conditions such as hypokalemic periodic paralysis, Addison's disease, pituitary pars intermedia dysfunction, and chronic corticosteroid or diuretic use could cause some of these clinicopathologic disturbances but not the combination of hyperchloremia, acidosis, hypokalemia, and a normal plasma anion gap.

Prompt recognition of the disease and quick institution of therapy are important because the untreated condition is potentially fatal. All reported equine cases of RTA have responded satisfactorily to treatment, as have the cases that the author has seen. Although the ability to differentiate between type 1 and type 2 RTA may be important in humans from a therapeutic perspective, the distinction has not seemed to be essential in horses. Regardless of the suspected type of the disease, treatment of the condition in horses is associated with HCO_3^- and K^+ replacement therapy. Although the administration of $KHCO_3$ would seem to be ideal, it is not readily available, and the need for prompt therapy means that treatment usually involves a combination of orally administered KCl and intravenously administered $NaHCO_3$ and KCl. It must be emphasized that one should not give $NaHCO_3$ without some form of potassium supplementation to ensure that hypokalemia does not get worse. Generally, a steady improvement in the patient occurs after 12 to 24 hours of treatment. Oral fluids usually are given 4 to 6 times per day for the first 48 hours, whereas intravenous fluids frequently

are given at a slow but steady rate. Inclusion of glucose or dextrose in intravenous fluids helps to promote intracellular uptake of K^+. Serum chloride concentration usually decreases as HCO_3^- concentration increases. In the author's experience, a steady improvement occurs in HCO_3^- concentration and tends to improve more rapidly than K^+ concentration. Serum concentrations of potassium appear to be slower to return to normal, possibly because intracellular stores are replaced first. Estimating the total potassium deficit before the onset of treatment is impossible because of the huge intracellular deficit these animals suffer. In the author's experience, total deficits of K^+ frequently exceed 4000 mmol.

With correction of the acid-base and electrolyte disturbances, muscle strength and appetite generally return within 48 hours of the onset of treatment. At this point, one usually can reduce potassium supplementation and subsequently discontinue it once the forage intake of the horse has returned to normal. Obviously, giving the horse a diet that includes ample amounts of good quality hay is important because of the high potassium content of this feedstuff. Bicarbonate therapy generally continues longer, although one usually discontinues intravenous fluids with return of appetite. Long-term oral supplementation with sodium bicarbonate is often required for the maintenance of normal acid-base status. Periodic rechecking is advised until it becomes clear that the condition is stable. Long-term follow-up of cases that the author has seen and those that have been reported in the literature suggest that the prognosis is favorable, but horses with evidence of renal disease may be more likely to relapse.[737]

Neoplasia of the Urinary Tract

Harold C. Schott II

Neoplasia of the urinary tract in horses is uncommon.[64,70,95,746-748] Primary renal neoplasms, which represent fewer than 1% of all equine tumors, include adenomata, renal cell carcinomata, and nephroblastomata.[749-751] Renal adenomata are small well-circumscribed lesions in the renal cortex that are usually incidental necropsy findings.[25]

The most commonly reported and best-described renal tumor in the horse is renal cell carcinoma or adenocarcinoma.[674,675,750-760] These neoplasms arise from the epithelium of the proximal convoluted tubules in most cases. In human beings, renal cell carcinomata are known as the *internist's tumor* because of their diverse and often obscure presenting signs. Although a classic triad of symptoms including flank pain, gross hematuria, and palpable renal mass has been described, these symptoms occur in fewer than 10% of affected human beings at presentation.[5] Similarly, affected horses usually have nonspecific presenting complaints, including poor performance, depression, weight loss, and recurrent colic (Table 14.13).[751] A paraneoplastic process leading to severe hypoglycemia has been reported in two cases of equine renal cell carcinoma, probably caused by production of an insulin-like factor, an abnormal variant of insulin-like growth factor II, or less likely from excessive glucose use by the tumor.[758,759] More specific clinical signs that increase suspicion of renal cell carcinoma include hematuria and detection of a palpable mass on rectal examination (see Table 14.13).[751] Renal cell carcinomata are typically unilateral, and the contralateral kidney maintains normal renal function. Therefore indices of renal function such as BUN and creatinine concentration are usually normal. A retrospective study reported leukocytosis with mature neutrophilia in 59% of cases and hyperfibrinogenemia in only 33%.[751] Abdominocentesis revealed hemoabdomen or exfoliated neoplastic cells in 71% of cases. Although nephrectomy is the treatment of choice in human beings, tumors are typically large and adherent to surrounding organs, especially local vascular structures, by the time that they are detected in horses. Thus surgical removal usually is not possible. Furthermore, frequent metastases (see Table 14.13) usually make renal adenocarcinoma an untreatable problem. The poor prognosis can be attributed to the fact that clinical signs of intraabdominal neoplasia in horses often are not apparent until the disease is advanced.[761] In one report of renal carcinoma, clinical signs of the tumor were absent until the horse was anesthetized for laryngeal surgery. After an uncomplicated surgery, the horse was repositioned for recovery but died shortly thereafter. Compression of the caudal vena cava by a large renal carcinoma was suspected to have led to a decrease in venous return as the cause of sudden death.[762] In another horse, clinical signs were not observed until bony metastasis to the olecranon caused lameness.[760]

Other neoplastic diseases that may affect the kidneys include nephroblastoma,[763-765] transitional cell carcinoma,[761,766] and squamous cell carcinoma.[767] Nephroblastoma (Wilms' tumor) is an embryonal tumor that arises in primitive nephrogenic tissue or in foci of dysplastic renal tissue, whereas the latter tumor types arise from the uroepithelium of the renal pelvis or ureter.[25] Papillary renal adenoma of distal nephron differentiation has been described as an incidental finding during necropsy of an aged mare.[768] Neoplastic involvement of the upper urinary tract also may occur with dissemination of lymphosarcoma, hemangiosarcoma, melanoma, or adenocarcinoma arising from other tissues in the abdomen.[25,95,749,761,769]

Finally, although they are not truly cancerous disease processes, mucinous hyperplasia of the renal pelvic and proximal ureteral uroepithelium or ureteropelvic polyp formation can lead to development of a tissue mass in either kidney, ureteral obstruction, and hydronephrosis.[41,770] Renal mucous gland cystadenomas have been found incidentally at necropsy.[771] Mucous gland hyperplasia of the renal pelvis or proximal urethra are differentiated from cystadenomas by their thin fibrous connective tissue capsule, compression of adjacent renal parenchyma, multiple proliferative intraluminal papillary projections, and large mucus-filled cystic lumens.

In addition to rectal palpation for a mass in the area of either kidney and examination of urine for red blood cells (hematuria), ultrasonographic evidence of a tissue mass destroying the normal architecture of the kidney would support renal neoplasia. Unfortunately, attempts to establish a definitive antemortem diagnosis were successful in only two previous case reports. In the first case, neoplastic cells were detected on analysis of peritoneal fluid,[755] whereas percutaneous biopsy of the tissue mass in a second horse demonstrated neoplastic tissue. Renal biopsy should be performed with caution as neoplasia can increase the risk of complications such as hemorrhage and colic. An ultrasound-guided renal biopsy is recommended to ensure sampling of the suspected mass. However, histopathologic examination may be inconclusive as renal neoplasms can often have poor histologic detail.[750] The majority of renal carcinomas are definitely diagnosed during postmortem examination. Thus these procedures are warranted in all horses with a mass consistent with a renal neoplasm. In addition to

TABLE **14.13 Clinical Features of 15 Horses with Renal Cell Carcinoma**

Breed	Age (Years)	Sex	Unilateral or Bilateral	Presenting Complaint	Weight Loss	Pain/Colic	Hematuria	Palpable Mass on Rectal Examination	Azotemia	Postmortem Findings	Reference
American Saddlebred	15	G	Bilateral	Recurrent colic	Yes	Yes	No	Yes	No	25-cm-diameter renal calculus, metastases to liver and other kidney	752
Albino	10	F	Unilateral, left	Abortion and ascites	No	No	No	Yes	Mild	75-cm-diameter, 31-kg mass, metastases to peritoneum	754
Standardbred	16	F	Unilateral, right	Weight loss, hematuria	Yes	No	Yes	Yes	No	30-cm-diameter, 8-kg mass, adhesions to liver and bowel, no metastases	754
Thoroughbred	16	F	Unilateral, left	Weight loss	Yes	No	Yes	Yes	Mild	35-cm-diameter, 20-kg mass, hemoperitoneum, no metastases	755
Thoroughbred	16	F	Unilateral, right	Weight loss, soft feces	Yes	No	No	No	Mild	Metastases to liver and lungs	756
Pony	15	G	Unilateral, left	Weight loss, hematuria	Yes	No	Yes	Yes	No	6.6-kg mass, metastases to liver and lungs	757
Pony	10	G	Unilateral, right	Weight loss, back pain, colic, polyuria/ polydipsia	Yes	Yes	Yes	No	No	6-cm-diameter mass hemoperitoneum, no metastases	757
Thoroughbred	4	G	Unilateral, left	Respiratory noise	No	No	NR	NR	No	30-cm-diameter mass, local invasion of sublumbar muscles	757
Grade	7	G	Unilateral, right	Hematuria, followed by weight loss and colic	Yes	Yes	Yes	No	Mild	40-cm-diameter, 23-kg mass, hemothorax and hemoperitoneum, metastases to liver and lungs	757
Thoroughbred	9	F	Unilateral, right	Recurrent colic, weight loss	Yes	Yes	No	Yes	No	30-cm-diameter mass, metastases to omentum and muscle	674
Shire	4	F	Unilateral, right	Hematuria, followed by weight loss	Yes	Yes	Yes	Yes	No	65-cm-diameter, 47.7-kg mass, adhesions to liver and bowel, no metastases	675
Grade	14	F	Unilateral, left	Pyrexia, hematuria, diarrhea	Yes	No	Yes	Yes	No	5-kg mass; metastases to liver, pancreas, and lungs	758

Mustang[a]	14	G	Unilateral, right	Collapse Hypoglycemia Colic Anorexia Diarrhea	Yes	Yes	No	No	No		760
Thoroughbred[a]	6	G	Unilateral, right	Depression Head pressing Obtunded Weight loss Weakness	Yes	Yes	No	Yes	No	35-kg mass, duodenum and jejunum loosely adhered to mass, metastases to liver	759
Arabian	21	G	Unilateral, right	Forelimb lameness Poor appetite	No	Yes	No	NR	NR	2 × 5–cm extrarenal mass at cranial pole of kidney, single metastasis to lung	5

[a]Paraneoplastic syndrome (hypoglycemia).

analyzing urine for hematuria, cytologic examination of urine for neoplastic cells is also indicated.[565]

The most common presenting complaint for bladder neoplasia is hematuria.[565,680,772] Unlike dogs, in which transitional cell carcinoma is the most commonly described bladder neoplasm, squamous cell carcinoma has been reported most frequently in horses.[565,680,773] Squamous epithelial cells are found to occur in the normal equine bladder, and it has been suggested that this may be the reason squamous cell carcinoma is more common in the horse than transitional cell carcinoma, which is a common bladder neoplasm in other species.

Other types of bladder neoplasms affecting horses include transitional cell carcinoma, lymphosarcoma, leiomyosarcoma, rhabdomyosarcoma, and fibromatous polyps. In contrast to cattle, which develop bladder neoplasia in association with chronic ingestion of bracken fern and other plants (enzootic hematuria), dietary factors have not been incriminated in the development of bladder cancer in horses.[25] Common presenting complaints often mimic those of cystic calculi: stranguria, pollakiuria, and hematuria.[773] One can establish diagnosis of bladder neoplasms by rectal palpation or ultrasonographic imaging of a bladder mass, endoscopic examination, biopsy (Fig. 14.43), and urine cytologic examination. Some horses with bladder neoplasia may develop secondary pyelonephritis. Treatment has included partial bladder resection or intravesicular instillation of 5-fluorouracil, but successful outcomes have not been reported.[565,773,774] Doxorubicin (30 mg/m^2 IV) therapy was unsuccessful for the treatment of an extensive and poorly differentiated bladder leiomyosarcoma in one case.[775] By the time that clinical signs are observed, most affected horses will have local metastatic involvement, notably of the aorta, iliac arteries, and lymph nodes, and prognosis is poor.

Tumors of the urethra and external genitalia are the most common urinary tract neoplasms of horses and account for 6% to 10% of all neoplasms, with squamous cell carcinoma being the most commonly reported.[776,777] Although reports describe a paraurethral lipoma[554] and fibrosarcomata[465] resulting in frequent urination or dribbling and urinary tract infection, respectively, tumors of the external genitalia are more common than urethral tumors.[86,87,560] Tumors affecting the external genitalia include squamous cell carcinoma, sarcoid, melanoma, mastocytoma, hemangioma, and papillomata or warts. Habronemiasis used to be a significant cause of genital lesions before the widespread use of ivermectin but should remain on the differential list because it can be distinguished from squamous cell carcinoma or sarcoid only by microscopic examination. Biopsy or simple impression smear of *Habronema* lesions will reveal extensive infiltration of eosinophils, which distinguishes habronemiasis from neoplasia, and habronemiasis is usually very pruritic.[778,779] Breeds with nonpigmented genitalia (Appaloosas and Paints) appear to be predisposed to squamous cell carcinoma. Similarly, a predilection for older geldings and stallions has been associated with a carcinogenic potential of smegma, which may cause chronic irritation that stimulates the progression of papillomas to squamous cell carcinoma.[777-780] As in men, infection with papillomavirus is a risk factor for the development of squamous cell carcinoma.[778,779] Presenting complaints include masses involving the penis, prepuce, or vulva; edema of the penis or vulva; frequent extrusion of the penis; and a malodorous sheath or hematuria if the distal urethra is involved. Urinary tract obstruction is uncommon unless the tumors are large. Diagnosis is often made by direct examination of the external genitalia, finding raised and ulcerated single or multiple lesions. Advanced lesions appear cauliflower-like with areas of ulceration or necrosis. Although metastasis is uncommon (12%–16%), rectal palpation and ultrasonographic examination of the penis, local tissues, and regional lymph nodes is recommended.[777,779] Diagnosis is by visual examination and collection of a biopsy. Collection of the latter often is by complete excision of the lesion. In addition to surgical removal, a rather high rate of recurrence has led to a number of adjunct therapies, including intralesional chemotherapy, immunotherapy, cryotherapy, hyperthermia, and radiation therapy. In male horses, surgery can range from local excision to posthioplasty, partial phallectomy, or en bloc resection with penile retroversion.[781] Some squamous cell carcinomas may respond well to adjunctive treatment with piroxicam (80 mg PO q 24 h).[782] Tumor response is likely dependent on expression of cyclooxygenase-2 (COX-2), and not all equine squamous cell carcinomas produce COX-2 equally. Piroxicam is a selective COX-2 inhibitor in other species. Inhibition of COX-2 may induce apoptosis in neoplastic cells, inhibit angiogenesis, or act as an immunostimulant. Adverse gastrointestinal effects are possible during piroxicam therapy and may be avoided by administration every 48 to 72 hours. Piroxicam administration has also been recommended in the treatment of transitional cell carcinoma in small animals.[715] Because all treatment combinations have had variable success, some authors recommend aggressive surgical treatment early in the course of the disease.[783] Local injection of cisplatin, a cytotoxic antineoplastic agent, has been used with a high success rate to treat equine sarcoid and squamous cell carcinoma.[784,785] Topical 5% 5-fluorouracil cream (every 24 hours in mares; every 14 days in males) with or without surgical debulking may be effective for treatment of noninvasive squamous cell carcinoma of the external genitalia.[786] Incidence of recurrence of squamous cell carcinoma is 11% to 30%.[777-779] Because of varying responses and success, a combination of surgical and adjunctive therapy is recommended.

Urinary Incontinence and Bladder Dysfunction

Warwick M. Bayly

Loss of control of bladder function is an infrequent problem in horses. When the condition is recognized, it is usually because a degree of incontinence develops, which by definition means that intravesicular pressure exceeds resting urethral pressure. Although a number of recognized abnormalities of bladder emptying can afflict human beings, dysfunctions of equine bladder control and micturition tend to fall into one of three categories, with the extent to which they are recognized depending on clinical signs. Basically, the three types of problems are (1) the reflex or upper motor neuron (UMN) bladder (also known as *spastic* or *autonomic bladder*), (2) paralytic or lower motor neuron (LMN) bladder, and (3) the myogenic or nonneurogenic bladder. Either of the last two conditions can be associated with the atonic bladder syndrome, which is probably appropriate given the similarity of clinical signs and subsequent treatment once either of the two types of conditions is recognized. In fact, although signs of UMN bladder dysfunction are initially different from those of the other two groups, this condition in horses also usually is not recognized until a degree of incontinence develops. A final form of bladder neuropathy that has been described in humans and dogs, but not horses, is reflex dyssynergia. In this condition, loss of coordination of detrusor contraction and urethral relaxation occurs, and the animal may make efforts to urinate but fail to do so. Such cases frequently appear similar to those of urethral obstruction, and one must distinguish between the two.

Although treatment options are limited and tend to be the same, regardless of what type of condition is responsible for incontinence, determining the origin of the problem is prognostically important. To accomplish this, the internist needs to have a good working knowledge of how micturition normally is controlled.

CONTROL OF MICTURITION

From a neurologic perspective, one can regard the bladder as having a body and an outlet, which can be divided further into the neck (or trigone) and the proximal urethra. Functionally, the bladder alternates between filling and storage and emptying and elimination phases.[787] Dysfunction in any of these locations or phases may result in clinical problems. Somatic innervation is primarily to the striated muscle of the urethra via a branch of the pudendal nerve, which originates from the sacral spinal cord (S1–S2). Other branches of this nerve go to the anal sphincter and perineum. The sympathetic nerve supply is provided via the hypogastric nerve, with the preganglionic fibers arriving from L1–L4 and synapsing in the caudal mesenteric ganglion. From there, postganglionic fibers supply the bladder (β_2-receptors) and proximal urethra (primarily α_1- and some α_2-adrenergic receptors).[19] Parasympathetic innervation also originates in the sacral cord, with neurons combining to form the pelvic nerve. Many complex interneuronal connections exist between sympathetic and parasympathetic nerves in the wall of the bladder, as well as small adrenergic cells that facilitate contact between sympathetic and parasympathetic pathways.[22] As a result, complete denervation of the bladder is virtually impossible. During the filling phase, the tone of smooth and striated muscles that together comprise the external and internal urethral sphincters increases. The pudendal nerve and the sympathetic nerves, respectively, innervate these muscles. Contraction of these muscles during filling maintains continence. Although the striated muscle forms a definite sphincter around the pelvic urethra, the anatomic existence of a bona fide internal sphincter is debatable.[788] However, restriction to urine outflow that follows stimulation of the α-adrenergic receptors at the neck of the bladder has a sphincter-like effect. The smooth muscle of the bladder, referred to as the *detrusor muscle,* is innervated by the parasympathetic pelvic nerve and α_2-adrenergic postganglionic fibers. Neurologic lesions anywhere in the spinal cord, not just the sacral segments, have the potential to produce bladder dysfunction.[789]

The storage or filling phase is dominated by sympathetic nerve activity and provides an excellent example of the effects of reciprocal innervation.[790] During filling, the detrusor muscle relaxes because of α-receptor–mediated inhibition of pelvic nerve afferents and stimulation of sympathetic β_2-receptors in the smooth muscle of the bladder body. The latter is a reflex response that involves sensory input from bladder stretch and pressure receptors via the afferent pelvic nerve fibers to the sacral spinal cord, interneurons in the cord, and preganglionic and postganglionic sympathetic axons in the hypogastric nerve. Relaxation of this muscle allows accumulation of large volumes of urine with little or no increase in intravesicular pressure.

Intravesicular pressure starts to rise once detrusor muscle fibers are stretched fully. Receptors in the bladder wall detect these increases, and impulses are transmitted via the pelvic nerve and ascending spinoreticular cord tracks to the pons, cerebrum, and cerebellum, where they are interpreted as the sensation of bladder fullness. Signals responsible for voluntary micturition originate in the cerebrum and exert their influence via the brainstem, from which UMNs descend in reticulospinal tracts to the sacral parasympathetic nuclei. This triggers the emptying phase. From these sacral segments, pelvic nerve impulses stimulate detrusor muscle contraction, and action potentials traveling via parasympathetic ganglia in the pelvic plexus or bladder wall to postganglionic fibers stimulate the smooth muscle. Depolarization spreads throughout the bladder via tight junctions, resulting in a strong, coordinated, contractile process. Simultaneous inhibition of the pudendal nerve and hypogastric α- and β_2-sympathetic activity further facilitates detrusor muscle activity and relaxation of the external and internal urethral sphincters, respectively. Part of this inhibitory activity represents reflex neuronal activity linking pelvic and pudendal nerve axons in the sacral spinal cord and inhibiting internuncial connections between sacral segments and sympathetic neurons in the lumbar spinal cord. Urethral sphincter relaxation also is coordinated centrally in a number of areas, including the cerebellum. Detrusor muscle contraction pulls the bladder neck open, and micturition occurs. The emptying phase ends when the bladder stretch receptors sense that the bladder is empty and afferent parasympathetic (pelvic nerve) impulses cease. Pelvic nerve efferent activity also stops and pudendal motor and sympathetic nerve activity resumes (because it is no longer inhibited), with the result that the detrusor muscle relaxes, restoring external and internal urethral sphincter tone.

CLINICAL SIGNS OF BLADDER DYSFUNCTION

Control of bladder function obviously is complex, and many sites exist where disruption of normal micturition can originate. In reality, problems are usually detectable in horses only when a degree of incontinence develops, which usually is manifested as constant or periodic dribbling of urine from the vulva or penis. In chronic cases, one frequently finds evidence of scalding and associated depilation of the perineum in mares and ventral abdomen in males, as well as the hindlimbs. Any activity that results in increased intraabdominal pressure, such as coughing or exercise, may exacerbate signs or be associated with their initial observation. Adult horses develop these problems much more frequently than foals. The duration of bladder dysfunction hugely affects prognosis and treatment because overflow incontinence may take years to months to be observed by horse owners and may not recognized until there is significant detrusor muscle atony and accumulation of large amounts of sabulous.[789]

Academically, being able to differentiate between the different neurogenic or myogenic forms of bladder dysfunction may seem important. In reality, the clinical signs and treatments tend to be the same, regardless of cause. UMN disease is characterized by increased urethral resistance, despite the presence of a full bladder, and may make catheterization or manual emptying of the bladder via rectal compression difficult. The condition usually occurs in association with broad, deep spinal cord lesions. In horses, these problems rarely are recognized because of the severe nature of associated clinical problems such as recumbency and myopathies. Frequently, such situations are deemed incompatible with life. Possibly, a focal lesion caused by a disease such as equine protozoal myeloencephalopathy or aberrant parasite migration could result in the development of spastic bladder without associated neurologic signs.

If horses suffering from this type of problem are able to stand, are kept in a sling, or have an isolated problem, in time they may develop the ability to urinate reflexively. This reflex develops because of the stimulation of pressure receptors connected to pelvic nerve afferents, which reflexively activate pelvic (parasympathetic) nerve efferents and the pudendal nerve. This activation results in detrusor muscle contraction and relaxation of the striated urethral muscle (external sphincter) leading to frequent urination, especially if the increases in abdominal pressure are regular, as may occur with any movement. These patients usually have some residual urine volume in the bladder after voiding. In such cases, urine dribbling usually is reported to occur intermittently, which is an important part of differentiating this type of dysfunction from paralytic (i.e., LMN) causes of incontinence.

As for the LMN bladder, lumbosacral trauma, equine herpesvirus–1 (EHV-1) myeloencephalitis, and cauda equina neuritis are probably the most common causes of this type of dysfunction, although in some parts of the world, Sudan grass toxicity[574] and sorghum cystitis-ataxia (enzootic ataxia cystitis)[564,574] are major problems. Tumors of the lumbosacral spinal cord, such as lymphosarcoma and melanoma, are also capable of inducing paralytic bladder. Finally, iatrogenic paralysis after epidural administration of alcohol occasionally has been reported in show horses. Because this practice is discouraged and unethical, how frequently it leads to complications is impossible to know.

With a paralytic (LMN) bladder, one usually sees other signs of LMN and lumbosacral dysfunction, including all or some of the following: loss of anal sphincter tone, tail paralysis, analgesia or hypalgesia over the perineum, atrophy of the muscles of the hip and hindlimb, and hindlimb weakness. Damage to the pudendal nerve and loss of external urethral sphincter integrity are therefore particularly important in the development of this problem. The bladder is atonic and distended with the urethral muscles relaxed, which results in urine dribbling because of overflow from the bladder. This incontinence may appear continuous, which helps to differentiate it from spastic (UMN) dysfunction. Sometimes the penis or vulva also may appear paralyzed. The prognosis is usually poor because of the development of secondary cystitis and general damage to the bladder wall and the detrusor muscle.

Idiopathic incontinence in geldings is a syndrome of bladder paresis or paralysis and sabulous urolithiasis without overt neurologic deficits.[789] Some cases may have a history of subtle neurologic disease or possible musculoskeletal conditions that prevent posturing to urinate and complete emptying of the bladder, which eventually leads to progressive detrusor muscle atony and accumulation of urinary sediment. The condition generally develops slowly, in association with the accumulation of large amounts of sabulous or mucoid urinary sediment or sludge in the bladder, which mainly is comprised of $CaCO_3$ crystals. In time, the weight and volume of this material, when coupled with that of normal urine accumulation, progressively stretch the detrusor muscle. Incontinence is not normally notable until the cranial aspect of the bladder begins to protrude over the edge of the pubis, which results in craniad and ventrad displacement of the sediment. This results in a bladder muscle that is stretched beyond its normal modulus of elasticity, and normal contraction and micturition are no longer possible. Severe distention and stretching also lead to breakdown in tight junctions that prevents depolarizing waves from passing from muscle fiber to muscle fiber. Eventually, overdistention becomes so significant that the ability to maintain sphincter function is lost and incontinence develops. These cases usually occur without any other signs of neurologic disease; however, because of the lack of any identifiable cause or specific pathophysiologic mechanism, specific focal lesions of a peripheral nerve such as the hypogastric nerve in fact could lead to a similar syndrome. Certainly, retention of urine in the bladder for any period results in the deposition of large quantities of sediment that in turn exacerbate the condition. One must recognize that part of the problem in cases of myogenic atony may stem from secondary cystitis, which develops after retention of urine for any period. The urea in retained urine breaks down to ammonia, which is irritating to the mucosal wall. Subsequent inflammation damages the bladder musculature further.

Cystitis and chronic urethritis per se can be nonneurogenic, nonmyogenic causes of apparent incontinence. Irritation of stretch receptors in the bladder wall apparently causes regular stimulation of stretch receptors in parasympathetic afferents and stimulates detrusor contractions that cannot be inhibited voluntarily. This effect results in an apparent increase in the frequency of urination (pollakiuria) and an inability to control when it occurs. The condition frequently is referred to as *urge incontinence* and also may occur in association with a unilateral ectopic ureter in which the bladder is much smaller than usual (because of disuse) and incapable of storing a normal volume of urine. The frequency of micturition again is increased.

In mares, incontinence may occur with cystolithiasis or secondary to foaling trauma to the urethral sphincter in multiparous mares, with or without a history of dystocia.[789] Hypoestrogenism also has been reported as a cause of nonneurogenic incontinence in an 18-year-old female Shetland pony.[791] A similar condition has been noted in older spayed bitches. The pathophysiologic mechanism of the condition is not known but probably is linked to a modulating effect of estrogen on norepinephrine and α-adrenergic receptor activity in the internal urethral sphincter.[792] In the documented case, the patient responded well to small doses (2 mg IM q 48 h) of estradiol cypionate.

A transient postoperative condition that results in urine retention after abdominal or perineal surgery has been noted in human beings.[793] The cause has not been explained, although the hypothesis is that a reflex depression of parasympathetic nerves may be responsible for detrusor muscle stimulation. This condition is distinct from the pain and reluctance to contract abdominal muscles after surgery. Whether such a condition exists in horses is unknown.

DIAGNOSIS

Careful physical and neurologic examinations are the basis for characterization of bladder dysfunction in equine patients and the basis for any efforts aimed at identifying a cause. Although never good, the prognosis appears to be most positive in cases in which the horse still can generate significant increases in intravesicular pressure. Therefore tests aimed at evaluating bladder and urethral pressure capacities may be diagnostically useful. Cystometry, which involves the inflation of the bladder with sterile water, isotonic saline, or carbon dioxide, has been described in horses and pony mares.[377,378] Briefly, one introduces a large-gauge (30-Fr) catheter into the bladder connected to a three-way stopcock to an infusion pump and pressure transducer. The pressure transducer is connected to a chart recorder. One fills the bladder until micturition occurs. Intravesicular pressure is recorded continuously. Usually a gradual increase in pressure is related to the infusion of fluid until the pressure suddenly rises, reflecting the onset of detrusor muscle contraction. The pressure at the point of this sharp increase is regarded as the contraction threshold. In normal horses, this threshold is about 90 ± 20 cm H_2O.[377] One determines the urethral pressure profile by using a catheter with multiple side openings and positioning the tip at the urethral sphincter. One then fills the catheter with fluid and withdraws it at a constant rate while recording the intraurethral pressure. Normal values are usually greater than 50 cm H_2O. Pressures were significantly lower in recordings of three incontinent mares.[378] Although these tests have not been used widely, they have considerable prognostic potential. Put simply, the higher the pressures are, the better the prognosis. One also can determine the distance over which high pressure is present in the urethra. Such determination also may be important because it gives some further information on the integrity of the urethral sphincters.

TREATMENT

Only 21% of cases (8 of 37) of urinary incontinence reported by Schott et al.[789] were successfully treated, and approximately 50% were eventually euthanized because of incontinence. Horses that respond to treatment for neurologic disease or with correctable predisposing conditions, such as cystoliths in mares or congenital lesions such as ectopic ureter, have a generally favorable prognosis. Prognosis is also better for horses that regain detrusor and bladder sphincter muscle function within 10 to 14 days after the onset of clinical signs. Chronically affected horses will require constant grooming and hygiene to treat and prevent urine scald, sporadic treatment for urinary tract infection, lowered dietary calcium (avoid legumes) to reduce urinary crystals, and occasional bladder lavage to remove sabulous and potentially improve bladder emptying and reduce cystitis.

Some horses with UMN disease recover gradually, especially if one can determine and treat a specific cause. A major complication with paralytic and myogenic forms of bladder dysfunction is that cases often are not recognized soon enough and atonia is irreversible. By that time, the prognosis tends to be poor, and identification of an initiating cause is difficult—and likely irrelevant. In such cases, treatment is often futile; however, one often can determine this definitively only by assessing the response to attempted treatment. Regardless of whether dealing with UMN, LMN, or myogenic disorders, treatment tends to be the same concerning the bladder.

If a definitive cause such as EHV-1 myeloencephalitis or equine protozoal myeloencephalopathy is identified, one should institute specific treatment for that disease. Concerning bladder dysfunction, the basic aim is to provide support while hoping for spontaneous recovery, which may take a long time (e.g., months in cases of pelvic nerve damage). A basic aim of therapy is to prevent retention of urine because of the secondary problems that this entails. Therefore promotion of bladder emptying is an important goal that one may attempt by regular catheterization or an indwelling catheter. (In male patients, one normally inserts such catheters via a perineal urethrostomy.) Although facilitating drainage, intermittent or indwelling catheterization appears to predispose the horse to secondary bacterial cystitis and therefore should not be used without some forethought. Some horses that are chronically incontinent seem to survive comfortably without any catheterization.[564] Antimicrobial therapy is important for treating any incontinence cases but is especially critical when one uses indwelling or regular catheterization.

One may give the α-adrenergic blocker phenoxybenzamine (0.7 mg/kg PO q 6 h) to eliminate any urethral resistance, thus facilitating emptying in the reflex UMN or in situations of great atonic overdistention. Bethanechol chloride is a parasympathomimetic agent resistant to the action of acetylcholinesterase and apparently has a selective effect on the smooth muscle of the gastrointestinal tract and bladder. The drug is used principally to stimulate detrusor muscle activity, and it acts by stimulating postganglionic parasympathetic effector cells rather than motor end plates. The recommended dosage ranges from 0.25 to 0.75 mg/kg subcutaneously every 8 hours. Starting the horse on the smallest dose is recommended. This drug reportedly has varying results.[794] Bethanechol has no effect when the bladder is completely atonic or areflexic. If the muscle is capable of generating weak contractions, bethanechol may be useful. One could determine whether contractions are possible by cystometry. Although bethanechol can increase intravesicular pressure, whether it helps evacuate the bladder also depends on the status of the urethral sphincter and striated muscle. One must remember that drugs such as phenoxybenzamine and bethanechol can have undesired side effects on other body systems. The use of general muscle relaxants

and an α-adrenergic blocker may be useful for achieving urethral muscle relaxation. Diazepam (0.2–0.5 mg/kg IV) and dantrolene are the most commonly used relaxants. Diazepam is effective in large doses, which also usually result in sedation. Dantrolene (10 mg/kg PO loading dose, then 2.5 mg/kg PO maintenance q 6 h) slows release of calcium from the sarcoplasmic reticulum and has been tried in dogs with varying effects.

Surgical removal of the sabulous sludge found in a number of these horses has been tried via perineal urethrostomy or cystotomy, with poor results.[566] Removal via cystotomy is not recommended because of difficulties in evacuating the material without contaminating the peritoneal cavity. Cystotomy to remove sabulous urolithiasis is unnecessary, and sediment is likely to return within a few weeks to months.[789] Perineal urethrostomy, combined with irrigation with large volumes of fluid while the horse is anesthetized, seems to be the most effective way of removing sabulous. Five affected horses were managed for up to 3 years by repeatedly emptying the bladder through a urinary catheter and using saline lavage with cystoscopic guidance to remove residual sabulous material.[795] Cystitis was treated with antimicrobial and antiinflammatory medications, and bethanechol chloride was also administered. Frequent catheterization resulted in a urethral stricture in one horse. Four horses returned to work, and one was retired because of persistent incontinence.[795] The prognosis for most affected horses is poor because of chronic irreversible changes in the bladder wall, which seem to prohibit any possible return of normal detrusor muscle function.
