However, the microbiota is just beginning to be recognized as an important player in pancreatic carcinogenesis and the interplay among microbes is greater than expected [1]. The microbiome is constantly evolving throughout life in each individual due to several extrinsic (environment, food, drugs, lifestyle, exercise) as well as intrinsic factors (sex, age, hormones, genetics/genotype, stress, and bile secretion) and thus forms the basis for microbial diversity, which has a huge impact on the host immune response and natural history of disease [2]. Hence, microbiotic homeostasis is important for maintenance of a healthy pancreatic microenvironment [3,4]. Risk factors for pancreatic ductal adenocarcinoma (PDAC) can easily impact the microbiome and influence the pancreatic microenvironment and its function. The exact mechanism for microbiota migration to the pancreas has been revealed, such as translocation via the pancreatic duct, portal circulation or mesenteric lymph nodes [5]. Unexpectedly, a 1000-fold increase in tumoral milieu bacteria was found in human PDAC compared with normal pancreatic tissue [6–8].

Collectively, specific well-studied oral, gastrointestinal, and intrapancreatic microbes and some kinds of hepatotropic viruses and bactibilia may have potential etiologic roles in pancreatic carcinogenesis or the modulation of individual responses to oncotherapy [9–11]. In addition, higher abundance and distinct compositions of fungi were also detected in PDAC.

The microbiome is an emerging frontier that provides new avenues for identifying microbial-based biomarkers for diagnosis, prognosis, predicted drug or therapy responses in patients with PDAC [7,12–14]. For instance, recently, McAllister and colleagues analyzed the microbiomes from tumors of long-term survivors (LTS) and short-term survivors (STS) of PDAC using 16S rRNA gene sequencing [8]. They found higher α-diversity in the tumor microbiome of LTS patients and identified an intratumoral microbiome signature highly predictive of long-term survivorship, which demonstrates the potential role of microbial communities with prognostic impact in PDAC individuals. Colonization of *Fusobacterium* was associated with a worse prognosis; Gammaproteobacteria were correlated with resistance to gemcitabine; *Acidovorax ebreus* has a positive impact on metastasis and high tumor grade in PDAC [15]. Modulating the microbiome, via tumor-promoting or inhibitory effects, might help in designing effective therapeutics, which opens a new strategy for this highly fatal disease.

In this chapter, we elaborate on the mechanisms of involvement of microbiota in cancer development, and interactions between the microbiota and chemo-/immunotherapy therapeutic resistance in PDAC.

Mechanisms of Involvement of Microbiota in Cancer Development

Although sufficient evidence has indicated that pancreatic disorders are often accompanied by microbial dysbiosis, the time sequence and causality of these two phenomena are difficult to define [11]. The emerging link between the microbiota and PDAC exhibits the following properties: bidirectional, heterogeneous, and dynamic [11]. Concrete mechanisms mainly involve supporting pancreatic oncogenic signaling, perpetuating inflammation, regulating the immune system microbe–tumor axis, altering metabolism, and remodeling the tumor microenvironment [10,16]. The role of the microbiome in the development of pancreatic cancer is well supported by recent research in genetically engineered murine models [7,17,18].

First, inflammatory pathologies like pancreatitis and obesity are associated with increased gut permeability and dysbiosis, thereby leading to possible bacterial translocation. Furthermore, persistent inflammation state and excessive oxidative stress exposure result in gene instability and facilitate tumor angiogenesis [19]. Peripancreatic inflammation promoted by the microbiome potentiates oncogenic signaling and suppresses innate and adaptive immunity. Tumor-associated microbiome was shown to promote an epithelial-mesenchymal transition process, thereby leading to epithelial barrier alterations and tumor-promoting inflammation. Viruses, including HBV/HCV, may promote the development of PDAC via activation of the inflammation process and modulation of the PI3K/AKT signaling pathway [20].

Together, these results suggest that the microbiota not only contributes directly to oncogenesis within the tumor microenvironment, but also induces a systemic inflammatory response that facilitates PDAC development [21].

Second, preclinical and epidemiologic studies suggested that the microbiota shapes systemic as well as tumor-specific immunity in pancreatic cancer [22]. On one hand, specific microbes are essential for the education and maturation of the host immune system [23,24], especially the alteration of Treg and Th17 cells which can maintain intestinal homeostasis and immune responses [25]. Possible mechanisms include stimulating goblet cells to secrete mucin to ensure the integrity of the mucosa as well as bacterial recognition of dendritic cells and their metabolites to induce intestinal mucosa-associated lymphoid tissue development [25]. Intratumor microbes may act as a potent antigen that further activates the immune system, associated with immune infiltrates of LTS with pancreatic cancer by encouraging the proliferation of host immune cells and their vascularization [8]. Also, microbiome diversity and composition of PDAC shape immune responses, promoting T-cell activation which ultimately influences survival.

On the other hand, the microbiota promotes immune suppression and modulates carcinogenesis. Immune cells respond to microbiota/pathogen/damage-associated molecular patterns (MAMPs/PAMPs/DAMPs) through pattern recognition receptors (PRRs) such as Toll-like receptors (TLRs). Mechanistically, the microbiome in primary PDAC exerts potent suppressive influences on the inflammatory tumor microenvironment, establishing the tumor-promoting inflammatory program by activating TLRs on myelomonocytic cells, which leads to the expansion of myeloid-derived suppressor cells (MDSCs) and antiinflammatory M2-like tumor-associated macrophages (TAMs). These tolerogenic innate immune cells promote the differentiation of suppressive populations of $CD4^+$ T cells and prevent the expansion of cytotoxic $CD8^+$ T cells [26]. Specifically, bacterial ligands stimulate TLRs and cause downstream immune suppression, leading to development of PDAC in the setting of genetic risk [27]. The activation of TLR2 and TLR5 facilitates downstream immune suppression and promotes PDAC development [7]. The intratumoral fungi could promote PDAC by activating the complement cascade (C3) and tumor progression by ligation of mannose-binding lectin (MBL) [28]. How MBL and the complement system integrate with the rest of the immune system during PDAC progression is still an unresolved question.

Third, abnormal microbial components and metabolism lead to the production of certain carcinogenic metabolites, such as cancer-promoting secondary bile acid, which could penetrate the systemic circulation of the host and be transported to the site where they exert hormone-like effects [29]. These bioactive metabolites can modulate signal transduction in the host to affect various pathways involved in the regulation of gene expression and transcription, enhance tumorigenic properties such as tumor proliferation, migration, invasion, and evasion of apoptosis, leading to immune suppression, or cause DNA damage [21]. In addition, microbiome communities from LTS and STS are associated with different metabolic pathways. The LTS cases exhibited enrichment in the pathways related to metabolism of amino acids, xenobiotics, lipids, terpenoids and polyketides, besides other cellular functions. Significantly better outcomes were predicted for PDAC patients demonstrating enrichment in xenobiotics biodegradation and lipid metabolism pathways [30]. This study revealed that microbial dysbiosis leads to the development of PDAC and drug resistance increased butyrate and decreased propionate in diabetes.

Finally, the mutual interplay between microbiome and PDAC is complicated; the microbiota and immune system have coevolved and affect each other directly

via intricate crosstalk. For example, KRAS mutant signaling alone is not sufficient to initiate invasive pancreatic cancer, but additional microbe-induced inflammation can potentiate oncogenesis, and intratumoral bacteria negatively impact antitumor immunity by promoting a tolerogenic immune microenvironment [7]. Meanwhile, microbiota-induced activation of PRRs recruits MyD88 or TRIF adaptor proteins to enhance MAPK and NF-kB signaling in pancreatic cancer cells, which synergizes with KRAS signaling [21]. Bacterial ligands sensed by TLRs create a Th1/Th2/Th17 imbalance in the tumor microenvironment and, in combination with oncogenic KRAS mutation, promote pancreatic tumorigenesis [27].

In brief, the complex role of the microbiota in pancreatic carcinogenesis is yet to be elucidated in detail. Parallel in-depth tumor, immune, metabolism and microbiome phenotyping may generate insight into the mechanisms.

Microbiota Involvement in Chemo-/Immunotherapy

Late-stage pancreatic cancer harbors a fibrotic and immune-excluded tumor microenvironment that impedes the efficacy of chemotherapy and immunotherapy. Accumulating studies suggest that cancer treatments reshape the microbiota profile in the microenvironment; for example, chemotherapeutic agents are known to imbalance the functional composition of microbes [31]. For instance, paclitaxel decreased the abundance of the butyrate-producing bacteria, while increasing the relative abundance in *Mucispirillum* in the colon, which may lead to chemotherapy-induced neuroinflammation. Moreover, irinotecan induced an increase in the relative abundance of Proteobacteria and Fusobacteria in fecal microbiota in male Sprague–Dawley rats, which may result in gastrointestinal dysbiosis [32]. Conversely, the microbiome modulated the therapeutic efficacy and side-effects of chemo-/immunotherapy. Rapid development of treatment resistance by modulation of various enzymes and drug transporters limits overall survival in PDAC patients.

Research has demonstrated that the gut microbiota and intratumoral microbiome may impact therapeutic drug sensitivity and disease survival [8]. Ablation of the microbiome with antibiotics reshapes the tumor microenvironment, inducing T-cell activation, improving immune surveillance, and increasing sensitivity to immunotherapy in tumors [33]. Accordingly, future studies should focus on detection of the dynamic evolution and detailed mechanisms of these processes; adjusting and reshaping the microbiota to enhance the efficacy of therapy is a fascinating direction.

The relationship between microbiota and therapeutic resistance of PDAC is multidimensional and complicated, not only because of the existing crosstalk between microbiota and therapeutic effect and host response. In addition, this effect is systemic, influencing more than the intratumor or adjacent areas. The microbiota influences PDAC chemotherapy resistance through the following aspects.

First, the gut microbiota directly affects drug absorption, metabolism, and bioactivity in both enteral and parenteral administration. Hence, the gut microbiota plays an pivotal role in altering the efficacy of pharmacotherapeutics involved in cancer treatment. Second, microorganisms have specific effects on certain drugs by regulating gene expression and metabolic pathways. For example, the presence of PDAC intratumoral Gammaproteobacteria has the potential to inactivate gemcitabine sensitivity and confer chemoresistance via the bacterial enzyme cytidine deaminase [6]. *Fusobacterium nucleatum*, which promotes oxaliplatin and 5-FU resistance to PDAC by modulating autophagy, was associated with poor prognosis [34].

Furthermore, the gut microbiota may mediate drug toxicity through a series of transformation processes. A typical demonstration is irinotecan, which can be converted to the active metabolite SN-38 with the help of tissue carboxyl esterase; it then exerts its anticancer effect via single-stranded DNA breaks (SSBs). SN-38 could be transformed into the inactive SN-38-G form by UDP-glucuronosyltransferases (UDPGTs) in the liver before being excreted in the gut. However, SN-38-G can be reconverted into the active form SN38 by the bacterial βglucuronidases, which are mainly found in the Firmicutes phylum [35]. SN-38 can induce serious intestinal toxicity similar to diarrhea. Ablation of βglucuronidase-positive bacterial species using specific antibiotics, certain inhibitors for βglucuronidase, and probiotics will help to overcome this defect [36,37].

Nevertheless, the existence of certain commensal microbiota is essential for the efficacy of chemotherapy drugs. Germ-free or antibiotic-treated mice exhibit a reduced anticancer response to oxaliplatin by reducing the production of reactive oxygen species (ROS) in myeloid cells [38], because reactive ROS can lead to DNA damage and apoptosis.

Thus, an intact commensal microbiota is vital to optimal responses to cancer therapy because of its role in modulating cell functions in the tumor microenvironment. Understanding this process provides the basis for the manipulation of microbiota for therapeutic purposes in cancer patients.

Microbial heterogeneity determines the impact on the efficacy of immunotherapy. Recent studies have shown that immune cell effector functions and responses to checkpoint

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. inhibitors are regulated by gut microbiome composition [39–41]. *Pseudoxanthomonas*, *Saccharopolyspora*, *Bacillus clausii*, *Streptomyces*, *Bacteroides*, and *Clostridia* species have a long-term and short-term effect on survival in PDAC. Treatment of a PDAC murine model with antibiotics in combination with anti-PD-1 displayed synergistic antitumor efficacy by restoring T-cell activation [8]. Specifically, bacterial eradication promotes immunogenic reprogramming towards an activation phenotype and enhances the efficacy of checkpoint-targeted immunotherapy in PDAC, including a decrease in myeloid-derived suppressor cells and an increase in tumor-protective M1 macrophage polarization, upregulating PD-1 expression by promoting intratumoral $CD4^+$ and $CD8^+$ T-cell activation [7,18].

Thus, antibiotic therapy combined with immunotherapy potentially represents a new strategy for treating patients with PDAC. Conversely, *Bifidobacterium* is believed to promote beneficial effects on the host immune system to enhance an anticancer response and improve immune checkpoint blockade treatment outcomes [23,42]. Based on these findings, clinical trials have been recruited to evaluate the synergistic effects of immunotherapy and antibiotics for PDAC.

Scientists had found evidence of crosstalk between human gut and tumor bacteria, and based on this they performed human fecal microbial transplants into mouse models of the disease, differentially altering tumor growth and immune profile, indicating a possible mechanism for bacteria to regulate tumors. Fecal microbiota transplantation (FMT) from LTS is more protective against tumor in murine models of PDAC compared to those who received FMT from either STS or those without PDAC [43]. Moreover, FMT has shown potential in dealing with the adverse effects of chemotherapy that cause diarrhea in other malignancies [44]. This indicated that restoring the gut with a favorable bacterial population is a feasible approach that can be used with other treatment regimens and might be very effective in treating cancer. That is, successful modulation of the microbiota can enhance the therapeutic response.

Clinical trials focusing on microbiota-modulating agents such as antibiotics and probiotics, diet and prebiotics may allow a tumor-specific and more personalized approach to sensitize tumors to facilitate the enhanced delivery of therapy and establish microbial-based combined treatment strategies.

Conclusion

The involvement of microorganisms in the initiation, progression, maintenance, drug resistance, and modulation of the immune environment in patients with PDAC has been increasing recognized. Identifying and picturing a distinct landscape of microbiota in a large cohort of the PDAC specimens is an imperative, which could be used to stratify patients into different subtypes and enable personalized interventions [8,45]. A better understanding of the microbiota in PDAC might generate insight into the establishment of screening or early-stage diagnosis methods, implementation of cancer bacteriotherapy, adjustment of therapeutic efficacy, including possibly alleviating the adverse effects, creating new opportunities and fostering hope for desperate PDAC patients [10].

Although there is a wide gap that needs to be filled by in-depth research exploring the diversity and composition of the microbiota and their differential occurrence and dysbiosis which is only partially understood, the future of cancer treatment looks promising for PDAC patients. Clinical trials are now underway and microbiome-modulating agents are poised to become *bona fide* anticancer strategies, complementing current treatments such as surgery, chemotherapy, targeted therapy, radiotherapy, and immunotherapies. These results could enhance our understanding of whether altering the composition of the microbiota is safe and effective or likely to impose other health issues and complications. Regulating the microbiota in the pancreatic tumor microenvironment may generate not only direct anticancer but also synergistic effects with other treatments, providing new directions in cancer therapy [11]. Combining microbiome profiling with liquid and tissue biopsy may enable more precise prognoses and personalized identification of tumor vulnerabilities, and validate the treatment approach of microbiome modulation.

Pancreatic Ductal Adenocarcinoma (PDAC) Genomics and Clinical Applications

Large-scale sequencing studies have mapped the genomic events that drive PDAC [1–6]. These studies have identified highly recurrent genetic alterations (deleterious single nucleotide variants and copy number losses) in a core set of oncogenes and tumor suppressors, including *KRAS*, *TP53*, *CDKN2A*, and *SMAD4*, that are key members of hallmark oncogenic signaling pathways. Greater than 50% of PDAC tumors harbor a deleterious genetic alteration in at least one of these core driver genes [6]. Mutational heterogeneity exists within most tumors and additional low-frequency driver events in genes including *KDM6A*, *MLL3*, *ARID1A*, *TGFBR2*, *RBM10*, and *BCORL1* are found in 5–10% of samples [3,4,6] (Fig. 122.1a). Importantly, recurrently altered driver genes can be grouped into 10 core pathways that control key aspects of tumor growth and survival [1,3,4] (Fig. 122.1b). A single tumor may harbor multiple genetic alterations affecting one or more of these pathways contributing to complex tumor genotypes that are only now being characterized in preclinical models (Fig. 122.1a).

Activating *KRAS* mutations are the most common initiating genetic alteration and occur in ~90% of PDAC [6]. *KRAS*-activating mutations constitutively activate MAPK-ERK signaling in PDAC cells driving proliferation, survival, and migration [7]. Virtually all *KRAS* mutations in PDAC are single nucleotide variants occurring in codon 12 (~91%), 13 (~2%), and 61 (~7%) [1–5,8]. *KRAS* allelic imbalances caused by copy number gains are commonly associated with metastatic disease and may result in increased RAS signaling [9]. The 10% of PDAC with wild-type (wt) *KRAS* typically harbor genetic alterations in alternative drivers such as mutations or amplifications in *BRAF*, *FGFR1* or *ERBB2* or fusions involving *NRG1-NTRK1* [10–12].

Single gene aberrations or so-called actionable mutations that can be matched to a selective therapy, such as *NRG1-NTRK1* fusions [12], *ERRB* amplifications [13] or *BRAF* mutations [14], are rare in PDAC. In fact, actionable mutations in PDAC occur at a prevalence of less than 5% with a median of less than 1% [3,15]. As an example, mutations in mismatch repair genes *MLH1*, *MSH2*, *MSH6* or *PMS2* occur at a frequency of ~1–3% in PDAC [3,16]. MMR genes normally recognize and repair erroneous nucleotide insertions, deletions or misincorporation of bases that can arise during DNA replication and recombination. Mutations in MMR genes can cause microsatellite instability (MSI) and exceptionally high mutational burdens that may result in greater sensitivity to immune checkpoint inhibitors [17,18]. Importantly, most actionable mutations have not been clinically validated in PDAC and the clinical utility of matched therapies remains limited to a relatively small number of drugs and indications (Fig. 122.1c).

A growing catalogue of potentially actionable mutations in DNA damage response genes that cause homologous recombination deficiency (HRD), such as *BRCA1* and *BRCA2*, have been identified in PDAC [3,16,19]. Mutations in these genes cause chromosomal instability due to faulty homologous recombination and increase the rate at which somatic mutations occur. Evidence from nonrandomized clinical trials suggests that HRD is a biomarker of response to platinum-based chemotherapy in patients with advanced PDAC [20–23]. Furthermore, *BRCA1* and *BRCA2* germline variants have been associated with

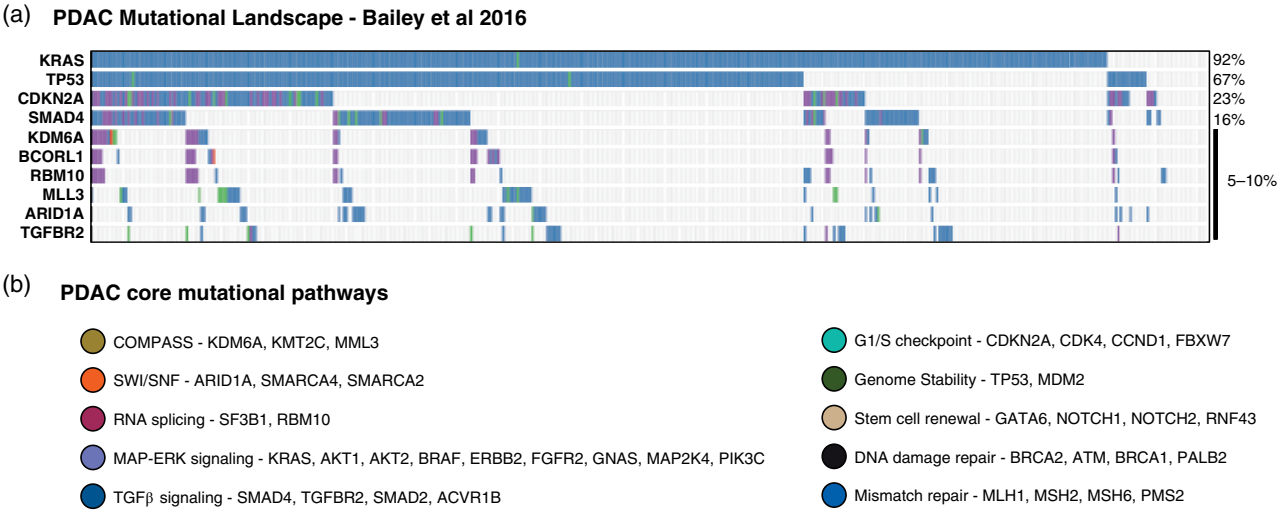

Figure 122.1 The mutational landscape of PDAC. (a) Oncoprint plot showing the most mutated genes in PDAC, using data generated in Bailey et. al. (2016). The prevalence of the mutations is shown on the right as a percentage. (b) Core pathways mutated in PDAC. (c) Gene mutations which have clinical utility in PDAC. The prevalence of genes indicative of response to therapy is shown in parentheses as a percentage.

improved progression-free survival in patients with platinum-sensitive metastatic PDAC treated with the poly ADP-ribose polymerase (PARP) inhibitor olaparib as maintenance therapy [23].

A meta-analysis of over 21 842 PDAC genomes has estimated that the pooled prevalence of germline and somatic mutations in genes causing HRD may be between 14.% and 16.5% [19]. Combined germline and somatic mutation prevalence was estimated at *BRCA1* (0.9%), *BRCA2* (3.5%), *PALB2* (0.2%), *ATM* (2.2%), *CHEK2* (0.3%), *FANC* (0.5%), *RAD51* (0%), and *ATR* (0.1%). Importantly, germline mutations make up the majority of HRD events in patient tumors. Germline testing in unselected populations with sporadic PDAC has shown that ~5% of patients harbor a germline mutation [24,25]. This percentage increases to 20% in patients with Ashkenazi Jewish ancestry [26]. Given that most newly diagnosed patients with a germline mutation do not have a family history of PDAC, current National Comprehensive Cancer Network guidelines recommend routine screening for germline variants including *BRCA1/2*, *ATM*, and *PALB2* [27]. An important caveat to these findings, however, is that the clinical relevance of HRD candidates, beyond *BRCA1*, *BRCA2*, and *PALB2*, has not been established [28].

Beyond single gene alterations in DNA repair genes, recent findings have demonstrated that patterns of genomic alterations such as structural variation and mutational signatures may predict whether a tumor is sensitive to therapy [3,29]. Waddell et al. identified four genomic subtypes based on genomic structural variations (SVs): Stable (20%, <50 SVs per genome); Scattered (36%, 50–200 SVs per genome); Locally rearranged (30%, >200 structural variants clustered on 1–2 chromosomes); and Unstable (14%, >200 SVs distributed across the genome) [3]. Of these, the Locally rearranged and Unstable genomic subtypes have potential clinical utility in PDAC. Locally rearranged genomes typically comprise focal gene amplification such as *ERBB2* or *FGFR* that are therapeutic targets, while the Unstable subtype is associated with HRD and mutations in *BRCA1/2* or *PALB2*, which are sensitive to both platinum and PARP inhibitors. Mutational signatures represent recognizable patterns of mutations (single nucleotide variants, insertions, and deletions) that have been linked to defined mutational processes such as HRD [30]. HRD mutational

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. signatures have been demonstrated to predict responses to platinum-based chemotherapy [3,29]. Moreover, Waddell et al. demonstrated that by integrating different genomic readouts of HRD (i.e., mutation in *BRCA1/2*, Unstable genome and HRD mutational signature), patient outcomes following platinum or PARP inhibitor therapy may be improved [3].

The translation of genomic discoveries into the clinic has been a focus of intensive study. The "Know Your Tumor" clinical trial has performed a retrospective analysis on 1856 biopsy-confirmed PDAC of any stage using targeted sequencing [31]. This analysis found that 26% of 1082 samples comprised a known actionable mutation. Out of a total of 677 patients for whom outcome was available, 46 patients received a matched second-line therapy (most receiving standardized chemotherapy in first line). Those patients who received a matched therapy had significantly longer overall survival than 488 patients who did not receive a matched therapy. Most patients who benefited from therapy had *BRCA2* HRD mutations or MSI.

While this study confirms that genomic profiling can benefit small subgroups of well-defined patients, its wider clinical utility remains to be determined.

PDAC Transcriptomic Subtypes

Transcriptomic profiling of patient samples, using either array-based hybridization (microarray) methods or bulk RNA sequencing, has been demonstrated to improve prognostication and allow optimization of treatment strategies by defining subgroups of patients that share phenotypic characteristics [32–35]. Subgroup identification efforts at the mRNA level have the potential to augment established histopathologic and imaging approaches.

Microarrays or bulk RNA sequencing measure the relative expression of mRNA between patient samples and report a complex admixture of gene expression values representing not only neoplastic cells but also stromal cell populations such as cancer-associated fibroblasts (CAFs), endothelium, and immune cells. PDAC classification schemes have ostensibly defined intrinsic transcriptomic subtypes by modeling tumor complexity as a whole (i.e., including both stromal and neoplastic gene expression) [4,36–38] or by filtering out stromal signals using bioinformatic approaches or by laser capture microdissection (LCM) to enrich the cancer epithelium [9,39]. Several PDAC subtyping schemes have been described, most notably the Moffitt [39], Collisson/Sadanandam [37], Bailey [4], Puleo [38], Dijk [36], and Chan-Seng-Yue [9], which are prognostic for patient survival in resected patient samples and have potential clinical utility, as described in Table 122.1.

Collisson and Sadanandam, Bailey, Puleo, and Dijk performed transcriptomic profiling on predominantly chemo-naive primary resected patient samples and defined PDAC subtypes by combining stromal and neoplastic signatures. These studies identified common neoplastic subtypes comprising an overlapping mesenchymal-like subtype (referred to as quasi-mesenchymal/basal/pure-basal/squamous), a more canonical epithelial subtype (classical/pancreatic-progenitor/pure-classical), and a cryptogenic subtype which shares many features of the healthy pancreas (referred to as exocrine-like). Bailey and Puleo et al. also defined stromal subtypes which are enriched for specific stromal cell subsets [4,38]. The "Immunogenic" subtype as defined by Bailey et al. was enriched for immune cell populations, including T cells and B cells. Puleo et al. defined two additional stromal subtypes, namely Stroma Activated (moderately differentiated and enriched for activated stroma markers a-SMA, SPARC, and FAP) and Immune Classical (predominantly classical neoplastic with immune cell enrichment) which was reminiscent of the Bailey Immunogenic subtype.

Moffitt et al. performed transcriptomic profiling using data derived from normal pancreata, chemo-naive primary resectable and metastatic PDAC [39]. These authors informatically dissected stromal and tumor-intrinsic gene expression signatures and identified two subtypes in both the stroma (Normal and Activated) and the neoplastic cell compartment (Basal versus Classical). Chan-Seng-Yue et al. performed a *de novo* reclassification of PDAC subtypes using primary resectable and metastatic PDAC that had undergone LCM to identify five neoplastic subtypes referred to as Basal-like A, Basal-like B, Hybrid, Classical A, and Classical B [9]. This subtyping scheme split the previously defined Basal and Classical subtypes and identified a new Hybrid subtype that comprised gene signatures common to both the Classical and Basal subtypes. The Basal-like A subtype was preferentially enriched in metastatic disease.

Despite differences in subtyping nomenclature, there is strong alignment between the Classical/Pancreatic Progenitor and Quasi-mesenchymal/Basal-like/Squamous subtype signatures. Accordingly, the field has now largely adopted a two-tier system that aligns with the Moffitt subtyping scheme identifying:

- **Classical/Epithelial/Pancreatic Progenitor** subtype cancers that are associated with better outcomes. These tumors are well differentiated and express key endoderm transcription factors such as GATA6, HNF1A, and PDX1 that specify and maintain pancreatic identity; and
- **Basal-like/Squamous (mesenchymal)** subtype cancers that are associated with the poorest patient outcomes. These tumors are also less differentiated than

Classical tumors and are associated with fibroblast-like cell morphology.

The Moffitt subtypes are prognostic for survival in multivariate analyses of patients with resected PDAC but not in patients with metastatic disease [9,39]. These subtypes may also guide therapy choice: Basal-like subtype patients had a relative (but nonsignificant) benefit from adjuvant treatment [37,39]. In contrast, in locally advanced and metastatic PDAC, Basal-like subtype tumors exhibited lower response rates for FOLFIRINOX than Classical tumors [40].

Although the Moffitt subtyping system provides a robust and easy to understand method for patient stratification using bulk transcriptomic data, an ever-growing number of single cell sequencing (scRNAseq) studies point to complex subtype diversity within tumors. scRNAseq has revealed that Basal-like and Classical subtype cells can be found in the same tumor [9,41]. These studies also suggest that the Basal-like and Classical subtypes may exist as a gradient within the same sample with Hybrid cells representing an intermediate state [9,41]. scRNAseq coupled with spatial transcriptomics and multiplexed immunofluorescence has revealed that Classical and Basal-like cells are associated with distinct immune cell types [42]. Notably, Classical subtype cells are associated with cytotoxic T cells and Basal-like cells are associated with increased macrophage infiltrates.

Understanding intratumoral complexity will be important for the design of effective therapies for PDAC and may also influence strategies for patient stratification in the future. Collectively, these findings underscore the utility of a simplified two-tier classification system but do not rule out the clinical importance of other PDAC subtypes, including stromal subtypes such as the Bailey Immunogenic subtype which may predict responses to selective immunotherapies.

Clinical trials in different disease settings are required to assess the utility of these transcriptional subtypes for both prognostication and clinical decision making. Several groups have established informatic methods for clinical use that can stratify patient samples based on transcriptional subtypes. These include PurIST (Purity Independent Subtyping of Tumors) based on the Moffitt subtypes which can be applied to low cellularity biopsied material or formalin-fixed samples using readouts obtained from low input targeted gene expression panels (e.g., Nanostring) [40]. Surrogate markers of the Classical and Basal-like subtypes may also be detected via *in situ* hybridization (ISH) or immunohistochemistry (IHC). Basal-like subtype cytokeratin markers (KRT17, KRT5, and KRT81) [43–45] and Classical-associated endoderm transcription factors (GATA6) [46] may assign subtype labels to a tumor and in addition identify subtype heterogeneity within the same sample. Ultimately, methods for patient stratification based on consensus subtyping will require validation in a CLIA-certified setting.

Translating Molecular Subtypes into the Clinic

Genomic profiling of advanced PDAC using targeted gene sequencing has defined small subgroups of patients that benefit from matched therapies [31,47,48]. The great majority of these patients harbor actionable mutations in DNA repair genes [19]. Clinical trials that have tested the utility of targeted sequencing for clinical decision making have been largely disappointing, with only 3–5% of patients showing any clinical benefit [31]. Systemic chemotherapy arguably remains the most effective therapy for the great majority of unselected PDAC patients. Importantly, several studies now suggest that transcriptomic subtypes may predict patient responses to standard chemotherapy, indicating that patient survival may be improved by selecting patients based on transcriptomic subtype [9,40]. Multiple clinical trials have now been established with the aim of developing optimal treatment strategies and medication regimens based on genomic profiling and subtyping.

The PANCREAS (NCT04683315) trial will perform PDAC subtyping on pretreatment EUS/FNA samples using PurIST. Neoadjuvant chemotherapy will then be selected according to subtype. Patients with Classical subtype tumors will receive mFOLFIRINOX whereas patients with Basal-like tumors will receive gemcitabine/nab-paclitaxel.

The EPPIC (Enhanced Pancreatic Cancer Profiling For Individualized Care Study) trial, which incorporates the COMPASS and PanGen studies, will perform integrated genomic and transcriptomic profiling of advanced PDAC in real time [49,50]. Patient molecular profiles will be related to chemotherapy responses.

The ESPAC-6 adjuvant trial (NCT05314998) in resectable patients and the ESPAC-7 neoadjuvant trial in locally advanced patients will evaluate responses to oxaliplatin- or gemcitabine-based chemotherapy randomized according to standard clinical criteria (control arms) or by transcriptomic stratification signatures (experimental arm). The transcriptomic stratification signature to be used in these trials is prognostic for therapy response and was developed *de novo* using matched transcriptomic and oxaliplatin- or gemcitabine-based chemotherapy response data.

The PASS-01 trial is a multicenter phase II trial that will evaluate responses to modified FOLFIRINOX and gemcitabine/nab-paclitaxel in patients with untreated metastatic PDAC. Approximately 150 patients diagnosed

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. with untreated metastatic PDAC will be randomized to either arm. Patient samples will undergo high content molecular profiling with the trial to assess whether chemotherapy sensitivity signatures and/or GATA6/KRT5/KRT17 subtype biomarker status can predict response to chemotherapy. As an additional experimental component, patient-derived organoids will be generated from patient samples and transcriptomic profiles from both organoid and matched metastatic samples analyzed for concordance. This will test whether patient-specific organoids can be used as tumor avatars for therapeutic testing.

The PREDICT-PACA co-clinical trial is an integrated biopsy-based approach to predict response to chemotherapy for patients with stage IV PDAC. This study has established a predictive transcriptomic signature associated with chemotherapy response. It will also generate organoids from patient samples and identify potential alternative third-line treatments by genomic profiling and high-throughput drug screening.

Conclusion

Improvements in surgical technique and optimization of chemotherapy regimens have increased the five-year survival rate for PDAC from 2.5% to 10%, reviewed in [51]. These gains are extremely poor compared to other common cancer types. Molecular profiling of PDAC has identified several molecular taxonomies that hold promise to improve patient outcomes by matching a selective therapy to a molecularly identifiable subtype. These could be existing therapies for which the molecular subtypes are predictive, or novel or repurposed compounds that target a subtype's vulnerabilities. Targeted therapies for advanced PDAC based on actionable mutations show benefit in only 3–5% of patients who receive a genome-matched therapy [31]. Most of these patients have germline mutations in *BRCA1/BRCA2* or are MSI [31]. A growing catalogue of potentially actionable mutations in DNA repair genes have been identified in PDAC although the actionability of these mutations has not been assessed in clinical trials [19]. Transcriptomic profiling of PDAC has defined intrinsic molecular subtypes that provide a robust and reproducible framework for patient stratification [39,40]. Existing evidence suggests that the Basal-like subtype may be more chemoresistant than the Classical subtype [9]. Clinical trials, including COMPASS, Precision Promise, ESPAC-6/7, PREDICT-PACA, PANCREAS, and PASS-01, will now evaluate transcriptomic response signatures and/or molecular subtypes in different disease settings.

Indications from early translational studies and more recently clinical trials such as "Know Your Tumor" have estimated that up to 26% of PDAC harbor an actionable mutation [31,48]. While these estimates seem promising, the clinical reality suggests that only a very small number of patients with a therapy-matched mutation see any clinical benefit [31]. A significant difficulty in delivering molecularly targeted therapies to patients is the length of time required to obtain a patient sample, perform genomic sequencing, and guide a patient to a matched therapy. Precision oncology trials in PDAC have largely focused on advanced disease with genome-matched therapies offered in the second line. Often, timelines for intervention are significantly reduced in these patients. These timelines may be extended in the neoadjuvant setting with precision therapies offering greater benefit in the second line. Furthermore, most clinical trials in PDAC up until now have focused on single-agent matched therapies which result in recurrence due to the emergence of resistant subclones. Genomically directed targeted agent combinations may overcome drug resistance to single-agent therapy. Combination therapies based on defined molecular biomarkers are emerging in PDAC although these are complex and require robust preclinical *in vivo* evidence to commence clinical trials.

Transcriptomic subtypes and/or treatment response signatures have the potential to select even larger subgroups of patients for targeted therapies. Initial indications suggest that transcriptomic subtypes may improve outcomes for patients treated with systemic chemotherapy with resectable and metastatic disease [40,9]. It is currently unclear, however, whether transcriptomic subtypes have any prognostic value in the neoadjuvant chemotherapy setting. The ability to deploy treatment response and/or subtyping signatures in the clinic is challenging, especially when variation in sample cellularity is high. The use of gene expression panels such as Nanostring and the mechanical enrichment of the cancer tumor-epithelium via laser capture microdissection may improve the reproducibility of transcriptome-guided patient stratification. Alternatively, immunohistochemistry or *in situ* hybridization of surrogate subtype biomarkers such as GATA6 may have greater clinical utility, especially as these techniques are in routine clinical use.

Spatial transcriptomics and multiplexed imaging modalities, such as mass spectrometry imaging (MSI), are uncovering the complex cellular communities that make up patient tumors [42,44]. These exciting new platforms are revealing novel therapeutic opportunities by mapping cell–cell interactions and receptor–ligand interactions in patient tumors. The ability to spatially map the location of different cell types, expression of gene/protein biomarkers and metabolites will likely usher in a new age of digital pathology that will help shape clinical decision making.

Tumor Microenvironment: Immune Cells and Immunosuppressive Functions of Carcinoma-associated Fibroblasts and Macrophages

Tony Pang, Zhihong Xu, Chamini Perera, and Minoti V. Apte

Pancreatic Research Group, South West Sydney Clinical Campus, School of Clinical Medicine, UNSW Medicine and Health, University of New South Wales, Sydney, NSW, Australia
Ingham Institute for Applied Medical Research, Liverpool, NSW, Australia

Introduction

The tumor microenvironment of pancreatic cancer (pancreatic ductal adenocarcinoma: PDAC) is complex and interactions between its components influence the progression of this cancer. Chapter 9 has described the role of pancreatic stellate cells on the proliferation and dissemination of cancer cells. This chapter focuses on how pancreatic stellate cells (PSCs; also known as carcinoma-associated fibroblasts: CAFs) and tumor-associated macrophages (TAMs) modulate the immune response to PDAC.

Compared to many other cancers, the tumor microenvironment (TME) of PDAC is particularly important as this cancer demonstrates a prominent stromal reaction [1] that has been shown to promote cancer progression.

In vitro and *in vivo* evidence indicates that the collagenous stroma facilitates cancer cell proliferation and invasion and decreases cancer cell apoptosis, thus promoting cancer cell survival [2,3]. In turn, cancer cells stimulate stromal cell proliferation, extracellular matrix (ECM) synthesis, and cell migration. The outcome of these interactions is a growth-permissive microenvironment for cancer cells [4]. Thus, opportunities for interactions between cancer cells and other components of the tumor play an important role in determining the progression of disease.

Another effect of the tumor stroma in PDAC is the promotion of an immunosuppressive state, allowing immune escape of cancer cells, known as the *cold immune microenvironment* [5,6]. The causes of this cold microenvironment are multifactorial and include the relative dearth of neoantigens compared to other solid tumors, as well as the interactions between CAFs, TAMs, and cancer cells. While other stromal cells, such as myeloid-derived suppressor cells (MDSCs), also contribute, these are outside the scope of this chapter, thus are not discussed in depth.

Key Players in PDAC Stroma

The simplified schema in Figure 123.1 shows the interactions between the key players within the tumor microenvironment, which lead to an immunosuppressive state. Note that this schema represents a gross generalization of the net effect of each cell type and does not consider heterogeneity within these cell types (see Section, *Heterogeneity of CAFS and TAMS*). It is also not an exhaustive schema, as there are many other stromal cells which interact with these cells as well.

Pancreatic Stellate Cells/Cancer-associated Fibroblasts

Cancer-associated fibroblasts are fibroblast-/myofibroblast-like cells within the PDAC stroma. These cells secrete ample amounts of collagen, fibronectin, etc., and are responsible for the extensive desmoplasia characteristic of PDAC. It is generally acknowledged that the predominant source of CAFs is PSCs (resident cells of the pancreas, described in detail in Chapter 9) [7]. Minor contributions to the CAF population may also come from a variety of extrapancreatic sources, such as pericytes, bone marrow-derived cells, and mesenchymal stem cells [8–11]. In the interests of simplicity, the terms PSCs and CAFs are used synonymously in this chapter.

In health, PSCs are in a *quiescent* state (identifiable by the presence of vitamin A lipid droplets in their cytoplasm)

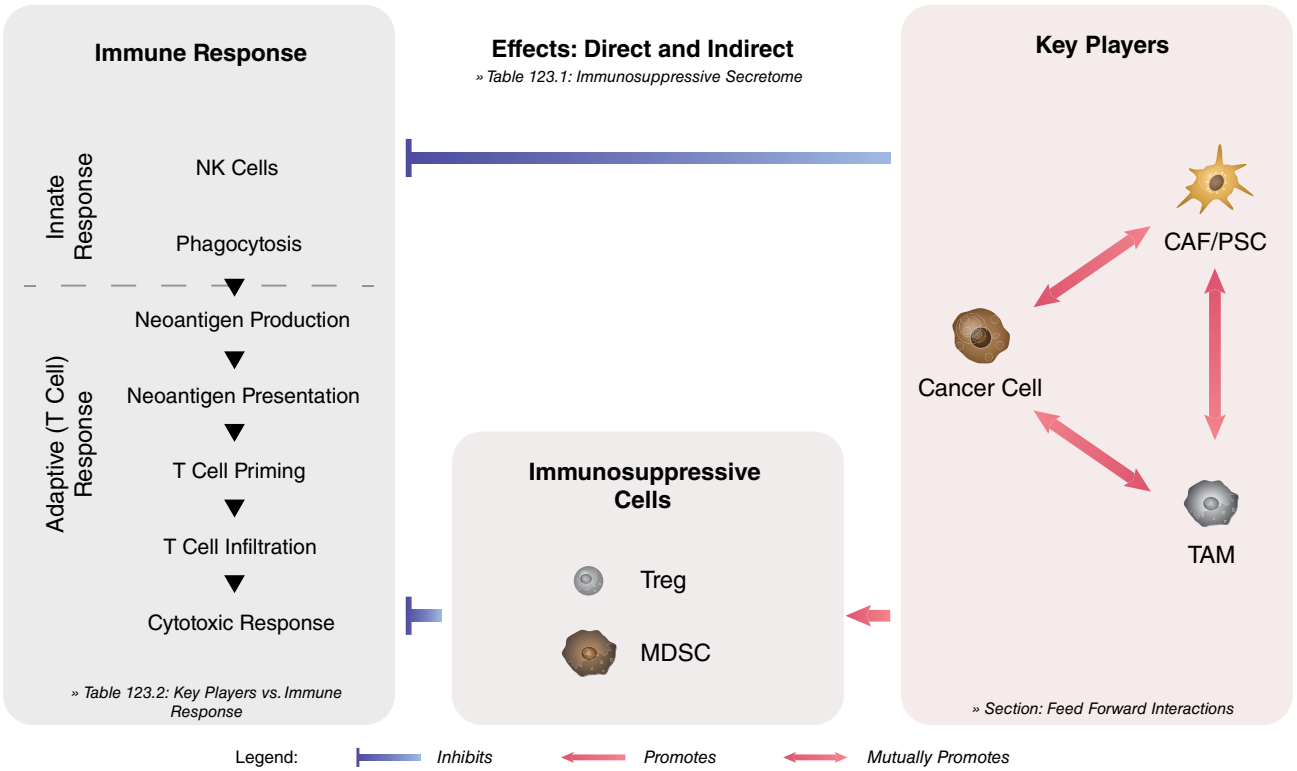

Figure 123.1 Simplified schema illustrating the effects of the key players (CAFs, TAMs, cancer cells) with the immune response (adaptive and innate). CAF, cancer-associated fibroblast; MDSC, myeloid-derived suppressor cell; NK, natural killer; PSC, pancreatic stellate cells; TAM, tumor-associated macrophage; Treg, tegulatory T cells.

and regulate ECM turnover through the secretion of metalloproteinases (MMP-2, -9, and -13) and their inhibitors, to maintain the architecture of the pancreas. PSCs are activated by cancer cells, and in this activated state (identified by activation marker α-smooth muscle actin [α-SMA] and a myofibroblast-like phenotype), PSCs synthesize excessive amounts of ECM proteins leading to the desmoplastic characteristic of PDAC [4,12]. CAFs/PSCs play an important role in the development of all stages of pancreatic cancer from being present around premalignant pancreatic intraepithelial neoplasms (PanINs) to advanced-staged PDACs [13]. Their role even extends to metastatic PDAC deposits [14].

Tumor-Associated Macrophages

Tumor-associated macrophages are macrophages in the tumor stroma. They may arise from tissue-resident macrophages or be recruited from bone marrow-derived monocytes [15]. Classically, TAMs are characterized as being on a spectrum between two polarities, M1 and M2 macrophages. M1 macrophages are proinflammatory and antitumoral, while M2 macrophages are anti-inflammatory and protumoral, although this dichotomy is generally considered an oversimplification [16]. In general, factors within the PDAC tumor microenvironment promote development into M2 phenotype macrophages, leading to protumoral and immunosuppressive effects (Table 123.1).

The protumoral effects of TAMs can broadly be classified into: (i) the promotion of progression from PanINs to PDAC, (ii) the promotion of metastasis, (iii) the development of chemotherapy resistance, and (iv) the inhibition of the host immune response to the tumor [17].

Pancreatic Cancer Cells

Pancreatic cancer cells are not themselves passive players but are central in the creation of the immunosuppressive TME [18]. Their actions can be direct, such as by modification of neoantigen presentation, or indirect, such as by providing signals to promote PSC activation and M2 polarization of TAMs.

Myeloid-derived Suppressor Cells

While not within the scope of this chapter, a key player in the immunosuppressive TME of PDAC is the myeloid-derived suppressor cell [19,20]. The proliferation and recruitment of these cells from bone marrow to tumor

Table 123.1 Immunosuppressive secretome released by the key players in TME.

Cell type	Cytokines/chemokines	Overall functions	References
CAF/PSCs	FGF, HGF, TGF-β, CXCL8, CXCL12, and CCL7 IL-1, IL-4, IL-6, CXCL1, CXCL2, M-CSF, MCP-1, SDF-1, IL-8 and IL-10	• Increased proliferation, stemness and metastasis of cancer cells • Angiogenesis	[22, 57]
TAMs	IL-10 TGF-β IL-8 CCL17 CCL22	• Suppression of NK cell and CD8+ T-cell activity • Induce differentiation of Tregs • Angiogenesis	[23, 58]
Cancer cells	IL-8 IL-6 IL-1β TNF-α IL-10 PGE2 TGF-β MIF VEGF HIF	• Inhibition of antitumor CD8+ activity • Inhibition of NK cells • Fibrogenesis • Angiogenesis • Invasion • Increased EMT • Metastasis	[23] [22, 58] [57]
MDSCs	ROS Arginase Reactive nitrogen species (RNS)	• Suppression of NK cell and T-cell activation	[23, 58]

CAF, carcinoma-associated fibroblast; EMT, epithelial mesenchymal transition; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; HIF, hypoxia inducible factor; IL, interleukin; MDSC, myeloid-derived suppressor cell; NK, natural killer; PGE, prostoglandin E; PSC, pancreatic stellate cells; TAM, tumor-associated macrophage; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

sites occur through cancer cell-derived factors, such as granulocyte- and granulocyte-macrophage colony-stimulating factor (G-CSF and GM-CSF). These cells exert their immunosuppressive effects both directly, by suppressing cytotoxic T-cell activity through cell–cell contact (e.g., PD-L1/PD ligation), and indirectly through the secretion of reactive oxygen species, arginase and inducible nitric oxide synthase (iNOS), and soluble factors (e.g., TGF-β, IL-10) [21,22].

Antitumor Immune Response

The above players create an immunosuppressive TME by modulating various steps in the tumor immune response. This section provides a brief overview of the relevant antitumor immune response to facilitate discussion of the mechanisms of immune suppression in PDAC.

The immune response can be divided into innate and adaptive parts. The key components of the innate response against malignancy include phagocytosis by macrophages and other cells, as well as the action of natural killer (NK) cells. The key component of the adaptive immune response against cancer involves the T-cell response (Figure 123.1).

Natural Killer Cells

Natural killer cells are cytotoxic immune cells in the TME with an inherent ability of identifying and killing tumor cells without affecting healthy cells. As part of the innate response, NK cells can recognize cancer cells without prior sensitization, through a variety of stimulatory and inhibitory "hard-wired" (germline-encoded) cell surface receptors. This mechanism ultimately leads to cytotoxic granule release. This germline-encoded response means that NK cells can react to cancer cells despite their immune evasion tactics; the latter are known to try to evade the T-cell response by downregulation of their major histocompatibility complex (MHC) class I expression, which reduces neoantigen presentation (a necessary step in the cytotoxic T-cell response, see below). NK cells also secrete an array of cytokines and chemokines such as interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α) and others, which potentiate the adaptive immune response [23,24].

T-cell Response

The T-cell response is the key host immune response to PDAC. It involves a series of steps, ultimately leading to the destruction of cancer cells by cytotoxic T cells (Figure 123.1).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. - *Production of neoantigens*: cancer cells produce neoantigens which will be the target of T-cell recognition. The production of neoantigens is a function of the mutational burden of the cancer [25].
- *Presentation of neoantigens*: activation of T cells requires presentation of the neoantigens by antigen-presenting cells (APCs) and macrophages after they phagocytize cancer cells containing neoantigens. These neoantigens are presented on MHC class II molecules on the surface of APCs.
- *T-cell priming*: T cells, circulating through the lymphatics and bloodstream, encounter APCs and bind to the MHC-antigen complex via specific T-cell receptors (TCR). This results in cytokine secretion and differentiation into cytotoxic T cells (CD8+ cells) or helper T cells (CD4+ cells).
- *T-cell migration and infiltration*: the cytotoxic T cells need to infiltrate into the tumor, as the effector cell cytotoxic effect on cancer cells (the next step) relies on direct contact.
- *T effector cell response*: like all nucleated cells, cancer cells present endogenous materials on HLA class I molecules. The tumor-infiltrating cytotoxic T cell will recognize antigens specific to its TCR, leading to a cytotoxic response against the cancer cell.
- *Modulation by regulatory cells and immune checkpoints*: the T-cell response is modulated by a variety of immunosuppressive cells (e.g., regulatory T cells [Tregs], MDSCs), through paracrine effects. Furthermore, processes which require TCR-antigen-MHC binding (T-cell priming and effector cell response) are modulated by coreceptors, both facilitatory and inhibitory, known as immune checkpoints.

Development of an Immunosuppressive Tumor Microenvironment

Using the above as a framework to understand the immunosuppressive TME, it can be noted that each of the key players exerts multiple immunosuppressive effects, albeit acting on different points of the host immune response (Table 123.2).

Cancer-associated Fibroblasts/Pancreatic Stellate Cells

Cancer-associated fibroblasts suppress the immune response by inhibiting the infiltration of T cells, impairing the effector function of cytotoxic T cells, recruitment of a variety of immune regulatory cells, and suppression of NK cells (see Table 123.2).

Cytokines such as TGF-β, CXCL12, MCP-1, SDF-1, IL-8, and IL-10 secreted by CAFs directly reduce CD4+ and CD8+ T cell numbers and decrease the M1/M2 macrophage ratio in the tumor [26]. Furthermore, through the action of CXCL12, CAFs reduce infiltration of CD8+ T cells into the tumor, reducing CD8+ cell access to, and thus killing of, cancer cells [27,28].

Cancer-associated fibroblasts also inhibit the cytotoxic T-cell response through physical alteration of the tumor microenvironment. CAFs are responsible for the desmoplasia of PDAC, which produces a poorly vascularized, hypoxic and acidic environment, which not only contributes to chemoresistance but also impairs immune cell infiltration and cytotoxic T-cell response [29].

Another mechanism of immune modulation is the recruitment of immunosuppressive cells and expression of inhibitory immune checkpoints. In other cancers, CAFs have been shown to facilitate the differentiation, recruitment, and proliferation of MDSCs, the differentiation of Tregs and the promotion of a TH2-mediated T-cell response [30,31].

Furthermore, CAFs can engage CD8+ T cells by the coexpression of neoantigen-MHC class I complex with inhibitory signals, such as programmed death ligand-2 (PDL2) and Fas ligand (FASL) [32]. Binding with CD8+ cells leads to antigen-selective deletion/inactivation of these cells.

PSCSs/CAFs have also been demonstrated to suppress the cytotoxicity of NK cells possibly by decreasing the production of IFN-γ, granzyme b and CD107, which further supports an immunosuppressive TME [33]

Tumor-associated Macrophages

Tumor-associated macrophages have wide-ranging immunosuppressive effects, including suppression of the T-cell effector response, induction of Treg differentiation, and inhibition of NK cells (see Table 123.2).

The effectiveness of the T-cell response is inhibited at multiple levels. A major mechanism by which TAMs exert their immunosuppressive effects is the secretion of a wide variety of immunosuppressive cytokines (particularly by M2 TAMs), including IL-10, TGF-β, IL-6, PGE, CCL2, CCL17, and CCL20. These serve to suppress the cytotoxic (CD8+) T-cell responses [6,34]. While not yet demonstrated in pancreatic cancer, TAMs in lung cancer have been shown to also reduce the infiltration of CD8+ T cells into the tumor, thus reducing their effectiveness [35]. It has also been shown that TAMs inhibit phagocytic activity against cancer cells through the expression of PD-1 (an inhibitory immune checkpoint) [36]. Such inhibition has two effects: impairment of phagocytosis as part of the innate immune response

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 123.2 The immunosuppressive effects of CAFs, TAMs, and cancer cells, classified according to the points of the immune process they inhibit.

Immune response	CAFs/PSCs	TAMs	Cancer cells
Adaptive			
Neoantigen production			• Low quantities of low-quality neoantigens
Neoantigen presentation[a]		• Inhibition of phagocytosis	• Reduced MHC class I expression leading to reduced neoantigen presentation
T-cell priming	• Reduce CD4+ and CD8+ T cells by variety of cytokines, e.g., TGF-β, CXCL12.		
T-cell infiltration	• Inhibits infiltration of CD8+ cells via CXCL12 • Inhibits migration and infiltration by excessive ECM	• Reduces infiltration of CD8+ T cells	
Effector cell response	• Inhibits cytotoxic response by hostile metabolic environment	• Inhibits T-cell response by variety of cytokines	• High intratumoral heterogeneity reduces effectiveness of specific T-cell response • Secretion of immunosuppressive cytokines and upregulation of inhibitory immune checkpoints
Modulation through immunosuppressive cells	• Recruitment of regulatory cells (Tregs, MDSCs) • Expression of inhibitory immune checkpoints • Antigen-selective deletion of CD8+ T cells by PDL2 and FASL	• Induces Treg differentiation through PD1 and PD-L1 and exosomes with miRNA cargo	• Facilitate recruitment of graulocytic MDSCs and immunosuppressive TAMs via chemokines, e.g., CXCL1 and CCL2 • Cancer cells facilitate recruitment of Tregs
Innate			
NK cell	• Suppress cytotoxicity of NK cells by IFN-γ, granzyme b and CD107	• Inhibits NK cell activation through a contact-dependent mechanism involving TGF-β	
Other[a]		• Inhibition of phagocytosis	

[a] Phagocytosis and neoantigen presentation are also part of the innate response, as it is an interaction point between innate and adaptive responses. However, as it is part of the chain of events in the T-cell response, we have included this in the adaptive response.
CAF, carcinoma-associated fibroblast; IFN, interferon; MDSC, myeloid-derived suppressor cell; MHC, major histocompatibility complex; NK, natural killer; TAM, tumor-associated macrophage; TGF, transforming growth factor.

and reduction of presentation of neoantigens derived from phagocytosed necrotic tumor, thus impairing the adaptive immune response.

Tumor-associated macrophages induce the differentiation and maturation of Treg cells through various mechanisms, including the action of PD-1 and PD-L1 [37], and through exosomes which carry miRNAs, such as miR-29a-3p and miR 21-5 [38]. These Treg cells in turn suppress the effectiveness of the T-cell response.

Finally, TAMs have been demonstrated to inhibit NK cell cytotoxicity through a contact-dependent mechanism involving TGF-β [39].

Cancer Cells

It is important to recognise that pancreatic cancer cells are not passive players in developing the immunosuppressive TME. Cancer cells contribute to the immunologically cold TME through the quality and quantity of neoantigen production and presentation, as well as by facilitating the recruitment of immunosuppressive cells (see Table 123.2).

The sensitization of the adaptive immune system is based on the detection of neoantigens. Pancreatic cancer cells not only present low *quantities* of neoantigens, but the antigens presented are also of low *quality*. The former

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. is due to the low number of mutations per patient, while the latter is due to the low degree of molecular differences between mutant and wild-type proteins [18]. Exacerbating the low tumor immunogenicity of PDAC is its high intratumoral heterogeneity. This can induce T-cell unresponsiveness and reduce the T-cell effector response, given that any specific T-cell clone can only target a small proportion of the tumor. Such impaired T-cell antigen dosing has been demonstrated in lung cancer and is associated with poorer patient outcomes [40]. This effect is further exacerbated by reduction in T cell–neoantigen interactions through the suppression of T-cell infiltration (such as by CAFs: see above); as well as reduced MHC class I expression in cancer cells (leading to reduced self-neoantigen presentation) [41]. Other immunosuppressive mechanisms of cancer cells include the secretion of immunosuppressive cytokines and upregulation of inhibitory immune checkpoints [42].

Similar to the effects of TAMs and CAFs discussed above, cancer cells themselves can also facilitate the recruitment of regulatory immune cells, further exacerbating the cold immune environment. Chemokine secretion, such as CXCL1 and CCL2, leads to increased recruitment of granulocytic MDSCs and immunosuppressive TAMs into the tumor [42,43]. Similarly, cancer cells also recruit Tregs into the TME.

Feed-forward Interactions

While each of the above cell types individually contributes to the immunosuppressive TME of PDAC, it should be noted that these effects are greatly amplified through positive feed-forward interactions amongst these cells (see Fig. 123.1).

Cancer cells activate resident PSCs/CAFs, promoting their proliferation and leading to the development of a protumoral phenotype. Cancer cells also secrete cytokines which recruit nonresident CAFs to the TME. In turn, PSCs/CAFs further promote cancer cell proliferation, invasion, angiogenesis, and metastasis [19]. Similarly, cancer cells promote an M2 polarity of TAMs. In turn, TAMs have been shown to promote epithelial mesenchymal transition (EMT), angiogenesis, and metastasis in PDAC [6]. Together, these protumoral effects of PSCs/CAFs and TAMs set up the conditions for further PSC/CAF activation and promotion of M2 TAM polarity.

Mutual stimulatory activity also occurs between CAFs and TAMs. CAFs have been shown to promote M2 TAM polarity while TAMs have been shown to activate PSCs [44].

Finally, PSCs/CAFs and TAMs further promote these feed-forward interactions through the conferral of treatment resistance of PDAC. PSCs secrete hyaluronan and other ECM proteins, leading to a dense fibrous stroma, impairing vascular function and reducing drug penetration [45]. TAMs induce resistance to gemcitabine by upregulation of cytidine deaminase and secretion of pyrimidine species which compete with gemcitabine [46,47]. PSCs have also been postulated to potentiate gemcitabine resistance by sequestering and activating gemcitabine within their cytoplasm, thus reducing availability of drug to cancer cells [48], and/or by secreting deoxycytidine which enters cancer cells through nucleoside transporters and competes with gemcitabine for the downstream phosphorylating enzyme deoxycytidine kinase, thereby reducing the activation of gemcitabine to its cytotoxic form [49].

Heterogeneity of CAFs and TAMs

There is significant heterogeneity within each cell type, such that subsets of these cells may exhibit antitumoral effects. While this does not negate the fact that the *net* effect is protumoral, the existence of such heterogeneity has important therapeutic implications.

Pancreatic Stellate Cells/Cancer-associated Fibroblasts

Even though PSC/CAFs morphologically represent myofibroblasts, their functions cross many physiologic and pathophysiologic areas. In addition to the function of ECM synthesis and degradation, these cells express Toll-like receptors 2, 3, 4, and 5 and exhibit phagocytosis, thus exhibiting an innate immune function. In response to inflammation and tumorigenesis, PSCs produce IL-6, 7, and 8, monocyte chemoattractant protein, CCL3, CCL11, and CXCL12, which can play roles in both proinflammation and immunosuppression [50].

While the *net* effect of CAFs/PSCs is widely accepted as protumoral, there are antitumoral effects at play also. For instance, a subset of CAFs, which express Meflin, suppress cancer progression, and knockout of this protein leads to poorly differentiated tumor in a murine model [51]. Also, earlier attempts at diminishing the protumoral stromal effects in PDAC by depletion of stroma appeared to worsen survival in stroma-depleted mice [52].

These observations indicate that there are distinct subpopulations of CAFs within PDAC. Two major classification systems have emerged in the last few years. The first was based on immunohistochemistry staining of fibroblast-activation protein (FAP), α-smooth muscle

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

actin (α-SMA) (and MHC Class II expression) and was proposed by Öhlund et al. [53], and was then refined and validated using single cell RNA sequencing by Elyada et al. [54]. This classification divided CAFs into myofibroblast CAFs (myCAFs), inflammatory CAFs (iCAFs), and antigen-presenting CAFs (apCAFs). These subtypes displayed distinctly different gene expression, functions, and even intratumoral localization. The second system, proposed by Neuzillet et al. [55] and based on transcriptomic analysis, divided CAFs into four subtypes, which demonstrated distinct phenotypic features and differences in patient prognosis. It remains to be fully elucidated how these different subtypes of CAFs mediate the immunosuppressive and protumoral effects of CAFs.

Tumour-associated Macrophages

The heterogeneity of TAMS is classically captured by the concept of M1 and M2 macrophage polarities (see above). While an oversimplification [16], the relative proportions of these cell subtypes provide a convenient way of quantifying experimentally the overall antitumoral/protumoral effect of a population of TAMs. Many cytokines, growth factors, and pathways are known to influence this well-recognized dichotomy, and are being actively investigated as therapeutic targets [6].

Further heterogeneity relates to cell origin and temporal relationship to tumor development. TAMs could originate from both local macrophages in the pancreas and the bone marrow. The transcriptional profile of the subtypes suggests that they play different roles, with bone marrow-derived TAMs functioning as APCs, while locally derived TAMs function more as myofibroblasts [15].

Another source of heterogeneity relates to the temporal relationship of the cells with tumor development, with early macrophages, associated with PanINs, being proinflammatory and facilitating cancer cell growth. Later TAMs, found in established PDAC, appear to play a more immunosuppressive role [19]. Such heterogeneity adds complexity but also provides opportunities for therapeutic manipulation.

Therapeutic Implications

It is clear from this chapter that many interrelated and redundant processes drive the immunosuppressive TME in PDAC. The same cell types mediating immunosuppression also have other protumoral effects, and multiple redundancies feed into positive feed-forward loops. It is believed that all these factors contribute to the poor prognosis and treatment resistance of PDAC.

Together, these factors mean that a finessed approach aiming to "adjust the equilibrium" to favor antitumoral subpopulations rather than a blanket obliteration of these cells is required. Simultaneously, treatments targeting different steps of the immune response, and combination immunotherapy with cytotoxic chemotherapy may help overcome the cold immune TME. Such treatments can be provided either concurrently or sequentially (so-called *therapeutic sequencing*) [43].

At the time of writing, there were 48 interventional clinical trials of immunotherapy for pancreatic cancer still recruiting patients (www.clinicaltrials.gov/). About two-thirds of these trials were investigating PD-1/PD-L1 either as sole treatment or in combination with other therapies, such as chemotherapy, targeted therapy, cytokine, chemokine, vaccine and radiation therapy.

A non-exhaustive but broad overview of possible approaches is as follows. Focusing on TAMs, drugs can be divided into those with the aim of activating TAMs toward M1 (e.g., CD40 agonists, TLR agonists), away from M2 (e.g., Tie2 inhibitors, anti-CD47), and those aiming to deplete the TME of TAMs (e.g., anti-CSF-1, anti-CSF-2, anti-CD11b). Against CAFs/PSCs, drugs can be divided into those aimed at reduction of myofibroblast CAF activity (e.g., targeting IL-1 and LIF/JAK/STAT pathway, targeting TGF-β, stimulating pathways that mediate PSC quiescence such as PPARg and nuclear vitamin D receptors), inhibition of inflammatory CAF activity (e.g., targeting IL-6, receptor and pathway), depletion of CAFs (e.g., targeting Shh signaling), and inhibition of specific downstream effects of CAFs (e.g., targeting CXCL12-CXCR4). For T-cell-based treatments, those which generate tumor-reactive T cells (e.g., CAR-T cell therapy), augment the T-cell response (e.g., agonists for costimulatory receptors), and overcome specific immune escape responses (e.g., recruitment of NK cells against downregulation of MHCI molecules in cancer cells) are all therapeutic options. These approaches and their rationales have been reviewed by other authors [6,43,56].

Conclusion

Cancer cells, TAMs, CAFs, and other cells conspire to create an immunosuppressive environment. This likely contributes to the poor prognosis and treatment resistance of PDAC. A multipronged treatment approach targeting multiple mechanisms of immunosuppression is likely required for treatment success.

Familial Pancreatic Cancer

Alison P. Klein

Departments of Oncology, Pathology, Medicine and Epidemiology, Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins School of Medicine, Baltimore, MD, USA

Introduction

Pancreatic cancer, like all cancers, is fundamentally a genetic disease driven by both acquired and inherited genetic changes. Having a family history of pancreatic cancer is one of the strongest risk factors for the development of pancreatic cancer [1,2].

Familial Pancreatic Cancer

Familial pancreatic cancer (FPC) is defined as a kindred in which a pair of first-degree relatives have been diagnosed with pancreatic cancer (i.e., a parent and child or a pair of siblings). Observational studies suggest that having at least one single family member with pancreatic cancer increases the risk of pancreatic cancer 1.5–13-fold [1,3–11]. Prospective studies within the National Familial Pancreatic Tumor Registry have shown that first-degree relatives of familial pancreatic cancer patients (individuals with at least two family members with pancreatic cancer) have a 6.79-fold (95% confidence interval [CI] 4.54–9.75) increased risk of pancreatic cancer [1].

Unlike other inherited cancer syndromes in which there is a profound difference in the mean age of onset between the familial and sporadic forms of the disease, the age of onset of pancreatic cancer in patients with a family history of pancreatic cancer is at most six years younger than those with sporadic disease [12,13], with other studies showing no age difference [9,14].

In addition to higher pancreatic cancer risk, relatives of familial pancreatic cancer patients have a higher risk of other cancers. They have a significantly increased risk of dying from breast (weighted standardized mortality ratio [wSMR] 1.66, 95% CI 1.15–2.34), ovarian (wSMR 2.05, 95% CI 1.10–3.49), and bile duct cancers (wSMR 2.89, 95% CI 1.04–6.39). Relatives of sporadic pancreatic cancer patients are at higher risk of bile duct cancer (wSMR 3.01, 95% CI 1.09–6.67) [15]. Other studies also showed pancreatic cancer patients are more likely to report a family member with prostate cancer (odds ratio [OR] 1.45, 95% CI 1.12–1.89) [11] or liver carcinoma (standardized incidence ratio [SIR] 2.70, 95% CI 1.51–4.46) [16].

Pathology of Familial Pancreatic Cancer

The pathologic phenotype of cancers that develop in individuals with a hereditary cancer syndrome can differ from the phenotype of cancers that develop in patients with apparently sporadic disease, such as mismatch repair deficient cancers among Lynch syndrome patients [17,18], or an excess of triple-negative breast cancers among *BRCA1* pathogenic variant carriers [19]. In contrast, familial and apparently sporadic pancreatic cancers appear remarkably similar. A review, blinded to family history, of 519 familial and 651 sporadic pancreatic cancers [20] reported no statistically significant differences in histologic subtypes between familial and apparently sporadic invasive pancreatic cancers. Additionally, among resected tumors there were no significant differences in mean tumor size, location, perineural invasion, angiolymphatic invasion, lymph node metastasis, or pathologic stage. The somatic genetic profile of familial pancreatic cancer does not differ from that of apparently sporadic cancer [12]. In combination, these data further support the finding that the etiology of familial and sporadic pancreatic cancer is very similar.

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

In contrast, there is evidence supporting an increased prevalence of pancreatic intraepithelial neoplasia (PanIN) and intraductal papillary mucinous neoplasia in the pancreata of individuals with familial pancreatic cancer compared to those with sporadic disease. Familial pancreatic cancer patients had a significantly higher rate of PanIN per square centimeter 2.75 (95% CI 2.05–3.70, adjusted for age) than patients with sporadic pancreatic cancer. The precursor lesions observed in familial patients were more advanced than those observed in patients with sporadic disease (relative rate of PanIN-3 lesions 4.20; 95% CI 2.22–7.93) and the observation of high-grade IPMN was limited to familial cases [21].

Predisposition Genes

The ability to understand the inherited genetic variation that increases risk of pancreatic cancer is hindered by its underlying genetic heterogeneity [22]. Advances in both genotyping and sequencing technology have led to the identification of several new high-penetrance genes associated with pancreatic cancer risk [22–24] and common genetic variation associated with an increase in pancreatic cancer risk [25–28]. However, pathogenic variants in the high-penetrance genes that are firmly associated with pancreatic cancer explain only about 20% of the familial clustering of pancreatic cancer and the underlying genetic basis has yet to be identified in ~80% of familial pancreatic cancer kindreds. Recent studies have demonstrated that 5–10% of all pancreatic cancer patients, unselected for family history, are also found to have pathogenic variants in high-penetrance cancer susceptibility genes [29–31].

Knowledge of the precise genetic variants can guide therapeutic decisions for those who develop pancreatic cancer and early detection screening choices for at-risk relatives. Examples include early detection screening clinical trials using imaging techniques for patients who have a strong family history of pancreatic cancer and/or carry germline pathogenic variants in established familial pancreatic cancer genes [32–36], increased sensitivity of *BRCA2*- or *PALB2*-deficient cancers to PARP inhibitors (PARP) or mitomycin C [37–40], and improved survival of pancreatic cancer patients with a family history of breast, ovarian, or pancreatic cancer when treated with platinum-containing agents [41] and clinical trials of PARP inhibitors in BRCA-deficient pancreatic cancer have shown survival benefits [42]. In addition, while very rare, patients with mismatched repair deficient pancreatic cancer, which is associated with germline pathogenic variants in *MSH2*, *MLH1*, *MSH6,* and *PMS2,* benefit from treatment with immunotherapy [43–44].

BRCA2

In individuals who undergo germline genetic testing of pancreatic cancer, pathogenic variants in *BRCA2* account for the largest proportion of individuals with an identifiable genetic basis [45]. Pathogenic variants in the *BRCA2* gene are best known for predisposing to breast and ovarian cancers yet carriers are also at increased risk of prostate and pancreatic cancer. The first report of an increased frequency of *BRCA2* pathogenic variants in pancreatic cancer was by Goggins et al., who reported deleterious *BRCA2* variants in 7% of pancreatic cancer patients, unselected for family history [46]. *BRCA2* pathogenic variant prevalence has been shown to vary somewhat by family history with prevalence estimates as high as 16% for pancreatic cancer patients reporting three or more family members with pancreatic cancer [47], 12% in German pancreatic cancer patients from families with a least two pancreatic cancers [48], and 6% among US and Canadian pancreatic cancer patients with a first- or second-degree relative with pancreatic cancer [49].

Like the initial report by Goggins et al., more recent studies have also demonstrated that a substantial fraction, up to 1.9–3.6%, of pancreatic cancer patients, unselected for family history, carry pathogenic variants in *BRCA2* [50]. While some families found to have deleterious *BRCA2* variants report a family history of breast and/or ovarian cancer, many do not [31,51,52]. Deleterious *BRCA2* variants have also been reported in 4.6% of resected Ashkenazi Jewish pancreatic cancer patients, irrespective of family history of cancer [51]. Studies of the lifetime risk of pancreatic cancer among *BRCA2* carriers are limited to families ascertained based on a history of breast/ovarian cancer, and suggest a 3.51–5.79-fold increased risk of pancreatic cancer [52,53].

BRCA1

Individuals who carry pathogenic variants in *BRCA1* have also been shown to be at increased risk of pancreatic cancer. However, risk of pancreatic cancer in *BRCA1* carriers is thought to be less than that of *BRCA2* carriers. Studies of the lifetime risk of pancreatic cancer in *BRCA1* carriers are limited to families ascertained based upon a history of breast and/or ovarian cancer. Risk estimates range from 2.26- to 4.11-fold [53,54]. While not all studies report an excess of *BRCA1* pathogenic variants among patient with pancreatic cancer [51,55], some studies have reported a prevalence of 1.2% in patients with familial pancreatic cancer [45]. As with *BRCA2*, the lack of a reported family history of breast and/or ovarian cancer does not rule out the presence of a pathogenic variant in *BRCA1*.

PALB2

Pathogenic variants in the *PALB2* gene, a binding partner of *BRCA2*, have also been associated with pancreatic cancer risk. While the initial reports suggested that up to 3% of FPC patients carry pathogenic *PALB2* variants [23], subsequent studies suggest the prevalence may be closer to 1% or lower [45,56,57].

ATM

Recently, pathogenic variants in the DNA repair gene *ATM* have also been associated with familial pancreatic cancer. Approximately 2.6–3.4% [22,24] of patients with familial pancreatic cancer harbor deleterious variants in *ATM*. Pathogenic variants in *ATM* have also been reported in apparently sporadic pancreatic cancer patients [58], and in a large-scale study of over 3000 pancreatic cancer patients, not selected based on family history, 2.3% of patients had pathogenic variants in the ATM gene. The lifetime risk of pancreatic cancer among individuals with pathogenic ATM variants has been estimated to be 9.5% by age 80 (59).

CDKN2A

Germline *p16/CDKN2A* pathogenic variants have been reported in up to 2.5% of patients with familial pancreatic cancer [45] and 0.3% of patients unselected based upon family history. Pathogenic variants in CDKN2A have been associated with a 38-fold increased risk of pancreatic cancer [60] with a lifetime risk of pancreatic cancer of approximately17% [61,62].

Lynch Syndrome

Individuals with Lynch syndrome, due to pathogenic variants in the DNA mismatch repair genes *MSH2*, *MLH1*, *MSH6,* and *PMS2,* have been shown to have a 3.68% (95% CI 1.45–5.88) risk of pancreatic cancer by age 70 [63]. Immune checkpoint inhibition, specifically PD-1 blockade, increases both overall survival and progression-free survival of patients with mismatch repair deficient cancers which includes but is not limited to mismatch repair deficient pancreatic cancers. Many clinical trials are underway exploring combinations of cytotoxic and immune therapy for pancreatic cancers [43,44].

Peutz–Jeghers Syndrome

Individuals with Peutz–Jeghers syndrome have a remarkably high risk of 11–32% [64] of developing pancreatic cancer [65,66].

Hereditary Pancreatitis

The risk of developing pancreatic cancer is extremely high among individuals with hereditary pancreatitis; the risk by age 70 is 30–40% [67,68]. Individuals with hereditary pancreatitis who smoke develop the disease 20 years prior to nonsmokers [68]. A portion of patients with hereditary pancreatitis have inherited pathogenic variants in the *PRSS1* genes [69–71]. In addition, variation in genes associated with an increased risk of pancreatitis or endoplasmic reticulum stress-inducing variants in pancreatic enzymes, including *CTRB2*, *CPA1*, and *CPB1*, have also been associated with an increased risk of pancreatic cancer [72–75].

Common Genetic Variants

In addition to pathogenic variants in high-penetrance genes, several recent genome-wide association studies have identified common variants in the following regions as also significantly associated with pancreatic cancer. Large-scale studies have been conducted in European ancestry populations, Chinese populations, and Japanese populations. Associations at 1q32.1, 1p36.33, 2p13.3, 3q29, 5p15.33, 7p14.1, 8q21.11, 8q24.21, 9q34.2, 13q12.2, 13q22.1, 16q23.1, 17q12, 17q25.1, 18q21.32, and 22q12.1 reached significance criteria when controlling for genome-wide statistical tests in the European populations [25–28,75] whereas regions on 6p25.3, 12p11.21, 7q36.2, 13q12.2, 13q221, and 16p12.3 were statistically associated with pancreatic cancer risk in the Japanese, and 21q21.3, 5p13.1, 21q22.3, 22q13.32, and 10q26.11 in Chinese ancestry populations [76–78]. Individually, these variants have only a small effect on pancreatic cancer increase, with per-allele odds ratios ranging from 1.1 to 1.3.

Many of these same variants have also been shown to have a similar association with familial pancreatic cancer [79]. Combining the effects of these variants into polygenic risk scores (PRS) has been examined as a way of identifying populations at increased risk of pancreatic cancer. However, to date these PRS scores alone are limited in their ability to discriminate between high-risk and moderate-/low-risk subgroups [80,81].

Conclusion

Inherited genetic variants play an important role in pancreatic cancer risk. Individuals with a family history of pancreatic cancer have been shown to be at increased risk of developing pancreatic cancer as well as other

cancers. The genetic underpinnings of the familial clustering of pancreatic cancer are highly heterogeneous. However, an understanding of the causative genetic variants can inform early detection screening in at-risk individuals and treatment decisions for those who do develop pancreatic cancer.

Introduction

The bulk of the normal pancreas is composed of acinar cells, yet most neoplasms of the pancreas have ductal differentiation. The classification of exocrine neoplasms of the pancreas is based on more than a century of integrating gross and microscopic findings with patient outcome. The recent introduction of molecular genetics and gene expression technologies has supported this gross and histological classification: most pathologically defined neoplasms of the pancreas have distinct genetic and gene expression profiles [1,2].

The purpose of this chapter is to describe the pathologic features of exocrine neoplasms of the pancreas, with emphasis on clinical correlates.

Ductal Adenocarcinoma

Pancreatic ductal adenocarcinoma (PDAC), commonly known as "pancreatic cancer," is defined as a malignant gland-forming epithelial neoplasm of the pancreas [3]. Although the overall five-year survival rate has finally risen to 10%, the overall incidence of pancreatic cancer appears to be rising as the population ages [4–6]. The high mortality rate from PDAC is due in large part to widespread local and metastatic disease at the time of diagnosis combined with the poor response of most PDACs to existing therapies [7].

Endoscopic ultrasonography can be used to define the local extent of disease and to biopsy lesions by fine needle aspiration (FNA), a technique that has a high sensitivity for diagnosis of PDAC when performed by experienced endoscopists [8]. Because only 15–20% of PDACs are considered surgically resectable at diagnosis, FNA is often the only way for most patients to receive a definitive diagnosis prior to treatment [7].

Gross

Pancreatic ductal adenocarcinomas are grossly white or gray sclerotic lesions that form firm, ill-defined masses that subtly infiltrate the normal soft, lobulated yellow pancreatic parenchyma (Fig. 125.1). These carcinomas often invade and obstruct the common bile duct, the main pancreatic duct, or both, which results in upstream dilation of the affected duct and fibrous atrophy of the pancreatic parenchyma (see Fig. 125.1). The majority of PDACs occur in the pancreatic head, followed by the body and tail; there are even rare case reports of PDACs arising in heterotopic pancreas [3,9].

Careful gross examination of pancreaticoduodenectomy (Whipple) specimens is critical for margin assessment and for accurate grading and staging of the tumor. Margins to investigate include the common bile duct (usually taken parallel to the margin as a "shave" section), the pancreatic neck/distal pancreatic margin (shave), the proximal and distal bowel margins, and the uncinate/retroperitoneal/superior mesenteric artery margin (radial). The pancreatic neck and retroperitoneal margins are important in distal pancreatectomies. These margins are important because patients with no residual tumor (R0) have a better prognosis than those with microscopically positive margins (R1) [10,11]. Adequate sampling of the primary tumor is important for grading of the carcinoma because overall grade depends on the highest grade component of the tumor.

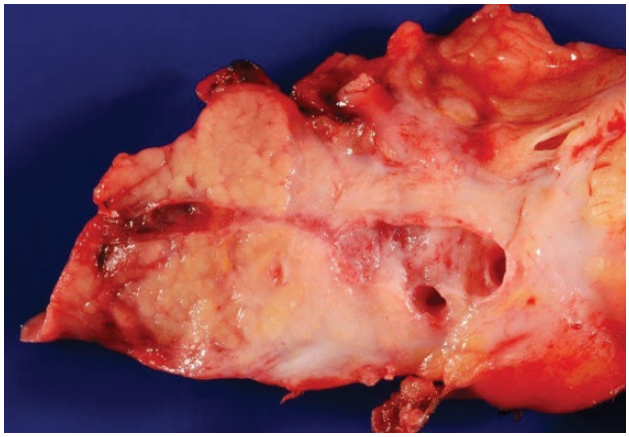

Figure 125.1 Cross section of a distal pancreatectomy for pancreatic cancer. Note the normal pancreatic duct (left), the infiltrative white mass narrowing the duct (center), and the upstream ductal dilatation (right).

Finally, assessment of at least 12 pancreatic lymph nodes is required for adequate staging, although in general, the more lymph nodes that can be examined, the more accurate the prognosis given to the patient [12,13].

Histology

Pancreatic ductal adenocarcinomas are characterized by haphazardly arranged glands and duct-like structures embedded in dense desmoplastic stroma (Fig. 125.2a). The cells forming the glands may be cuboidal or columnar and often have intracytoplasmic mucin.

Two histologic features stand out in PDAC. First, the neoplastic cells are extremely infiltrative. Perineural and intravascular invasion are present in practically all cases (Fig. 125.2b). The perineural invasion may explain some of the pain experienced by patients with PDAC, and nerves also serve as pathways for neoplastic spread beyond the pancreas [14]. Vascular invasion often leads to widespread dissemination of the neoplastic cells to other organs, particularly the liver. PDACs can grow into the lumina of vessels in a very distinctive way. Instead of forming a tumor thrombus, the neoplastic cells of PDACs can flatten out and grow along the endothelial surface of a vessel, mimicking the appearance of a duct (Fig. 125.2c) [15]. PDACs can also grow into preexisting pancreatic ducts in a similar fashion. This extension of the malignancy along a preexisting duct is referred to as "cancerization" of a duct. An abrupt transition from benign to malignant cytology favors cancerization (Fig. 125.2d) [16].

A second striking feature of PDAC is the dense, desmoplastic stroma. This stroma explains the firm consistency of PDAC, and it has been suggested that the stroma may impede the delivery of chemotherapy to the neoplastic cells [17–19].

Histologic grading of PDAC takes into account both cytologic and architectural features of the malignancy. PDACs that resemble normal pancreatic ducts are designated as "well-differentiated" while those that do not form glands, or which form poorly formed glands, are designated as "poorly-differentiated." When more than one grade is present in a tumor, the highest/worst grade should be given; this grade drives prognosis [20,21].

Well-differentiated PDAC can be quite bland by histology with well-formed ductal structures and relatively uniform nuclei. Well-differentiated PDACs can be histogically distinguished from the reactive glands of chronic pancreatitis using "architectural" features: loss of normal lobular architecture, incomplete glands, and the presence of ducts next to muscular arteries. Other helpful features include necrosis within glandular lumina, perineural invasion, and vascular space invasion [22]. A particularly tricky histologic variant of well-differentiated PDAC is the "large duct" variant, which can mimic cystic neoplasms grossly and histologically. The glands of the large duct variant form irregular dilated structures lined with a mucinous epithelium. Again, clues to the diagnosis of an invasive PDAC are primarily architectural: loss of lobular organization and large ducts that dissect through a desmoplastic stroma [23].

When compared to well-differentiated cancers, moderately-differentiated PDAC has greater variation in cytologic appearance and increased numbers of mitotic figures. Poorly-differentiated PDAC is defined by the presence of solid sheets and/or individual neoplastic cells that range in morphology from small cells with scant cytoplasm to larger, bizarre cells with abundant eosinophilic cytoplasm. Histologic grading is important because the prognosis of a poorly-differentiated PDAC is worse than that of a well or moderately differentiated one [3,21].

Gene expression in PDAC is important for multiple reasons. First, the protein products can be interrogated for diagnostic purposes. These include keratins 7 and 19, carcinoembryonic antigen (CEA), mesothelin, and mucin 1 (MUC1). In addition, expression studies may be useful for separating out subsets of pancreatic cancer with predictive and prognostic implications [24].

Histologic Variants of Ductal Adenocarcinoma

Several morphologic variants of PDAC with distinct clinical features have been described.

Adenosquamous Carcinoma

Adenosquamous carcinoma is, as the name suggests, an adenocarcinoma with a significant component with

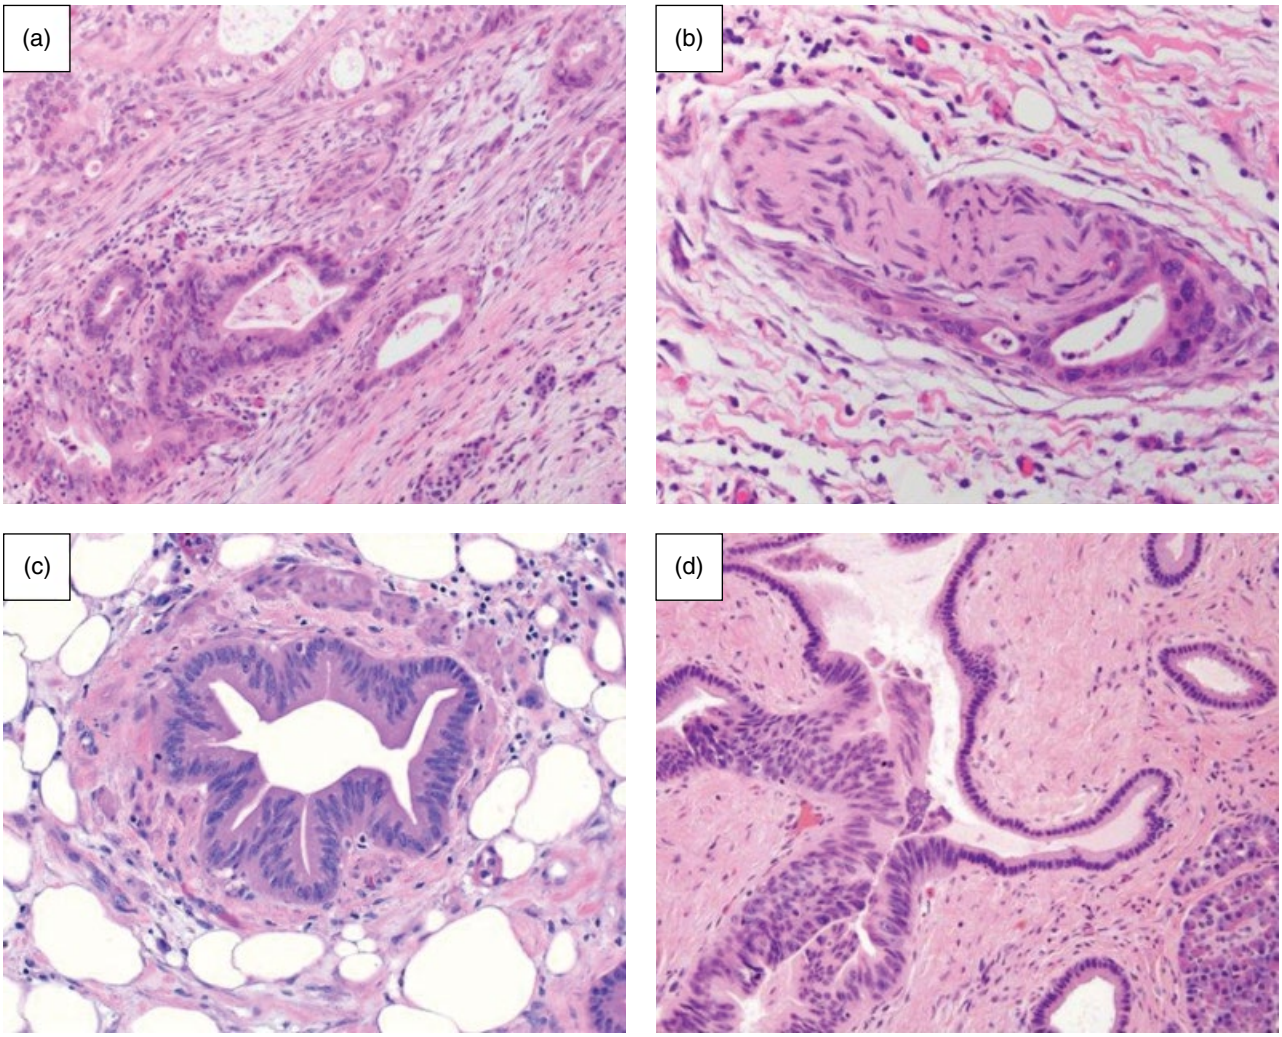

Figure 125.2 Infiltrating ductal adenocarcinoma. a) haphazardly arranged glands embedded in dense desmoplastic stroma. b) Perineural invasion. c) Venous invasion with the neoplastic cells replacing the endothelial cells and mimicking pancreatic intraepithelial neoplasia. d) Cancerization of a duct with the cancer (lower left) invading a preexisting pancreatic duct (center).

squamous differentiation (at least 30%). If no adenocarcinoma component can be found on extensive sampling, a metastasis from a primary squamous cell carcinoma from another organ must be considered. Patients with adenosquamous carcinoma of the pancreas have a worse prognosis compared to patients with PDAC, but recent studies have reported that some adenosquamous carcinomas respond to platinum-containing chemotherapies [25,26].

Colloid Carcinoma

Colloid, or mucinous noncystic, carcinoma is a variant of PDAC associated with intestinal-type intraductal papillary mucinous neoplasms (IPMNs, discussed below). In this subtype, pools of mucin dissect through stroma, and associated mucin-producing neoplastic epithelium either lines the mucin pools or floats within the mucin. Care must be taken not to overcall a ruptured cyst with mucin extruded into the stroma with a truly invasive colloid carcinoma. Malignant epithelium must be seen with the stromal mucin for a diagnosis of invasion [27].

Medullary Carcinoma

Like its counterpart in other organs, this variant is characterized by the syncytial growth of poorly differentiated epithelioid neoplastic cells with large nuclei. Medullary carcinomas also have "pushing" rather than infiltrating borders, and there is often a brisk inflammatory infiltrate of predominantly lymphocytes surrounding and infiltrating into the tumor, but fibrous stroma is scant [28].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Medullary carcinomas are important to recognize for three reasons. First, despite their poor differentiation, they are associated with a good prognosis [29,30]. Second, patients with a medullary carcinoma are more likely to have a family history of cancer [28]. Third, medullary carcinomas are more likely than ductal adenocarcinomas to have the genetic change of microsatellite instability (mismatch repair defect) [31]. Not only may these mismatch repair deficient PDACs be the first presentation of Lynch syndrome [32,33], but new treatment options such as PD-1 inhibitors may be effective in mismatch repair deficient malignancies [34].

Undifferentiated Carcinoma

Undifferentiated carcinomas are composed of predominantly spindled cells or bizarre large cells without a clear direction of differentiation. A lower grade component of conventional PDAC can often be found in these neoplasms, but the histologic grade and prognosis are defined by the undifferentiated "grade 4" component [3,35]. Undifferentiated carcinomas are less cohesive than typical PDAC, a feature that can be demonstrated by loss of e-cadherin expression and that may contribute to the extremely poor prognosis of this variant: the mean survival is less than one year [36]. Undifferentiated carcinomas with rhabdoid features are important to recognize because they may harbor distinct somatic mutations [37,38].

Undifferentiated Carcinoma with Osteoclast- like Giant Cells

Undifferentiated carcinoma with osteoclast-like giant cells is a distinctive neoplasm characterized by the presence of numerous intratumoral multinucleated nonneoplastic giant cells. Admixed with these giant cells are undifferentiated spindled or bizarre malignant cells which often, but not always, label with antibodies to keratins by immunohistochemistry. The giant cells express histiocytic markers, such as CD68. Genetic analyses of single cells microdissected from these carcinomas have shown that the multinucleated giant cells are not neoplastic, but that the undifferentiated cells in between the giant cells are [39]. As is true for undifferentiated carcinomas, the prognosis of patients with an undifferentiated carcinoma with osteoclast-like giant cells is poor, with mean survival of less than one year [40,41].

Uncommon Variants

The hepatoid and signet ring cell variants of PDAC are unique in that they can resemble metastases from other organs to the pancreas. As the name suggests, the hepatoid variant consists of polygonal eosinophilic cells that mimic a hepatocellular carcinoma and that may even label with hepatocyte antigens, such as Hep-Par and α-fetoprotein [42,43]. Metastasis to the pancreas from the liver must be ruled out before a diagnosis of primary hepatoid PDAC is rendered [3].

The signet ring variant of PDAC is characterized by cells that contain intracytoplasmic mucin with indented and displaced nuclei. The neoplastic cells grow as single, infiltrating cells rather than in well-formed glands or sheets [44]. This carcinoma most closely mimics lobular breast carcinoma or diffuse gastric carcinoma, both of which should be considered in the differential for a malignancy of this morphology.

Ductal Malignancies with Mixed Differentiation

Carcinomas of the pancreas can rarely have multiple different directions of differentiation. These include mixed ductal-neuroendocrine carcinoma and mixed ductal-neuroendocrine-acinar carcinoma. Diagnosis of a "mixed" carcinoma requires that at least one-third of the malignancy be composed of each neoplastic component. The prognosis for patients with a mixed carcinoma is generally driven by the worst component, in most cases the PDAC [45,46].

Staging

The staging of PDAC and its variants by the WHO and the American Joint Committee on Cancer, 8th edition, takes into account the size of the malignancy, regional lymph node involvement, and distant metastases (the TNM system) [3,47]. The extent of local tumor spread is no longer the dominant criterion for determining pathologic T stage.

Cystic Neoplasms

Intraductal Papillary Mucinous Neoplasm

The intraductal papillary mucinous neoplasm (IPMN) is a mucin-producing, duct-based, usually papillary neoplasm that, by definition, is greater than 1.0 cm [16,48]. IPMNs may arise in the main pancreatic duct or within a branch duct. Main duct IPMNs are more likely to be symptomatic and to progress to invasive carcinoma [49]. IPMNs are often multifocal, and patients are at risk for synchronous and metachronous disease. Genetic analyses have suggested that these multifocal lesions are often genetically distinct, but intraductal spread of neoplastic cells can also occur [50]. Because of this multifocality, patients who undergo partial pancreatectomy for IPMN

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

remain at risk for additional neoplastic cysts and even PDAC in their remnant pancreas [51]. Endoscopic ultrasound (EUS)-guided biopsy with sampling of cystic fluid for cytology and molecular studies can be important for preoperative diagnosis and planning [52,53].

Gross

Main duct IPMNs diffusely dilate the main pancreatic duct. Long finger-like papillae can often be seen projecting into the duct, and the duct typically contains thick, tenacious mucin. Branch duct IPMNs, by contrast, more often appear as a small group of cysts, often compared to a cluster of grapes, adjacent to but not involving the main duct. Many IPMNs are mixed and involve both main and branch ducts [48]. Foci of dense sclerosis adjacent to an IPMN suggest the possibility of an associated invasive adenocarcinoma. For this reason, and because invasion can be focal, the general rule for pathologic examination of IPMNs is very extensive, if not complete, submission for histology [54].

Histology

Histologically, the enlarged dilated ducts of IPMNs are lined by columnar mucin-producing neoplastic epithelial cells that may have intestinal, gastric, biliary, or pancreatobiliary type differentiation (Fig. 125.3). A single IPMN may have mixed differentiation, making the correlation between subtype and prognosis all the more complicated [48].

Intestinal-type IPMNs have interspersed goblet cells, typical of intestinal epithelium, and immunolabel with antibodies to MUC2, MUC5AC, and CDX-2 [48]. Of interest, many intestinal-type IPMNs have been found to harbor *GNAS* gene mutations [55]. Early somatic *GNAS*

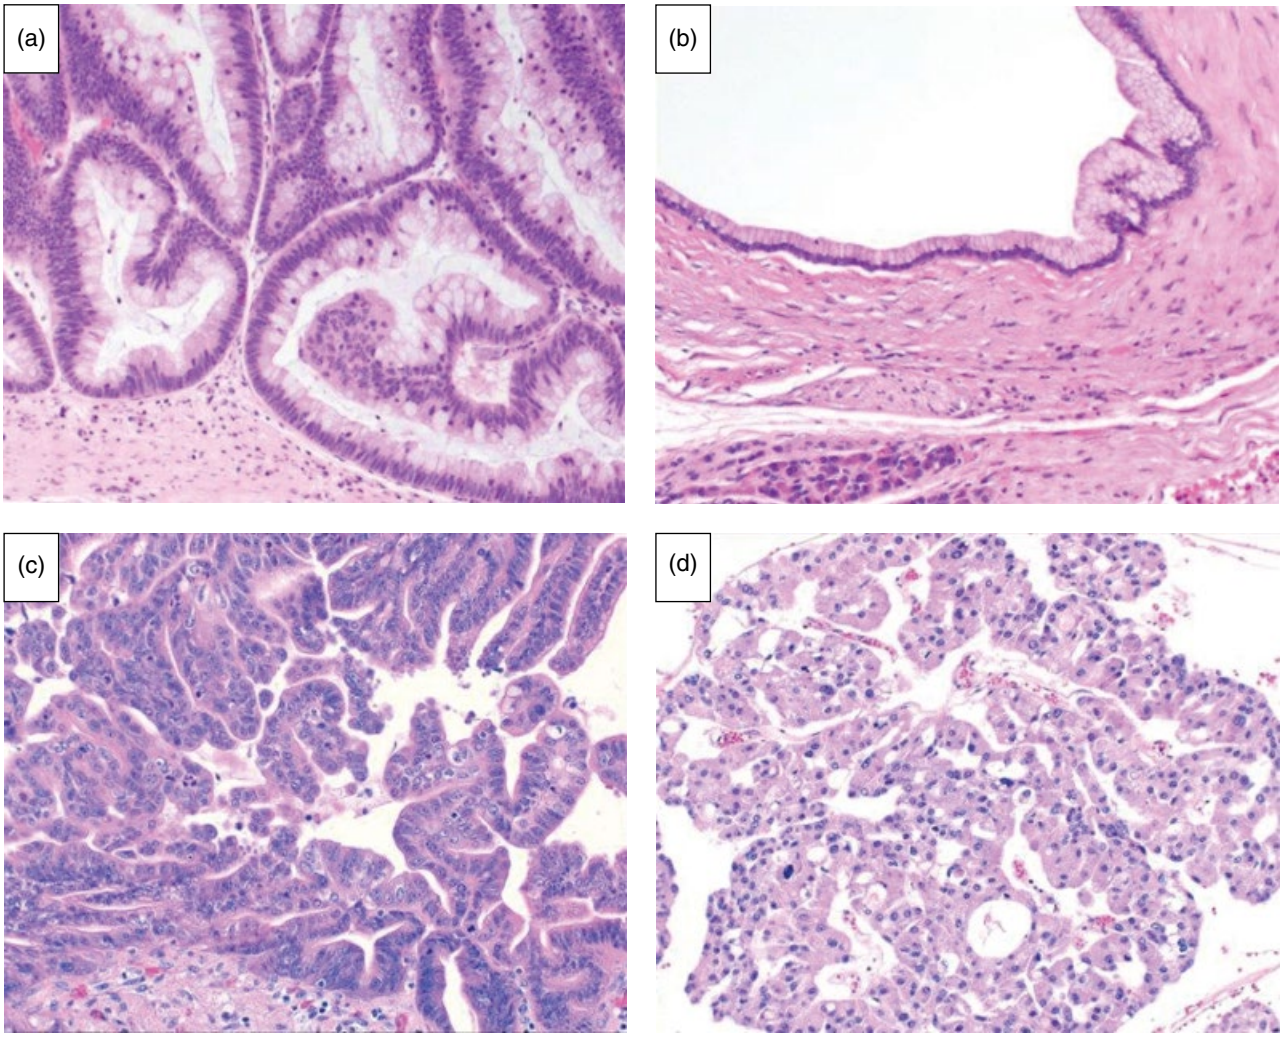

Figure 125.3 Intraductal papillary neoplasms. a) Intraductal papillary mucinous neoplasm- intestinal type. b) Intraductal papillary mucinous neoplasm- gastric type with low-grade dysplasia. c) Intraductal papillary mucinous neoplasm- pancreatobiliary type with high-grade dysplasia. d) Intraductal papillary oncocytic neoplasm.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mutations are the underlying genetic defect in McCune–Albright syndrome, and IPMNs are known to be associated with this disorder [56].

Gastric-type IPMNs have small nuclei with an apical, eosinophilic mucin cap similar to foveolar cells of the stomach, and these IPMNs label with antibodies to MUC5AC. Pancreatobiliary type IPMNs are composed of cuboidal cells with increased nuclear:cytoplasmic ratio and minimal intracytoplasmic mucin, and they immunolabel with antibodies to MUC1 and MUC5AC.

Intraductal neoplasms with oncocytic differentiation are designated intraductal oncocytic papillary neoplasms (IOPNs). IOPNs are composed of an eosinophilic, multilayered epithelium with large nuclei and prominent nucleoli; this variant immunolabels with antibodies to MUC6. Despite the marked atypia in oncocytic IPMN, invasive carcinoma is not common in this subtype [54]. IOPNs have been found to have unique gene fusions involving *PRKACA* and *PRKACB* that are not found in other pancreatobiliary lesions, and IOPNs are therefore now classified as distinct neoplasms (not as a subtype of IPMN) [57].

Intraductal papillary mucinous neoplasms are graded as having low- or high-grade dysplasia based on the degree of architectural and cytologic atypia. Low-grade dysplasia is defined as a single layer of cells with small, uniform nuclei growing along cyst walls with well-formed papillae. High-grade dysplasia is characterized by loss of nuclear polarity with nuclear hyperchromasia and pleomorphism along with architectural irregularities including irregular papillae and cribriform growth. Most gastric IPMNs are low-grade, while pancreatobiliary and oncocytic IPMNs are usually high-grade. Intestinal-type IPMNs may have low- or high-grade dysplasia [48,49].

Approximately one-third of surgically resected IPMNs have an associated invasive PDAC. The risk is greater with main duct IPMNs, if a mural nodule is present, and with increasing grades of dysplasia. High-grade intestinal-type and pancreatobiliary-type IPMNs are the most likely to have an associated invasive adenocarcinoma of colloid (mucinous noncystic) and tubular type, respectively [54]. Genetic analyses have shown that the carcinomas that are in direct anatomic association with the IPMN usually arose from the IPMN [58].

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms (MCNs) are mucin-producing epithelial neoplasms of the pancreas that typically do not involve the duct system, and which, by definition, have a characteristic ovarian-type stroma (Fig. 125.4a). MCNs, like IPMNs, also can progress to invasive adenocarcinoma. MCNs are most often located in the tail of the pancreas, and the vast majority arise in women [3].

Gross

Gross examination of MCN shows a well-demarcated multilocular cystic lesion. The cysts can be filled with mucin or in some instances blood-tinged fluid. The cysts can have a smooth lining or papillary projections may protrude into the lumina. The latter finding often corresponds to high-grade dysplasia and increased risk for invasive carcinoma. In contrast to IPMNs, the cysts do not communicate grossly with the duct system.

Histology

Histologically, MCN is lined by columnar mucin-producing epithelium that may have intestinal or gastric differentiation with varying degrees of dysplasia that is graded similarly to IPMN as low or high-grade. The key diagnostic feature for MCN is the specialized "ovarian-type"

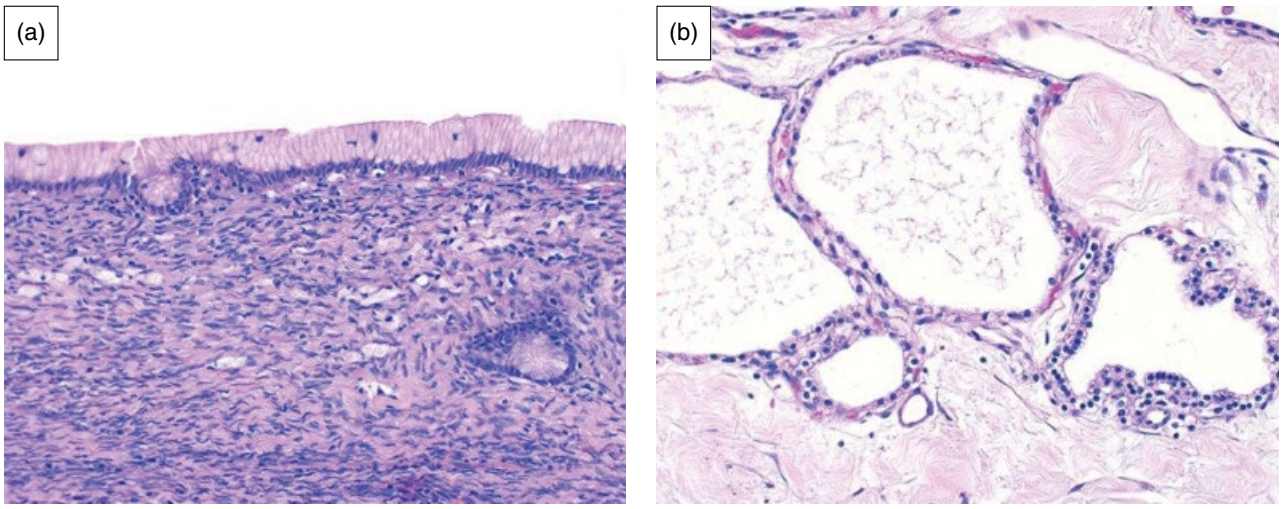

Figure 125.4 a) Mucinous cystic neoplasm with low-grade dysplasia. Note the characteristic ovarian-type stroma. b) Serous cystadenoma. Note the uniform cuboidal cells with clear cytoplasm.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

spindle cell stroma seen underlying the epithelium. Immunohistochemical stains for inhibin and progesterone receptor can be used to highlight the ovarian stroma [59].

Because MCNs are unifocal lesions, surgical resection of an MCN without invasive carcinoma is considered curative; however, up to 30% of MCNs have an associated invasive adenocarcinoma. The invasive component is usually a typical PDAC rather than a colloid carcinoma [59]. The depth and extent of invasion of the carcinoma are important prognosticators [60].

Serous Cystadenoma

Serous cystadenomas (SCAs) are cystic neoplasms of the pancreas composed of multiple cysts lined by glycogen-rich cells (Fig. 125.4b). The cyst fluid is watery or serous rather than mucinous.

Gross

The most common form of SCA is the microcystic SCA. Microcystic SCAs have innumerable small (millimeter) cysts, often surrounding a central scar. The macrocystic variant of SCA consists of one or at most a few large cysts. This latter variant can mimic an IPMN or MCN on imaging. Multiple SCAs throughout the pancreas suggest the von Hippel–Lindau (VHL) syndrome, as do mixed serous-neuroendocrine tumors [61]. The solid serous adenoma is a variant of SCA that, as the name suggests, grossly appears to be solid. Because solid serous adenoma remains well circumscribed, the differential diagnosis on both imaging and gross examination includes a neuroendocrine tumor [62].

Histology

All SCA variants are lined by a serous epithelium made up of cuboidal cells with clear to eosinophilic cytoplasm and small, centrally placed uniform nuclei. Transformation to a malignant serous cystadenocarcinoma (as defined by the presence of metastatic disease) is vanishingly rare; therefore, asymptomatic patients usually do not require surgery. In symptomatic cases, surgical resection of an SCA is considered definitive therapy [3,63,64].

Solid-Pseudopapillary Neoplasm

The solid-pseudopapillary neoplasm (SPN) is a neoplasm of uncertain histogenesis and low malignant potential [65,66]. SPNs occur with equal frequency in the pancreatic head, body, and tail.

Gross

On imaging and gross examination, SPNs are often large and heterogeneous but well demarcated. On cross-section, the tumor may be predominantly solid or cystic, and is often filled with hemorrhagic and necrotic material (Fig. 125.5a).

Histology

By light microscopy, SPNs are composed of loosely cohesive monomorphic epithelial cells with clear cytoplasm and round to oval grooved nuclei growing in pseudopapillae (Fig. 125.5b and 125.5c). Touch preparations at the time of intraoperative consultation can beautifully demonstrate the branching vascular architecture, cellular uniformity, and poor cohesion of the neoplastic cell population (Fig. 125.5d). Hyaline globules are often seen within the epithelial cytoplasm, and foreign body giant cells may be present. SPNs label with β-catenin (nuclear), which reflects the underlying β-catenin gene mutation in this neoplasm, and with LEF1 and CD10 [65,67,68].

All SPNs are classified as malignant. Although the majority of SPNs are indolent and cured by resection, cases of widespread metastatic disease are reported [69,70].

Acinar Cell Lesions

Acinar Cell Cystadenoma

This lesion is the subject of case series due to its rarity, and the reactive vs neoplastic nature is disputed because these lesions have not been found to harbor clonal mutations commonly associated with pancreatic neoplasia [71,72]. On gross examination, the cysts are well circumscribed and filled with clear, nonmucinous fluid. Histologic examination reveals an epithelial lining composed of cells with acinar differentiation and granular two-toned cytoplasm. There have been no reports of malignant transformation of this lesion, and the entity has therefore been renamed "cystic acinar transformation." [71].

Acinar Cell Carcinoma

Acinar cell carcinoma (ACC) of the pancreas is also quite rare, making up less than 2% of resected pancreatic neoplasms. ACCs have been reported in children as well as adults [73,74], and this malignancy usually harbors a high number of mutations [75].

Gross

Acinar cell carcinomas are well-circumscribed but bulky, fleshy, and often hemorrhagic neoplasms that may resemble the more common pancreatic neuroendocrine tumor (PanNET).

Histology

Histologic review shows a predominantly cellular neoplasm composed of a monomorphic population of

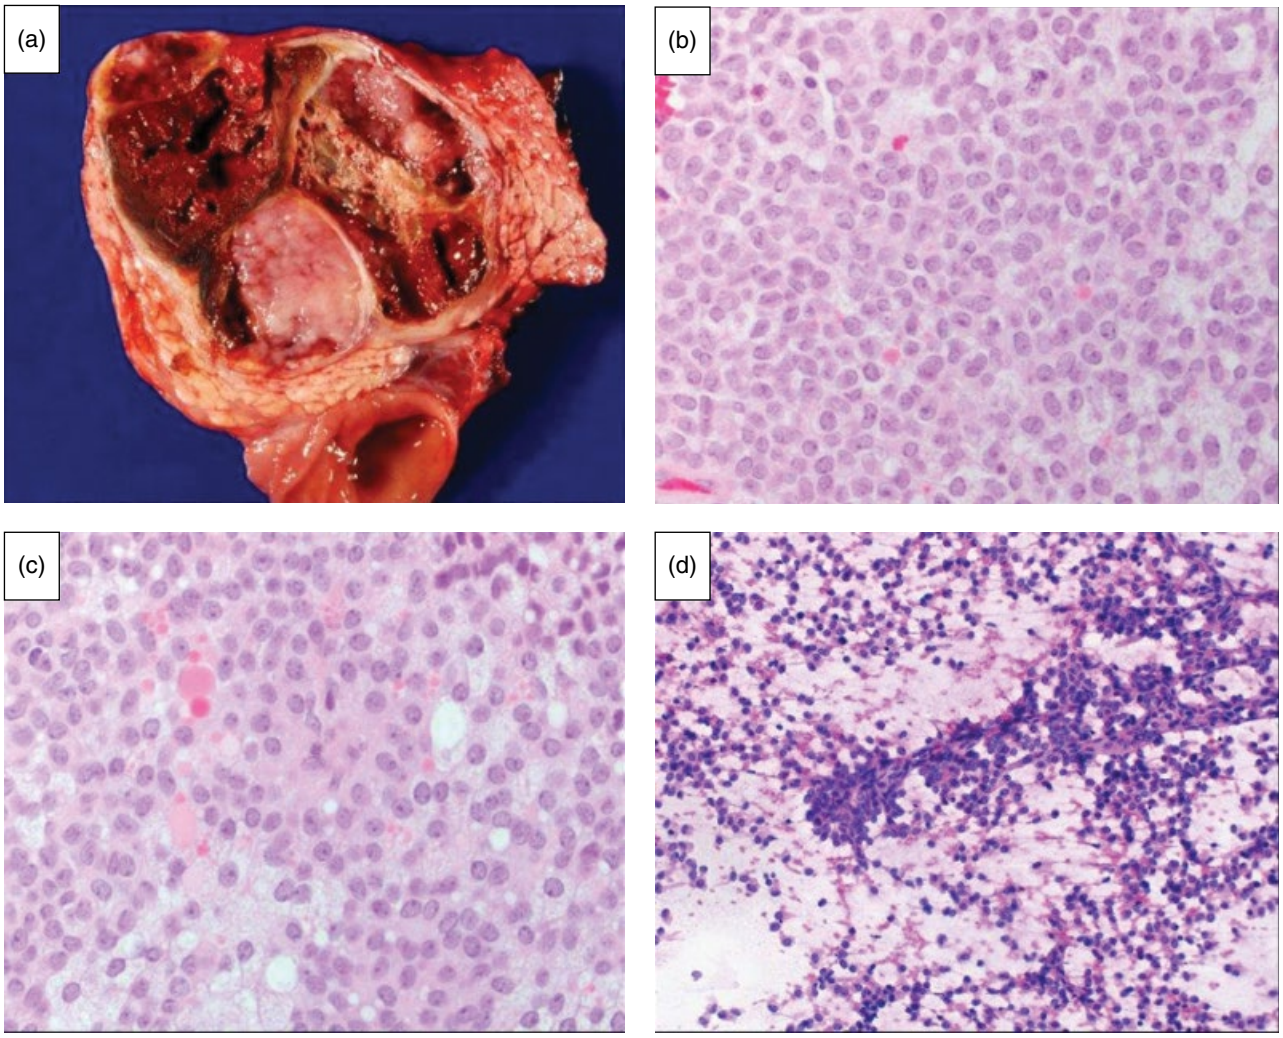

Figure 125.5 Solid pseudopapillary neoplasm. a) Grossly, some cysts contain viable tumor with a vaguely papillary architecture (center), while others (top) contain hemorrhagic debris. b) The nuclei of the neoplastic cells often have grooves. c) Hyaline globules are frequently found. d) A touch preparation helps highlight the delicate vessels and the poorly cohesive nature of the neoplastic cells.

cells with granular cytoplasm, large nuclei, and single prominent nucleoli (Fig. 125.6a). Several architectural patterns can be seen, from the formation of well-defined acini to solid sheets of cells. Desmoplastic stroma is not a prominent feature of ACC [74].

Ancillary stains are usually necessary to definitively diagnose an acinar cell carcinoma. Immunolabeling with antibodies to the pancreatic enzymes trypsin and chymotrypsin will highlight the cells, although a simple periodic-acid Schiff with diastase (PAS-D) can also highlight the enzymatic granules [74]. Some antibodies to BCL-10 cross-react with carboxyl ester hyrodrolase, and we find immunolabeling for BCL-10 to be particularly useful in identifying acinar differentiation [76]. Up to one-third of acinar cell carcinomas will show patchy labeling with neuroendocrine markers, specifically chromogranin A [74]. To diagnose a true mixed acinar cell/neuroendocrine carcinoma, however, at least 25–30% of the neoplastic cells need to have definitive neuroendocrine differentiation in addition to the cells with definitive acinar differentiation [77]. These neoplasms are given the unwieldy designation "mixed neuroendocrine–nonneuroendocrine neoplasm" (MiNEN). Mixed acinar/ductal adenocarcinomas have also been described [46].

The prognosis in mixed tumors is driven by the most aggressive component [46,77]. In pure acinar cell carcinoma, the prognosis is better than that of stage-matched PDAC, with a 25–50% five-year survival rate. Staging of acinar cell carcinoma follows the rules of PDAC [3].

Pancreatoblastoma

The pancreatoblastoma is one of the most common pancreatic malignancies of childhood [78,79]. Although most are nonsyndromic, pancreatoblastomas have been reported in infants with Beckwith–Wiedemann

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 125.6 a) The neoplastic cells of acinar cell carcinomas form small lumina, and the nucleoli characteristically have single prominent nucleoli. b) Pancreatoblastomas, by definition, have squamoid nests (center).

syndrome and in older children/young adults with familial adenomatous polyposis [80–82]. Cases in adult patients can occur, but with even less frequency than in children [83,84].

Gross

On gross examination, fleshy lobules of tumor, fibrosis, necrosis, and calcifications may all be present in a single neoplasm [85].

Histology

On histologic review, pancreatoblastomas are composed of neoplastic cells with acinar cell differentiation admixed with squamoid nests (Fig. 125.6b). Squamoid nests are aggregates of cells with spindled to epithelioid morphology. Squamoid nests differentiate pancreatoblastoma from pure acinar cell carcinoma. Cells with neuroendocrine differentiation are also usually present, and rarely heterologous elements or small cell features may be seen within a pancreatoblastoma [73,86].

Like an acinar cell carcinoma, pancreatoblastoma is reactive for PAS-D, trypsin, chymotrypsin, and BCL-10, and scattered neuroendocrine markers may be expressed across the tumor. Abnormal, often patchy, nuclear labeling with antibodies to β-catenin is seen in a subset of pancreatoblastoma.

Surgical resection is considered the first line of treatment, and patients with nonresectable disease have a dismal prognosis. Even with resection, the five-year survival rate for pancreatoblastoma is only 65% [79,87].

Conclusion

Exocrine malignancies of the pancreas include benign lesions as well as some of the deadliest malignancies known. The importance of accurate pathologic diagnosis and staging for patient prognosis and treatment cannot be overstated, especially when dealing with the complicated area of cystic neoplasia. A new understanding of the molecular drivers of pancreatic neoplasia supports the current gross and histologic classification presented here. We hope that this chapter has provided the tools for confident gross examination and histologic diagnosis of exocrine pancreatic lesions.

Pancreatic Cancer: Precancerous Lesions

Michael J. Pflüger[1], Michaël Noë[2], and Lodewijk A.A. Brosens[2]

[1] *Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, USA*
[2] *Department of Pathology, University Medical Center Utrecht, Utrecht, The Netherlands*

Introduction

Different precursor lesions can give rise to pancreatic ductal adenocarcinoma (PDAC). The basis for the current classification of these lesions was established in an international consensus meeting in 1999 [1]. Since then, additional consensus meetings have been held [2,3].

At present, five precursor lesions are recognized: pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasm (IPMN), intraductal oncocytic papillary neoplasm (IOPN), intraductal tubulopapillary neoplasm (ITPN), and mucinous cystic neoplasm (MCN) [4]. These noninvasive precursors exhibit a unique multistep morphologic and genetic progression to invasive carcinoma [5–7]. Histologically, these changes are reflected by different grades of dysplasia. By convention, the highest degree of atypia determines the histologic grade of the lesion. The previous three-tiered grading system has been replaced by a two-tiered system for PanINs, IPMNs, and MCNs and now distinguishes between low-grade and high-grade (occasionally referred to as "carcinoma in situ") lesions [3].

Pancreatic Intraepithelial Neoplasia

Clinical Features

Pancreatic intraepithelial neoplasia (PanIN) is the most common precursor lesion of PDAC and it is believed that most PDACs arise from PanINs. Hulst (Boerhaave Laboratory, Leiden, The Netherlands) was the first to describe this microscopic lesion a century ago as a lesion in between ("Zwischenform") normal tissue and invasive carcinoma [8]. These lesions were shown to be more common in pancreata with an invasive carcinoma than in pancreata without cancer [9]. PanINs were found in 82% of pancreata with PDAC, in 60% of pancreata with chronic pancreatitis, and in 16% of normal pancreata. Both sexes are equally affected and the incidence tends to increase with age [10]. In patients with a strong family history of pancreatic adenocarcinoma, PanINs are more frequently found and show a higher degree of dysplasia and multifocality [11,12].

Pancreatic intraepithelial neoplasia are not associated with specific clinical signs or symptoms and are typically found incidentally in resection or biopsy specimens. PanINs are more frequently located in the head of the gland than in the tail [9]. Because of their small size, PanINs are macroscopically invisible and cannot be diagnosed on imaging. However, nonspecific findings such as lobular atrophy and fibrosis can suggest their presence [11,13]. Some PanINs may present with obstruction or stricture and subsequent retrograde ductal dilation [14–16].

Pathologic Features

Pancreatic intraepithelial neoplasia are microscopic (usually <0.5 cm in diameter), noninvasive epithelial neoplasms. They are characterized by cuboid-to-columnar cells with varying amounts of apical cytoplasmic mucin and varying degrees of cytologic and architectural atypia. The epithelium almost always shows gastric-foveolar differentiation and has a flat or (micro)papillary architecture [3,4].

Since the first classification of the precursor lesions in 1999, three grades have been discriminated in the progression of PanIN, based on the increasing degree of epithelial atypia and architectural complexity: PanIN-1, PanIN-2, and PanIN-3 [1]. PanIN-1 lesions were characterized by minimal nuclear atypia, inconspicuous nucleoli,

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Companion website: www.wiley.com/go/beger/thepancreas4e

and absent mitotic figures and could be further subdivided into flat (PanIN-1A) and micropapillary types with slight nuclear stratification (PanIN-1B). Because of the absence of nuclear atypia and presence of mucin, which is not normally observed in pancreatic ductal cells without histochemical staining, these lesions had been previously designated as "mucinous metaplasia" or "mucous cell hypertrophy." Moderate nuclear atypia, pseudostratification, loss of polarity, hyperchromasia, and rare mitotic figures were features of PanIN-2. Features of PanIN-3 lesions were marked atypia, (atypical) mitotic figures, loss of polarity, and a papillary, micropapillary, or occasionally flat architecture. Cribriform structures, necrosis, and budding of epithelial cells into the lumen could be present.

Poor interobserver agreement between PanIN-1 and PanIN-2 as well as the very limited progression of both PanIN-1 and PanIN-2 to PDAC led to the recommendation from an expert panel to replace this traditional three-tiered grading system [3]. The new two-tiered grading system distinguishes between low-grade PanIN (former PanIN-1[A/B] and PanIN-2) and high-grade PanIN (former PanIN-3) and is now commonly adopted (Fig. 126.1) [4].

High-grade (HG) PanIN is almost exclusively found in association with invasive PDAC [9]. This association is so striking that in pancreata without PDAC, a HG-PanIN lesion may raise strong suspicion for invasion at a different part of the organ [3]. When PDAC is present, HG-PanIN is very hard to differentiate from the infiltrating carcinoma growing into preexisting pancreatic ducts and ductules (i.e., "intraductal spread of invasive carcinoma," "cancerization of the duct," or "colonization"). Signs indicative of this phenomenon frequently observed in PDAC

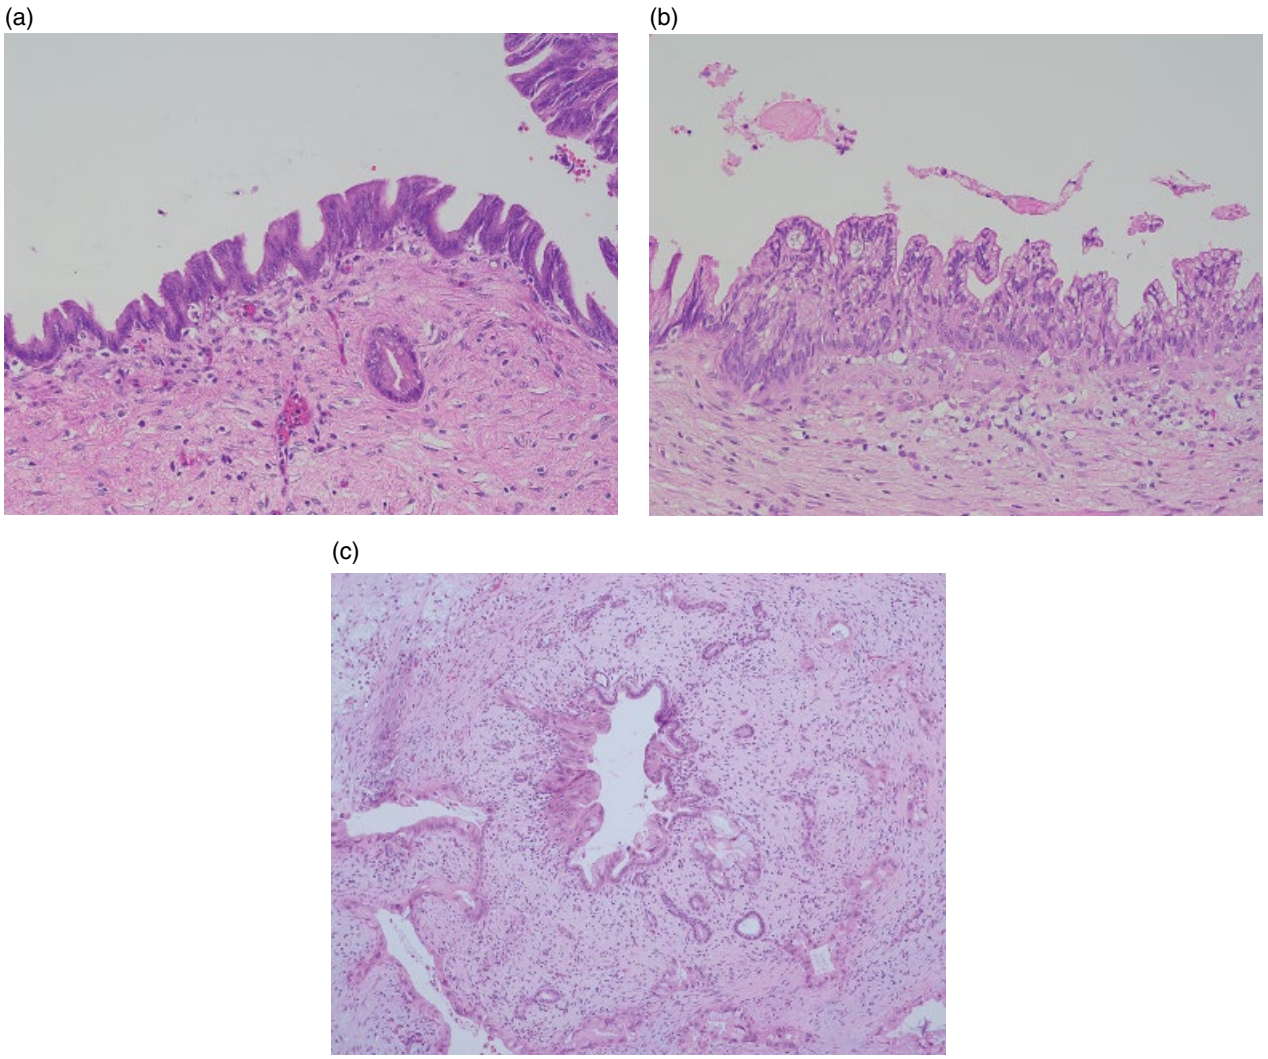

Figure 126.1 Dysplastic grades of PanIN. (a) Low-grade PanIN (formerly PanIN-2) shows moderate atypia and pseudostratification. (b) High-grade PanIN shows irregular nuclei and micropapillary architecture. This grading is reserved for the most severe nuclear and architectural atypia. (c) Cancerization of duct. Histomorphologic signs indicating ductal cancerization are the presence of normal-appearing ductal epithelium together with high-grade dysplasia within a single duct with abrupt transition. In addition, adjacent invasive carcinoma infiltrating the stroma favors the diagnosis of ductal cancerization.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. specimens are an invasive carcinoma immediately adjacent to the intraductal lesion with histologic similarity and an abrupt transition from highly atypical epithelium to normal duct epithelium within the same duct [4,17]. Distinguishing HG-PanIN from ductal cancerization has clinical relevance as the presence of an intraductally growing PDAC at the surgical resection margin may impact outcomes, whereas the presence of PanIN of any grade at the surgical margin in patients resected for PDAC does not influence survival and no additional resection is required [17,18]. Genetic analysis for alterations in *SMAD4* or *TP53* or immunohistochemical staining for the corresponding proteins may be helpful to distinguish ductal cancerization from HG-PanIN [16,17,19].

Some morphologic variants of PanIN have been described in the literature: foamy gland type, intestinal type, and oncocytic type [20,21]. However, the latter two could be early manifestations of IPMN or IOPN, respectively. PanINs lack MUC2 expression, but usually show expression of EMA/MUC1, MUC4, and MUC5AC [4]. MUC6 positivity may be seen in low-grade PanIN.

Molecular Features

The lowest grade PanIN lesions with minimal cytologic atypia were not originally regarded as neoplastic, but instead were interpreted as hyperplasia. After finding activating *KRAS* mutations, these lesions were considered neoplastic and the term "pancreatic intraepithelial neoplasia" was proposed [1,22–24]. A recent study confirmed the high prevalence of *KRAS* mutations in PanINs, with >90% positivity in both LG and HG lesions [19]. Telomere shortening has been observed as an almost universal feature in PanINs, including in PanIN-1A, indicating that this is a very early genetic event [25].

In a subset of PanINs, activating *GNAS* mutations were found, which may even precede *KRAS* alterations in some cases [19,26]. However, *GNAS* mutations are a genetic hallmark feature of IPMNs, so that presence of *GNAS* mutations in early PanIN could indicate a later development to IPMN [27–29]. Further in the progression of PanIN, genetic and epigenetic inactivation of *CDKN2A/p16* is seen [19,30]. *TP53* and *SMAD4* mutations are considered late events in the progression of PanIN; however, the latest research suggests that especially *SMAD4* mutations may only be seen after progression to invasive PDAC has occurred [16,17,19].

Intraductal Papillary Mucinous Neoplasm

Clinical Features

In 1936, György Habán described a pancreatic lesion with "aneurysma-like" cyst formation, papillary growth of the epithelium, and mucin production, which is considered to be the first description of what is today known as intraductal papillary mucinous neoplasms (IPMN) [31,32]. The term itself was first proposed by Morohoshi et al. in 1989 and later in the 1990s and early 2000s became the consensus name for a defined type of pancreatic lesion, previously referred to by various names [2,33].

Initially, IPMN was considered a disease of older, cigarette-smoking men. However, a metaanalysis showed that there are geographic differences in the gender of patients with an IPMN [34]. In Asia, main duct and branch duct-type IPMNs affect more men than women. In the United States and Europe, main duct-type IPMNs affect more men, while branch duct-type IPMNs affect more women. Patients diagnosed with IPMN are usually in their mid-60s, regardless of geographic region or type of duct involvement [34,35]. The mean age of patients diagnosed with IPMN with invasive carcinoma is a few years higher than the mean age of patients diagnosed with noninvasive IPMN, suggesting a window for interference with an advancing tumorigenic process [36,37].

A recent study based on genetic data estimated that the progression interval between high-grade IPMN and invasive carcinoma is over three years, with notable interpatient variability [5]. Once the lesion has advanced to PDAC, survival rates decrease significantly (five-year survival after resection: 94% HG-IPMN vs 31% invasive IPMN) [38]. Although early-stage IPMN-associated carcinomas have a relatively favorable prognosis and contribute to the better overall survival of IPMN-associated carcinomas as compared to resected standard PDAC (i.e., without preceding IPMN), the prognosis can be equally poor when IPMN-associated carcinoma is diagnosed at a late stage [39]. In fact, when adjusted for tumor stage or adverse pathologic characteristics (e.g., nodal involvement, perineural/vascular invasion), the survival difference between IPMN-associated carcinoma and conventional PDAC can vanish, indicating a similarly aggressive tumor biology [38,40]. These findings highlight the critical role of noninvasive IPMNs for early detection and intervention to improve survival.

Beyond invasive carcinomas that arise directly from IPMN ("IPMN-associated carcinoma" or "PDAC derived from IPMN"), invasive carcinomas can also develop independently from an IPMN within the same specimen ("IPMN with concomitant invasive carcinoma" or "PDAC concomitant with IPMN") [3,41–43]. Measuring the distance between invasive carcinoma and IPMN, complete histologic examination of the intervening tissue, and genetic analyses may aid in assessing the relationship and origins of the invasive carcinoma. However, the exact differences between these two entities, their specific mechanisms of tumorigenesis, and the clinical implications of their distinction are not fully understood yet.

Intraductal papillary mucinous neoplasms are seen more frequently in patients with a family history of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. pancreatic cancer, Peutz–Jeghers syndrome, familial adenomatous polyposis (FAP), Lynch syndrome, Carney complex, and McCune–Albright syndrome. In addition, an increased prevalence of extrapancreatic malignancies has been observed in patients diagnosed with IPMN, potentially indicating an overall increased risk for neoplasia in these individuals [44,45].

Due to the widespread implementation of cross-sectional abdominal imaging techniques, macroscopic pancreatic cysts are relatively common findings. Epidemiologic studies show great variety in the prevalence of pancreatic cysts due to the use of different imaging techniques and different study populations. In asymptomatic cohorts undergoing cross-sectional imaging, pancreatic cysts were detected in more than 2% of patients [46–48]. Of these incidentally discovered cysts, more than 80% were radiologically diagnosed as IPMN. Both, the prevalence of pancreatic cysts overall and the prevalence of IPMN, increased with age, reaching up to 13.5% and 12.2%, respectively, in patients over 80 years of age.

Despite their macroscopic appearance and radiographic visibility, patients diagnosed with IPMN are frequently asymptomatic [35,49]. However, unspecific abdominal symptoms, such as pain or discomfort, can be present. Some patients present with more objective symptoms like jaundice, weight loss, or acute pancreatitis. On endoscopy, a patulous papilla extruding mucus can be seen in some patients with IPMN. This so-called "fish-mouth" appearance is virtually diagnostic for the presence of an IPMN (Fig. 126.2a).

Intraductal papillary mucinous neoplasms are most frequently located in the proximal pancreas (i.e., pancreatic head, uncinate process) [35,38]. Based on the involvement of the pancreatic duct system, IPMNs are classified as main duct type, branch duct type, or mixed type. The rationale behind this classification is that lesions with main duct involvement harbor a significantly higher risk of malignancy. Pooled data from multiple studies showed that invasive carcinoma is present in 43.6% of main duct-type, 16.6% of branch duct-type, and 45.3% of mixed-type IPMNs [50]. However, there can be considerable discrepancy in the assessment of duct involvement between radiologic and histopathologic examination. For example, imaging studies may fail to accurately diagnose minimal main duct involvement of IPMNs that primarily affect the branch ducts [51]. Therefore, distinction of IPMNs according to their duct involvement (i.e., main-, branch- or mixed-type) is primarily an imaging classification and not a pathologic criterion. However, it plays a key role in the clinical management of patients with suspected IPMN [4].

Based on preoperative imaging, clinical presentation, and cyst fluid analysis, surgical resection is recommended in a subset of IPMN patients at high risk for malignant progression [52–55]. However, even if invasion is absent in final pathology, recurrence in the remnant pancreas in the form of a new IPMN or PDAC has been reported in up to every fifth patient, indicating that surgical intervention should be seen as risk reduction rather than definitive cure and demands ongoing postoperative surveillance [56–60]. Recurrence following resection of noninvasive IPMN along with molecular studies suggest that IPMN may be a multifocal disease affecting the entire gland in some patients ("field cancerization/defect"), placing them at risk for malignant neoplasia [42,58,59].

Pathologic Features

Intraductal papillary mucinous neoplasms has been defined in consensus meetings as: "*grossly visible, predominantly papillary or rarely flat, noninvasive mucin-producing epithelial neoplasm arising in the main pancreatic duct or branch ducts*" [1–3]. This definition incorporates the two hallmark features of IPMN: papilla formation and mucin production. The diameter of IPMN is usually ≥1.0 cm, highlighting its macroscopic visibility. An intraductal neoplastic precursor lesion larger than a PanIN (≥0.5 cm) but smaller than a typical IPMN (<1.0 cm) can be either a large PanIN or a small IPMN.

Features that occur predominantly in the setting of an IPMN, like the differentiation towards intestinal-type epithelium or a mutation specific for IPMN (such as an activating *GNAS* mutation), are clues for a small IPMN [28]. If one of these features is present, the lesion can be called "incipient IPMN" [3,4]. Gastric-type differentiation can be seen in both PanIN and IPMN, making it a nondistinctive feature. Gastric-type lesions of at least 0.5 cm but smaller than 1.0 cm lacking features of incipient IPMN should be documented descriptively. Of note, during surgical resection or tissue processing, the lesions' size may be reduced from its original *in situ* size, so that combination with radiographic data for size assessment can be helpful to establish the correct diagnosis.

Similar to PanINs, a consensus meeting recommended replacing the three-tiered with a two-tiered grading system [3]. The former "IPMN with low-grade dysplasia" and "IPMN with intermediate-grade dysplasia" are now "IPMN, low-grade" while the former "IPMN with high-grade dysplasia" is now "IPMN, high-grade".

Histologically, IPMNs can be subtyped by their direction of differentiation as gastric, intestinal, or pancreatobiliary [4,61]. Gastric-type IPMN is characterized by cells that resemble the foveolar epithelium of the stomach and is the most common IPMN subtype. Gastric-type IPMNs typically involve the branch ducts [62]. The epithelium consists of a monolayer of columnar cells with basally oriented nuclei and abundant mucinous cytoplasm (Fig. 126.2b). Gastric-type IPMNs are usually low-grade dysplastic and commonly show mutations in *KRAS* and *GNAS* [29]. Moreover, they have the lowest risk for invasion compared to other subtypes. IPMNs containing

an admixture of morphologic subtypes often show gastric-type epithelium along with either pancreaticobiliary or intestinal epithelium [63].

It has been proposed that gastric-type IPMNs are an early type of lesion from which other subtypes may emerge. Traditionally, gastric-type IPMNs have been linked to precede the pancreaticobiliary type; however, a recent study suggested an evolutionary linkage between gastric- and intestinal-type IPMN [64,65]. The growth pattern of gastric IPMNs can be flat, papillary, or tubular. The tubular growth pattern can sometimes predominate. The tubular-predominant, gastric-type IPMN (formerly "intraductal tubular adenoma, ITA") needs to be distinguished from intraductal tubulopapillary neoplasm (ITPN; formerly "intraductal tubular carcinoma, ITC"), with high-grade cytonuclear features in the latter being a clue for their distinction.

The pancreatobiliary-type IPMN is least frequently seen and lined by mucin-depleted cells with nuclei with marked variation in size and shape. These nuclei have irregular contours and prominent nucleoli (Fig. 126.2c). Pancreaticobiliary-type IPMNs are predominantly graded as high-grade dysplastic and are the subtype most frequently associated with invasion [62].

The intestinal-type IPMN is morphologically similar to a colonic villous adenoma. The papillae are typically long and occasionally branching. The nuclei of the cells are hyperchromatic, elongated ("cigar-shaped"), and show some degree of pseudostratification. The cells contain variable amounts of mucin and dispersed goblet-cells can be observed (Fig. 126.2d). This subtype typically shows high-grade dysplasia and is predominantly found in the main duct [61,62].

The 2019 World Health Organization classification of tumors of the digestive system provided an immunohistochemical aid for subtyping these IPMNs based on mucin glycoprotein-stains [4]. All IPMNs stain positive for MUC5AC. In addition, intestinal-type IPMNs show positivity for MUC2 and CDX2, whereas the pancreatobiliary type is positive for MUC1/EMA. However, definitive assignment to one of the histologic subtypes may not be possible in a considerable proportion of IPMNs due to uncharacteristic morphology, mixed epithelial subtypes, or discordant immunohistochemistry [63]. In addition, moderate interobserver agreement has been reported [66]. Given these limitations in subtyping of IPMNs, the associations between subtype and prognosis may be even stronger than previously indicated [62,63,67]. Alternatively, the differences in prognosis between the various subtypes of IPMN may mainly reflect inherent differences in the grades of dysplasia between subtypes.

Intraductal papillary mucinous neoplasms can progress into tubular carcinoma or colloid carcinoma. Tubular carcinomas are associated with gastric- and, especially, pancreatobiliary-type IPMNs [62]. They resemble conventional PDAC, both histologically and in terms of survival [68]. Similar to conventional PDAC, *KRAS* mutations were the predominant genetic alterations in this tumor type [29]. In contrast, colloid carcinomas are associated with intestinal-type IPMNs, show a more favorable prognosis than tubular or conventional PDACs, and harbor frequent *GNAS* mutations [29,62,68].

Molecular Features

Whole-exome sequencing of IPMNs revealed an average of 26 mutations per IPMN [69]. *KRAS* and *GNAS* are the most commonly mutated genes, each reported to be altered in 50–80% of IPMNs [27,69]. Primary locations of the mutations are at codon 12 and 201, respectively [69]. In almost all IPMNs, either a *KRAS* or *GNAS* mutation can be found and co-occurrence of these alterations within the same lesion is frequently observed [27,70]. The overall third most prevalent somatic mutation in IPMNs is *RNF43,* reported to be altered in 14–75% [69–72]. *CDKN2A/p16* is another gene commonly mutated in IPMNs. Alterations in *TP53* can be found in high-grade dysplasia and *SMAD4* mutations are usually not observed until invasion is present [70,71]. In turn, mutations in *KLF4*, a member of the Krüppel-like transcription factor family, show a high prevalence in low-grade dysplasia [71]. Beyond the degree of atypia, the histologic subtype affects the prevalence of somatic mutations in IPMNs [73].

Recent analyses of somatic driver gene mutations revealed significant genetic heterogeneity within IPMN lesions, especially with respect to mutations in *KRAS*, *GNAS*, and *RNF43*. Along with computational modeling, this suggests an evolutionary development, in which selection, expansion, and progression of multiple subclones eventually lead to emergence of an invasive subclone that has accumulated a distinct set of mutations in various driver genes. It has been proposed that this clonal selection incites with multiple subclones that arise independently from each other at a very early stage of tumorigenesis (*polyclonal origin*) and that the subsequent clonal selection process may be different between individuals and driven by varying selective pressures at different time points [5,27,29,43,71,74].

Intraductal Oncocytic Papillary Neoplasm

Clinical Features

First described as an entity in 1996, intraductal oncocytic papillary neoplasms (IOPNs) were classified as oncocytic-type IPMNs until recently [75]. Emerging evidence of their distinct morphologic and genomic features as

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

compared to other IPMN subtypes led to their classification as separate precursor lesions in the 2019 WHO classification of the digestive system [4]. This reclassification also appreciates the similarity of IOPNs to a group of other oncocytic tumors in various extrapancreatic organs (e.g., thyroid, kidney, salivary gland) [76–79]. Besides their oncocytic features, this heterogeneous group of tumors shares its rare occurrence and a usually more indolent course. Therefore, they are commonly classified separately from their respective conventional-type (i.e., nononcocytic-type) tumors.

Despite their relatively large size (reported mean 4.6–6 cm) [75,77,80,81], previous studies indicated a favorable biologic behavior of IOPNs with an excellent prognosis following surgical resection [76,82]. Although higher recurrence rates compared to other IPMN subtypes have been hypothesized, survival was excellent, even if an invasive component was present or recurrence occurred.

Intraductal oncocytic papillary neoplasms show a relatively equal sex distribution and about half of the resected cases were asymptomatic [76,82]. Approximately two-thirds of IOPNs are located in the pancreatic head and the lesions can resemble PDAC on preoperative imaging due to their complex composition [75–77,81,82]. Given the rarity of these lesions and their changing classification, larger cohorts are needed to allow for more robust analysis of their clinical behavior and prognosis. The most recent classification as a separate entity will likely aid in these efforts.

Pathologic Features

The growth pattern of IOPN is distinctive, consisting of arborizing papillae, lined by 1–5 layers of cuboidal epithelium. These epithelial cells are characterized by abundant eosinophilic cytoplasm due to the accumulation of mitochondria. The nuclei of these oncocytic cells contain a single, prominent, eccentric nucleolus. A specific feature is the punched-out spaces in the epithelium (Fig. 126.2e). Given the architectural complexity and nuclear atypia, IOPNs are typically regarded as high-grade dysplastic [4]. Of note, histopathologic observations that suggest invasion (e.g., growth along adjacent benign ducts, myxoid/edematous stromal changes simulating desmoplasia, complex architecture) are commonly present, but may frequently only mimic invasiveness (e.g., as a result of tangential sectioning), likely explaining the differing rates of cases with associated invasion described in the literature (12–61%) [76–78,81,82]. However, a dedicated analysis found predominantly local invasion (i.e., pT1 or pT2), if true invasion was identified [82]. If PDAC is found in association with IOPN, extracellular mucin accumulation, in which neoplastic cells are suspended, can often be seen and resembles colloid carcinoma [81].

Immunohistochemical staining for MUC5AC, MUC6, and HepPar-1 is typically positive in IOPNs [4,78]. Recently, CD117 expression has been proposed as an additional marker to distinguish IOPN from other differentials and the presence of hyalinized stroma may aid in establishing the diagnosis of IOPN [78,80,83]. Similar to the nomenclature in IPMNs, small lesions with a diameter between 0.5 and 1.0 cm can be called "incipient IOPN" when oncocytic differentiation is present [4].

Molecular Features

Genetic studies of IOPN have repeatedly confirmed the absence of established driver gene mutations commonly present in PDAC or other precursor lesions. IOPNs typically lack somatic mutations in *KRAS* and *GNAS*. Missense mutations and frameshift deletions in *ARHGAP26*, *ASXL1*, *EPHA8*, and *ERBB4* have been reported [77]. A recent study indicated that recurrent gene fusions, rather than isolated mutations in specific genes, may be the genetic drivers of IOPN [81]. *ATP1B1-PRKACB*, *DNAJB1-PRKACA*, and *ATP1B1-PRKACA* fusions were present not just in the lesion but also in their corresponding associated invasive carcinoma and preoperative cyst fluid analyses, the latter highlighting potential clinical utility for preoperative diagnosis.

Intraductal Tubulopapillary Neoplasm

Clinical Features

Intraductal tubulopapillary neoplasms ITPNs are rare intraductal neoplasms of the pancreas. Grossly, they are rather solid, noncystic lesions with intraductal growth and typically do not secrete mucin. They occur equally in men and women. About half of the patients are symptomatic and present with nonspecific gastrointestinal complaints, such as abdominal pain [84]. The lesions are distributed across the entire organ, with a slight predominance in the pancreatic head and with about a quarter of cases diffusely involving the gland [84]. Assessment of invasiveness and, if present, its extent can be challenging. In previous studies, up to 80% of patients had an invasive component, but nodal involvement was rarely seen [84,85]. The prognosis of an ITPN-associated invasive carcinoma is significantly better than the prognosis of conventional PDAC.

Pathologic Features

Extracellular mucin production is not prominent and cyst formation is less evident than in IPMN. ITPN is characterized by densely packed tubules that frequently lie back-to-back, forming large sheets. Tubulopapillary

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

growth is sometimes seen, with focal papilla formation present in about a third of ITPN cases [84]. Overall, ITPNs are relatively homogeneous in histologic appearance (Fig. 126.2f) [4]. The cells are cuboidal with modest amounts of eosinophilic cytoplasm and do not contain apparent mucin. There is nuclear atypia and increased mitotic activity and the lesions are usually graded as high-grade dysplastic. Necrosis is frequently observed in the nodules, presenting with a comedo-like pattern [84].

In contrast to IPMN and IOPN, immunohistochemistry for MUC5AC is typically negative in ITPNs [84,86]. EMA/MUC1 is almost always positive and MUC6 is positive in about two-thirds of cases. MUC2 is consistently negative, indicating a closer relatedness to gastropancreatic than intestinal epithelial lesions [85]. ITPN has formerly been called "intraductal tubular carcinoma" (ITC).

Molecular Features

Intraductal tubulopapillary neoplasms usually lack the driver gene mutations frequently found in IPMNs or PDAC, such as *KRAS*, *GNAS*, *RNF43*, *TP53*, or *SMAD4*. Genetic alterations in *CDKN2A* or the PI3K pathway (e.g., *PIK3CA*) were identified in about a quarter of ITPNs each [85,87]. Mutations in chromatin remodeling genes (e.g., *MLL* family) have been found in about a third of cases. In addition, *FGFR2* fusions have been reported and *MCL1* amplifications were commonly found.

Mucinous Cystic Neoplasms

Clinical Features

Although mucinous cystic neoplasms (MCNs) were first described by Compagno and Oertel in 1978, it was not until 2006 that the presence of ovarian-type stroma was adopted as an obligate criterion for their diagnosis [88,89]. In addition to this hallmark feature, the lack of communication with the pancreatic duct system aids in the discrimination between MCNs and IPMNs. MCNs predominantly occur in female patients at perimenopausal age in the distal part of the pancreas (i.e., body or tail) in the form of solitary lesions. Morphologically, they commonly show a "cyst-in-cyst" growth pattern by the formation of septae. It has been previously hypothesized that MCN has its origins in embryology [90]. A recent study highlighted the striking clinical, histomorphologic, and molecular similarities between pancreatic MCNs and mucinous ovarian tumors [91].

Elias *et al.* indicated that MCNs may originate from tissue of primordial germ cells that get stuck in the pancreatic body or tail during their physiologic descent to the gonads in embryogenesis. This concept could also potentially explain the existence of similar, MCN-like lesions in the liver or kidney or mixed epithelial stromal tumors (MEST) of the kidney, if cells remain at other sites during their caudal migration. However, the exact mechanisms, including the role of hormonal influences or other potential triggers like smoking, are yet unknown.

Patients with noninvasive MCN are significantly younger than patients with invasive carcinoma, with an age difference of about 10 years (44 versus 55 years) [92]. This link between increased patient age and presence of an invasive component, as well as the observation of different dysplastic grades within one lesion, suggest an adenoma-to-carcinoma-like progression pattern in MCNs. The majority of surgically resected patients presented with symptoms and with median radiographic sizes of 3.5–5 cm (range 0.5–20.0 cm), the size range highlighting the immense potential for voluminous growth in these lesions [92,93].

Surgical resection of noninvasive MCNs is curative and without recurrence [92–95]. Presence of an associated invasive carcinoma has been reported in 6–25% of resected MCNs and is associated with a five-year disease-specific survival of 57–79.6% [92–96]. Recurrence following surgical resection has been reported in more than a third of patients with an invasive component, occurs commonly early, and leads to rapid death [92,96]. However, these findings in invasive MCNs indicate a significantly better overall prognosis following resection than for conventional PDAC or IPMN with invasive carcinoma. This difference may be partially explained by the lower rate of lymph node involvement in invasive MCNs, which is only present in up to one-third of these patients at surgical resection [92–95,97].

Despite a correlation of increased cyst size with the risk for malignancy, recent studies indicate that size may be less accurate in distinguishing between noninvasive and invasive MCNs [93,97]. Instead, radiographic features (e.g., solid component/mural nodule, duct dilation) [95], elevated serum levels of CA19-9 [93,95,96], weight loss [93], location in the pancreatic head [95], male sex [93,95,97], and high age [92,96,97] suggest presence of an invasive component. In addition, radiographic evidence of splenic vein thrombosis has been reported to be strongly associated with invasiveness [94].

Pathologic Features

Mucinous cystic neoplasms are defined as having two components. The cyst is lined by neoplastic, mucinous, columnar epithelial cells, surrounded by a nonneoplastic, ovarian-type stroma. The epithelial dysplasia is graded in a two-tiered fashion, as recommended by the latest consensus meeting [3]. "MCN, low-grade" comprises the former "MCN with low-grade dysplasia" and "MCN with

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

intermediate-grade dysplasia" and is contrasted against "MCN, high-grade" (formerly "MCN with high-grade dysplasia"). Coexistence of low- and high-grade epithelium within one lesion, eventually located in different loculues of the MCN, is common [98]. In addition, denudation of the epithelial layer is seen in many cases and can be extensive. Therefore, histologic examination of the entire MCN is required, which can be laborious in large lesions, to properly assess the highest dysplastic grade within the MCN and reliably exclude invasion.

Irrespective of the histologic grade, morphology and mucinous quantity of the epithelium can vary from flat or cuboidal cells without significant intracytoplasmic mucin to tall, columnar cells with abundant supranuclear mucin (Fig. 126.3). Although a mix of mucin-rich and mucin-depleted epithelial cells is common within a single lesion, MCNs that have predominantly mucin-rich epithelium are more frequently associated with high-grade dysplasia or invasion [99–101].

Ovarian-type stroma is mandatory for diagnosis of MCN but may be only focally present or not obvious due to fibrosis, hyalinization, or hypocellularity, which can impede the correct diagnosis [102]. Sometimes, nests of epithelioid cells are seen in the stroma, suggesting luteinization. The cells of the ovarian-type stroma frequently express progesterone and estrogen receptor, α-SMA, and luteinized cells, if present, are positive for inhibin [98]. These stains can be useful in establishing the diagnosis of MCN.

The invasive carcinoma typically associated with an MCN is a tubular adenocarcinoma; however, other tumor types, such as adenosquamous or undifferentiated carcinoma, have also been reported [98].

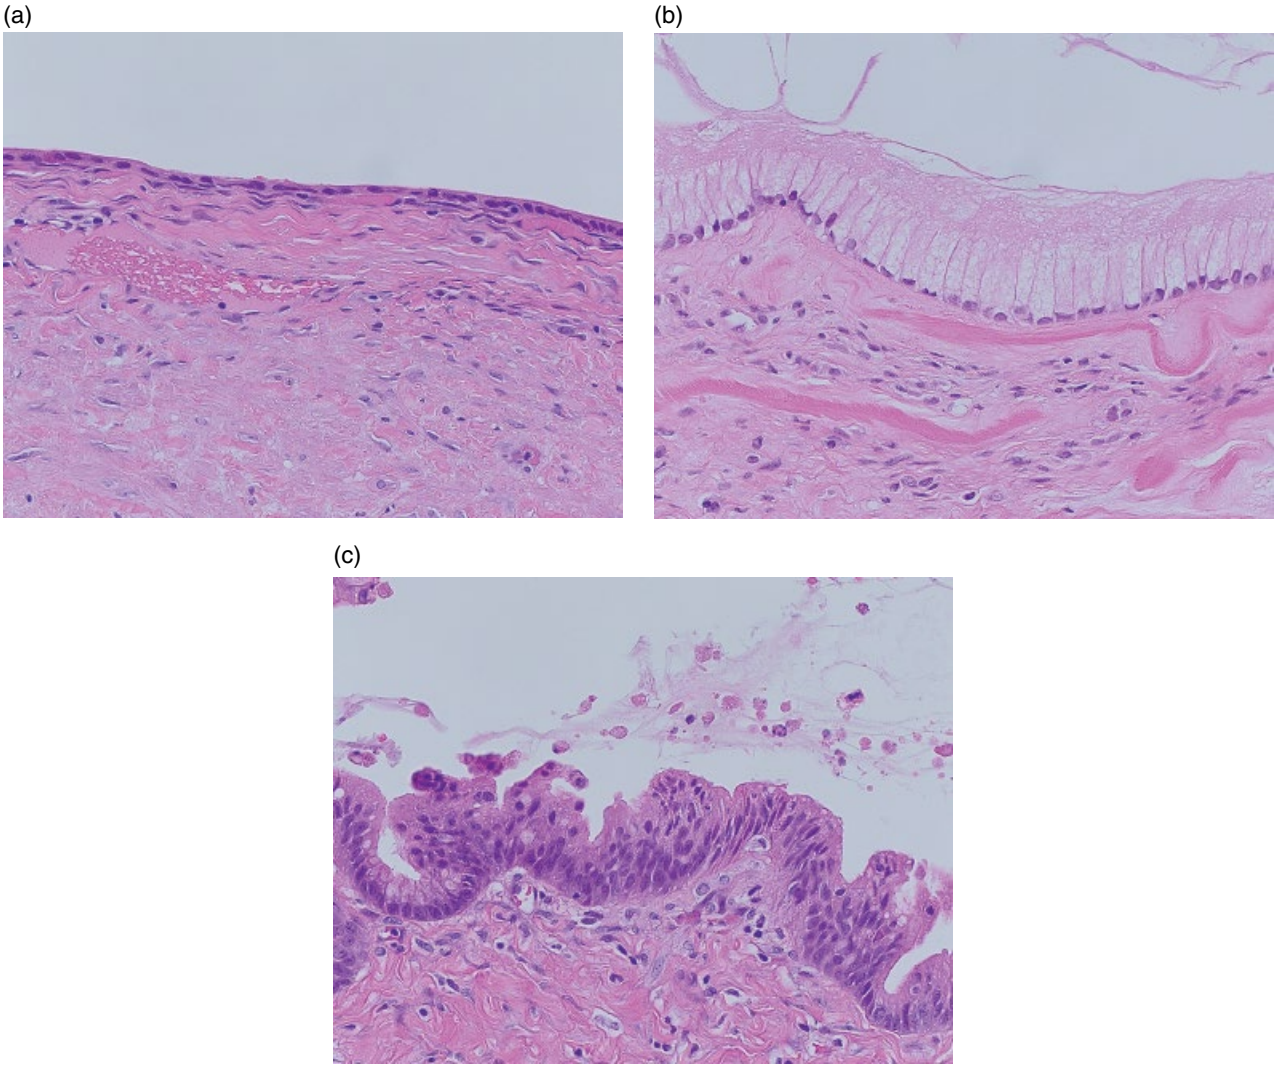

Figure 126.3 MCN with characteristic, spindle-shaped ovarian-type stroma covered by an epithelial monolayer. (a) Low-grade MCN with flat epithelium and little to invisible intracytoplasmatic mucin. (b) Low-grade MCN with tall columnar cells and abundant supranuclear mucin. (c) High-grade MCN with marked architectural atypia.

Molecular Features

Whole-exome sequencing of MCNs showed on average 16 nonsynonymous somatic mutations and relatively few "loss of heterozygosity" events compared with IPMNs [69]. Alterations in *RNF43* have been described in low- and high-grade MCNs. Hotspot mutations in *KRAS* are a common finding in MCNs, particularly in lesions with high-grade dysplasia or invasion (up to 100%) and in lesions with predominantly mucin-rich epithelium [101,103,104]. Alterations in *TP53* and *CDKN2A* are frequent events in about half of high-grade or invasive MCNs and *SMAD4* has been reported in a small subset of MCNs with associated invasive carcinoma [104]. Of note, *GNAS* mutations are absent in MCNs and can serve as a useful genetic feature to distinguish MCN from IPMN [103,104].

Clinical History and Risk Factors of Pancreatic Cancer

Norbert Hüser, Volker Aßfalg, and Helmut Friess

Department of Surgery, Klinikum rechts der Isar, Technische Universität München, Munich, Germany

Introduction

It does not matter which way you look at it or by what means you endeavor to access the extensive field of pancreatic carcinoma, whether as a nonspecialist but interested reader, an oncology expert, or even as an afflicted patient, and no matter the angle of view or the basic discipline you use to acquaint yourself with pancreatic carcinoma, whether by pathology, internal medicine, or surgery, the catchy introductory phrase is almost always followed by the stereotypical statement: "The diagnosis of pancreatic carcinoma most frequently implies an unfavorable prognosis." This monotonous introduction to pancreatic carcinoma is clear evidence of the lack of effective therapeutic options, especially in the case of an unresectable tumor.

There are multiple reasons for this but undoubtedly, the relatively long period of freedom from symptoms greatly contributes to the fact that only around one-fifth of patients are diagnosed early enough to consider a curative approach. Moreover, numerous widespread but rarely specific factors exist that often cannot be influenced but may increase the likelihood of developing pancreatic carcinoma. However, it should be noted that phenomena such as pancreatitis or diabetes tend to be part of the clinical appearance of the tumor disease rather than risk factors.

This chapter aims to make a connection between current knowledge in terms of relevant risk factors and the clinical appearance and symptoms of pancreatic carcinoma. Finally, by raising the reader's awareness, it is hoped to improve early detection and intervention as a basis for a more effective therapeutic approach and thus a better prognosis for the patient.

Clinical History of Pancreatic Cancer

Probably the greatest hindrance to the prompt diagnosis of pancreatic carcinoma is the lack of early disease-specific indicators. On the one hand, it is difficult to distinguish these from other nonspecific symptoms, and on the other hand, afflictions that possibly indicate malignant disease can often be explained otherwise and may be misinterpreted. Moreover, symptoms may vary significantly depending on the tumor's location in the pancreas.

Functional Impairment of the Pancreas

Increasing loss of exocrine function is one potential tumor-related symptom. The absence of important digestive enzymes in the functionally complex interaction of intestinal digestion causes inadequate fragmentation of carbohydrates, proteins, and fats. Therefore, resorption across the intestinal wall into the portal system is insufficient and the major portion of undigested fat remains in the gut, which causes so-called *fatty stools* (*steatorrhea*). This may lead to considerable *diarrhea*, *flatulence*, and *abdominal cramps*.

Furthermore, the tumor may noticeably compromise the endogenous function of the pancreas. Several studies have proved that *diabetes* frequently predates a diagnosis of pancreatic carcinoma [1,2]. A diabetic disorder caused by a pancreatic carcinoma is also called pancreatic cancer-related, pancreatic cancer-associated, or -induced diabetes. It is also categorized type 3c diabetic disease (pancreoprivic diabetes according to the American Diabetes Association) which includes diabetes due to both malignoma and other pancreatic conditions such as acute or chronic pancreatitis [3]. Chari et al. analyzed the medical histories of patients with pancreatic cancer and

revealed new-onset diabetes in 52% of the patients prior to assessment and hyperglycemia in 80% of the cases at the time of detection of the disease [4].

It is therefore likely that the mechanism of diabetes development in pancreatic carcinoma is not only due to β-cell destruction because even pancreatic carcinomas that involve only small parts of the organ are already associated with diabetes. A recently published review emphasizes the impact of pancreatic stellate cells on possible modulations of β-cell function and peripheral insulin resistance [5]. Furthermore, metabolic changes (such as serum glucose levels) diagnosed only a few months before detection of pancreatic cancer support the hypothesis of a paraneoplastic phenomenon of this malignancy [6].

Invasion into Intra- and Extrapancreatic Nerve Plexus

Rapid *loss of body weight* and reduced general state of health in afflicted patients are frequently triggered by *pain symptoms* in the upper abdomen and the back. Pain in the upper abdomen can be found in approximately 70% of patients with pancreatic carcinoma. Symptoms usually start intermittently and after a distinct period of time develop into continuous pain. Inside the pancreas, nerves are altered and damaged as tumor cells invade intra- and extrapancreatic perineural structures. Perineural invasion is characteristic for pancreatic cancer and it occurs in almost all cases [7]. It is believed that the extent of perineural invasion is linked to the severe pain syndrome of pancreatic cancer patients. Noticeably, patients with severe abdominal pain show a higher degree of neural invasion and increased nerve hypertrophy compared with patients who are pain free [7,8].

Pancreatic cancer-associated pain has characteristics of *neuropathic pain*, as well as *nociceptive pain*, which is why it is considered to be of "mixed" type. The continuous spread of tumor cells and the consequent increased severity of neural invasion are independent prognostic factors for worse overall and disease-free survival. The development of neuropathic pain is affected not only by neurons but also by immune cells, Schwann cells, and glial cells of the central nervous system [9]. Current research is investigating the genesis of neuropathic pain with the aim of developing adequate pain management.

Tumor Cell Ingrowth into Adjacent Organs and Nearby Vessels

Whereas a tumor located in the head of the pancreas characteristically causes both pain-free *jaundice* and intra- and extrahepatic cholestasis, lesions in the pancreatic corpus and tail rarely give rise to these symptoms [10].

Jaundice of sclerae and skin and the accompanying troublesome *pruritus* are caused by intrapancreatic biliary obstruction with storage of bile acids and bilirubin in the tissue. The tumor causes constriction of the common bile duct that passes through the pancreatic head and then leads to the major duodenal papilla and the duodenum together with the pancreatic duct. With constriction of the pancreatic duct, *acute pancreatitis* may develop. Nevertheless, this phenomenon is rare due to the slow tightening of the pancreatic duct. Patients usually also report *discoloration of feces and urine*. As a consequence of impaired biliary excretion via the bowel, feces become light and clay-colored. The accumulated bilirubin in the serum is then compensatorily excreted by the kidneys, turning the urine brown.

Furthermore, local tumor growth and infiltration of adjacent organs may cause gastric emptying disorders or duodenal obstructions, resulting in *nausea*, *loss of appetite*, *a sensation of pressure in the upper abdomen*, and *increasing emesis*. Because of the close anatomic proximity of the pancreas to adjacent vessels (portal vein, celiac trunk, and superior mesenteric artery), even relatively small tumors may invade vessels. However, the so-called *paraneoplastic syndromes* (especially thromboses of the major femoral and lower leg veins with respective clinical appearance) are independent of local tumor growth.

Clinical Symptoms of Neuroendocrine Tumors of the Pancreas

Apart from the afore-mentioned nonspecific and sometimes nondirective symptoms of pancreatic carcinomas, neuroendocrine tumors (NET) of the pancreas often secrete hormones into the bloodstream. Various types of NET produce different hormones, which in turn may cause varying clinical symptoms. However, not all NET of the pancreas are hormonally active.

Gastrinomas are functionally active NET that produce the hormone gastrin, which causes increased secretion of gastric acid. Typically, gastric and intestinal ulcers resistant to medication develop in up to 95% of afflicted patients over time or rapidly reoccur after end of treatment. Subsequently, *intense abdominal pain* and/or *intestinal bleeding* may appear. A smaller number of patients (~60%) develop pathologic *gastroesophageal reflux* with *pyrosis* or *dysphagia*. Over 30% of patients suffer from *diarrhea* and/or *steatorrhea*.

Insulinomas are the most frequent type of functionally active NET of the pancreas. These tumors typically lead to elevated insulin levels, which depress blood glucose levels and provoke symptoms of *hypoglycemia* such as *trembling*, *ravenous appetite*, and *confusion*.

Glucagonomas may cause nonspecific *loss of capability* or *body weight*. Hyperglycemia caused by release of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. glucagon and *necrotizing dermatitis* are characteristic symptoms of glucagonomas.

Somatostatomas, ***vasoactive intestinal peptide-releasing tumors (VIPomas)***, and ***pancreatic polypeptide-producing tumors (PPomas)*** are rare hormone-producing NET. A list of specific and nonspecific symptoms is shown in Table 127.1, together with symptoms of the afore-mentioned tumors.

Risk Factors for Pancreatic Cancer

Malignancies typically develop by interaction of diverse factors but it is impossible to specify them for pancreatic cancer in every single case. However, large observational studies have defined risk factors that statistically foster development of pancreatic carcinoma. This implies that these risk factors cannot be found retrospectively in all patients with pancreatic cancer nor do all individuals with these factors inevitably evolve a pancreatic carcinoma.

Smoking

The etiology of numerous diseases can be attributed to inhalation of tobacco smoke. This mainly applies to the respiratory organs, cardiovascular system, and malignant tumors. Smoking is an unambiguous risk factor for development of pancreatic cancer. A metaanalysis of 82 cohorts and case–control studies reports a relative risk of 1.7 (95% confidence interval [CI] 1.6–1.9) for smokers and 1.2 (95% CI 1.1–1.3) for ex-smokers independent of gender and region. Investigation of cigar smokers and pipe smokers ascertained pooled risks of 1.5 (95% CI

Table 127.1 Clinical symptoms of pancreatic carcinoma.

By functional impairment of the pancreatic gland

Digestive difficulties (diarrhea, abdominal pain, flatulence)

Changes in stools

Development of diabetes

Loss of weight

By intra- and extrapancreatic nerval invasion

Pain in the upper abdomen and the back

By infiltrative tumor growth into adjacent organs and vessels

Jaundice

Nausea and vomiting

Inappetence

Sensation of pressure in the upper abdomen

Acute pancreatitis

Thromboses (including paraneoplastic syndromes)

By specific hormones of neuroendocrine pancreatic tumors

Type of tumor	Hormone	Symptoms
Gastrinoma	gastrin	Acid reflux, burning abdominal pain, excess fat in stool, weight loss
Glucagonoma	glucagon	High blood glucose, anemia, weight loss, swelling/irritation of skin
Insulinoma	insulin	Low blood glucose, perspiration, confusion, shakiness, accelerated heartbeat
Somatostatinoma	somatostatin	Nonspecific symptoms like diabetes, gallstones, diarrhea, weight loss
VIPoma	vasoactive intestinal peptide	Watery diarrhea, fatigue, nausea
PPoma	pancreatic polypeptide	Belly pain, enlarged liver, watery diarrhea

VIPoma, vasoactive intestinal peptide-releasing tumor; PPoma, pancreatic polypeptide-producing tumor.

1.02–2.3) and 1.4 (95% CI 0.94–2.0), respectively [11]. The authors depict a linear trend for risk of carcinoma development with increasing smoking exposure. However, the correlation could not be proved in a metaanalysis by Zou and colleagues [12].

Another pooled analysis studied the impact of cigar and pipe tobacco and smokeless tobacco on pancreatic cancer risk. The results principally confirm an association between cigarette smoking (odds ratio [OR] 1.5, 95% CI 1.4–1.6) and cigar smoking (OR 1.6, 95% CI 1.2–2.3) and pancreatic carcinoma. However, any impact of pipe smoking on later occurence of pancreatic carcinoma could not be demonstrated [13]. Data on smokeless tobacco use (mainly snuff) are rare. Here the authors show results consistent with a metaanalysis, which does not indicate any excessive risk of pancreatic carcinoma in several case studies [14]. Conversely, another metaanalysis refers to an association between smokeless tobacco and pancreatic carcinoma [15]. However, the consumption of smokeless tobacco in particular has not been proven to be a distinct risk factor because of the marked heterogeneity of ingredients.

Recent data from a comprehensive European case–control study confirm a 72% increased risk for pancreatic carcinoma in current smokers versus never-smokers. A positive, nonlinear correlation could be revealed for length of exposure to cigarette smoke, intensity, and increased levels of cumulative dose [16]. The elevated risk of pancreatic cancer diminishes after complete cessation of smoking. Due to the high prevalence of smoking worldwide, experts assume that as many as 25% of pancreatic carcinomas can be attributed to cigarette consumption [17].

Diabetes Mellitus

As stated in the introduction to this chapter, risk factors and early symptoms of pancreatic cancer can be difficult to distinguish. A comprehensive study revealed a threefold increased risk of pancreatic cancer in patients with type 2 diabetes (OR 3.22, 95% CI 3.03–3.42) [18]. These results can be supported by data from an earlier metaanalysis that also identified diabetes type 2 as a risk factor for pancreatic carcinoma (OR 1.82, 95% CI 1.66–1.89) [19]. The authors hint at the fact that in a majority of the included studies, there was no distinction between type 1 and type 2 diabetes. Nevertheless, it could be assumed that most individuals had type 2 diabetes as it is the predominant type of diabetes in the elderly [19]. Therefore, these study populations do not allow for a transfer of results to individuals suffering from type 1 diabetes.

It remains unclear whether these patients are at risk for developing pancreatic malignancies. In a metaanalysis of three cohorts and six case–control studies, the investigators took this factor into account and analyzed 39 patients with type 1 diabetes and juvenile-onset diabetes (interpreted as type 1). Type 1 diabetes could be identified as a risk factor for pancreatic carcinoma with a relative risk of 2.00 (95% CI 1.37–3.01) but the authors urgently call for confirmation by further studies because of the low number of patients [20]. In a large international study, the incidence of pancreatic cancer in patients with proven type 1 diabetes was compared to the incidence in the nonaffected population. An increased risk for pancreatic cancer could be revealed in this way. However, interestingly, individuals with new-onset diabetes showed a higher risk of tumor disease within the first year compared to patients with a long-term diagnosis of diabetes [21]. These findings again support the hypothesis of a bidirectional relationship of diabetes and pancreatic carcinoma, as recent-onset diabetes may be an early symptom and therefore the manifestation of pancreatic cancer (as outlined in the earlier section "Functional impairment of the pancreas"), whereas a longer time of diabetes disease is a risk factor for this malignancy.

Other factors associated with disturbed glucose metabolism may possibly trigger an increased risk for pancreatic cancer. A prospective cohort study was initiated to determine the independent association between postload plasma glucose concentration and the risk of pancreatic cancer development among patients without self-reported diabetes. After an observation period of 25 years and after adjusting for age, race, cigarette smoking, and body mass index (BMI), the relative risk of pancreatic cancer mortality was 1.65 (95% CI 1.05–2.60, for postload plasma glucose levels between 6.7 and 8.8 mmol/L) [22]. Another study reported a positive association between pancreatic cancer and elevated baseline fasting serum concentrations of glucose and insulin, and insulin resistance, respectively [23].

Overweight and Obesity

The World Health Organization (WHO) defines overweight and obesity by use of the body mass index (BMI) calculated as weight in kilograms divided by height in meters squared. Thereby, underweight (BMI <18.5 kg/m^2), normal weight (18.5–24.9 kg/m^2), overweight (25–29.5 kg/m^2), and obese (30 kg/m^2 and above) can be differentiated. In several cohort studies and case–control studies, an up to three-fold increased risk for development of pancreatic carcinoma was found for overweight individuals. Next, it was shown that overweight (OR 1.67, 95% CI 1.20–2.34) and obese individuals (OR 2.58, 95% CI 1.70–3.90) had an elevated risk for pancreatic carcinoma independent of concomitant diabetic

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. disorders [24]. One aspect of this study was the finding that overweight and obesity during early adulthood (between 20 and 49 years) increased the risk of developing pancreatic cancer and that it usually develops 2–6 years earlier than average. This was an important report of an association between excess body weight across the life span and the risk of pancreatic cancer, which emphasizes the importance of these findings with regard to public health. Moreover, it was shown that there is an increased risk of obesity-associated pancreatic cancer in males [24]. These results were confirmed in a pooled analysis of 20 prospective cohort studies which determined an association between increased pancreatic cancer mortality and BMI during early adulthood in individuals who are overweight or obese [25].

The question arises whether those (rather few) individuals who manage to reduce their body weight significantly and approach normal weight during their life can thereby reduce the risk of pancreatic cancer development. Therefore, an important prevention measure is body weight control at younger ages.

Pancreatitis and Consumption of Alcohol

The positive correlation between chronic pancreatitis and development of pancreatic carcinoma was proven in a precedent-setting cohort study [26]. Including 2000 patients with chronic pancreatitis, the authors demonstrated an increased lifetime risk of nearly 4% in this population group in terms of development of pancreatic carcinoma. Population-based prospective surveys assume a standardized incidence ratio of 4.8, which approximates to a risk of 0.6% after 20 years. Amongst around 1500 patients who were observed for a period of at least two years, the percentage distribution of pancreatitis was alcohol induced in 77%, idiopathic in 17%, hereditary in 1.9%, and of different origin in 4.1%. Even though the relation may have turned slightly towards a higher rate of hereditary pancreatitis during the last two decades, this study identified chronic pancreatitis to be a risk factor, which is independent of age, region, and underlying origin.

Numerous other reports suggest that chronic pancreatitis is a risk factor for pancreatic carcinoma; however, the relative risk varies considerably in the literature (range 2.3 [27] to 18.5 [28]). Most likely, these variations can be attributed to methodologic concerns and the retrospective design of many studies. In a prospective analysis of 373 patients with proven chronic pancreatitis and a follow-up of at least two years, a significantly increased risk for pancreatic cancer was found compared with the general population [29].

Recent investigations also indicate an increased risk of pancreatic carcinogenesis in cases of acute pancreatitis and recurrent pancreatitis. A comprehensive cohort study based on data from the Swedish National Registry identified an episode of acute pancreatitis in nearly 70% of patients who later developed pancreatic cancer. The risk was especially increased within the first years after diagnosis of acute or recurrent pancreatitis but decreased to the common population risk level after a period of 10 years [30]. These data are in line with a Danish nationwide, population-based, matched cohort study including more than 41 000 patients with proven acute pancreatitis. A two-fold increased risk for pancreatic carcinoma after five years (95% CI 1.57–2.61) was demonstrated even though the incidence decreased over the course of time [31].

The true impact of alcohol as a direct risk factor for pancreatic cancer is under debate and different mechanisms are postulated. Inducing different cascades of inflammation, alcohol might indirectly induce carcinogenesis via both chronic pancreatitis and diabetes [32]. However, one point of criticism of the partially inconsistent studies is the fact that analyses were performed without considering the relationship of doses and pattern of alcohol exposure. Heavy alcohol consumption was associated with an increased risk for development of pancreatic cancer in males in a population-based study. According to dose, duration, and pattern of alcohol abuse, the OR was increased 1.5–6-fold [33].

Environmental Factors

A range of environmental factors has been identified as having a possible association with pancreatic carcinoma development. Table 127.2 gives a list of these triggers. Aromatic amines seem to be the substrate of the

carcinogenic effect of both smoking and consumption of cooked meat and fish. The same applies to occupations with comparatively high exposure to these amines.

Hereditary Factors

A positive family history of pancreatic carcinoma has repeatedly been shown to be a risk factor. These aspects and the respective tumor predisposition syndromes are the subject of Chapters 124 and 130.

Conclusion

The identification of early symptoms of pancreatic cancer and the subsequent timely start of diagnostics in daily clinical practice remain highly demanding. Several specific and nonspecific risk factors for pancreatic carcinoma have been identified with more or less certainty, which can be proved by respective studies. If possible, abstinence and avoidance should be practiced to the greatest extent to prevent development of pancreatic cancer. However, with regard to numerous predisposing factors and especially a positive family history, this cannot be performed satisfactorily. An early diagnosis is the only possibility to improve patient survival. Therefore, every worrisome finding should be investigated and resected in case of doubt.

Finally, particular attention must be drawn to the group of cystic pancreatic tumors with their numerous different entities and distinct clinical and morphologic characteristics. These neoplastic and nonneoplastic, mucinous, and serous cystic lesions can be detected even earlier and at a smaller stage because of continuing improvements in imaging methods. Nowadays, these tumors can be investigated by highly precise risk stratification, which results in distinct therapeutic recommendations. Based on several clearly defined criteria, pancreatic cystic tumors should be either observed or resected. This strategy allows for early resection of precancerous lesions or even pancreatic cancer with the chance of cure.

The Role of Endoscopic Ultrasonography in the Diagnosis and Differential Diagnosis of Neoplastic Lesions

Yoshiki Hirooka, Senju Hashimoto, and Eizaburo Ohno

Department of Gastroenterology and Hepatology, Fujita Health University, Toyoake, Aichi, Japan

Introduction

A wide range of neoplastic lesions occur in the pancreas, roughly divided into solid tumors and cystic tumors. Transabdominal ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and other imaging modalities are available for diagnosis of pancreatic neoplastic lesions. The malignant potential of pancreatic ductal adenocarcinomas (PDACs) is particularly high compared to other pancreatic neoplastic lesions, with the five-year survival rate reported to range from several percent to 10% [1,2]. There are some reports that the five-year survival rate is about 80% in the case of pancreatic carcinomas ≤10 mm [3]. Endoscopic US (EUS) is superior to US, CT, MRI, and other imaging modalities in its ability to qualitatively diagnose focal lesions and local progression of a lesion, and it allows diagnosis of small pancreatic neoplastic lesions that are difficult to detect with US, CT, and MRI. In addition, cytologic and histologic diagnosis of the target are possible (EUS-guided fine-needle aspiration [biopsy]: EUS-FNA[B]).

As is the case with other organs, a paradigm shift is currently under way from one-size-fits-all cancer therapy regimens to mutant gene-based cancer genomic medicine for cancers of the pancreas. Tissue collected via EUS-FNA(B) is becoming more and more important as a specimen source for comprehensive genomic profiling (CGP) as opposed to simple histologic diagnosis.

In this chapter, we will first discuss the latest characteristics of EUS. We will then discuss the role of EUS in the differential diagnosis of solid tumors and cystic tumors of the pancreas. Lastly, we will discuss the current status of EUS-FNA(B) in CGP.

Characteristics of Endoscopic Ultrasonography

Endoscopic ultrasonography is the most popular endoscopic technique used to diagnose and evaluate pancreatic masses. High-resolution images of the pancreas can be generated by placing a high-frequency probe in close proximity to the pancreas [4].

Endoscopic ultrasonography equipment includes probes for various imaging procedures (Fig. 128.1): radial probes allow 360° imaging perpendicular to the long axis, and convex probes allow imaging along a plane parallel to the long axis of the instrument (Table 128.1). The former allows only diagnostic imaging, whereas the latter was developed for fine-needle aspiration (biopsy) (FNA[B]) [5,6]. Pancreatic masses can be detected by EUS with 93–100% sensitivity and a negative predictive value approaching 100%, particularly when combined with FNA [7]. Small masses (<2 cm) that can be detected by EUS may be identified as occult according to other imaging modalities and in patients with previous indeterminate findings.

The National Comprehensive Cancer Network (NCCN) guidelines for pancreatic adenocarcinoma state that patients without a pancreatic mass evident on cross-sectional images should undergo further evaluation with EUS and/or endoscopic retrograde cholangiopancreatography (ERCP) as clinically indicated [8]. Another advantage of EUS is that pancreatic masses can be detected and characterized without intravenous contrast, which is of particular importance when patients have renal dysfunction or other contraindications.

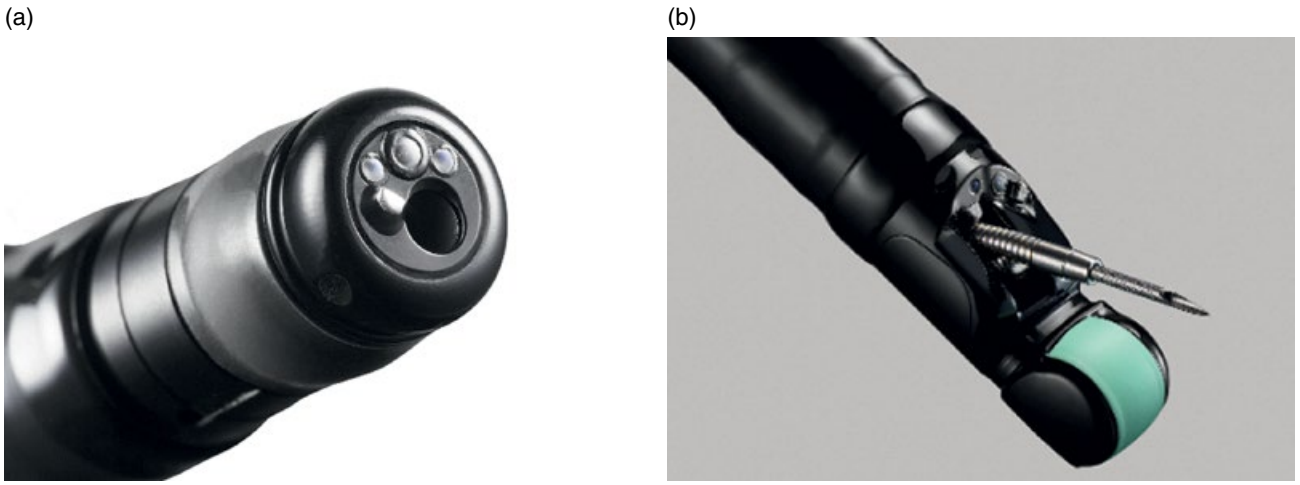

Figure 128.1 (a) The tip of a radial endosonoscope. The radial EUS image is 360° perpendicular to the long axis. (b) The tip of a convex endosonoscope with FNA needle. The convex EUS image is parallel to the long axis of the instrument.

Table 128.1 Advantages and disadvantages of EUS imaging modalities.

	Radial scope	Convex scope
Advantages	• Scanning range is 360°	• Histologic diagnosis is possible
	• Pancreas is easily seen as a longitudinal and continuous image	• Junction between the pancreatic head and body can be seen from the stomach
Disadvantages	• Histologic diagnosis is impossible	• Scanning range is 150° to 180°
	• Operator-dependent	• Images of the body and tail of the pancreas become cross-sectional images

Potential of Radial Scope with Forward-viewing Optics

Radial scopes with forward-viewing optics are commercially available. In addition, radial scopes with forward-viewing optics developed by the Fujifilm Corporation have 190° upward bending capability and a 2.8 mm working channel, which may offer a screening program of the pancreas as well as the esophagus, stomach, and duodenum at the same time, and some facilities, including our university hospital, are interested in this program to detect the early stages of pancreatic cancer in Japan.

Various Imaging Modalities Used with EUS

An endoscope is used for EUS, but it relies on US diagnostic imaging technologies. Representative diagnostic imaging technologies are outlined below [4,9,10].

The most fundamental diagnostic imaging technology is B-mode imaging, which is the first step to detecting and diagnosing a lesion; we cannot find any intrinsic value in EUS without improvement of B-mode images. The first technology developed for EUS was mechanical radial scanning. The quality of B-mode imaging markedly improved thereafter, which led to the incorporation of electronic scanning in the early 2000s [11–13]. Current EUS B-mode imaging may be approaching its completed form with the addition of tissue harmonic imaging technology.

Color Doppler and power Doppler imaging were subsequently incorporated into EUS, which greatly improved its diagnostic ability by providing the characteristic hemodynamic information of a target lesion in addition to B-mode information.

Moreover, after the development of US contrast agents that can be administered intravenously, diagnosis with color Doppler and power Doppler imaging in combination with US contrast agents, as well as contrast-enhanced EUS using harmonic imaging techniques developed for use with US contrast agents, began to show their usefulness. Many pancreatic tumors exhibit characteristic hemodynamics, making use of contrast agents indispensable in the diagnosis using CT and MRI. However, CT and MRI are useless in patients in whom they are contraindicated, such as those with renal dysfunction and those allergic to contrast agents. On the other hand, US contrast agents can be used in many cases (excluding patients with egg allergy) even when CT and MRI contrast agents cannot be used. It can be said that EUS, which allows evaluation of hemodynamics by using a US contrast agent in combination with clear B-mode images, is useful for the diagnosis of pancreatic tumors [14–16] (Figs 128.2 and 128.3).

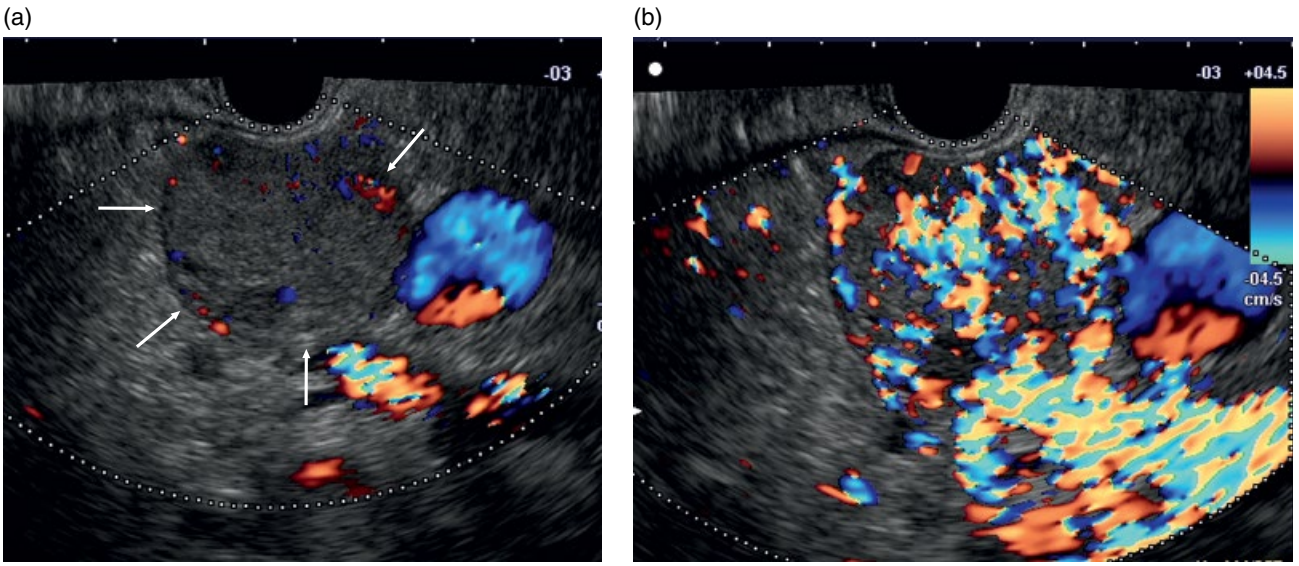

Figure 128.2 Intraductal papillary mucinous carcinoma. (a) Color Doppler imaging revealed the subtle vasculature inside the papillary growth-like structure. (b) After intravenous injection of ultrasound contrast agent (Sonazoid®, GE Healthcare), blood flow was seen inside the papillary growth, resulting in the diagnosis of IPMC.

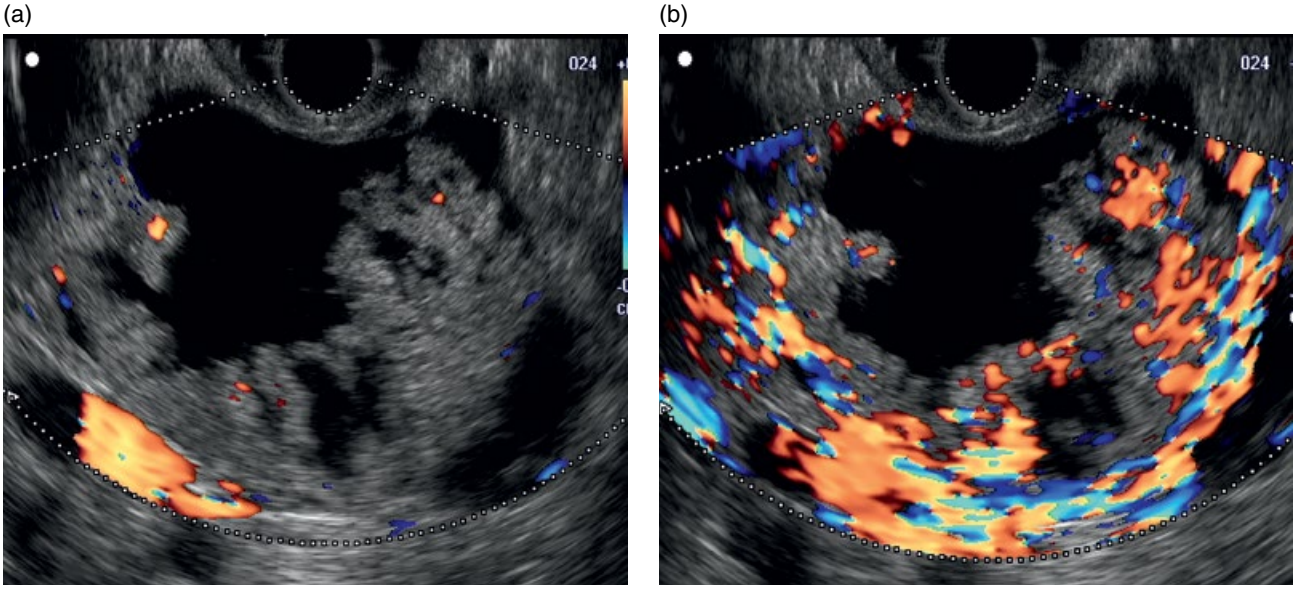

Figure 128.3 Pancreatic neuroendocrine neoplasm. (a) Plain color Doppler imaging demonstrated a hypoechoic tumor with a smooth contour (arrow). (b) After intravenous injection of ultrasound contrast agent (Sonazoid), blood flow was seen inside the tumor. The findings of both B-mode imaging and hypervasculature resulted in the diagnosis of pancreatic neuroendocrine neoplasm.

Lastly, we will discuss elastography. Elastography is a diagnostic imaging modality that can be used to qualitatively or quantitatively evaluate the stiffness of a target lesion. There are two types of elastography: strain and shear wave. Only strain elastography was available in early EUS elastography units, but shear wave elastography became available very recently [17,18]. With strain elastography, stiffness is evaluated by measuring the degree of strain (displacement) in response to deformation of the target by cardiovascular pulsation or manual compression. The degree of strain is small in the case of hard lesions and large in the case of soft lesions.

With shear wave elastography, acoustic radiation force impulse (ARFI) is applied to the target. Shear waves propagate in every direction from the point in the target where ARFI is applied. What is measured is shear wave speed. It is known that higher shear wave speeds indicate a greater degree of stiffness, resulting in the following

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

relationship. The shear wave speed is displayed in meters per second or kilopascals through Young's modulus E = 3 (Vs2ρ), where E is Young's modulus, Vs is the shear wave velocity, and ρ is the tissue density; that is, stiffer tissue corresponds to faster shear wave velocity. While strain elastography is qualitative, stiffness can be quantitatively evaluated with shear wave elastography.

A more accurate diagnosis can be made by acquiring hemodynamic information with color Doppler and power Doppler imaging in addition to the base information from B-mode imaging (plus tissue harmonic imaging). Additionally, a more detailed hemodynamic evaluation is possible by adding a US contrast agent to color Doppler and power Doppler imaging, and to harmonic imaging. It is also possible to add information on the stiffness of the target by using elastography. It is our opinion that neglecting diagnostic imaging and relying on EUS-FNA(B) alone should be avoided.

Solid Pancreatic Tumors

The types and histopathologic characteristics of solid pancreatic tumors are described in detail in another section. The main purpose of this section is to describe the differential diagnosis of pancreatic tumors using EUS.

In terms of solid tumors, the differentiation of pancreatic ductal adenocarcinomas (PDACs) and pancreatic neuroendocrine neoplasms (PNENs) seems to be of particular importance. Here, we will discuss the characteristics of PDACs, which are the most important pancreatic cancer, and PNENs, which we need to differentiate from PDAC. As mentioned above, we describe the differential diagnosis of PDACs and PNENs from the stance that we should not purely rely on EUS-FNA(B).

Pancreatic Ductal Adenocarcinomas

Pancreatic ductal adenocarcinomas are epithelial malignant tumors that arise from the pancreatic duct (pancreatic duct branches). They are characterized by being more hypovascular than PNENs.

First, we will discuss EUS B-mode imaging of PDACs. In terms of the echogenicity of PDACs, most are hypoechoic. On B-mode imaging, the contour is distinct and the border irregular. When the tumor is located in the head or body of the pancreas, the caudal main pancreatic duct is occluded and stenosed, and dilation of the main pancreatic duct is found in most cases. Obstructive pancreatitis occurs to one degree or another on the caudal side of the tumor due to an increase in pressure in the caudal pancreatic duct. The border on the caudal side of the tumor sometimes becomes slightly indistinct as the border of the area of inflammation becomes slightly indistinct [19].

With color Doppler or power Doppler imaging alone, the sensitivity is generally not sufficient to detect blood flow; therefore, there are few cases where the tumor is seen as hypovascular compared with the surrounding pancreatic parenchyma. It has been reported that it is possible to diagnose 90–95% of PDACs by studying the hemodynamics using a combination of a US contrast agent and color Doppler or power Doppler imaging and simultaneously combining it with B-mode imaging. In addition, the accuracy of contrast-enhanced harmonic imaging, which combines harmonic imaging and a US contrast agent, has been reported to be 95–98% [4,7–10].

Next, we will discuss elastography for PDACs. Strain elastography is an index of the relative stiffness in the region of interest (ROI). In the case of PDACs, the value of strain elastography as add-on information to B-mode imaging and blood flow information is considered to be high as the tumor tissue is harder than the pancreatic parenchyma. In fact, there are reports that accuracy in diagnosing PDACs is further improved by adding elastography information to B-mode and harmonic imaging. On the other hand, there are some shortcomings, e.g., the elastography pattern differs when the size of the ROI is changed, due to the fact that strain elastography provides the relative stiffness in the ROI. In addition, it is difficult to compare different cases [20–22].

A parameter called *strain ratio* has been put forward based on the hypothesis that the stiffness of peripancreatic connective tissue is likely almost constant in individuals [23,24]. That is, when the strain ratio is set at S1/S0, with the stiffness of the target regarded as S1 and the stiffness of the surrounding connective tissue designated S0, it is possible to compare different S1s with each other as S0 is constant. Based on our investigations, we are skeptical of strain ratio as the value being sought is not determined by what site we designate as S1 within the selected ROI, i.e., it lacks reproducibility.

As for shear wave elastography, objective comparison of different targets seems to be possible as it yields the actual speed at which the waves propagate through a target. More evidence for this modality needs to be gathered going forward [17,18].

Pancreatic Neuroendocrine Neoplasms

Neuroendocrine neoplasms (NENs) are tumors that originate from the diffuse neuroendocrine system (DENS), which is distributed throughout the body, and NENs that occur in the pancreas are called PNENs. While PDACs grow in an invasive manner, PNENs are generally considered to grow in an expansive manner, although this depends on the degree of malignancy. They are also generally considered to be hypervascular tumors.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Due to these characteristics, they exhibit EUS imaging findings that differ from those of PDACs.

On EUS B-mode imaging, the echogenicity of PNENs is generally hypoechoic, but it is often slightly more hyperechoic than PDACs. In addition, the contour is distinct and the border is regular. PDACs have an irregular border, and this is a major indicator when making the differential diagnosis on B-mode imaging. Furthermore, PNENs about 20 mm in size often do not have dilation of the main pancreatic duct on the caudal side of the tumor. The main pancreatic duct is displaced at the tumor portion because it does not exhibit invasion-induced stenosis or occlusion [19].

Pancreatic neuroendocrine neoplasms are often observed as hypervascular on color Doppler or power Doppler imaging without use of a contrast agent. In the case of enlarged tumors with hemorrhagic necrosis in the central portion, the said portion becomes anechoic or hyperechoic (which indicates fresh bleeding), and a blood flow signal is not observed at such areas. Contrast-enhanced harmonic imaging often shows similar findings.

Pancreatic neuroendocrine neoplasms are generally soft tumors, with EUS strain elastography often showing stiffness comparable to that of the surrounding pancreatic parenchyma.

We have described EUS diagnosis of pancreatic tumors that are often encountered as solid tumors in routine clinical practice [9,10,14,16].

Cystic Pancreatic Tumors

Detailed information on cystic pancreatic tumors has already been provided in another section. Here, we will describe the role of EUS in the diagnosis of intraductal papillary mucinous neoplasms (IPMNs), the cystic pancreatic lesion most commonly encountered in routine clinical practice.

Many IPMN-related clinical practice guidelines have been published [25–28], but here we will describe the role of EUS in the diagnosis of IPMNs based on "Revisions of international consensus Fukuoka guidelines for the management of IPMN of the pancreas" (2017). In short, the role of clinical practice guidelines is to ascertain as accurately as possible cases that require surgery and cases that can be referred to follow-up.

According to the 2012 International Association of Pancreatology (IAP) guidelines, although sensitivity increased, specificity remained relatively low. In the revised Fukuoka guidelines, the two-step (high-risk stigmata and worrisome features) method for predicting malignancy was revised. The size of enhancing mural nodules in high-risk stigmata was limited to ≥5 mm, while nonenhancing mural nodules were excluded from worrisome features. In addition, CA19-9 >37 ng/mL and enlargement ≥5 mm in two years were added. We will need to wait for the results of future investigations to determine whether or not the specificity of prediction of malignancy improves.

The diagnosis and treatment algorithm based on the 2017 IAP guidelines is shown in this paper. Surgery is recommended in cases with high-risk stigmata. Enhancing nodule ≥5 mm is in the high-risk stigmata category, and we assume that contrast-enhanced EUS would be necessary to actually diagnose this. In the absence of any high-risk stigmata, whether or not any worrisome features are observed is important, and EUS is recommended if even one worrisome feature is found. In terms of the role of EUS after finding a worrisome feature(s), EUS is recommended for confirming the presence or absence of any malignant cells in intracystic fluid collected using EUS-FNA, in addition to confirming the presence of an enhancing nodule ≥5 mm.

In the case of EUS-FNA(B), the frequency is unknown, but the possibility of tumor cell seeding has been pointed out even if a lesion is fundamentally a solid tumor. The possibility of tumor seeding occurring is even more likely with a cystic lesion than with a solid lesion. Therefore, careful judgment is necessary.

We described the role of EUS in the diagnosis of IPMNs, the cystic pancreatic tumor most commonly encountered in routine clinical practice.

EUS-FNA(B) and Comprehensive Genomic Profiling (CGP)

This section in the 3rd edition of this book was written based on the stance that EUS-FNA should be performed as a matter of course if its result would change or determine the treatment strategy. Seeding associated with EUS-FNA was thought to occur in only a small number of cases, if at all, and the above stance was regarded as the prevailing opinion with respect to performing EUS-FNA. Oddly enough, the essence of EUS, i.e., US diagnostic imaging, was left out of the discussion.

Later, reports that tumor seeding associated with EUS-FNA is seen at a frequency of 5–6% began to appear in the literature [29–32]. The frequency is statistically low, but if we put ourselves in the shoes of the patient and their family, we believe that we cannot ask the patient to undergo EUS-FNA based on a low frequency of tumor seeding.

There is an important point that needs to be made here. A paradigm shift is currently under way in the way cancers

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of every kind are treated, not just PDACs. A standard therapy is determined after a number of clinical studies have been conducted. However, we know that there are some PDAC patients who respond to the standard therapy and some who do not. In other words, there are cases where the standard therapy is not the best therapeutic approach for the patient. Performing oncogene panel testing in order to carry out cancer genomic medicine is on its way to becoming common practice [33–36]. There are ways to perform oncogene panel testing using a blood sample, etc., but the most common method currently is oncogene panel testing using a histologic specimen.

In many cases, PDACs are inoperable by the time they are detected. We have conventionally preferred to collect a histologic specimen using EUS-FNA rather than selecting cytology. In recent years, the terminology has changed from EUS-FNA to EUS-FNA(B), with EUS-FNA(B) being distinguished from EUS-FNA given that it is a method for collecting a histologic specimen. Submission of the tissue collected via EUS-FNA(B) for immunostaining or oncogene panel testing is now understood to be important.

When considering diagnosis of pancreatic lesions using EUS, whether or not it is possible to collect an

EUS-FNA(B) specimen suitable for CGP may become a major issue in the future. In our department, all the EUS-FNA(B) specimens collected using a 22 gauge puncture needle have been suitable for in-house oncogene panel testing to date. On the other hand, even if an abnormality is detected by oncogene panel testing, the likelihood of it actually leading to a druggable abnormality is no higher than several percent. However, performing EUS-FNA(B) to discover genetic mutations that match drugs currently in development is important. In the case of inoperable PDACs, it appears to be extremely important to perform EUS-FNA(B) to reliably obtain a specimen for CGP, in addition to actively making use of conventional diagnostic approaches (Figs 128.4 and 128.5). On the other hand, whether or not EUS-FNA(B) should be performed in the case of operable pancreatic cancers (in which case tissue is obtained during surgery) is admittedly an open question requiring further research.

Radiologic Diagnosis of Pancreatic Cancer: CT, MRI

Hannah S. Recht[1] *and Elliot K. Fishman*[2]

[1] *Northwestern University Feinberg School of Medicine, Department of Radiology, Chicago, IL, USA*
[2] *Johns Hopkins University School of Medicine, The Russell H. Morgan Department of Radiology and Radiological Science, Baltimore, MD, USA*

Introduction

Pancreatic cancer is a relatively common malignancy, with an estimated 60 430 new cases in the United States in 2021 [1]. However, despite recent advances in the surgical and medical oncologic treatment of pancreatic cancer, it still carries an extraordinarily poor prognosis with a high mortality. It represents the fourth leading cause of cancer-related mortality in the United States, with an estimated 48 220 deaths in 2021 [1]. Fewer than 20% of patients are considered to be candidates for curative resection at the time of presentation, and unfortunately, even in patients considered to be candidates for curative resection, the overall survival rate is less than 15% [2,3].

Despite the poor prognosis, imaging plays an extraordinarily important role in the evaluation of patients with pancreatic cancer, particularly when surgical resection is still considered a potential option. Not only does modern imaging (particularly CT and MRI) play an important role in identifying these aggressive malignancies in their earliest stages (when they are still potentially resectable), it also plays a critical role in terms of properly staging these tumors. It provides the information necessary to determine whether a patient is truly capable of undergoing an R0 surgical resection (i.e., complete surgical resection with negative tumor margins) [2–4].

This chapter will describe the two most important imaging modalities in the preoperative evaluation of pancreatic cancer, namely multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI). MDCT is currently the most important as well as most commonly utilized modality for the evaluation of pancreatic cancer, playing a vital role in the initial identification of tumors, allowing optimal staging of a tumor's local extension (including vascular involvement) and identifying the presence/absence of distant metastatic disease. MRI, alternatively, may allow the identification of tumors in difficult cases where tumors may be small or isodense to the pancreatic parenchyma on CT (and thus not adequately visualized), and can also be helpful in terms of staging distant metastatic disease in equivocal cases, particularly when evaluating indeterminate liver lesions [5,6]. This chapter will discuss standard protocol options for both MDCT and MRI, the typical imaging findings of pancreatic cancer on each of these two modalities, and the strengths and weaknesses of each in terms of lesion identification and tumor staging. This chapter will also briefly discuss the novel three-dimensional visualization technique of cinematic rendering.

Multidetector Computed Tomography

Technique

Utilizing proper technique is essential to obtaining high-quality images required for the optimal evaluation of pancreatic cancer. Per National Comprehensive Cancer Network (NCCN) guidelines, the images should be obtained on a helical, multidetector row scanner, preferably 64-multidetector row scanner or more, with the thinnest possible slices, preferably submillimeter (0.5–1 mm) if available [7].

The administration of intravenous contrast is absolutely critical, as noncontrast images make adequate visualization of small tumors nearly impossible (with the vast majority of small pancreatic cancers appearing invisible

Companion website: www.wiley.com/go/beger/thepancreas4e

on noncontrast imaging). Typically, roughly 100–120 cc of intravenous contrast media are administered through a peripheral IV, and a small amount of water (neutral oral contrast), roughly 500–750 cc, is ingested by the patient immediately prior to the scan in order to distend the stomach and duodenum and allow the radiologist to distinguish duodenal or gastric pathology from a true pancreatic mass. Positive oral contrast is not recommended as it might interfere with three-dimensional and maximum intensity projection reformats [7].

Most standard pancreaticobiliary CT protocols employ a dual-phase technique, with the acquisition of both arterial and venous phase images. Per NCCN guidelines, arterial phase/pancreatic parenchymal phase images are typically acquired at roughly 40–50 seconds after contrast injection, often using bolus tracking software, while venous phase images are typically acquired at 60–70 seconds after contrast administration, typically using a fixed delay.

Noncontrast and delayed images have little utility in the evaluation of pancreatic cancer and are usually not acquired as a part of these protocols [2,3,7]. However, utilization of dual-energy CT allows for the creation of virtual noncontrast images without obtaining additional sequences, and may provide added value in difficult cases [8].

Images on the most recent generation of CT scanners can be acquired with extremely thin collimation (0.625–0.75 mm), and these thin collimation images can subsequently be reconstructed into thicker axial images (3–5 mm) for standard radiology review, and to facilitate the reconstruction of high-quality coronal and sagittal reformations directly at the CT scanner. In addition, the evaluation of pancreatic cancer is one instance where 3D reconstructions can be very helpful, particularly when evaluating vascular involvement by tumor. Thin collimation images are typically sent to an independent workstation where the radiologist can use advanced 3D visualization software to create 3D images in real time. The two most important 3D reconstruction algorithms being used widely today in clinical practice are maximum intensity projection imaging (MIP), a 3D technique that entails the acquisition of the highest attenuation voxels in a data set and their projection into a 3D image (a very important technique when seeking to evaluate a tumor's involvement of the adjacent vasculature), and volume-rendered imaging (VR), a complex computational algorithm that assigns a specific color and transparency to each voxel in a data set. Which of these two techniques is most useful will depend on the individual radiologist's preferences, the specific tumor being imaged, and the imaging feature being evaluated [2,3,9–13].

Cinematic rendering (CR) is an new 3D visualization technique which utilizes a novel global illumination model to create photorealistic images from standard volumetric CT data sets [14–16]. As a new technology, its clinical role remains under study, but it may prove valuable in the diagnosis, staging, and treatment of pancreatic cancer [17,18].

Diagnosis

Pancreatic adenocarcinoma appears as an infiltrative, hypodense, poorly marginated mass with frequent extension posteriorly into the retroperitoneum to involve critical vascular structures (Figs 129.1–129.4) [4,13,19–21]. The literature has shown that MDCT is an excellent modality for the identification of pancreatic cancer, with sensitivity rates well over 95%, and it is very likely that this underestimates the true sensitivity of CT, particularly given the rapid improvements in both temporal and spatial resolution seen with the most recent generation of CT scanners. In most cases, pancreatic cancer is most apparent in the arterial/pancreatic phase, when the pancreatic parenchyma is most enhancing, providing contrast to the hypoenhancing pancreatic tumor [4,19]. Accordingly, the acquisition of images using a dual-phase technique does improve sensitivity, particularly when seeking to identify subtle or small tumors [4,22–24]. Nevertheless, it is worth remembering that there are small subcentimeter tumors (probably representing less than 5% of all lesions) that are isodense to the pancreatic

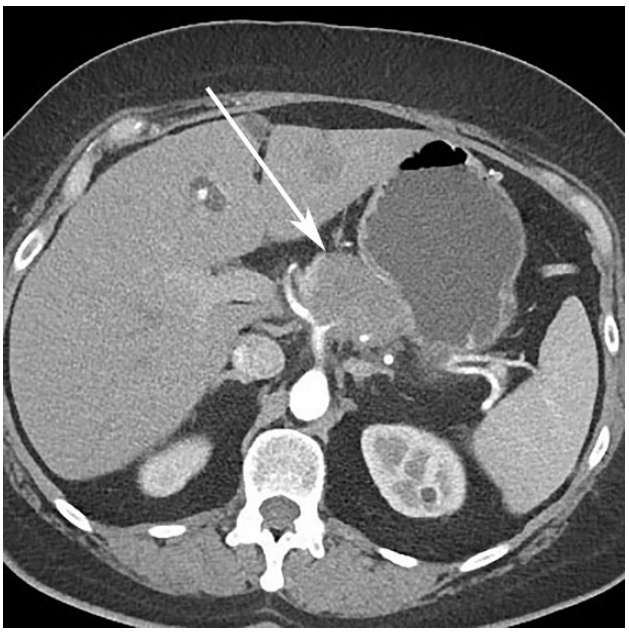

Figure 129.1 Axial contrast-enhanced CT image demonstrates a hypodense mass centered in the pancreatic body (arrow), with infiltrative, poorly defined margins, classic for pancreatic adenocarcinoma. Note that the tumor involves the celiac artery, hepatic artery, and splenic artery, and abuts the adjacent stomach.

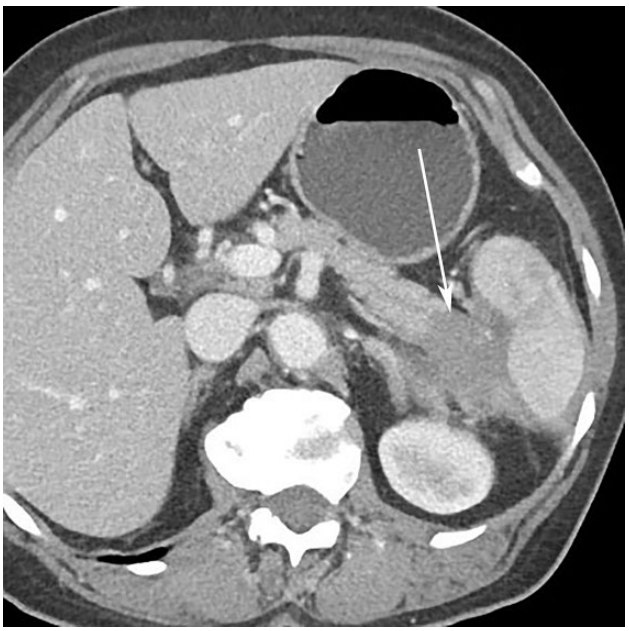

Figure 129.2 Axial contrast-enhanced CT image demonstrates a poorly defined hypodense mass (arrow) centered in the pancreatic tail, compatible with pancreatic adenocarcinoma. The tumor in this case is markedly infiltrative, not only involving the adjacent spleen but also extending to involve the adjacent left adrenal gland.

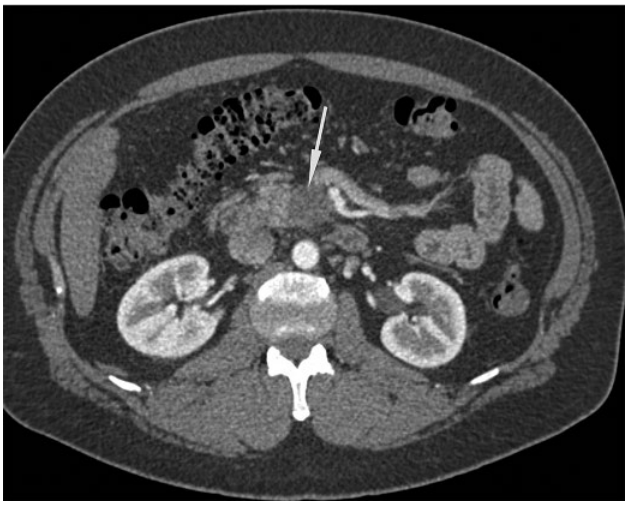

Figure 129.3 Axial contrast-enhanced CT demonstrates a subtle hypodense mass (arrow) in the uncinate process, a location in which pancreatic tumors are commonly missed on CT.

parenchyma on all phases of imaging, and can thus be very difficult to identify in the absence of secondary signs of malignancy [25].

Even if the primary tumor is not clearly visualized, secondary signs of malignancy can be extraordinarily helpful for identifying subtle or small lesions. In particular, the most important secondary signs of malignancy

Figure 129.4 Axial contrast-enhanced CT demonstrates a large hypodense infiltrative mass (arrow) involving nearly the entirety of the pancreas, found at resection to represent pancreatic adenocarcinoma.

include focal or upstream pancreatic atrophy, pancreatic ductal dilation/obstruction with abrupt cut-off of the pancreatic duct, biliary ductal obstruction (especially with pancreatic head malignancies), and an abnormal contour of the pancreas [26–28]. Of these secondary signs, by far the most important is the presence of a dilated pancreatic duct; a dilated pancreatic duct with abrupt cut-off should always be considered suspicious for an occult obstructing mass/tumor, even if the primary lesion is not clearly visible on CT, and should prompt further evaluation with another modality, usually endoscopic ultrasound (Figs 129.5 and 129.6) [28,29].

Staging

Computed tomography currently represents the best modality for the local staging of pancreatic adenocarcinoma, including a tumor's involvement of adjacent retroperitoneal vascular structures and other organs. In particular, tumor involvement of several critical retroperitoneal vascular structures plays a crucial role in determining whether a patient is capable of undergoing an R0 surgical resection. The five vessels that are most important in determining a patient's resectability are three major arteries (celiac artery, superior mesenteric artery [SMA], and hepatic artery), and two major veins (portal vein, superior mesenteric vein [SMV], and portal/SMV confluence) [7,8]. It should be noted that only these five major vessels are important in terms of dictating a

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 129.5 Axial contrast-enhanced CT demonstrates a very subtle hypodense mass (arrow) in the pancreatic body segment, representing pancreatic adenocarcinoma. Noticeable is severe atrophy with a dilated pancreatic duct in the upstream pancreas, features that are highly suggestive of an underlying malignancy. The presence of a dilated pancreatic duct with pancreatic atrophy, even in the absence of a discretely visualized mass, should raise strong concern for an occult tumor.

Figure 129.6 Axial contrast-enhanced CT demonstrates a hypodense pancreatic mass in the body (arrow) resulting in severe upstream pancreatic atrophy and abrupt obstruction of a dilated pancreatic duct.

patient's resectability, while smaller vascular structures (such as the gastroduodenal artery or inferior mesenteric vein) do not have the same presurgical significance.

When evaluating the central mesenteric arterial vasculature using CT, tumoral involvement is typically stratified using a quantitative system, with tumoral involvement delineated as either involving <180° or >180° of the vessel circumference. The ability of CT to distinguish such subtle degrees of vascular involvement by tumor has become increasingly critical, as the line between "resectable" and "unresectable" tumors has increasingly become blurred. The NCCN currently describes three categories for resectability status: resectable, borderline resectable, and local advanced [7]. At one time, tumors that demonstrated *any* significant involvement of the celiac, SMA, or hepatic artery were considered "unresectable," while a tumor was considered "resectable" only if it did not involve any of these major mesenteric arteries. Increasingly, however, it is possible to have some degree of arterial involvement and be considered "borderline resectable," and still undergo surgical resection [8,30]. Placing the patient into this "borderline resectable" category requires very careful evaluation of tumoral involvement of the vessel, in order to make quite subtle distinctions between <180° and >180° involvement of the vessel, although these distinctions have become slightly easier given improvements in image quality on the latest generation of scanners (Figs 129.7–129.10).

Compared to the arterial vasculature, involvement of the central mesenteric venous vasculature has recently become less of a hindrance for complete surgical resection because of the increasing utilization of modern vascular surgical reconstruction techniques (such as interposition grafts or other vein reconstruction procedures). Accordingly, a strict numerical descriptor of tumoral involvement of the portal vein or SMV is less important than providing the surgeon with enough information to determine whether a surgical reconstruction of the vein is feasible (when involved by tumor). In other words, the radiologist's report should provide information regarding the length and degree of venous involvement and whether there is sufficient normal portal vein above or normal SMV below the tumor to allow an interposition graft to be placed (Fig. 129.11).

Metastatic Disease

The most common sites of distant metastatic disease in patients with pancreatic cancer include locoregional lymph nodes, liver, and peritoneum, with metastatic disease to the lungs and bone relatively less common. As with many other malignancies in the abdomen/pelvis, the assessment of peripancreatic and retroperitoneal

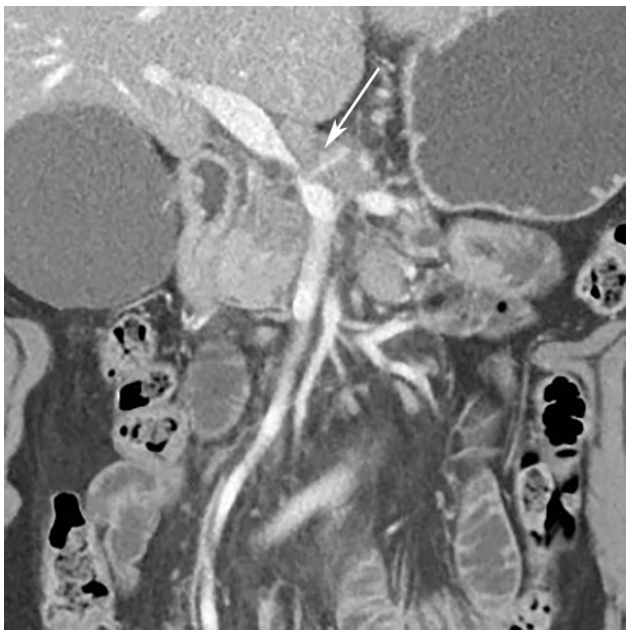

Figure 129.11 Coronal contrast-enhanced CT imaging of the venous phase demonstrates a hypodense pancreatic adenocarcinoma (arrow) resulting in narrowing of the distal main portal vein near the portal/SMV confluence.

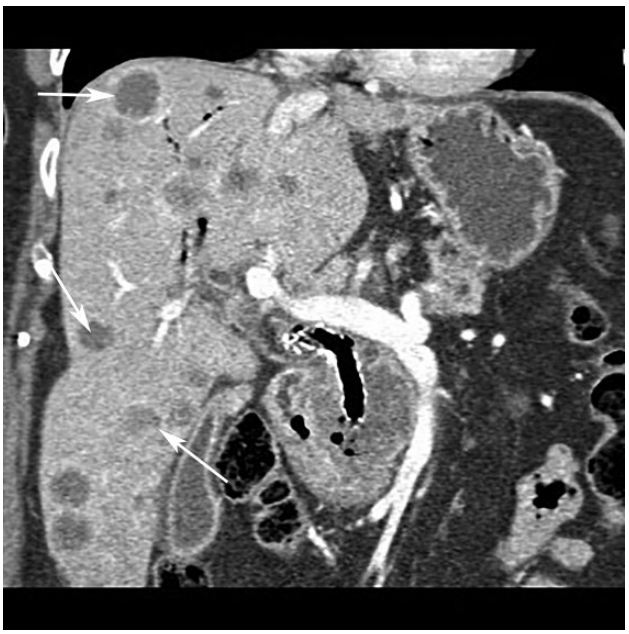

Figure 129.12 Coronal contrast-enhanced CT imaging in a patient with a pancreatic head adenocarcinoma demonstrates multiple hypodense lesions (arrows) in the liver, some of which demonstrate peripheral enhancement, compatible with extensive metastatic disease to the liver.

lymphadenopathy using CT is relatively limited, particularly given that CT relies primarily on size criteria when delineating a node as "normal" or "suspicious." However, normal-sized nodes can often harbor metastatic disease, while enlarged nodes may be reactive and be histologically normal on surgical resection [31,32]. Accordingly, several studies looking at the sensitivity and specificity of CT for metastatic lymphadenopathy have shown that CT is relatively limited, with accuracy rates under 60% [2,3,33]. Fortunately, the accuracy of MDCT for metastatic lymphadenopathy is not of significant consequence, as locoregional lymph node metastases do not typically preclude a patient from undergoing surgical resection.

However, distant metastatic disease is critical in determining the patient's resectability, as the presence of distant metastases (most often to the liver or peritoneum) precludes surgical resection, making radiation and/or chemotherapy the only palliative options. The liver is by far the most common site of distant metastatic disease in patients with pancreatic cancer, and in virtually all cases, is the first site of distant metastatic disease (prior to the development of peritoneal, lung, or osseous metastatic disease). While the arterial phase of imaging may have some utility in the identification of liver metastases (demonstrating peripheral hyperenhancement around a lesion or perfusion abnormalities near a metastasis), the venous phase images are the most critical for the identification of liver lesions (Fig. 129.12). The overall sensitivity of CT for liver metastases is relatively good for lesions that measure over 1 cm, with sensitivity rates ranging above 75%.

However, regardless of the type of primary tumor, the sensitivity of CT for smaller lesions (particularly lesions measuring under 1 cm in size) is relatively limited [34]. In particular, part of the problem when assessing small liver lesions is accurately differentiating small benign lesions (such as cysts or hemangiomas) from malignant lesions, as standard imaging criteria can be very difficult to utilize for tiny liver abnormalities which are too small to characterize. Nevertheless, the vast majority of these tiny nonspecific liver lesions (in the absence of clear morphologic features of malignancy) are benign, and MRI may be an additional helpful tool if it is necessary to further characterize these small lesions [35,36].

The second most common site of distant metastatic disease in patients with pancreatic cancer is peritoneal carcinomatosis. Regardless of the primary tumor, CT is well known to struggle in the identification of early peritoneal metastatic disease. The imaging appearance of peritoneal metastases can range from a subtle micronodular pattern (with tiny nodular foci in the omentum and adjacent stranding/induration) to the development of frank confluent omental soft tissue with an "omental caking" pattern. In most cases, peritoneal carcinomatosis is accompanied by the presence of ascites, so the presence of free fluid in a patient with pancreatic cancer

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

should prompt a very careful, thorough search of the omentum and peritoneal cavity for tumor implants (Figs 129.13 and 129.14) [37]. FDG PET/CT can also prove advantageous in the detection of peritoneal carcinomatosis [38].

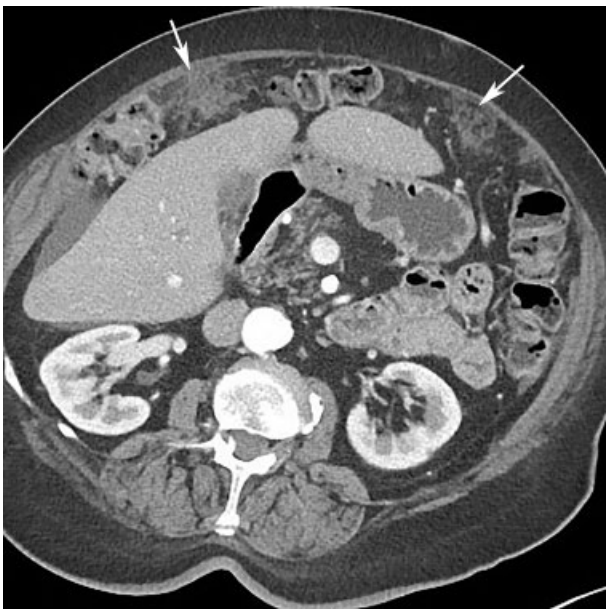

Figure 129.13 Axial contrast-enhanced CT imaging of a patient with known peritoneal carcinomatosis demonstrates a small amount of ascites, as well as ill-defined soft tissue and nodularity in the omentum (arrows), compatible with peritoneal carcinomatosis.

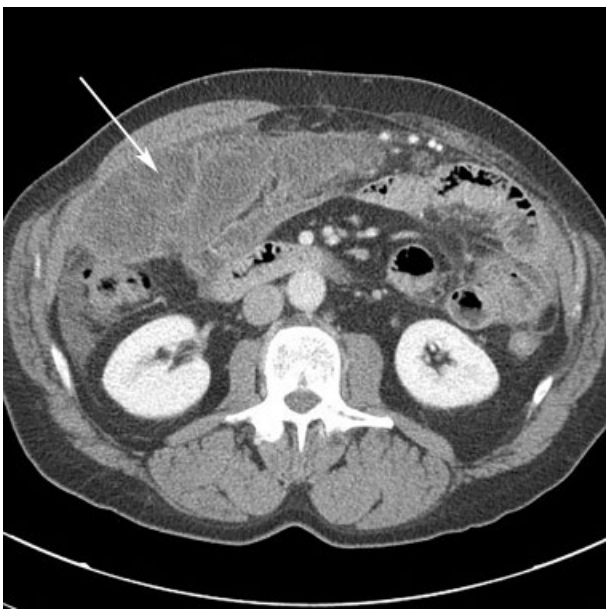

Figure 129.14 Axial contrast-enhanced CT demonstrates extensive hypodense soft tissue throughout the omentum, compatible with peritoneal carcinomatosis and "omental caking" in this patient with underlying pancreatic cancer.

Magnetic Resonance Imaging

Technique

While CT protocols for pancreatic imaging are relatively standardized across institutions, there is considerable variability in both the MRI protocols and field strengths of MRI scanners being utilized at different institutions. The NCCN recommends a protocol including coronal (with or without axial) T2-weighted single-shot fast spin-echo images, axial T2-weighted fat-suppressed spin-echo images, axial T1-weighted in-phase and opposed-phase gradient echo, coronal T2-weighted MR cholangiopancreatography (MRCP) images, axial diffusion-weighted imaging, and axial precontrast and dynamic gadolinium-enhanced 3D T1-weighted fat-suppressed gradient echo (pancreatic, portal venous, and equilibrium phases) [7,8]. One of the advantages of MR is that protocols can be tailored to the exact indication for the study with more sequences added as necessary.

Lesion Identification

In most of the organs of the abdomen, T2-weighted images are of critical importance, and often pathology will appear conspicuous as a result of its T2 hyperintensity. However, the pancreas is somewhat unique, given that its intrinsic T2 signal intensity can be quite variable depending on the age of the patient and the degree of fatty infiltration. This T2 signal variability in normal pancreatic tissue leads to pancreatic adenocarcinoma being relatively inconspicuous on standard T2-weighted images in many cases.

On T1-weighted images, the normal pancreas (in the absence of underlying chronic pancreatitis) is typically relatively T1 bright (roughly equal in signal intensity to the liver parenchyma) due to the large amount of acinar protein it contains. As a result, pancreatic cancers, which are usually relatively T1 hypointense and fibrotic, are often conspicuous when juxtaposed against the intrinsically T1 bright pancreatic parenchyma. T1-weighted images can therefore be relatively useful for lesion identification in patients who cannot receive gadolinium as a result of allergy. The pancreas upstream from the mass often appears atrophic and abnormally T1 hypointense as a result of fibrosis, and the upstream dilated/ obstructed pancreatic duct is often nicely accentuated on T2-weighted/MRCP images (Figs 129.15–129.18) [5,39–41]. The highly T2-weighted MRCP images nicely depict the ductal anatomy, which can aid in palliative techniques such as stent placement and biliary drainage [41].

Dynamic contrast-enhanced T1 imaging is also an essential component of the imaging protocol. Pancreatic adenocarcinomas are typically best seen on the arterial/

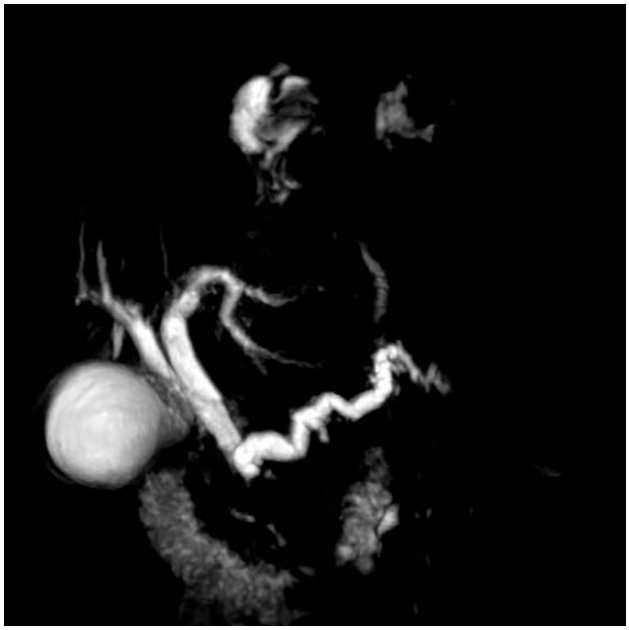

Figure 129.15 Coronal MRCP images with maximum intensity projection reconstruction demonstrates a classic double duct sign of pancreatic adenocarcinoma, with marked dilation of both the biliary tree and the pancreatic duct to the level of the pancreatic head, at the site of the patient's known pancreatic adenocarcinoma.

pancreatic parenchymal phase, when they appear hypointense to the avid pancreatic background parenchymal enhancement, as well as appearing poorly marginated and infiltrative [41,42].

While not reliably seen in all cases, many pancreatic tumors demonstrate restricted diffusion, offering another means of identifying subtle or small tumors that may be relatively inconspicuous on standard imaging sequences [5,39,43–48].

In most cases, MRI is not utilized for the initial screening or diagnosis of pancreatic tumors (although many sources suggest that it can be quite accurate when asked to do so), but rather as a troubleshooting tool to be used when a tumor is not adequately visualized on MDCT or there are indeterminate findings. In particular, MRI can be quite valuable in cases where a primary tumor is strongly suspected on the basis of secondary findings (such as a dilated duct), but where the tumor is not seen on MDCT because it is too small or isodense to the pancreatic parenchyma. MRI can also provide value in differentiating pancreatic adenocarcinoma from mimics, including focal chronic pancreatitis and autoimmune pancreatitis [41,49].

(a)

(b)

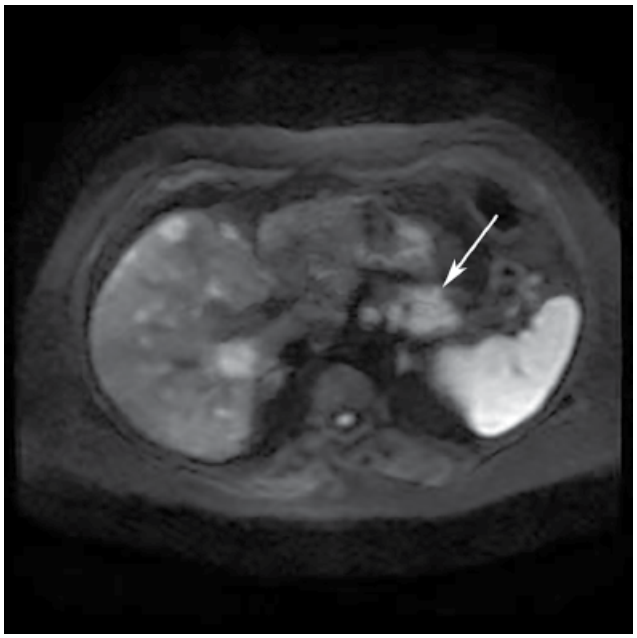

Figure 129.16 Axial postgadolinium T1-weighted image (a) and axial DWI (b) demonstrate a mass in the pancreatic tail (arrows), which demonstrates hypoenhancement on the postgadolinium image and demonstrates restricted diffusion (i.e., bright on the DWI image). Notice the multiple metastases in the liver, which also demonstrate hypoenhancement and restricted diffusion.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 129.17 Axial DWI (a), axial T1 without gadolinium (b), and axial T2 FSE with fat saturation (c) demonstrate a pancreatic adenocarcinoma (arrow) in the tail. Notice how the mass is relatively conspicuous on the pregadolinium T1-weighted images, juxtaposed against the T1 bright pancreatic parenchyma, and is also quite conspicuous on the DWI images as a result of restricted diffusion. However, as with many pancreatic adenocarcinomas, the mass is relatively inconspicuous on the T2-weighted images.

Tumor Staging

Magnetic resonance imaging has generally been considered inferior to MDCT in the local staging of pancreatic adenocarcinoma, and in particular, in evaluating tumor involvement of the critical retroperitoneal mesenteric vasculature. In general, CT is better for evaluating involvement of the mesenteric arteries and veins because of its superior temporal resolution. CT images are much

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 129.18 Axial T1 without gadolinium (a), axial T1 post gadolinium in the arterial phase (b), and axial T1 post gadolinium in the delayed phase (c) demonstrate a hypodense mass (arrows) in the pancreatic tail, conspicuous on both the pre- and postgadolinium images. The mass does demonstrate evidence of delayed enhancement, a relatively common feature with these tumors.

less likely than MRI to be plagued by motion artifacts or other technical artifacts that might make subtle determinations of vascular involvement difficult. Some authors have recently argued that technical advancement in MRI protocols and scanners may have made this gap less significant than was previously thought [50–53].

Magnetic resonance imaging suffers from many of the same problems as CT in terms of evaluating locoregional lymph nodes, as MRI also largely relies on size criteria for the differentiation of benign from malignant lymph nodes. In some cases, a lymph node can be delineated as abnormal based on morphologic characteristics (such as

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

abnormal shape or central necrosis), but this is relatively comparable to CT. Unfortunately, while diffusion-weighted imaging was originally thought to hold promise in terms of differentiating benign from malignant lymph nodes, it is now clear that there is a significant overlap in the ADC values of benign and malignant lesions (including normal and abnormal lymph nodes), and the presence or absence of restricted diffusion within a lymph node is of little value in terms of making an absolute judgment as to whether or not a lymph node is infiltrated by tumor.

However, one area where MRI does have clear advantages over CT is in the evaluation of indeterminate liver lesions, in particular in terms of characterizing lesions under 1 cm in size [54–58]. Multiple MRI pulse sequences can be used in combination to make a more specific diagnosis such as tiny cysts (which demonstrate a fluid signal on T2-weighted images) or small hemangiomas (which also demonstrate marked T2 hyperintensity). MRI has been shown to identify liver metastases that are occult on CT, in one study altering management in 10% of patients [56,57]. MRI has also been shown to improve detection of peritoneal disease [59]. One recent study demonstrated that the addition of MRI to CT in patients with pancreatic ductal adenocarcinoma changed resectability status from resectable to unresectable in 14.4% of patients, due to the detection of liver metastases, vascular involvement, para-aortic lymph node enlargement, and peritoneal seeding [60]. While not every patient with pancreatic adenocarcinoma requires evaluation with MRI, MRI may be a helpful tool to determine surgical resectability.

Emerging Techniques: Cinematic Rendering

Cinematic rendering is a novel technique that creates photorealistic three-dimensional images from isotropic volumetric data, which is readily generated from modern CT scanners. While 3D imaging has often been used for pancreatic cancer staging, cinematic rendering takes three-dimensional visualization to another level. The improved anatomic detail and realism created by cinematic rendering may aid in detection of subtle pancreatic lesions (Figs 129.19–129.21) [17]. Cinematic rendering may also help delineate the relationship of the tumor to adjacent structures given its improved 3D visualization, and may also aid in surgical planning when vascular reconstruction and grafting may be required [18].

Conclusion

There is little doubt that MDCT is currently the most important imaging modality for the identification of pancreatic tumors, local tumor staging (including

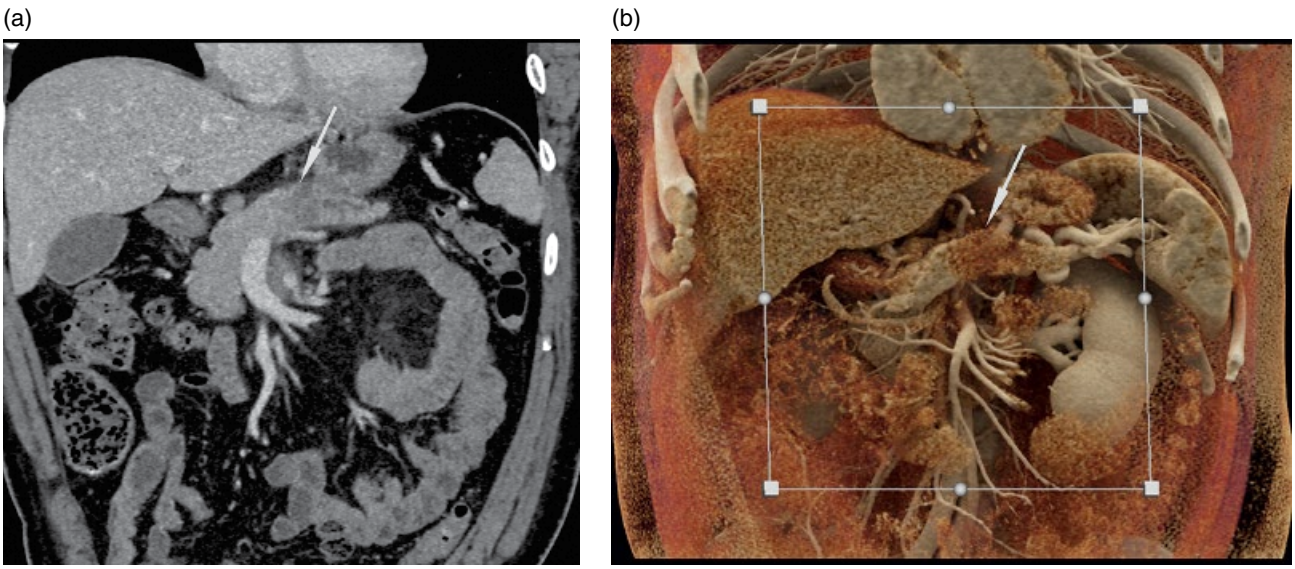

Figure 129.19 Coronal contrast-enhanced CT (a) and coronal cinematic rendered image (b) demonstrate an ill-defined pancreatic adenocarcinoma in the body of the pancreas (arrows) with upstream dilation of the main pancreatic duct. The lesion is better demonstrated on the cinematic rendered image, which highlights the textural changes associated with the tumor.

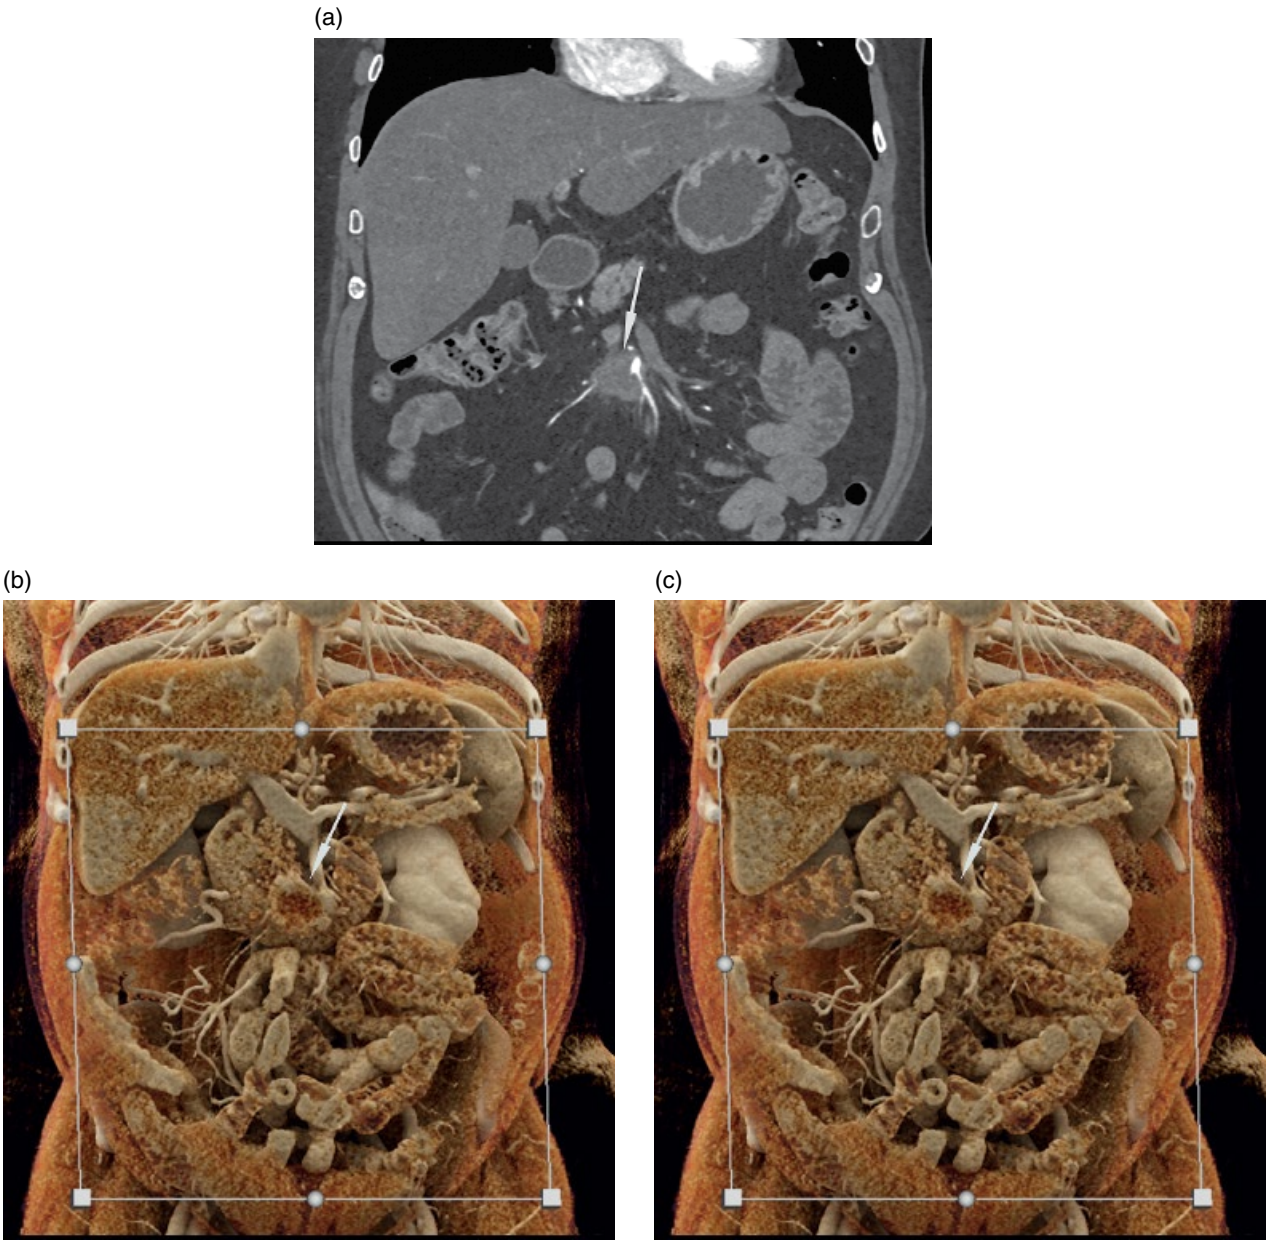

Figure 129.20 Coronal contrast-enhanced CT (a), coronal cinematic rendered image (b), and axial cinematic rendered image (c) demonstrate a mass in the head of the pancreas consistent with adenocarcinoma of the pancreas (arrows). The cinematic rendered image shows the three-dimensional relationship of the mass with the adjacent mesenteric vasculature.

a tumor's involvement of adjacent retroperitoneal vasculature and other organs), and the identification of distant metastatic (most commonly the liver and peritoneum) disease. While MRI is not currently a first-line modality in the identification and staging of pancreatic cancer, it does have a great deal of utility in terms of identifying lesions that may be occult or subtle on CT, and serving as a troubleshooting tool that might help provide more definitive answers when confronted with an indeterminate or occult liver lesion on CT. Emerging three-dimensional visual techniques such as cinematic rendering can provide improved anatomic detail and visualization of complex anatomy, which may aid in pre-surgical and treatment planning.

Screening of Hereditary Pancreatic Cancer

Michael Goggins

Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Pancreatic Cancer Risk

Pancreatic cancer is expected to be the second leading cause of cancer-related deaths in the USA in the next decade [1]. In the USA, the average lifetime risk of developing pancreatic cancer is ~1.4%. Until recently, the long-term benefits of pancreatic screening were not well known, and for this reason screening is only offered to those individuals whose risk of pancreatic cancer is sufficiently high that the potential benefits are estimated to be greater than the potential risks of screening. Experts such as those from the Cancer of the Pancreas Screening consortium consider that pancreatic screening may be justified if the lifetime risk of developing pancreatic cancer is at least 5% which is equivalent to a ~4-fold increased relative risk) [2]. Estimating an individual's future cancer risk is an important step in deciding whether an individual should be considered for pancreatic screening.

The main tool used to quantify pancreatic cancer risk is the family history. A detailed cancer family history will determine whether or not an individual is a first-degree relative of one or more subjects with pancreatic cancer and at what age pancreatic cancer developed in the family [3]. The estimates of pancreatic cancer risk in families have been achieved by following families long term in pancreatic cancer family registries [4]. Familial pancreatic cancer has been defined as kindred having two first-degree relatives with pancreatic cancer, although pancreatic cancer often runs in families who do not meet this definition. The risk of developing pancreatic cancer in first-degree relatives increases with the number of affected relatives [5]. This risk has been estimated to be sufficiently high in individuals with at least two affected first-degree relatives on the same side of the family (lifetime risk ~8–10%), and in those with a first- and second-degree relative with pancreatic cancer on the side of the family (lifetime risk ~5%) [5]. The relative risk among those with only a first-degree relative with pancreatic cancer is not considered sufficiently high (2–3-fold elevated) to warrant long-term surveillance, unless the relative carries a susceptibility gene mutation (discussed below). The risk of pancreatic cancer is also higher in familial kindred with a young-onset pancreatic cancer (age <50 years, relative risk [RR] 9.3) in their family, compared to those without a young-onset case [3]. Individuals who have one first-degree relative with pancreatic cancer on each side of the family (bilineal risk) are not thought to have a sufficiently high risk to warrant surveillance. Other patterns of inheritance are more challenging to estimate (such as having multiple affected second-degree relatives). The increased risk of developing pancreatic cancer in pancreatic cancer families identified through prospective studies points to inherited factors, although it is suspected that in some families shared environmental factors play a role in pancreatic cancer susceptibility.

Since the risk of developing hereditary pancreatic cancer is likely to be influenced by the same factors that influence the development of sporadic forms of the disease, in principle, pancreatic cancer risk factors such as smoking, obesity, diabetes and pancreatitis history could be used to refine estimates of cancer risk. However, to date these risk factors do not confer sufficient risk on their own to be useful in clinical practice [6].

The increasing use of hereditary gene testing of patients with pancreatic and other cancers has led to more relatives being identified with susceptibility gene mutations. Indeed, in the US multiple guidelines recommend offering susceptibility gene testing not only for patients with pancreatic cancer, but also for their first-degree relatives [7,8]. This guideline recommendation is

based on studies that find the prevalence of deleterious mutations is about 5–10% among unselected cases with pancreatic cancer [9–11]. Indeed, most patients with pancreatic cancer who have a susceptibility gene mutation do not have a family history of the disease, and often do not have personal or family histories that point to an inherited cancer syndrome [12]. The identification of such a mutation in a pancreatic cancer family provides an opportunity for cascade testing and cancer surveillance. Gene testing to look for pancreatic cancer susceptibility genes is best performed on an affected individual with pancreatic cancer from a familial pancreatic cancer kindred, but the rapid mortality of the disease in patients often precludes such testing being done. Among patients enrolled in the CAPS program because of their familial risk, those with a germline mutation had a significantly higher risk of progression than those with a familial risk alone (and gene tested to identify known susceptibility gene mutations) [13]. Similar results were found in a Dutch cohort [14]; in this study all the pancreatic cancers were diagnosed in those with germline mutations.

The genes known to cause hereditary forms of pancreatic cancer when mutated in the germline that have implications for pancreatic surveillance include *BRCA2*, *ATM*, *PALB2*, *CDKN2A (p16)*, *BRCA1*, *STK11*, *PRSS1* genes [15–18], and the hereditary nonpolyposis colon cancer (Lynch) syndrome [19,20]. Among kindred with a significant family history of pancreatic cancer, germline mutation pancreatic cancer susceptibility genes are only identified in ~10% of individuals, indicating that much of the familial clustering of pancreatic cancer remains unexplained.

In the early years of pancreas surveillance in the CAPS program, priority was placed on enrolling subjects with the highest risk at least until the benefits of surveillance were known, and that meant limiting enrollment of germline mutation carriers in genes such as *BRCA2*, *BRCA1*, and later *ATM* to those with a family history of the disease. As the benefits of surveillance have become clearer, along with the limitations of family history in predicting an individual mutation carrier's risk, there is more interest in opening up surveillance to all *BRCA2* mutation carriers.

The average lifetime risk of developing pancreatic cancer among all *BRCA2* gene mutation carriers is thought to be >5%, likely higher in those with a family history of the disease [21,22]. Those with germline *BRCA1* mutations are estimated to have a ~2–2.5-fold elevated pancreatic cancer risk [21,22]. For this reason, the CAPS guidelines did not reach consensus on the question of whether carriers of *BRCA1* mutations should undergo pancreas surveillance, particularly in the absence of a family history of pancreatic cancer. Recent guidelines from the ASGE address the question of surveillance of *BRCA1* and *BRCA2* mutation carriers, pointing out the limitations of restricting surveillance to those with a family history of the disease [20].

One other notable difference between *BRCA1* and *BRCA2* mutation carriers is their risk of developing biliary cancer, which is higher for *BRCA1* carriers [21,22]. To date, pancreas surveillance guidelines have not addressed the potential role of early detection of biliary cancer, in large part because biliary cancer is much rarer than pancreatic cancer, but in one Japanese study the lifetime risk of biliary cancer in *BRCA1* carriers approached 10% [21]. More data are needed, but the biliary cancer risk in *BRCA1* mutation carriers may justify their inclusion in pancreatic-biliary cancer surveillance.

Germline *ATM* mutations are the second most common known cause of hereditary pancreatic cancer [15,23]. Individuals with germline *ATM* mutations are at increased risk of developing multiple types of cancer. The protein product of *ATM* functions in DNA repair pathways and undergoes somatic mutation in a variety of cancers. In one study from the National Familial Pancreas Tumor Registry, the lifetime risk of pancreatic cancer among *ATM* mutation carriers was estimated to be approximately 10% [24]. Germline *CDKN2A (p16)* gene mutations cause familial atypical melanoma mole syndrome (FAMMM syndrome). The lifetime risk of developing pancreatic cancer among *CDKN2A* mutation carriers is estimated to be ~20% [25–27] and for this reason, patients are recommended to start surveillance at age 40. It may be appropriate to reduce the surveillance interval such as to every six months in these patients though more data are needed.

Germline *PALB2* (Partner and Localizer of Brca2) mutations are found in <1% of patients with familial forms of pancreatic cancer [28]. The risk of developing pancreatic cancer among *PALB2* gene mutation carriers is thought to be similar or somewhat lower than that of *BRCA2* [29,30]. Hereditary nonpolyposis colorectal cancer (Lynch syndrome) kindred which arises from germline mutations in mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*) gene mutations have an estimated lifetime risk of pancreatic cancer of 3.7% [19,31].

The pathologic features of pancreatic cancers with mismatch repair defects can be characteristic [32], and should be suspected when tumor sequencing shows high somatic mutation burdens, although most of these cases arise somatically, not via germline mutation. Less than 1% of pancreatic cancers have mismatch repair defects but are important to identify as these patients are more likely to respond to immunotherapy with checkpoint inhibitors [33]. Patients with Peutz–Jeghers syndrome (PJS) (who generally carry germline *STK11* gene mutations) have a very high risk of developing pancreatic

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancer (cumulative lifetime risk 11–36%) (reviewed in [34]) and are also recommended to start pancreas surveillance at age 40.

It is known that long-standing chronic pancreatitis predisposes to the development of pancreatic cancer. Hereditary pancreatitis is a rare condition, and few such patients are enrolled into pancreas surveillance programs. The gene most commonly implicated in hereditary chronic pancreatitis is *PRSS1* [35], and affected individuals typically develop pancreatitis in their teens and have many decades of pancreatitis that often results in pancreatic insufficiency [36]. Pathologically, the pancreas of *PRSS1* mutation carriers undergoes progressive lipomatous atrophy with increasing age [37].

The pancreatic cancer risk associated with hereditary recurrent acute pancreatitis was initially estimated to be very high (40% lifetime [38] and even higher for smokers), but more recent estimates find the risk to be <10% [39]. While other genes such as *CPA1* that have been identified as pancreatitis susceptibility genes and are now suspected to be causes of hereditary pancreatic cancer [40,41], this has not been shown to be true for carriers of the pancreatitis modifier genes, *SPINK1* and *CFTR* [42] that increase the likelihood of developing pancreatitis [43]. Patients with long-standing chronic pancreatitis from hereditary causes would likely benefit from pancreatic surveillance, though imaging the pancreas in these cases is more challenging, and the best modality for imaging is not certain. Rare variants in the pancreatic secretory enzymes *CPA1* and *CPB1* that induce endoplasmic reticulum stress are enriched in patients with pancreatic cancer compared to controls [40,41]. Many of these patients do not have a history of pancreatitis. The relative risk of pancreatic cancer in such patients is not well defined and such patients are not currently enrolled in pancreatic surveillance.

Other low-penetrance genetic variants associated with pancreatic cancer susceptibility have been identified through genome-wide association studies (GWAS). Thus, carriers of non-O blood groups have an approximately 1.4-fold elevated risk of developing pancreatic cancer relative to O-blood group carriers. GWAS has also identified variants *CTRB2*, *PDX1*, *Tert* and at other loci as being associated with pancreatic cancer risk [44–46]. There is considerable interest in trying to utilize such low-risk variants clinically. Polygenic risk scores can refine risk estimates, but show promise in more common cancers [46]. Their value in refining the risk of less common diseases like pancreatic cancer remains to be determined. Combining polygenic risk scores with other risk factors (family history, smoking, obesity, etc.) is another approach, but it has yet to generate high enough risk scores to identify those at high risk [6]. Polygenic risk scores have been used to estimate PDAC risk in patients with new-onset diabetes [47]. The potential value of using polygenic risk scores with other clinical risk data to identify candidates for surveillance needs further investigation.

At What Age Should Pancreatic Screening Begin and End?

Pancreatic surveillance protocols are designed to screen individuals starting a few years earlier than their peak incidence of pancreatic cancer. The average age at diagnosis for those with familial/inherited forms of pancreatic cancer is 68 [3], similar to sporadic pancreatic cancer, although pancreatic cancer diagnosis averages a few years younger in those with germline mutations. For this reason, the CAPS screening program (clinicaltrials.gov NCT02000089) has recommended pancreatic screening to begin at age 55 for those with familial risk, or 10 years less than the youngest pancreatic cancer in the family, and age 50 for those with germline mutations in *BRCA2/ATM/PALB2/*mismatch repair genes and age 40 for those with *CDKN2A* and *STK11* mutations. Many screening programs use age 50 for familial risk and age 45 for mutation carriers. One reason for beginning pancreatic cancer screening a decade or more before the average age of pancreatic cancer diagnosis was to provide an opportunity to identify and manage the precancerous lesions in affected individuals [48].

Not all pancreatic screening guidelines have the same recommendations regarding the age at which to commence surveillance [49]. Consensus guidelines do not agree on when pancreatic screening should be discontinued in pancreatic cancer families [50]. Pancreatic screening often continues beyond age 75 in subjects who have pancreatic cysts but it is probably appropriate to discontinue pancreatic screening by age 75 or 80 in high-risk individuals without any evidence of pancreatic precancerous lesions on prior screening.

Pancreatic Screening Tests

Currently, pancreatic screening utilizes pancreatic imaging tests. In a head-to-head blinded comparison of pancreatic endoscopic ultrasound (EUS), MRI/MRCP and pancreatic protocol CT performed as part of the CAPS3 study of high-risk individuals, EUS had the highest rate of detection of pancreatic cysts, followed closely by MRI/MRCP [48]. MRCP provides the best visualization of cyst communication with the main pancreatic duct to determine the nature of the pancreatic cyst [51]. EUS has the advantage that it can probably identify subcentimeter solid lesions better than MRI, but it is more operator

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dependent [52]. One Dutch study that performed a blinded analysis of diagnostic yield of MRI and EUS in patients undergoing pancreatic surveillance found two solid lesions identified by EUS, but not by MRI, one of which was a small PDAC [53]. Such studies are valuable, though more evidence is needed, as diagnostic yield depends on operator performance and changes with evolving technology such as MRI magnet strength.

Pancreatic-protocol CT is currently less sensitive at detecting subcentimeter cysts [48] and also had the disadvantage of giving a low dose of radiation, although the technology continues to improve. Pancreatic-protocol CT is also an excellent test to evaluate selected patients undergoing screening and surveillance when lesions of uncertain significance are identified. The diagnostic potential of pancreatic imaging may improve as artificial intelligence-based methods are applied to detect subtle changes in the gland, such as changes in volume or shape or texture [54].

Lesions Identified by Pancreatic Imaging

Pancreatic cysts are commonly identified in pancreatic screening cohorts. In the CAPS3 study, the average age of the study population was 56 and over one-third of the study population had at least one pancreatic cyst, with the prevalence increasing with increasing patient age [48]. Multiple other pancreatic screening studies of high-risk groups have reported a high prevalence of pancreatic cysts [48]. With improved pancreatic imaging in recent years, it is clear that pancreatic cysts are very prevalent in the general population, particularly among subjects in their 70s and older [55]. The high prevalence of pancreatic cysts in the general population and the recognition that most of these individuals are not going to develop pancreatic cancer has also raised questions as to the significance of pancreatic cysts in high-risk individuals. Although most pancreatic cysts identified in the screening population are branch-duct intraductal papillary mucinous neoplasms (IPMNs), the vast majority are subcentimeter in diameter and will not progress to invasive cancer [56]. To date, the number of pancreatic cancers detected by pancreatic screening in the literature is quite low (~1–5% of subjects under surveillance) [57] which is consistent with the expected age-specific incidence of pancreatic cancer of those undergoing screening.

Some patients who undergo pancreatic screening will have suspicious pancreatic cysts or solid lesions detected that are found at pancreatic resection to be nonneoplastic or of minimal malignant potential (such as serous cystadenomas, pancreatic neuroendocrine tumor or lobulocentric parenchymal atrophy associated with PanIN) [58,59].

Pancreatic Pathology Not Detected by Current Screening Tests

Pancreatic cysts can be detected by pancreatic imaging even when they are quite small (~2 mm). But in the resected pancreata of patients who undergo resection for pancreatic cysts, the most common neoplasm detected is pancreatic intraepithelial neoplasia (PanIN) [58]. These lesions are generally too small (<5mm diameter by definition) to be identified by current imaging modalities [60]. Although EUS can detect subtle changes like microcysts and hyperechoic foci that are often associated with the presence of PanIN, these EUS changes are not specific for PanIN [58].

Low-grade PanINs are common in the population and have very low malignant potential, whereas high-grade PanINs are thought to have a significant risk of progressing to invasive cancer. Most pancreatic cancers are thought to arise from PanINs, and although pancreatic cysts (IPMNs) are common in patients with hereditary forms of the disease, it is thought that most cancers that arise in these patients arise from PanINs. Evidence for this comes from multiple sources. A blinded histologic review of hundreds of familial and sporadic pancreatic cancers found no significant differences in the histologic features of familial and sporadic cases, including no difference in the number of IPMN-associated cancers [61]. Second, the genetic profiles of pancreatic ductal adenocarcinomas are similar to PanINs [62,63]. Finally, although ~66% of IPMNs harbor *GNAS* mutations, *GNAS* mutations are not typically found in the pancreatic ductal adenocarcinomas from patients with a family history of pancreatic cancer [64].

Surveillance Intervals

Surveillance recommendations for high-risk individuals have developed initially from clinical judgment, and then initial experience with surveillance, and the experience of surveillance of subjects with sporadic pancreatic cysts [65], to evidence of outcomes of surveillance. Most patients are recommended to undergo annual surveillance. This recommendation reflects what is known about the underlying biology of pancreatic cancer as well as the limitations of current pancreatic imaging tests. One study that estimated the time to progression of pancreatic cancer through its clinical stages determined that it takes approximately one year on average to progress from stage I disease to stage IV disease [66]. It may be appropriate to have longer surveillance intervals (several years apart) when the risk of pancreatic cancer is lower (such as for subjects in their 50s), increasing it to annually

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for older subjects, but more evidence is needed. The presence of pancreatic cysts generally does not affect that recommendation as most pancreatic cysts (including those identified as IPMNs) have low malignant potential.

Early studies of pancreatic cancer diagnosis in the high-risk setting found many subjects with screen-detected pancreatic cancers had stage II disease [67]. Although this represented significant downstaging, many such patients are not cured despite earlier detection. However, more recent studies from the CAPS program found that the majority of patients diagnosed at stage I disease had maintained their recommended surveillance interval. Surveillance intervals can be shortened in those with concerning, "worrisome" lesions, though notably most of the pancreatic cancers diagnosed in the CAPS program do not arise from an IPMN, despite having pancreatic cystic IPMNs in their gland [57]. Similarly, a multicenter study examining the pancreatic abnormalities prior to a pancreatic cancer diagnosis found evidence that pancreatic cancers often do not arise from a clear precursor lesion detectable by imaging [68].

The choice of surveillance test is often influenced by practical considerations such as patient preference and insurance. Surveillance protocols often alternate EUS and MRI to provide complementary imaging and limit the burden of annual EUS [69]. Subjects who have large pancreatic cysts, pancreatic duct abnormalities or solid lesions undergo fine needle aspiration of any focal concerning lesion(s) and close surveillance.

Surgery for Lesions Identified by Pancreatic Screening

As clinicians have gained experience with pancreatic screening, the indications for pancreatic resection in the screening setting have become more selective. Pancreatic resections are usually undertaken once there is evidence that a pancreatic cyst has features concerning for invasive cancer or for a cancerous solid mass or suspicious mass. Most patients are likely to develop their cancer from PanIN that will grow into a solid mass and not a cystic lesion. The strategy of waiting for the emergence of a cancer risks missing opportunities for cure as most patients who present with resectable cancers will not be cured, but operating on subjects with IPMN without a cancer or strong suspicion of cancer often results in overtreatment (the detection of low-grade dysplasia in PanIN and IPMN). The rationale for performing pancreatic resection for high-risk patients with multiple medium-sized pancreatic cysts that do not individually meet criteria for resection is that some of these patients have high-grade PanIN in their resected pancreata [58,59].

The choice of operation for high-risk patients with lesions identified by pancreatic screening can be challenging since some patients will have concerning cysts or other lesions in both the head and tail of the pancreas. However, total pancreatectomy is only occasionally undertaken in this setting because of the potential morbidity associated with diabetes after total pancreatectomy. Instead, patients usually undergo partial pancreatectomy for screen-detected lesions and are then recommended to continue surveillance postoperatively. These cases are evaluated on a case-by-case basis preferably by an experienced multicenter team and at a high-volume center [70,71]. Surgical outcomes in the CAPS program have been excellent [72].

Evaluating Long-term Outcomes of Patients Who Undergo Pancreatic Screening

Proving the benefits of pancreatic surveillance requires large multicenter studies involving many patients followed for many years. Recently, the CAPS program updated its experience with pancreas surveillance, combining the results of the multicenter CAPS5 study with the overall Hopkins experience that extends over 20 years [57]. We find that the median survival of patients who maintained annual surveillance and were diagnosed with pancreatic cancer was 9.8 years, suggesting that most such patients are cured of their disease [57]. This survival benefit is likely to be largely driven by the detection of pancreatic cancer at stage I when cure is most likely. Indeed, a recent analysis of sporadic pancreatic cancer outcomes in patients in the NCI SEER registry found that five-year survival among cases with pancreatic ductal adenocarcinoma who underwent surgical resection and had stage I disease was 80%, decreasing to 60% at 10 years [73]. And the survival trends have been improving. This study builds upon our prior CAPS experience (74). Although the majority of patients diagnosed in the CAPS program have had stage I disease, some patients present with higher stage disease, pointing to the need for better risk assessment and diagnostic tests. The detection of high-grade dysplasia in PanIN or IPMN is also an important goal of pancreatic screening, as such patients have excellent long-term outcome and it is likely that removing high-grade dysplasia can reduce pancreatic cancer death.

In addition to the CAPS experience, long-term outcomes of patients enrolled in European centers have been published that include a large number of

CKDN2A/p16 Leiden mutation carriers [75]. They reported downstaging from surveillance compared to historical controls with a five-year survival of 24%.

Developing Better Pancreatic Screening Tests

The recent outcomes of pancreatic surveillance of high-risk individuals highlight the benefits of pancreatic imaging tests, but there are also limitations. Some patients do not maintain surveillance, and some patients are diagnosed late despite surveillance. There has been considerable research into developing better diagnostic tests. Based on the experience using pancreatic imaging, diagnostic tests need to be able to perform well at diagnosing stage I pancreatic cancer. One strategy would be to combine pancreatic imaging with a blood test. A screening test that performs well at detecting stage II cancers would not have a major impact on survival since the median survival of patients with stage II pancreatic cancer is less than two years [73]. Serum CA19-9 is still the best available test but has not had the performance characteristics needed for early diagnosis. Among patients with resectable pancreatic cancers, it has a diagnostic sensitivity of only ~60%, lower still in patients with stage I disease, and false-positive elevations of CA19-9 that have limited its potential as a screening test [76]. One strategy to improve the diagnostic performance of CA19-9 is to combine it with a gene test that personalizes an individual's CA19-9 reference range, by determining variants in the genes responsible for CA19-9 synthesis (*FUT2* and *FUT3*) [77].

Another diagnostic testing approach is to test for ctDNA, but less than half of patients with resectable pancreatic ductal adenocarcinoma have detectable circulating tumor DNA mutations [78]. Other recent studies have utilized ctDNA in the form of changes in DNA fragmentation [79], methylated DNA [80] or hydroxymethylated DNA [81]. Other studies have evaluated protein markers in combination with CA19-9 [82]. Although these studies show promise, more evidence is needed. Most other circulating markers that have been reported as potential pancreatic cancer markers do not have the diagnostic characteristics that would make them suitable for pancreatic screening. Most of these circulating biomarkers have yet to be evaluated as clinical tests in the pancreas surveillance setting.

The inability of current pancreatic screening tests to detect high-grade dysplasia in PanIN lesions limits our ability to identify patients most likely to progress to cancer. Approaches that have been used to identify PanINs by pancreatic screening include pancreatic juice analysis and molecular imaging. Analysis of secretin-stimulated pancreatic juice collected endoscopically from the duodenum of patients enrolled in the Cancer of the Pancreas Screening trials (CAPS) revealed that these patients are more likely to have mutations in their pancreatic juice, especially *KRAS* mutations that are thought to arise from small PanIN lesions, and *KRAS* and *GNAS* mutations that arise from IPMN (close to what would be expected if one directly analyzed their IPMNs) [56,83,84]. Next-generation sequencing applied to pancreatic juice can identify other mutations, including those enriched in patients with pancreatic cancer and high-grade dysplasia *TP53* and *SMAD4* [85,86]. Collecting secretin-stimulated pancreatic juice from the duodenum is safe, but the low concentration of mutations in pancreatic juice in these patients is an obstacle to early detection [83].

Molecular imaging offers the possibility to detect small pancreatic cancers and precursor lesions. One molecular target is the integrin α(v)β(6) which has been shown to detect micrometastatic pancreatic cancer [87].

Conclusion

Long-term outcomes of pancreatic surveillance in high-risk individuals find that patients diagnosed with pancreatic cancer, especially those diagnosed with stage I disease, can achieve long-term survival. This downstaging and survival benefit is only evident for those who maintain annual surveillance. Similarly, resecting precancerous neoplasms with high-grade dysplasia (in PanIN or IPMN) is likely to be beneficial in preventing cancer in many cases. Managing concerning but indefinite pancreatic lesions identified by screening is best done by experienced multidisciplinary teams.

There are major unanswered questions about pancreatic screening. There is a need to better define pancreatic cancer risk so as to improve the targeting of individuals who most need pancreatic screening. There is also a need to develop better screening tests. Current pancreatic imaging tests do not reliably detect PanIN which are the most common precursor lesion. With the development of more accurate blood tests, it may ultimately be possible to improve the detection of small, potentially curable stage I pancreatic cancers.

The Role of PET in Diagnosis of Pancreatic Cancer and Cancer Recurrence

Norbert Hüser[1], Volker Aßfalg[1], Isabel Rauscher[2], and Helmut Friess[1]

Introduction

Positron emission tomography (PET) is a noninvasive functional imaging technique that is used to observe metabolic processes in the body. The patient is given a radioactive glucose analogue carrying a positron emitter. During the radioactive decay of the so-called radiotracer, positrons are emitted. The positrons next collide with electrons, which cause the release of photon pairs. Detectors arranged in a circle around the patient can then record the latter. Thereby, PET can analyze both the localization and the intensity of the radioactive tracer in the patient's body. Compared with morphologic imaging, PET provides functional data of the investigated tissue, which can also be measured quantitatively.

Different radiotracers can be applied depending on the clinical problem. Currently, the radiotracer 2-[^{18}F]-fluoro-2-deoxy-D-glucose (FDG) is most commonly used. Its uptake reflects glucose metabolism in the cells which is significantly increased in malignant tumors. However, FDG is not a cancer-specific agent and its uptake has been described in a number of nonneoplastic inflammatory lesions.

Integrated PET-computed tomography (PET-CT) was introduced in 1999 [1]. These PET-CT scanners provide simultaneous acquisition of both high-resolution anatomic CT data and high-resolution metabolic PET information. However, as PET-CT is still a cost-intensive diagnostic tool with limited availability, reliable data evaluating the actual benefit of PET and PET-CT are of crucial importance. Therefore, this chapter gives an overview on currently available data of PET and PET-CT imaging in pancreatic cancer, summarizing its value and possible indications in the settings of primary diagnosis, staging, detection of tumor recurrence, and therapy monitoring. Finally, the potential value of recently introduced integrated whole-body PET-MRI is outlined.

Role of PET and PET-CT in Primary Tumor Diagnosisof Pancreatic Carcinoma

Despite excellent registration of anatomic and pathologic structures, morphologic imaging is unable to distinguish malignant from benign processes unconditionally. The sensitivity of multidetector CT (MDCT) has improved over the past few years. According to data from the literature, the sensitivity of MDCT in pancreatic carcinoma was reported to be between 75% and 100% in so-called multiphase scans with a specificity of 70–100%. However, concerning lesions smaller than 2 cm, the sensitivity reaches values of no higher than 77% [2,3], which mandates complementary histopathologic investigation of suspicious lesions. Magnetic resonance imaging (MRI) appears to be of outstanding impact in detection and assessment of tumor lesions of the pancreas, which cannot be directly depicted in CT imaging because of isoenhancing [4]. Concerning magnetic resonance cholangiopancreaticography (MRCP) in primary tumor diagnostics, Fusari et al. demonstrated sensitivity, specificity, accuracy, and positive and negative predictive values (describing the probabilities of FDG-positive lesions to be malignant and of negative lesions not to be malignant) to be 100%, 88%, 98%, 97%, and 100%, respectively [5]. For comparison purposes, the sensitivity and accuracy of endo-ultrasound for lesions smaller than 2 cm are reported to be as high as 100% and 95%, respectively [3].

Tumor detection and assessment of tumor dignity with FDG-PET encounter problems of a different nature. As FDG-PET displays areas of increased glucose metabolism within the body, those tissues with a naturally high metabolism and all hypermetabolic processes are depicted regardless of its dignity. This might lead to false-positive diagnosis in, for example, inflammation. The differentiation of pancreatic lesions is complicated whenever a local pancreatitis is present at the time of FDG-PET examination [6]. The glucose oxidation of activated leukocytes in inflammatory sites is highly increased, which causes an intense FDG uptake in this area as well. Additionally, within autoimmune pancreatitis an increased FDG uptake can be demonstrated in up to 100% of cases [7]. In contrast, in patients with chronic pancreatitis without active inflammatory components, PET shows a FDG uptake in only 13% [8]. Therefore, pancreatic carcinoma can be distinguished from chronic pancreatitis, because most pancreatic adenocarcinomas show a relatively high FDG uptake (Fig. 131.1).

However, recent studies have highlighted difficulties in differentiation between metastasis-free pancreatic carcinoma and mass-forming pancreatitis because of an overlap of the maximum standardized uptake value of both diseases [9]. Further, FDG uptake in tumor tissue and normal tissue is influenced by dietary state, as FDG is a glucose analogue. The investigator has to ensure a well-controlled serum glucose concentration in the patient to allow for adequate PET diagnostics. This is especially important in diabetic patients, because glucose concentrations above 8.4 mmol/L significantly reduce the detection rate of pancreatic carcinoma [6].

Kauhanen et al. reported a higher diagnostic accuracy of PET-CT compared to conventional MDCT and MRI in primary diagnosis of pancreatic cancer [10]. In their analysis including 38 patients, the pooled sensitivity and specificity were 85% and 94%, respectively. For comparison, sensitivity and specificity were 85% and 92% for MDCT, and 85% and 72% for MRI. In two prospective studies on primary diagnostics of pancreatic cancer, the sensitivity of PET-CT (89%) was comparable to both CT [11] and endo-ultrasound [12]. However, no homogeneous consent has been reported so far concerning any superiority of PET or PET-CT compared with MDCT and MRI. A published metaanalysis including 35 studies reports on pooled sensitivity (SN), specificity (SP), positive predictive value, and negative predictive value of 90%, 76%, 90%, and 76% for PET and 90%, 76%, 89%, and 78% for FDG-PET-CT, respectively. In contrast, sensitivity and specificity of CT and MRI are 91% and 85% versus 84% and 82%. Therefore, Rijkers and colleagues could not derive any superiority or additional benefit of both FDG-PET and FDG-PET-CT in primary diagnosis of pancreatic carcinoma [13]. These data therefore support the current guidelines of the NCCN, which do not recommend PET-CT for standard primary diagnostics in patients with pancreatic carcinoma.

Taken together, PET-CT is a useful diagnostic method *in addition* to conventional imaging procedures, especially when the results are inconclusive or show cystic and complex lesions in the pancreas [14]. Therefore, currently, the role of PET and PET-CT in diagnosis of primary pancreatic carcinoma cannot be finally determined.

Role of PET and PET-CT in Oncologic Staging of Pancreatic Carcinoma

Whereas primary diagnostics exclusively aim for the detection and proof of a pancreatic carcinoma, TNM staging focuses on gathering information on the oncologic extent of the primary tumor and its potential metastases, which is essential for individual evaluation of therapeutic options.

Regarding tumor resectability and reasonableness of surgical procedures, both local tumor infiltration of vessels and detection of distant metastases have a crucial impact on therapeutic strategy. As a result of high surgical standards and improvements in downstaging of

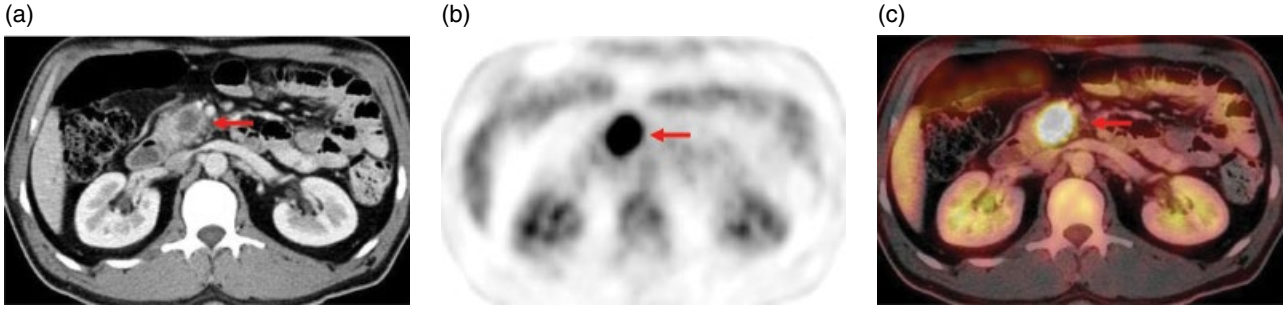

Figure 131.1 (a–c) FDG-PET-CT examination of a patient with primary diagnosis of pancreatic cancer presenting with an intense, focal FDG uptake in the pancreatic head.

pancreatic carcinomas, the classification of *resectable*, *borderline resectable*, *locally advanced/irresectable*, and *metastasized* tumors has gained increasing attention. MDCT and MRI are the most commonly used methods in staging of pancreatic carcinomas. Here, T-staging is of special importance because unresectability of pancreatic cancer is defined morphologically as infiltration of the superior mesenteric artery and/or the celiac trunk. The preference of either method depends on both local availability and experience of the investigator. The NCCN guidelines support both contrast-enhanced pancreatic CT and MRI and the International Study Group of Pancreatic Surgery (ISGPS) recommends investigation of the pancreas by use of contrast-enhanced CT imaging. Nevertheless, assessment of local resectability remains difficult even with these tools. In ambiguous cases, the decision has to be forwarded to a pancreatic surgery reference center.

A study by Strobel et al. revealed that the use of enhanced FDG-PET-CT as a one-stop-shop imaging protocol for assessing the resectability of pancreatic cancer is feasible and accurate. In their study, enhanced PET-CT was significantly superior to PET alone and although not being significant, there was a trend for enhanced PET-CT to be superior to unenhanced PET-CT [15]. Therefore, PET-CT should always include diagnostic contrast-enhanced CT as unenhanced PET-CT has limited value in T-staging.

During recent years, combined FDG-PET-CT has made distinct progress in the staging of malignant pancreatic tumors. The advantage of this whole-body examination especially concerns the M-staging where its specificity reaches up to 100%, for example in the detection of lung and bone metastases [15]. Heinrich et al. proved that in patients with known metastatic spread, more metastases were visible by PET compared with CT scan alone [11]. In addition, the authors evaluated the oncologic impact of PET-CT on further therapeutic decision making. In 16% of the patients investigated, the detection of metastasis prompted the physicians to refrain from surgical therapy. This is concordant with the results of Bang et al. who revealed that PET scan increased the tumor stage in approximately a quarter of investigated patients because metastases had not been visible with CT imaging alone [16].

Another study demonstrated the superior sensitivity of FDG-PET (88%) compared to MDCT (38%) and MRI (38%) regarding the detection of liver metastases. This study also reported a change of therapeutic strategy in 29% of patients as the palliative situation made surgical procedures unnecessary [10]. These results could be augmented by a metaanalysis which reported an increased sensitivity of PET-CT compared to PET alone (82% vs 67%) regarding the detection of liver metastases [17].

The sensitivity of PET-CT in the detection of lymph node metastases has been reported to be as low as 21–38% [10,11]. Conversely, other studies underline the role of PET-CT in staging of locoregional and distant lymph node metastases. Here, PET-CT has been reported to be more accurate than CT or PET alone with regard to locoregional N-staging. However, the differences were rather small (85.3% vs 83.8% and 79.4%) [18]. Because of the contrary results published in the literature, the value of PET-CT for N-staging has to be questioned.

In summary, PET seems to be more sensitive in detection of distant metastases but has not achieved significance in routine staging and has not given proof of cost-effectiveness yet [19] (Fig. 131.2).

Therapy Control and Diagnostics of Malignant Pancreatic Tumor Recurrence by PET and PET-CT

The impact of FDG-PET and PET-CT in terms of response prediction after neoadjuvant chemotherapy in patients with pancreatic adenocarcinoma is promising. They are particularly expected to allow for decision

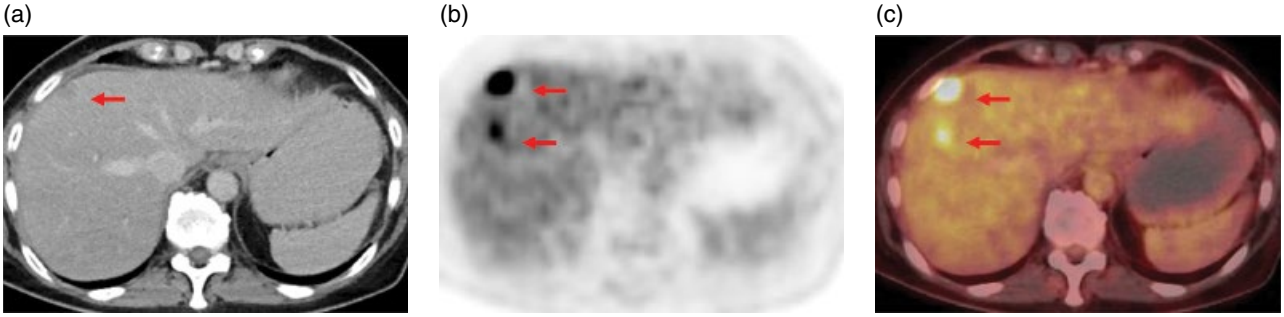

Figure 131.2 FDG-PET-CT of a patient presenting with two liver metastases of pancreatic cancer with high, focal FDG uptake (b,c). However, note that only one of them was visible with diagnostic CT (a).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. making in tumors that were initially described as borderline. Both the depiction of metabolic processes and the morphologic evaluation of lesions are highly difficult because of neoadjuvant chemotherapy-induced regional alterations around the tumor. Katz and coworkers demonstrated that the resectability of a tumor could be predicted on the basis of imaging procedures in only 0.8% of investigated patients after intended downstaging. However, tumors actually turned out to be resectable in 66% of the patients during surgical exploration [20]. The ISGPS therefore recommends explorative laparotomy in all patients without proof of metastatic spread or other indicators of tumor progress after neoadjuvant therapy.

FDG-PET and PET-CT show a significant advantage compared with CT and MRI in the detection of local recurrence after initial surgical resection of pancreatic carcinoma. Tumor recurrence could be confirmed in 96% of patients by use of FDG-PET but in only 39% when CT or MRI imaging were performed [21]. In another study, proof of tumor recurrence by FDG-PET was successful in 96.8%, whereas CT scan was accurate in only 55.6% [22]. Therefore, PET gains some significance in monitoring of surgical patients after resection of pancreatic cancer.

However, pancreatic tumors are often unresectable when diagnosed. FDG-PET served as therapy control of pancreatic carcinoma in several investigations. Advantages of PET-CT compared with CT scan could be demonstrated in terms of decreasing standardized uptake values in case of a tumor response in both follow-up monitoring after radiotherapy [23] and after chemotherapy [24]. These findings allow for some prognostic assessment concerning the survival of every single patient. Nevertheless, the correlations between metabolic response and prognosis remain under debate because of very heterogeneous results. However, new therapeutic agents can be tested and validated by use of FDG-PET-CT within studies.

Value of PET-MRI in Patients with Pancreatic Cancer

With the introduction of integrated whole-body PET-MRI into clinical practice, a novel metabolic anatomic imaging technique is available with the opportunity to perform multiparametric oncologic imaging that reflects different aspects of tumor biology (tumor diffusion, perfusion, and glucose metabolism). It also combines the strengths of PET (metabolic imaging) with the advances of MR (soft tissue contrast, functional imaging, e.g., using diffusion-weighted imaging and dynamic contrast-enhanced imaging) (Fig. 131.3). This multiparametric approach allows for noninvasive phenotyping of tumor biology which, by combining different functional and molecular imaging methods, might lead to higher

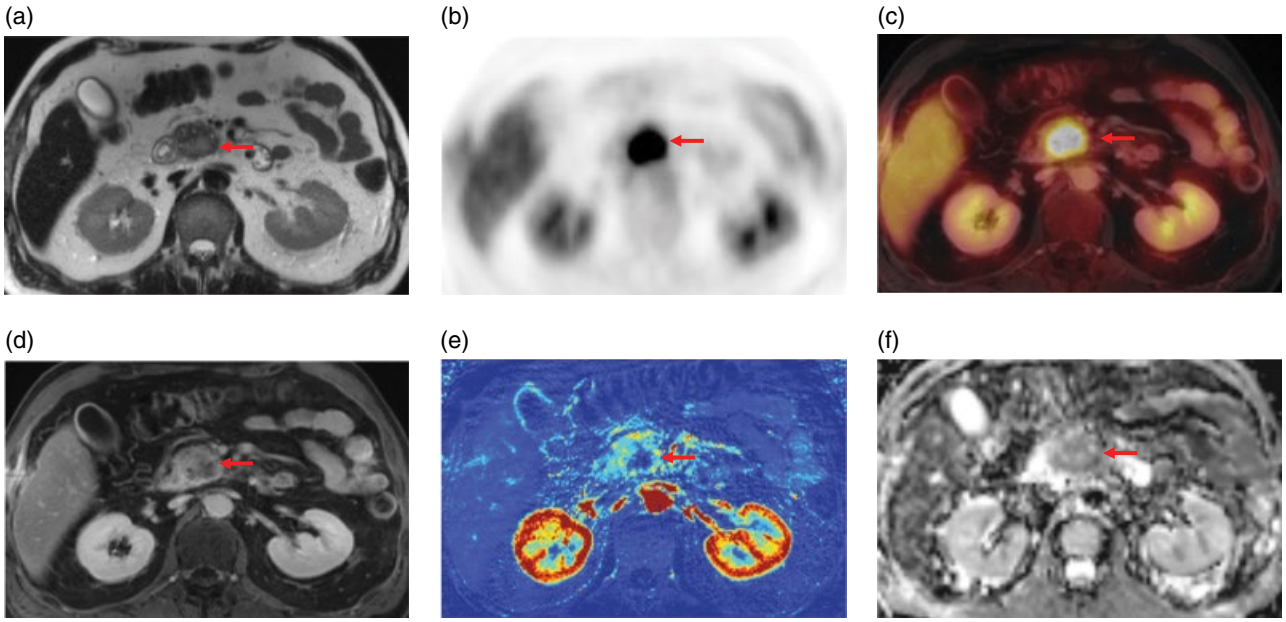

Figure 131.3 Multiparametric FDG-PET-MRI of a patient with primary diagnosis of pancreatic cancer. The MR image shows an inhomogeneous, hypointense tumor in the pancreatic head (a) with a high, focal FDG uptake (b,c). Dynamic contrast-enhanced (DCE) MRI shows peripheral hypervascularity (d) and the parametric map of iAUC60 (initial area under the DCE-MRI contrast agent concentration-time curve after 60 s) confirmed a high wash-in rate (e). Corresponding diffusion-weighted imaging presents low ADC values within the tumor indicating low cellularity (f).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 131.4 FDG-PET-MRI of a patient with pancreatic cancer before (a–c) and six weeks after beginning chemotherapy (d–f). Note the decrease of SUV values (b,e) after chemotherapy indicating a tumor response (decrease of SUVmean/max 18% and 53%).

accuracy for tumor detection and differentiation as well as response (Fig. 131.4).

In a study by Joo et al., a similar diagnostic performance in the preoperative staging and resectability assessment of pancreatic neoplasms was obtained comparing PET-CT plus contrast-enhanced CT with FDG-PET-MR imaging [25]. Further, in a preliminary study by Gao et al., multiparametric and textural features of primary tumors in FDG-PET-MR images were reliable biomarkers for predicting synchronous metastatic disease in pretreatment PDAC, which might be helpful for the selection of optimal therapeutic methods [26]. In detail, metastatic PDAC patients showed significantly larger tumor sizes, more frequent body/tail locations and higher SUVpeak, MTV, and TLG values in the primary tumor than those in nonmetastatic patients (P <0.05 for all). Further, significant differences between M0 and M1 PDAC for two first-level features (histogram skewness and kurtosis from ADC map) and 15 third-level features (four from PET and 11 from ADC map) were found. Additionally, Chen et al. showed that multiparametric PET-MR imaging biomarkers of pancreatic cancer patients were associated with overall survival [27].

Few data on sequential FDG-PET-MRI for response prediction in PDAC have been reported in the literature so far. In a preliminary analysis by Harder et al., FDG-PET-MRI was performed before and two weeks after therapy initiation indicating that early changes in FDG-PET-MRI-derived biomarkers MTV, TLG, and ADC enable differentiation between responders and nonresponders [28]. In a similar study, Wang et al. evaluated FDG-PET-MRI before and four weeks after treatment initiation in advanced PDAC [29]. Here again, FDG-PET-MRI-derived parameters MTV, TLG, and ADC enabled early discrimination between responders and nonresponders, further underlining the potential role of early PET-MRI after treatment initiation.

Conclusion

The final appraisal of the patient-relevant benefit of PET and PET-CT with regard to primary diagnostics, diagnostics of tumor recurrence, or staging cannot be based on a comparison with standard methods only. In fact, the major matter of interest is the question of the impact of an improved diagnostic tool on therapy and therefore patient morbidity, mortality, and quality of life. Randomized studies are needed to investigate the impact of findings from PET and PET-CT in all those cases where they indicate different results or tumor stages compared with standard methods. At the moment, there are no studies that allow for any statement concerning PET and PET-CT in this respect. However, many studies validate the quality of PET and PET-CT by scrutinizing the improvement in primary diagnostics, diagnostics of tumor recurrence, and tumor staging of pancreatic carcinoma compared with standard methods without PET.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. The current literature does not obligatorily recommend the use of PET-CT within primary diagnostics of pancreatic carcinoma, but it is considered to be a useful modality. However, PET-CT plays a promising role in the assessment of borderline resectable tumors and locally advanced tumors. Furthermore, the additional use of PET scanners demonstrated auspicious results in the staging of locally resectable lesions with synchronous CT and MRI morphologically occult metastases. Nevertheless, the sensitivity of detection of lymph node metastases is rather low. The impact on therapeutic consequences in tumor therapy will play a relevant role in future socioeconomic concerns, however, while sparing patients unnecessary surgical procedures. Finally, PET-CT already plays an important role in detection of tumor recurrence after surgical resection and therapeutic monitoring in unresectable pancreatic cancer.

PET-MR is a new and increasingly used multimodal imaging technique, which is expected to improve diagnostic performance especially in oncologic patients. The combination of PET and MR in hybrid whole-body PET-MR systems has the potential to combine excellent morphologic, functional, and biologic information in one imaging session with precise image coregistration. In contrast to PET-CT, the MR part of PET-MR provides superior soft tissue contrast and imposes no ionizing radiation.

The application of PET-MR has just started, and more research is needed to determine its potential value. Radiomics in nuclear medicine is developing fast and might improve the clinical value of multiparametric PET-CT and PET-MR in predicting disease phenotypes and personalizing diagnosis and treatment.

Tumor Markers in Pancreatic Malignancies

Shin Hamada and Atsushi Masamune

Division of Gastroenterology, Tohoku University Graduate School of Medicine, Miyagi, Japan

Conventional Tumor Markers for Pancreatic Cancer

Carbohydrate Antigen 19-9

Carbohydrate antigen (CA) 19-9 is a sialyl-Lewis A antigen, which is recognized by a mouse monoclonal antibody NS 19-9 established by Koprowski et al. [1]. This monoclonal antibody was established by immunizing mice with human tumor cell lines and binds to glycosphingolipid. Elevation of CA 19-9 was confirmed in the pooled serum samples from patients with advanced adenocarcinoma of the upper gastrointestinal tract, pancreas and biliary tract, compared to healthy donors [2].

In the normal pancreas, CA 19-9 expression is limited to the apical surface of pancreatic duct epithelium, while its expression increases in the pancreatic cancer cells [3]. Synthesis of CA 19-9 sialyl-Lewis A antigen requires α-1,4-fucosylation of sialyl-Lewis C precursor, which is regulated by the *Le* gene encoding fucosyl transferase [4]. Patients lacking the *Le* gene are unable to synthesize CA 19-9, and thereby represent low serum CA 19-9.

CA 19-9 is a standard marker of pancreatic ductal adenocarcinoma (PDAC). For PDAC diagnosis, the sensitivity of CA 19-9 was 79% and the specificity was 82% [5]. However, CA 19-9 is not a suitable marker for "early" detection of pancreatic cancer in the general population. Another study assessed the diagnostic ability of CA 19-9 according to the stage of PDAC, and the diagnostic sensitivity of CA 19-9 was only 55.6% in stage I [6]. Currently, the clinical usefulness of CA 19-9 is mainly for follow-up after surgery, assessment of chemotherapy effect, and prognosis. Patients with a low postoperative CA 19-9 value have a better prognosis [7]. Similarly, patients with low CA 19-9 before surgery or adjuvant chemotherapy also have a better prognosis [7]. Another study reported that decrease of CA 19-9 during gemcitabine-based chemotherapy could predict better median survival, suggesting the possibility as a determinant factor of chemotherapy continuation [8]. Based on this line of evidence, measurement of CA 19-9 before and after surgery or during chemotherapy is strongly recommended.

Measurement of CA 19-9 is also useful for detection of recurrence. Patients who received resection of pancreatic cancer with continuously elevated CA 19-9, referred as denormalization, frequently developed early recurrence [9]. Multivariate analyses revealed that CA 19-9 denormalization was an independent risk factor for early recurrence, together with no postoperative adjuvant chemotherapy and serosal invasion. In another study, patients who developed postoperative recurrence revealed elevation of CA 19-9 prior to the detection of recurrence by imaging studies [10]. The sensitivity and specificity of 2.45 times elevated CA 19-9 were 90% and 83.33%, respectively, with an area under the curve of 95%.

Elevation of CA 19-9 could be a feature of malignant intraductal papillary mucinous neoplasm (IPMN) [11]. CA 19-9 elevation was a preoperative predictor of malignant IPMN. A subsequent study also confirmed that CA 19-9 could be a noninvasive diagnostic tool for differentiating invasive IPMN [12]. The diagnostic sensitivity and specificity of CA 19-9 were 0.74 and 0.859, respectively. Preoperative CA 19-9 elevation is also a risk factor of postoperative recurrence of IPMN [13], similar to pancreatic cancer. A metaanalysis confirmed that raised CA 19-9 is most specific for the prediction of malignant IPMN [14], which will be beneficial for follow-up.

Several noncancer conditions also lead to the elevation of CA 19-9 besides pancreatobiliary cancers. Obstructive jaundice is a cause of CA 19-9 elevation [15]. Biliary drainage reduces serum CA 19-9 in these patients,

suggesting that basal CA 19-9 level needs to be measured after biliary drainage. Elevation of CA 19-9 is also seen in patients with liver disease. Patients with acute hepatitis, liver cirrhosis, and hepatocellular carcinoma showed CA 19-9 elevation [16]. Lymphoepithelial cyst is a rare benign cystic tumor of the pancreas, and is accompanied by CA 19-9 elevation. In this report, half of the cases revealed CA 19-9 elevation [17]. Some polycystic liver disease and polycystic kidney disease patients also had elevated serum CA 19-9 [18,19]. Furthermore, a wide variety of diseases such as bronchiectasis, interstitial lung disease, endometriosis, and even diabetes mellitus could present with CA 19-9 elevation [20]. In cases of CA 19-9 elevation without evidence of pancreatobiliary malignancy, these possibilities should be considered.

DU-PAN-2

DU-PAN-2 is a sialyl-Lewis C antigen, which is a precursor of CA 19-9. Mouse monoclonal antibody against DU-PAN-2 was established by immunizing mice with the HPAF human pancreatic cancer cell line [21]. Since Lewis-negative individuals can synthesize this antigen [4], DU-PAN-2 becomes an alternative marker of pancreatic cancer in these patients. DU-PAN-2 elevation is also reported in patients with biliary obstruction, similar to CA 19-9 [15]. Elevation of DU-PAN-2 in pancreatic cancer patients who received surgical resection also predicts worse disease-specific survival, suggesting similar utility to CA 19-9 [22].

SPan-1

SPan-1 is recognized by a monoclonal antibody raised against mucins purified from the SW1990 pancreatic cancer cell line [23], which therefore recognizes both sialyl-Lewis A and C antigens [24]. Pre- and postoperative SPan-1 elevation also has prognostic impact in patients with resectable pancreatic cancer [25]. Figure 132.1 shows an algorithm for measuring CA 19-9 or DU-PAN-2/SPan-1 during pancreatic cancer diagnosis.

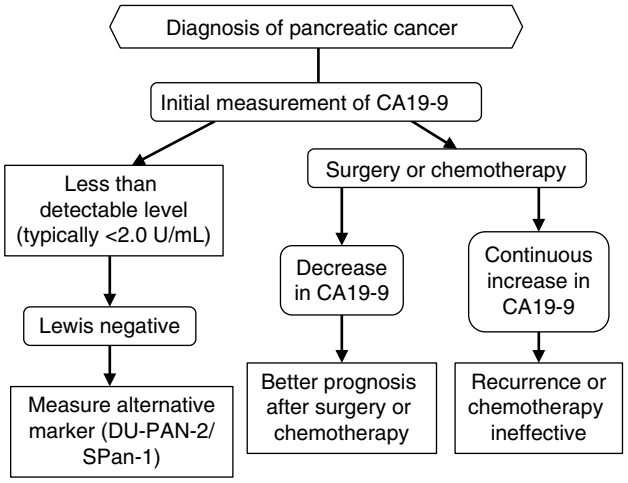

Figure 132.1 Clinical flowchart for CA 19-9 measurement in patients with pancreatic cancer.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) is a cell surface glycosylphosphatidylinositol (GPI) anchor glycoprotein, frequently used as a tumor marker for colorectal cancer [26]. Elevated serum CEA has been reported in patients with pancreatic cancer [27].

A recent systematic review summarizing 19 studies analysed the diagnostic ability of serum CEA in pancreatic cancer [28]. The pooled diagnostic sensitivity and specificity of CEA for pancreatic cancer diagnosis were 0.43 and 0.82, respectively. The pooled diagnostic sensitivity and specificity of CA 19-9 were 0.78 and 0.73, respectively, in the same study. Regarding prognostic significance, higher CEA level was associated with worse overall survival (OS) (hazard ratio 1.43) [28]. Similarly, measurement of CEA after surgical resection of pancreatic cancer had prognostic significance [29]. In this study, patients with elevated postoperative CEA had shorter recurrence-free survival and OS.

Elevated CEA in IPMN is also useful in distinguishing invasive IPMN [12]. The diagnostic sensitivity and specificity of CEA were 0.40 and 0.924, respectively.

These studies suggest that CEA measurement at the time of diagnosis or surgery would be useful for pancreatic cancer or IPMN.

Tumor Markers for Other Pancreatic Malignancies

α-Fetoprotein (AFP)

Acinar cell carcinoma is a rare type of pancreatic cancer. Elevation of AFP has been reported in cases of acinar cell carcinoma [30], and a decrease in serum AFP levels after therapeutic intervention has also been described [31]. Measurement of AFP in patients with pancreatic tumor suggestive of acinar cell carcinoma by imaging studies or pathologic diagnosis will be beneficial for follow-up after surgery and during and after chemotherapy.

Neuron-specific Enolase (NSE)

Neuron-specific enolase is a neuron-specific glycolytic enzyme and is also expressed in peripheral neuroendocrine cells [32]. Serum NSE is a marker of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

gastroenteropancreatic neuroendocrine tumor (GEP-NET). Serum NSE level reflects tumor burden and was correlated with OS of stage IV GEP-NET [33]. Another study reported increased serum NSE level according to the increase of tumor grade of pancreatic NET [34].

Chromogranin A (CgA)

Chromogranin A belongs to the granin family of acidic glycoproteins, regulating secretory granule biogenesis [35]. Since CgA is a major component of secretory granules, its serum level correlates with amount of endocrine cells. CgA is another marker of pancreatic NET. Similar to NSE, increase of serum CgA level was observed according to tumor grade of pancreatic NET [34]. Elevated CgA level was an independent risk factor for recurrence and OS by multivariate analysis.

Novel Marker Candidates

MicroRNAs

MicroRNA is a noncoding, single-stranded RNA of 21–24 nucleotides length [36]. MicroRNAs contribute to regulation of a wide variety of cellular functions, in both normal cells and cancer cells. MicroRNAs are released from cells in a small extracellular vesicle called an exosome, encapsulated by a lipid bilayer [36]. Exosomes are found in biological fluids such as urine, saliva, serum, and so on.

Many studies have tried to detect pancreatic cancer by microRNA detection in samples obtained via noninvasive methods. Detection of oncogenic microRNA, such as miR-21, miR-196, and miR-1246, in serum or urine samples had some diagnostic capability comparable to conventional tumor markers [37]. Some of these microRNAs were detectable in early-stage pancreatic cancer, suggesting the possibility of early diagnosis. However, further validation and confirmation of superiority over conventional biomarkers are necessary for clinical application.

Circulating Tumor Cells

Circulating tumor cells (CTCs) in peripheral blood are detectable in many solid tumors, including pancreatic cancer. Among patients with pancreatic cancer who received surgical resection, epithelial cell adhesion molecule (EpCAM)-positive CTCs were detected in 68.8% [38]. Patients with detectable CTCs in peripheral blood had a shorter OS after surgery, indicating predictive value. For CTC collection, surface marker-based and size-based filtration methods have been developed, which affect the quality of collected CTCs [39]. Optimization of sampling methods and timing of detection would be the next steps for clinical application.

Cell-free DNA

Peripheral blood also contains cell-free DNA (cfDNA). Several studies have reported an altered status of cfDNA in pancreatic cancer patients, affecting prognosis. The cfDNA contains circulating tumor DNA (ctDNA), which represents tumor-derived gene mutations [40]. This systematic review identified a negative impact of detectable ctDNA for the prognosis of patients with pancreatic cancer [40]. Another study reported that ctDNA samples from pancreatic cancer patients could be subjected to next-generation sequencing (NGS), as a screening method for panels of gene mutations [41].

Recent advances in NGS have enabled detection of gene mutations in each case, and detection of druggable mutations changes therapeutic strategy. For example, use of platinum-based therapy or poly-ADP ribose polymerase inhibitors is recommended for *BRCA*-mutant pancreatic cancer patients [42]. Even though the prevalence of the *NTRK* fusion gene is rare, targeted therapy for this fusion gene is now available, such as entrectinib and larotrectinib [43].

Introduction

Pancreatic cancer (PC) is the fourth leading cause of cancer-related death for both males and females, with five-year survival rates of 39%, 13%, and 3% for localized, regional, and distant PC, respectively, in the United States [1]. One of the main reasons for the dismal prognosis is the delayed diagnosis at later stages. More than 80% of patients are estimated to have unresectable disease at the time of initial diagnosis due to local invasion and/or distant metastases involving the liver and peritoneum [2]. Despite advances in imaging, peritoneal metastases and small liver metastases on the liver surface are frequently missed during preoperative evaluation. Such a condition is called radiologically "occult metastases." A metaanalysis including 16 studies with a total of 1146 participants demonstrated that 41% of patients with potentially resectable pancreatic and periampullary cancers on contrast-enhanced computed tomography (CE-CT) actually presented with unresectable diseases at laparotomy [3]. Since inaccurate evaluation of resectability may result in unnecessary "open-and-close laparotomy," accurate evaluation before laparotomy is crucial for the better management of pancreatic cancer.

Staging laparoscopy (SL) is a minimally invasive approach to detect such occult metastases. The standard procedure of SL is exploration of the peritoneal cavity including the Douglas pouch and the liver surface. With more extensive SL procedures, surgeons can explore the lesser sac, perform lavage cytology, and sample possible metastatic tissues for histologic evaluation. Furthermore, intraoperative ultrasound (IOUS) can be utilized in searching for potential liver metastases and assessing the extent of local invasion.

Detection of radiologically occult metastases during SL can preclude unnecessary laparotomy and facilitate appropriate treatments based on accurate staging. In a metaanalysis including 2827 patients with potentially resectable pancreatic/peripancreatic cancers, the pooled sensitivity in detecting unresectable diseases by SL with IOUS was 64% (95% confidence interval [CI] 61–66%) [4]. In particular, the sensitivities in detecting liver and peritoneal metastases were 88% (83–92%) and 92% (84–96%), respectively. Unnecessary laparotomy was avoided in 25% of patients, and the resection rate improved from 61% to 80% using SL with IOUS.

In this chapter, we describe the indications and procedure of SL and the significance of peritoneal cytology for PC with special reference to current topics in the era of highly sensitive imaging modalities and minimally invasive approaches to pancreatic resections.

Indication for Staging Laparoscopy

The National Comprehensive Cancer Network (NCCN) Guidelines Version 2.2021 (https://www.nccn.org/professionals/physician_gls/pdf/pancreatic.pdf) recommend considering SL in high-risk patients for potential metastases, including those with borderline resectable disease, markedly elevated CA 19-9, large primary tumors, or large regional lymph nodes. The optimal cutoff value of CA 19-9 varies among studies, but 150 U/mL has been most commonly adopted [5–8]. The cutoff value of primary tumor size considered as an indication of SL would be 30 mm [5,7,9]. Body and tail tumors are at higher risk of peritoneal dissemination than head tumors [10,11], because the former directly face the free space of the lesser sac compared to the latter which is

Companion website: www.wiley.com/go/beger/thepancreas4e

covered by the gastrocolic ligament and transverse mesocolon. Therefore, the threshold for SL should be lowered for body and tail tumors. Even for locally advanced unresectable tumors, the presence or absence of occult peritoneal or liver metastases would still affect prognosis, and SL should be considered in this setting [12,13].

Procedure

Typically, three or four ports are placed. Both sides of the infraphrenic space are explored along with the liver surface (Fig. 133.1a). In the Trendelenburg position, the small intestine is gently moved upward and the Douglas pouch becomes accessible. The sample for lavage cytology is usually taken from the Douglas pouch by washing with 100 mL of normal saline (Fig. 133.1b). The posterior liver surface, paraduodenal retroperitoneum, proximal jejunal mesentery, and lesser sac are possible sites of metastasis, which might be missed during standard SL [14]. By dividing the midportion of the gastrocolic ligament, the lesser sac can be easily entered (Fig. 133.1c). Primary tumors may be visualized and the presence or absence of direct invasion into surrounding organs can be evaluated.

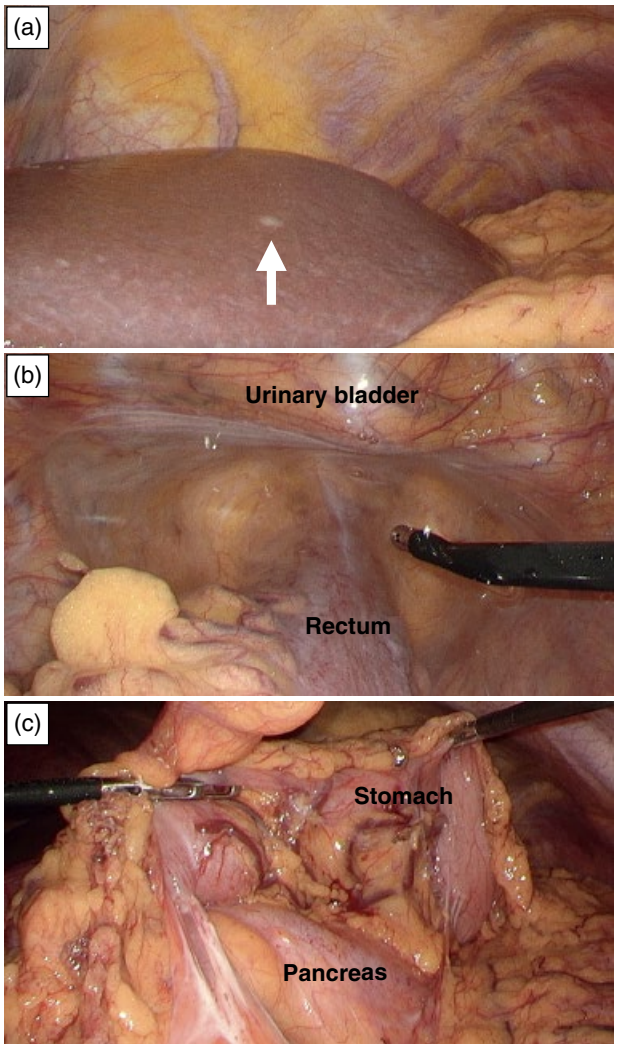

Figure 133.1 (a) An occult liver metastasis was found on the liver surface during SL, which was not detected on CE-CT, EOB-MRI, or FDG-PET. (b) By moving the small intestine upward, the Douglas pouch becomes accessible. Lavage cytology is collected at the Douglas pouch. (c) By dividing the gastrocolic ligament widely, the lesser sac can be fully explored.

Intraoperative US is useful for detection of liver metastases and assessment of local invasion of the major vessels. Contrast-enhanced IOUS facilitates the detection and characterization of liver masses (Fig. 133.2). The procedure is relatively safe with reported morbidity and mortality rates of <0.5% and <0.05%, respectively [4].

Significance of Peritoneal Cytology

Positive peritoneal cytology is considered as the precursor of peritoneal dissemination. The American Joint Committee on Cancer staging system defines CY+ as M1 [15]. However, the prognostic significance of CY+ and whether resection should be precluded only by CY+ have been controversial. A recent Japanese nation-wide cancer registry-based study including 1970 patients who underwent pancreatectomy for PC between 2008 and 2012 showed that the prognosis was significantly worse for patients with CY+ than those with CY- (the median survival times were 17.5 and 29.4 months respectively, and the five-year survival rates 13.7% and 31.1%, respectively) due to higher risk of peritoneal recurrence [10]. Meanwhile, a single-institution retrospective study including 523 patients demonstrated that although the overall survival of patients with resected CY+ tumors was worse than that of patients with resected CY- tumors, it was significantly better than the survival of unresected patients regardless of CY status [16].

These findings suggest that CY+ otherwise resectable is not always a contraindication for pancreatectomy, but upfront surgery may not be recommended in the era of neoadjuvant therapy. In order to reduce the risk of peritoneal recurrence, strong chemotherapy and other modalities are needed in the neoadjuvant setting for patients with CY+ otherwise resectable PC. In such cases, repeated SL after neoadjuvant therapy might be useful for restaging and determining the indication for subsequent pancreatic resections.

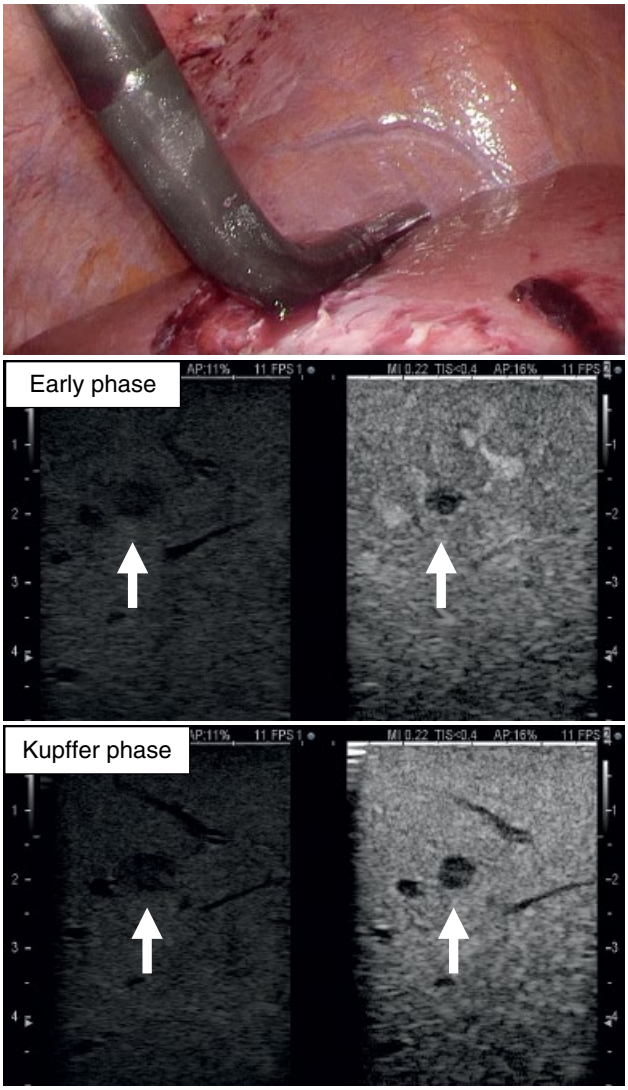

Figure 133.2 Contrast-enhanced IOUS using Sonazoid® facilitates detection and characterization of liver masses. A 5 mm nodule exhibited rim enhancement on early phase (middle panel) and clear defect on Kupffer phase (lower panel), which was considered to be a liver metastasis. The left-hand images are B-mode and the right-hand images are their simultaneous Sonazoid® mode.

Recent Topics in Staging Laparoscopy

Superiority of SL to Imaging Modalities in the Modern Era

Several metaanalyses have demonstrated the usefulness of SL in detecting occult metastases of the liver and peritoneum compared to conventional CE-CT [3,4,17]. However, there has been a limited number of studies examining the superiority of SL to gadoxetic acid disodium-enhanced magnetic resonance imaging (EOB-MRI) or ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) combined with conventional CE-CT. EOB-MRI has been recognized as the most reliable imaging modality in detecting liver metastases. In a retrospective series of patients with potentially resectable PC diagnosed with CE-CT, the sensitivity and specificity of EOB-MRI for liver metastases, which CE-CT had failed to detect, were 77.5% and 94.7%, respectively [18]. FDG-PET is useful in detecting metastatic deposits, including those in the liver and lymph nodes, and sometimes in the peritoneum as well. In a metaanalysis, the pooled sensitivity and specificity of FDG-PET were 64% and 81% for N staging, and 67% and 96% for liver metastases, respectively [19]. These findings suggest that SL is still useful for avoiding unnecessary laparotomy after negative EOB-MRI and FDG-PET studies for unresectable diseases, but positive EOB-MRI or FDG-PET study could preclude SL. Further accumulation of evidence would be needed to define the additional diagnostic value of SL to these imaging modalities in the modern era.

Staging Laparoscopy with Intent for Minimally Invasive Pancreatectomy

Recently, minimally invasive (laparoscopic or robot-assisted) distal pancreatectomy has become common and minimally invasive pancreatoduodenectomy is also undertaken in specialized high-volume centers. By means of these minimally invasive approaches, "unnecessary laparotomy" can be avoided even if unresectable disease is detected intraoperatively. Complete abdominal exploration should be undertaken to rule out unresectable disease before the point of no return. Even in cases of minimally invasive pancreatectomy, SL should be done beforehand for high-risk patients to save costs and resource use.

Conclusion

Staging laparoscopy is a useful, minimally invasive technique for detecting occult metastases and avoiding unnecessary "open-and-close laparotomy" in patients with potentially resectable PC. Although CY+ is not always a contraindication for pancreatectomy, neoadjuvant therapy should be considered for patients with CY+ otherwise resectable PC. SL still plays a significant role in the era of highly sensitive imaging modalities and minimally invasive pancreatectomy and may contribute to best practice for patients with a high risk for recurrence.

Clinical Assessment and Staging of Advanced Pancreatic Cancer

James M. Lindberg, Giles F. Whalen, and Jennifer LaFemina

University of Massachusetts Chan Medical School, Department of Surgery, Division of Surgical Oncology and Endocrine Surgery, Worcester, MA, USA

Introduction

Pancreatic ductal adenocarcinoma (PDAC) is a global problem with 495 773 new cases and 466 003 new deaths attributed to this lethal disease worldwide in 2020 [1]. In the United States, PDAC is the fourth leading cause of cancer deaths [2]. However, with an increased incidence and limited improvements in survival outcomes, it is projected to be the second leading cause of death by 2030 [3]. With vague symptoms at presentation, PDAC is often diagnosed at an advanced stage and treatment is limited to palliative interventions to manage symptoms and prolong survival.

This chapter focuses on the clinical assessment, diagnosis, and staging of patients diagnosed with advanced pancreatic cancer.

Clinical Presentation

Pancreatic ductal adenocarcinoma is a deadly disease with five-year overall survival of only 10% [2]. This has changed marginally over the past 40 years, in part because most newly diagnosed patients present with advanced disease. Of the estimated 60 430 newly diagnosed cases of PDAC in the US in 2021, only 15–20% will be candidates for surgical resection. The remainder will harbor metastatic disease (40–50%) or locally advanced tumors (30–40%) that are radiographically confined to the pancreas and peripancreatic tissues, but unresectable due to regional vascular involvement [2,4].

Symptoms of pancreatic cancer are often vague, resulting in a delay in diagnosis and advanced stage at presentation. Common clinical features for newly diagnosed patients include abdominal pain, back pain, abnormal liver function tests, nausea or vomiting, change in bowel habits, fatigue, and weight loss [5]. Tumor location plays an important role in the type and timing of symptoms at diagnosis. For lesions in the head and uncinate process, biliary obstruction often leads to an earlier presentation due to associated jaundice, pruritus, acholic stool, and choleuria. Tumors in the neck and body of the pancreas are marked by local extension to the celiac nerve plexus and present with epigastric and back pain that is often a hallmark of locally advanced disease. Those in the tail of the gland are frequently diagnosed at an advanced stage as tumor growth in this location is less likely to impact the function of regional structures and produce symptoms [6]. Regardless of tumor location, chronic obstruction of the pancreatic duct with resultant gland atrophy can promote both endocrine and exocrine insufficiency leading to new-onset diabetes, diarrhea, malabsorption of fat-soluble vitamins, and steatorrhea [7].

Examination can confirm signs of biliary obstruction with scleral icterus and jaundice. For obstructing right-sided tumors, a distended and palpable gallbladder may be appreciated. The presence of ascites, confirmed with a distended abdomen and fluid wave, raises suspicion for peritoneal disease. Involved supraclavicular (Virchow's node) or umbilical (Sister Mary Joseph node) nodes or peritoneal implants found in the pelvic cul de sac on rectal exam (Blummer's shelf lesions) are consistent with metastatic disease.

Evaluation for Pancreatic Cancer

Serologic and Genetic Evaluation

Serologic workup may include a comprehensive metabolic panel inclusive of liver function tests, complete blood count, amylase, lipase, coagulation studies, and albumin. Patients

with obstructive jaundice will present with a conjugated hyperbilirubinemia and elevated alkaline phosphatase level. Elevations in transaminases may be absent or mild. For those who are newly diabetic, hemoglobin A1C (HgbA1C) may be grossly elevated or demonstrate a rapid rate of rise, similar to those with type 1 diabetes [8].

CA 19-9 is the only FDA-approved serologic tumor marker for PDAC. Initially described in colon cancer, the test is based on a sialyated Lewis (a) antigen (Le^a) produced by epithelial cells on the surface of erythrocytes and in the mucin produced by pancreatic cancer cells [9]. With a sensitivity of 79–81% and specificity of 82–90% in symptomatic patients, it is an important assay for diagnosis, treatment response, and prognosis. False-positive values are seen in patients with biliary obstruction and pancreatitis, and a baseline value should be obtained only after adequate biliary drainage is achieved. False-negative values are seen in the 5–10% with a Lewis-a-negative genotype who are unable to secrete CA 19-9 [10].

Pretreatment CA 19-9 levels have been shown to correlate with disease stage and resectability, making it a useful tool for treatment planning [11,12]. In patients with resectable disease, a postoperative reduction in CA 19-9 levels and an absolute level less than 180–200 U/mL have been shown to be strong predictors of survival [13,14]. For those with localized disease treated with preoperative therapy, normalization of pretreatment CA 19-9 predicts survival, while failure to normalize after neoadjuvant therapy and resection is associated with a greater than four-fold increased risk of death [15]. CA 19-9 has also shown prognostic value in patients with advanced disease treated with chemotherapy where higher baseline levels and increasing levels during treatment were associated with worse survival [16]. Additionally, CA 19-9 levels exceeding 305 U/mL combined with CEA levels greater than 7 ng/mL were reported as having a 91.4% positive predictive value in diagnosing advanced pancreatic cancer [17].

Current guidelines recommend measuring serum CA 19-9 levels prior to initiating treatment, after completing neoadjuvant therapy, before surgery, prior to initiating adjuvant therapy, and for surveillance [18]. In Lewis antigen nonsecretors, additional carbohydrate antigens have been evaluated as diagnostic biomarkers, including CA 242, CA 50, CA 195, CA 72-4, CEA, and CA 125. However, due to inferior sensitivity relative to CA 19-9, all are of limited clinical utility [19,20].

Pancreatic ductal adenocarcinoma biomarker development has been an area of active research over the last decade, with over 300 novel biomarkers reported in the literature [21]. This effort has been driven by the need for innovative tools to aid in early tumor detection, understanding individual tumor biology and behavior, predicting response to therapy, and prognosis [22].

Among the most promising are newly described techniques of serum liquid biopsy. Liquid biopsy describes the identification of biomarkers such as circulating tumor cells (CTCs), circulating tumor DNA, and tumor-derived exosomes to diagnose and characterize tumor behavior from circulating fluids as an alternative to standard tissue biopsies [23]. In a recent metaanalysis, Zhu et al. reported on the diagnostic utility of CTCs in PDAC with a pooled sensitivity of 74% and pooled specificity of 83% [24]. MicroRNA expression panels obtained from whole blood samples combined with CA 19-9 levels have been used to distinguish patients with pancreatic cancer from healthy controls with greater accuracy than CA 19-9 levels alone [25]. As a predictive tool, the identification of the exosomal miRNA, miR-17-5, in serum samples of pancreatic cancer patients is associated with advanced stage at diagnosis [26]. Additionally, the presence of CTCs has been shown to be of prognostic value, with CTC-positive PDAC patients having worse overall and progression-free survival [27].

Liquid biopsy is an appealing diagnostic modality for patients with locally advanced PDAC where tissue samples for diagnostics are less likely to be obtained through surgical resection. Collectively, these and other emerging biomarkers in development show promise for the future but await further large-scale validation studies prior to adoption in clinical practice.

Current guidelines recommend genetic testing for all patients with newly diagnosed pancreatic cancer [28]. Approximately 1 in 10 PDACs is associated with a hereditary component, which can be divided into three general categories: hereditary pancreatitis (e.g., related to mutations in *PRSS1*, *SPINK1*, *CTRC*, and *CFTR*), hereditary cancer predisposition syndromes (e.g., familial atypical mole malignant melanoma syndrome, Peutz–Jeghers syndrome, von Hippel–Lindau disease, Li–Fraumeni, breast and ovarian cancer syndrome, adenomatous polyposis coli and Lynch syndromes, among others), and familial pancreatic cancer syndrome [29]. Presently, the results of germline testing are of greatest utility to patients with advanced PDAC harboring *BRCA1/2* and *PALB2* mutations, for whom treatment with platinum-based chemotherapy and the PARP inhibitor olaparib is preferred [30,31]. This and other precision medicine approaches to treatment are an area of active research for patients with advanced PDAC and offer the promise of improved outcomes through tailored treatment strategies [32].

Radiologic Evaluation

Imaging studies are of vital importance in the initial diagnosis and staging of PDAC. With a sensitivity exceeding 90%, dual-phase multidetector CT angiography of the pancreas with thin axial cuts is the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

recommended initial imaging assessment [33,34]. A pancreas protocol study is performed with intravenous contrast and a neutral enteral contrast agent. Late arterial phase images are obtained 25–35 seconds after IV contrast administration during peak contrast enhancement of the pancreas. This phase is optimal for pancreatic tumor detection as most tumors appear hypodense relative to normal pancreatic tissue. Additionally, the late arterial phase allows for assessment of the relationship of the tumor to the regional arterial vasculature and identification of aberrant arterial anatomy. The portal veinous phase images are obtained 60–70 seconds after IV contrast administration and are most useful in assessing the relationship of the tumor to regional venous structures, identifying unique regional venous anatomy, and identifying liver, lymph node, and peritoneal metastases.

Computed tomography is the preferred initial diagnostic imaging study as it is widely available, fast, familiar to providers, and has excellent spatial resolution (Fig. 134.1). An initial pancreas protocol CT is ideally obtained prior to any biliary interventions or attempts at tissue diagnosis, and prior to initiating treatment as these factors may prompt peripancreatic inflammation that obscures the tumor–vascular interface, thereby limiting the sensitivity of the study in determining resectability [34–38].

Contrast-enhanced MRI with magnetic resonance cholangiopancreatography (MRCP) is an alternative to CT for patients unable to receive intravenous iodinated contrast. MRI provides superior soft tissue contrast and can be a useful adjunct in the identification and characterization of subtle liver findings or iso-attenuating pancreatic tumors not visualized on CT. Additionally, MRCP offers a more detailed look at the biliary tree and pancreatic duct [38]. A CT chest is obtained to complete the assessment for metastatic disease and radiographic staging. Positron emission tomography (PET) CT with 18F-fluorodeoxyglucose (FDG) is not routinely obtained during imaging assessment but is useful for identifying metastatic disease in patients with high-risk features including large tumors, enlarged regional lymph nodes, and markedly elevated CA 19-9 levels [39].

Endoscopic Evaluation and Treatment of Advanced Pancreatic Cancer

Endoscopic ultrasound (EUS), endoscopic retrograde cholangiopancreatography (ERCP), and other advanced endoscopic techniques are critical in the diagnosis and treatment of patients with pancreatic cancer. EUS is a useful adjunct to CT in the detection of small, radiographically occult tumors. In a recent metaanalysis, EUS successfully identified a mass in 70% of patients with clinical suspicion of a PDAC but indeterminant CT findings with a mean tumor size of 21 mm [40]. With a sensitivity of 85–91% and specificity of 96–98%, EUS with fine needle aspiration (FNA) has also supplanted ERCP, with duct brushings as the preferred mode of tissue acquisition for diagnosis [41].

Recently, dedicated EUS fine needle biopsy (FNB) devices have been developed, allowing endoscopists to collect both cytologic and histologic tissue specimens. FNB offers the advantage of gross visual inspection for specimen adequacy and requires fewer passes to obtain a

diagnostic sample [42]. Additionally, the larger sample sizes and preserved tissue architecture of FNB samples permit immunohistochemical, biomolecular, and genomic profiling of PDAC tumor tissue without the need for a surgical specimen or core needle biopsy [43,44].

Presently, current guidelines recommend genomic assessment of PDAC tumor specimens to identify actionable somatic fusion proteins (*ALK*, *NRG1*, *NTRK*, *ROS1*), mutations (*BRAF*, *BRCA 1/2*, *HER2*, *KRAS*, *PALB2*), and mismatch repair deficiency [18]. EUS/FNB will likely play an important future role in tailoring the treatment approach for patients with advanced PDAC as novel therapies are developed to target tumor-specific somatic changes.

Endoscopic transpapillary biliary drainage via ERCP and stent placement is the preferred approach to managing PDAC patients with malignant biliary obstruction (MBO). Compared to surgical bypass, endoscopic biliary drainage (EBD) is equally effective and associated with lower morbidity, lower cost, and improved quality of life [45–49]. Similarly, EBD has been shown to be more effective with faster resolution of hyperbilirubinemia than percutaneous transhepatic biliary drainage [50].

When rapid cytologic assessment confirms a PDAC diagnosis, placement of self-expanding metal stents (SEMS) is preferred over plastic stents as they have greater long-term patency. Uncovered metal stents are standard, but can be associated with tumor ingrowth, leading to occlusion [51]. Covered metal stents may offer more durable patency for patients with advanced disease who are not candidates for surgical resection. Additionally, covered metal stents are potentially removable if a PDAC diagnosis is uncertain, but are associated with higher cost and higher risk of both cholecystitis and pancreatitis [52].

EUS-guided biliary drainage is an important alternative when endoscopic transpapillary drainage is not achievable. Using this technique, the biliary tree is accessed endoscopically under US guidance via a transgastric approach to the left biliary tree or transduodenal access to the common hepatic duct. Following guidewire placement, a self-expanding metal stent is positioned to create a hepaticogastrostomy or choledochoduodenostomy. Alternatively, in a rendezvous procedure, the guidewire may be advanced distally across the ampulla to facilitate transpapillary drainage. These techniques are particularly important in patients with simultaneous malignant bowel and biliary obstruction, as advanced tumors in the head of the pancreas that cause obstruction in the second portion of the duodenum will also prevent endoscopic access to the major papilla [53].

Gastric outlet obstruction (GOO) is observed in up to 25% of patients presenting with advanced PDAC [54]. Options for management include surgical gastrojejunostomy, enteral stent placement, and EUS-guided gastroenterostomy (EUS-GE). Laparoscopic gastrojejunostomy is safe, effective, and associated with a lower rate of reinterventions compared to enteral stenting. This approach is favored for patients with advanced PDAC who have preserved functional status, are candidates for cancer-directed therapy, and have a life expectancy exceeding six months [55]. Alternatively, endoscopic placement of self-expanding enteral stents is considered for patients with advanced disease, poor performance status, limited life expectancy, and those who wish to avoid the potential morbidity of a surgical procedure [56]. Compared to gastrojejunostomy, stent placement is associated with more rapid symptom resolution, but higher rates of symptom recurrence.

Occlusion due to tissue ingrowth is frequently seen in patients with stents in place longer than 2–3 months [52,57]. To combat this issue, EUS-guided gastroenterostomy has been advanced as a novel approach to relieve GOO that combines the durability of surgical bypass with the more limited morbidity of an endoscopic approach. In this procedure, a bypass is created between the stomach and small bowel using EUS and fluoroscopic guidance to place lumen-apposing metal stents [58]. Ge et al. recently reported a lower rate of stent failure, greater initial success, a similar rate of adverse events, and greater stent durability for malignant GOO patients treated with EUS-GE compared to enteral stent placement [59]. EUS-GE is an attractive alternative to enteral stent placement at centers with expertise in advanced endoscopy; however, it should be employed with caution in patients where resection may be considered as its impact on subsequent pancreatoduodenectomy is unreported.

Surgical Evaluation in Advanced Pancreatic Cancer

Surgery for the initial diagnosis and management of advanced PDAC has largely been supplanted by endoscopic procedures and imaging studies in the modern era. However, staging laparoscopy remains a useful adjunct in the search for radiographically occult metastatic disease.

There is no consensus regarding the routine use of staging laparoscopy in PDAC patients with localized disease on imaging. However, multiple studies suggest high-risk features for occult metastases including large tumors (>3 cm), enlarged regional lymph nodes, CA 19-9 values above 150 U/mL, and significant abdominal pain at diagnosis. Under these circumstances, the diagnostic yield of staging laparoscopy is as high as 20–30% [60–62]. During laparoscopy, all visible peritoneal surfaces should be examined for evidence of gross tumor implants with special

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

attention paid to the liver, omentum, and peritoneal surfaces overlying the diaphragm and anterior abdominal wall. Tissue samples of suspicious lesions can be obtained via core needle biopsy of the liver, partial omentectomy, and local peritonectomies. Intraoperative ultrasound may be considered for further evaluation of the liver and the tumor–vascular interface. Peritoneal washings with isotonic fluid should be collected as positive peritoneal cytology, even in the absence of gross peritoneal tumor deposits, is considered metastatic disease [63].

In the unfortunate scenario where metastatic or unresectable local disease is noted during attempted resection, the value of palliative surgical procedures to maximize patient quality of life should be weighed against the potential morbidity of those procedures and resultant delay in initiating alternative cancer-directed therapies. Consideration should be given to gastrojejunal bypass in patients with GOO, while surgical biliary bypass should be reserved for individuals without endoscopic means of palliating MBO. Additionally, celiac plexus neurolysis (CPN) performed in this setting is an effective means to palliate cancer-related pain, improve quality of life, and survival [64].

Staging for Advanced Pancreatic Cancer

Patients with advanced PDAC are staged per the American Joint Cancer Committee (AJCC) TNM Staging System, 8th edition [65]. Validation studies have demonstrated a correlation between TNM stage and survival (Table 134.1) [66,67]. Although useful as a prognostic tool, the TNM stage has limited utility in guiding treatment decisions at diagnosis.

Table 134.1 Summary of AJCC Staging, 8th edition with correlation to five-year survival.

TNM staging	Five-year survival (%)
Stage IA T1N0M0	39.2
Stage IB T2N0M0	33.9
Stage IIA T3N0M0	27.6
Stage IIB T1-3N1M0	21.0
Stage III T1-3N2M0 T4N0-2M0	10.8
Stage IV T1-4N0-2M1	3.0

Amended from [65–67].

For patients with locoregional disease, surgical resection in combination with systemic therapy is the only treatment associated with long-term survival, and status as a surgical candidate is the most important factor in treatment planning [68]. Determinants of resectability include patient factors (performance status, goals of care, perioperative support), tumor biology (CA 19-9 level, response to preoperative therapy), and the anatomic relationship of the tumor to regional vascular structures.

Originally described by MD Anderson and later refined by the International Association of Pancreatology, PDAC tumors are defined as resectable, borderline resectable (BR), locally advanced (LA), and metastatic based on their appearance on pancreas protocol CT (Table 134.2) [69,70]. LA tumors demonstrate any/all of the following criteria without evidence of metastatic disease: narrowing or occlusion of the portal vein/superior mesenteric vein (SMV) without options for vascular reconstruction, ≥180° abutment or encasement of the superior mesenteric artery (SMA), and abutment of the celiac artery or proper hepatic artery. While nearly 70% of patients with BR tumors undergo surgical resection after neoadjuvant therapy, most with LA tumors are not candidates for pancreatectomy and are treated with palliative intent similar to those with metastatic disease [71]. Ineligibility for surgical resection due to local anatomic factors or metastatic disease defines advanced PDAC.

For patients with advanced PDAC, palliative chemotherapy is standard first-line treatment to address symptoms and prolong survival. FOLFIRINOX is the preferred regimen for those with good performance status (ECOG 0–1) as it has been shown to prolong survival compared to gemcitabine alone in patients with metastatic disease (median OS 11.1 months vs 6.8 months; P <0.001) [72]. In a recent systematic review, patients with LA disease treated with FOLFIRINOX had a pooled median survival of 24.2 months [73]. In a separate observational study, 29% of LA patients treated with FOLFIRINOX had a 30% reduction in CT tumor volume and half of those underwent surgical resection [74]. Even without a significant radiographic treatment response, there is growing enthusiasm for the aggressive treatment of local disease in patients who remain free of metastases after 4–6 months of induction chemotherapy. In the era of modern chemotherapy, multiple centers have reported favorable surgical and oncologic outcomes for patients with LA disease treated with neoadjuvant therapy followed by pancreatectomy employing vascular resections or periarterial divestment (Table 134.3) [75–80].

These reports highlight the emerging challenge of restaging LA patients after neoadjuvant therapy to determine who may benefit from surgical resection. Ferrone et al. demonstrated that posttreatment CT was

ineffective in determining resectability in LA patients as 92% meeting LA imaging criteria underwent an R0 resection after neoadjuvant FOLFIRINOX [81]. Combined with findings from Gemzenetzis et al. that showed a 77% treatment response rate in LA PDAC specimens after neoadjuvant therapy, these data suggest that posttreatment CT imaging is unable to differentiate between treatment-induced peritumoral fibrosis and viable tumor tissue and may be of limited utility to determine resectability [82].

Chatzizacharias et al. recently proposed and validated a dichotomized refinement to the LA classification based on pretreatment CT imaging findings at diagnosis into LA type A tumors with anatomic features suggesting surgery may be possible after neoadjuvant therapy (≤270° SMA encasement, >180° celiac encasement but without extension to the aorta, >180° encasement of the hepatic artery with option for reconstruction), and LA type B tumors for whom resection is unlikely (see Table 134.2). In their study set, 62% of LA type A patients underwent

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. resection with an 80% R0 resection rate compared to only 24% of LA type B patients; they reported a median overall survival for resected patients of 38.2 months [79].

Beyond imaging findings, CA 19-9 response to neoadjuvant therapy has been shown to be a powerful predictor of outcome for LA patients treated with resection. Truty et al. recently showed that LA patients with an elevated or normal CA 19-9 level at diagnosis that normalized or remained normal at <37 U/mL after neoadjuvant therapy had a significantly longer median survival after resection (27.3 vs 10.5 months, P <0.001) [76]. At present, defining resection criteria for LA patients after neoadjuvant therapy remains an ongoing area of active research as traditional anatomic criteria are reassessed in the context of emerging biomarkers of treatment response.

Given the limited data available to guide patient selection, surgery for LA PDAC should be approached with caution and is best performed at high-volume centers with extensive experience in vascular resection and reconstruction. Additionally, the oncologic benefit of surgical resection for LA patients remains to be defined in larger, multiinstitutional prospective studies. Without these data, it is difficult to justify the procedure-associated risks attributable to these highly complex operations, including a 90-day mortality of 6.7% that is nearly double the expected value for high-volume hospitals after standard pancreatoduodenectomy [76,83].

In addition to surgery, alternative local ablative therapies have been proposed for the treatment of LA disease without metastases after induction chemotherapy. These include chemoradiation or stereotactic body radiation therapy (SBRT), irreversible electroporation (IRE), and radiofrequency ablation (RFA). However, none has demonstrated a survival benefit relative to chemotherapy alone for patients with LA PDAC and, at present, they should be reserved for patients with isolated local progression or for symptom management [18].

In addition to defining treatment options and prognosis, accurate staging for patients with advanced PDAC can help facilitate early palliative care consultation. The American Society of Clinical Oncology recommends a goals of care and advanced directive discussion, a full symptom evaluation, and a psychosocial status and social support assessment at diagnosis [84]. In patients with advanced PDAC, palliative care consultation is associated with a reduction in chemotherapy use near death, ED visits, ICU admissions, and hospitalizations [85].

Conclusion

Despite an extensive research effort, PDAC remains a devastating disease, in part due to the high percentage of patients who present with advanced tumors at diagnosis. Management of these patients requires a comprehensive clinical, radiologic, and endoscopic approach to define the tumor and stage. Treatment involves a multidisciplinary approach, and many times, the tools employed for clinical workup, as summarized here, can also be extrapolated for palliation of symptoms in the advanced setting. While emerging diagnostics have the potential to identify patients at an earlier stage, and incremental improvements in survival have been seen with the initiation of modern chemotherapeutics, much work remains to be done to improve outcomes for patients with advanced PDAC.

Pancreatic Cancer: Indications for Resection

Akimasa Nakao and Suguru Yamada

Nagoya Central Hospital, Nagoya, Japan

Introduction

Pancreatic cancer has the worst survival outcomes among all gastrointestinal neoplasms. In the United States, an estimated 48 220 patients died of pancreatic cancer in 2021 [1]. This disease is now the fourth most common cause of death among all malignant neoplasms in the United States and Japan. Despite recent developments in surgical techniques and the clinical spread of effective chemotherapy, the prognosis of pancreatic cancer remains poor. However, surgical resection offers the only possibility of a cure. Although the morbidity and mortality of pancreatoduodenectomy (PD) were extremely high around 30–40 years ago, the morbidity and especially mortality of PD have since greatly decreased, and the operative mortality rate has fallen to 2.8% in Japan [2].

Clinical Criteria for Surgical Resection

Age and Concomitant Diseases

The peak incidence of pancreatic cancer occurs in the seventh and eighth decades of life. In our experience and that of high-volume centers, the morbidity and especially mortality of pancreatic resection have been greatly reduced, and no statistically significant difference in the mortality rate between patients aged >70 and <70 years has been reported [2]. In recent years, patients' age, comorbidities, performance status, and frailty have all been topics for discussion during multidisciplinary reviews. One of the few medical contraindications for PD is liver cirrhosis with ascites and portal hypertension.

Diagnosis and Staging

The diagnosis of pancreatic cancer is discussed at length in Chapter XX. For preoperative disease staging, multidetector-row computed tomography (MDCT) is an extremely useful diagnostic tool. Endoscopic ultrasound (EUS) is also useful for both diagnosis and staging of pancreatic cancer. Laparoscopy is another potentially valuable diagnostic tool for cancer staging, especially in patients with distant metastasis such as liver metastasis or peritoneal dissemination.

Biopsy

Confirmation of malignancy by biopsy is considered necessary before proceeding with surgical resection. Histologic diagnosis of pancreatic adenocarcinoma is often performed using fine-needle aspiration biopsy with either CT or EUS guidance. Pancreatic ductal blushing or biopsies can also be obtained at the time of endoscopic retrograde cholangiopancreatography. However, histologic or cytologic diagnosis of the malignancy is not always essential before surgical resection, such as in patients with a high clinical suspicion of pancreatic cancer.

Tumor-associated Antigens

The clinical usefulness of tumor-associated antigens, such as carcinoembryonic antigen, carbohydrate antigen (CA) 19-9, DU-PAN-2, and SPan-1, has been advocated in connection with pancreatic cancer. In particular, a CA 19-9 concentration of >1000 U/mL might be correlated with the presence of distant metastasis or unresectable tumors in patients with pancreatic cancer [3].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Surgical Criteria for Resection

Preoperative Staging for Extent of Disease

There are no universally accepted criteria for resection of pancreatic cancer. However, it is clear that patients with liver, peritoneal, and pleural metastases derive no benefit from pancreatic resection. Therefore, preoperative staging to assess the extent of disease is indispensable.

The initial staging procedure involves the use of MDCT with contrast imaging, which reportedly predicts resectability well. Factors contraindicating surgical resection are extrapancreatic disease, obstruction of the portal or superior mesenteric vein, and direct tumor extension to the celiac axis and superior mesenteric artery (SMA), which are assessed by MDCT. Since 2006, the use of criteria to define the resectability status (resectable, borderline resectable, or locally advanced) according to the National Comprehensive Cancer Network (NCCN) guidelines (Table 135.1) has been widespread in the clinical setting [4]. This resectability classification accurately reflects survival outcomes [5,6]; thus, the fourth edition of the Japan Pancreas Society classification of pancreatic carcinoma proposed a similar scheme based on the probability of achieving R0 resection [7] (Table 135.2). As other diagnostic tool, EUS is complementary to CT, providing additional information for patients in whom CT shows no lesions in the pancreas or who have questionable involvement of major vessels or lymph nodes. Laparoscopy can reveal peritoneal deposits or liver metastasis that might be missed even with the use of MDCT.

Surgery for Pancreatic Cancer

The ideal surgical procedure for pancreatic cancer is isolated pancreatectomy. "Isolated" refers to *en bloc* resection using a nontouch isolation technique. Isolated distal pancreatectomy for cancer in the pancreatic body or tail is easier to perform than isolated PD, which is technically difficult because of the complex vascular anatomy in the pancreatic head region. However, isolated PD is also technically possible using a mesenteric approach [8] along with catheter bypass for the portal system [9] if necessary.

The indication for total pancreatectomy or PD in patients with pancreatic head cancer is an important clinical question in pancreatic cancer surgery. In this regard, previous studies using histopathologic and immunohistochemical analyses of total pancreatectomy specimens have clarified that cancer development from the head to the body or tail of the pancreas is continuous [10,11]. Thus, rapid intraoperative histopathologic diagnosis using frozen sections is indispensable to detect the development of intrapancreatic cancer during PD for pancreatic head cancer as well as during distal pancreatectomy for pancreatic body or tail cancer [12].

Historically, pylorus-preserving PD was performed in an effort to improve delayed gastric emptying and provide nutritional benefits [13]; however; no consistent data have suggested that pylorus preservation leads to better quality of life or improved nutritional status [14]. The superiority of recent laparoscopic or robotic surgery compared with open surgery for pancreatic cancer has not yet been clarified either surgically or oncologically.

Invasion

Local Invasion

Invasion into the distal bile duct, duodenum, stomach, or mesocolon can often be treated by *en bloc* resection. The retroperitoneal margin is often involved in pancreatic cancer. This margin includes connective tissues composed of extrapancreatic nerve plexuses behind the pancreas and adjacent to the SMA. Achieving a negative margin is considered an important prognostic factor [15], and the mesenteric approach is an ideal procedure to obtain negative surgical margins [8,16].

Extrapancreatic Nerve Plexus Invasion

Pancreatic carcinoma often invades the extrapancreatic nerve plexus [17–19]. There is no clear explanation for invasion of the extrapancreatic nerve plexus in the Union for International Cancer Control classification [20]; however, the precise anatomy of the extrapancreatic nerve plexus is explained in the third English edition of the Japan Pancreas Society classification [21] (Fig. 135.1).

The grade of intrapancreatic neural invasion correlates with extrapancreatic nerve plexus invasion, and the manner of neural invasion has no relationship with lymph node metastasis [19]. In patients with pancreatic head cancer, complete dissection of the extrapancreatic nerve plexus, especially the second portion of the pancreatic head nerve plexus, is necessary to obtain a cancer-free surgical margin (Figs 135.2 and 135.3). However, complete or right-half dissection of the nerve plexus around the SMA can cause refractory diarrhea after surgery [22], and the prognosis of pancreatic cancer invading the extrapancreatic nerve plexus is poor [15]. The main cause of cancer-positive surgical margins is extrapancreatic nerve plexus invasion [15,17,19]. Although the term "mesopancreas" is sometimes used [23], it is better to use the term "second portion of the pancreatic head nerve plexus."

Table 135.1 Criteria defining resectability status.

Resectability status	Arterial	Venous
Resectable	No arterial tumor contact (celiac axis [CA], superior mesenteric artery [SMA], or common hepatic artery [CHA]).	No tumor contact with the superior mesenteric vein (SMV) or portal vein (PV) or ≤180° contact without vein contour irregularity.
Borderline resectable	Pancreatic head/uncinate process: • Solid tumor contact with CHA without extension to celiac axis or hepatic artery bifurcation allowing for safe and complete resection and reconstruction • Solid tumor contact with the SMA of ≤180° • Presence of variant arterial anatomy (ex: accessory right hepatic artery, replaced right hepatic artery, replaced CHA and the origin of replaced or accessory artery) and the presence and degree of tumor contact should be noted if present as it may affect surgical planning. Pancreatic body/tail: • Solid tumor contact with the CA of ≤180° • Solid tumor contact with the CA of ≥180° without involvement of the aorta and intact and uninvolved gastroduodenal artery (some members prefer this criteria to be in the unresectable category).	• Solid tumor contact with the SMV or PV of >180°, contact of ≤180° with contour irregularity of the vein or thrombosis of the vein but with suitable vessel proximal and distal to the site of involvement allowing for safe and complete resection and vein reconstruction. • Solid tumor contact with the inferior vena cava (IVC).
Unresectable	• Distant metastasis (including nonregional lymph node metastasis). *Head/uncinate process*: • Solid tumor contact with SMA >180° • Solid tumor contact with the CA >180° • Solid tumor contact with the first jejunal SMA branch. *Body and tail*: • Solid tumor contact of >180° with the SMA or CA • Solid tumor contact with the CA and aortic involvement.	*Head/uncinate process*: • Unreconstructible SMV/PV due to tumor involvement or occlusion (can be due to tumor or bland thrombus) • Contact with most proximal draining jejunal branch into SMV. *Body and tail*: • Unreconstructible SMV/PV due to tumor involvement or occlusion (can be due to tumor or bland thrombus).

Vascular Invasion

Cancer invasion into the superior mesenteric and portal veins is common in patients with pancreatic head cancer. During the past 40 years, the operative mortality rate of PD combined with portal vein resection has decreased, and portal vein resection in pancreatic cancer surgery has become a safe procedure [24].

In our institution, 344 patients with pancreatic cancer underwent tumor surgery during the past 10 years, and portal vein resection was performed in 149 (43.3%) of these patients. Arterial resection was undertaken in 10 patients. The survival outcomes in these patients are shown in Fig. 135.4. Higher operative morbidity, more advanced stages of cancer, and a higher incidence of positive cancer invasion on the dissected peripancreatic margin were observed in the combined portal and arterial resection group.

Basically, upfront surgery is not recommended in patients with cancer invasion to the SMA, celiac artery, and common hepatic artery. One exception is pancreatic body cancer that invades the celiac axis. This type of cancer can be resected by distal pancreatectomy with celiac axis resection; however, introduction of neoadjuvant therapy should be considered as well. Thus, vascular resection is

Table 135.2 Japan Pancreatic Society resectability classification.

Resectable: R
No tumor contact with SMV or PV or less than 180 degrees contact or invasion without occlusion. Clear fat Planes around SMA, CA, and CHA, showing no contact or invasion.

Borderline resectable: BR
Subclassified according to SMV/PV invasion alone or arterial invasion.

BR-PV (SMV/PV invasion alone)
No findings of contact and invasion of SMA, CA, and CHA. Tumor contact or invasion of the SMV/PV of 180 or more degrees or occlusion of the SMV/PV, not exceeding the inferior border of the duodenum.

BR-A (Arterial invasion)
Tumor contact or invasion of SMA and/or CA of less than 180 degrees without showing stenosis or deformity. Tumor contact or invasion of CHA without showing tumor contact or invasion of PHA and/or CA.

Unresectable: UR
Subclassified according to the status of distant metastasis.

UR-LA (Locally advanced)
Tumor contact or invasion of SMV/PV of 180 or more degrees or occlusion of SMV/PV, exceeding the inferior border of the duodenum. Tumor contact or invasion of SMA and/or CA of 180 or more degrees. Tumor contact or invasion of CHA showing tumor contact or invasion of the PHA and/or CA. Tumor contact or invasion of the aorta.

UR-M (Tumor with distant metastasis)
Distant metastasis including non-regional lymph node metastasis.

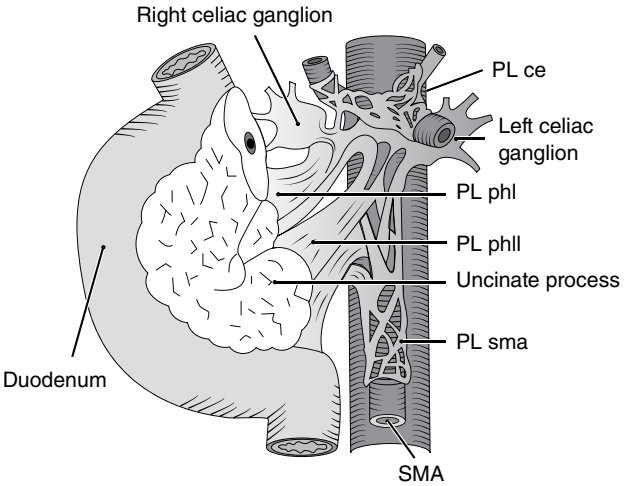

Figure 135.1 Extrapancreatic nerve plexus. PLce, celiac plexus; PLphI, first portion of pancreatic head nerve plexus; PLphII, second portion of pancreatic head nerve plexus; PLsma, nerve plexus around the superior mesenteric artery; SMA, superior mesenteric artery. Source: Japan Pancreas Society, Classification of Pancreatic Carcinoma, 3rd English edition, 2011.

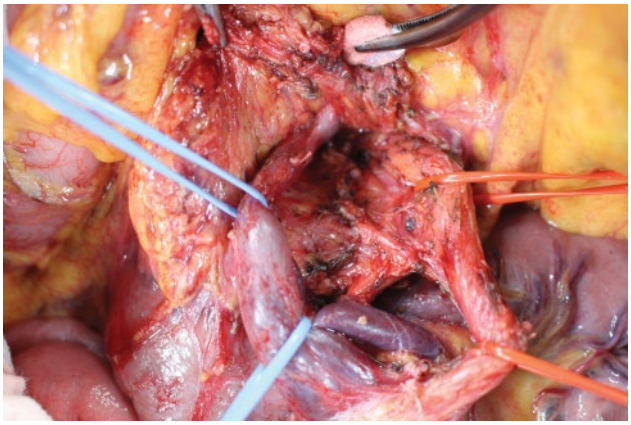

Figure 135.2 Exposure of the mesopancreas (second portion of the pancreatic head nerve plexus) using the mesenteric approach. The nerve plexus around the superior mesenteric artery is completely preserved in this case.

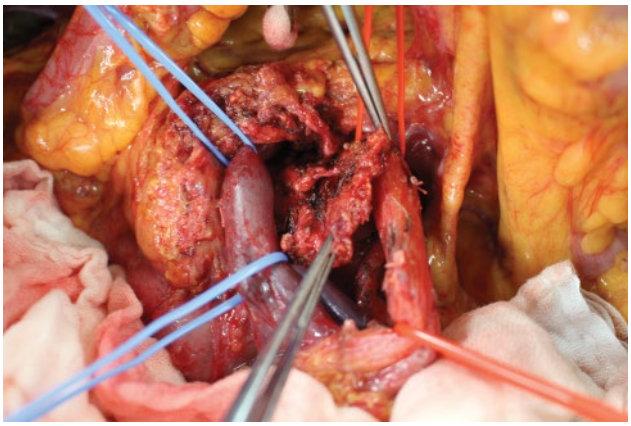

Figure 135.3 Total mesopancreas excision along the superior mesenteric artery.

indicated when cancer-free surgical margins are necessary. Conversely, there is no indication for extended resection in patients in whom surgical margins could become cancer positive, although such operations are conducted.

Metastases

Lymph Node Metastases

Optimum lymph node dissection is an important component of pancreatic cancer surgery. The high cancer incidence of 56–77% [25–28] in resected lymph node specimens is the reason for extensive dissection of lymph

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

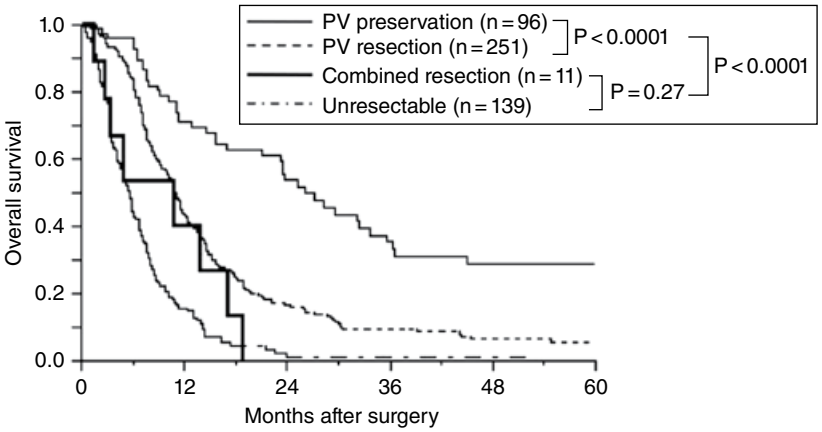

Figure 135.4 Cumulative survival rates of the portal vein (PV) preservation, PV resection, and arterial resection groups.

nodes in pancreatic cancer surgery. Notably, there are few reports concerning para-aortic lymph node metastasis: its reported incidence in pancreatic head cancer is 16% [26] and 26% [27,29], while that in pancreatic body and tail cancer is 13% [30] and 17% [31]. Although the efficacy of extended lymph node dissection in pancreatic cancer was historically suggested, it was not verified in some prospective controlled studies [32–36]. Therefore, extended dissection of lymph nodes, including the para-aortic lymph nodes, should not be considered a routine part of PD. However, although it does not have survival benefit, it might allow accurate staging.

Peritoneal Metastases

Peritoneal dissemination frequently occurs in pancreatic cancer and is one of the contraindications for surgical resection. Peritoneal deposits are too small to diagnose by preoperative CT or ultrasound images in patients with no ascites. Therefore, the diagnosis of peritoneal dissemination is confirmed by direct visualization using laparoscopy or at the time of surgical exploration. Using conventional staining, the incidence of cancer cells ranges from 0% to 17% [37–39]. However, high incidences of 58% [40], 39% [41], and 22% [39] have been obtained by immunocytochemical staining using monoclonal antibodies to tumor-associated antigens and cytokeratins.

Positive washing cytology is certainly a significant prognostic factor in pancreatic cancer; however, the clinical implications for surgical exploration in this situation have been discussed [42,43]. In the era of neoadjuvant chemotherapy in pancreatic cancer, it is weakly recommended that surgical resection with a surgery-first approach should not be performed in patients who have resectable pancreatic cancer with positive washing cytology.

Liver Metastases

Liver metastases are also common in patients with pancreatic cancer, and the expected survival period is so short that resection of the primary tumor is contraindicated [44]. Metastases are usually multiple in number, and there are no data showing longer survival by pancreatectomy either with or without resection of liver metastases.

Other Distant Metastases

Distant metastases to the lungs, bone, and supraclavicular lymph nodes are also contraindications for resection of a primary tumor.

Treatment Options for Recurrent Disease

In the management of pancreatic cancer, the high recurrence rate, even when curative resection is accomplished, is a major problem. There are various initial recurrence patterns, such as local or lymph node recurrence as well as peritoneal, liver, lung, and bone metastasis. Chemotherapy or radiotherapy should be a treatment option in these situations to prolong the patient's life. Among the various recurrence patterns, solely recurrent pancreatic cancer in the remnant pancreatic cancer might be an indication for surgery. This treatment option could offer a favorable outcome and a chance for cure in selected patients [45].

Conversion Surgery for Initially Unresectable Disease

In our clinics, most patients (70–80%) diagnosed with pancreatic cancer have initially unresectable disease based on the NCCN criteria [4]. However, recent advances in multimodal treatment have provided better clinical responses; thus, conversion surgery for this initially unresectable disease has become widespread in our practice of pancreatic surgery. Even in patients with peritoneal metastasis, conversion surgery has been aggressively pursued after effective chemotherapy [46]. The indication for surgery is considered to be a clinical response or decreased concentrations of tumor markers (CA19-9, DU-PAN-2, etc.) after multimodal treatment [47]. Notably, early recurrence after surgery has been reported despite improved survival [48]. In this regard, a further prospective study is necessary to clarify the optimum indication for conversion surgery.

Effect of Clinical Volume

Several studies have revealed the effect of institutional volume on patients' clinical outcomes. In 1995, Lieberman et al. assessed 1972 pancreatectomies, including total pancreatectomy, performed in 184 institutions in the state of New York and showed that high-volume centers with >40 cases per year had significantly lower mortality than low-volume centers (4.0% vs 12.3%, respectively) [49]. Several other studies have also shown decreased mortality rates, shorter lengths of hospitalization, and lower overall costs in high-volume than low-volume centers [50]. Furthermore, negative margin status and five-year survival rates are reportedly higher in high-volume centers [51]. The definitions of high- and low-volume centers vary among all these studies, but the NCCN Panel recommends that pancreatic resections should be conducted at institutions that perform at least 15–20 pancreatic resections annually [4].

Pancreatoduodenectomy for Pancreatic Cancer: Short- and Long-term Outcome after Kausch-Whipple and Pylorus-preserving Pancreatoduodenectomy

Benedict Kinny-Köster, John L. Cameron, and Jin He

Department of Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Dr William Stewart Halsted performed the first successful resection of a periampullary tumor in 1898. The first successful regional resection of the head of the pancreas was performed by Kausch and reported in 1912. The operative procedure of pancreatoduodenectomy was then popularized by Whipple, when he presented three patients to the American Surgical Association in 1935. During that era, and extending into the 1970s, pancreatoduodenectomy was performed only infrequently because of a hospital mortality in the range of 25%. Since the 1980s, pancreatoduodenectomy has become a safe procedure, performed in virtually any age group in high-volume centers, with an in-hospital mortality rate reaching less than 1% [1].

Pancreatic ductal adenocarcinoma (PDAC) is a common cause of cancer death and difficult to treat because of late presentation, a high propensity to metastasize, and treatment resistance. Long-term overall survival remains poor with a five-year survival rate of 12%. Nevertheless, for PDAC in the head of the pancreas, pancreatoduodenectomy is the only treatment modality that offers a chance for cure. With the development of multiagent neoadjuvant chemotherapy, more patients with PDAC will benefit from pancreatoduodenectomy [2].

Accurate diagnosis of PDAC relies on high resolution computed tomography (CT), preferred with a pancreas-specific protocol. Tissue diagnosis is necessary if neoadjuvant chemotherapy is part of the treatment plan. This can be achieved by endoscopic ultrasound-guided fine needle aspiration. PDAC without visible distant metastasis is currently classified into resectable, borderline resectable (BRPC), or locally advanced (LAPC) based on tumor–vein–artery relationships indicated by CT imaging at the time of diagnosis [3]. However, the utility of this resectability staging is increasingly being challenged as outcomes in PDAC are observed to be superiorly predicted by individual tumor biology than by anatomic criteria [4].

In this chapter, we will discuss the established short- and long-term outcomes after pancreatoduodenectomy for pancreatic cancer. In addition, we summarize the recent literature covering innovative developments to advance vascular and robotic resections.

Perioperative and Oncologic Outcomes

Approximately 10–20% of patients with PDAC present with resectable disease. Surgery with curative intent should achieve an R0 resection. The five-year overall survival rate after a successful resection is approximately 20% and close to 40% for those with negative nodes and margins [6,7].

Regardless of the disease stage in patients undergoing pancreatoduodenectomy (resectable vs BRPC vs LAPC), factors affecting the short-term surgical outcome include patient age, vessel resection and reconstruction, extension of lymph node dissection, and techniques of intestinal reconstruction. In patients aged 80 or above, pancreatoduodenectomy is associated with higher morbidity (55% vs 44%) and in-hospital mortality (4% vs 1%) [1]. Younger patients (below 45) have fewer complications after curative resections and better survival compared to older patients (over 70) [8].

In patients with resected BRPC/LAPC, Ferrone et al. reported no postoperative pancreatic fistula (POPF) in 40 patients after preoperative FOLFIRINOX and a lower postoperative morbidity rate (36% vs 63%) compared to 87 patients after upfront surgery [9]. In contrast, in a multicenter cohort of 171 and 375 patients with and

without preoperative chemotherapy in Japan, Motoi et al. published similar postoperative morbidity rates (60% vs 52%) and POPF grade B/C frequencies (both 12%) after PDAC resection [10]. Extended lymphadenectomy is not universally indicated as randomized trials and systematic reviews have shown no benefit and more postoperative complications [11].

For reconstruction of the pancreatic duct, pancreaticojejunostomy is preferred at our hospital. POPF can be significantly reduced by a meticulous anastomosis with optimization of blood supply at the pancreaticojejunostomy. While similar with regard to POPF rate, pancreaticogastrostomy has a slightly increased incidence of postpancreatectomy hemorrhage compared to pancreaticojejunostomy (14% vs 9%) [12].

In an initiative to determine benchmark outcomes (benchmark defined as the 75th percentile of median values from participating centers), an international multicenter retrospective study analyzed almost 2400 patients with low-risk comorbidities after pancreatoduodenectomy. For in-hospital mortality, severe complications (Clavien–Dindo grade ≥IIIa) or overall complications, frequencies of ≤1.6%, ≤30.0%, and ≤73.0% were determined benchmarks (Table 136.1) [13].

Table 136.1 Published pancreatoduodenectomy (PD) benchmark values in patients with low-risk comorbidities. Benchmarks represent the 75th percentile of median values of the 23 participating international high-volume centers for each of the variables.

	PD	PD with mesoportal venous resection
Multicenter benchmark cohort	N = 2375 patients	N = 840 patients
In-hospital mortality	≤1.6%	≤4.0%
Duration of PD	≤7.5 hours	≤8.0 hours
Intraoperative blood transfusion rate	≤23.0%	≤27.0%
Length of hospital stay	≤15.0 days	≤14.0 days
90-day complications, any CD	≤73.0%	≤83.0%
90-day complications, severe (CD grade ≥IIIa)	≤30.0%	≤34.0%
90-day complications, CCI	≤20.9	≤23.0
Until discharge, POPF grade B/C	≤19.0%	≤14.0%
Until discharge, severe PPH (grade ≥III)	≤7.0%	≤7.0%

CCI, Comprehensive Complication Index; CD, Clavien–Dindo; POPF, postoperative pancreatic fistula (ISGPS); PPH, postpancreatectomy hemorrhage (ISGPS).
Source: Table compiled from published data by Sánchez-Velázquez et al. [13] and Raptis et al. [28].

In our institution's series of open pancreatoduodenectomy for 1687 patients with PDAC, the overall complication rate was 41%, with the most common complications including delayed gastric emptying (DGE, 16%), wound complications (11%), and POPF (6%) [6]. DGE and wound complications are often triggered by POPF. Patients with DGE might benefit from prokinetics such as metoclopramide and erythromycin. The antecolic location for the gastrojejunostomy has been shown to reduce the incidence of DGE in several publications. In a series of 160 pancreatoduodenectomies, Nakamura et al. analyzed that a side-to-side anastomosis for gastrojejunostomy on the greater curvature significantly reduced the incidence of DGE (2.5% vs 21% from end-to-side anastomosis) [14]. Our standard practice is therefore an antecolic side-to-side gastrojejunostomy. However, the influence of an antecolic vs retrocolic reconstruction on DGE has recently been questioned in a Japanese multicenter randomized controlled study (DGE in 12.6% vs 15.6%, $P = 0.06$) [15].

Oncologic outcomes after pancreatoduodenectomy for patients with PDAC are not optimistic. Although the 30-day mortality has been low at 1% since the 1990s, the median survival for PDAC remained at 19 months in our analysis of PDAC patients from 1981 to 2011 [6]. In this large series, resection margin status and lymph node positivity were associated with overall survival. For patients with negative resection margin and negative lymph node metastasis, the overall survival was 42 months compared to 18 months for patients with either positive margin or nodal metastasis. The commonly proven prognostic factors of five-year survival include tumor size, lymph node status, margin status, tumor differentiation, lymphovascular and perineural invasion, and adjuvant chemotherapy. Completion of the full course of adjuvant chemotherapy was an independent prognostic factor for survival, but time to treatment initiation after surgery was not [16]. Notably, these parameters are time dependent and their prognostic value is restricted to the first five years following pancreatoduodenectomy.

More recently, we characterized patterns and timing of recurrence in detail for patients after pancreatoduodenectomy for both upfront surgery and preoperative chemotherapy with subsequent resection. In the Baltimore upfront surgery cohort of 692 patients with complete follow-up data (96% pancreatoduodenectomy), 77% of patients developed recurrence with a median recurrence-free survival of 11.7 months. At the time of the initial recurrence diagnosis, of all patients who developed recurrence, 58% were at distant-only (most commonly hepatic), 24% at local-only, and 19% at local and distant locations [17]. In 581 patients who underwent preoperative chemotherapy (70% pancreatoduodenectomy), the median recurrence-free survival was 16.6 months (from start of systemic treatment)

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. with detected recurrence in 70% of patients. Of all patients who developed recurrence, the initial location at onset was 40% at distant-only (mostly hepatic), 36% at local-only, and 24% at local and distant locations [18]. Here, 5-fluorouracil (5-FU)-based chemotherapy (mostly FOLFIRINOX) was predictive for improved overall but not recurrence-free survival when compared to gemcitabine-based treatment.

Whether patients benefit from upfront chemotherapy is intensively investigated. During the last decade, neoadjuvant chemotherapy and/or chemoradiation therapy have been increasingly utilized, especially for patients with BRPC and LAPC [9]. A metaanalysis of more than 4000 patients with PDAC showed that 32% of those with locally advanced disease underwent conversion surgery after neoadjuvant chemoradiation therapy, with a survival rate similar to patients with resectable disease [19]. The most commonly used regimen for neoadjuvant chemotherapy is FOLFIRINOX (5-FU, oxaliplatin, irinotecan, and leucovorin) if the patient has a good performance status. The rationale for using FOLFIRINOX is based on data extrapolated from the metastatic and adjuvant settings where FOLFIRINOX showed better improvements in median overall survival (11.1 months and 54.4 months, respectively) compared to gemcitabine [20,21]. An alternative established regimen for neoadjuvant chemotherapy is gemcitabine with nab-paclitaxel. This is also based on data from metastatic and adjuvant settings where the combination of both drugs improved overall survival (8.7 and 40.5 months) [2,22]. An alternative gemcitabine-based regimen is gemcitabine with oral capecitabine which demonstrated a median overall survival of 28.0 months as an adjuvant regimen (ESPAC-IV trial) [23].

A completed randomized controlled trial that tested preoperative gemcitabine-based chemoradiotherapy for resectable and BRPC patients is PREOPANC-1 conducted in the Netherlands. Although the initial results after a median follow-up 27 months demonstrated similar overall survival, a survival improvement was observed after an extended median follow-up of 54 months in the BRPC subgroup that underwent preoperative chemotherapy [24,25].

Several national trials are enrolling patients with resectable PDAC (SWOG S1505), BRPC (Alliance A201501), or LAPC (RTOG 1201) to determine the benefit of neoadjuvant chemotherapy and/or radiation. We are expecting level I evidence in the next few years regarding the benefit of neoadjuvant chemotherapy and/or radiation therapy. Prospective data are also being collected for patients with limited liver metastasis (oligometastatic, often defined as less than three lesions) and response to a full course of neoadjuvant chemotherapy (12 cycles or six months).

Outcomes of Vascular Pancreatic Surgery and Periadventitial Dissection

Approximately 70% of patients with PDAC and undetectable distant metastasis have tumor contact to a major surrounding vessel (mesoportal venous axis, common hepatic artery, and/or superior mesenteric artery) [5]. Therefore, surgeons face additional complexity in achieving a margin-free resection and safe operation [26]. In the late 1990s, early experience with resection and reconstruction of the mesoportal venous axis during pancreatoduodenectomy showed no 90-day postoperative mortality [27]. These encouraging results were reproduced at other institutions. In 2020, an international multicenter study that included almost 1500 patients with pancreatoduodenectomy and portomesenteric vein resection calculated an in-hospital mortality rate benchmark of below, further demonstrating the feasibility and safety of vein resections (see Table 136.1) [28].

For arterial resections, initial experiences were gained and safety achieved from distal pancreatectomies with celiac axis resections which often do not require reconstruction of hepatic arterial inflow due to retrograde blood supply through the intact arterial superior mesenteric-gastroduodenal arcade [29]. For hepatic artery and superior mesenteric artery reconstructions, an increased perioperative morbidity and mortality (5–14%) has been recognized across centers, although it is consistently decreasing with advancement on the learning curve at three high-volume centers (Heidelberg, Strasbourg, and Rochester). To prevent fatal events and achieve safety, applied strategies included optimization of vascular conduit characteristics (e.g., utilization of autologous veins) and relatively liberal conversion from pancreatoduodenectomy to total pancreatectomy (rules out POPF to protect the vascular anastomoses and conduit) [30–32].

Collectively, acknowledging the impact of surgical complexity on perioperative outcomes, Mihaljevic et al. directly compared 90-day mortalities of different types of pancreatoduodenectomies within their single-center cohort of 4000 cases accumulated during the last two decades. When differentiating for four types of pancreatoduodenectomy, perioperative mortalities were 2.9% (standard pancreatoduodenectomy), 4.2% (with mesoportal vein resection), 6.3% (with additional organ resection), and 10.3% (with arterial resection) [33].

An intriguing finding from pancreatoduodenectomy specimens after vein or arterial resections was that major vein or artery contact translated to a spectrum of invasion depths at the microscopic level. In a case series of 41 specimens that met these criteria, true invasion into the mesoportal vessel wall was confirmed in 41% of patients [34]. This feature, as well as the capability of invasion into small veins as apparent in 65% of pancreatic cancers, may reflect

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. a selective advantage of the tumor to metastasize hematologically (following venous flow into the liver) [35]. As observed in veins, however, tumor contact with the common hepatic or superior mesenteric artery also does not universally mean true wall invasion. In contrast to the thin tunica media of veins, this layer is prominent in arteries through abundant elastic fibers and smooth muscle cells. Although dynamically exposed to the systemic pulse wave, this relatively rigid texture is exploitable surgically.

Pioneered in 2017 by Miao et al. in patients after induction chemotherapy, entering and dissecting off the adventitial plane on top of the tunica media allowed for margin-free resection while ensuring arterial continuity. This technical refinement and substep during pancreatic surgery has been termed (peri)arterial divestment or periadventitial/subadventitial dissection [36]. A radiologic "halo sign" was described to be potentially predictive for the feasibility of this technique, whereas a "string sign" may be indicative of tunica media invasion with a consecutive mass effect [36]. While this novel development of an arterial resection-sparing technique is still being investigated, case series suggest a perioperative mortality of 4.7–8.0% and superiority over arterial resection (adjusted odds ratio 3.31, $P = 0.01$) [31,37].

In addition to safety, oncologic efficacy of the proposed implications from the histologic tumor–vessel relationship on surgical techniques needs to be determined. Patients with arterial involvement frequently undergo preoperative chemotherapy according to guidelines for LAPC. Loos et al. found equal long-term outcomes between the cohorts of 190 patients with periadventitial dissection and 195 patients with arterial resection (combined postoperative median overall survival 20.1 months) [31]. In contrast, upfront surgery is performed in the majority of patients with isolated venous involvement. In almost 1200 patients with pancreatoduodenectomy and mesoportal venous resection from 23 centers, retrospective survival analyses revealed higher R0 rates (57% vs 47%) and superior oncologic outcomes (five-year overall survival 29% vs 18%) in the 26% of patients who underwent neoadjuvant treatment [38]. However, inferences need to be carefully reevaluated with the acquisition of prospectively randomized controlled trial data.

Outcomes of Minimally Invasive Pancreatoduodenectomy

After surgeons succeeded in advancing open pancreatoduodenectomy toward a safe operation, efforts emerged to perform resection in a minimally invasive fashion. A total laparoscopic pancreatoduodenectomy was first described in 1994 by Gagner et al. in a patient with chronic pancreatitis.

Recently, a large multicenter randomized controlled trial conducted in China that enrolled 656 patients investigated safety and postoperative complications of laparoscopic vs open pancreatoduodenectomy. The results demonstrated similarity in postoperative 90-day mortality rates (both 2%), severe complication rates (Clavien–Dindo grade ≥IIIa, 29% vs 23%, $P = 0.13$) and overall morbidity assessed by the Comprehensive Complication Index (median 8.7 vs 0, $P = 0.06$). Postoperative length of stay was one day shorter after laparoscopic resection (median 15 vs 16 days, $P = 0.02$). Importantly, both procedures were exclusively performed by surgeons with high laparoscopic pancreatoduodenectomy experience (at least 104 prior cases) [39]. In potentially less experienced hands, even after completion of a specifically designed training curriculum, securing safety remains controversial as presented in the multicenter randomized controlled Dutch LEOPARD-2 trial (terminated prematurely after 50 laparoscopic procedures due to postoperative mortality in five patients) [40].

Besides the utilization of rigid laparoscopic instruments for pancreatoduodenectomy, robotically assisted techniques have emerged which substantially increase dexterity for the operating surgeon. Pioneered in 2001, Giulianotti et al. applied the DaVinci® Surgical System for a hybrid pancreatoduodenectomy (resection laparoscopically, gastrointestinal reconstructions robotically) and eventually the total robotic approach. Starting in 2008, Zeh et al. established a program in Pittsburgh implementing structured training with evolving anatomic criteria for patient selection. While experience accumulated, a well-recognized finding was the acknowledgment of learning curves for optimized performance of the individual surgeon (approximately 20 cases to reach the benchmark conversion-to-open rate and 80 cases for operative time) [41]. Their retrospectively reported short-term survival of 500 consecutive robotic pancreatoduodenectomies demonstrated 30- and 90-day mortality rates of 1.4% and 3.1% [42]. Comparable 90-day mortality rates were achieved in international high-volume centers in Shanghai (2.7%, 450 patients), Pisa (3.6%, 112 patients), and Baltimore (2.1%, 96 patients) [43–45].

When compared to open pancreatoduodenectomy, two analyses of propensity score-matched cohorts coherently suggested no differences in perioperative mortality, anastomotic insufficiencies (any site), and POPF rate. In contrast, the robotic approach resulted in decreased wound infections, intraoperative blood loss, and postoperative hospital length of stay [43,45]. Notably, most of the available data reported robotic pancreatoduodenectomies without venous end-to-end or short segmental reconstructions. Nevertheless, a few centers started to

explore techniques to achieve segmental mesoportal venous resection and arterial resection with reconstruction robotically [46,47]. Overall, data from randomized controlled trials comparing robotic vs open pancreatoduodenectomy are unavailable but under way and will be essential to confirm the proposed inferences (EUROPA trial).

Furthermore, oncologic efficacy is yet to be determined. To meet this aspiration, critical state-of-the-art surgical techniques of the open approach for radical tumor margins, such as retropancreatic nerve plexus and TRIANGLE resections (retropancreatic nerve plexus resection within triangular-shaped space between the mesoportal vein, common hepatic artery and superior mesenteric artery with periadventitial dissection of arteries), were recently demonstrated to be feasible (Fig. 136.1) [48]. Therefore, they should be transferred to the robotic procedure to deliver noninferior oncologic outcomes.

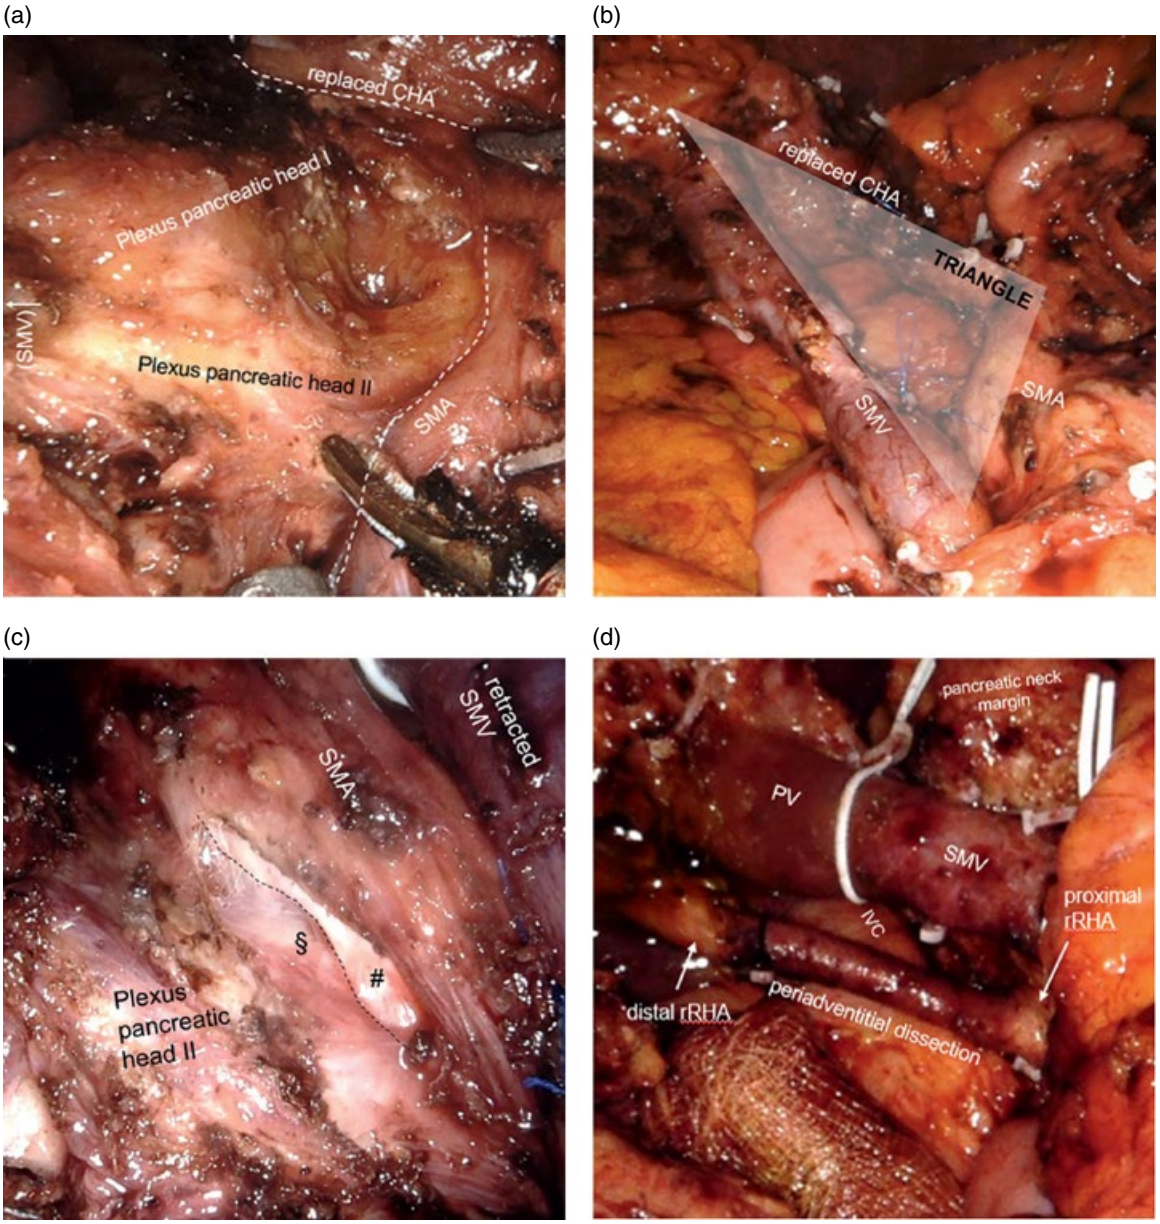

Figure 136.1 Achieving a radical dorsal resection margin during robotic pancreatoduodenectomy. Illustration of the retropancreatic nerve plexuses before resection (a) and after resection (b) within the TRIANGLE area. Periadventitial dissection of arteries such as the superior mesenteric artery (c; # marks the tunica media and § the dissected internal surface of the tunica adventitia) and replaced right hepatic artery (d) is feasible and should be considered. CHA, common hepatic artery; IVC, inferior vena cava; PV, portal vein; rRHA, replaced right hepatic artery; SMA, superior mesenteric artery; SMV, superior mesenteric vein. *Source:* [48], Kinny-Köster et al. Besides surgical performance in regard to specimen margin, lymphadenectomy, and *en bloc* resection, survival is strongly determined by tolerability, timing, and response to systemic chemotherapy [7]. The often underlying micrometastatic disease burden of PDAC at the time of diagnosis is recognized due to the high probability to demonstrate distant recurrences (33–59% of patients after upfront surgery, discussed above) [17,49]. More specifically, retrospective analyses of recurrences in the Baltimore cohort after 692 upfront pancreatoduodenectomies revealed a recurrence-free survival of 18 vs 10.5 months ($P = 0.008$) in patients who underwent adjuvant vs no adjuvant chemotherapy [17]. Further dissecting the reasons for failing administration of adjuvant chemotherapy, Wu et al. found that severe postoperative complications (Clavien–Dindo grade >IIIa) after pancreatoduodenectomy (vast majority underwent an open approach) were associated with no receipt of adjuvant chemotherapy and that any complication independent of severity was associated with a delay in systemic treatment [50]. In contrast, when quantifying the cumulative dose of adjuvant chemotherapy, prospectively randomized data from the ESPAC-3 trial illustrated that completion of systemic treatment (six cycles of either gemcitabine or fluorouracil/folinic acid) was strongly associated with improved survival compared to less than six cycles of chemotherapy in a cohort of 985 patients (median survival 28.4 vs 19.3 months, $P < 0.001$) [16].

Taken together, robotic pancreatoduodenectomies, if technically feasible and performed safely, may be oncologically valuable through a favorable tolerability of adjuvant chemotherapy due to decreased complications, systemic inflammation, and length of hospital stay as surrogates for subsequently enhanced recovery.

Future Perspectives

Promisingly, our expanding understanding of the genetic PDAC features is driving the concept of tumor biology which may translate into clinical decision making. This paradigm is opposing the current practice of predominantly relying on anatomic-morphologic criteria. Furthermore, focus on tumor biology is reflected by contemporary research efforts to identify patients who benefit from preoperative treatment and who have predicted sensitivity to distinct chemotherapeutic regimens. A modern surgical posture to offer curative-intent care has resulted in the emergence of vascular pancreatic surgery as a discipline and implies a versatile skillset of the operating team.

Future technologic innovations and results from rigorously conducted randomized controlled trials will determine the ability of the robotic approach to produce optimized clinical outcomes. Surgery together with early detection and improved efficacy of systemic treatments, potentially immunotherapy as an alternative to chemotherapy, will lead to better outcomes in patients with PDAC in the future.

Introduction

Approximately 25% of patients with pancreatic ductal adenocarcinoma (PDAC) present with a tumor in the pancreatic body or tail [1]. Patients with these tumors typically present more often with larger tumors and metastatic disease compared to patients with PDAC in the pancreatic head (metastatic disease: head 42%, body 69%, tail 84%; P <0.001; tumor size >4 cm: head 21%, body 40%, tail 51%; P <0.001) [1]. In fact, less than 15% of PDAC of the body and tail tumors is resectable at initial presentation [2,3].

Pancreatic cancer is defined in this chapter as pancreatic ductal adenocarcinoma (PDAC). In the literature, different definitions are used which often results in different interpretations of oncology outcomes, including survival. According to the 2019 World Health Organization classification of tumors of the digestive system, PDAC may also include, albeit rarely, adenosquamous carcinoma, colloid carcinoma (mucinous noncystic carcinoma), hepatoid carcinoma, medullary carcinoma, signet ring cell carcinoma, undifferentiated carcinoma, and undifferentiated carcinoma with osteoclast-like giant cells [4]. Precursor lesions, including pancreatic intraepithelial neoplasia, intraductal papillary mucinous neoplasms and mucinous cystic and other types of lesions (e.g., acinar cell), are considered a different entity and not classified as PDAC.

Diagnosis of Pancreatic Body and Tail Cancer

Diagnosis and treatment modalities are optimally decided by a multidisciplinary team. The preferred imaging in case of suspicion of pancreatic body or tail cancer is abdominal computed tomography (CT) (pancreas protocol) so vascular involvement can be assessed. If the CT images are inconclusive, endoscopic ultrasound (with or without fine needle aspiration [FNA] or biopsy [FNB]) can provide additional information. Magnetic resonance imaging (MRI) and positron emission tomography (PET)-CT scan are not generally used as diagnostic modalities but can be of important value in specific cases. In addition, tumor markers (carbohydrate antigen [CA] 19-9 and carcinoembryonic antigen [CEA]) should be measured. However, these tumor markers are not sensitive enough to differentiate between a benign and malignant tumor [5–8]. Pathology proof is not mandatory before performing surgical resection, unless in the setting of neoadjuvant treatment.

Staging and Resectability

Pancreatic tumors are staged according to the 2016 Union for International Cancer Control (UICC) 8th edition TNM classification for pancreatic carcinoma [9]. In this classification, T-stage is based on tumor size and vascular involvement. Different criteria for resectability of pancreatic body and tail cancer are available. Tumor involvement of the celiac axis is generally regarded as a criterion for unresectable [10–13] or borderline resectable disease [14–17] (Table 137.1). In case of borderline or unresectable tumors, neoadjuvant or palliative/induction treatment should be considered. With the introduction of FOLFIRINOX chemotherapy, in case of unresectable tumors, restaging after 4–6 cycles of chemo(radio)therapy could be performed and in case of tumor regression to borderline tumor, diagnostic laparoscopy or laparotomy could be considered [18].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Table 137.1 NCCN 2.201 resectability criteria for pancreatic body and tail cancer.

Vascular structure	Resectable	Borderline resectable	Locally advanced
Arteries	No tumor contact with: celiac axis (CA) common hepatic artery superior mesenteric artery (SMA)	≤180^0 contact with CA >180^0 contact with CA **without** involvement of the aorta and gastroduodenal artery	>180^0 contact with SMA Contact with the CA **and** aortic involvement
Veins	No tumor contact with: portal vein (PV) superior mesenteric vein (SMV) ≤180^0 contact without contour irregularity	>180^0 contact with the PV/SMV ≤180^0 contact with the PV and SMV **with** contour irregularity/thrombosis and suitable for complete resection and reconstruction tumor contact with the inferior vena cava	Unreconstructible PV/SMV (can be due to tumor or bland thrombus)

Surgical Technique

In case of resectable disease, surgical resection in combination with systemic treatment is the treatment of choice and provides the highest chance of cure. Resection of the pancreatic body and tail is usually referred to as distal pancreatectomy. Surgery for patients with a proven or suspected malignancy in the pancreatic body or tail is specifically referred to as radical antegrade modular pancreatosplenectomy (RAMPS), proposed by Strasberg et al. [19,20] for open surgery, and laparoscopic radical "no-touch" left pancreatosplenectomy (LRP) for minimally invasive left pancreatectomy, proposed by Abu Hilal et al. [21]. Both techniques allow safe and complete oncologic resection of the pancreatic body and tail. It is advised that if an open resection is performed, a diagnostic laparoscopy is carried out first to check for peritoneal or liver metastasis [22].

The goal of surgery is to perform a radical (R0) resection and an adequate regional lymph node dissection. Extended resections (beyond pancreas and spleen) should be classified according to the International Study Group on Pancreatic Surgery extended resection guideline [23].

Whichever procedure is performed and whichever technique is followed, the bottom line is that splenectomy and resection of Gerota's fascia are advised in left pancreatectomy for PDAC or high suspicion of PDAC. For lymphadenectomy, the ISGPS criteria for lymph node resection should be followed [24]. These include resection of lymph node stations 10, 11, and 18 for tumors of the pancreatic body and tail (Fig. 137.1). Additional resection of stations 8 and 9 will be performed when tumors affect the body of the pancreas. In specific cases, an extended lymphadenectomy could be considered.

Minimally Invasive vs Open Resection

Laparoscopic distal pancreatectomy was first described by Gagner in 1996 [25]. In 2019, the first multicenter randomized trial was published: the LEOPARD trial, comparing minimally invasive distal pancreatectomy (laparoscopic and robot) with open distal pancreatectomy in 14 Dutch hospitals. This trial showed a two-day reduction in time to functional recovery, less blood loss, and less delayed gastric emptying seen after the minimally invasive approach. Other complications (including postoperative pancreatic fistula) were comparable. Quality of life in the first 30 days after surgery was improved and overall costs were less after minimally invasive distal pancreatectomy [26]. Quality of life and costs were comparable between groups after one year [27]. In 2020, a second (monocenter) randomized trial was published: the LAPOP trial. This showed shorter hospital stay (one day less), faster time to recovery, and less blood loss after laparoscopic distal pancreatectomy. Postoperative complications were comparable between groups [28].

However, both the LEOPARD and LAPOP trials included only a minority of patients with PDAC and are therefore insufficient to draw solid conclusions on the oncologic efficacy of MIDP. Therefore, the oncologic safety of MIDP remains a subject of debate which hampers its further implementation [29,30]. A European survey on minimally invasive pancreatic surgery performed in 2016 demonstrated that 31% of participating surgeons expected MIDP to be inferior to open distal pancreatectomy (ODP) concerning oncologic outcomes [31].

Based on these results, the European Consortium on Minimally Invasive Pancreatic Surgery (E-MIPS) initiated an international propensity score-matched study including 1377 patients after distal pancreatectomy (minimally invasive or open) for PDAC [32]. This study showed

higher R0 resection rates for MIDP, but lower median number of harvested lymph nodes with similar survival months for MIDP and ODP [32]. However, MIDP was associated with lower rates of lymphovascular tumor invasion, perineural tumor invasion, and lower lymph node stage, suggesting that, despite matching, treatment allocation bias could still have influenced these results. Therefore, in 2019 the DIPLOMA trial was initiated. This European multicenter, patient- and pathologist-blinded, noninferiority randomized trial completed recruitment of all 244 patients in 2021. Primary outcome of this trial is radical (R0) resection. The short-term outcomes are expected in 2023 [22].

Radical Antegrade Modular Pancreatosplenectomy (RAMPS)

In 2003, Strasberg et al. described a technique for safe oncologic resection of malignant tumors of the pancreatic body and tail [19]. The RAMPS technique relies on early control of major blood vessels, improved visualization of the posterior resection margin, and extensive lymph node dissection [19,20].

The dissection takes place in an antegrade fashion (from right to left). The parenchyma is dissected first at the pancreatic neck using a stapler and the underlying vascular structures are exposed. The splenic vessels are ligated first, followed by extended dissection of celiac and superior mesenteric artery nodes. The final resection plane is decided based on tumor extension. The anterior renal fascia (i.e., Gerota) is always excised; if the pancreatic lesion invades the ipsilateral adrenal gland or further, the resection plane extends towards the anterior surface of the kidney, behind the perinephric fat (posterior RAMPS).

Improved five-year survival has been reported in patients with PDAC of the left pancreas who underwent RAMPS but the available evidence is limited [20,34]. Modifications of the RAMPS procedure can also be found in the literature [34,35]. Randomized trials comparing standard distal pancreatectomy and RAMPS will be needed to support the improved oncologic outcome of these techniques.

Laparoscopic Radical "No-Touch" Left Pancreatosplenectomy

This technique was proposed by Abu Hilal et al. in 2016 [21,36]. In that time, laparoscopic left pancreatectomy became more and more popular. The technique was developed to facilitate an oncologic laparoscopic resection introducing specific laparoscopic tips and tricks. The most important steps are mobilization of the pancreas (including Gerota's fascia) proximal and distal from the tumor, permitting a pancreas "hanging" on to slings and therefore avoiding tumor touching and manipulation. The dissection of the inferior margin and the development of the posterior plane are continued

clockwise towards the splenic/superior mesenteric vein junction. Subsequently, the dissection is continued in a medial–lateral direction. The pancreas is transected at the neck, keeping a clear margin from the lesion. A full nodal clearance, including station 8, and splenectomy is performed.

Distal Pancreatectomy with *En Bloc* Celiac Artery Resection

Distal pancreatectomy with celiac artery resection (DP-CAR) is performed for PDAC of the pancreatic body or tail with involvement of the celiac artery [37]. After resection of the celiac axis, compensatory retrograde flow from the superior mesenteric artery via the inferior pancreatoduodenal arcades feeds the pancreatic head and the liver (Fig. 137.2). In the current era, the use of neoadjuvant FOLFIRINOX (folinic acid, fluorouracil, irinotecan, oxaliplatin) may lead to higher downstaging rates for pancreatic cancer which may increase the application of this type of surgery [18,38]. In 2017, Klompmaker et al. [39] collected data on DP-CAR in 20 centers from 12 countries. Data on 68 patients were collected and in 62 patients, the pathology report showed PDAC. Outcomes showed high major morbidity (25%) and 16% 90-day mortality. Median overall survival was 18 months and 82% received neoadjuvant or adjuvant chemotherapy.

These outcomes show the importance of strict patient selection for performing DP-CAR. A flowchart guiding this patient selection was also proposed by Klompmaker et al. (Fig. 137.3).

Standardized Pathology Reporting

Currently, consensus regarding macroscopic assessment of distal pancreatectomy specimens is lacking. Since the most recent (8th edition) of the TNM classification is mostly based on tumor size, standardized measuring and reporting are necessary. As part of the previously mentioned DIPLOMA trial [33], a standardized pathology assessment is proposed [40]. This approach includes standardized measurement of the resected part of the pancreas and inking of relevant surgical margins and anatomic surfaces. Then, measurement of tumor size (for T-stage) is performed and assessment of splenic vessel involvement (and other organs if present) (Fig. 137.4). All margins are assessed and relevant blocks are selected to confirm these parameters microscopically. This standardized assessment will hopefully improve uniform reporting of outcomes (most importantly R0 resection) in the future.

Postoperative Pancreatic Fistula

Morbidity rates after distal pancreatectomy are high (up to 50%), even in high-volume centers [41]. Postoperative pancreatic fistula (POPF) is the most common major

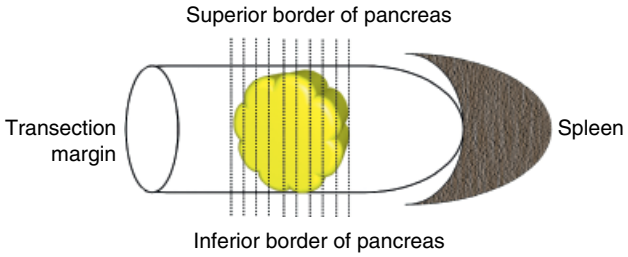

Figure 137.4 Standardized block taking for pathology specimens after distal pancreatectomy.

complication of this procedure, with reported rates up to 20–30% [42–44]. POPF is classified according to the 2016 ISGPS guideline [43]. Risk factors for the development of POPF after distal pancreatectomy identified in the literature are younger age, smoking, obesity, hypoalbuminemia, neuroendocrine or nonmalignant pathology, pancreas thickness, concomitant splenectomy, extensive lymphadenectomy, and vascular resection [45–48].

Numerous studies investigating ways to minimize POPF after distal pancreatectomy have been published [49–53]. Multiple closure techniques have been proposed over the years; suturing, (reinforced) stapling, stepwise compression stapling, direct ligation of the main pancreatic duct, and fibrin sealant patches [49–55]. So far, no high-quality evidence has been presented in favor of one of these approaches; this was also stated in the 2020 expert consensus guidelines by the ISGPS [56].

Routine Surgical Drain Placement

The benefit of routine placement of postoperative drain(s) on the surgical bed after distal pancreatectomy remains unclear. The goal of this prophylactic drain placement is to recognize a pancreatic leak early and allow controlled drainage of the pancreatic fluid when a leak is present. However, it is also suggested that routine drain placement could facilitate the development of POPF or introduce bacteria in the initially sterile peripancreatic fluid [57,58]. Alternatively, a selected drain strategy based on preoperative risk factors is proposed. But evidence showed that the prediction of POPF after distal pancreatectomy remains difficult [46].

Evidence on routine prophylactic versus no drain placement is limited. One multicenter randomized trial found no difference in complications and POPF rates in the drain vs the no-drain group [59]. A recent systematic review by Lyu et al. confirmed that clear evidence on prophylactic drainage after DP is lacking [60]. Therefore the PANDORINA trial was developed. This binational

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 137.2 Postoperative complications.

Postoperative complication	Percentage
New-onset diabetes mellitus	7–28%
Exocrine insufficiency	12%
Clavien–Dindo score 3 or higher	17–22%
Postoperative pancreatic fistula grade B/C	20%
Delayed gastric emptying grade B/C	2–7%
90-day mortality	2–4%
90-day readmission	14%

(The Netherlands and Italy), multicenter, randomized controlled trial will randomize 280 patients into drain vs no-drain groups and will compare postoperative morbidity and POPF rates [61]. Results are expected in 2023.

Postoperative Metabolic Complications

Pancreatic surgery is associated with several metabolic complications such as new onset or worsening of preexistent diabetes mellitus (Table 137.2). High-quality prospective studies focusing on this complication are lacking. A systematic review showed a cumulative incidence of new-onset diabetes varying from 7% to 28% [62]. Among these patients with new-onset diabetes, 36–100% were reported to have insulin-dependent diabetes. New-onset diabetes is less often seen after left pancreatectomy for cancer compared to chronic pancreatitis. Risk factors associated with the development of new-onset diabetes are age, higher BMI, higher preoperative Hba1c, fasting plasma glucose, and lower remnant pancreatic volume [63].

Data regarding a switch from insulin-independent to insulin-dependent diabetes is lacking although one study did report that an increase in diabetic medication claims was seen in patients who preoperatively already received diabetic medication [64]. Even less information is available on exocrine insufficiency after distal pancreatectomy; a median prevalence of 12% was mentioned but this was based on subjective diagnosis without additional testing [65].

Conclusion

Patients diagnosed with PDAC of the pancreatic body and tail more often present with locally advanced or metastatic disease. In those cases where the tumor is resectable on preoperative imaging, oncologic surgery with negative margins combined with neo- or adjuvant chemotherapy provides the best survival rates. Postoperative morbidity rates remain relatively high. Data of future trials will give more insight into the oncologic safety of MIDP.

Total Pancreatectomy: Indications and Limitations

Seiko Hirono[1] *and Hiroki Yamaue*[2]

[1] *Department of Hepato-Biliary-Pancreatic Surgery, Hyogo Medical University, Nishinomiya, Hyogo, Japan*
[2] *Second Department of Surgery, Wakayama Medical University, School of Medicine Wakayama, Japan*

Introduction

Total pancreatectomy (TP) was first described by Rockey in 1943 [1], and its popularity increased during the 1960s [2]. The rationale for TP was to avoid pancreatic anastomosis-related complications and to optimize oncologic surgical radicality in pancreatic cancer patients. After the first enthusiasm for TP, results of large series of TP for pancreatic cancer were published in the late 1980s and 1990s [3–8]. They showed that TP could not improve the rates of R0 resections for pancreatic cancer, had perioperative mortality rates similar to or higher than partial pancreatic resections (13–27%), and no survival advantage was found [3–8]. Furthermore, TP was complicated by permanent pancreatic endocrine and exocrine deficiencies [9]. These results led to surgeons largely abandoning TP and no longer considering it as a viable option for pancreatic disease.

However, recently, surgical techniques, perioperative management, and the development of high-volume surgical centers have advanced, and TP can be performed with lower mortality rates than in the past [10–14]. Furthermore, with improved long-acting insulin and high-quality enzyme replacement formulations, brittle diabetes mellitus and malabsorption from exocrine insufficiency can be controlled more effectively after TP [10–15].

In this chapter, recent indications and limitations of TP are considered, based on short- and long-term outcomes after TP reported in the literature.

Elective Total Pancreatectomy and Salvage Completion Pancreatectomy

Total pancreatectomy is classified mainly into elective TP and salvage completion pancreatectomy for complications after partial pancreatectomy [12,16,17].

An elective TP includes primary TP and two-stage TP after previous partial pancreatic resection. Primary elective TP is performed in cases with central tumor location in the pancreas or multifocal tumors with preoperatively planned TP, the intraoperative finding of a more extended tumor than preoperative imaging suggested, or tumor-positive intraoperative frozen pancreatic transection margin with the need for extension of the pancreas. Two-stage elective TP is performed in cases of tumor recurrence or new tumors developing in the remnant pancreas after partial pancreatic resection.

Indications for salvage completion pancreatectomy arise when the clinical options for the patient with a severe complication after pancreatic resection, such as pancreatic fistula or abdominal hemorrhage, and conservative treatment strategies have been exhausted [12,17].

Perioperative Outcomes After Total Pancreatectomy

Elective TP

High perioperative mortality and morbidity rates after TP have long been reported [3–8] but a dramatic decrease has been achieved in recent years by improvement of surgical techniques and postoperative management [10–13,16,17]. Recent single-institution series have reported perioperative mortality rates ranging from 3% to 12.5%, and perioperative morbidity rates ranging from 25% to 54% (Table 138.1) [10,12,16–21]. Advanced age (>70 years), the presence of comorbid conditions, long operative time (>420 minutes), high blood loss (>2000 mL), and/or arterial resections were reported as independent risk factors for mortality after TP [21,22].

Surgical complications after TP include delayed gastric emptying, intraabdominal abscess, abdominal hemorrhage,

IPMN, intraductal papillary mucinous neoplasm; PDAC, pancreatic ductal adenocarcinoma.

anastomotic leak, and wound infection. Several reports described that the rate of delayed gastric emptying was the most common perioperative complication after TP [12,20,21], and the relationship between delayed gastric emptying and surgical technique, whether preserving the pylorus or not during TP, was not clear [12,21].

Although mortality rates after TP have decreased, perioperative morbidity rates remain substantial. Therefore, careful patient selection, surgical procedure, and postoperative management are essential for decreasing morbidity rates after TP.

Salvage Completion Pancreatectomy

High mortality rates after emergent complete pancreatectomy have been reported, ranging from 39% to 48%, and reported morbidity rates were also high, ranging from 79% to 91% [12,17]. Furthermore, postoperative outcomes after salvage completion pancreatectomy, including complications, hospital stay, and survival, were significantly worse than those after elective TP [12,17]. The poor outcomes after salvage completion are associated with severe abdominal sepsis or hemorrhage after partial pancreatectomies.

As the techniques of interventional radiology, including drainage of pancreatic fistula or intraabdominal abscess, and arterial embolization for abdominal hemorrhage have advanced, salvage TP should be avoidable for complications after partial pancreatectomies, if possible, according to the reported poor outcomes [23,24].

Minimally Invasive TP

There have been a few reports about outcomes after minimally invasive TP, including laparoscopic and robotic TP, compared to those after open TP [25–28]. According to these reports, although operative time was significantly longer in minimally invasive TP than in open TP, there were no significant differences in other factors, such as intraoperative blood loss, morbidity rate, and mortality rate, between minimally invasive and open TP [25–28]. Furthermore, a European group reported that the incidence of major morbidity, defined as Clavien–Dindo ≥3a complications, after minimally invasive TP was significantly lower than that after open TP [25]. Therefore, minimally invasive TP may be feasible and safe in selected patients, although further large-scale studies and/or prospective studies are necessary to confirm this.

Long-term Outcomes After Total Pancreatectomy

With the increased number of long-term survivors after TP [21,29,30], management of late complications and evaluation of quality of life (QOL) after TP are important, although there have been few reports about long-term outcomes [10,12,16,19–21,31,32]. Late complications after TP include anastomotic ulcer at gastrojejunostomy and hepatic steatosis as well as diabetes mellitus and malabsorption caused by endocrine and exocrine insufficiency. Furthermore, long-term QOL

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

may be associated with postoperative symptoms, such as diarrhea, appetite loss, and weight loss [10,12,21,32].

Diabetes Mellitus After Total Pancreatectomy

Diabetes mellitus after TP is caused by a complete lack of endogenous insulin and glucagon, leading to frequent and deep states of hypoglycemia with hyperglycemic episodes that can be difficult to control (brittle diabetes) [9]. Recently, advanced management of the diabetic state using well-established long-acting insulin formulations [10] and continuous subcutaneous insulin infusion systems [33] has dramatically improved diabetic outcomes after TP [20,24]. Several reports have shown that hemoglobin A1c (HbA1c), as a long-term marker of blood glucose concentrations, could be kept within a tolerable range (median HbA1c, ranging from 6.5% to 8.0%) (Table 138.2) after TP [10,12,16,19–21]. However, the potential morbidity associated with endocrine deficiency must not be underestimated, because there are several reports of deaths owing to hypoglycemia and hyperglycemia after TP [10,20]. Therefore, preoperative endocrinology referral and determination of postoperative management using insulin formulations and postoperative education by specialists are essential for the treatment of diabetes mellitus in patients undergoing TP.

Exocrine Insufficiency After Total Pancreatectomy

Exocrine insufficiency is also an important late complication after TP [9]. Exocrine insufficiency may cause diarrhea, steatorrhea, weight loss, osteopathy and osteoporosis, and hepatic steatosis (see Table 138.2). Diarrhea and/or steatorrhea after TP contributes to the loss of fat-soluble vitamins, especially vitamin D, magnesium, and trace elements, leading to osteoporosis and hepatic steatosis [34]. Increasing attention has been devoted to the development of hepatic steatosis after pancreatectomy, because it may potentially progress and lead to life-threatening hepatic decompensation [35–37]. However, the etiology and pathogenesis remain largely unknown. Malnutrition from lack of pancreatic enzyme formulations can be hypothesized [36,37], and female sex and early postoperative nutritional status were reported to be independent risk factors for hepatic steatosis after TP [35].

Pancreatic exocrine enzymes process ingested food into micronutrients for absorption [34,38]. Disruption of this process leads to severe diarrhea and steatorrhea with subsequent nutritional deficiencies [34]. Therefore, nutritional interventions, such as low-fat diets and pancreatic enzyme replacement therapy, are used to improve clinical symptoms. Pancreatic enzyme replacement, including ingestion of more than 40 000–50 000 units of lipase per day, is a standard therapy for pancreatic exocrine insufficiency after TP, because it significantly improves absorption of fat and nitrogen as well as clinical symptoms [35,39,40]. Therefore, specific attention should be paid to patient educations with regard to exocrine insufficiency and pancreatic enzyme treatment after TP.

Anastomotic Ulcer After Total Pancreatectomy

An anastomotic ulcer at gastrojejunostomy can occur both in the early postoperative course and in the long term after TP [20,41]. This complication can be severe,

Table 138.2 Long-term outcomes after total pancreatectomy reported in main literature.

Author	Total number	HbA1c % of patients	Diabetes symptoms	Weight loss	Digestive
Billings et al. [10]	27	7.4% (5.0–11.3%)	Three deaths owing to hypoglycemia	70%	–

resulting in reoperation or even death. An anastomotic ulcer could be observed after TP with or without pylorus preservation, indicating that this complication could not be prevented technically [20]. However, it was reported that routine administration of a proton pump inhibitor could prevent anastomotic ulcer after TP [20].

Long-term QOL After Total Pancreatectomy

There have been a few reports evaluating long-term QOL after TP [10,12,21,32]. According to these reports, overall QOL after TP was acceptable, although most impaired items after TP were symptom scales, with a decrease of QOL focusing mainly on fatigue and diarrhea, and the score of healthcare satisfaction was also slightly poor [10,12,21,32]. Therefore, information delivery before and after TP may be necessary to increase QOL for patients who underwent TP.

Indications for Total Pancreatectomy

Total pancreatectomy is a reasonable procedure in some diffuse pancreatic disease, as perioperative mortality is low and long-term consequences are now better managed, with an acceptable morbidity and QOL [10–13,16,17, 19–21]. Therefore, TP should no longer be generally avoided for patients in whom the complete removal of the pancreas is required for oncologic prophylactic reasons. Furthermore, with extension of resection criteria in pancreatic malignant or premalignant disease, and more advanced knowledge of specific disease entities of the pancreas, which often affect the whole pancreas and require TP, the number of cases requiring TP has been increasing. Diseases which might require TP include extensive pancreatic head or body cancers, recurrence or new tumors developing in the remnant pancreas after previous partial pancreatic resection, diffuse or multifocal intraductal papillary mucinous neoplasms (IPMNs), renal cell metastases, multifocal neuroendocrine tumors and inherited neoplastic disease, including multiple endocrine neoplasia 1 (MEN1) syndrome, history of familial pancreatic cancer, and hereditary chronic pancreatitis. Furthermore, TP may also be performed in cases with avoidance of pancreatic-enteric anastomotic-related complications or salvage complete pancreatectomy for severe complications after partial pancreatectomies [12,21], although these indications are controversial.

Pancreatic Ductal Adenocarcinoma

The frequency of TP in patients with pancreatic ductal adenocarcinoma (PDAC) varies from 3% to 9%, according to previous reports [17,30,42,43]. Less than one year of median overall survival time was reported in the past [6,43,44] but recent reports described better overall survival after TP, ranging from 12 months to 18 months [21,29,30,42] because of improved surgical techniques and postoperative management, and advanced adjuvant therapies.

Hartwig et al. reported that poor tumor grade, high American Joint Commission on Cancer tumor stage, age 70 years or more, and an R1 resection were independent risk factors of poor survival for patients who underwent TP [21]. Satoi et al. reported that the rate of completion of adjuvant therapy was lower and the frequency of postoperative liver metastasis was higher in PDAC patients undergoing TP, compared to those with pancreatoduodenectomy; however, overall survival was similar between the TP and pancreatoduodenectomy matched-pairs groups [42]. Schmidt et al. reported that among PDAC patients with positive transected margin at permanent pathological findings in the absence of other margin positivity, patients undergoing subsequent TP to achieve a R0 resection were compared with the R1 patients undergoing pancreatoduodenectomy, and they showed that mortality and morbidity rates were similar between the two groups; however, conversion of pancreatoduodenectomy to TP was associated with survival benefits [30]. However, it was unclear whether oncologic surgical radicality, including extended lymphadenectomy and increased soft tissue clearance around the pancreatic gland by TP, could improve survival or not, compared to partial pancreatectomies [21,31,30,42].

Based on these results, TP seems to be a powerful strategy for patients with positive margin of transected pancreas after pancreatoduodenectomy to achieve a R0 resection, and completion of adjuvant therapies after TP is necessary to improve survival, as with other pancreatectomies. Then, adequate control of endocrine and exocrine pancreatic insufficiency after TP is essential to improve survival for PDAC patients undergoing TP.

Intraductal Papillary Mucinous Neoplasm

According to international consensus guidelines for the management of IPMN [45], main duct IPMN is an indication for surgical resection, because of the risk of malignancy. Diffuse main duct IPMNs or multifocal branch duct or mixed IPMNs sometimes require TP, and long-term outcomes for these cases are favorable [21,23,46,47]. Therefore, these IPMNs are a good indication for TP, although careful preoperative diagnosis of malignancy [17,48] and patient selection are necessary to obtain survival benefits.

Inherited Diseases

Patients with a family history of hereditary pancreatic cancer and those suffering from hereditary chronic pancreatitis have a considerable risk of developing

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. pancreatic cancer during their lifetime [23,49]. Therefore, TP is a prophylactic measure for patients with high risk of pancreatic cancer, used to eliminate the risk of cancer development, although the timing and extent of surgery are still controversial.

Tumor Recurrence or New Tumor Developing in the Remnant Pancreas After Previous Partial Pancreatic Resection

Tumor recurrence or new tumor, such as PDAC or IPMN, developing in the remnant pancreas without distant metastasis is sometimes found, and several reports showed survival benefits by a two-stage completion pancreatectomy with low rate of mortality and morbidity [12,16,21,50–53]. Therefore, tumor developing in the pancreas remnant is an indication for two-stage complete pancreatectomy.

Conversion from Partial Pancreatectomy to Total Pancreatectomy to Avoid Pancreatic-Enteric Anastomosis-related Complications

Pancreatic-enteric anastomotic leakage, called pancreatic fistula, after partial pancreatectomy could cause life-threatening complications, and conversion to TP from pancreatoduodenectomy is sometimes performed intraoperatively. Hartwig et al. reported that in 20% of all TP cases, intraoperative conversion to TP was performed because of the morphology of the remaining pancreas, including extremely soft or lipomatous pancreas that would have a high risk of postoperative pancreatic fistula, and combined arterial reconstruction during pancreatectomy, which could cause life-threatening complications by pancreatic fistula [21]. However, this indication for conversion to TP from pancreatoduodenectomy for avoidance of postoperative pancreatic fistula, causing endocrine and exocrine insufficiency, remains controversial.

Salvage Complete Pancreatectomy for Complications After Partial Pancreatectomy

As described above, the mortality and morbidity rates of salvage TP for severe complications after partial pancreatic resections are extremely high, so this procedure should be avoided, if possible [12,17]. The significant decline in the use of salvage complete pancreatectomy relative to a pancreatoduodenectomy reflects a shift in the management of pancreatic fistula and postoperative hemorrhage, with radiologic drainage and arterial embolization now readily available and preferred to relaparotomy [24,54].

Limitations of Total Pancreatectomy

Although mortality rates after TP have dramatically decreased, perioperative morbidity rates remain substantial [10–13,16,17]. Especially in salvage completion pancreatectomy for severe complications after partial pancreatectomy, both mortality and morbidity rates remain extremely high [12,17], so this procedure should be avoided, if possible. Furthermore, postoperative endocrine and exocrine insufficient state could cause life-threatening complications [10,12,16,19,20,21]. Therefore, careful patient selection, considering the balance between clinical benefits and postoperative risks, and delivering information about postoperative management before and after TP are necessary to improve survival and QOL for patients who undergo TP.

Minimally Invasive Resection for Pancreatic Cancer

Patricio M. Polanco, Imad Radi, and Herbert J. Zeh III

Department of Surgery, University of Texas Southwestern Medical Center, Dallas, TX, USA

Introduction

As in many other fields of surgery, minimally invasive approaches have revolutionized the face of surgical practice since the first laparoscopic appendectomy was performed in 1980[1]. This approach has extended to complex hepato-pancreato-biliary (HPB) procedures, but the adoption of minimally invasive techniques in pancreas surgery has been sluggish, especially for pancreaticoduodenectomy (PD). This is mainly due to the complexity of the procedure, the steep learning curve, and the limitations of the laparoscopic approach.

The introduction of robotic surgical systems, the report of the first robotic PD in 2001, and the subsequent optimization of robotic techniques have resulted in a surge of minimally invasive pancreatectomy numbers over the last two decades [2]. Given the advantages of the robotic approach, such as three-dimensional stereotactic vision, tremor attenuation, optical magnification, high degree of articulation and improved ergonomics, minimally invasive complex pancreatic resection (MIPR) has evolved significantly to become a safe and feasible procedure with low morbidity and mortality when performed in high-volume centers [1,3]. The aim of this chapter is to provide an updated overview of current trends, surgical techniques, and outcomes data associated with minimally invasive pancreatic surgery for cancer, focusing on proximal (pancreaticoduodenectomy) and distal pancreatectomy.

Minimally Invasive Pancreatic Resections: Indications

Currently, the resectability of pancreatic cancers remains defined, primarily, by the level of celiac artery, hepatic artery, or mesenteric vessel involvement by the tumor [4]. The approach to be utilized depends on the experience of the surgeon and surgical team. In the hands of expert minimally invasive pancreas surgeons, most pancreas head tumors with resectable features are amenable for minimally invasive technique.

While our group and others perform robotic pancreatic resections on highly selected patients with vascular involvement (*borderline and locally advanced* cancers), we do not recommend it as standard of care unless surgeons are highly experienced. For surgeons at the early stages of their learning curve, and for patients with locally advanced tumors where superior mesenteric vein (SMV)/artery (SMA) or hepatic artery resection and reconstruction is anticipated, we recommend the open approach.

After a negative workup for metastatic disease, a robust preoperative assessment for vascular involvement is warranted. Imaging is crucial, and the combination of endoscopic ultrasound (EUS) and triphasic computed tomography (CT) scan helps identify the best candidates for MIPR. Preoperative diagnostic laparoscopy is also encouraged to look for occult peritoneal metastasis.

While there are no absolute contraindications for MIPR, potential contraindications exist such as patients with CO2-retaining conditions unable to undergo pneumoperitoneum, and patients with extremely high body mass index (BMI), previous upper abdominal operations with a prohibitive amount of adhesions, and multiple comorbidities.

As a general recommendation, the treatment plan and surgical approach must be thoroughly considered and discussed in a multidisciplinary team with the participation of surgeons, medical oncologist, gastroenterologist, and radiation oncologist among others. At our institution, all pancreas tumors are discussed in a multidisciplinary pancreatic cancer clinic.

Minimally Invasive Pancreaticoduodenectomy: Technique

Robotic Pancreaticoduodenectomy

The robotic platform offers a multitude of advantages allowing an improved dexterity and enhanced visibility, facilitating dissection and reconstruction without compromising quality of the intervention. For these reasons, our group favors this approach over conventional laparoscopy. Our technique and outcomes have previously been reported [3].

The patient is placed in a supine position, with arms tucked and on a split leg table that allows the bedside assistant surgeon to stand between the legs in an ergonomic position. Depending on the room size, disposition, and which Da Vinci® System (Intuitive Surgical, Sunnyvale, CA) is used, the operating room (OR) setup can vary.

Pneumoperitoneum is then created by inserting a 5 mm optical separator in the left upper quadrant. Open peritoneum or Veress technique are both acceptable alternatives. Trocars are placed afterwards as depicted in Figure 139.1 and the robotic arms are docked.

Our robotic pancreaticoduodenectomy (RPD) technique can be summarized in seven major surgical steps.

First comes the *mobilization* of the right colon and duodenum by dividing the gastrocolic, gastroepiploic, and hepatic flexure attachments as well as the Toldt's fascia planes. This is followed by an extensive Kocher maneuver where the ligament of Treitz (LOT) is dissected and the proximal jejunum is pulled under the mesenteric vessels and transected about 10 cm distal to the LOT using a laparoscopic/robotic linear stapler (Fig. 139.2). The anterior surface of the pancreas is separated from the posterior stomach, which is then divided using a laparoscopic or robotic linear stapler. The stomach is divided proximal to the pylorus in the classic approach and distal to the pylorus in the pylorus-preserving one.

The second step is the *porta hepatis dissection* that starts with the removal of the anterior common hepatic artery lymph node, allowing for better visualization of the common hepatic artery, gastroduodenal artery (GDA), and portal vein (PV) (Fig. 139.3). Using a linear vascular stapler, the GDA is transected. This is followed by a periportal and portocaval lymphadenectomy, keeping in mind a possible aberrant replaced or accessory right hepatic artery.

Cholecystectomy is the third step and is often performed in a top-down fashion using a robotic hook cautery. The common bile duct is then isolated and divided using a gastrointestinal linear stapler to avoid bile spillage unless the RPD is performed for a proximal or middle-portion cancer of the common bile duct, for which we prefer a sharp transection using robotic scissors, allowing us to sample and study frozen sections of the margins.

The fourth step is dissecting the SMV off the inferior border of the pancreas and creating a tunnel over the portal vein (Fig. 139.4), and then *dividing the neck of the pancreas* using electrocautery and scissors for the duct (Fig. 139.5). Additionally, this step involves the *uncinate process and posterior retroperitoneum dissection*. After freeing the uncinate process of the SMV, the pancreas head and uncinate are rotated clockwise on the cephalocaudal axis to dissect the SMA, which allows the surgeons to identify the first jejunal vein and the junction of the gastroepiploic towards the portal vein. The first jejunal branch should be preserved unless the tumor extends and invades it.

Dissection proceeds along the SMA by separating it from the uncinate process and the retroperitoneal tissue. Pancreaticoduodenal veins are identified, dissected, and transected using a vessel sealer.

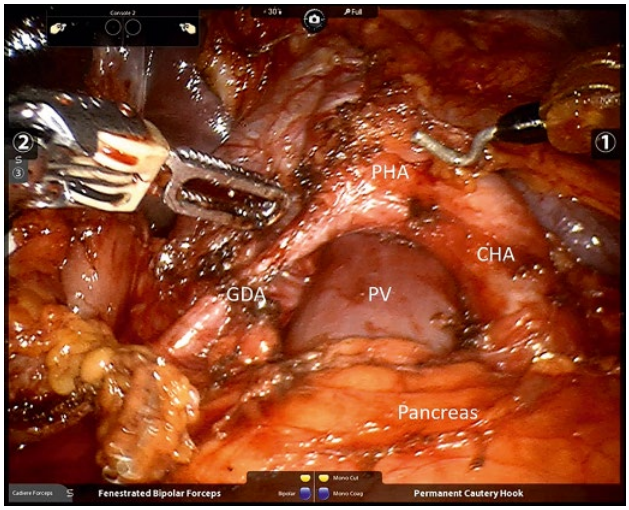

Figure 139.3 Suprapancreatic dissection of common hepatic artery (CHA), gastroduodenal artery (GDA), portal vein (PV), and proper hepatic artery (PHA).

The resection phase is complete at this point and the duodenum-pancreas-gallbladder specimen is collected in an endoscopic large bag and removed through the left lower bedside assist port that undergoes a 4–5 cm extension.

The fifth step marks the beginning of the reconstruction phase and is highlighted by *creating a two-layered end-to-side duct to mucosa pancreaticojejunal anastomosis* in a modified Blumgart technique (Fig. 139.6). The posterior mattress and anterior seromuscular bowel-to-pancreas approximations are performed using three 2-0 silks. The duct-to-mucosa anastomosis is performed with interrupted 5-0 PDS stitches. A ductal stent is used, especially when the duct is small, to confirm patency and facilitate anterior row stitching.

A *hepaticojejunal anastomosis* is then created and marks the sixth step (Fig. 139.7). After removing the stapled line of the common bile duct, the anastomosis is

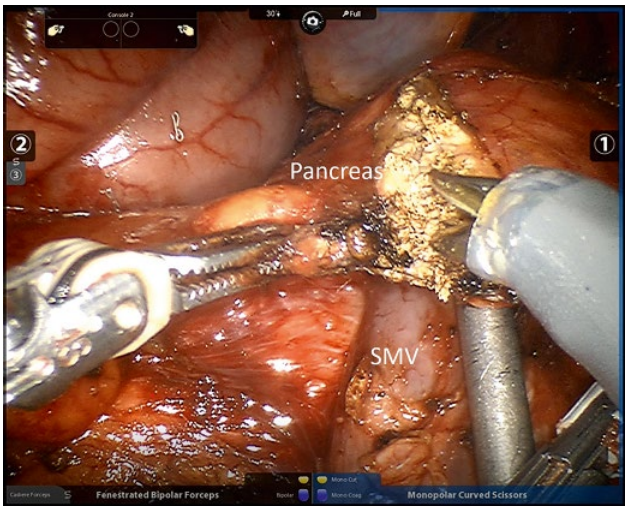

Figure 139.5 Pancreas transection. SMV, superior mesenteric vein.

performed using either interrupted or continuous stitching, depending on the width and thickness of the hepatic duct. For small ducts, 5-0 PDS interrupted sutures are used whereas for large and thick-walled ducts, running sutures with absorbable 4-0 barbed sutures are preferred for the anastomosis.

Creation of a *gastrojejunostomy* marks the last step of reconstruction and the end of this procedure (Fig. 139.8). It is performed using the loop of proximal jejunum roughly at 60 cm from the hepaticojejunostomy. A two-layered end-to-side gastrojejunal anastomosis is created using 3-0 absorbable barbed sutures. If the pylorus is preserved, a duodenojejunal anastomosis is fashioned with 4-0 absorbable barbed sutures in a two-layer running suture. Following the anastomosis, we create a pedicled falciform ligament flap that we place carefully over the GDA stump to prevent direct contact with pancreatic secretions and enzymes in case a pancreatic leak occurs.

Finally, depending on surgeon preference, one or two (anterior and posterior to pancreaticojejunostomy) 19 French drains are usually placed, trocars are removed under direct visualization, and wounds are closed.

Laparoscopic Pancreaticoduodenectomy

Laparoscopic PD (LPD) technique has previously been described by multiple institutions around the world [5–8]. The following steps summarize the procedures mostly used. Patients are preferably positioned in split leg supine position, pneumoperitoneum is achieved through the left upper quadrant, and trocars are placed in a semilunar shape facing the duodeno-pancreas region. After ruling out the presence of occult metastatic peritoneal tumor implants, the surgery proceeds in a fashion similar to the open and robotic approach. The right colic flexure is mobilized, and an extensive Kocher maneuver is carried out followed by a division of the LOT and the gastric antrum with a linear stapler. Cholecystectomy, dissection of the hepatic artery and the GDA, and division of the GDA are the next steps. The retropancreatic tunnel is then created between the pancreatic neck and the portal vein, and the pancreas is divided using electrocautery and laparoscopic scissors for the duct.

Minimally Invasive Pancreaticoduodenectomy: Outcomes

Perioperative Outcomes

Robust data have been published so far, including large institutional series of MIPD, metaanalysis, systematic reviews, and randomized trials, and showed that minimally invasive pancreaticoduodenectomies are feasible and safe when performed by high-volume centers and expert surgeons who have overcome their learning curve.

Although initial experience with LPD was concerning, later reports described the safety and feasibility of LPD. In the largest series of laparoscopic pancreaticoduodenectomy, including 130 patients, Palanivelu et al. demonstrated the feasibility and advantages of the MI approach when performed by high-volume expert surgeons [9]. They reported a mean operative time of 310 minutes, mean estimated blood loss of 110 mL, average hospital stay of eight days and one conversion to open surgery. The postoperative pancreatic fistula, overall postoperative morbidity, and overall mortality rates were respectively 8.5%, 30%, and 1.5%.

Systematic reviews and metaanalyses have consistently shown that MIPD is associated with comparable postoperative morbidity in terms of pancreas-specific complications (i.e., pancreatic fistulas and delayed gastric emptying), perioperative morbidity and postoperative mortality, with a decrease of length of stay (LOS) and blood loss but increased OR time for MIPD when compared to open [10,11]. Using a propensity-matched analysis in a US national dataset, our group reported that patients with MIPD (excluding conversions) have a lower rate of prolonged LOS, decreased wound complications and transfusions, and no differences were noted in morbidity and mortality, when compared to the open approach [12].

In the largest documented cohort of RPD, the University of Pittsburgh group reported their 10-year experience of 500 consecutive RPDs [3]. In this series, the authors report an 8% rate of clinically relevant postoperative pancreatic fistula, with major complications occurring in less than 24% of patients and a median LOS of eight days. The 30- and 90-day mortality rates were 1.4% and 3.1%, respectively. These optimal outcomes were highlighted owing to the structured implementation and adoption of a robust robotic pancreas surgery program. Subsequent retrospective propensity-matched analysis of institutional and large national datasets has corroborated the association of RPD with a decreased rate of clinically relevant postoperative pancreatic fistula (CR-POPF) [13–15]. See Table 139.1 for selected case series of laparoscopic and robotic PD, and Table 139.2 for selected comparative studies of RPDs and open pancreaticoduodenectomy (OPD).

At least four randomized control trials comparing OPD and LPD have been published in recent years. The outcomes of two completed single-center nonblinded RCTs (PLOT and PADULAP) comparing LPD to OPD have demonstrated clear advantages for MIPD in terms of blood loss, functional recovery, and LOS with an increased operative time and comparable or reduced postoperative complications [16,17]. However, the LEOPARD-2 trial, a multicenter, patient-blinded phase II/III RCT comparing LPD against OPD, raised concerns of increased 90-day postoperative mortality rate of 15%

(3/20 patients) in the LPD arm that led to the early termination of the trial [18]. While this study is commended for being the first multicenter blinded and randomized trial, questions were raised regarding the learning curve of surgeons participating in this trial and the adoption of a laparoscopic technique for PD. The lack of technical expertise specific to the LPD could have resulted in the unfavorable outcomes observed, as described by Strobel and Büchler [19]. A more recent Chinese randomized trial comparing these two approaches, with 328 patients in each arm, confirmed that LPD decreased LOS while other perioperative outcomes remained comparable among groups [20]. In this study, the surgeons have a documented preceding experience of over 100 LPD.

Currently, no RCT comparing either RPD to OPD or RPD to LPD has been published but ongoing trials are being performed (Table 139.3). Notably, the DIPLOMA-2 trial lead by the Dutch Pancreas Study Group will enroll 288 patients in a randomized international multicenter study comparing the morbidity and mortality of RPD and OPD (ISRCTN27483786). Similarly, the Robotic Versus Open Pancreaticoduodenectomy for Pancreatic and Periampullary Tumors (PORTAL) study is a phase III multicenter noninferiority RCT that aims to enroll 244 participants to compare RPD and OPD using time to functional recovery as main outcome [21]. See Table 139.3 for a summary of selected ongoing randomized trials comparing RPD and OPD.

Until further data are provided by these ongoing trials, we recommend that MIPD be performed in high-volume centers by surgeons with formal training in minimally invasive approaches who have clearly surpassed their learning curve. In their hands, MIPD is safe and feasible and provides an acceptable alternative to OPD with several potential benefits regarding blood loss, transfusions, length of stay, and fistula rates. The learning curve for RPD is steep and difficult to overcome as described by a US high-volume institution that demonstrated in a retrospective analysis a decrease in blood loss, fistula rate, and operative time after 20, 40, and 80 cases respectively [22].

While both laparoscopic and robotic approaches are good alternatives in experienced hands, we believe that RPD technique is more reproducible and may allow the completion of more complex pancreatic surgeries with a lower number of conversions. Our suggestion is based

on our previous experience, clinical observations, and reported findings of significantly lower conversion rates for RPD (11%) when compared to LPD (27%) in a national cohort of patients [23].

Oncologic Outcomes

Based on previously published retrospective single-center, multicenter, and national database analyses [24–29], and after critical review of these data by a group of pancreatic surgery experts, the Miami International Evidence-Based Guidelines on minimally invasive pancreatic resection addressed the question of whether MIPD should be used to treat pancreatic head tumors. This group concluded that both minimally invasive and open approaches are valid for patients with malignancies and show no major differences in perioperative outcomes and survival [30].

A recent systematic review and metaanalysis included 18 nonrandomized trials and performed an analysis on 13 636 patients with periampullary malignancies who underwent either RPD (N = 1593) or OPD (N = 10 046). The authors found that R0 resections and lymph node harvest rates were comparable between the two approaches [31]. Another metaanalysis by Da Dong et al., with focus on the resection rate as primary outcome, included 12 579 patients from 24 previous studies and showed that RPD provides better histopathologic outcomes. The authors found that R1 rates were significantly lower in robotic PD (15.6% vs 19.9%) [32].

While most of the studies included in the metaanalysis showed similar oncologic results, Kendrick and collaborators from the Mayo Clinic hospitals showed that patients undergoing LPD had longer progression-free survival. After comparing 108 LPD to 214 OPD, they found that LPD was associated with shorter length of stay, faster recovery, and less delay in adjuvant therapy delivery, which could explain the better survival outcomes [33].

When comparing RPD to LPD and using a national cohort of 1623 patients with pancreatic adenocarcinoma from the National Cancer Database, our group reported no significant differences in lymph node harvest, margin status, and overall survival between both approaches [34]. A recent review and metaanalysis identified 3426 patients (1025 RPD and 2437 LPD) from 44 studies, of which six were nonrandomized comparative studies. The authors reported no differences in R0 rates [35].

In summary, while there is a paucity of prospective randomized data reporting oncologic outcomes of MIPD and based on large retrospective series and US national data, we conclude that the minimally invasive approach has comparable results with the open approach when performed for periampullary malignancies.

Minimally Invasive Distal Pancreatectomy: Technique

Robotic Distal Pancreatectomy

Our standard technique has been previously reported [36]. Patients are positioned supine in a split leg table with arms tucked, in 14–16° of reverse Trendelenburg and with 4–6° of tilt towards the patient's right side (left side up). The peritoneum is accessed via an optical separator through the left upper quadrant and staging laparoscopy is performed to rule out occult metastatic disease in the peritoneum or elsewhere. Four robotic ports are then placed across the abdomen with the addition of one or two bedside assist ports.

Dissection begins by entering the lesser sac through the gastrocolic omentum and exposing the entire distal pancreas and the anterior aspect of the tumor. Cauterization and division of the short gastric vessels are performed and the splenic artery and left gastric pedicle are identified. The splenic artery and vein are dissected and isolated followed by the creation of a retropancreatic tunnel medial to the lesion. Note that intraoperative ultrasound is helpful with tumor identification or in case of uncertain vascular anatomy. The splenic artery and veins are then transected using a vascular load stapler followed by division of the pancreas using a linear stapler.

The remainder of the procedure follows the steps of a radical antegrade modular pancreato-splenectomy (RAMPS). The anterior Gerota's fascia, pancreas tail, spleen, and short gastric vessels are resected. A lymphadenectomy is carried out starting from the left side of the SMA laterally and including nodal regions 10 (supra-pancreatic) and 18 (infrapancreatic), as per the ISGPS guidelines [37]. The spleen is then mobilized from the splenocolic ligaments, the pancreas separated from the spleen, and both are placed in different laparoscopic bags and extracted. A drain is routinely placed before closure.

Based on our experience, the robotic approach confers an advantage if large tumors are encountered and involve the colon or the fourth portion of the duodenum as it allows fine *en bloc* resections with elaborate reconstructive techniques comparable to the open approach [38].

Laparoscopic Distal Pancreatectomy

Previous reports have described similar techniques for LDP [39,40]. The patient is placed in a supine position, legs apart, with 20–25° reverse Trendelenburg and tilted 15–20° to the right. With an optical separator inserted in the left hypochondrium, pneumoperitoneum is induced, metastatic disease is assessed and followed by the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

insertion of four trocars. The lesser sac is then accessed, allowing the exploration of the pancreas. A laparoscopic ultrasound is helpful in assessing the exact level of resection and to check for potential liver metastasis. The short gastric vessels are resected, and the splenic flexure is mobilized, exposing the inferior border of the pancreas for dissection. The pancreas is then moved out of the retroperitoneum by creating a subpancreatic tunnel.

The following dissection is focused on exposing, isolating, and dividing the splenic vessels, allowing a safer pancreas transection that is then performed with a linear stapler or harmonic scalpel. By excising its suspending ligaments, the spleen is mobilized and placed in a bag extracted through an access incision. Drains are kept next to the resection bed before closure.

Minimally Invasive Distal Pancreatectomy: Outcomes

Perioperative Outcomes

Minimally invasive distal pancreatectomy is a safe and feasible approach for pancreatic cancer resection, as has been shown in multiple studies [41]. Although these reports are mostly comparative and retrospective, MIDP has become a routine practice in many institutions around the world. See Table 139.4 for selected case series of MIDPs.

In a patient-blinded, multicenter RCT performed by a Dutch group (LEOPARD trial), 108 patients with left-sided pancreatic tumors were randomized to either MIDP (N = 51) (laparoscopic or robotic) or ODP (N = 57). Patients in the MIDP arm had significantly reduced blood loss (150 vs 400 mL), time to functional recovery (4 vs 6 days), grade B/C delayed gastric emptying (6% vs 20%) and an increased OR time (217 vs 179 min) [42]. Another unblinded, single-center RCT performed by a Swedish group, the LAPOP trial, enrolled 29 patients in the LDP arm and 29 in the ODP arm. The analysis showed a significant reduction of LOS in the LDP arm, time to functional recovery, blood loss, and comparable OR time [43]. See Table 139.5 for a summary of selected ongoing randomized trials comparing MIDP and ODP.

Focused analysis and trends are currently aiming to compare the robotic and laparoscopic approaches. A recent European multicenter analysis included 1551 patients (407 RDP and 1144 LDP) and matched 402 patients from each group. No differences were noted in terms of postoperative major morbidity and CR-POPF, which highlights the fact that both approaches are equally safe and feasible. Interestingly, RDP showed significantly fewer conversions to open surgery (6.7% vs 15%), lower rates of readmission (11% vs 18%), and higher rates of spleen preservation (81% vs 63%). However, RDP was associated with longer LOS (8.5 vs 7 days) and OR time (285 vs 240 min) [44].

Similarly, Guerrini et al. found in their review and metaanalysis of 813 patients that RDP, compared to LDP, had a significantly lower rate of conversion (8.2% vs 21.6%) and a significantly higher rate of spleen preservation (49% vs 27). This metaanalysis, contrary to the previous described multicenter study, showed that RDP was associated with a shorter LOS (7 vs 9 days). Finally, both groups showed similar outcomes in terms of major morbidity and POPF rates [41].

Oncologic Outcomes

While postoperative outcomes of MIDP have been well published, data regarding the oncologic outcomes remain scarce. In a recent Chinese single-center retrospective comparative analysis, no major differences between LDP and ODP groups were noted in terms of time to adjuvant therapy (50 vs 52 days), rate of adjuvant therapy (71% vs 66%), R0 rates (97% vs 91%), and survival rates. Differences were noted in lymph node retrieval favoring the LDP approach over ODP (14.4 vs 12.7) [45].

A recent metaanalysis of 11 studies included 4829 patients and found better oncologic outcomes with MIDP over ODP in terms of R0 margin rates (odds ratio [OR] = 0.71, 95% confidence interval [CI] 0.56–0.89; $P = 0.003$), but no difference in three-year and five-year overall survival outcomes [46].

Another recent metaanalysis of 21 studies included 11 246 patients and concluded that MIDP was comparable with ODP with respect to R0 resection rate and use of adjuvant therapy. However, the lymph node yield was lower with MIDP. In this study, fewer patients in MIDP received neoadjuvant chemotherapy and radiation therapy. In addition, MIDP patients were more likely to have smaller tumors, less perineural invasion, and less lymphovascular invasion. This generated an allocation bias and could not conclude on the oncologic efficacy of MIDP [47].

A pan-European propensity score-matched study included 1212 patients from 34 centers in 11 countries and that underwent either MIDP or ODP for PDAC. This study revealed comparable overall survival between groups (28 vs 31 months), with significantly higher R0 resection rates (67% vs 58%) but lower lymph node yield (14 vs 22) with MIDP [48]. This study paved the way for an international blinded RCT (DIPLOMA) that will compare R0 resection rates (primary outcome) between patients with PDAC undergoing MIDP versus ODP. Currently, this trial has just completed enrollment of all 258 patients from 34 centers.

Using the National Cancer Database, Raoof et al. analyzed 605 patients who underwent LDP versus 99 who underwent RDP. No major differences between these two approaches were noted in lymph nodes examined (12 vs 11), margin-positive rate (15% vs 16%), overall survival, time to chemotherapy (50 vs 52 days; $P = 0.65$), and mortality rates (1% vs 0%; $P = 0.28$) [49].

Learning Curve of Minimally Invasive Pancreatic Surgery

One of the biggest challenges in the adoption of minimally invasive surgery in pancreatic surgery is the steep learning curve (LC) needed to achieve optimal outcomes. The significant difference in the level of complexity of distal and proximal pancreatectomies is also reflected in the LC for the minimally invasive approach. As expected, the LC of MIDP is significantly shorter than for MIPD as reported by Chan et al. in a systematic review of 32 studies [50].

In our initial experience of 100 consecutive RDP, we reported that the LC for RDP includes 20 cases for an initial reduction of operative time and noted a subsequent significant reduction after 40 cases. Additionally, we noted an improvement of readmission rates and grade B/C pancreatic fistulas after 40 cases [51].

The LC for RPD also varies based on the outcome to be analyzed. Boone et al. reported our initial experience of 200 consecutive RPDs at the University of Pittsburgh. The main findings included that 20, 40, and 80 cases were needed to decrease the rate of conversions, blood loss, and operative time, respectively [52]. Another case series of 100 patients from Zhang et al. had undergone RPD by a single surgeon. CUSUM analysis showed two phases in the LC with a cut-off of 40 cases. [29].

We strongly recommended that any minimally invasive pancreatic resections should be performed at high-volume centers with expert surgeons. In that regard, and after critically reviewing the available data, the experts of the Miami Consensus Guidelines recommended an annual minimum of 20 LPD or RPD per year to optimize outcomes [30].

Besides the volume factor, it is extremely important to emphasize the need for formal training to mitigate the LC of these complex procedures. We support the use of a step-wise and proficiency-based simulation training as reported by Hogg et al. for training surgical oncology and hepato-pancreato-biliary trainees [53]. Moreover, based on individual hospital resources and access to robotic simulation and training systems, we endorse the early exposure and training of surgical residents [54]. Besides virtual reality and inanimate simulation, surgical coaching and proctoring is essential to achieve ideal results. Incorporating these elements and training tools will allow for an even safer adoption of the robotic technology for pancreatic resections or any complex procedures.

Conclusion

Minimally invasive pancreatic resections are safe and feasible for benign and malignant indications in the hands of experienced surgeons who have overcome their learning curve and achieved proficiency. Current data suggest that minimally invasive pancreatectomies could be associated with a quicker recovery, reduced blood loss, and equivalent oncologic outcomes compared to the open approach. Ongoing trials comparing the robotic to the open approach for PD will further define the role of minimally invasive surgery in this complex operation. While the adoption of robotic technique includes a steep learning curve, this could be mitigated by structured proficiency-based training.

Robotic Resection for Pancreatic Cancer

Renyi Qin

Department of Biliary-Pancreatic Surgery, Affiliated Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei, China

Introduction

Pancreatic cancer is a fatal disease, and it is becoming an increasingly common cause of cancer mortality [1]. Despite five-year survival rates of 10–25% for patients who can undergo surgical resection, surgery remains the most important treatment that offers curative potential [2]. Pancreaticoduodenectomy was described and popularized in 1935 by Allen et al. The Whipple procedure, which was initially a two-stage procedure, has been refined into the single-stage procedure that we use today [3]. Since its inception, pancreatic surgery has resulted in high morbidity and mortality, which has prevented its widespread use for many years [4].

Minimally invasive techniques have begun to revolutionize the surgical management of benign and malignant pancreatic diseases. In 2001, the first cases of robotic distal pancreatectomy (RDP) and robotic pancreaticoduodenectomy (RPD) were performed by Melvin et al. and Giulianotti et al., respectively [5,6]. RDP and RPD are increasingly being utilized for pancreatic malignancies because of the perceived benefits of stereotactic vision, magnification, platform stability, and favorable ergonomics [7–9]. Robot-assisted approaches to pancreatic surgery have been shown to be safe and feasible in high-volume centers of excellence performers [10,11].

Compared with their open counterpart, robotic resections have now been shown to be superior in perioperative outcomes with lower intraoperative blood losses and shorter durations of hospitalization [12]. Additionally, the robotic resection approach has been demonstrated to improve the traditionally high morbidity rates and has similar oncologic outcomes to its open counterpart [13].

We present in this chapter a description of robotic resection techniques for pancreaticoduodenectomy (PD) and distal pancreatectomy (DP), focusing on the current data on techniques, safety, morbidity, oncologic outcomes, and learning curve.

Robotic Pancreaticoduodenectomy

Technique of RPD

In the current literature, the definition of RPD has not been standardized, since in many studies the technique was defined as robotic, robotic-assisted, robotic-assisted laparoscopic, or robotic hybrid. Therefore, the current chapter aims to evaluate the current state of total robotic PD, which includes robotic dissection, resection, and reconstruction.

Brief Procedure of RPD [14]

The patient should be placed in a supine position with the legs parted and the table placed at 20° in the reverse Trendelenburg position and tilted to the left side. The robotic surgeon should operate from the dVss console, while the laparoscopic surgeon should stand between the patient's legs. The ports should be placed as shown in Fig. 140.1.

After the diagnostic laparoscopy, the gastrocolic ligament should be opened from left to right until the right colonic flexor is mobilized. The right gastroomental blood vessels should be identified and cut with Hem-o-lok®. The gastroduodenal artery should be ligated with a double proximal end and separated. The common bile duct should be separated using a ligation or clip to avoid overflow of the bile duct, and a frozen section of the edge of the bile duct should be sent for histologic examination.

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Companion website: www.wiley.com/go/beger/thepancreas4e

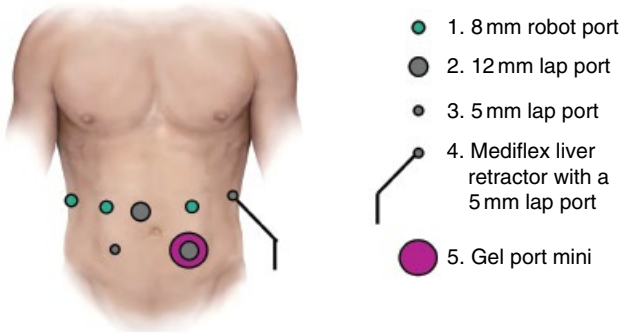

Figure 140.1 Port configuration for robotic pancreaticoduodenectomy.

A Kocher operation should be performed until the first loop of the jejunum is brought to the right of the upper mesenteric vessel by lifting and retracting the duodenum to the left. The pancreatic neck should be separated from the superior mesenteric vein (SMV) and portal vein (PV), the upper and lower borders of the glands sutured, and the glands separated with scissors. A frozen section of the margin of the pancreas should be sent for histologic examination. When the duodenum is retracted to the right, it should be peeled from the distal end to the proximal end along the peripheral plane of the SMA. The pancreaticoduodenal artery and vein should be ligated.

Reconstructive surgery should be performed in the same manner as a laparotomy. The intestinal loop should be rebuilt when the anastomosis is performed. First, the pancreatic stump should be anastomosed with the jejunum. The two-layer end-to-side pancreaticojejunostomy invagination or a catheter-mucosal technique should be used. The hepatic-jejunal anastomosis should be side-to-side, double-layered, and approximately 7–10 cm away from the jejunal limbs and the pancreas-jejunal anastomosis. Duodenojejunostomy or gastrojejunostomy should be performed in two layers, 40 cm downstream of the hepatic jejunostomy.

Outcomes of RPD

Robotic surgery assists surgeons in overcoming many obstacles to the widespread application of laparoscopic pancreatic surgery. The superior visualization, improved three-dimensional imaging, enhanced dexterity, improved ergonomics, and restoration of hand–eye coordination help surgeons complete complex procedures and reconstructions, with results that are at least equivalent to the open approach [7].

Robotic procedures lead to faster recoveries, reduced respiratory complications, reduced wound infections, and shorter postoperative stay compared to open surgeries [15]. Several case–control studies and case series that aimed to evaluate the outcomes of RPD have been conducted, and these showed a significantly lower estimated blood loss (EBL). In addition, the length of hospital stay was significantly shorter in the RPD group with no increase in operative mortality compared to the open cohort. None of the studies to date have demonstrated an improvement in overall morbidity, postoperative pancreatic fistula (POPF) rates, or operative times (Table 140.1).

However, despite the small number of studies demonstrating the feasibility of robotic surgery for PD, safety outcomes must be rigorously scrutinized, and the learning curve needs to be identified for safe use of this platform and to allow for comparisons with other techniques [16–19] (Table 140.2).

LC, learning curve; RPD, robotic pancreaticoduodenectomy; EBL, estimated blood loss; RDP, robotic distal pancreatectomy.

To date, one of the largest series of RPDs has been that reported by Boone et al. from the Pittsburgh Center in 2015 [20]. They conducted a retrospective review of a prospectively maintained database of 200 consecutive patients who underwent an RPD in a large academic center from October 3, 2008, to March 1, 2014. In addition, the important metrics of quality were evaluated. Their data showed that the 90-day mortality rate for the entire period was 3.3%. The mean (SD) operative time was 483 (113) minutes, and the median estimated blood loss was 250 mL (interquartile range, 150–500 mL). Conversion to open surgery was required in 13 patients (6.5%). Thirty-four patients (17.0%) developed a pancreatic fistula (ISGPF grade A, 17 [50.0%]; B, 10 [29.4%]; or C, 7 [20.6%]). Complications occurred in 135 patients (67.5%) with major complications (Clavien–Dindo classification ≥3) occurring in 52 (26.0%) patients. The median length of hospital stay was nine days, with a 90-day readmission rate of 29.2%. An R0 resection was performed in 184 patients (92.0%), with the median number of lymph nodes harvested being 22. No statistically significant differences in mortality or major morbidity rates were observed in this study. As the learning curve increased, statistically significant improvements in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. the estimated blood loss and conversion to open surgery occurred after 20 cases (600 mL vs 250 mL [P = 0.002] and 35.0% vs 3.3% [P <0.001], respectively), decreased incidence of pancreatic fistula was seen after 40 cases (27.5% vs 14.4%; P = 0.04), and a shortened operation time was observed after 80 cases (581 min vs 417 min; P <0.001). Although a continuous improvement in complication rates, lengths of hospital stay, and readmission rates was observed, these did not reach statistical significance. The outcomes of the last 120 cases, which represented optimized metrics beyond the learning curve, showed a mean operative time of 417 minutes, median estimated blood loss of 250 mL, conversion rate of 3.3%, 90-day mortality of 3.3%, clinically relevant pancreatic fistula (grade B/C) rate of 6.9%, and median length of hospital stay of nine days.

Shi et al. conducted a retrospective study on 450 consecutive patients who underwent robot-assisted RPD between May 2010 and December 2018 at Shanghai Ruijin Hospital [21]. The mean operative time and EBL were 309.6 ± 86.7 minutes and 419.0 ± 285.8 mL, respectively. Five cases of conversion to open surgery occurred because of massive bleeding (three cases) and severe vascular invasion by the tumor (two cases). An R0 resection was achieved in 418 (92.9%) patients, with the mean number of lymph nodes harvested being 16. Thirty-nine (8.8%) patients developed biochemical pancreatic leaks. Grade B or C POPF occurred in 44 patients (9.8%). A total of 181 (40.2%) patients developed complications, with severe complications (Clavien–Dindo ≥3) in 32 (7.1%) patients. Seventeen (3.8%) patients underwent reoperation, and the 90-day mortality rate was 2.7% (12 patients). The mean postoperative length of hospital stay was 22.3 ± 14.9 days. As the learning curve increased, the operative time decreased gradually over time from 405.4 ± 112.9 minutes (case 1–50) to 273.6 ± 70 minutes (case 301–350) (P <0.001), and the EBL reduced from 410 ± 563.5 mL (case 1–50) to 149.0 ± 103.3 mL (case 351–400) (P <0.001), respectively. According to the CUSUM curve, three phases were observed in the RPD learning curve. The inflection points were observed in cases 100 and 250. The incidence of a pancreatic leak (fistula) in the last 350 cases was significantly lower than that in the first 100 cases (30.0% vs 15.1%; P = 0.003).

Robot Distal Pancreatectomy

Technique of RDP

After the peritoneum is accessed in a similar fashion to that obtained using the laparoscopic approach, additional trocars should be placed, and the robot docked

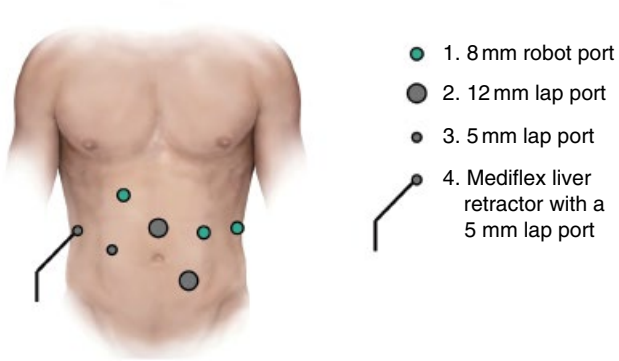

Figure 140.2 Port configuration for robotic distal pancreatectomy.

(Fig. 140.2) [22]. The splenic artery should be isolated at its take-off from the celiac trunk and divided with a vascular stapler. A lymphadenectomy should then be performed, starting from the left side of the SMA laterally, taking out the posterior pancreatic fascia *en bloc*, with a complete celiac lymphadenectomy being performed. With large tumors involving the fourth portion of the duodenum or colon, the robot allows meticulous *en bloc* resections with reconstructions performed in a similar fashion to the open technique [22] (Table 140.3).

Outcomes of RDP

In contrast to open distal pancreatectomy, patients who underwent RDP had decreased length of hospital stay, reduced blood loss, and equivalent complication rates [16]. In view of the need for complex operational requirements, RDP should be carried out in high-volume centers [13].

At the University of Pittsburgh, Shakir et al. studied 100 RDP patients and found precipitous reductions in the operative time from an initial time of 331–266 min and 210 min, after the first 20 and 40 cases, respectively (P <0.0001) [23]. The likelihood of readmission decreased significantly after the first 40 cases (P = 0.04). Nonsignificant reductions were observed in the occurrence rates of major (Clavien–Dindo Grade III or higher) morbidity and Grade B/C pancreatic fistula, as well as the length of hospital stay.

Daouadi et al. retrospectively compared the outcomes of LDP and RDP in a matched cohort [24]. Patients who underwent RDP had comparable age, sex, race, American Society of Anesthesiologists score, and tumor size with those who underwent LDP. The postoperative length of hospital stay and rates of pancreatic fistula, blood transfusion, and readmission were not statistically different. However, patients in the RDP group showed lower

conversion rates to open surgery and less blood loss than those in the LDP group.

Shyr et al. reported a prospective study which included 70 patients who underwent RDP [18]. They found that 37 cases were required to get ahead of the learning curve. The median console time (112 minutes vs 225 minutes, P <0.001) was significantly shorter, and the median blood loss was significantly less (30 cc vs 100 cc; P = 0.003) at the late stage. The clinically relevant pancreatic fistula rate was 22.9%, with 32.4% at the early stage and 12.1% at the late stage (P = 0.043).

Conclusion

Early adopters have guaranteed the safety and feasibility of robotic resection for pancreatic cancer. It is recommended that to perform robotic pancreatic surgery in high-volume pancreatic centers, the volume is as important as the outcomes, and decreasing the learning curve for new centers that may be interested in performing robotic pancreatectomy is critical for the successful and sustainable dissemination of such techniques.

Extended Radical Surgery for Pancreatic Cancer

Thilo Hackert[1], *Anna Nießen*[2], *and Markus W. Büchler*[2]

[1] *Department of General, Visceral and Thoracic Surgery, University Hospital Hamburg-Eppendorf, Hamburg, Germany*
[2] *2Department of General, Visceral and Transplantation Surgery, Heidelberg University Hospital, Heidelberg, Germany*

Introduction

Surgery is possible in only 15–20% of all patients suffering from pancreatic ductal adenocarcinoma (PDAC), by the time of diagnosis, which offers the chance of long-term survival in 20–25% when combined with adjuvant chemotherapy [1,2]. With the ongoing development of specialization and centralization for pancreatic surgery since the late 20th century, not only has postoperative mortality been considerably decreased but also the borders of resectability have been extended [3–7]. This has led to the development of so-called "extended resections" which exceed the standard historic approaches of partial pancreatoduodenectomy and distal or total pancreatectomy. In particular, extended lymphadenectomy, resection of adjacent vessels (superior mesenteric and/or portal vein, celiac axis, superior mesenteric artery) and organs have been performed and investigated in a large number of studies [8–18].

These developments raised the need for a definition and standardization of local resectability to better compare publications on this topic and to establish pathways for the diagnostic and therapeutic management of these patients. Today, the only situation that represents a clear contraindication for surgery is the finding of systemic spread, especially peritoneal carcinomatosis or diffuse liver metastases [19,20]. Regarding limited metastatic PDAC (i.e., single liver metastasis), resections are technically possible and several small case series have been reported [21]. Despite some encouraging results in these studies, surgery in metastatic PDAC remains a highly individual concept and the oncologic outcome is unclear to date [21].

The definition of "extended resection" in PDAC is closely correlated with the definition of "resectability." The critical anatomic structures to evaluate for local resectability in PDAC are the arterial and venous vessels located close to the pancreatic head and body, namely the superior mesenteric (SMV)/portal vein (PV) and the celiac axis (CA) as well as the superior mesenteric artery (SMA).

Resectability is defined as primary resectable PDAC, borderline resectable (BR-PDAC) or irresectable PDAC according to the criteria published by the International Study Group for Pancreatic Surgery in 2014 [16], which are mainly based on the recommendations of the National Comprehensive Cancer Network (NCCN) [11]. Besides these two recently published definitions, two other classifications are in clinical use, namely the definition of the AHPBA/SSO/SSAT published in 2009 [17] and the MD Anderson criteria, published in 2006 [18].

All these definitions are similar with regard to resectable PDAC. This implies that the tumor does not involve any vascular structures (no distortion of SMV or PV and clearly preserved fat planes towards CA and SMA).

Borderline resectable PDAC is characterized by a distortion/narrowing or occlusion of the respective veins but with a technical possibility of reconstruction on the proximal and distal margins of the veins (Fig. 141.1). PV involvement according to the MD Anderson definition does not include contact or narrowing of the vein, but gives occlusion as the criterion for BR-PDAC. With regard to the arterial structures, all definitions describe a semi-circumferential abutment (≤180°) of the SMA or an attachment at the hepatic artery (HA) without contact towards the CA as borderline resectable.

Unresectable PDAC is defined as a more extended involvement of the SMA, CA, aorta or inferior vena cava as well as a SMV/PV venous involvement without a possibility for surgical reconstruction of the venous tract due to lack of a suitable luminal diameter of the feeding and/or draining vein. This situation is most likely to be

associated with tumor-related portal cavernous transformation. Beyond the topic of vascular tumor involvement, the involvement of adjacent organs, i.e., mesocolon, colon, stomach, adrenal gland or kidney, may require extended radical resection approaches. There is international consensus that these extended approaches are feasible in terms of surgical and oncologic outcome and organ involvement should not be considered an obstacle for resection as long as a radical tumor removal is possible [21].

All the above-mentioned definitions of resectability are based on anatomic and technical aspects, but it has become obvious that such considerations do not include tumor- and patient related factors that determine long-term oncologic outcomes to a great extent. As a consequence, these factors have been evaluated and included in a more recent definition of resectability, published by the International Association of Pancreatology (IAP) in 2018 [22]. This consensus includes the pretherapeutic criteria "A: anatomic" (comparable to all other definitions), "B: biological" (depending on level of CA 19-9 and suspicion or proof of positive lymph nodes), and "C: conditional" (defined by the patient's ECOG status), and recommends that patients may be classified as "borderline resectable" based on categories B or C despite given resectability in category A. This may lead to a change in clinical decision, namely offering a neoadjuvant therapy (i.e., in case of unfavorable findings in category B) instead of upfront surgery.

Besides the classification of resectability, the operative procedures themselves have been classified in terms of the extent of surgery. This comprises four-tier classifications for partial and total pancreatectomies, which are specifically defined as "standard" (type 1), additional venous resection (type 2), additional organ resection (type 3), and additional arterial resection (type 4) [23,24]. This classification is based on the fact that procedure-specific complications as well as mortality are significantly different between these four types and allows a standardized reporting of the respective operations and outcomes.

Surgical Procedures and Outcomes

Lymphadenectomy

Lymph node spread is one of the most important prognostic factors for long-term outcome after PDAC resection [25,26]. The extent of lymphadenectomy during PDAC surgery is well defined and included in national guidelines and international consensus statements [27,28]. In partial pancreatoduodenectomy, the lymph nodes of the hepatoduodenal ligament, those along the common hepatic artery, portal vein and the cranial portion of superior mesenteric vein as well as right-sided lymph nodes of the celiac trunk and along the superior mesenteric artery are evaluated [28]. In distal pancreatectomy for tumors of the body and tail of the gland, tumor spread is mainly observed in the lymph nodes attached to the pancreas [29]. Further frequent metastatic sites are the nodes along the splenic artery, the paraaortic area and along the inferior margin of the pancreas as well as along the superior mesenteric artery. These lymph nodes should be routinely removed [30,31].

Lymphadenectomy during total pancreatectomy can be regarded as a combination of the approaches of lymph node dissection in partial pancreatoduodenectomy and distal resection. It includes dissection of the hepatoduodenal ligament, the lymph nodes along the hepatic artery, both sides of the celiac trunk, the splenic artery, and the inferior pancreatic margin. This procedure will usually result in approximately 30–50 lymph nodes included in the resected specimen. The most commonly reported extended approach in lymphadenectomy is the dissection of interaortocaval and paraaortic lymph nodes, especially when these are macroscopically suspicious during exploration [14–18].

Although there are differences between the studies with regard to the total number of harvested lymph nodes and outcome of certain subgroup analyses, there is no evidence that extended lymphadenectomy results in a better oncologic outcome or survival. This is confirmed by a recent metaanalysis including 13 studies and demonstrating that positive paraaortic lymph nodes are associated with significantly worse survival [32]. Furthermore, extended lymphadenectomy is associated with a significantly increased surgical morbidity (i.e., chyle leakage and fluid collections) and decreased quality of life (i.e.,

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

diarrhea and intestinal discomfort) in the postoperative follow-up [18]. Consequently, the concept of extended lymphadenectomy during PDAC resection is not recommended as an uncertain oncologic value is achieved at the price of a high postoperative morbidity.

Vascular Resections

Historically, major vessel involvement has been a contraindication for PDAC resection. In 1973, Fortner described a surgical approach of regional pancreatectomy with *en bloc* resection of peripancreatic soft tissue, regional lymph nodes, and PV resection (type I), or resection and reconstruction of a major artery (type II) [33]. These initial extended resections, which were associated with a high morbidity (67%) and mortality (23%) as well as low survival rates (three-year-survival rate 3%), discouraged generalized adoption of major vessel resection and reconstruction [33]. However, major advances in radiologic and surgical techniques improved preoperative staging and reduced surgical morbidity and mortality [2,3,34].

Venous Resections

Resection of the PV and/or SMV during PDAC surgery can be performed without an increased perioperative morbidity or mortality and with good oncologic outcome compared to standard resections [6–9,11,12,34]. This has been demonstrated in a large number of studies and metaanalyses and has consequently been implemented in national guidelines and consensus recommendations [19,20,35].

Venous resection can be done by either a tangential or a segmental resection [6–9]. A small defect can be closed by direct suture if the vein is not narrowed as this may cause thrombosis in the postoperative course. If a tangential resection defect needs to be augmented, this is possible by an autologous peritoneal patch [36]. In case of segmental resection, the reconstruction requires an end-to-end anastomosis (Fig. 141.2). Depending on the length of the resection, either a direct suture is possible or an autologous venous/prosthetic graft must be inserted. For this purpose, autologous grafting (e.g., renal vein, saphenous vein, internal jugular vein) is possible but requires venous harvesting before clamping and resection [37,38]. Alternatively, a synthetic graft, i.e., a 10–12 mm ringed Gore-Tex® prosthesis, can be chosen to bridge the resected vein segment [39].

When resection of the venous confluence is required during partial PD, the splenic vein should be reinserted by an end-to-side anastomosis as long as this does not create any lateral tension on the anastomosis. This avoids left-sided portal hypertension and restores free drainage

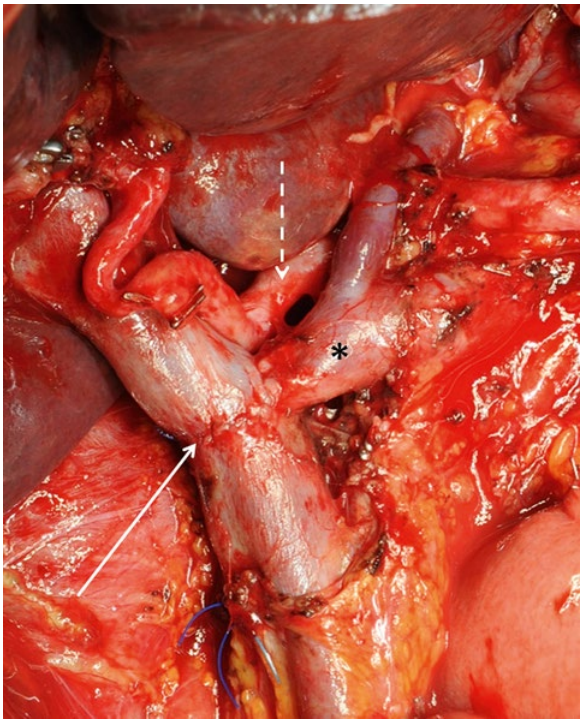

Figure 141.2 Intraoperative situs after PV confluens resection. End-to-end anastomosis (white arrow) between SMV and PV under preservation of the gastric coronary and splenic vein (black star). Celiac axis with splenic artery (broken white arrow) and hepatic artery.

of the stomach. In case of total pancreatectomy with splenectomy, stomach drainage is an important topic as well. In this situation, the gastric coronary vein may be preserved or reinserted, if necessary [40].

Another important aspect during PV/SMV resection is the diameter of the distal venous vessel, especially in tumors located in the uncinate process. The presence of a SMV branch of a sufficient diameter has to be confirmed before resection as otherwise it may be impossible to restore small bowel drainage afterwards, which may be a technical limit for resectability. Furthermore, for all attempts at venous resection, the mesenteric root should be mobilized completely by resolving the attachment of the right hemicolon to the retroperitoneal adhesions (Cattell–Braasch maneuver) [41]. This allows bridging of long distances after resection of the vein, and graft interposition can often be avoided by this approach.

When other surgical outcome parameters are considered, it has been demonstrated that both resection with a direct anastomosis and interposition of a graft can be performed safely. Numerous authors have reported a mortality rate below 5% in patients undergoing venous resection with PD, similar to that of standard PD [6–9, 37–39]. A systematic review [8] of outcome of synchronous PV/SMV resection during pancreatectomy included

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. 52 studies encompassing 1646 patients undergoing venous resection mainly together with partial PD (71%) or total PD (24%). The median morbidity rate for patients undergoing PD with venous resection was 42 %, and the mortality rate was 6% with a median survival of 13 months and one-, three-, and five-year overall survival rates of 50%, 18%, and 8%. Another more recent metaanalysis [9] included 19 studies and compared 661 patients with and 2247 patients without venous resections. Both groups showed similar surgical outcomes without any difference in overall survival. Furthermore, in terms of oncologic results, no difference in overall survival between both patient collectives was found, resulting in a five-year survival rate of 12.3%, certainly superior to palliative treatment. This demonstrates that resection of the PV or SMV is potentially curative and that involvement of the SMV or PV seems to be a consequence of the tumor being located close to these structures rather than a reflection of an uncommonly aggressive tumor biology.

Arterial Resections

Arterial resection during PDAC surgery has remained an area of controversy since Fortner first introduced the concept as part of regional pancreatectomy. Many authors regard invasion of the hepatic artery and celiac axis of the SMA as a contraindication for surgery because of the high morbidity and mortality rates associated with arterial resection and reconstruction as well as assuming a rather poor oncologic outcome [11–13,42].

Recently, with the introduction of effective neoadjuvant and adjuvant therapies, attention is being refocused on the potential benefit of removing the primary tumor, even in the setting of complex arterial abutment or encasement, when this is the only site of disease. Although in some patients, arterial invasion is considered as borderline resectable according to the ISGPS consensus statement, an upfront resection is rarely recommendable, even if it can technically be performed [35]. Furthermore, arterial invasion usually predicts extensive involvement of the mesenteric neural plexus with an inability to achieve a negative resection margin even with radical extended surgery. However, there is growing evidence that patients after neoadjuvant therapy should be subjected to surgical exploration as long as no signs of systemic tumor spread are present. Using this approach, in 33–50% of all primarily unresectable patients, a radical resection might be possible and R0 resection rates comparable to standard resections can be achieved [43–49]. An artery-first approach with evaluation of the SMA and celiac axis should be routinely used early during surgical resection in order to explore arterial as well as retroperitoneal tumor invasion [50–53]. Various artery-first approaches during PD can be carried out, either through a right-sided route after Kocher maneuver or through a left-sided route after lowering the duodenojejunal flexure or by an infracolic route [50]. These techniques offer several oncologic benefits, such as facilitating interaortocaval lymphadenectomy at the origin of the SMA and checking resectability at the retroperitoneal margin.

The first comprehensive metaanalysis on arterial resections included 26 studies with 366 patients undergoing arterial resection and 2243 patients without arterial resection [42]. This analysis showed median perioperative morbidity of 54% and mortality of 12%, respectively. Survival analysis did not show a benefit compared with patients who underwent only venous resection. However, compared with patients who underwent only palliative treatment, the one-year survival was favorable, being threefold greater for patients with arterial resection, especially when resections of the hepatic artery or CA were considered.

Another metaanalysis focusing specifically on SMA resection included a total of 70 patients. It confirmed that the resection is technically possible and various types of reconstruction (i.e., end-to-end anastomosis or grafting with the saphenous vein) are possible [54]. However, as these approaches were burdened by a high morbidity and oncologic outcome finally equalled a palliative therapy with FOLFIRINOX (median survival 11 months), the authors concluded that SMA resections should not be performed.

Despite these initially disappointing results, arterial resection in PDAC surgery has been reappraised in recent years with regard to several larger series that have been published. A single-center cohort study reported that pancreatectomy with artery resection can be performed without increased postoperative mortality and results in five-year survival rates of 23%, clearly superior to palliation alone for patients with locally advanced tumors [55]. Another recent study covering nearly 40 years of experience showed that any type of arterial resection was performed at a frequency of 6% (44/730 patients) but confirmed the safety and efficacy of these operations, additionally suggesting neoadjuvant therapy before arterial resection as a mandatory concept for locally advanced pancreatic cancer [56]. Two more important aspects of such surgical approaches were shown in the two largest single-center collectives of 111 and 195 patients, respectively [57,58]. Both of these studies underline the importance of selecting patients properly as well as gaining sufficient surgical experience demonstrated by the impact of the surgical learning curve to safely perform such procedures.

Overall, these recent publications justify the approach of pancreatectomy with arterial resection and reconstruction. From the technical point of view, after celiac axis or hepatic artery resection reconstruction can be

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 141.3 Intraoperative situs after modified Appleby resection for PDAC of the pancreatic body combined with PV resection (white circle). Cut CA basis (white arrow), dissected SMA (broken white arrow), subcardial cut margin of the stomach (dotted white arrow), cut margin of the duodenum (black arrow), preserved gastroduodenal artery for hepatic perfusion (broken black arrow).

carried out by direct anastomosis, by interposition of a venous graft (i.e., reversed saphenous or internal jugular vein) or with a prosthesis. The celiac axis might be resected down to its aortal orifice in PD as well as in DP or total pancreatectomy. As long as the proper hepatic artery can be preserved, a reconstruction is possible. An arterial graft (i.e., splenic artery) can also be used [59].

Regarding DP, celiac axis resection without revascularization (modified Appleby procedure) is an option for tumor removal as long as the proper hepatic artery is preserved and a sufficient arterial inflow via the gastroduodenal artery is present (Fig. 141.3). Numerous case series have described this procedure with reasonable results in terms of surgical and oncologic outcomes which seem to be nearly equal to the standard approaches [60–67]. According to the larger series in the literature, including more than 10 patients, these procedures can be carried out with mortality rates of 0–7% and an average overall morbidity of around 50%. Median survival in these reports ranges between 10 and 25 months; in the majority of publications approximately 20 months can be achieved. According to these retrospective studies, the modified Appleby procedure seems to be a good option in terms of postoperative and long-term outcome, but no high-level evidence is available to support these findings.

Combined Vascular Resections

Data on combined vascular procedures (venous and arterial resection) are scarce. There is only very limited literature published on this topic, and no conclusive evidence with regard to perioperative morbidity and oncologic outcome is available. The approach is technically feasible, but is not recommended as a standard procedure and must be based on individual decisions.

Arterial Divestment

A novel approach following neoadjuvant therapy is the concept of "arterial divestment" [68,69]. The idea of this technique is the observation that, despite pretherapeutic visible arterial abutment or even encasement, an arterial resection can often be avoided by sharp dissection in the subadventitial layer, as in many patients only fibrous tissue without any viable tumor is found after pretreatment. Consequently, tumor removal without resection of the artery itself is possible without compromising radicality (Fig. 141.4). As this technique has only been introduced recently, there are few data on the oncologic long-term outcome, but postoperative histopathologic workup supports this concept in terms of R0 resection rates.

Multivisceral Resections

If adjacent organs are affected by locally advanced PDAC (i.e., colon, stomach, left adrenal gland, small bowel or left kidney), complete tumor removal requires partial or total resection of these organs, which also fulfills the

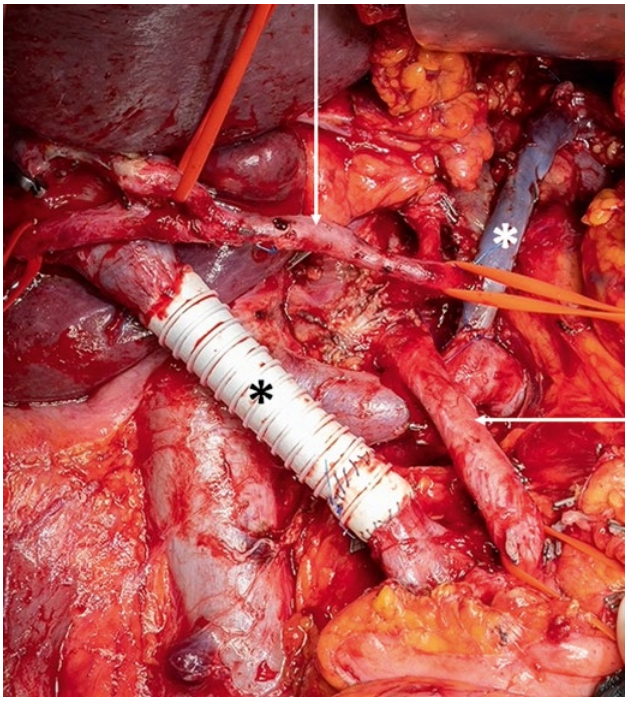

Figure 141.4 Intraoperative situs after total pancreatectomy with divestment of the SMA and hepatic artery (white arrows). Resection of the PV/SMV axis with ringed allograft reconstruction (black star). Reinsertion of the coronary vein into the left renal vein (white star).

criteria of "extended resections" defined by the ISGPS in 2014 [35]. A neoadjuvant treatment is not indicated if technically a complete resection can be achieved based on the preoperative cross-sectional imaging. In larger series, between 20 and more than 270 patients are included and the most commonly resected organs are the colon and stomach [5,10,70–72]. In many patients also PV/SMV resections are often performed synchronously, reflecting local extension of the tumor and the close anatomic relationship of these venous structures.

Multivisceral resections have been investigated in large patient collectives and are associated with increased postoperative morbidity predicted by a long operation time and the resection of two or more additional organs [10,70–72]. Postoperative mortality is not increased unless patients show a relevant preoperative comorbidity. Regarding oncologic outcome, survival is similar to standard resections and in approximately 10–15% of these patients, five-year survival can be achieved, which is clearly superior to any palliative treatment options.

These results underline that extended surgery is a feasible approach if patients are accurately selected for these procedures, as certain subgroups seem to have a much greater benefit from surgery than others. For this purpose, common cross-sectional imaging is not sufficient and other markers need to be defined in the future. Tumor markers, especially CA 19-9, are used in clinical practice. A cutoff value of 400 U/mL has been identified as the threshold for a poor oncologic outcome and may help to stratify patients preoperatively [73].

Metastases Resection

According to international guidelines and clinical practice, stage IV PDAC patients are generally referred to palliative treatment by chemotherapy [2,19,20]. With the administration of modern chemotherapy regimens, a median survival of 11 months can be achieved in a palliative setting [74]. However, these regimens are often associated with severe side-effects that can impair patients' quality of life and no long-term survivors have been reported.

Although it remains unquestionable that PDAC with diffuse tumor spread to the liver, peritoneum or the lung is a situation in which surgery is not indicated, the approach of a surgical resection or liver-directed therapies in oligometastatic situations has been performed in a limited number of studies in the past with partly conflicting results [67–79]. An older metaanalysis published in 2007 [21] showed no clear benefit for resection of metastases. As the study was based on small case series, the level of evidence was highly limited. Previous studies showed more encouraging results with a median survival of 12 months [80], which was superior to historically reported survival times of 6–7 months following palliative monochemotherapy (i.e., gemcitabine) but did not exceed modern palliative multidrug protocols (i.e., FOLFIRINOX). However, especially when such protocols are applied and an additional metastases resection can be performed after induction therapy, the picture has changed and properly selected patients may benefit from metastases-directed surgery, either syn- or metachronously, and achieve up to two years median survival [81].

In addition and most importantly, in contrast to the palliative setting, the addition of metastases-directed surgery to the multimodal approach can enhance the possibility of long-term survival, with five-year survival rates of 10%, which is impossible without surgery in stage IV PDAC and underlines the importance of an interdisciplinary approach and proper patient selection of surgical candidates with stage IV PDAC. Besides synchronous resection in an oligometastatic situation, metachronous approaches to liver metastases have also been reported [76–78,80]. In this context, the interval between the initial and the consecutive operation or liver-directed therapy may be useful as an additional criterion for patient selection, and probably best reflects the tumor biology and potential prognosis of the individual patient. In general, clinical experience suggests that a time interval of 12 months can probably be regarded as a reference, although not based on high-level evidence. As this observation period cannot be used for synchronous resection of liver metastases, the decision for surgery in this situation is even more challenging and additional studies and markers are warranted for prognostic patient stratification and to evaluate these approaches in the future.

Palliative Pancreatic Resection: Is It Justified?

Kira C. Steinkraus[1], Max Heckler[2], Christoph W. Michalski[1], and Felix J. Hüttner[1]

[1] *Department of General Visceral and Transplantation Surgery, Heidelberg University Hospital, Heidelberg, Germany*
[2] *Department of General, Visceral and Transplantation Surgery, University Hospital Heidelberg, Heidelberg, Germany*

Introduction

While surgical removal of the tumor remains the only curative treatment option for patients suffering from pancreatic ductal adenocarcinoma (PDAC), only a minority of diagnosed cases are amenable to undergo resection with curative intent. The main reason is that PDAC is mostly diagnosed in an advanced stage or even with distant metastatatic disease at diagnosis [1]. Another issue is that despite the increasing centralization of pancreatic surgery, referral to a specialized center is often delayed, which provoked claims in recent years that pancreatic cancer should be treated as a medical emergency [2].

For localized or regional stages, resection of the primary pancreatic tumor together with regional lymphadenectomy remains the treatment of choice with the intention to cure. However, if strict pathology assessment is applied, rates of margin-positive resection (R1) are remarkably high (>70%) [3,4]. Nonetheless, in PDAC surgery R1 resection especially on the medial margin is not actually considered as "palliative resection" because a survival benefit and even long-term survival may be observed in these cases. Therefore, the term "palliative resection" is usually only used in cases of gross R2 tumor debulking procedures [5]. The current literature does not support such "palliative resections," or debulking procedures for PDAC, as no improvement of survival has been observed despite substantial morbidity of such procedures [6–9]. Thus, surgical palliation of advanced PDAC should avoid tumor resection and palliation of symptoms should be achieved by interventional procedures and/or bypass surgery [10,11].

Definition of Palliative Resection

Although substantial progress in imaging procedures has been achieved, it remains one of the greatest clinical challenges to accurately evaluate whether a PDAC is in fact locally confined or advanced. While metastases are usually found before treatment initiation, the local resectability is more difficult to assess. Therefore, standardized criteria have now been widely implemented including specific findings of cross-sectional imaging enhanced with biomarkers and conditional factors as criteria of biologic resectability [12]. These criteria can help to guide treatment decisions and avoid unnecessary surgical exploration.

While putative invasion of the superior mesenteric/portal vein axis can be managed surgically in order to achieve margin negativity (at least at the vein margin), tumor extension towards the superior mesenteric artery (SMA) is at times hard to determine in preoperative scanning and in some cases is only detected intraoperatively or even in the final pathology specimen. Similarly, the medial margin (the so-called "mesopancreas") is frequently at risk but can mostly only be judged definitely when the resection has been performed. Thus, exploratory laparotomy followed by dissection of the superior mesenteric artery axis (and/or celiac axis) is sometimes necessary to determine local resectability.

Review of the Literature

The development of higher resolution in cross-sectional imaging and the advance in surgical techniques have led to an increase in patients receiving surgery. A cohort

study including over 16 000 patients receiving pancreatic resection identified an in-hospital mortality of 5% [13], illustrating both the risk of pancreatic surgery and the rising standard of intraoperative and postoperative treatment. However, a multidisciplinary approach and surgical pancreatic expertise are essential in order to allow best patient care and treating these patients successfully. This is essential for initial assessment of tumor resectability, which determines further therapy approaches.

Difficulties of Imaging and Preoperative Staging and Surgical Approaches to Avoid Incomplete Resections

Contrast-enhanced helical computed tomography (CT) (triphasic pancreatic-protocol CT) and/or magnetic resonance imaging (MRI) of the abdomen and pelvis represent the essential diagnostic techniques for preoperative tumor staging and assessment of resectability [14,15]. Involvement and invasion of major abdominal vessels including the SMA, superior mesenteric vein (SMV), portal vein, and celiac axis are crucial determinants of local operability and possible extension of surgery beyond classic procedures such as the Whipple operation.

While venous and/or portal vein involvement are not strict contraindications for a potentially curative approach [16], tumors with advanced arterial involvement are regarded as locally incurable [17]. In such cases, true R0 resections are technically difficult to achieve, and extension of surgery, in terms of major arterial resection, may increase morbidity and mortality. On the other hand, a recent study comparing pancreatectomy with arterial resection to palliative surgery for borderline resectable or locally advanced pancreatic cancer demonstrated a superior one-, three, and five-year survival in the resection group. This study suggests that arterial resection might be feasible and beneficial in highly selected patients [18]. However, such an approach should only be performed in selected cases within a multimodal treatment approach at specialized centers and preferably within clinical studies.

Another approach for locally advanced tumors with arterial involvement, which is currently being assessed in the trial setting, is to split arterial reconstruction and tumor resection into separate procedures. The aim is to reduce perioperative morbidity and mortality in comparison to simultaneous tumor resection with arterial reconstruction. In this trial, patients undergo visceral debranching/arterial reconstruction followed by neoadjuvant chemotherapy and subsequent tumor resection [19].

As an alternative to arterial resection, a novel technique, the so-called subadventitial divestment, has recently been described with promising results. With this technique, which might be of particular interest after neoadjuvant therapy, the periarterial soft tissue is fully cleared in the subadventitial plane, allowing for radical resection without the need for arterial resection [20,21].

The adherent posterior resection margin of the SMA is the most common location of microscopic tumor residues (R1 situation) [4]. Since neither of the cross-sectional imaging modalities provides high accuracy in predicting SMA infiltration, surgical exploration remains the only reliable diagnostic means. During classic pancreatoduodenectomy, the medial and posterior resection margins can only be reliably assessed after transection of the pancreas has been performed. These findings have led to the so-called posterior artery-first approach for locally advanced tumors [22], which allows for precise intraoperative assessment of the SMA before transection of the pancreas.

In addition to palpation and visual control, intraoperative ultrasonography (IOUS) has further increased the accuracy of resectability assessment [23,24]. This illustration of the diagnostic process, which in many cases only begins at the time of laparotomy, suggests that only specialized surgeons in high-volume centers should perform operations on borderline resectable and locally advanced tumors of the pancreas.

Perioperative Multimodal Therapy

Due to highly invasive growth and early-stage metastases, PDAC can almost always be considered a systemic disease. While surgery is the only curative option in early tumor stages, the systemic nature of advanced disease PDAC justifies the need for a multimodal therapeutic approach.

If local unresectability is confirmed intraoperatively, surgery is terminated and chemotherapy or chemoradiation may be initiated. Because FOLFIRINOX-based chemotherapy regimens have been shown to be the most effective, with considerable response rates [25–28], we advocate administering 4–6 cycles of FOLFIRINOX before restaging, followed by pancreas CT staging. If the tumor was primarily unresectable, resection rates after neoadjuvant therapy can be up to 40–50% [29,30] and in borderline cases can even reach >80% [31]. If no distant metastases occur during neoadjuvant therapy and preferably there is a decrease in CA 19-9, reexploratory laparotomy should be performed and resectability judged again, if the patient's performance status is good [32]. This approach has shown

considerable local response to chemotherapy with margin negativity. However, intraoperative judgment is complex because of the remaining local fibrotic tissue, which cannot be differentiated from the presence of remaining cancer cells, resulting in a longer, more demanding operation compared to surgery without neoadjuvant treatment [33]. Intraoperative frozen sections may be helpful in distinguishing the fibrotic tissue from viable tumor tissue.

Another potential therapy approach is intraoperative radiotherapy, which is a treatment option when an intraoperatively obtained frozen section shows margin positivity. A recent systematic review on the topic suggests possible survival benefits for selected patients, but so far without reaching statistical significance [34].

Similarly, irreversible electroporation in patients with locally advanced PDAC has demonstrated promising results in a prospective multicenter study and in a recent systematic review, but higher quality evidence is still needed to finally elucidate its effectiveness [35,36].

Standardized Classification of Margin Status

Verdecke et al. demonstrated that after application of a standardized pathology protocol, a significantly higher number of patients (85%) had a positive margin [3]. Esposito et al. presented similar data and showed that most pancreatoduodenectomy specimens (surgery with curative intent) in their series of 111 patients had a locally incomplete resection (76% R1 resections) [4]. This led the authors to the assumption that a standardized protocol on tissue workup rather than the extent of surgery predominantly determines the R1 status.

An intriguing but difficult-to-prove hypothesis is that R1 status in resected PDAC may be linked to the underlying biologic phenotype. A more aggressive biologic tumor phenotype in R1 resected tumors with an elevated lymph node ratio and more microvascular invasion compared with R0 resected tumors was identified in a study by Kimbrough et al. [37]. This underlines the urgent need for a diagnostic approach reaching beyond macroscopic and microscopic description of the cancer towards a biologic model allowing for individualized, tumor-adapted treatment.

Palliative Surgery

In patients with jaundice and/or gastric outlet obstruction diagnosed with an unresectable tumor, bypass surgery is considered the therapy of choice (see Chapter 144) in order to ensure symptomatic relief. Because debulking is sometimes inevitable, there are a few studies evaluating outcomes after debulking procedures.

A systematic review performed by Gillen et al. [7] included four patient cohorts with a total of 399 patients. Of these patients, 138 received pancreatic resection (R2 status), whereas the others underwent surgical bypass (biliary and/or enteral). Operation time, morbidity, and mortality were significantly increased in the resection group, whereas overall survival was only minimally extended. In line with these results, another systematic review and metaanalysis demonstrated higher morbidity after R1/R2 resections compared to bypass surgery. While R1 resections resulted in improved survival, there was no such benefit for R2 resections compared to bypass surgery only [8]. Thus, both authors conclude that in the context of locally advanced carcinoma, planned incomplete resections should be avoided.

Management of Preoperatively Understaged Patients

Because of the limitations of contemporary diagnostic methods and the resulting vagueness in preoperative imaging, some patients are discovered to have locally advanced tumors during operation. Nevertheless, routine staging laparoscopy is not recommended, due to the limited detection rate and absence of benefit after switching from surgical to endoscopic palliation [38].

For patients without presence of distant metastasis but a locally unresectable primary tumor, surgery is terminated and neoadjuvant therapy indicated. Palliative bypass (biliary and gastric) operations in such patients depend on tumor extent and symptoms. For example, in patients with functional biliary stents, bypass operations are not recommended. However, if the patient has biliary obstruction, biliary and gastric bypass operations are performed. After completion of neoadjuvant therapy, patients are reevaluated. All patients without clear evidence of distant metastasis are offered surgical reexploration, with the intention of tumor resection. In case of intraoperative confirmation of metastases, exploration is terminated. All patients without metastases may receive, if available at the institution, another boost of intraoperative radiation therapy (15 Gy) regardless of resection status, and all tumors classified as resectable after neoadjuvant treatment are removed surgically.

In patients without evidence of distant metastases and a resectable primary tumor, surgery of the tumor will be performed. In cases of tumor-positive margins in the intraoperative frozen sections, patients may receive intraoperative radiation, if available.

In the event of positive SMA and/or celiac trunk margin verification by frozen section after resection of the pancreas is performed, a careful surgical attempt is made in order to convert an R2 resection into an R1/R0 resection (it can also be argued that once tumor integrity is disturbed, it is no longer possible to achieve an R0 resection). It should be emphasized that such an attempt could create a domino effect that may ultimately necessitate the ligation of major vessels or rearterialization of the liver or bowels. Therefore, it should be kept in mind that such procedures may potentially increase morbidity and mortality rates, and they should not be attempted outside referral centers.

Conclusion

Standard palliative pancreatoduodenectomy in PDAC (i.e., with macroscopically positive margins) did not prove to be beneficial over nonsurgical treatment and should therefore not be performed. Nevertheless, with currently limited diagnostic tools, it is inevitable in approximately 10% of patients. Under such circumstances, most R2 resections may be converted to R1 resections with careful and diligent surgery. It should be emphasized that such an attempt is not based on evidence and should only be performed as part of a scientific study in tertiary referral centers. Nonetheless, aggressive surgical approaches are justified, since resection provides the only chance of cure for some, and the best palliation for most, of the patients. Further research to preoperatively stratify the patient cohorts is necessary to identify groups who would benefit from extended resections from those who do not.

Outcome of Patients after R0 Resection for Locally Advanced Pancreatic Cancer Combined with Hepatic Metastasectomy: Indications and Limitations

Tingbo Liang

Department of Hepatobiliary and Pancreatic Surgery, First Affiliated Hospital of Zhejiang University School of Medicine, Zhejiang Provincial Key Laboratory of Pancreatic Disease, Hangzhou, China

Introduction

Surgical resection of pancreatic cancer combined with systemic chemotherapy offers the only chance for cure of this disease. However, over 50% of patients diagnosed with pancreatic cancer are deemed to have unresectable disease because of distant metastases [1]. The liver is the most common site of pancreatic cancer metastases, accounting for over 50% of all cases [2]. In pancreatic cancer patients with liver metastasis, the prognosis is extremely poor, with a five-year survival rate of less than 1% [3]. Because of the dismal prognosis and the lack of high-quality evidence, surgical resection is generally contraindicated in the current guidelines when synchronous liver metastases are present at the time of surgery.

The only exception may be oligometastases, which are regarded as an intermediate stage between localized disease and widespread metastatic disease [4]. There has been increasing interest in exploiting the role of curative surgical resection, which has been used to successfully treat colorectal and neuroendocrinal tumors with liver oligometastases. Available data suggest that curative pancreatectomy in combination with metastasectomy may benefit some highly select patients with liver oligometastases. In a recent large international survey, 31.4% of the pancreatic surgeons interviewed would conduct surgical exploration and offer possible resection for oligometastatic liver metastases to patients with resectable disease who had an excellent response to neoadjuvant therapy [5]. However, in view of current evidence derived from retrospective analyses, case series, and case reports, questions regarding the surgical and oncologic outcomes, indications, and contraindications of hepatic metastasectomy have yet to be answered.

Outcomes

For pancreatic cancer patients with synchronous liver metastasis, resection with curative intent involves radical pancreatectomy with concomitant hepatic metastasectomy. It is clear that any possible benefit should be carefully weighed against the potential risk of such an aggressive surgical approach. This procedure would only be justified by a good safety profile in the short term and a survival benefit in the long term after surgery. However, currently available data regarding the outcomes of such procedures are from small retrospective cohorts and are deemed insufficient and inconclusive.

Survival

The first case series in the literature on synchronous resection of liver metastases and pancreatic tumors dates from 1996 [6]. In this report, curative R0 resection was achieved in 69% of patients with synchronous liver metastases (N = 16). The median survival time was 8.3 months after synchronous hepatic resection.

In the largest retrospective study conducted thus far, reported by Andreou et al., 76 patients who underwent resection for pancreatic cancer and concomitant hepatectomy for synchronous liver metastases were analyzed [7]. The one-, three-, and five-year overall survival (OS) rates were 41%, 13%, and 7%, respectively. The second largest study, conducted by Tachezy et al., enrolled 69 patients who underwent pancreatic resection and synchronous hepatic metastasectomy [8]. They reported that OS was prolonged in the group of resected patients (median 14 vs 8 months). Interestingly, in the subgroup analysis, only patients with tumors located in the

Companion website: www.wiley.com/go/beger/thepancreas4e

pancreatic head benefited from surgery, while those with tumors in the pancreatic body and tail received no benefit from resection.

Another study, by Hackert et al., analyzed the outcomes of 85 patients after pancreatic and concomitant liver resection, of whom 62 patients underwent synchronous hepatic metastasectomy [9]. The median survival for the whole cohort was 12.3 months, and it was 10.6 months for patients undergoing synchronous hepatic metastasectomy. No significant difference in survival outcomes was observed between the synchronously and metachronously resected patients regardless of neoadjuvant treatment, tumor localization in the pancreas, number and size of liver metastases, and preoperative CA 19-9 levels.

The most promising survival outcome thus far has been reported by Frigerio et al. [10]. In their relatively small cohort (N = 24), only patients who achieved successful downstaging (disappearance of liver metastasis on radiologic examination, normalization or significant reduction in serum CA 19-9) after neoadjuvant chemotherapy were enrolled. Unsurprisingly, R0 resection was achieved in 88% of patients, and the median OS reached 56 months.

Although the above studies favor resection, there are also studies that failed to show a possible survival benefit following synchronous liver resection. Dünschede et al. reported on 14 patients who underwent synchronous liver resection for metastatic pancreatic cancer [11]. They found no differences in the survival outcomes of patients with synchronous liver metastases of pancreatic cancer treated either by resection of the primary tumor combined with partial hepatectomy or by gemcitabine (8 vs 11 months).

Safety

Although the safety of pancreatic resection has dramatically improved, it is still a challenging procedure. Undoubtedly, synchronous hepatic metastasectomy further increases the complexity of surgery and thus theoretically contributes to higher morbidity and mortality. This concern is indeed supported by some early reports [12,13]. However, reports over the last few years, including the three largest series, showed comparable surgical morbidity and mortality outcomes [7–9]. The safety of such extended resections seems acceptable provided that the procedures are performed in high-volume centers.

Indications

The currently limited evidence indicates that synchronous pancreatic and liver resection for metastatic pancreatic cancer can be carried out safely. It is still far from clear who is most likely to benefit from such extended resections. Thus, establishing criteria upon which patients can be selected to undergo synchronous pancreatic and liver resection is necessary. Based on the currently available data, a low metastatic burden and a good response to neoadjuvant therapy are generally considered potential indications for curative surgery.

Metastatic Burden

In metastatic pancreatic cancer, widespread or high-volume metastases contraindicate resection with curative intent. For liver metastasis, oligometastatic disease makes curative synchronous pancreatic and liver resection possible. Unfortunately, the term “oligometastases” in pancreatic cancer has been poorly defined in the literature [4,14]. Recently, Damanakis et al. proposed a new definition of oligometastatic disease from pancreatic cancer that incorporated biologic behavior into the criteria [15]. Patients with fewer than five metastases in a single organ, serum CA 19-9 baseline <1000 U/mL (with bilirubin <2 mg/dL), and responsive or stable disease after first-line chemotherapy were considered to have oligometastatic disease. In this study, 10 patients meeting the criteria had a significantly longer OS time (median 19.4 vs 7.2 months) than the remaining patients.

The combination of anatomic and biologic criteria may facilitate candidate selection for surgery. However, clinicians should still be prudent when making a diagnosis of oligometastatic disease. A thorough evaluation of tumor burden using multimodality imaging techniques, including contrast-enhanced computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET)-CT, is warranted. Biomarkers including serum tumor markers, circulating tumor cells or DNAs, and gene mutations that may reflect the biology of the tumor should be taken into account if available. Recommendations for surgery should be made within the framework of a multidisciplinary panel.

Neoadjuvant Therapy

According to current guidelines [16], neoadjuvant therapy is recommended for patients with borderline resectable and locally advanced pancreatic cancer. The rationale for neoadjuvant therapy includes downstaging or downsizing of the tumor, elimination of occult micrometastases, and early assessment of tumor biologic behavior to facilitate the selection of patients who can potentially benefit from aggressive surgery [17].

For patients with potentially resectable pancreatic cancer, a good response to neoadjuvant therapy paves

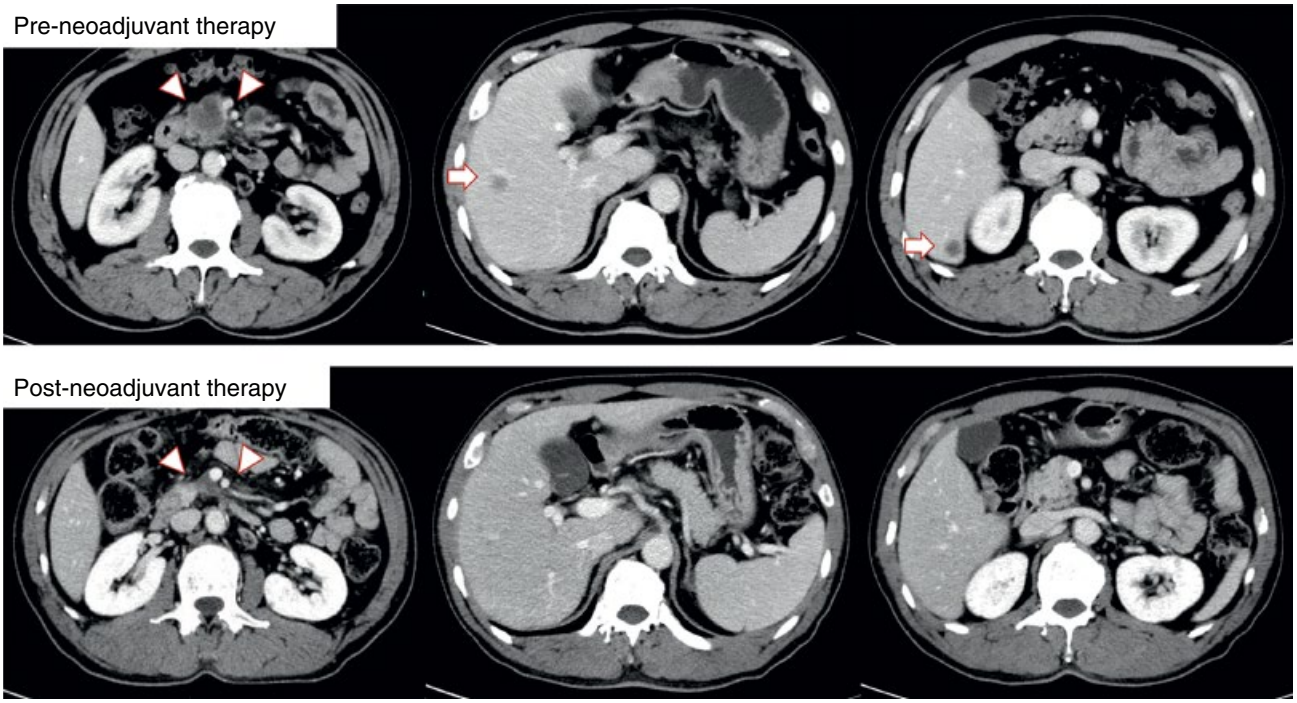

Figure 143.1 A case of locally advanced pancreatic cancer with multiple liver metastases. After six months of neoadjuvant therapy, the primary tumor (arrowheads) decreased in size, and all liver metastases (arrows) disappeared on imaging. Pathologic evaluation of resected specimens confirmed a complete response of the primary tumor and liver metastases.

the way for surgical resection. This may also be the case for patients with metastatic disease, as efficient neoadjuvant treatment may not only shrink the primary tumor but also control or even eliminate metastases in select cases (Fig. 143.1). This may at least partially explain why survival results from some older studies are dismal, while the results from other, mostly recent reports are promising. Indeed, most satisfactory survival data of synchronous pancreatic and liver resection come from cohorts in which neoadjuvant therapy was administered and a good response was achieved prior to surgery. In several small cohorts, patients who had a good response to neoadjuvant chemotherapy and underwent pancreatic and liver resection had a significantly longer survival time than patients who did not undergo subsequent resection [7,10,18]. In the report by Andreou et al., no preoperative chemotherapy was an independent predictor for worse OS in the multivariate analysis [7].

The criteria for surgical intervention after neoadjuvant therapy are also ambiguous. Although the potential benefit of neoadjuvant therapy in the setting of borderline and locally advanced disease is well established based on current knowledge, less evidence is available with regard to the timing of surgery when a good response to neoadjuvant therapy is achieved. As indicated in the NCCN guidelines [16], resection for locally advanced pancreatic cancer should be considered if there is a >50% decrease in the CA 19-9 level and clinical improvement in performance status, pain, early satiety, and weight/nutritional status. In the setting of metastatic pancreatic cancer, little if any evidence evaluating the timing of surgery is available. In particular, indicators of a favorable response and the time interval before surgery are far from being clarified.

In the study by Frigerio et al., indicators of successful downstaging for surgery included disappearance of liver metastasis and reduction in serum tumor marker CA19-9 [10]. In another study, conducted by Crippa et al., surgical resection was only considered if a major biochemical response and a complete or a major radiologic response of the liver metastases were observed [18]. It has been reported that changes in the CA 19-9 level could be used to improve the selection of borderline and locally advanced pancreatic cancer patients who can benefit from resection after primary chemotherapy [19]. However, for metastatic pancreatic cancer, large-scale studies are needed to clarify the role of CA 19-9 in surgical decision making.

Conclusion

Along with advancements in preoperative evaluation, neoadjuvant therapy, surgical techniques, and adjuvant therapy in recent years, synchronous resection of pancreatic tumors and liver metastases in highly selected patients has been proven to be feasible and even to prolong patient survival in some small case series. Based on the current evidence, patients with a low metastatic burden, or so-called oligometastases, who show a good response to neoadjuvant therapy appear to benefit the most from such an aggressive surgical approach. However, no prospective trials have been conducted to confirm this notion. Thus, the exact oncologic benefit cannot be fully assessed beyond individual clinical experiences, and the selection of candidates who could benefit most from surgery remains challenging.

A thorough evaluation of the metastatic burden, both anatomically and biologically, and precise assessment of the response to neoadjuvant therapy should be performed in future studies.

Introduction

Irrespective of recent developments in multimodal therapeutic concepts, complete surgical resection is still the only curative therapy for pancreatic cancer [1]. However, most cases of pancreatic cancer are diagnosed at an advanced stage and thus, only a small percentage of patients are candidates for curative surgery [2]. At the time of diagnosis, approximately 50% of patients have distant disease, approximately 30% have regional or locally advanced disease, and only about 15–20% of patients are diagnosed in a localized stage eligible for potentially curative resection [3,4].

The five-year relative survival rate for all patients with pancreatic cancer remains around 10% [4]. Therefore, palliative therapy is needed in a considerable number of patients not eligible for curative-intent surgery to reduce or prevent symptoms [5]. Furthermore, histologic confirmation should be obtained in potentially palliative cases detected during exploratory laparotomy in order to guide further treatment. Palliative therapy primarily aims to reduce pain, obstructive jaundice and malignant gastric outlet or duodenal obstruction. The latter two are nowadays most frequently palliated using endoscopic and interventional methods, but can also be treated with bypass surgery.

However, the potential benefit of a surgical procedure must be weighed carefully against perioperative morbidity and length of hospital stay. This holds particularly true for patients with a presumed limited life expectancy. The decision to perform a surgical bypass procedure is made in patients in whom the tumor was initially deemed resectable, in those where endoscopic/interventional therapy is technically impossible, or in select cases with a potentially good prognosis (e.g., over one year of expected survival). This chapter focuses on the indications for surgical bypass procedures and the respective operative techniques and approaches.

Background

Before the mid-1980s, palliation of biliary and/or duodenal obstruction was provided primarily through surgical bypass [6]. In some series, up to 57% of patients with unresectable pancreatic cancer underwent surgical bypass [7]. Palliative surgical bypass of the gastrointestinal and biliary tracts has been the reference standard of therapy in many of these cases [8]. Due to great improvements in interventional and endoscopic therapies, palliation of jaundice and/or gastric outlet obstruction is nowadays mostly performed endoscopically.

Symptoms

While tumors in the body and tail of the pancreas mainly cause epigastric or back pain, those in the head of the gland cause a variety of symptoms including obstructive jaundice, gastric outlet or duodenal obstruction, and symptoms of exocrine insufficiency due to obstruction of the main pancreatic duct [9].

Biliary obstruction with jaundice is the most frequent presenting symptom [10]; it occurs in about 60–80% of patients with tumors of the pancreatic head. In patients with a carcinoma of the body or tail of the pancreas, it may occur in the late course of the disease and thus only rarely requires palliative bypass procedures. Because obstructive jaundice causes malaise, malabsorption and anorexia, severe and resistant pruritus, and impaired

liver function leading to liver failure, its palliation is clinically important. Mechanical gastric outlet obstruction historically occurs in only 2–25% of patients without surgery, but with new advances in chemotherapy and radiation, the life expectancy of pancreatic cancer has increased and up to 38% of patients eventually develop symptomatic duodenal obstruction requiring duodenal stent or surgical bypass [11]. This rate will likely increase further in the upcoming years as patients survive longer with advances in multimodal therapy for pancreatic cancer. Yet, importantly, nausea and vomiting occur in the majority of pancreatic cancer patients without suffering from duodenal obstruction. This is attributed to retroperitoneal infiltration of autonomic nerve plexus leading to gastric dysfunction and cannot be sufficiently palliated by a bypass procedure [12].

Biliary Bypass Procedures

Endoscopic stenting through endoscopic retrograde cholangiopancreatography (ERCP) is widely accepted as the standard palliative treatment for patients with malignant biliary obstruction [13,14]. Due to the low invasiveness of the procedure, endoscopic stenting relieves biliary obstruction within a short period of hospitalization. Palliative endoscopic transpapillary drainage was first described in 1980 [15] and nowadays endoscopic decompression has a 99% technical success rate and low morbidity and mortality [16].

Although endoscopic stenting is the preferred method for treating bile duct obstruction, it is technically unsuccessful in a considerable number of patients because of altered anatomy or duodenal obstruction [17]. In such cases, biliary stenting can be performed via percutaneous transhepatic drainage (PTCD) or as endoscopic ultrasound-guided biliary drainage (EUS-BD). PTCD, which was initially described in 1974 [18], is a valid option, despite the higher risk of major complications (i.e., bleeding, biliary fistula, liver abscess) and its conflicting therapeutic success rate [19,20]. With EUS, technologic advances in recent years have rapidly translated into the shift of endoscopic ultrasound from a strictly diagnostic tool into an interventional and therapeutic option as well. EUS-BD is feasible with excellent technical success, limited adverse events, and a beneficial effect on cancer-associated pain [21].

Despite the success of endoscopic treatment of biliary obstruction, surgery continues to be an important alternative option for select patients. Surgery was historically the first option as a biliodigestive bypass procedure and the initial techniques were described as cholecystojejunostomy by Monastyrski in 1887, as choledochoduodenostomy by Sprengel in 1891, and as hepaticojejunostomy by Dahl in 1909 [22]. Cholecystojejunostomy is a relatively simple procedure but has low long-term patency rates, with 8–11% of recurrent jaundice compared to 0–3% after choledochojejunostomy [7]. In a large cohort study of 1919 patients, cholecystoenterostomy was significantly inferior to other bypass procedures [23]. Similarly, in a small randomized controlled trial (RCT) comparing cholecystoenterostomy to choledochoenterostomy, the latter resulted in fewer postoperative complications and fewer failures of the biliary bypass [24].

Occlusion of the cystic duct might explain the lack of long-term patency since the hepatocystic junction was located most frequently within 1 cm distance from the biliary obstruction. Because of this anatomic situation, cholecystojejunostomy was frequently found to be inadequate for the permanent relief of recurrent obstruction [25]. We believe that this procedure is only an option in cases where dissection of the porta hepatis is technically challenging, for example because of local variceal conversion due to portal hypertension/portal vein thrombosis. Hepaticocholecystojejunostomy is another potentially viable alternative to hepaticojejunostomy with similar functional results but a technically less demanding construction of the bypass [26,27].

While laparoscopic biliary decompression is feasible in principle, laparoscopy does not easily allow for judging resectability to the same extent as during open surgery. It is thus infrequently used and has not been established widely in clinical practice [28,29]. Robotic surgery may facilitate the judgment of resectability and also the technical procedure of minimally invasive biliary bypass, but there are very few reports about palliative robotic surgery in pancreatic cancer in the literature [30].

Gastroduodenal Bypass Procedures

The placement of a nasogastric tube or percutaneous gastrostomy is an option for palliative gastrostomy that reduces quality of life substantially and does not give nutritional support for the patient. The endoscopic method of bridging malignant stenosis with a (self-expandable) metal stent has been proven to be an alternative to surgical bypass [31]. Equally, EUS-guided gastroenterostomy has recently been shown to be a safe and effective method for malignant gastric outlet obstruction [32].

Surgical gastric bypass was initially described by Wölfler and Wosler in 1881 in an antecolic way. Retrocolic gastrojejunostomy was performed first by Courvoisier in 1883 with the patient not surviving the operation, while von Hacker performed it successfully in 1885. After years of debate about the value of gastrojejunostomy due to high morbidity and mortality, the results

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of gastroenterostomy have improved significantly [33]. Today's standard side-to-side gastrojejunostomy can be performed in antecolic or retrocolic fashion, with delayed gastric emptying still being a relevant clinical issue after the procedure [34]. Through developments in minimally invasive surgery the procedure can now be laparoscopically performed in suitable patients [32].

Prophylactic retrocolic gastrojejunostomy at diagnosis of unresectable disease during explorative laparotomy was studied by Lillemoe et al. [8]. They showed an increase in operation length as expected, but no differences in blood loss or transfusion or in postoperative morbidity and mortality, including delayed gastric emptying rate, length of hospital stay, and mean survival (8.3 months) compared to no gastric bypass. About 80% of patients received additional hepaticojejunostomy. Late gastric outlet obstruction appeared more frequently in the control group (19% vs 0%, $P = 0.01$) after a median of two months. Therefore, the authors concluded that prophylactic gastrojejunostomy should be performed routinely in patients with unforeseen unresectable periampullary cancer. This was later confirmed in a meta-analysis and systematic review [33].

Van Heek et al. [34] compared double bypass (hepaticojejunostomy and retrocolic gastrojejunostomy) to single bypass, finding no significant differences in terms of postoperative morbidity including delayed gastric emptying, length of hospital stay, survival, and quality of life. Gastric outlet obstruction occurred significantly more often in the single bypass group, leading to an increased rate of repeat gastrojejunostomy. A longitudinal analysis of quality of life after double bypass by the same authors showed that quality of life can be preserved for a considerable time [35]. Similarly, Jeurnink et al. demonstrated in a RCT of 39 patients with malignant gastric outlet obstruction (28 with pancreatic cancer) that surgical gastrojejunostomy resulted in better long-term results, while stent placement resulted in more rapid symptom relief. Thus, they concluded that gastrojejunostomy should be considered in patients with a life expectancy of >2 months [36]. If a palliative gastrojejunostomy is performed, a Roux-en-Y reconstruction should be considered, since it may result in lower rates of delayed gastric emptying and a shorter hospital stay, as shown in the trial by Szymanski et al. [37].

In 2018, a Cochrane review compared interventional and surgical palliation for malignant gastric outlet obstruction. The authors found that duodenal stent placement has the benefits of a quicker resumption of oral intake and a reduced hospital stay; however, it was also associated with earlier recurrence of symptoms and higher reintervention rates compared to surgery [38]. In another Cochrane review investigating prophylactic gastrojejunostomy in patients with periampullary cancer that were unresectable at exploratory laparotomy, the authors found a significantly lower rate of long-term gastric outlet obstruction. Thus, they concluded that surgical gastrojejunostomy remains the reference standard of care in this situation [33].

Comparison of Endoscopic Versus Surgical Approach

In general, surgical bypass has been linked to a higher risk of morbidity and mortality but better long-term patency [39]. In 2020, Fabian et al. published a meta-analysis comparing palliative double stenting for malignant duodenal and biliary obstruction with surgical double bypass [16]. Clinical success of endoscopic biliary stenting was higher than that of surgery and double stenting was associated with fewer adverse events but more frequent need for reintervention than double bypass. In line with these data, the incidence of recurrent jaundice in surgical patients is consistently lower than that in stented patients even though surgery itself tends to be associated with a higher early complication rate [40–42].

Apart from the biliary bypass, two randomized controlled trials demonstrated that an additional prophylactic gastrojejunostomy (i.e., double bypass) is effective in preventing the development of potential gastroduodenal obstruction without increasing surgery-related morbidity and mortality [8,34]. However, surgery itself is more extensive and may significantly affect the quality of life of patients with a short life expectancy. Advantages of surgical bypass increase with longer survival of the patient, avoiding frequent readmissions and recouping initial higher costs with fewer future management costs than in nonsurgical patients [43]. Thus, surgical bypass is a good option for those patients in whom unresectable cancer is found during surgery for planned tumor resection, and also occasionally for patients who have a relatively long life expectancy [8,44]. Several factors were found to predict early mortality following palliative bypass: presence of distant metastatic disease, poor tumor differentiation, severe preoperative nausea and vomiting, and lack of previous placement of a biliary stent [45]. These factors may be helpful in selecting appropriate interventions for this group of patients undergoing a palliative bypass procedure. Nevertheless, individual clinical judgment is still important when discussing options with the patient.

Importantly, the recent increases in survival even in Stage IV disease using polychemotherapy [46] may render surgical bypass a more frequently used procedure in the near future. Vreeland et al. recently published an analysis of patients who underwent surgical exploration with planned partial pancreatoduodenectomy after neoadjuvant therapy. Of 271 patients, 47 (17.3%) planned

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

resections were intraoperatively aborted, of which six underwent hepaticojejunostomy and nine underwent gastrojejunostomy. Although 53% of patients without a biliary bypass required endoscopic biliary intervention and 37% required intervention for gastric outlet obstruction in the further course of their disease, all cases were manageable without palliative surgery. Thus, they concluded that prophylactic surgical bypass is not required during aborted partial pancreatoduodenectomies [47].

Current Approach and Future Perspectives

Given the current data, a double bypass procedure with gastrojejunostomy and hepaticojejunostomy should still be considered in symptomatic patients with pancreatic cancer that is deemed unresectable during surgical exploration to reach palliation of these symptoms in one definite procedure [48]. Patients with primarily unresectable disease should undergo endoscopic biliary drainage, but surgical bypass may also be considered in select cases with a presumed favorable survival time. However, constant improvement in preoperative staging in recent years has led to a significant reduction in the number of such bypass procedures. On the other hand, the progress in multimodality treatment may considerably increase survival time for many patients, which in turn may again increase the number of surgical bypass procedures as the definitive long-term palliation method. In order to keep the surgical trauma as well as postoperative morbidity as low as possible, the role of minimally invasive surgery and in particular the robotic approach needs to be explored in future trials.

Another crucial aspect, which is currently underrepresented in the literature, is the perspective of patients. Future research on this topic needs to assess patient-reported outcome parameters, e.g., quality of life, as a central aspect and in a structured way. Furthermore, individual patients' perspectives and wishes should be considered in detail in the decision-making process on palliative measures to tailor a personalized approach in each case.

Endoscopic and Interventional Palliation of Pancreatic Cancer

Kazumasa Nagai and Takao Itoi

Department of Gastroenterology and Hepatology, Tokyo Medical University, Tokyo, Japan

Introduction

Cases of pancreatic cancer have been rapidly increasing worldwide. The latest data show that the number of cases of pancreatic cancer has increased to more than 60 000 in the USA [1]. It is well known that most pancreatic cancers are usually in their advanced stage when they are detected. In fact, more than 80% of patients present with disease that is not surgically resectable [2]. Furthermore, most patients with advanced pancreatic cancer show resistance to adjuvant therapies such as chemotherapy, resulting in a mortality of more than 49 000 in the USA [1].

The main problem with unresectable pancreatic cancers is that they cause various complications, such as obstructive jaundice, gastric outlet obstruction, abdominal pain, pancreatic duct obstruction, and pancreatitis, according to cancer progression. This consequently delays the start of adjuvant therapy. Surgical interventions such as choledochojejunostomy and gastrojejunostomy in such patients are usually not indicated because they are more invasive. Surgical interventions may also cause delay in starting adjuvant therapy.

At present, nonsurgical interventions such as interventional endoscopy (IVE) and interventional radiology (IVR) allow palliative therapy in most cases. In terms of endoscopic therapy, endoscopic ultrasonography (EUS) has become widely used in selected institutions in addition to therapeutic endoscopic retrograde cholangiopancreatography (ERCP) for the treatment of such complications. This chapter reviews the latest palliation in pancreatic cancer by IVE and IVR.

Biliary Obstruction

Malignant biliary obstruction, particularly in the extrahepatic bile duct, is the most common symptom in patients with advanced pancreatic cancer. The progression of biliary obstruction causes mainly cholestasis and jaundice, and rarely cholangitis, leading to fat malabsorption, malnutrition, and cachexia. Absence of therapy for obstructive jaundice leads to exacerbation of liver dysfunction and eventually liver failure.

Thus, biliary drainage has been traditionally performed to improve the quality of life of patients. For resectable pancreatic cancer with jaundice, preoperative biliary drainage (PBD) has been preferred to improve the postoperative morbidity and mortality rates. However, recent high-quality studies [3,4] have reported that PBD should not be performed routinely. However, there are several reports in the literature on the selection of drainage methods (mixed procedures, percutaneous transhepatic biliary drainage [PTBD], and endoscopic drainage by ERCP) and endoscopic stent selection (small-bore plastic stent). Recently, PBD using a large-bore metal stent has been reported as a preferable technique of biliary decompression with a low adverse event rate as a bridge to surgery [5].

Traditionally, biliary decompression in patients with unresectable pancreatic cancer has been conducted by ERCP and PTBD as nonsurgical and palliative interventions. The choice of drainage method depends on the preference of the principal physician and the presence of skilled ERCP endoscopists and interventional radiologists in each institution [6]. Recently, endoscopic

ultrasonography-guided biliary drainage (EUS-BD) has emerged as a salvage therapy in cases of failed ERCP [7].

Palliation of Obstructive Jaundice by ERCP

(Table 145.1)

Conventional ERCP

Endoscopic plastic stent placement by ERCP is the most common procedure for biliary decompression since the first report by Soehendra and Reynders-Frederix in 1980 [8]. Early randomized controlled trials (RCTs) revealed that endoscopic plastic stent placement has a similar outcome in terms of technical success, morbidity, and mortality, or is more preferred to reduce morbidity (P = 0.02) and mortality (P = 0.01) in the palliation of biliary obstruction than surgical intervention [9,10]. Plastic stents are usually used for the initial biliary drainage because they are less expensive and can be removed easily while pancreatic masses are evaluated. On the other hand, self-expandable metal stents (SEMSs) were developed in 1989 for the palliation of biliary obstruction [11,12]. Theoretically, a large-bore stent (approximately 8–10 mm) allows long stent patency, reducing the number of reinterventions compared with small-bore plastic stents (7–10 Fr). Plastic stent occlusion occurs within four months compared with SEMS occlusion which occurs at about nine months to nearly one year. Thus, the Cochrane review suggests that SEMSs are preferable to plastic stents in patients with an expected survival period of more than four months because of lower numbers of stent failure, decreased total hospitalizations secondary to stent-related issues, a lower risk of cholangitis (relative risk [RR] 0.48), and overall low costs [13].

However, recent progress in adjuvant therapies such as chemotherapy has allowed prolongation of survival time. Furthermore, cholangitis due to stent occlusion causes an interruption of scheduled chemotherapy. Thus, SEMSs may be suitable for biliary decompression at the first session as a first-line stent once pancreatic cancer is definitively diagnosed and as long as standard chemotherapy is scheduled. In fact, Davids et al. [14] have suggested that the initial use of SEMSs results in a 28% decrease in overall procedures compared with the initial use of plastic stents. Even in the case of borderline resectable pancreatic cancer undergoing neoadjuvant therapy, SEMSs appear to be preferable to avoid preoperative serious complications [3,15]. A more recent RCT has demonstrated that endoscopic metal stent placement has a similar outcome for palliation of the biliary obstruction when compared with surgical bypass in patients with metastatic pancreatic cancer [16].

At present, two types of SEMSs are used: uncovered SEMSs and fully/partially covered SEMSs. Theoretically, as covered SEMSs can preclude tumor ingrowth, these stents have prolonged stent patency. In contrast, SEMSs have the possibility of inward and outward stent migration and may cause acute cholecystitis due to cystic duct obstruction. Recent metaanalyses have shown that the superiority of covered SEMSs is controversial compared with uncovered SEMSs [17,18]. However, a more recent RCT has demonstrated the usefulness of covered SEMSs [19]. The uncertain conclusion may be due to several biases such as heterogeneity of diseases and stent selection (i.e., stainless or nitinol, braided type or laser cut type, fully covered or partially covered, and with or without an antimigration system).

One of the most critical issues of endoscopic stenting is reintervention owing to stent dysfunction. Although a plastic stent is easily exchanged with a new stent, removal of SEMSs, particularly uncovered SEMSs, was usually not considered possible. Thereafter, the stent-in-stent technique (i.e., a new stent within the existing occluded metal stent) is performed using a plastic stent or an uncovered/covered SEMS. Theoretically, a large-bore second SEMS appears effective, but one study has demonstrated that plastic stent placement may be as effective as second SEMS placement [20]. These data suggest that an occluded first SEMS may impair the second SEMS.

Recently, a new concept of removal of SEMSs, that is, mostly covered SEMSs and rarely uncovered SEMSs, has emerged when stent occlusion occurs [21,22]. Furthermore, one study has demonstrated that covered SEMSs could be safely removed at the time of stent occlusion and that the patency rates were similar for the initial stent placement and the reintervention [23].

Roux-en-Y (RY) reconstruction, including RY gastrectomy and RY gastric bypass, is always a challenging procedure. Traditionally, conventional colonoscopy has been used in such patients but the success rate was not very high (<50%). Recently, single-balloon enteroscopy (SBE) and double-balloon enteroscopy (DBE) have allowed access to the papilla and successful endoscopic procedures in the setting of RY reconstruction [24–26]. Thus, most patients with biliary obstruction in the case of pancreatic cancer and RY reconstruction can be treated by balloon enteroscopy (BE)-assisted ERCP [27].

In patients following pancreatoduodenectomy (Whipple resection), malignant or benign stenosis of the hepaticojejunostomy site causes obstructive jaundice with or without intrahepatic bile duct stones. BE-assisted ERCP is also useful for resolving the stenosis by balloon dilation or stent placement in such patients [28].

Palliation of Obstructive Jaundice by EUS

Selective biliary cannulation by ERCP for biliary decompression is not always successful, even when performed by ERCP experts, for several reasons, including intradiverticular papillae, surgically altered anatomy, or gastroduodenal obstruction. Traditionally, in the case of failed ERCP, PTBD has been performed as a useful and safe salvage technique. EUS-BD has emerged as another salvage technique, reported by Giovannini et al. in 2001 [29]. EUS-BD includes several transmural approaches such as the EUS-rendezvous technique (EUS-RV), EUS-guided choledochoduodenostomy (EUS-CDS), EUS-guided hepaticogastrostomy (EUS-HGS) (Fig. 145.1), and EUS-guided antegrade stenting (EUS-AS). To date, many studies regarding each procedure have shown high technical and clinical success rates of more than 80–90% with moderate adverse event rates of 10–30% (e.g., bile leakage, bleeding, stent migration), although the severity of most adverse events was mild or moderate [30]. Recently, covered SEMSs have been frequently used to avoid unexpected adverse events (e.g., bile leakage) for biliary decompression, although accumulated data have shown no difference between plastic stents and covered SEMSs in the EUS-HGS procedure [31].

Of the EUS-BD procedures, EUS-RV appears to achieve minimum invasive drainage because conventional ERCP and even BE-assisted ERCP can be performed although it may be technically difficult compared with other procedures. Notably, the current data have been reported from high-volume centers with expertise in EUS. Furthermore, as each EUS-BD technique including accessories has not yet been established, EUS-BD has not become an alternative to conventional ERCP. However, a recent RCT has shown that EUS-CDS can be an effective and safe alternative to PTBD with a similar success rate, complication rate, cost, and patient quality of life [32]. Furthermore, EUS-CDS with a single-step delivery system using an electrocautery enhanced, lumen-apposing metal stent (LAMS) is associated with successful stent placement rates of over 90 percent in patients with malignant biliary obstruction [33,34]. Although larger studies with long-term outcome data are needed to compare its efficacy and safety with percutaneous drainage, EUS-BD may become an alternative to PTBD in failed ERCP cases in the near future.

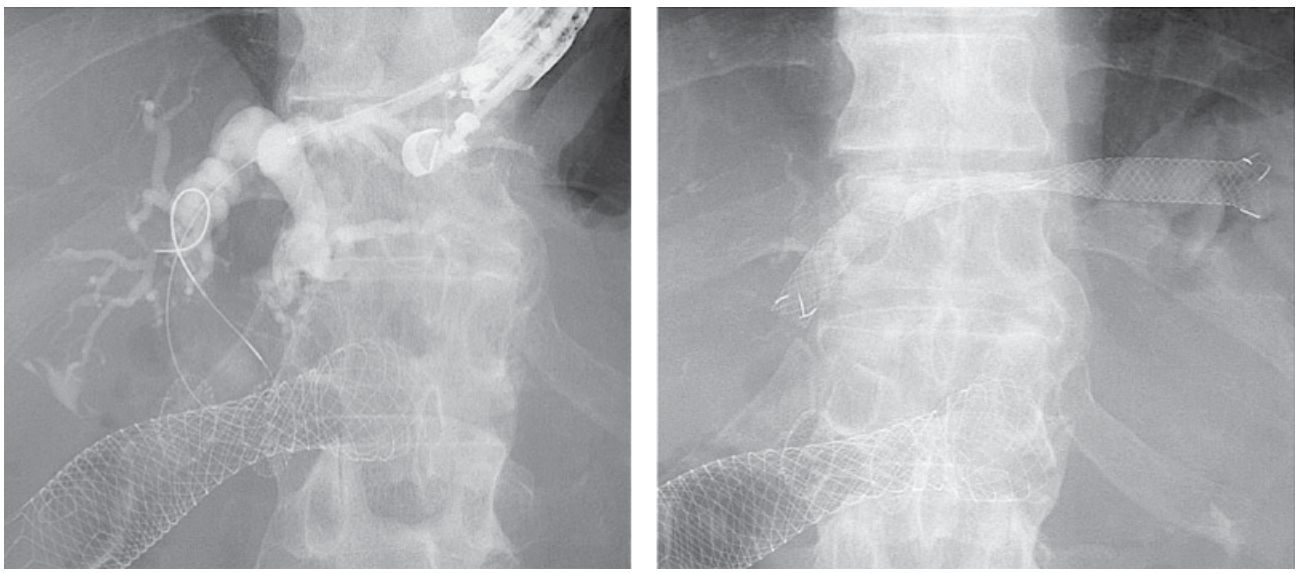

Figure 145.1 EUS-guided hepaticogastrostomy. The metal stent delivery system was inserted in the intrahepatic bile duct (left). Hepaticogastrostomy was completed using a metal stent.

Palliation of Obstructive Jaundice by IVR

Percutaneous transhepatic biliary drainage has been performed traditionally by radiologists as one of the biliary decompression methods, although it is becoming less common due to the widespread use of endoscopic biliary drainage regardless of the choice of the plastic stent and SEMS by ERCP. PTBD is divided into three types according to the percutaneous tube condition in the bile duct across the stenosis, namely, external drainage, internal-external drainage, and internal drainage. A 7–8 Fr percutaneous tube is used which allows sufficient drainage for the therapy of obstructive jaundice. From the viewpoints of physiological bile flow, activities of daily living, and the quality of life of patients, internal drainage appears to be desirable. In most PTBD cases, eventually, internalization appears to be technically possible using several accessories such as a hydrophilic guidewire.

However, the most desirable procedure in patients undergoing percutaneous transhepatic therapy is percutaneous stenting without any percutaneous tube. In particular, the present percutaneous SEMS placement using a small-caliber (approximately 6–7 Fr) delivery system allows good efficacy, with few complications and reduced associated pain [35]. Similarly to ERCP, percutaneous covered SEMS placement provides long stent patency compared with percutaneous uncovered SEMS placement for the treatment of extrahepatic biliary obstruction [36]. However, an earlier RCT that compared percutaneous therapy with endoscopic therapy has demonstrated that the endoscopic method had a significantly higher success rate in relieving jaundice and a significantly lower 30-day mortality from complications associated with liver puncture [37]. Even at the time of writing, serious complications due to percutaneous stent placement are still common [38]. It is probable that needle puncture and tract dilation in patients who have coagulopathy and hemorrhagic tendency cause serious complications such as massive bleeding. Furthermore, needle puncture is not always successful even by skilled radiologists. Quality improvement guidelines for percutaneous transhepatic biliary cholangiography, biliary drainage, and percutaneous cholecystostomy have described that the success rate of needle puncture in a nondilated bile duct was lower than that in a dilated bile duct (63% vs 86%) [39].

Nonetheless, since PTBD is an effective and established technique, it should remain as a salvage therapy before shifting to surgical intervention, even at institutions with expertise in both ERCP and EUS [40]. In fact, PTBD is performed even in ERCP and EUS high-volume centers [41].

Malignant Gastric Outlet Obstruction

Malignant gastric outlet obstruction (MGOO), which is often caused by unresectable pancreatic cancer at the end stage, causes inadequate food intake with nausea and vomiting, leading to malnutrition and deterioration of the quality of life. Surgical gastrojejunostomy (GJ) under open laparotomy or laparoscopy, which has been the standard palliative treatment for MGOO, is associated with good functional outcome and long-term relief of symptoms. However, surgical GJ shows high morbidity and mortality [42,43].

Duodenal Metal Stent Placement

At present, duodenal stent placement using a 20–22 mm diameter SEMS under fluoroscopic guidance or, more recently, endoscopy owing to the development of a thinner 10 Fr delivery system for MGOO treatment, has been gaining popularity as an alternative to surgical GJ because the stent can be inserted through the accessory channel with a high technical success rate and less invasiveness [42–47]. A previous systematic review [42] revealed that the initial clinical success rate was higher after stent placement than after surgical GJ (89% vs 72%, respectively) with fewer minor complications (9% vs.33%, respectively). However, recurrent obstructive symptoms were more frequent after stent placement (18% vs 1%, respectively) owing to tumor ingrowth, preventing the patient from being able to eat soft solid food or a full diet.

These results suggest that endoscopic stenting might be preferable in patients with a relatively short life expectancy, whereas surgical GJ might be preferable in patients with a longer expected survival (>2 months) [42,43]. However, recent systemic chemotherapies for pancreatic cancers have shown marked improvements, making it harder to predict a patient's life expectancy. This may lead to an increase in cases of endoscopic stent occlusion, which often occurs during longer follow-up periods owing to tumor ingrowth. In this cohort, an additional stent is often placed within the original stent which can lead to early stent occlusion or stent-related adverse events such as perforation.

Thus, several investigators have recently attempted nonsurgical GJ for longer efficacy while maintaining a less invasive procedure using magnet compression anastomosis, interventional EUS, and natural orifice transluminal endoscopic surgery in animal models. In particular, EUS-guided GJ has been developed and one clinical study has demonstrated that EUS-guided GJ

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 145.2 EUS-guided gastrojejunostomy. A lumen-apposing metal stent was placed over the wire using a dedicated double-balloon tube.

using a dedicated double balloon and a fully covered lumen-apposing SEMS (15 mm diameter) shows high technical and clinical success without causing serious adverse events (Fig. 145.2) [48]. Several systematic reviews and metaanalyses report on the safety and efficacy of EUS-guided GJ compared with other treatments [49–51]. While the data are promising, further studies are warranted prior to widespread adoption.

Duodenal and Biliary Stent Placement: Double Stenting

In patients with unresectable pancreatic cancer, progression of the cancer is accompanied not only by MGOO but also by biliary obstruction, which is usually a late manifestation. In such patients, both biliary stent placement and duodenal stent placement, so-called "double stenting," is often required. The methods and ease of the procedure vary according to the site and timing of the duodenal obstruction. In particular, the duodenal obstruction site appears to be more important in terms of planning the biliary stenting strategy.

The duodenal obstruction site is classified in relation to the position of the major papilla, namely, type I (the obstruction site is at the entrance of the principal papilla), type II (the obstruction site is somewhat convoluted with the papilla present in the second portion), and type III (the obstruction site is closer to the anal side than to the major papilla) [52]. In double stenting, biliary drainage with or without the rendezvous technique is performed using three kinds of approaches: percutaneous transhepatic approach, ERCP approach, and EUS approach. In double stenting by ERCP, if the duodenal obstruction site is convoluted around the major papilla (type II), the treatment is most complicated. Even if the balloon is stretched or the duodenal stent is placed first, cancer invasion makes it difficult to identify the major papilla and confirm the distance from the scope. In addition, it is very difficult to pass the biliary stent through the mesh gap of the duodenal stent. Thus, in type II cases, the traditional percutaneous transhepatic approach including biliary drainage and rendezvous appears preferable for double stenting than the ERCP approach.

Recently, the EUS approach has allowed biliary drainage including EUS-HGS, EUS-CDS, EUS-AS, and EUS-RV even in type I and type II MGOO. In type I and type II MGOO, EUS-HGS and EUS-AS appear to be suitable drainage techniques for the treatment of obstructive jaundice and can replace the percutaneous transhepatic approach because of the minimum invasive procedures involved [53].

Management of Pain Derived from Cancer

Pain due to cancer invasion of the celiac plexus is a major manifestation of pancreatic cancer, occurring in approximately 70% of patients with unresectable pancreatic cancer [54]. At present, pain is comparatively controllable by opioid analgesics, IVE, and/or IVR. Celiac plexus neurolysis (CPN) is a unique technique that can potentially improve pain control in pancreatic cancer to avoid further dose escalation of opioid medication. CPN is most often performed by injecting a local anesthetic followed by absolute alcohol into the celiac plexus neural network of ganglia with the intention of ablating the tissue transmitting pain from the pancreas and adjacent visceral organs. Interventions targeting CPN have been performed percutaneously with computed tomography or transabdominal ultrasound, while the EUS-guided approach has been increasingly utilized in clinical practice.

EUS-CPN

EUS-CPN has emerged as a promising approach to CPN that has the potential for better visualization of the celiac plexus through close proximity and real-time high-resolution ultrasound, possibly allowing for more precise and safer injections [55]. Standard EUS-CPN is

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

performed using a 19–25 gauge EUS-guided fine-needle aspiration (EUS-FNA) needle. The needle is advanced anterior to the lateral aspect of the aorta at depiction of the celiac trunk. Then, after confirming the absence of backflow of blood, absolute alcohol is injected following local anesthetic injection. A previous metaanalysis demonstrated that pain was reduced in 80% of the patients following EUS-CPN for pancreatic cancer [56]. Although most adverse events of EUS-CPN are mild and include transient hypotension, diarrhea, constipation, and pain exacerbation, although serious and fatal adverse events appear to be occasionally inevitable [57].

Unilateral neurolysis is conducted by a single injection into the base of the celiac artery takeoff. In contrast, bilateral neurolysis is performed by injecting into both sides of the celiac plexus. A previous metaanalysis demonstrated the superiority of bilateral injection over central injection for pain reduction (85.54% vs 45.99%, respectively) [56]. However, an RCT comparing the two approaches in pancreatic cancer among 50 patients showed no significant difference in terms of pain control or adverse events [57].

Recently, EUS-guided celiac ganglia neurolysis (EUS-CGN) has been developed in which alcohol is injected directly into the celiac ganglia (detection rates of 80–90% by EUS). A RCT comparing EUS-CGN with unilateral EUS-CPN has shown significantly greater pain relief in the CGN group than in the CPN group (73.5% vs 45.5%, $P = 0.026$) with similar adverse events [58]. However, the latest trial indicated that EUS-CGN resulted in decreased survival without a pain control benefit compared with EUS-CPN (survival time 5.6 versus 10.5 months; hazard ratio 1.49; 95% confidence interval [CI] 1.02–2.19) [59]. In addition, a RCT showed EUS-CPN for patients with pancreatic cancer-associated pain did not appear to improve pain, quality of life, or opioid consumption compared with those who did not undergo EUS-CPN and medicated with oxycodone/fentanyl [60]. From those results, although EUS-CPN or CGN can be an option, it cannot be used routinely in clinical practice.

Anticancer Therapy

To date, several anticancer therapies for pancreatic cancers have been reported [61–66]. EUS-guided or percutaneously guided intratumoral TNFerade biologic with 5-fluorouracil and radiotherapy has been used as first-line treatment for locally advanced pancreatic cancer in a phase III study [61]. However, this study demonstrated that although it was safe, it was not effective for prolonging survival. In terms of brachytherapy, EUS-guided interstitial implantation of 125I seeds has been performed and the obtained data suggested improvement in pain, but there was no long-term survival benefit [62].

Several investigators have performed EUS-guided radiofrequency ablation (EUS-RFA) of unresectable pancreatic

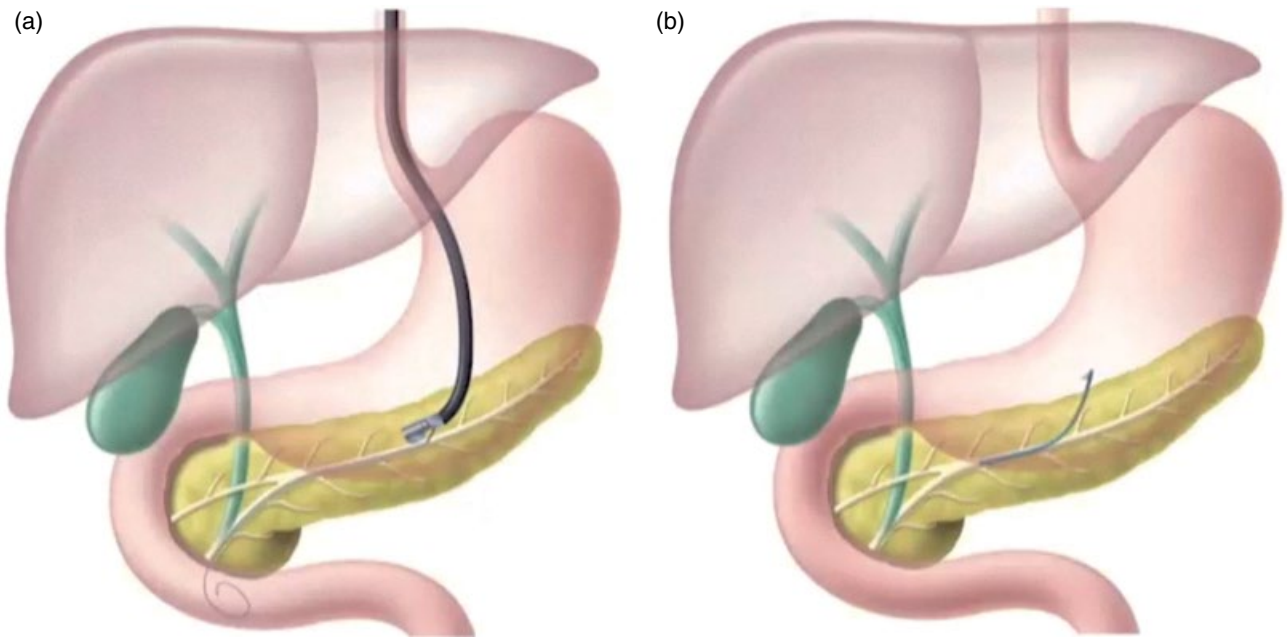

Figure 145.3 EUS-guided pancreatic duct stent placement. The mechanism of EUS-guided pancreatic duct stent placement using a plastic stent. A plastic stent was placed in the pancreatic duct (b) after insertion of a guidewire into the pancreatic duct under EUS guidance (a).

cancer and concluded that it could be a technically feasible and safe option [63]. However, long-term efficacy should be evaluated in the near future. Currently, EUS-guided cryothermal ablation therapy [64] and EUS-guided dendritic cell injection therapy [65,66] have also been reported, but their efficacies are not apparent because the studies involved a small case series without a control group.

Miscellaneous

Patients with pancreatic duct (PD) obstruction which blocks the outflow of pancreatic juice owing to pancreatic cancer experience abdominal pain. Although this condition is infrequent in such patients, transpapillary PD stent placement is useful. In case of failed ERCP, EUS-guided PD stent placement is performed as salvage therapy (Fig. 145.3). Anastomotic stricture of pancreatojejunostomy causes pain and pancreatitis as a late adverse event after pancreatoduodenectomy for pancreatic cancer. EUS-guided PD stent placement is also effective for decompression of dilated PD [67]. Acute pancreatitis due to pancreatic cancer is rare but is observed in some patients. Pancreatic fluid collections, including walled-off necrosis and pseudocyst, require EUS and/or percutaneous drainage. Furthermore, endoscopic necrosectomy may be required to remove the infected necrotic tissue.

Neoadjuvant Treatment of Pancreatic Cancer: Evidence for Treatment Effect

Robert A. Wolff

Department of GI Medical Oncology, The University of Texas M.D. Anderson Cancer Center, Houston, TX, USA

Introduction

Neoadjuvant treatment (NAT) has long been established as leading to superior outcomes in other gastrointestinal malignancies, specifically rectal cancer and gastroesophageal cancers, compared with upfront surgery. In rectal cancer, a landmark randomized trial of preoperative chemoradiotherapy (CRT) followed by surgery compared with initial surgery and adjuvant CRT led to improvement in clinically meaningful endpoints with evidence of downstaging and treatment effect [1]. These included a higher chance of sphincter-sparing surgery, an increase in pathologic T1 with a concomitant decrease in T3 tumors (40% vs 60%), and a decrease in positive lymph nodes (LNs) (25% vs 40%). Pathologic complete responses occurred in 8% of resection specimens. In gastroesophageal cancers, the evidence for the benefit of NAT was also demonstrated. Similar to the experience in rectal cancer, NAT generated pathologic evidence of downstaging and treatment effect with lower T stages and lower rates of positive lymph nodes, in addition to longer overall survival (OS) [2,3].

For years, the standard approach to resectable pancreatic cancer was upfront surgical resection followed by AT [4–6]. Over time, it became apparent that the completeness of surgical resection, deemed the "R" factor, had prognostic implications. Better survival has generally been observed for patients undergoing complete resection with microscopically negative surgical margins (R0) [7–9]. Reports from several AT trials have consistently shown that R1 resections occur quite frequently with upfront surgery and confer a worse prognosis [7,10,11]. While high-quality cross-sectional imaging can predict the surgeon's ability to remove all gross tumor [12], the diffusely infiltrating nature of pancreatic adenocarcinoma often results in positive surgical margins, particularly with upfront surgery [13,14].

Defining Localized Pancreatic Cancer: Resectable, Borderline Resectable, or Locally Advanced?

High-quality imaging can distinguish between tumor/vessel interfaces with interposed fat planes (potentially resectable), from tumor/vessel contact (<180°) without encasement (BR), or evidence of tumor encasement of critical vascular structures (LA). Broadly defined, BR tumors represent a subset of localized pancreatic cancers that may be grossly resected, but pose high risk for positive margins with upfront surgical intervention based on a tumor's contact with surrounding vascular structures [15] Given the cumulative evidence demonstrating that NAT can produce local tumor regression in resectable disease, leading to higher R0 resection rates compared with upfront surgery, early reports of NAT in BR pancreatic cancer patients showed that a subset could undergo R0 resection with survival rates similar to those reported for patients with resectable disease [16,17]. Importantly, broader recognition of BR disease provides a framework for better defined, more homogeneous subsets of patients for entry into clinical trials of NAT [18]. This allows for three separate categories of localized pancreatic cancer: potentially resectable, BR, and LA pancreatic cancer, and prospective studies are now emerging on the role of NAT for these three distinct subsets.

Neoadjuvant Therapy for Resectable Pancreatic Cancer

The rationale for delivering NAT to patients with potentially resectable tumors is based on: (1) the potential to produce primary tumor regression, thereby improving

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Companion website: www.wiley.com/go/beger/thepancreas4e

the chances of an R0 resection; (2) early treatment of micrometastatic disease; (3) delivery of anticancer therapy prior to a complex procedure, avoiding the risk of prolonged surgical recovery, which delays delivery of AT; (4) providing a time interval to assess the underlying tumor biology, thus identifying patients for surgery who have the highest likelihood of benefit from it.

Downstaging Resectable Pancreatic Cancer

From a technical perspective, downstaging a resectable pancreatic cancer is not required to allow for tumor resection. However, despite advances in cross-sectional magnetic resonance imaging (MRI) and computed tomography (CT), and their proper interpretation, modern trials of AT continue to demonstrate the significant risk of an R1 resection with upfront surgery. For example, three of the most recent AT trials had R1 resection rates of 24–60% [13,14,19]. The discrepancy between radiographically resectable disease and achievement of an R0 resection may be in part explained by the findings of Verbeke et al. who found that tumor cell dispersion at the periphery of pancreatic head tumors was greater than observed in other gastrointestinal cancers [20].

Retrospective analyses from a variety of datasets show consistent benefit of NAT leading to lower rates of R1 resections, lower rates of positive lymph nodes and improved survival in potentially resectable pancreatic cancer in comparison with upfront surgery (Table 146.1) [21–24]. While "downstaging" resectable pancreatic cancer may be a misnomer, these results clearly suggest sufficient treatment effect from NAT to justify its use. Importantly, the criteria for surgical removal of a resectable tumor after NAT are based on the absence of disease progression rather than primary tumor response. This is distinct from the setting in BR and LA disease, where some evidence of treatment effect is usually required to attempt tumor resection.

Downstaging Borderline Resectable Disease with Neoadjuvant Therapy

A number of academic centers have reported on results with NAT for BR disease. An early retrospective report came from UTMDACC, where 160 patients were classified as having BR disease [16]. Among those patients, all of whom were treated with NAT, approximately 40% had some combination of clinical, serologic (drop in tumor marker), or radiographic response to therapy sufficient to attempt resection. For the patients who ultimately underwent resection, the R0 rate was 94% with a median overall survival of 40 months. Of note, the survival of patients who did not undergo surgery was consistent with patients having LA pancreatic cancer managed with nonoperative therapy (13 months). Other groups have also published results after NAT for BR tumors with resection rates around 60–65% [25,26]. More recently, prospective data from a multiinstitutional trial of

Table 146.1 Retrospective analyses of R0 resection rates and lymph node involvement comparing upfront surgery with neoadjuvant therapy followed by surgery using nonrandomized datasets.

Author Study details Year	Clinical stage	Number of patients	R0 resection rate (%)		Lymph node involvement (%)		Comments

FOLFIRINOX followed by capecitabine-based CRT for patients with BR disease were reported. Among the 23 patients enrolled, 68% underwent surgery with curative intent; the R0 rate was 93% [27]

In the recent past, a series of randomized trials from Korea, Japan, and Europe have compared NAT and subsequent surgery with initial surgery and AT, and all demonstrated clinical benefits using NAT, particularly for those patients with BR disease (Table 146.2) [28–31]. In patients with resectable pancreatic cancer, the survival benefits using NAT are mixed based on intention to treat (ITT) analyses. However, if survival results are analyzed among patients who ultimately underwent surgical resection with curative intent, the survival benefit of NAT becomes more evident for those patients with either resectable or BR disease. Note that in Table 146.2, the specific NAT regimens used in these reported trials are quite variable, with some delivering systemic therapy alone (gem + S1, gemcap, or FOLFIRINOX), while others have used 5FU-based or gem-based CRT alone, or before and after some systemic gem.

At the present time, the NCCN Pancreatic Cancer Guidelines subcommittee recommends NAT for patients presenting with BR disease [32]. In addition, for patients having potentially resectable tumors, the guidelines suggest consideration of NAT for those patients with high-risk features to include markedly elevated pretreatment CA 19-9 level, large primary tumor, enlarged regional LNs or excessive weight loss. The guidelines generally recommend NAT with combination chemotherapy such as FOLFIRINOX, gem/nab-p, or gemcap with or without CRT.

Downstaging Locally Advanced Disease with Neoadjuvant Therapy

The potential to downstage LA pancreatic cancer to potentially resectable disease has been touted in the medical literature for years. Single institutions have reported widely varying conversion rates ranging from 1% to as high as 68% [33,34]. Note that many of these reports were published in an era before BR tumors were defined as a distinct subset and the patients likely represent a heterogeneous population of those having tumors that would currently be considered BR and those defined as LA.

Recent reports of NAT in LA pancreatic cancer patients suggest a select subset may be considered for surgery after a period of preoperative treatment as shown in Table 146.3 [34–38]. A retrospective experience from investigators at Duke University analyzed patient cohorts treated from 1995 to 2000 and partitioned patients as either potentially resectable (53) or locally advanced (58) [35]. The resection rate among potentially resectable patients was 53% and 19% for the LA group; R0 resections were achieved in 72%. This was consistent with retrospective data from the Johns Hopkins Hospital using modern regimens of induction systemic therapy with 96% of patients also receiving CRT [36]. Within this cohort, 20% of patients underwent resection with an R0 rate of 89%. Recent data from LAPACT, a prospective phase II trial of gem/nab-p in 107 patients with LA disease, reported that only 16% of enrolled patients were able to undergo surgical resection with an R0 rate of 44% [38]. Of note, LAPACT was a multicenter trial not designed to investigate chemotherapy as a neoadjuvant strategy in patients with LA disease.

The results from Duke and Johns Hopkins coupled with the prospective data from LAPACT are at odds with recent results from Massachusetts General Hospital in which a select group of 49 LA pancreatic cancer patients received FOLFIRINOX and losartan followed by short- or long-course CRT [34]. In this study, the resection rate was almost 70% with an R0 resection rate of 88%. Somewhat similar results were reported from NEOLAP-AIO-PAK-0113 which was likewise designed as a neoadjuvant trial and delivered gem-based therapy alone or gem-based therapy followed by FOLFIRINOX [37]. Here, the resection rate was 40%, 67% of which were R0.

Taken together, the clear variability in resection rates and R0 resections demonstrates a spectrum of LA tumors, some unlikely to ever be resectable, with others potentially resectable after NAT. In a report from the Medical College of Wisconsin, the authors proposed a new classification of locally advanced disease to aid in the identification of patients more likely to benefit from eventual resection [39]. LA type A patients had anatomic tumor–vessel relationships which allowed for consideration of surgery after NAT; in LA type B patients, resection and long-term survival were far less likely.

Challenges of Neoadjuvant Therapy in Borderline Resectable and Locally Advanced Pancreatic Cancer

Despite keen interest, questions remain about tumor downstaging using a neoadjuvant approach.

- What is the best chemotherapy regimen?
- What is the optimal duration of NAT?
- What is the relative contribution of neoadjuvant systemic therapy and radiotherapy to tumor downstaging?
- What response criteria can identify patients most likely to benefit from surgical resection after NAT?
- Is total NAT better than perioperative therapy?

At the present time, only partial answers are available to these questions.

Table 146.3 Retrospective reports and prospective trials of chemotherapy +/– chemoradiotherapy (CRT) in patients with locally advanced (LA) pancreatic cancer.

Study	Study period Study type	Number of patients	Regimen(s)	Resection rate (%)	R0 rate (%)	Survival (months)	
Duke	1995–2000 Retrospective	58	5FU-based CRT +/– MMC or cisplatin or both	19	72	NS	NS
Johns Hopkins	2013–2017 Retrospective	415	FFX or G + nab-p or both 96% received CRT	20	89	No resection 16.3	Resected patients 35.3
Massachusetts General	2013–2018 Prospective	49	FFX followed by short or long course CRT	69	88	Entire cohort 31.4	Resected patients 33.0
NEOLAP-AIO-PAK-0113	2014–2018 Prospective	130	Gem + nab-p or gem+ nab-p followed by FFX	40	67	No resection 13.9	Resected patients 27.5
LAPACT	2015–2018 Prospective	107	Gem + nab-p (with option for CRT and or surgery)	16	44	Entire cohort 18.8	Resected patients NS

5FU, 5-fluorouracil; FFX, FOLFIRINOX; MMC, mitomycin C; NS, not significant.

What is the Best Chemotherapy Regimen?

Two recent randomized trials suggest similar outcomes using FOLFIRINOX or gem/nab-p as part of perioperative or NAT [40,41]. S1505 was a cooperative group study that treated 103 patients with potentially resectable disease and randomized them to perioperative treatment with FOLFIRINOX or gem/nab-p [40,42]. The surgical resection rate (75%), R0 rate (85%), and two-year survival rate were all similar (47–48%). In a smaller randomized trial from Japan with 51 patients, no difference in outcomes were observed using FOLFIRINOX or gem/nab-p as NAT [41].

What is the Optimal Duration of Therapy Prior to Considering Surgical Resection?

Single-institutional data suggest that in BR and LA disease, longer durations of NAT provide greater benefit compared with shorter periods of treatment [43–45]. This appears to be supported by prospective trials. For example, in ESPAC 5F, patients randomized to NAT received just eight weeks of FOLFIRINOX or gemcap, or 5.5 weeks of capecitabine-based CRT [31]. If one assumes a four-week break thereafter for restaging and recovery from NAT, nonprogressing patients would undergo surgery within 10–12 weeks of initiating NAT. In that trial, the resection rate among patients randomized to NAT was 55%.

In the PREOPANC trial, patients randomized to NAT underwent laparotomy within 14–18 weeks from time of randomization, with a resection rate of 61% [30]. Lastly, Alliance A021101 (a US multiinstitutional trial), enrolled patients with BR pancreatic cancer with about a 24-week interval from start of treatment to surgery [27]. Here, the resection rate was 68%.

In the future, perhaps shorter courses of NAT will be devised for patients with resectable disease while longer courses are reserved for those with BR or LA pancreatic cancer.

What are the Relative Contributions of Systemic Therapy and Chemoradiation?

While many single-institutional efforts have routinely incorporated CRT as a component of NAT, multiinstitutional and cooperative group trials are beginning to present results in which patients with BR disease are being randomized to systemic therapy alone, to CRT alone, or some combinational approach. Preliminary results from ESPAC 5F showed that patients who received NAT CRT and surgery had a higher R0 resection rate compared with patients who underwent resection after receiving either gemcap or FOLFIRNOX [31]. In contrast, in Alliance A021501, patients with BR disease were randomized to eight courses of FOLFIRINOX with planned surgery thereafter (arm A) or to seven courses of FOLFIRINOX followed by five fractions of stereotactice body radiation therapy (SBRT) with subsequent surgery for nonprogressors (arm B). Preliminary results demonstrated an 18-month overall survival rate of 67.9% among patients randomized to arm A alone versus 47.3% in arm B. Among patients who underwent pancreatectomy, the 18-month OS rate was 93.1% for those assigned to arm A and 78.9% for arm B [46].

PREOPANC 2 is a randomized controlled trial of NAT in resectable and BR disease designed to compare NAT

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

FOLFIRINOX (eight cycles) with gem and gem-based CRT. However, since the systemic therapy used in both arms is different, this trial will not provide a definitive answer as to the role of radiation in NAT for pancreatic cancer. In the setting of LA pancreatic cancer, for those patients who benefit from induction chemotherapy, NAT CRT is usually recommended, with surgical candidacy reassessed upon the completion of NAT.

What Response Criteria can Identify Patients Most Likely to Benefit from Surgical Resection After Neoadjuvant Therapy?

Prior studies have found that post-NAT imaging is unable to reliably identify tumor downstaging [25,47], likely related to tumor desmoplasia thwarting radiographic evidence of tumor shrinkage despite significant tumor destruction. Furthermore, it is rare to see a change in critical tumor–vessel relationships, particularly arterial abutment or encasement after NAT (Figure 146.1). Retrospective data from a few centers are now suggesting that normalization of CA 19-9 in response to NAT is associated with better long-term survival in resected patients in comparison with those patients who do not have a normal CA 19-9 level post-NAT [48,49].

Is Total NAT Better Than Perioperative Therapy?

Whether patients should undergo total NAT or perioperative therapy is an unresolved question. In other gastrointestinal tumors such as gastroesophageal and rectal cancer, both approaches have been utilized. In Prep-02/JSAP-05, ESPAC 5F, and PREOPANC, in patients assigned to NAT and underwent surgery, AT was also intended. Retrospective data from UTMDACC suggest a potential survival advantage for patients with resectable or BR disease who undergo NAT, surgery, and subsequent AT compared with those who undergo NAT and surgery only [50]. These results are based on a small number of patients who received perioperative therapy (36) compared to a larger number who did not (227). An interesting finding was that AT only benefited patients whose tumors had a positive lymph node ratio of 0.15 or less. This result may be useful in future trials of perioperative therapy as a stratification factor for randomized trials that deliver a uniform NAT regimen with randomization to AT or observation for patients who undergo resection.

In the future, postoperative therapy may be based on specific selection criteria such as pathologic staging, serum tumor markers, or as yet undefined biomarkers.

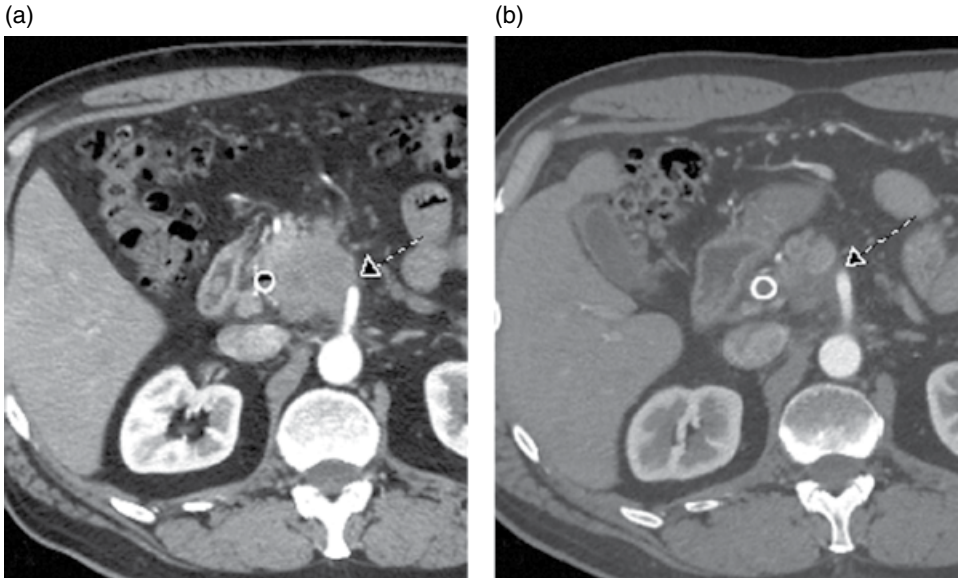

Figure 146.1 (a) Baseline CT image of a mass in the head of the pancreas from a 60-year-old man diagnosed with locally advanced pancreatic cancer. The arrow depicts tumor abutting the superior mesenteric artery by greater than 180°. (b) CT image obtained after treatment with induction FOLFIRINOX × 8 doses followed by capecitabine-based CRT delivered to 50.4 Gy. Note that while the tumor has reduced in size, the degree of arterial abutment has not changed (arrow). Patient underwent successful R0 resection with complete pathologic response. However, disease recurred locally approximately eight months postoperatively. He eventually died 34 months after his initial diagnosis.

Future Directions

Diagnostic Innovations for Precision Medicine

CT Imaging Biomarkers

At UTMDACC, signal characteristics of tumor–parenchymal interface from pretreatment CT images were analyzed and characterized primary tumors as high-delta, with a well-defined interface between the tumor and surrounding parenchyma, or low-delta, with an ill-defined interface. Patients with high-delta tumors had inferior median PFS compared to those with low-delta tumors (7.5 months vs 23.5 months, P <0.01) and inferior OS compared to those with low-delta tumors (17.1 months versus not reached, P <0.01) [51]. If validated, these findings may allow for alternative treatment strategies in high-delta vs low-delta primary tumors.

Biopsy Material for Molecular Profiling

As precision medicine in pancreatic cancer slowly emerges, acquisition of sufficient primary tumor tissue for molecular profiling is desirable. In a small, randomized trial, 60 patients undergoing endoscopic ultrasound for biopsy of a pancreatic mass were randomized to undergo aspiration with a 25 gauge needle followed by biopsy with a 19 or 22 gauge needle or vice versa. The investigators found that needle biopsy material provided more DNA for molecular profiling than aspiration (P <0.01); adequate material was obtained for profiling in 78% of biopsies compared with 14% of aspirates (P <0.001) [52].

Circulating Tumor DNA-Liquid Biopsy

The power of ctDNA assays has implications in cancer management as a marker of tumor burden, molecular residual disease or relapse, detecting actionable mutations, and elucidating mechanisms of resistance to therapy. In a retrospective analysis of blood samples from 60 patients with pancreatic cancer (13 patients with localized disease and 47 with metastases), ctDNA was detected in 10% and 57% of samples, respectively. In localized disease, pretherapeutic ctDNA detection significantly correlated with the numbers of involved locoregional lymph nodes (P = 0.030) and was associated with shorter DFS (3.3 vs 18.1 months, P = 0.001). In another study with 112, KRAS mutated ctDNA was detected in 62% of preoperative and 37% postoperative cases. At a median follow-up of 38.4 months, ctDNA detection in the preoperative setting was associated with substantially inferior recurrence-free survival (RFS) (P = 0.002) and OS (hazard ratio [HR] 4.1, P = 0.015). Detectable ctDNA following curative intent resection was also associated with inferior RFS (HR 5.4, P <0.0001) and OS (HR 4.0, P = 0.003). Recurrence occurred in 13/13 (100%) patients with detectable ctDNA postoperatively [53].

Thus, in the setting of resectable, BR, and LA disease, ctDNA may prove to be a useful biomarker for prognostic purposes and to identify the patients most likely to benefit from surgical resection after NAT. In addition, detection of ctDNA postoperatively may influence the decision to deliver postoperative therapy.

Emerging Therapeutic Strategies

The complex biology of the microenvironment of pancreatic adenocarcinoma, with stromal elements that may act to both sequester malignant cells and protect them from cytotoxic therapy or immunologic attack, is steadily being elucidated. Important cellular components of the tumor microenvironment (TME) include CD8+ T cells with effector memory phenotype capable of cell killing, in addition to immunosuppressive myeloid cells and CD4+ regulatory T cells. Of note, conventional NAT by itself can alter the TME, generating a less immunosuppressive milieu [54,55]. NAT can lead to selective depletion of inhibitory CD4+ T cells and myeloid-derived immunosuppressive cells with enrichment of antitumor immune cells. Coupling conventional NAT with other therapeutic manipulations may tilt the balance from an immunosuppressive TME to one that is more susceptible to tumor cell death using a combination of cytotoxic therapy, targeting agents, and immune check point inhibitors.

Reports of agents designed to modulate the TME in nonmetastatic pancreatic cancer are being investigated in the clinic [56]. Recent efforts include the administration of the autophagy inhibitor HCQ or CD40 agonists to cytotoxic NAT [57,58], in addition to investigations of vaccines [59], and immune checkpoint inhibitors combined with chemotherapy or radiation to augment tumor killing from NAT.

Local Therapies

As discussed previously, while a randomized NAT trial failed to show an added benefit for SBRT after induction chemotherapy in BR pancreatic cancer [46], novel approaches to deliver higher doses of radiation therapy [60] or to enhance radiation killing while protecting surrounding tissues are being explored in patients with locally advanced pancreatic cancer [61].

Lastly, based on improvements in systemic therapy, more interest in local control to include aggressive surgical intervention is certain to develop. While venous resection with reconstruction is commonly performed in pancreatic cancer centers of excellence, there is renewed interest in performing arterial resections with reconstruction at the time of surgery. In a previous era, arterial

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. resections were associated with poor outcomes. With modern chemotherapy regimens and improved CRT, encouraging results have been reported in small numbers of patients where arterial resection and reconstruction have been performed [62,63]. With increasingly active NAT regimens, greater numbers of patients with localized disease may be able to undergo surgery with curative intent.

Conclusion

Neoadjuvant treatment is a rational approach to therapy for localized, nonmetastatic pancreatic cancer. It is also a strategy to uncover aggressive tumor biology or frailty prior to surgical intervention. Radiographic evidence of tumor downstaging is not required in the setting of resectable pancreatic cancer, but NAT may lead to pathologic downstaging and improve the likelihood of an R0 resection. In borderline resectable disease, which places the patient at high risk for an R1 resection, treatment with NAT is sufficiently active in 40–60% of patients to ultimately allow for surgical resection. For those with locally advanced pancreatic cancer, although the chances of ultimately undergoing surgery with curative intent are lower than in resectable or BR disease, newer drug therapies intended to alter the TME or enhance immunologic cell killing may expand the proportion of patients who can be considered for surgery.

Lastly, the recognition of and formalized definitions for BR disease which is intermediate in the spectrum of resectable and LA/unresectable pancreatic cancer will allow for more reliable comparison of results in clinical trials of various neoadjuvant regimens.

Locally Advanced Pancreatic Cancer: Does the Addition of Stereotactic Body Radiation Therapy to Neoadjuvant Chemotherapy Lead to a Significant Survival Improvement after R0 Resection?

Marco Del Chiaro[1,3], Michael J. Kirsch[2], and Richard D. Schulick[1,3]

Neoadjuvant Treatment in Pancreatic Cancer Patients

Long-term survival of patients who undergo surgical resection for pancreatic cancer (PC) has significantly improved over the last few decades but remains below that of other tumors [1]. One of the major contributors to the improvement of PC prognosis has been the implementation of more effective systemic treatments [2,3]. Neoadjuvant chemotherapy has become the standard of care for the multimodal treatment of borderline resectable (BR) and locally advanced pancreatic cancer (LAPC). Unlike other types of cancer, neoadjuvant treatment (NAT) very rarely causes downstaging of PC. Radiologic response to the most commonly used NAT, FOLFIRINOX, is seen in a minority of cases. However, absence of a radiologic response does not necessarily equal absence of pathologic or biologic response [4]. In contrast to chemotherapy, the use of neoadjuvant radiation therapy (RT) is not universally accepted or standardized across geographical regions [5].

Given the limited number of patients with downstaged disease after NAT, the main goal of NAT in PC is not to downstage local disease, but rather:

- biologic selection of the best candidates for surgical resection (e.g., patients who do not have progression of disease during NAT)
- determining the optimal neoadjuvant chemoradiation therapy in combination with surgery (especially considering that a significant percentage of patients cannot receive adjuvant treatment postoperatively due to surgical complications)
- early systemic control of the disease.

In a recent analysis of the role of neoadjuvant RT in a large cohort of patients from the National Cancer Data Base, the retrospective study did not show any survival advantage for patients who received neoadjuvant chemoradiation compared with patients who received neoadjuvant chemotherapy alone. This is despite RT being associated with a significant higher rate of R0 resections. In contrast, single-center, retrospective studies of LAPC have reported impressive results in terms of long-term survival with preoperative chemoradiation therapy followed by surgery [6].

Use of Stereotactic Body Radiation Therapy in Borderline Resectable/ Locally Advanced Pancreatic Cancer

The authors group BRPC and LAPC due to the lack of significant difference in prognosis in the literature [7]. We previously published a retrospective analysis of 103 patients (85 BRPC and 18 LAPC) who underwent preoperative chemotherapy followed by SBRT. For patients who underwent resection in this series, the rate of R0 was 97.3% and complete pathologic response was seen in 7%. The median overall survival of the resected group was 24 months [8]. Another recent retrospective study reviewed 155 patients (64 BRPC and 91 LAPC) who underwent preoperative chemotherapy followed by SBRT. Patients who underwent surgical resection achieved an R0 resection in 96% for BRPC and in 88% for LAPC. However, the median overall survival was 18.7 months from the end of SBRT [9].

Another study retrospectively comparing patients affected by BRPC and LAPC who underwent either neoadjuvant chemotherapy or neoadjuvant chemoradiation demonstrated an advantage in the radiation group in achieving RO resection (92% vs 70%), node-negative disease (59% vs 42%) and a complete pathologic response

(7% vs 0). However, there was no observed benefit in overall median survival (22.1 vs 24.5 months) [10].

However, all these studies were retrospective and exposed to several biases. For this reason, a multicenter, prospective, randomized trial (Alliance A021501) was designed in the US. The study sought to compare the use of neoadjuvant FOLFIRINOX chemotherapy with combined neoadjuvant chemotherapy and SBRT. Patients who received chemotherapy alone had a better overall median survival than those who received chemoradiation (31 vs 17.1 months) [11].

Interpretation of the Data Behind Neoadjuvant SBRT in Pancreatic Cancer

The majority of data in the current literature suggest a higher rate of R0 resections and complete pathologic response. However, despite these promising results, they do not show any improvement in survival. In contrast, in the only prospective, randomized trial performed so far, the opposite trend appears to emerge. Addition of SBRT to neoadjuvant chemotherapy was associated with a decrease in median overall survival.

In the authors' view, the role of neoadjuvant SBRT for the treatment of BRPC and LAPC remains unclear. Pancreatic cancer is a systemic disease. For this reason, local control is not the only important aspect of treatment. Distant disease recurrence occurs in at least 80% of the cases in most of the recent series [12]. Even if SBRT can help achieve a more radical resection from a pathologic perspective, this local effect of treatment may not have any influence on tumor biology and overall prognosis.

On the other hand, a negative result from a single prospective, randomized trial is probably not sufficient to say that there is no role for SBRT in the treatment of pancreatic cancer. Future studies will better clarify SBRT's role in the multimodal treatment of pancreatic cancer.

The authors caution against, however, the use of preoperative radiation therapy in patients with LAPC that have the potential to undergo arterial resection and reconstruction. Even though solid evidence is lacking, we believe that the possibility of actinic arteritis caused by radiation may increase the risk of complications during arterial reconstruction [13].

Conflict of interest

Dr. Del Chiaro has been awarded an industry grant (Haemonetics, Inc) to conduct a multi-center study to evaluate the prognostic implications of TEG in pancreas cancer.

Dr. Del Chiaro is a co-PI of a sponsored Boston Scientific study on the use of intra-operative pancreatoscopy in IPMN's patients.

Introduction

Pancreatic ductal adenocarcinoma remains the most common malignancy of the pancreas, and is the fourth highest cause of cancer death in the developed world. An estimated 367 000 new cases were diagnosed worldwide in 2015, and it is likely to become the second leading cause of cancer mortality within the next decade, overtaking deaths from breast cancer [1,2].

The majority of patients with pancreatic cancer present with advanced disease. Surgery remains the only potentially curative option, but even in specialized centers just 10–15% of patients are suitable for resection [3]. The mortality associated with major pancreatic surgery has reduced considerably in recent years, and is now routinely reported as less than 5% [4]. Following surgery alone, prognosis remains dismal with a median survival of around 13 months and only 10% surviving for five years [5]. Increasingly radical resections that include extended lymphadenectomy or total pancreatectomy have been employed in an attempt to improve long-term outlook, but prospective trials comparing these more radical resections with classic surgical techniques have failed to demonstrate any survival benefit, with significant disadvantage in terms of postoperative quality of life [6].

Around 70% of patients undergoing curative intent surgery succumb to distant metastases rather than local recurrence [7] and so attention has turned to additional therapies that may delay or prevent the development of recurrence in an effort to improve long-term outcome. Adjuvant therapy is used with the aim of reducing these occult micrometastases and the results from contemporary randomized studies provide the most compelling evidence so far to support its use after surgery for pancreatic cancer.

This chapter aims to provide a summary outline of key trials in adjuvant therapy, as well as to highlight potential future avenues to improve outcomes in this deadly disease.

Rationale for Adjuvant Therapy

The first randomized trial assessing the role of adjuvant treatment for pancreatic cancer was the small 1985 Gastrointestinal Tumor Study Group (GITSG) study, where 43 resected patients were randomized to receive either 5-fluorouracil (FU) concurrent with radiation (50 Gy) followed by maintenance 5-FU, or observation alone. The trial closed prematurely because of failure to recruit, but despite these problems, median survival was considerably longer for the adjuvant therapy arm (20 months vs 11 months, $P = 0.04$) (Table 148.1) [8]. It was impossible to tell whether it was systemic chemotherapy or radiotherapy that led to this improvement.

Subsequent to this, a larger European study (EORTC 40891) assessed concurrent 5-FU and radiation (40 Gy) versus observation alone for 120 patients with resected pancreatic head cancer and periampullary tumors but demonstrated no difference in median or long-term survival, even when the pancreatic head group was evaluated independently [9,10].

The European Study Group of Pancreatic Cancer (ESPAC)-1 trial provided a further challenge to the value of chemoradiation and suggested that chemotherapy alone provided the primary survival benefit seen in

GITSG [11,12]. The study used a 2 × 2 factorial design to stratify patients undergoing curative intent surgery for pancreatic adenocarcinoma by center, type of tumor, and resection margin status. Patients were then randomized to one of four arms: (i) chemoradiation (50 Gy split course), (ii) six months of systemic chemotherapy (bolus 5-FU), (iii) combination chemotherapy and chemoradiotherapy, or (iv) observation. A total of 289 patients from across Europe were randomized. At a median follow-up of 47 months, five-year survival was significantly higher for those receiving chemotherapy versus those who did not (21% vs 8%, $P = 0.009$). Median survival for those treated with chemotherapy was 20.1 months compared to 15.5 months for those without ($P = 0.009$). Median survival was also significantly longer in the group who did not receive chemoradiotherapy (17.9 vs 15.9 months, $P = 0.05$), which translated to an estimated five-year survival rate of 10% for those treated with chemoradiation compared to 20% for those who did not ($P = 0.05$) (Fig. 148.1) [11,12]. The survival rates for patients treated with chemoradiation in ESPAC-1 were broadly in keeping with those from other series, and the superior outcomes seen after systemic chemotherapy led to a move away from adjuvant radiotherapy in favor of systemic chemotherapy across Europe.

The promising results of ESPAC-1 led other researchers to question whether the use of more active systemic chemotherapies would translate to improved long-term outcome. The Charité Onkologie (CONKO)-001 trial compared six cycles of systemic gemcitabine with observation alone in 368 patients who had undergone resection, and found a significant improvement in median disease-free survival (13.4 vs 6.7 months, $P < 0.001$), which also translated into improved five-year survival (20.7% vs 10.4%, $P = 0.01$) [13,20]. This benefit was consistent irrespective of tumor stage, nodal status, and margin status. However, patients with a postoperative CA 19-9 level >92.5 KU/L were excluded from trial entry, meaning the patient population included were a prognostically more favorable group.

Both ESPAC-1 and CONKO-001 therefore confirmed the role of adjuvant therapy as standard of care after

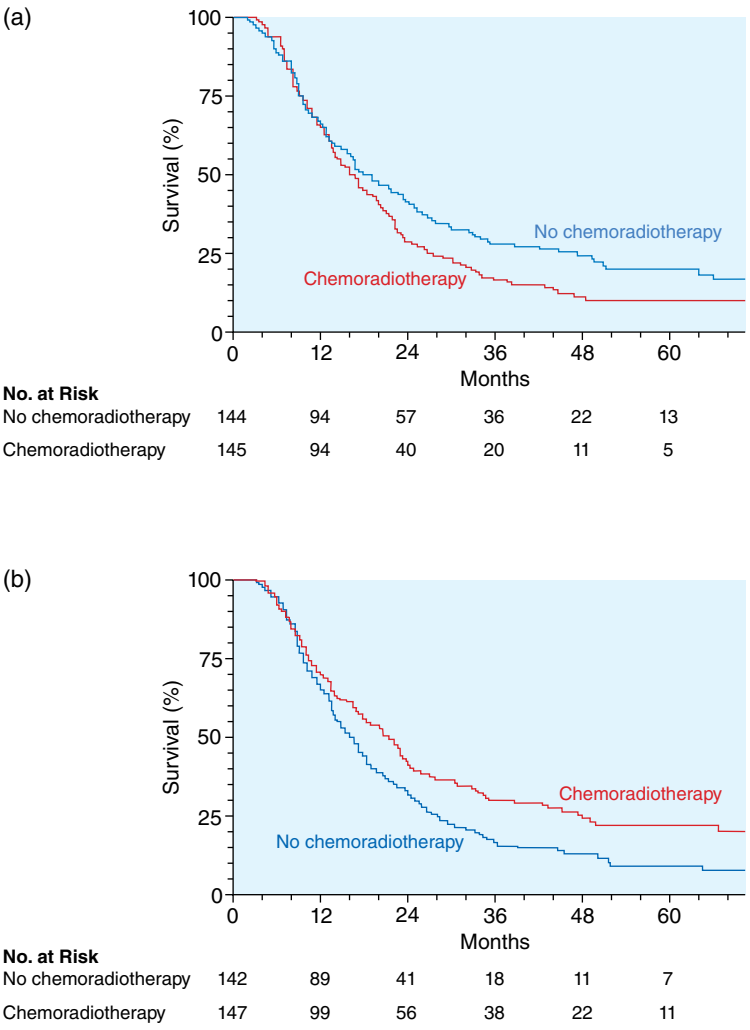

Figure 148.1 Overall survival from the ESPAC-1 trial. *Source:* Reproduced from [12]/With permission of Massachusetts Medical Society.

curative resection, and led to an almost doubling in the five-year survival after surgery.

ESPAC-3 built on these findings by randomizing 1088 patients to observation, bolus 5-FU/leucovorin, or bolus gemcitabine for six months after surgery [14]. The observation arm was closed when the final results of ESPAC-1 were published. Final analysis at a median follow-up of 34.2 months demonstrated equivalence in median survival (23.0 months for 5-FU/leucovorin vs 23.6 months for gemcitabine, $P = 0.39$) (Fig. 148.2) but significantly lower grade 3/4 toxicity in the gemcitabine arm (7.5% vs 14%, $P < 0.001$). These results defined gemcitabine as the optimal adjuvant monotherapy for patients who had undergone curative resection.

The Japan Adjuvant Study Group of Pancreatic Cancer (JASPAC)-01 trial assessed S-1 (a 5-FU analogue with marked efficacy in the Japanese population) versus gemcitabine in the adjuvant setting. This noninferiority study randomized 385 Japanese patients, and found overall survival at two years of 70% for the S-1 group compared with 53% for the gemcitabine group, with a five-year overall survival of 24.4% in the gemcitabine group and 44.1% in the S-1 group (P <0.0001 for noninferiority, P <0.0001 for superiority) [17]. While these results are impressive, it remains unclear whether they are applicable to a non-Japanese population with different S-1 metabolism where efficacy is lower and toxicity higher. In addition, randomized patients were a prognostically favorable group with only 13% having an R1 resection and only 21% having a raised CA 19-9. As such, the results may have limited applicability in a real-world Western population.

Combination therapy with gemcitabine and capecitabine has become increasingly common in the palliative treatment of metastatic pancreatic cancer, with good response rates and acceptable toxicity [21,22]. The ESPAC-4 study therefore assessed whether these improved response rates translated to improved overall survival in the adjuvant setting. A total of 732 patients were randomized to six cycles of intravenous gemcitabine

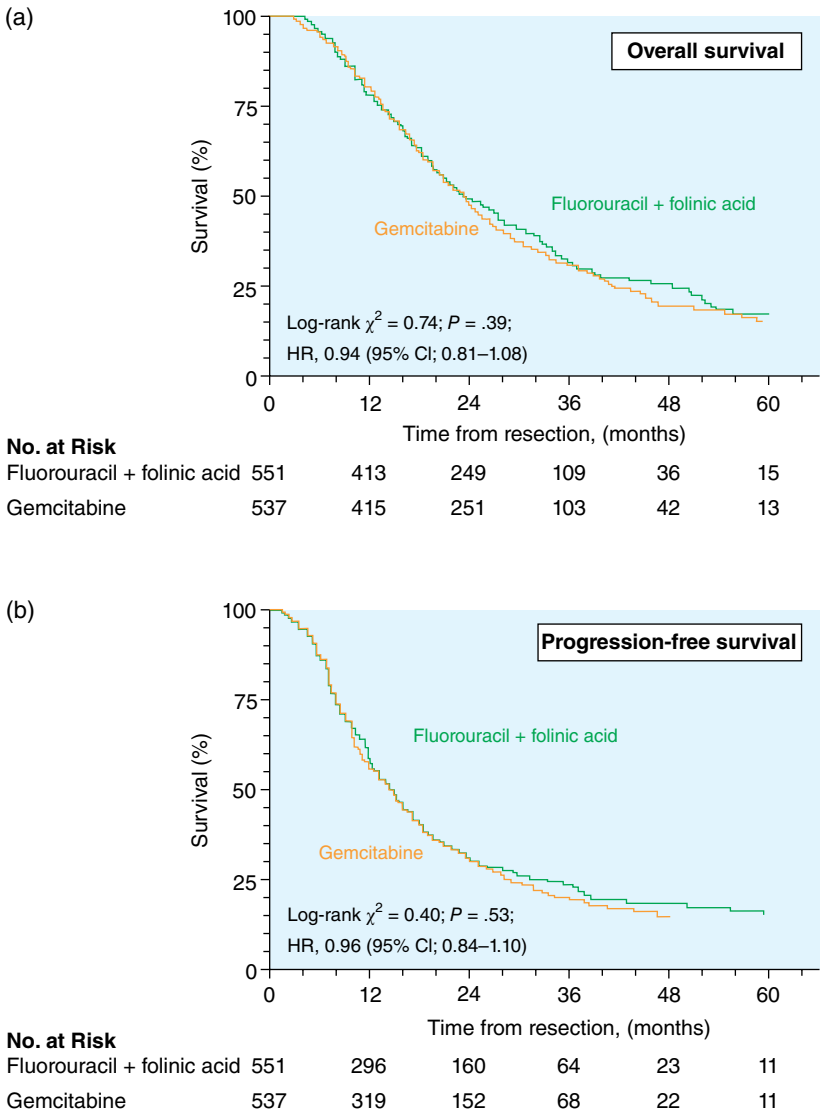

Figure 148.2 Overall survival from the ESPAC-3 trial. *Source:* Reproduced from [14]/With permission of American Medical Association.

with or without oral capecitabine. Median survival was slightly longer in the combination therapy arm (25.5 vs 28.0 months, $P = 0.03$). However, the five-year survival rates were considerably higher for patients receiving dual therapy rather than gemcitabine alone (28.8% vs 16.3%) (Fig. 148.3) [16]. Severe toxicities were similar, and both regimens were well tolerated. It is also important to note that ESPAC-4 recruited a wider variety of patients than other studies (Table 148.2). For example, patients with raised postoperative CA 19-9 and without immediate preadjuvant imaging were eligible for inclusion. These findings suggest that combination therapy with gemcitabine/capecitabine is proving more effective than single agent gemcitabine and is a standard of care for this patient population.

The PRODIGE and Canadian cancer trials group (PRODIGE 24 - ACCORD) randomized 493 patients with resected pancreatic cancer to receive adjuvant modified FOLFIRINOX (oxaliplatin, irinotecan, leucouvorin, and fluorouracil) or gemcitabine [18]. After a median follow-up of three years the median disease-free survival was 21.6 months in the FOLFIRINOX group compared to 12.8 months in the gemcitabine group ($P < 0.001$), with a disease-free overall survival of 39.7% vs 21.4% respectively. Median overall survival was 54.4 months and 35 months in the FOLFIRINOX and gemcitabine groups respectively [18]. The striking increases in survival are partly explained by inclusion criteria. ages of patients being maximally 79, WHO performance of 0 or 1, patients with high CA 19-9 (>180 U 21 days before randomization) and those with an incomplete resection (R2). The adverse events of grade 3 and 4 occurred in 75.9% of patients treated with FOLFIRINOX and 52.9% of patients treated with gemcitabine. The

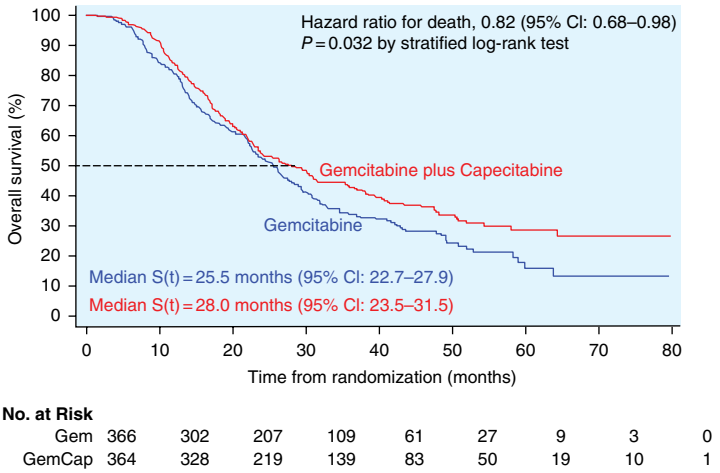

Figure 148.3 Kaplan–Meier plot for overall survival in the ESPAC-4 trial.

Table 148.2 Comparison of patient populations in JASPAC-01, CONKO-01, and ESPAC-4 trials.

Prognostic factor	JASPAC-01 [15] (N = 377)	CONKO-01 [12] (N = 368)	ESPAC-4 [18] (N = 730)
WHO PS 0	68.7%	–	42.2%
PS 1	31.3%	–	54.9%
PS 2	0.0%	–	2.9%
Grade 3	–	35.9%	40.4%
LN positive	62.9%	67.9%	80.4%
R1 positive	13.0%	16.6%	60.3%
Postop CA 19-9 > 37 KU/L	21.0%	–	31.7%
Postop CA 19-9 >92.5 KU/L	–	0.0%	17.1%

toxicity of the multiagent FOLFIRINOX precludes older and comorbid patients from receiving treatments. This explains the inclusion criteria but still demonstrates the significant benefit FOLFIRINOX has over gemcitabine as a adjuvant treatment agent.

The APACT phase III trial compared 866 patients with resected pancreatic ductal adenocarcinoma randomized into two adjuvant groups: nab-paclitaxel plus gemcitabine (nab-P + Gem) vs gemcitabine (Gem) alone in six 28-day cycles. The study did not reach the primary endpoint of independently assessed disease-free survival. The median follow-up was over five years and there was a median overall survival of 41.8 and 37.7 months (P = 0.009, nab-P + Gem vs Gem) with the nab-P group having a five-year survival of 38% compared to 31% in the Gem group [19].

The use of FOLFIRINOX and gemcitabine/capecitabine has become routine in patients with good performance status. FOLFIRINOX and nab-paclitaxel have yet to be compared in a trial setting. Gemcitabine may be preferable in older patients with poor performance status. The side-effect profile and chemotherapy regimen schedules are important considerations for patients and should be discussed with the oncologist, for fully informed decision making [23].

Adjuvant Chemoradiotherapy

The data presented from the CONKO-001, JASPAC-1, and ESPAC-1, -3, and -4 trials provide compelling evidence to support systemic chemotherapy for six months after surgical resection as standard of care. The role of additional adjuvant chemoradiotherapy remains less clear, with no randomized trial providing clear benefit in terms of overall survival.

Although the previously described GITSG and EORTC 40891 trials provide some evidence, they do not allow direct comparison of chemotherapy versus chemoradiotherapy. Concerns about the long-term survival benefit of additional adjuvant radiotherapy are supported by retrospective reviews and metaanalyses. Merchant et al. performed a pooled analysis of 646 patients from seven high-volume centers, 299 of whom were treated with surgery followed by chemoradiation and 347 with surgery alone [24]. Median overall survival was 20 months for the adjuvant chemoradiation arm, versus 14.5 months for surgery alone (P = 0.001). The investigators found a significant survival advantage only in patients with lymph node-positive disease. Somewhat surprisingly, they also identified reduced disease-free survival in patients with lymph node-negative disease who received adjuvant chemoradiotherapy (14.5 months vs 18.6 months, P = 0.034). These findings were further supported by another large retrospective series that

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

compared 1130 patients treated with surgery, with or without adjuvant chemotherapy or chemoradiotherapy, at eight major US centers over 10 years. The authors identified reduced local recurrence after chemoradiation, but no impact on distant recurrences (in contrast to systemic chemotherapy) and therefore no impact on overall survival [25].

The first attempt to directly compare systemic chemotherapy with systemic chemotherapy and additional radiotherapy was the 2010 EORTC 40013 study, which randomized 90 patients to four cycles of gemcitabine versus gemcitabine with concurrent chemoradiation (50.4 Gy). Median overall survival was the same for both arms at 24 months, with comparable toxicity profiles. Eighty-seven percent of patients treated with gemcitabine alone completed all planned treatments, compared to 73% undergoing combination therapy [15]. Supporting previous retrospective series, local recurrence as site of first progression was 24% for the chemotherapy arm compared with 11% in the chemoradiotherapy arm. However, this did not translate into a long-term survival benefit.

In 2005, Stocken et al. performed a metaanalysis assessing the impact of adjuvant chemoradiation and chemotherapy on survival and included patient-level data from five randomized trials of adjuvant therapy [26]. Individual patient data were available in four of the five studies (94% of patients). Analysis demonstrated a 25% reduction in the risk of death (hazard ratio [HR] 0.75, 95% confidence interval [CI] 0.64–0.90, $P = 0.001$) with chemotherapy compared to no chemotherapy but no significant difference between chemoradiation and no chemoradiation (HR 1.09, 95% CI 0.89–1.32, $P = 0.43$). On subgroup analysis, chemoradiation was more effective and chemotherapy less effective in patients with positive resection margin.

In 2013, Liao et al. performed an updated metaanalysis of adjuvant 5-FU versus gemcitabine versus chemoradiation with 5-FU or gemcitabine, and showed that chemotherapy alone with either 5-FU (HR 0.65, 95% CI 0.49–0.89) or gemcitabine (HR 0.59, 95% CI 0.41–0.83) was associated with significant overall survival benefit. By contrast, adjuvant chemoradiation was associated with worse overall survival when compared with 5-FU (HR 1.69, 95% CI 1.12–2.54) and gemcitabine (HR 1.86, 95% CI 10.4–3.23) as monotherapy with significant additional toxicity [27].

The results of the RTOG 0848 phase III trial are still anticipated. Between 2009 and 2014, 856 patients who had a pancreatoduodenectomy for ductal cancer were randomized to receive either gemcitabine or gemcitabine with erlotinib for five cycles. After the final cycle, the patients were imaged and a further randomization step was performed to enter a no radiotherapy arm or a chemoradiotherapy arm using intravenous 5-FU or capecitabine as a radiotherapy sensitizer. Recently, the trial published a phase II report of the trial of 336 patients to answer the question of adjuvant erlotinib, reporting no additional benefit of the drug. They report there are no adverse effects of chemoradiation but maturation and analysis still await [28].

The role of adjuvant chemoradiotherapy therefore remains unclear, with benefit seeming to be limited to a subset of patients yet to be fully elucidated.

Timing and Duration of Adjuvant Therapy

The optimal timing of adjuvant therapy after surgery remains unclear. Patients need sufficient time to recover from the physiologic insult, whilst treatment needs to commence soon enough to prevent the establishment of micrometastatic deposits.

Valle et al. assessed the optimal timing to start therapy in the ESPAC-3 trial. A total of 985 patients were included, of whom 486 received gemcitabine, 675 (68.5%) received all six planned cycles of adjuvant therapy, and 457 (46.4%) started treatment within eight weeks of surgery. Overall survival was much better in those who received the full six cycles of treatment (28 months vs 14.6 months) (HR 0.516, 95% CI 0.443–0.601, $P < 0.001$) whilst time to start of treatment did not predict overall survival (HR 0.985, 95% CI 0.956–1.015, $P = 0.99$). However, for the subgroup of patients who did not complete all six cycles of treatment, the time to initiation of therapy was important, with overall survival better in those who waited more than eight weeks (HR 0.92, 95% CI 0.86–0.97, $P = 0.004$). These findings suggest that completion of a full course of treatment is more important than early initiation, and that allowing patients to fully recover from surgery may lead to better tolerability of therapy and an increased likelihood of completing treatment [29].

Second-line Chemotherapy

By definition, second-line chemotherapy is treatment of recurrent pancreatic cancer after surgery and adjuvant chemotherapy. There are no specific trials reviewing recurrent disease but there are a number of phase III randomized controlled trials in advanced pancreatic cancer focusing upon second-line agents. These are summarized in Table 148.3.

In the palliative setting, up to 86% may undergo second-line therapy, and in the PRODIGE 4 trial of advanced cancer, 165 of 342 patients proceeded along this strategy [30,31]. The CONKO-003 trials randomized

Table 148.3 Summary of phase III randomized trials of second-line chemotherapy for advanced pancreatic cancer.

Trial	Year	Regimen	N	Median survival (m)	*P*
CONKO-003 [32]	2014	Oxaliplatin, 5-FU FA	76	5.9	0.01
		5-FU FA	84	3.3	
PANCREOX [33]	2014	FOLFOX6	54	6.1	0.02
		5-FU FA	54	9.9	
NAPOLI-1 [34]	2016	Liposomal irinotecan, 5-FU FA	117	6.2	0.009
		5-FU FA	149	4.2	

160 gemcitabine-refractory patients to 5-FU and folinic acid (FA) or 5-FU and FA combined with oxaliplatin. They found a significant increase in survival of 2.6 months, without clinically relevant toxicity [32]. The PANCREOX study randomized 108 similar patients into treatment arms of 5-FU leucovorin (LV) and FOLFOX6 which includes 5-FU, LV, and oxaliplatin. They found overall survival was significantly worse with FOLFOX6 by 2.8 months and 63% had grade 3/4 adverse events [33]. Nanoliposomal irinotecan is an irinotecan base encapsulated in a liposome and maintains a higher level of the drug intratumorally. The NAPOLI-1 trial used this drug in combination with 5-FU FA against 5-FU FA alone in gemcitabine-refractory advanced pancreatic cancer patients. They found an increase in survival of two months with nanoliposomal irinotecan [34].

Given these trials, the evidence base for patients tolerating second-line chemotherapy is increasing, especially when maintaining good performance status. FOLFIRINOX is a clear agent of choice in a palliative setting but no trials exist with its use as a second-line agent. There are phase II trials that have reviewed capecitabine and monoclonal antibody but not progressed to phase III [35]. The current options with second-line agents in recurrent pancreatic cancer, refractory to gemcitabine treatment, are nanoliposomal irinotecan and 5-FU FA. There is a need for studies reviewing second-line agents post FOLFIRINOX, potentially exploring the use of gemcitabine with nab-paclitaxel.

Future Directions in Adjuvant Therapy

As well as attempting to use increasingly active regimens, targeted adjuvant therapies offer great appeal. Whole-genome sequencing of large numbers of tumors has led to the identification of frequently mutated genes in pancreatic cancer, as well as identifying distinct molecular subtypes [36,37]. Unfortunately, the four most commonly mutated genes (*KRAS*, *CDKN3A*, *TP53*, and *SMAD4*) are not currently actionable, with druggable mutations occurring with much lower frequencies. Although the reducing cost of whole-genome sequencing means that precision therapy based on identifiable and actionable mutations on a case-by-case basis is a possibility, its mainstream use remains some way in the future.

To overcome some of these limitations, targeted agents with wider mechanisms of action have been investigated. Erlotinib is an oral tyrosine kinase inhibitor that has demonstrated improvements in overall survival when added to gemcitabine in the palliative setting [38]. CONKO-005 therefore randomized 436 resected patients to receive gemcitabine or gemcitabine/erlotinib. However, there was no difference in disease-free survival (11.6 months for both) or overall survival (24.6 months for combination therapy vs 26.5 months for gemcitabine alone) [39].

Immunotherapy has shown great promise in other cancer types. Around 90% of pancreatic cancers contain an activating mutation in *KRAS*. A small phase II trial therefore assessed the use of a novel *KRAS* vaccine in the adjuvant treatment of 23 patients with resected pancreatic cancer. The researchers found an immune response in 85% of patients, with a median survival of 28 months [40]. However, these results have not been replicated by other groups [41].

During repeated rounds of DNA replication, the telomeric ends of DNA become progressively shortened, leading to eventual cell death. Reactivation of telomerase, the telomere repair enzyme, is a crucial event in oncogenic transformation and occurs in nearly all pancreatic cancers. The TELOVAC trial therefore compared gemcitabine/capecitabine with or without a novel telomerase peptide vaccine (GV1001) in the palliative setting, but demonstrated no significant survival benefit, suggesting that further ways to enhance the immune response are required for clinical efficacy [42].

As well as trialing novel agents, there are increasing efforts to improve patient stratification for existing treatments. Penetration of gemcitabine into dense pancreatic stroma appears to be highly variable. Koay et al.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. demonstrated widely variable incorporation of gemcitabine into tumor DNA despite consistent serum pharmacokinetics. They also identified and validated a series of novel radiomic markers that would allow preoperative assessment of gemcitabine efficacy. This issue was further confused by the demonstration of widely varying incorporation of gemcitabine even within individual tumors, suggesting intratumoral heterogeneity may pose a problem not only for novel targeted agents but also for existing cytotoxic regimens [43,44].

Biomarkers to predict response to treatment also offer significant potential to improve the stratification of treatment. Human equilibrative nucleoside transporter 1 (hENT1) is a cell surface protein that bidirectionally transports gemcitabine across pancreatic cell membranes. Greenhalf et al. assessed hENT1 expression in 434 patients from the ESPAC-3 trial, of whom 176 received gemcitabine. Median survival for patients treated with gemcitabine was 17.1 months for those with low hENT1 expression compared to 26.2 months for those with high hENT1 expression (P = 0.002), suggesting hENT1 may predict response to gemcitabine chemotherapy [45]. This finding was not confirmed in the prospective LEAP (Low hENT1 Adenocarcinoma of the Pancreas) trial in patients with metastatic disease where there was no difference in overall survival following treatment with gemcitabine in the hENT1 high and low groups [46].

Further publications from the Greenhalf group have elicited that hENT1 alone may not select patients who benefit from gemcitabine; further markers from the metabolism process can combine with hENT1 to personalize chemotherapy regimens. High levels of dihydropyrimidine dehydrogenase (DPD) have been found to be a negative prognostic marker in combination with low hENT1 expression in the ESPAC-3 patients who received 5-FU but not gemcitabine [47]. Similar findings were found using cytidine deaminase (CDA) transcript levels in the same group of patients, where low mRNA levels were associated with improved survival overall with either gemcitabine or 5-FU. Patients with low levels of hENT1 had better outcomes with 5-FU if the CDA levels were low compared to high (29.3 vs 14.2); the differences were less pronounced with gemcitabine (18.3 vs 14.6) [48].

The use of a single biomarker has not proved successful in the management of pancreatic cancer, though using a combination may personalize patients into effective chemotherapy arms. The ESPAC group has developed a specific stratification signature in order to randomize patients into oxaliplatin- or gemcitabine-based chemotherapy arms. The phase III trial aims to recruit 394 patients, with the primary outcome measure being disease-free survival [49].

Conclusion

The last 20 years have seen a paradigm shift in the management of pancreatic cancer. The routine use of adjuvant treatment has led to significant increases in median and five-year overall survival. The results of ESPAC-4 and PRODIGE trials define standard of care, with growing recognition of the importance of patients receiving the full planned treatment course (Fig. 148.4). Future directions for adjuvant therapy include the use of more active regimens, as well as better stratification of patients to existing therapies.

Role of Radiation Therapy for Pancreatic Cancer

Baho U. Sidiqi[1], *Abhinav V. Reddy*[2], *Joseph M. Herman*[1], *and Amol K. Narang*[2]

Introduction

The role of radiation therapy (RT) for pancreatic cancer (PCA) remains highly controversial amid recent technologic advances in radiation oncology and systemic therapy improvements. The origins of this debate arise from key landmark trials with conflicting results regarding the relative merits of radiation. However, the manner in which this data should be applied to RT as delivered in the modern day using contemporary techniques is unclear. Nevertheless, fluency in the clinical literature exploring the role of RT for PCA across the disease stage is critical. Equally important is an understanding of the way in which conformal radiation techniques and charged particle therapy can be used to improve the therapeutic window. Knowledge of these topics will yield both an appreciation of the value of modern RT for patients with PCA and an ability to better customize treatment regimens to individual patients in a multidisciplinary discussion.

In the context of improving systemic control with advances in chemotherapy, there is an evolving role for RT in providing durable locoregional control. Herein, we review the role of RT in the adjuvant and neoadjuvant settings and discuss advanced modalities including stereotactic body radiation therapy (SBRT), intraoperative radiation therapy (IORT), MRI-guided radiation therapy, and proton beam therapy (PBT).

Radiation in the Adjuvant Setting

The optimal management of patients with resectable PCA continues to evolve. Appreciation of the potential that modern RT may have for resected PCA requires an understanding of clinical trials that have explored the value of adjuvant chemoradiation (CRT). Early institutional reports demonstrated high rates of local failure (>50%) after surgical resection of PCA [1]. Therefore, the Gastrointestinal Tumor Study Group (GITSG) compared adjuvant 5-fluorouracil (5-FU)-based chemoradiation (CRT) with observation and found that CRT improved two-year overall survival (OS) (42% vs 15%, $P = 0.03$), sparking adoption of adjuvant CRT in the United States [2]. However, this survival benefit could not be replicated in subsequent trials by the European Organisation for Research and Treatment of Cancer (EORTC) and European Study Group for Pancreatic Cancer (ESPAC), with the latter trial suggesting improved survival with chemotherapy alone [3,4].

Importantly, key pitfalls of all these trials must be acknowledged, including slow accrual and poor trial adherence. Perhaps most importantly, the radiation techniques employed in all these trials were antiquated by modern standards, including suboptimal doses, nonconformal techniques, and split-course schedules. As a result, the latter two trials failed to demonstrate improved rates of local control (LC) in the CRT arms [3,4].

Since the early trials results, European trials for patients with resected PCA have focused on defining the optimal adjuvant chemotherapy-alone regimen. The Partenariat de Recherche en Oncologie Digestive Intergroup (PRODIGE) trial showed that adjuvant mFOLFIRINOX significantly improves median disease-free survival (DFS), distant metastasis-free survival (DMFS) and OS (median OS, 54.4 vs 35.0 months, $P = 0.003$) compared to gemcitabine alone [5]. Locoregional recurrence was 29.0% in the whole cohort and 23.1% in the adjuvant mFOLFIRINOX arm, highlighting a potential role for radiation even in the setting of improving chemotherapy.

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Companion website: www.wiley.com/go/beger/thepancreas4e

In the United States, outcomes with more conformal radiation techniques using higher doses without split-course schedules have been explored. The Radiation Therapy Oncology Group (RTOG) 9704 trial randomized patients to initial chemotherapy with either 5-FU or gemcitabine, followed by 5-FU-based chemoradiation to 50.4 Gy, followed by additional chemotherapy with 5-FU or gemcitabine and resulted in fewer local recurrences in both arms (25–30%) [6]. This local failure rate compared favorably with historical controls despite a predominance of patients with risk factors for local recurrence, including 35% with positive margins, 66% with positive lymph nodes, and 75% with advanced T-stage. Despite the high R1 rate and LN positivity, an analysis by Berger et al. comparing per protocol RTOG 9704 outcomes to chemotherapy-alone outcomes in a subset of CA 19-9 <90 U/mL showed median OS at 24 months vs 22 months and five-year OS of 34% vs 21% in favor of inclusion of RT [7].

These results highlight the potential benefits of radiation in the setting of high locoregional recurrence risk factors and improving OS benefit in a cohort of long-term survivors. Importantly, RTOG 9704 was the first trial to evaluate whether radiation field design influenced outcomes [8]. Failure to adhere to specified RT guidelines was associated with reduced survival. In fact, nearly 50% of the RT plans deviated from protocol guidelines. Consensus panel guidelines are now available for clinical target volume design, but the subset analysis of RTOG 9704 underscores the importance of appreciating the quality of radiation delivered when interpreting results from clinical trials [9]. Despite improved results seen in RTOG 9704, reported acute toxicity was still substantial, with 70.5% patients experiencing any grade ≥3 toxicity and 59% experiencing grade ≥3 nonhematologic toxicity [6]. To this end, technologic advances have allowed a more focused form of RT, termed "intensity-modulated RT" (IMRT), that may be helpful in sparing organs at risk (OAR) and minimizing toxicity. Less toxicity associated with IMRT allows for incorporation of more aggressive concurrent chemotherapy or targeted therapies.

Given the potential merits of IMRT, it was incorporated into the NRG/RTOG 0848 two-step randomization trial, which was examining gemcitabine plus erlotinib compared to gemcitabine alone and is still evaluating whether radiation to 50.4 Gy with 5-FU improves outcomes beyond gemcitabine chemotherapy alone. In the phase II setting, the addition of erlotinib to gemcitabine did not provide an OS benefit [10]. We await the maturation and results of the radiotherapy research question from RTOG 0848. Initial publication regarding quality assurance from the trial reported 86% IMRT usage [11]. Of note, quality assurance from the trial reported 33% resubmission rates for RT treatment plans prior to starting radiation therapy, again confirming the importance of the quality of radiation delivered. IMRT with volumetric arc therapy (VMAT) allows for more rapid treatment of therapy and further sparing of adjacent normal tissues including bowel, stomach, and kidneys.

Whether these advances translate into clinically meaningfully outcomes remains to be seen, especially as mFOLFIRINOX has changed the adjuvant therapy landscape per PRODIGE trial. Given the relatively high positive R1 resection rate of 40.1% and high rate of local and regional failure at 23.1% [5] in the PRODIGE study, pending results of RTOG 0848 is sure to add controversies surrounding the use of adjuvant radiation therapy in the setting of resected pancreatic adenocarcinoma.

Stereotactic body radiation therapy is another technique being evaluated in the adjuvant setting given recent technologic advances and early data demonstrating its safety. Adjuvant SBRT would allow for early initiation of systemic therapy after radiation and has been explored in patients with close or positive margins [12]. Local failure was only observed in six patients (12.5%) and local progression-free survival at one and two years was 85% and 77% respectively. The median OS was 20.0 months and one- and two-year OS was 68% and 50% respectively. Additionally, adjuvant SBRT is being explored in combination with other novel agents such as anti-programmed cell death agents and GVAX pancreas vaccine. In a pilot feasibility study, 19 patients were treated with adjuvant SBRT, GVAX pancreas vaccine, and FOLFIRINOX [13]. While preliminary, the study suggests that SBRT can be safely utilized in the adjuvant setting with a combination of different therapies with minimal acute or chronic side-effects.

Currently, there are no consensus guidelines on the appropriate SBRT volumes in the adjuvant setting. However, postoperative patterns of failure offer insight into potential SBRT volumes for treatment that would include a dose painted approach targeting high-risk areas with higher doses (33 Gy) with elective nodal areas covered in lower doses (25 Gy) in five fractions. Additionally, post-SBRT patterns of failure note that most failures occurred outside targeted PTV volumes of SBRT but within traditional conventional RT volumes described in RTOG 0848 [14].

The use of SBRT in the adjuvant setting remains an open question. The results of RTOG 0848 using IMRT in the context of growing use of SBRT and new standards in mFOLFIRINOX are sure to add further debate on best-use practices in the adjuvant radiation setting.

Radiation in Resectable, Borderline Resectable, and Locally Advanced Disease

The role of neoadjuvant therapy is rapidly evolving in the setting of growing multidisciplinary approaches to pancreatic cancer (Fig. 149.1). There is a growing role for neoadjuvant chemotherapy with or without RT in PCA as neoadjuvant approaches offer several benefits, including early treatment of micrometastases and appropriate patient selection for surgery. Further, early chemotherapy avoids unnecessary surgical morbidity in patients whose cancer biology is unfavorable and rapidly progresses despite neoadjuvant therapy. In the context of neoadjuvant therapy, the use of neoadjuvant radiation is increasing, in part due to improvements in radiation technique and delivery. Neoadjuvant radiation is predominantly used for margin sterilization and local recurrence risk reduction in the resectable/borderline resectable setting and for improved LC in the locally advanced, unresectable setting [15–17].

Early data on neoadjuvant chemoradiation in resectable PCA and borderline resectable pancreatic cancer (BRPC) were limited to small phase II and single-institution data prior to the publication of the PREOPANC-1 study. The PREOPANC-1 trial is the first large phase III randomized trial to evaluate the use of neoadjuvant chemoradiation in resectable and borderline resectable PCA. A total of 246 (133 resectable and 113 BRPC) patients were randomized to preoperative chemoradiation consisting of three cycles of gemcitabine with concurrent radiation to 36 Gy in 15 fractions followed by surgery and four cycles of adjuvant gemcitabine vs immediate surgery followed by six cycles of adjuvant gemcitabine [15]. In the preoperative chemoradiation group, median OS was 15.7 months and five-year OS was 20.5% compared to 14.3 months and 6.5% in the immediate surgery group (P = 0.025) [15,16]. Additional secondary endpoints including DFS, local failure-free survival (LFFS), and pathologic findings were significantly improved with neoadjuvant chemoradiation. Of significance, the R0 resection rate by intent to treat was 41% (49/119) in patients who received preoperative chemoradiotherapy and 28% (35/127) in patients assigned to immediate surgery (P <0.001). Among patients who underwent surgery, the R0 resection rate was 71% (51 of 72) in patients who received preoperative chemoradiotherapy and 40% (37 of 92) in patients assigned to immediate surgery (P <0.001). On prespecified subgroup analysis of patients who underwent surgery and started adjuvant chemotherapy (N = 55 [46%] in neoadjuvant CRT vs N = 65 [51%] in immediate surgery arm), there was significantly higher OS with preoperative chemoradiotherapy (35.2 vs 19.8 months; P = 0.029). Additionally, in the subset of BRPC patients, preoperative CRT compared to immediate surgery showed a significantly improved OS and DFS with median OS of 17.6 vs 13.2 (P = 0.029). Given improvements in clinical outcomes with mFOLFIRNOX, the

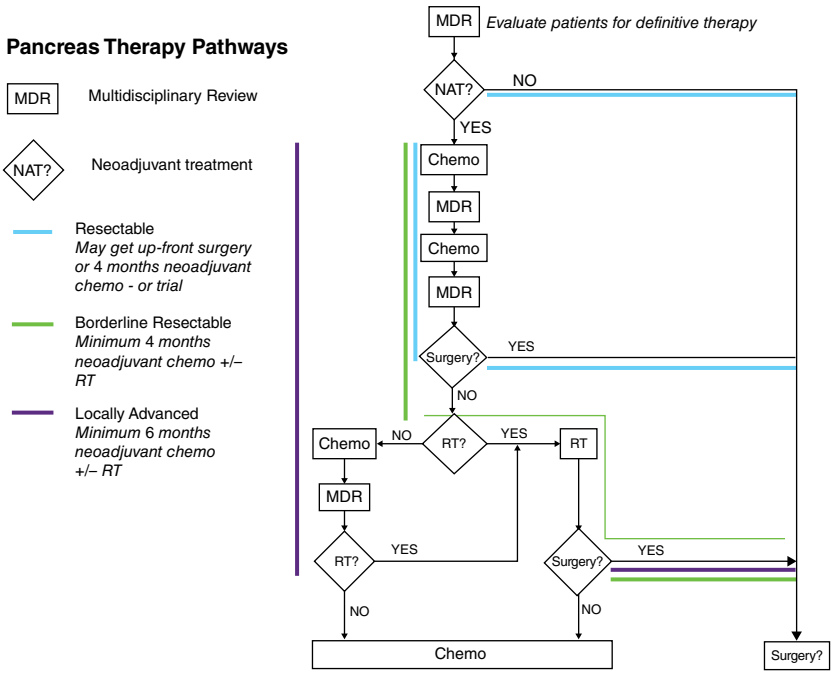

Figure 149.1 Definitive multidisciplinary therapy pathways across the different stages of pancreatic cancer with incorporation of neoadjuvant chemotherapy +/– radiation prior to surgery.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. PREOPANC-2 trial is comparing neoadjuvant FOLFIRINOX vs CRT as outlined in PREOPANC-1 (NTR7292). The NorPACT 1 and PANACHE01-PRODIGE48 trials (NCT02919787, NCT02959879) meanwhile are exploring chemotherapy-alone arms in comparison to initial surgery.

In the context of BRPC, a multicenter South Korean study randomized patients with BRPC to receive neoadjuvant CRT to 54 Gy with concurrent gemcitabine followed by surgery versus upfront resection followed by radiation [17]. The trial was terminated early on the basis of statistically significant neoadjuvant treatment efficacy on interim analysis after 50 out of planned 110 patients were enrolled. The two-year OS (40.7% vs 26.1%) and median survival (21 vs 12 months; $P = 0.028$) were both in favor of chemoradiation and a significant benefit in R0 resection rate was seen in the neoadjuvant CRT arm (51.8% vs 26.0%; $P = 0.004$). These data are in line with findings of PREOPANC-1 trial showing the benefit of neoadjuvant RT for localized pancreatic cancer.

Stereotactic body radiation therapy in the neoadjuvant setting is an area of active investigation given its safety and ability to shorten overall treatment duration, by allowing early resumption of systemic therapy or for early surgical resection. Early phase I/II studies using single-fraction SBRT (25 Gy) demonstrated excellent freedom from local progression (FFLP) at one year (>90%) and minimal acute toxicity, but high rates of late grade 2–4 gastrointestinal toxicity [18]. Subsequently, a single-arm phase II multiinstitutional study evaluated the safety of gemcitabine followed by SBRT to 33 Gy in five fractions in LAPC [19]. Forty-nine LAPC patients received gemcitabine followed by SBRT and continued gemcitabine until progression or toxicity. Rates of acute and late grade ≥2 gastritis, fistula, enteritis, or ulcer toxicities were 2% and 11%, respectively. Global quality of life scores remained stable from baseline to after SBRT and patients reported a significant improvement in pain (P <0.001) at four weeks after SBRT. Median serum cancer antigen CA-19-9 was reduced following SBRT (post-SBRT 4.2 weeks, 220 vs 62 U/mL; P <0.001) and median OS was 13.9 months. FFLP at one year was 78% and five patients with LAPC at diagnosis were deemed resectable, with four patients undergoing margin- and node-negative resections, with the fifth patient declining surgery.

Early work from the Moffitt Cancer Center and Johns Hopkins reported on the safety and efficacy of neoadjuvant SBRT after chemotherapy. A retrospective study of 159 patients (110 BRPC, 49 LAPC) [20] at Moffitt reported that amongst BRPC patients, 51% underwent surgery with 97% achieving a R0 resection and 7% had a pathologic complete response. Acute grade ≥3 toxicity was 2%, late grade ≥3 toxicity was 5% and median OS in the resected BRPC patients was 34 months. In a larger LAPC population, Johns Hopkins reported outcomes on 88 patients (14 BRPC, 74 LAPC) who received induction chemotherapy followed by 25–33 Gy SBRT [21]. Of the 19 patients (22%) who underwent surgery (including 17 LAPC) following SBRT, 84% had a R0 resection and 16% had a pathologic complete response. Median OS of resected patients was 20.2 months versus 12.3 months in unresected patients ($P = 0.07$).

The promising results of early studies on SBRT in the treatment of localized pancreatic cancer prompted its evaluation in a multicenter phase II Alliance A021501 that evaluated neoadjuvant mFOLFIRINOX with or without SBRT in BRPC. Patients were randomized to receive eight cycles of mFOLFIRINOX (Arm A) or seven cycles of mFOLFIRINOX followed by SBRT (33–40 Gy/5 fractions or 25 Gy/5 fractions) (Arm B). The study used a standardized intergroup definition of BRPC and centrally reviewed imaging prior to randomization to ensure quality of diagnosis. The goal of the study was to define the standard of care regimen for future phase III trials, and outcomes were compared to historical controls of OS of 50% at 18 months. Though not yet published, preplanned interim analysis resulted in early termination of the SBRT arm as it did not meet the prespecified R0 resection rate to be >11 out of first 30 patients who were enrolled.

Early results from the trial were presented at the ASCO 2021 GI Symposium [22] and provided early insights and considerable discussion on the challenges of PCA trial design and use of SBRT for BRPC. After enrolling 30 patients in each arm, interim analysis showed Arm A had a 57% R0 resection rate vs 33% in Arm B, which prompted the arm closure. When evaluating the SBRT arm, about half the patients did not make it to surgery due to development of progression or metastasis and only 35% of patients at final analysis underwent surgery in comparison to 49% in the chemotherapy-alone arm. One proposed explanation for the higher rates of progression of disease or metastasis prior to surgery in Arm B (14/155, 25.5%) compared to Arm A (8/65, 12.3%) could be the higher median CA 19-9 levels noted (median 248 U/mL vs 171 U/mL) respectively. Among patients who underwent pancreatectomy, 18-month OS rates were similar at 93.1% and 78.9% in Arm A and B, respectively. Surgical pathologic outcomes reported pathologic complete response of 11% vs 0% favoring RT and near complete response (defined as <5% viable cells) of 26% vs 13% favoring the RT arm. The 18-month OS rate by intention to treat was 66% vs 47% in favor of the chemotherapy-alone arm, and the SBRT arm did not meet the final efficacy rule of >50% OS at 18 months.

Given the conflicting findings of the PREOPANC and South Korean studies, and recent ALLIANCE trial, further studies are warranted to better elucidate how to

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

select which patients are more likely to benefit from neoadjuvant RT and subsequent surgery. In addition, a large proportion of patients still succumb to both local and systemic recurrence, suggesting a need to enhance both local and systemic therapies.

The role of RT in LAPC remains controversial, similar to BRPC, but new techniques allowing for the safe delivery of ablative doses of radiation have provided hope to improve outcomes. The LAP-07 phase III trial showed no OS benefit in adding CRT (54 Gy with concurrent gemcitabine) compared to chemotherapy alone (median OS 15.2 vs 16.5 months; $P = 0.83$) [23]. CRT was well tolerated with no increase in toxicity and notably did improve local progression with 32% vs 46% ($P = 0.03$) and time off chemotherapy (6.1 vs 3.7 months; $P = 0.02$).

Given the suboptimal outcomes with older radiation techniques used in LAP-07, SBRT and SBRT-like techniques are being investigated. A pooled analysis of 19 total SBRT trials with unresectable PCA showed a median OS of 17 months with LC of 72%, offering a potential avenue for improvement in outcomes [24]. In another meta-analysis comparing SBRT to conventional fractionated RT, SBRT was statistically favored with two-year OS at 26.9% for SBRT vs 13.7% for conventionally fractionated radiation therapy and decreased rates of toxicity [25]. Further, with the consideration that patients originally deemed unresectable may be taken to the operating room, neoadjuvant SBRT in LAPC may improve margin-negative resection rates, with 10–20% resection rates reported retrospectively at Moffitt and Hopkins with 100% and 80% R0 rates [20,21]. In LAPC or high-risk patients, the recently opened MASTERPLAN (NCT04089150) trial is evaluating the safety of SBRT with multiple chemotherapy regimens in a multicenter phase II trial.

Similar to SBRT volumes in the adjuvant setting, treatment volumes in the neoadjuvant and definitive settings are an area of increasing debate. Although historically SBRT or high-dose volumes were limited to gross tumor (Fig. 149.2), growing data on the safety and tolerability of elective nodal irradiation (ENI) [26], and early closure of the Alliance trial with success of PREOPANC with larger target volumes have ignited controversy on best practice [27]. In a propensity-matched cohort study, Miller et al. reported that SBRT to 40 Gy to gross tumor with ENI to 25 Gy per RTOG guidelines improved locoregional progression at the expense of increased (60% vs 20%; $P < 0.001$) acute grade 1–2 nausea, with control rates of 22.6% vs 44.6% ($P = 0.21$) in favor of ENI vs SBRT to tumor alone. A recent patterns of failure study of 510 patients who received SBRT for LAPC offers insight on location and distance of common failures including the celiac and super mesenteric axis commonly covered as part of ENI [28]. Such information may guide selection

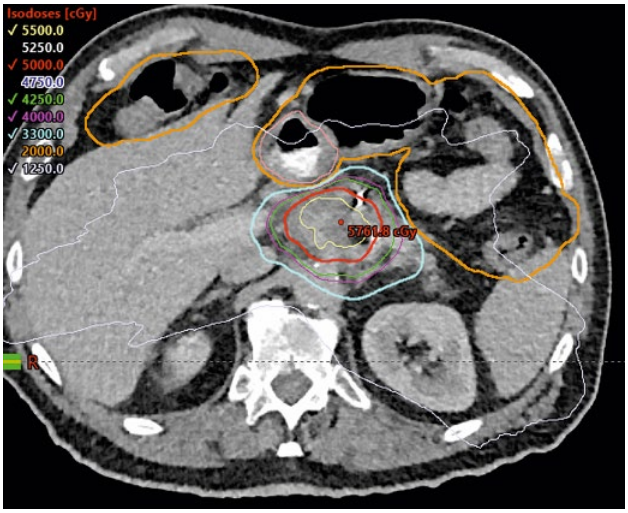

Figure 149.2 Pancreas SBRT plan demonstrating a highly conformal plan with a dose painted approach, 50 Gy to PTV (minus bowel PRV) and 35 Gy to PTV to meet strict dose constraints of nearby OAR including duodenum, small bowel, and stomach.

of appropriate SBRT volumes. Though current SBRT guidelines from the European Society of Radiation Oncology (ESTRO) currently advise against ENI due to lack of prospective evidence [29], there is growing consideration of and debate on the need of ENI.

Outside treatment volumes, there is considerable discussion regarding dose escalation in pancreatic cancer with the goal of reaching ablative doses (biologically effective dose $[BED]_{10} \geq 100$) [30]. However, dose escalation is limited by radiosensitivity of nearby gastrointestinal organs. Stereotactic magnetic resonance (MR)-guided adaptive radiation therapy (SMART) uses recent technologic advancements in MR-guided radiation therapy (Fig. 149.3) that allow for improved soft tissue contrast and ability to use real-time intrafraction assessment of tumor and OAR structures with on-table replanning and automatic beam gating. SMART to a dose to 50 Gy produced a 4.6% grade 3 GI toxicity with one-year LC of 84.3% [31] though OS was 68.2% and 37.9% at one and two years respectively, with 93% of radiation plans reoptimized during the course of treatment. Choung et al. reported on their outcomes of 35 patients treated with SMART showing 2.6% late grade 3 toxicity with one-year LC of 87.8%. Of note, ENI to 50 Gy was also completed in 57.1% of patients, highlighting the safety of MR guidance for both gross and regional nodal disease outside of OARs [32].

The use of MR-guided radiation therapy brings promise for the future of radiation therapy, including daily adaptive therapy. It is currently undergoing prospective evaluation for LAPC in a multiinstitutional phase II trial—SMART (NCT03621644).

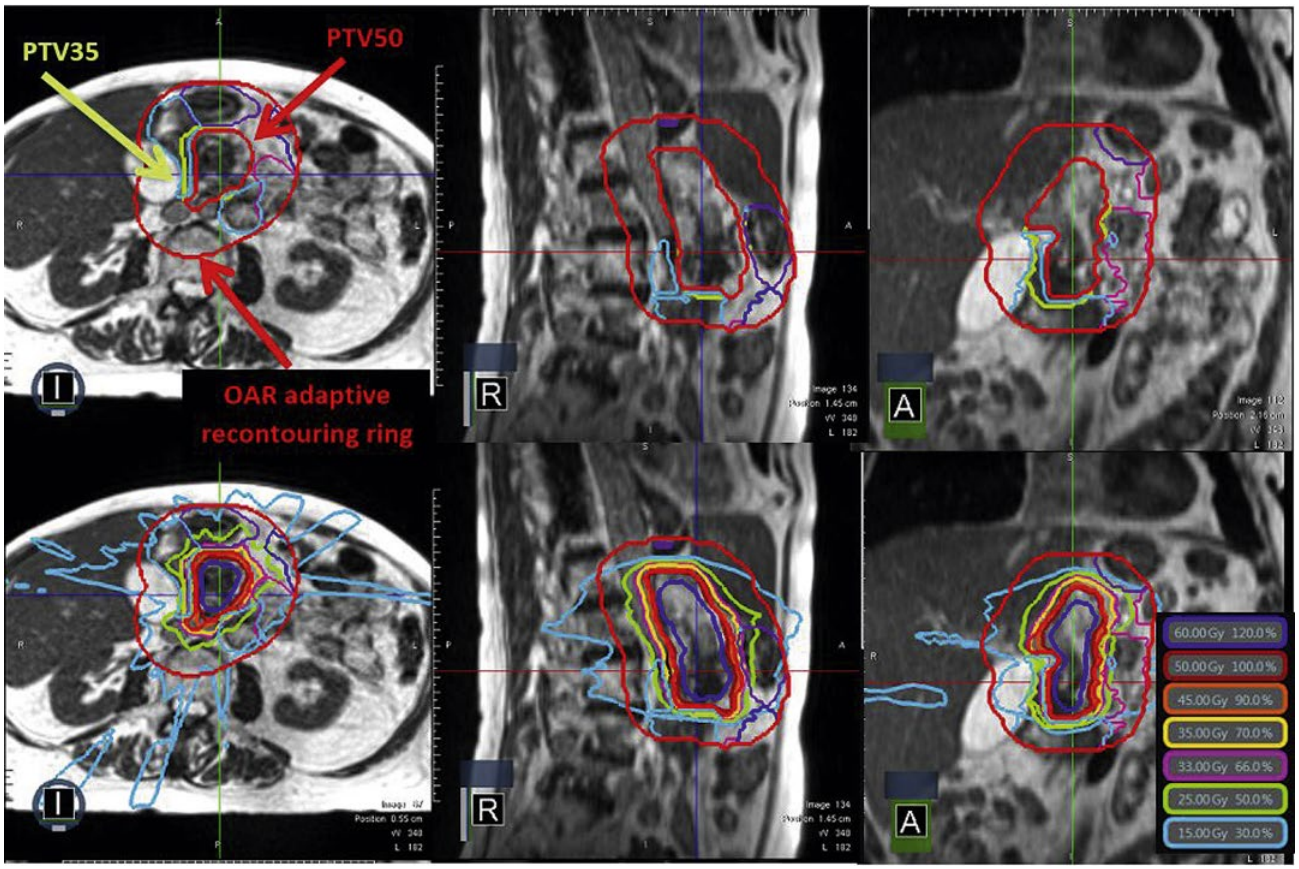

Figure 149.3 Target volumes (top row) and isodose lines (bottom row) for pancreas patient treated with SMART radiation using daily MRI and on-table adaptive replanning.

Dose-escalated intensity-modulated radiation therapy (DE-IMRT) using standard or moderate hypofractionation has also shown promise in the treatment of LAPC/unresectable pancreatic cancer. Retrospective single-institution work by Memorial Sloan Kettering demonstrated that a dose painted ablative radiation therapy approach with 75 Gy in 25 fractions (BED_{10} = 97.5 Gy) for tumors less than 1 cm from critical dose-limiting structures or 67.5 Gy in 15 fractions (BED_{10} = 97.88 Gy) for tumors >1 cm away from critical structures can be safe and effective [33]. In 119 patients with inoperable tumors, median OS was 26.8 months with 12- and 24-month OS rates of 74% and 38%, respectively. Locoregional failure rates at 12 and 24 months were 17.6% and 32.8%, respectively. Ablative radiation therapy using dose painted approaches allows high-dose ablative doses favored in SBRT with coverage of ENI volumes and is another growing area of interest in LAPC that are unlikely to undergo surgery. The use of dose-escalated radiation is currently undergoing prospective evaluation in a single-institution phase II trial—MAIBE (NCT03523312) at Memorial Sloan Kettering with a goal of completion in 2023.

Intraoperative Radiation Therapy

One method of delivering ablative doses of radiation involves intraoperative radiation therapy (IORT). Advantages of IORT include the ability to directly visualize the site of interest and shield normal OARs. Delivery methods of IORT include linear accelerator-based electron therapy, low-dose rate brachytherapy, high-dose rate (HDR) brachytherapy, or low-energy photons. Although there are no consensus guidelines on the indications for IORT, growing literature supports its use for close or positive margins at time of surgical resection and unresectable disease at time of surgical exploration with no to limited increase in the risk of perioperative or postoperative toxicity. Typical IORT doses range from 10 to 15 Gy in a single fraction.

Initial reports of IORT use in pancreatic cancer first came from Japan where doses of 20–40 Gy in one fraction were associated with improved outcomes and pain relief [34]. More recently, IORT has been used and investigated at Massachusetts General Hospital (MGH) where multiple large retrospectively publications highlight its benefit. Sekigami et al. reported IORT use for resectable

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

disease in 201 patients treated with neoadjuvant FOLFIRINOX and chemoradiation (50.4 Gy in 28 fractions) followed by surgical resection with or without IORT to 10 Gy in one fraction [35]. In the no-IORT group, patients with R1 resection had significantly worse DFS and OS. However, in the IORT group, there was no difference in DFS or OS between patients who had R0 and R1 resections, suggesting that IORT may mitigate the negative effect of an R1 resection. Just as important, there was no difference in 30-day Clavien-Dindo III/IV toxicity (IORT 17% vs no-IORT 22%; $P = 0.477$) and 90-day mortality (IORT 3.4% vs no-IORT 2.7%; $P = 0.999$) between the two groups. The use of IORT is undergoing prospective evaluation in a single-institution phase II trial—PACER (NCT03716531) at MGH.

Proton Beam Therapy

While IMRT and SBRT can minimize the high doses received by OARs and therefore decrease the likelihood of adverse effects compared to 3D-CRT, pancreatic RT doses remain compromised by the proximity of these normal tissues. Therefore, some have looked to proton beam therapy (PBT) to improve the therapeutic ratio for PCA patients as well as to dose escalate doses, with encouraging early results. Protons have an inherent advantage over photons in that they deliver much of their dose at a specified depth beyond which there is no dose to normal tissues. Because proton beams have no exit dose, as few as two beams are needed to create highly conformal dose distributions (Fig. 149.4). Therefore, PBT can significantly minimize radiation dose from large volumes of normal tissue.

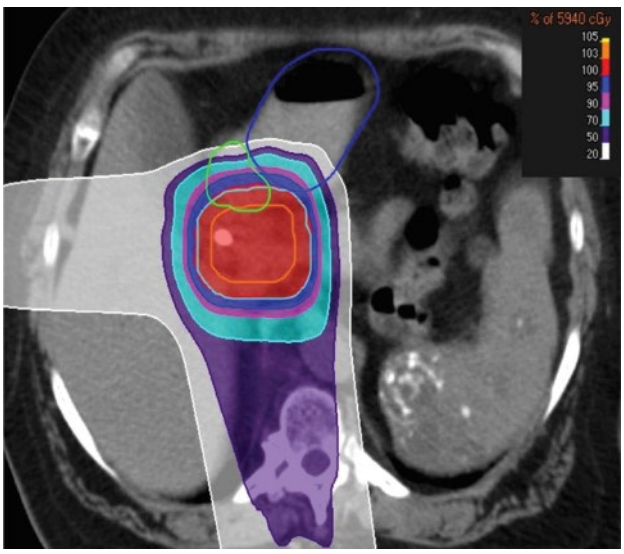

Figure 149.4 PBT treatment plan illustrating the delivery of a highly conformal dose (to 59.4 Gy) to the tumor while minimizing dose to surrounding normal tissue.

Multiple dosimetric studies have illustrated that PBT for PCA can significantly reduce dose to normal tissues compared to photon therapy, importantly without sacrificing target volume coverage. Nichols et al. compared IMRT and passive scattering PBT prescribed to 50.4 Gy for eight patients with resected pancreatic head tumors [36]. PBT plans had significantly lower doses to adjacent structures such as the right kidney V18 Gy (27.3 vs 50.5%; $P = 0.0156$), small bowel V20 Gy (15.4 vs 47%; $P = 0.0156$), and stomach V20 Gy (2.3 vs 20%; $P = 0.0313$). In a similar analysis, Ding et al. evaluated 3D-CRT, IMRT, passive scattering PBT, and a more conformal proton delivery technique called modulated scanning or pencil beam scanning for 11 resected PCA patients and found PBT (specifically the pencil beam scanning plans) had the lowest right kidney V18 Gy, stomach V20 Gy, and small bowel V15 Gy [37].

Another area of interest is the combination of PBT with SBRT, which would theoretically allow for deposition of therapeutic dose at a specified depth and steep dose fall-off. A recent study by Liu et al. compared photon SBRT plans with proton SBRT plans for 19 patients with localized disease [38]. The prescribed dose was 30 GyE in five fractions to the target and 45 GyE in five fractions to the boost area. Two-field proton SBRT led to lower maximum duodenum dose and lower maximum stomach dose when compared to photon SBRT in patients with pancreatic head lesions while photon SBRT led to lower maximum stomach dose when compared to the proton SBRT. These findings highlight the need for further investigation into the relationship between tumor location and selection of optimal treatment modality/technique.

While the published clinical experiences using PBT for PCA are limited, the outcomes from these studies are encouraging (Table 149.1). Investigators from MGH published outcomes of a phase I trial that evaluated neoadjuvant hypofractionated PBT with concurrent capecitabine for resectable PC [39]. A total dose of 25 Gy delivered in five consecutive fractions was well tolerated; no dose-limiting toxicities occurred. A subsequent MGH phase I/II trial of neoadjuvant PBT (25 Gy in five fractions) with capecitabine for resectable PCA enrolled 50 patients, with 35 being treated in the phase II portion [40]. Grade 3 toxicity occurred in only two patients (4.1%). With median follow-up of 38 months for all patients, median progression-free survival was 10 months and median survival was 17 months.

The initial results of a Japanese phase I/II trial of PBT with concurrent gemcitabine for LAPC were reported in 2012 [41]. Fifty patients were enrolled and were prescribed an aggressive regimen of gemcitabine for three

LRC = locoregional control, PFS= progression free survival, OS = overall survival, RBE = relative biological effectiveness.
* Levels 2 and 3 treated on nonconsecutive days; level 4 treated on consecutive days.

weeks concurrent with PBT and 80% of patients were prescribed 67.5 Gy in 25 fractions. With median follow-up of 12.5 months, outcomes were encouraging and included a grade 3 toxicity rate of ~10%. However, a subsequent publication that included 91 patients had a nearly 50% incidence of radiation-induced ulceration in the stomach and duodenum [42]. While margin expansions up to 5 mm were permitted during treatment planning to account for respiratory motion, no specific description of motion management usage was given in the manuscript. Therefore, the aggressive nature of the treatment regimen, and not PBT itself, is likely responsible for this high complication rate. This should serve as a reminder that despite the dosimetric advantages of PBT, we must remain vigilant about limiting dose to normal tissues and that motion management should always be considered.

While there is much potential to improve the therapeutic ratio for PCA patients with PBT, some practical proton planning and delivery considerations should not be overlooked. Proton dose deposition is strongly influenced by tissue densities within the beam path and changes in these densities, such as from respiratory motion, setup errors, and even bowel peristalsis, can potentially lead to underdosing of target and overdosing of normal tissues. As such, motion management strategies like respiratory gating, breath hold, or abdominal compression for targets in the upper abdomen should be used.

Finally, image guidance for PBT is currently limited to only kV imaging and this is not ideal for soft tissue assessment in PCA patients. Cone beam CT (CBCT) for PBT has only recently become available at a few select proton centers and is expected to become more widely available over the next several years. CBCT will enable more selective margins to be used, thereby further reducing normal tissue dose.

Future Directions

Perhaps most critical to the appropriate use of radiation in patients with PCA is appropriate patient selection. Identifying those patients at greatest risk for local versus distant progression can help determine selective administration of RT and/or surgery. Development of predictive biomarkers that can identify those patients at greater risk for local failure is needed. One autopsy series of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

consecutive patients who succumbed to PCA demonstrated that roughly 30% of patients most likely died from locally destructive disease, highlighting the importance of achieving better LC [43]. In these patients, expression of Smad4 was highly associated with a locally destructive phenotype, findings which have also been replicated in a phase II study of chemoradiation for LAPC [44].

As we await identification of more biomarkers, clinical investigation into identifying optimal treatment dose, fractionation, and volumes may allow the benefit of time to understanding an individual patient's biology and risk of local failure. Recent reports highlight the benefit of dose escalation, and as a result, techniques to optimize radiation delivery (SBRT, SMART, DE-IMRT) are being actively investigated [31,32,45]. Furthermore, the ideal radiation treatment approach and volumes in the preoperative/definitive and adjuvant setting require consensus.

Finally, we eagerly await the results of combination therapy trials involving radiation and other novel immunologic and radiosensitizing agents such as GRECO2 (NCT04698915). These results may help guide clinicians in selecting more personalized therapy as improvements in systemic control and the promise of immunotherapy create an evolving role for RT in providing improved LC that results in OS benefits to select patients. Future studies are needed to determine how to optimally integrate these novel therapeutic advances in multidisciplinary clinical trials with meaningful endpoints that improve outcomes (OS and quality of life) of patients with pancreas cancer.

Introduction

Pancreatic ductal adenocarcinoma (PDA) is not one of the most common types of cancers diagnosed, yet it is the third-leading cause of cancer-related deaths in men and women [1]. The only current chance of cure remains surgical resection but <30% of patients who present with PDA are candidates for curative resection. In patients with locally advanced unresectable PDA, the role of radiation therapy is still questionable so for the majority of patients, palliative chemotherapy is the only known option that can prolong survival [2–6]. Although neoadjuvant chemotherapy has converted more patients into candidates for curative resection, adjuvant chemotherapy in the combination format following surgical resection is required to significantly prolong disease-free survival and overall survival. Despite the broad application of adjuvant chemotherapy, the majority of those who undergo surgical resection will ultimately relapse and die from their disease [1]. As a result of all these efforts, the five-year survival of all-stage PDA patients is rising, but slowly, and has only risen to 9%.

More recently, metastatic PDA patients who carry a germline mutation in *BRCA1* or *BRCA2*, who constitute a small subgroup of PDA patients, were found to benefit from poly-ADP-ribose polymerase inhibitors (PARPi) in the maintenance setting [7]. Otherwise, there has not been any significant progress in the development of targeted therapies for PDA patients because the most common genetic alterations in PDA, such as *KRAS*, *SMAD4*, and *TP53*, are not currently targetable.

Since 2014, the emergence of immunotherapy has changed the treatment landscape of many aggressive malignant diseases, but PDA remains one of most challenging tumors to treat. Although there have been positive advances created by harnessing the immune system to help combat PDA, the current immunotherapeutic strategy is still not effective for PDA. Nevertheless, in the last five years, our understanding of the immunotherapy resistance mechanism in PDA has advanced owing to a more in-depth analysis of the tumor microenvironment (TME) of pancreatic cancer.

Immunology of Pancreatic Cancer

The TME of pancreatic tumors is renowned for its stromal density and heterogeneity, containing numerous cellular components including fibroblasts, pancreatic stellate cells, blood vessels, and immune cells [8].

The immune system is classically activated in response to foreign antigens, whereas cancer cells can express tumor-associated antigens as well as neo-antigens that occur in response to the tumor's continuously changing molecular composition. In both cases, the immune system can be activated to recognize these tumor antigens. However, tumor cells are more likely to interact with the immune system and lose antigen recognition through the process of immunoediting [9]. This dynamic process consists of three phases: elimination, where the immune system successfully destroys the tumor cell; equilibrium, where the system controls tumor growth but does not destroy the tumor cell; and escape, where the tumor cell overcomes the immune system and progresses to a clinically detectable disease state.

The innate immune system consists of immune cells (e.g., macrophages, granulocytes, dendritic cells) that serve as "first responders" of the immune response and

are attracted to regions of inflammation or infection within minutes or hours. The adaptive immune system comprises B- and T-cell lymphocytes which respond to foreign invasion of cells, typically by infectious agents. Professional antigen-presenting cells (APCs) (dendritic cells and macrophages) are alerted and take up foreign proteins for processing and presentation, subsequently triggering B- and T-cell responses. B lymphocytes are responsible for mounting a long-term response to foreign antigens by producing antibody-secreting effector cells. T lymphocytes, categorized according to cell surface markers, and cytokines, as well as the chemokines they produce, have many distinct effector functions. Cytotoxic T-lymphocytes (CTLs) express CD8 and eradicate cells by secreting molecules that induce apoptosis.

When an APC expresses an antigen on major histocompatibility class II (MHCII), a CD4+ T cell (helper T cell, Th) becomes activated and differentiates into distinct effector subtypes, mediating the immune response through the secretion of specific cytokines (Fig. 150.1). A specific subtype of CD4+ T cell, Treg, suppresses T-cell activation, thereby protecting the body from autoimmune reactions. CD4+ T cells make up the majority of T cells in PDA and are associated with metastasis and negatively associated with survival [10,11].

The protective role of the immune system in cancer is demonstrated by the observation that increased amounts of tumor-infiltrating lymphocytes (TILs) correlate favorably with survival in many tumor types, including melanoma and PDA [12,13]. The complexity of the immune system results in certain immune components promoting immune suppression, such as myeloid-derived suppressor cells (MDSC), tumor-associated macrophages (TAM), and tumor-associated neutrophils (TAN) [14,15]. Preclinical models which faithfully recapitulate the progression of precursor pancreatic lesions in their development from preinvasive pancreatic intraepithelial neoplasia (PanIN) to invasive PDA show that immunosuppressive cells dominate the TME, even during the early stages of tumor development [16]. These cells, which include MDSC, Treg and TAM, result in reduced T-cell development and infiltration (specifically effector T cells) which indirectly drives tumor promotion. This has led to efforts to directly target these immunosuppressive cells, e.g., targeting colony-stimulating factor 1 (CSF-1R) which regulates the differentiation and survival of TAM [17].

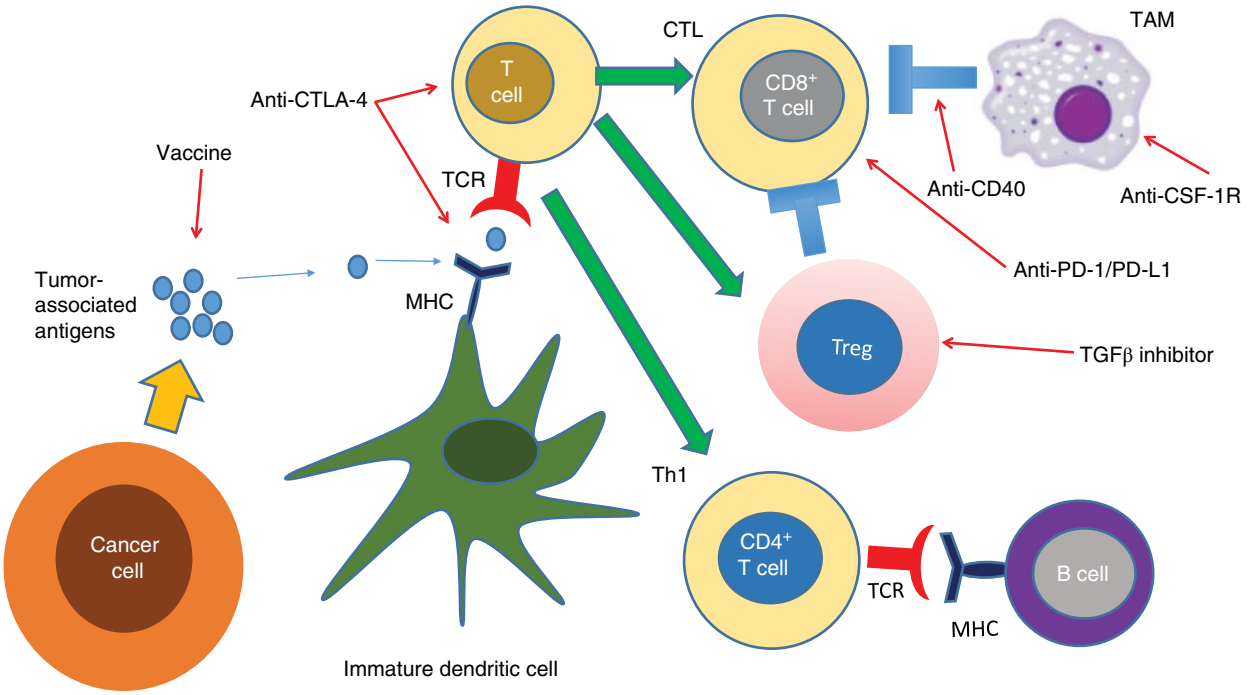

Figure 150.1 Components of immunotherapy in pancreatic cancer. Tumor cells express specific antigens which can activate antigen-presenting cells by binding to MHC molecules on their cell surface which in turn bind to T-cell receptors (TCR) on T cells. Anti-CTLA-4 therapy directly targets this interaction. This results in T-cell activation and differentiation into various T-cell subtypes including CD8+ cytotoxic T lymphocytes (CTL), regulatory T cells (Treg), and Th1 (T helper cells). CTL activity can be eliminated by tumor-associated macrophages (TAM) resulting in tumor progression. Pharmacologic inhibition of CSF-1R (colony-stimulating factor-1 receptor) and CD40 can reduce this effect. Tregs can also suppress CTLs, an effect which can be negated by targeting TGF (transforming growth factor) β. Th1 cells induce B-cell activation which results in antibody production and activation of humoral immunity.

The procarcinogenic inflammatory response found in most tumors is highly regulated by the progressive genetic alterations that occur with cancer development and progression. For example, the *KRAS* proto-oncogene is mutationally activated in 90% of PDA and results in constitutive activation of *KRAS* and its downstream signaling pathways. *KRAS* activation drives cancer cell migration and metastasis [18]. Preclinical models have shown that *KRAS* inactivation results in the high expression of granulocyte-macrophage colony-stimulating factor (GM-CSF) [19,20]. GM-CSF has been shown to result in the accumulation of MDSC by inducing the proliferation and differentiation of precursor c-kit$^+$ stem cells which leads to the suppression of CD8+ T-cell mediated antitumor immune responses, thereby permitting tumor growth.

T cells express a number of stimulatory and inhibitory signals depending on the type of inflammation they encounter. Whether a T cell becomes activated or deactivated depends on the net sum of the signals that are engaged. Two T-cell inhibitory signals, cytotoxic T-lymphocyte associated protein 4 (CTLA-4) and programmed death-1 (PD-1) have been shown to have significant clinical relevance in cancer. CTLA-4 acts as an immune checkpoint striving to maintain immune homeostasis by downregulating T-cell function once CD28 binds to its ligand B7, therefore inducing T-cell cycle arrest (Fig. 150.2) [21]. Due to its role as a negative regulator of immunity, it was the first checkpoint to be clinically targeted after preclinical models showed that antibody blockade of CTLA-4 lead to antitumor immunity [22,23]. PD-1 is also an immune checkpoint which negatively regulates T-cell activity when it interacts with its ligands, PD-L1 and PD-L2 [24]. PD-1 is expressed on many immune cells and inhibits effector T-cell function [25]. Antagonist antibodies that inhibit these molecules, also called immune checkpoint inhibitors (ICIs), have recently become standard of care for cancers that naturally attract effector T cells into their tumor.

Despite the paragidm shifting implications of ICIs in many tumors, PDA has been ICI treatment refractory. The TME of PDAs is considered an immune "desert" because of the paucity of natural infiltration of effector T cells, the very cells that respond to ICIs [26,27]. Thus, PDAs are considered to be immunogenically "cold" tumors [28–30]. To convert PDAs into ICI-responsive tumors, effective immunotherapy strategies are required at a minimum to increase antigenicity, enhance effector T-cell infiltration and function, and overcome immunosuppressive signals in TMEs [31–33]. Emerging data from our group and others provide strong evidence that PDAs require all three to respond to ICI therapy.

We have been testing the hypothesis that cancer vaccines are effective in inducing effector T cells that can infiltrate PDAs. We have reported that our GM-CSF-secreting allogeneic PDA cell vaccine (GVAX) can induce the formation of tertiary lymphoid aggregates in PDAs just two weeks following single vaccination and that these aggregates serve as sites of T-cell education to PDA antigens [34]. Furthermore, PD-L1 expression is induced on both the tumor epithelium cells and myeloid cells within these lymphoid aggregates, suggesting that vaccine therapy may prime PDAs to respond to ICIs [34,35]. However, the current challenge is to identify the additional immune suppressive signals within the complex PDA TME that require further modification to effectively enhance effector T-cell function. Additionally, it is still not clear how best to activate the most potent effector T cells. Further studies are required to identify the best T-cell activating vaccines and combination ICIs for durable anticancer responses in the majority of PDA patients.

In an effort to seek an effective immunotherapy strategy for PDA, essentially all types of immunotherapy have been investigated in PDA patients. Consequently, PDA has been more and more recognized as a typical "cold" tumor model and thus an appropriate tumor platform

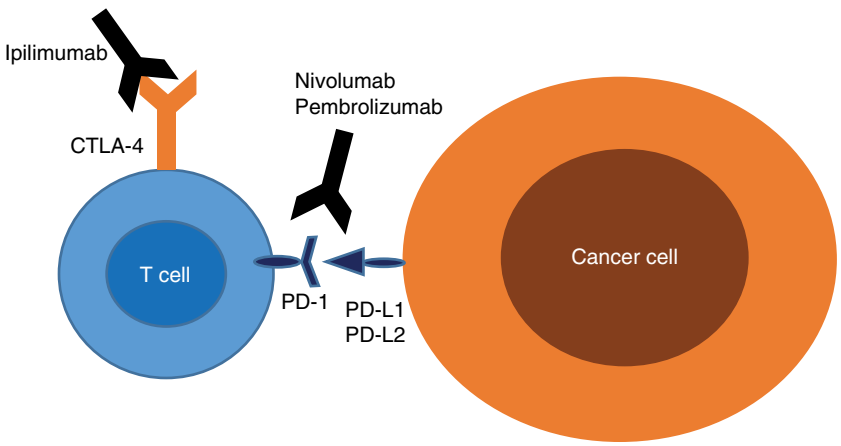

Figure 150.2 Checkpoint inhibitors in pancreatic cancer. T cells express CTLA-4 (cytotoxic T-lymphocyte associated-4) antigens on their cell surfaces which downregulate T-cell function. Anti-CTLA-4 antibodies (e.g., ipilimumab) can bind to CTLA-4 receptors on T cells and reverse immunosuppressive T-cell functions. PD-1 (programmed death-1) receptors on T cells bind to PD-L1 and PD-L2 ligands on cancer cell surfaces. Anti-PD-1 antibodies bind to PD-1 receptors preventing interactions with its ligands.

for developing immunotherapeutic treatment strategies for "cold" tumors in general. Although presently there has not been a breakthrough in developing clinically successful immunotherapy for PDA, many different approaches have been attempted and are currently being further developed in treating PDA, as outlined below. Together, these efforts offer a rational approach that will ultimately lead to a breakthrough immunotherapy strategy for PDA, which would turn scientific hope into reality.

T-cell Priming in Pancreatic Cancer: From Therapeutic Vaccines to Adoptive T-cell Therapy

Cancer vaccines are used to generate a humoral/cellular immune response to stimulate the immune system as a defense mechanism against tumor cells. Therapeutic vaccines deliver specific pancreatic tumor antigens systemically with the aim of further stimulating the patient's immune system to recognize minor differences in the antigen that exists between normal and tumor cells. These vaccines are generally well tolerated because of their antigen specificity. Therapeutic vaccines can be broadly categorized into whole-cell vaccines and antigen-specific vaccines. ×

Whole-cell Vaccines

Polyvalent vaccines are derived from whole cells or cell lysates and have the capacity to allow the targeting of multiple antigens.

The allogeneic whole-cell pancreatic tumor vaccine GVAX developed by Jaffee et al. [36] was derived from two human pancreatic cancer cell lines stably transfected to produce the human cytokine GM-CSF. GM-CSF has the capacity to overcome tumor-induced suppression and promote the recruitment and maturation of APCs, resulting in upregulation of MHC class II costimulatory molecules and cytokine production. GM-CSF-producing tumor cells are subsequently irradiated and administered to patients intradermally. The phase I study comprised 14 patients with stages I–III pancreatic cancer who received multiple administrations of vaccine with concentrations ranging from 1–50 × 10^7 cells after surgical resection and standard adjuvant therapy. This study found that three patients who received ≥10 × 10^7 vaccine cells developed increased delayed-type hypersensitivity (DTH) responses and that these patients remained disease free for over 10 years [36]. GVAX was well tolerated without any local or systemic dose-limiting toxicities observed. The most common adverse effects were self-limiting skin reactions (erythema, induration, pain) at the sites of immunization.

The phase II study involved administering 5 × 10^8 GM-CSF-secreting cells to 60 patients with resected PDA [37]. Patients received five doses of vaccine in addition to 5-fluorouracil (5FU)-based chemotherapy. The median disease-free survival was 17.3 months (95% confidence interval [CI] 14.6–22.8) and the median survival was 24.8 months (95% CI 21.1–31.6). The addition of immunotherapy to chemotherapy did not result in additional toxicities and the development of mesothelin-specific CD8+ T cells in HLA-A1+ and HLA-A2+ patients was correlated with improved disease-free survival.

Based on preclinical data that giving cyclophosphamide (Cy) prior to immunotherapy could enhance the intended immune responses by inhibiting CD4+/CD25+ Treg cells [38–41], Laheru et al. designed a clinical study comparing the effects of administering Cy prior to GVAX vaccine in patients with advanced PDA. Fifty patients received Cy one day prior to the vaccine or the vaccine alone and minimal toxicities were observed in both arms. Survival data from this nonrandomized study suggested that adding Cy prolonged median survival (130 vs 69 days). This study also found that mesothelin-specific immune responses were detected in this cohort of patients with advanced disease.

Pancreatic ductal adenocarcinoma has traditionally been regarded as a nonimmunogenic cancer compared to melanoma or lung cancer. A neoadjuvant and adjuvant clinical trial was designed to test whether GVAX ± Cy could convert the relatively nonimmunogenic TME of PDA into an immunogenic tumor with infiltrating effector lymphocytes [42]. Two weeks prior to surgical resection, 39 patients were randomized to receive GVAX alone, GVAX preceded by a single intravenous Cy dose, or GVAX with daily Cy on alternate weeks. Examination of the resected PDAs showed that vaccines induced intratumoral tertiary lymphoid structures (TLS) in 85% of patients. Further analysis of these TLS aggregates showed that they consisted of organized T- and B-cell zones with a germinal center-like structure, indicating that they represented adaptive immunity. Specific gene expression signatures were found in these intratumoral aggregates, including those showing that a suppressed Treg pathway and enhanced Th17 pathway were associated with improved survival. Consistent with prior studies, there was an association between those who developed an immune response/lymphoid aggregates and improved survival. This study also showed that the expression of immune checkpoint signaling, such as PD-1 and PD-L1, was induced by vaccination, suggesting that GVAX therapy could play a role in priming patients to combat the lack of response

to anti-PD-1 therapies seen in PDA. The final publication after the clinical trial completed the enrollment of 87 patients has confirmed the safety and feasibility of conducting a window-of-opportunity neoadjuvant clinical trial of examining the effect of an experimental immunotherapy on the TME and also confirmed that the density of vaccine-induced intratumoral TLS is associated with improved survival following the surgery and the neoadjuvant/adjuvant treatment of the vaccine [43].

Antigen-specific Vaccines

Antigen-specific vaccines take advantage of inherent defects in the genetics of PDA and translate these into functional targets for immunotherapy. As *KRAS* mutations are universal in PDA and are known for their role in driving the PDA development [44,45], they are an obvious target for immunotherapy.

Early studies which involved administering synthetic KRAS peptides to patients with unresectable PDA showed that it was safe and induced an immune response in two out of five patients [46]. Another phase I/II trial coadministered mutant KRAS peptides with GM-CSF in a study involving 48 patients with PDA [47]. Immune responses were elicited in 58% of patients and in those with advanced disease, a peptide-specific immune response was associated with improved survival. A further study evaluated the administration of patient-specific KRAS mutations (codon 12) with a 21-mer epitope containing the patient's mutation and GM-CSF in patients with resected PDA [45]. They demonstrated median recurrence-free survival and overall survival of 8.6 months and 20.3 months, respectively. However, there were low rates of immunogenicity, with a single patient developing a detectable mutation-specific immune response and 13% of patients developing a non-specific DTH.

Interest first arose in mesothelin, a tumor-associated antigen overexpressed in most PDAs, as a target for immunotherapy in PDA based on the observation that mesothelin-specific responses were associated with improved disease-free survival after GVAX therapy [48,49]. This led to the development of CRS-207, a recombinant live-attenuated, double-deleted strain of *Listeria monocytogenes* (LADD-Lm) which was engineered to secrete mesothelin into the cytosol of infected APCs which ultimately are processed and presented as major histocompatibility complex molecules. The phase I study involving CRS-207 demonstrated that multiple administrations were well tolerated and sufficient to induce mesothelin-specific T-cell responses [50]. Preclinical data suggested that a heterologous prime-boost strategy combining GVAX and LADD Lm-expressing mesothelin induced a synergistic T-cell induction and antitumor effect.

A subsequent phase II study randomized patients with previously treated metastatic PDA to receive Cy/GVAX followed by CRS-207 vs Cy/GVAX alone [42]. Overall survival for all patients was higher in the Cy/GVAX + CRS-207 group (6.1 vs 3.9 months). For those patients who received at least three doses, overall survival for the Cy/GVAX + CRS-207 group was 9.7 months compared to 4.6 months for the Cy/GVAX alone group. Enhanced mesothelin-specific CD8+ T-cell responses were associated with longer survival in both treatment groups. However, the clinical efficacy of this heterologous prime-boost vaccine therapy strategy was not substantiated in the follow-up randomized study in comparison with chemotherapy, suggesting that vaccine therapy by itself may not be sufficient to elicit an effective antitumor response.

Neoantigen-based Vaccines

Somatic gene mutations occurring in individual tumors can generate novel epitopes or "neoepitopes' which serve as targets for immune responses [51]. The technology to recognize individual neoepitopes now exists which can scan the entire cancer exome (coding regions). It is important to note that for neoepitopes to be functional, their mutant peptides must be processed by MHC molecules and T cells must recognize these peptide–MHC complexes. An added complexity lies in the fact that these epitopes must have been tolerated by the immune system to permit the tumor to grow. This tolerance appears to be mediated by immune checkpoints, e.g., PD-L1 [52]. It is unsurprising that these tumor types are typically sensitive to immune checkpoint inhibition since they induce effector T-cell infiltration that resembles untreated melanomas [53].

Unlike tumors typically associated with high rates of mutations, e.g., melanoma, PDA typically harbors fewer mutations, although neoepitopes do exist [54]. Notwithstanding the challenges of identifying tumor neoantigens suitable for immunization, determining the number of neoantigens required for targeting and the challenges of producing personalized vaccines, recent efforts have concentrated on developing shared neoantigen-based vaccines [55] such as mutant KRAS epitopes-based vaccines. Nevertheless, mutant KRAS peptide sequences are known to be weak CD8+ T-cell epitopes although T cells reacting to the mutant KRAS peptides do exist [56]. The key for the development of neoantigen-based vaccines for pancreatic cancers is unlocking how to activate the T cells that recognize the KRAS-mutation associated neoepitopes.

In situ Vaccination

Although cancer vaccine can serve as an approach to T-cell priming in a cold tumor like PDA, it remains unknown whether sufficient tumor-specific T cells have infiltrated into PDA. On the other hand, evidence suggests that certain neoantigens in PDA are associated with long-term survival following surgical resection. Thus, PDA naturally has the potential to generate neoantigen-specific T cells. The question remains, however, how we can amplify these neoantigen-specific T cells and simultaneously unleash them to attack bulky diseases present at the metastasis stage.

Conventional chemotherapy and radiation have been studied as avenues to induce innate immune responses. The role of chemotherapy in antitumor immune response is controversial. Multiple preclinical and clinical studies have shown that chemotherapy decreases vaccine-induced T cells [37]. However, a preclinical study in a mouse syngeneic model of PDA found that gemcitabine enhances therapeutic efficacy of dendritic cell (DC) vaccination despite its negative influence on vaccine-induced T-cell proliferation [57]. This study also showed that the cytotoxicity function of T cells was preserved and that gemcitabine was able to further sensitize tumor cells to cytotoxic T-cell-mediated lysis in the *in vitro* assay. In addition, gemcitabine facilitated recruitment of CD8+ T cells into tumors.

In contrast, a more recently published preclinical study showed that chemotherapy induces an initial infiltration of proinflammatory macrophages and activation of cytotoxic T cells, leading only to a temporary restraining of PDA progression [58]. After stopping treatment, neutrophils were recruited to the tumors and enabled the regrowth of tumors by expressing growth arrest-specific 6 (Gas6) to activate the AXL receptor on tumor cells. The Vonderheide group thus showed that the addition of chemotherapy optimized myeloid activation and T-cell function following the CD40 agonist treatment [59]. Their studies further demonstrated that CD40 stimulation caused a clonal expansion of T cells in the tumor, demonstrating an *in situ* vaccination effect of the CD40 agonist. More importantly, such an effect is independent of the canonical innate immune response pathways, including toll-like receptors (TLRs), inflammasome, and stimulator of interferon genes (STING) [60,61].

Building upon this rationale, a clinical trial testing the combination of CD40 agonist with chemotherapy showed promising results. In this nonrandomized, open-label, multicenter, four-cohort, phase Ib study, untreated metastatic PDA with RECIST (response evaluation criteria in solid tumors criteria) measurable disease were treated with 1000 mg/m^2 intravenous gemcitabine and 125 mg/m^2 intravenous nab-paclitaxel. Patients received 0.1 mg/kg CD40 agonist antibody sotigalimab in cohorts B1 and C1 and 0.3 mg/kg in cohorts B2 and C2. In cohorts C1 and C2, patients also received 240 mg intravenous anti-PD-1 antibody nivolumab. Thirty patients were enrolled and received at least one dose of any study drug; 14 (47%) of 30 patients (four each in B1, B2, C1; two in C2) had a treatment-related serious adverse event. Objective response rate was 58% (14 of 24 dose limit toxicity-evaluable patients; four each in B1, C1, C2; two in B2), which is higher than what is anticipated for chemotherapy with gemcitabine and nab-paclitaxel [62]. Nevertheless, a challenge remains to tease out the contributive effect of each agent used in this study, in future follow-up studies.

Radiation has been shown to trigger the release of damage-associated molecular pattern (DAMP) signals and subsequently induce TLR2/4 and the receptor for advanced glycation endproducts (RAGE) pathways [63]. However, most studies with radiation or chemotherapy in either a preclinical setting or a clinical study have not found that radiation can induce effector T-cell infiltration as observed in the studies with innate immune agonists. However, our group's unpublished results from clinical studies suggest that radiation in combination with vaccine therapy can induce cytotoxic effector T-cell infiltration in PDA tumors, although radiation also induced immunosuppressive myeloid cells [64]. By combining radiation with myeloid cell-targeting agents, an *in situ* vaccination effect with intratumoral infiltration of cytotoxic effector T cells was achieved without the presence of vaccine therapy according to a preclinical study. In this preclinical study, such an *in situ* vaccination effect can similarly prime the tumors for ICI therapy (Wang et al. *Journal of Experimental Medicine* accepted).

Although chemotherapy agents have been shown to have immune-modulating effects, in the clinical setting, chemotherapy treatment is often associated with a decrease of effector T cells in the tumor. However, our recent unpublished preclinical study showed that chemotherapy in a sequential combination with innate agonists including STING and NLRP3 (NLR family pyrin domain containing 3) agonists and ICIs, but not chemotherapy alone or ICIs alone, led to a significantly enhanced infiltration of cytotoxic, activated, effector memory T cells, and such an enhancement is associated with improved antitumor activities. Therefore, combining innate immune agonists with conventional chemotherapy and/or radiation therapy as an *in situ* vaccination strategy and a T-cell priming mechanism for sensitizing the tumors for ICI therapies warrants further clinical testing.

Other *in situ* vaccination strategies include oncolytic viruses which are designed to be able to selectively replicate within and eradicate tumor cells, sparing healthy tissues. Beyond the oncolytic mechanism of direct

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tumor eradication, these specialized viruses are also able to induce and promote tumor-directed immune responses, leading to further tumor killing by a variety of mechanisms [65]. For example, through a CD8+ T-cell-mediated specific adaptive antitumor response, these oncolytic viruses are able to induce long-lasting tumor-specific inflammatory cascades and immunogenic cell death (ICD) [66]. The oncolytic activity of these viruses increases tumor-associated antigen availability, where immunogenic cell death and inflammation promote recruitment of dendritic cells, inducing activation of the adaptive immune response. Genetic engineering has specifically permitted the insertion of genes, such as GM-CSF and type I cytokines, which allow the viruses to have additional immune priming mechanisms [67].

The immunomodulatory transgene enhancement of oncolytic activity and immunogenicity leading to clinical activity in malignancies is best illustrated with the first FDA-approved oncolytic virus for the treatment of melanoma, talimogene laherparepvec (T-VEC) [68]. This genetically engineered vector utilizes an attenuated herpes simplex virus that also contains genetic instructions for GM-CSF production. A clinical trial of locally administrated TVEC for locally advanced PDA is ongoing (NCT03086642). New oncolytic viruses that can be administered systemically, but still maintain a tumor preferential delivery and/or carry tumor antigens, are particularly attractive for being developed as novel treatments for PDA, which nearly always presents as a systemic disease.

Cytokines

T-cell priming achieved by the *in situ* vaccination mechanism includes both an induction of antigen specific T cells and a proliferation of existing antigen-specific T cells. The former can be enhanced by cytokines that enhance antigen presentation and maturation of dendritic cells. The latter may be achieved in a more robust way by direct cytokine therapy. Despite its narrowed use and benefit in melanoma and renal cell carcinoma (RCC) [69], as well as its toxicity profile, interleukin (IL)-2 has led to ongoing investigations of IL-2 agents with a better safety profile or an intratumoral delivery as well as other cytokines in the treatment of a broader spectrum of cancers.

It has recently been reported that currently there are over 40 clinical trials looking at various recombinant cytokines, with a significant number involving GM-CSF [70]. However, the focus recently has shifted to cytokines that are selective in their cellular targets and more refined in their immune actions, such as IL-12, IL-15, and IL-21 [70]. IL-12 induces natural killer (NK) cells and activates CD4+ cells into Th1 type signaling [71,72]. IL-15 is another T-cell growth factor that promotes the growth of intestinal epithelium, T cells, and NK cells, and enhances CD8+ memory T-cell survival [73]. IL-21 is an inducer of Th2 signaling and induces proliferation of T cells, B cells, and NK cells [74].

All these cytokines present as viable targets for inhibition by which the TME can be modulated in favor of pro-immunotherapy and antitumor response. Nevertheless, the research on cytokine therapy has been primarily focused on ICI-sensitive malignant diseases whereas limited studies of cytokine therapy as a single agent in PDA have been disappointing [75]. The efficacy of cytokine therapy is impeded by the fact that cytokines have significant pleiotropism, redundant signaling, and dual functionality, which can both activate and suppress the immune system [76]. To overcome some of these challenges, novel strategies of incorporating cytokines as an *in situ* vaccination mechanism into other immunotherapies need to be investigated.

T-cell Therapy

At the core of vaccine therapy's capacity to eradicate cancer stands the ability to prime T cells with specific antigen responses. Similarly, adoptive transfer of T cells, particularly those genetically engineering T cells, is another T-cell priming venue. Chimeric antigen receptor (CAR) T-cell therapy, which binds to the tumor antigens in a non-HLA type restricted manner and is self-sustainable in both proliferation and activation, was thought to be an ideal therapy for PDA. However, CAR T cells often fail to traffic efficiently into solid tumors, particularly PDA which is more desmoplastic than most other malignancies.

The best studied target for CAR T therapy in PDA patients is mesothelin since more than 80% of PDA express mesothelin [77–79]. However, evidence supporting a clinical efficacy of mesothelin-targeting CAR T-cell therapy in PDA patients is still lacking. PD-1 and T-cell receptor (TCR)-deficient mesothelin-specific CAR T cells using CRISPR-Cas9 technology were evaluated in a dose escalation study of 15 PDA patients [80]; the best response was stable disease in only two patients. In a phase I study of HER2-targeting CAR T cells in 11 cases of advanced PDA [81], one patient has a partial response and five achieved stable disease. Other targets being evaluated in clinical studies include PSCA, CEA, Claudin18.2, MUC1, and CEACAM7 [82,83]. Thus, these studies focus on testing different tumor antigens for CAR T therapies in PDA. Indeed, more studies are needed in order to investigate how to overcome the barriers of CAR T-cell trafficking to solid tumors by using PDA as a study model.

TCR T-cell therapy, which delivers T cells engineered with TCR that recognizes corresponding specific antigenic epitopes, is an alternative T-cell therapy option for PDA treatment. Although TCR-engineered T cells depend on *ex vivo* activation and do not proliferate *in vivo*, evidence suggests that they can infiltrate desmoplastic PDA tumors in genetically engineered mice. Thus, TCR T-cell therapy may potentially achieve T-cell priming in PDA. Bispecific antibody T-cell engagers such as BiTE may be another effective T-cell priming therapy for PDA.

T-cell Immunomodulators in Pancreatic Cancer: Reinvigorating and Activating T Cells

Whether a T cell becomes activated or deactivated depends on the sum of the signals that are engaged. Therefore, treating PDA with T-cell priming therapies alone would not be sufficient. T-cell immunomodulators are also needed. Two T-cell inhibitory signals have already been proved to have therapeutic relevance in cancer, CTLA-4 and PD-L1/PD-1, which are also among the most studied immunotherapeutic targets in PDA.

CTLA-4

Ipilimumab is a fully human IgG1κ antibody which recognizes CTLA-4 and blocks its interaction with B7-1 and B7-2 on APCs. This results in prolonged T-cell activation and amplification of T-cell-mediated immunity [84]. Ipilimumab has received FDA approval for use in stages III–IV melanoma due to improved recurrence-free survival (adjuvant setting) [85] and overall survival (metastatic setting) [86]. More recently, ipilimumab has received FDA approval for use in advanced non-small cell lung cancer, hepatocellular carcinoma, and squamous cell carcinoma of esophagus in a combination with nivolumab.

A phase II study evaluated single-agent ipilimumab for patients with locally advanced or metastatic PDA [87]. Twenty-seven patients received ipilimumab 3 mg/kg every three weeks for a maximum of eight doses. There were no responders by RECIST although one subject experienced a delayed response after initially being diagnosed with progressive disease. This study suggested that an immune checkpoint inhibitor as single agent is not effective in an immunogenically "cold" tumor such as PDA.

Le et al. thus conducted a phase Ib study of ipilimumab alone versus the combination of GVAX and ipilimumab for treatment of patients with chemotherapy-resistant advanced PDA [88]. Thirty patients with previously treated PDA were randomized 1:1 to ipilimumab at 10 mg/kg alone or in combination with GVAX. CA 19-9 declines were seen for 7/15 patients in the combination arm whereas 0/15 patients who received ipilimumab alone had CA 19-9 declines. Median overall survival was 3.7 months for the single-agent arm and 5.7 months for the combination arm (P = 0.072). The percentage of patients alive after one year also favored the combination arm (7% vs 27%) [88]. The best RECIST response was stable disease seen in both arms. The quality of the responses in the two arms, however, was different. Two patients with stable disease in the single-agent arm had continuous disease progression that did not reach the 20% growth cutoff at week 7 and 22. All three patients with stable disease in the combination arm maintained stable disease until week 31, 81, and 71, respectively, when they were taken off the study. One patient initially received GVAX as a participant in the above-mentioned neoadjuvant and adjuvant vaccine study in 2009. After he had recurrence, he received additional chemotherapy and radiation therapy, but continued to have disease progression. However, after he received the combination of ipilimumab and GVAX treatments, even after he had an early local progression and developed a new omental lesion at week 7 after beginning the combinatorial treatment, thereafter he had a delayed but durable disease stabilization starting at week 22 until week 71 when he received his last treatment. Although his CT scan still showed soft tissue density in the local pancreatic region and peritoneal nodularity, biopsy of these lesions failed to demonstrate malignant cells. He remains alive today.

These data, albeit anecdotal, suggest that the combination of checkpoint inhibitor and vaccine therapies may reverse an unfavorable TME that is dominated by immune suppressive signals and allow for the generation of a productive antitumor response.

PD-1/PD-L1

A number of FDA-approved antibodies disrupting the PD-1 axis have been developed. At the time of writing, there are seven US FDA, European EMA, and/or China NMPA-approved anti-PD-1 antibodies and four anti-PD-L1 antibodies for the treatment of over 10 malignancies [89]. These drugs target PD-1 by blocking its interaction with PD-L1 and PD-L2 or target the ligand, PD-L1. Initially, they demonstrated objective responses in advanced cancer patients who have progressed through one or multiple lines of chemotherapy. However, they demonstrated durable response rates in multiple types of cancer including melanoma, lung cancer, and renal cell cancer [90,91], thus changing the prognosis of several malignant diseases in their late stages. More recently, they have gradually replaced conventional treatments and become the first-line therapies or part of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the first-line combination for advanced cancer patients. In the most contemporary studies, their indications have been advanced to the early-stage cancers either in the adjuvant setting following surgical resection or in the neoadjuvant setting prior to surgical resection [92–94]. Nevertheless, none of these anti-PD-1/PD-L1 antibodies, as single agents, have demonstrated a reproducible efficacy in treating PDA except the rare subtype with a high microsatellite instability. The results of combining anti-PD-1/PD-L1 with chemotherapy in PDA have also been disappointing [95].

Therefore, a number of clinical trials have been conducted to test the hypothesis that vaccine therapy can prime PDA for anti-PD-1 therapy. In a recently completed phase II clinical trial [96], PDA patients who received one prior therapy for metastatic disease and had RECIST measurable disease were randomized 1:1 to receive a heterogeneous prime/boost dual vaccine treatment including GVAX and CRS207, the above-described live, attenuated *Listeria monocytogenes*-expressing mesothelin, with or without nivolumab anti-PD-1 antibody. Ninety-three patients were treated (GVAX/CRS207+nivolumab arm, 51 patients; GVAX/CRS207 arm, 42 patients) and demonstrated median overall survival of 5.9 and 6.1 months, respectively, with a hazard ratio (HR) of 0.86 (95% CI 0.55–1.34). Objective responses were seen in three patients using immune-related response criteria (GVAX/CRS207+nivolumab, 4%, 2/51; GVAX/CRS207, 2%, 1/42). The high-grade adverse event rate was higher in the GVAX/CRS207+nivolumab arm than the GVAX/CRS207 arm (35.3% vs 11.9%) but these toxicities were manageable. Although the clinical efficacy was modest, the changes in the TME, including increase in CD8+ T cells and decrease in CD68+ myeloid cells, were observed only in long-term survivors who received the combination of GVAX/CRS207 and nivolumab. Therefore, additional studies are needed to identify the best T-cell activating strategy in combination with the anti-PD-1 antibody treatment for durable anticancer responses in the majority of PDA patients.

T-cell Exhaustion

The upregulation of T-cell coinhibitory receptors is a hallmark of T-cell exhaustion upon chronic infections and in cancer. Following the T-cell priming treatment, the presence of persistent tumor antigen stimulation is anticipated to induce prolonged and increased expression of cell surface inhibitory signals. In addition to CTLA-4 and PD-1, T-cell exhaustion signals such as mucin-3/T-cell immunoglobulin (TIM-3), T-cell activation gene (LAG-3), and T-cell immunoreceptor with Ig and ITIM domains (TIGIT) were all reported to have elevated expression in PDA [97,98]. However, targeting these T-cell exhaustion signals has not yet been supported by preclinical studies in PDA. Despite this, it is possible that a proper strategy of applying specific targeting agents to T-cell exhaustion signals in PDA treatment may lead to therapeutic efficacy. This successful approach in PDA remains to be identified.

T-cell Agonist

In contrast, many preclinical studies strongly support antitumor roles for agonists of T-cell costimulatory receptors [99,100]. Clinically, the combinations of ICIs and a T-cell agonist were tested on a limited scale in other malignancies, and the development of anti-CD137 antibody or anti-OX40 antibody was aborted due to toxicity concerns [101,102].

Recently, Muth et al. compared the triple combo of GVAX, anti-PD-1 antibody, and anti-CD137 agonist antibody to the double combo of either GVAX and anti-PD-1 or GVAX and anti-CD137 antibody for antitumor efficacy in a syngeneic liver metastasis model of mouse PDAC and found that the triple combinabtion significantly prolonged the survival of PDA-bearing mice compared to double combination treatments [103]. However, similar to anti-PD-1 antibody, the antitumor effect of anti-CD137 antibody was dependent on the presence of GVAX. Our group thus conducted a three-arm clinical trial of neoadjuvant and adjuvant immunotherapy in resectable PDA patients. Adults with clinically resectable, untreated PDA were enrolled in one of three study treatments: Arm A (GVAX alone), Arm B (GVAX + anti-PD-1 antibody nivolumab), or Arm C (GVAX, nivolumab, and anti-CD137 agonist antibody urelumab) [104]. At median follow-up of 23 months (Arm A), 26 months (Arm B), and 22 months (Arm C), median disease-free survival was 14.82 months and 16.23 months, for Arms A and B respectively and not reached for arm C. The combination of GVAX, nivolumab and urelumab was associated with nearly significant improved disease-free survival compared to GVAX alone (HR 0.38, 95% CI 0.12–1.19) and GVAX+nivolumab (HR 0.38, 95% CI 0.12–1.21).

Targeting Stroma in Pancreatic Cancer: Overcoming Immunosuppressive Signals

As described above, another strategy is to identify the additional immune suppressive signals within the PDA TME that require further modification to effectively enhance effector T-cell function. It has been determined in a number of preclinical and clinical studies that stroma and/or myeloid cell modulating agents can overcome the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

barrier of the effector immune cell infiltration in PDA. Inflammatory response mediated by stromal fibroblasts and myeloid cells is anticipated to restrain tumor initiation and inhibit growth. However, evidence also suggests that these innate immune response components are reprogrammed epigenetically by the tumor cells and subsequently acquire the capability of attenuating effective T-cell infiltration and function [105–108].

Fibrotic Stroma

Recently, a nonreceptor protein tyrosine kinase, focal adhesion kinase (FAK), which is implicated in the proliferation, differentiation, and signal transduction cascades of various tumors, has been investigated as a target for TME immunomodulation. Preclinical studies have revealed that tumor-intrinsic FAK signaling modulates the activity of MDSCs, TAMs, and Treg within the TME. In both squamous cell carcinoma and PDA mouse models, the small molecule FAK inhibitor VS4718 was shown to decrease immunosuppressive MDSCs, TAMs, and Treg cells and consequently led to increased CD8+ T cells within the tumor and enhancement of CD8+ T-cell-mediated suppression of cancerous cells [109,110]. Osipov et al. showed that another small molecule inhibitor of FAK sensitized PDA for radiation therapy in a CD8+ T-cell-dependent manner and in association with a decrease in myeloid cell infiltration in mouse PDA tumors [111].

More recently, our group explored whether the addition of VS4718 to hyaluronidase augments modulation of cancer-associated fibroblasts (CAFs) and myeloid cells leading to enhanced intratumoral infiltration of effector memory T cells and survival of PDA-bearing mice. We found that simultaneous modulation of both FAK signaling in the cellular compartment of the stroma and of extracellular matrix by using hyaluronidase to degrade hyaluronic acid had a synergistic effect on decreasing the infiltration of tumor-associated granulocytes, particularly those expressing a known immunosuppressive cell surface receptor, CXCR4 (unpublished data).

IL-1β emerges as another therapeutic target of CAFs in PDA. Multiple published studies suggest that tumor-derived IL-1β drives tumor fibrosis, chemoresistance, and poor prognosis in PDA [112,113]. These studies showed that tumor-derived IL-1β promotes immune suppression in PDA. Tumor cell expression of IL-1β *in vivo* was driven by microbial-dependent activation of TLR4 signaling and subsequent engagement of the NLRP3 inflammasome [112]. Anti-IL-1β antibody enhanced the antitumor activity of anti-PD-1 antibody in the preclinical model of PDA, which was accompanied by an increased tumor infiltration of CD8+ T cells [113]. Therefore, we hypothesize that the combination of anti-IL-1β antibody and anti-PD-1 antibody can overcome the resistance of PDA to anti-PD-1 antibody therapy. To test this hypothesis, our group has proposed a phase II study of the combination of anti-IL-1β and anti-PD-1 antibody as a neoadjuvant therapy for resectable PDA. A similar combination has recently been tested in metastatic PDA (NCT04581343).

Tumor-associated Macrophages

Tumor-associated macrophages (TAM) alter their functional subtypes based on signals in the TME in an attempt to maintain immune homeostasis [114]. Higher density of TAMs in pancreatic tumors is associated with worse survival due to their tumor-promoting effects [115]. In addition to CSF-1 and CSF-1R as described above, one of the best studied targets is the chemokine receptor CCR2 and its cognate ligand CCL2, which has been implicated in tumor infiltration by immunosuppressive cells, notably protumoral M2-like TAMs and MDSCs. PDA patients with tumors that exhibit high CCL2 expression and low CD8 T-cell infiltrate have significantly decreased survival [116]. In mice, CCR2 blockade depletes inflammatory resident monocytes and macrophages from the primary tumor and premetastatic liver, resulting in enhanced antitumor immunity, decreased tumor growth, and reduced metastasis [117]. Tumor-derived CCL2 was shown to mediate the resistance to radiation in a mouse model of PDA by recruiting CCR2+ monocytes [118].

More recently, it was found that CCR2 blockade synergizes with radiation for antitumor activity by targeting CCR2+ monocytic MDSCs [119]. Targeting TAM with a CCR2 inhibitor (PF-04136309) in combination with FOLFIRINOX chemotherapy in patients with stage III pancreatic cancer was tested in a phase Ib trial showing a promising, high objective tumor response rate [120]. Nevertheless, this is a small, nonrandomized study in which the CCR2 inhibitor was given in the absence of ICIs, and the role of CCR2 inhibitor in controlling systemic disease and conferring survival benefit has not been established. A randomized phase II clinical trial testing the combination of a small molecule dual antagonism of CCR2 and CCR5 with chemotherapy with and without nivolumab in metastatic PDA has recently completed enrollment (NCT03496662) but the results have not been reported yet.

In a prior study, anti-CSF-1R antibody failed to confirm its benefit in metastatic PDA in the phase II study (NCT03336216) of cabiralizumab administered in combination with nivolumab and chemotherapy in patients with metastatic PDA. However, the early phase Ib study (NCT02526017) of cabiralizumab and nivolumab in the absence of chemotherapy did demonstrate an objective response in three patients who had been heavily pretreated with chemotherapy. Taken together, how

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

immunotherapy may be combined with chemotherapy in clinical trials appears to be a more crucial question for the field to address first before the combination of immunotherapy and chemotherapy can be tested in the future.

Tumor-associated Neutrophils

The granulocytic population of myeloid cells including PMN-MDSC is composed of eosinophils, basophils, and neutrophils. Neutrophils are the most abundant type of granulocytes, and form the first line of defense in our immune system against microbial infection and facilitate wound healing [121]. Studies in recent years have demonstrated that tumor-associated neutrophils (TANs) promote angiogenesis and immunosuppression in the TME which can support tumor initiation, growth, and metastasis [121–125]. In PDA, this has lead to more attention on TANs as a therapeutic target. IL-8 is a proinflammatory chemokine in the CXC family and has been demonstrated to be a potent chemoattractant, recruiting granulocytic myeloid cells into the TME in order to promote tumor progression and immune escape [126]. In cancer patients, the main sources of IL-8 include tumor cells, CAFs, and TAMs. Studies have shown that high IL-8 levels in the plasma correlate with poor prognosis in multiple cancer types [127–129] and poorer outcomes in patients who received PD-1 therapies [130,131]. Thus, IL-8 and its receptors are considered to be novel molecular targets on TANs in cancer treatment [132,133].

Monoclonal antibodies and small molecular inhibitors that block the IL-8–CXCR1/CXCR2 axis have been in clinical development [134,135]. Among them, BMS-986253 is a first-in-class, fully human IgG1 κ monoclonal antibody inhibitor of IL-8 [136]. A phase I trial of BMS-986253 in patients with advanced solid tumors was completed, and BMS-986253 is currently being tested in combination with nivolumab in a phase Ib/II "basket" clinical trial (NCT03400332) that is currently focused on non-small cell lung cancer.

Our group recently completed the first preclinical study of anti-IL-8 therapeutic antibodies in a mouse model of human PDA. In this humanized mouse model, reconstituted with human myeloid cells and *ex vivo* activated T cells, we demonstrated the antitumor activity of an anti-IL-8 and anti-PD-1 antibody combination *in vivo*. We also revealed that one potential mechanism of action of anti-IL-8 antibody is to reeducate granulocytic myeloid cells by activating their innate immune response and type I cytokine response. A clinical trial testing the combination of nivolumab and BMS-986253 as neoadjuvant and adjuvant therapies for resectable PDA is ongoing (NCT02451982).

Conclusion

Pancreatic cancer has notoriously poor survival rates which are not dramatically improved with the use of traditional cytotoxic chemotherapy. Immunotherapy has the potential to produce durable remissions which has been demonstrated in other tumor types. Cancer vaccines have shown the ability to reverse the relatively non-immunogenic phenotype associated with PDA and induce subsets of immune cells which can, in turn, be sensitized to immune checkpoint blockade [42,53]. The future success of treating PDA with immunotherapy likely lies in the use of combinatorial regimens to further activate and sustain the function of effector T cells and to overcome the immunosuppressive mechanisms in the TME. There is also potential for optimizing these regimens with alternative strategies including epigenetic modulation, T-cell transfer therapies, and *in situ* vaccination, which have the added advantage of targeting other cell types in the TME.

Given the marked heterogeneity in tumor genetics and phenotypes, there is also a need to discover novel biomarkers which can reliably predict which subsets of patients are likely to respond to immunotherapy. Further research and development of combinatorial treatment strategies, novel targeting agents, and unique predictive biomarkers will lead to the greatest changes in clinical outcomes in patients with PDA.

Targeted Therapies for Pancreatic Cancer

Anirban Maitra

Department of Translational Molecular Pathology, Sheikh Ahmed Center for Pancreatic Cancer Research, The University of Texas MD Anderson Cancer Center, Houston, TX, USA

Introduction

Despite a continuously evolving understanding of the molecular underpinnings of pancreatic ductal adenocarcinoma (PDAC), current therapeutic strategies have only achieved modest improvements in patient outcomes. With FOLFIRINOX and gemcitabine-based therapies being the main weapons in our armamentarium, intrinsic and acquired chemoresistance has prevailed as the rule rather than the exception in this disease.

In the past two decades, the majority of phase III studies in this disease have failed, underscoring the challenges of drug development in PDAC [1]. Despite the setbacks, subsets of patients with PDAC now have the opportunity to receive several newly developed, molecularly targeted therapies. Recent large-scale efforts in next-generation sequencing (NGS) technologies have allowed us to interrogate the genomic landscape of PDAC and with this, the ability to tailor personalized therapeutic options that exploit tumor-specific molecular abnormalities [2]. Further, while immunotherapy has been largely ineffective in this recalcitrant disease, we are finally beginning to see the emergence of combinations that are showing promising activity [3].

In this chapter, we describe how insights from understanding the molecular pathogenesis of PDAC have translated into novel therapies with the hope of improving survival in this aggressive disease.

Genomic Landscape of PDAC

Significant efforts through the International Cancer Genome Consortium (ICGC) and the Cancer Genome Atlas (TCGA) have allowed us to make meaningful progress in deciphering the genomic landscape of PDAC [4,5]. Among the earliest events in PDAC pathogenesis is the activating point mutation in the *KRAS* oncogene, which is present in more than 90% of these cancers. In the multistep progression model, there is progressive accumulation of additional genetic alterations, including loss of function mutations in *TP53*, *SMAD4*, and *CDKN2A*. Aside from these four key oncogenic drivers, it is important to note several low-frequency mutations that have been identified that converge on core signaling tumorigenic pathways, including regulation of apoptosis, DNA damage, cell cycle, *KRAS* signaling, invasion, and transforming growth factor (TGF)-β signaling (Fig. 151.1) [6]. By identifying and understanding how these altered genes and pathways can affect tumorigenesis, we begin to interrogate how targeting these key nodes can be exploited for therapeutic stratification.

Targeting the Previously "Undruggable" KRAS Oncogene

KRAS is among the most commonly mutated oncogenes in human cancers, making it the most obvious choice for targeted therapies. Activation of the Ras protein is the result of growth factor receptor signaling, which induces cycling between an active GTP-bound (ON) and an inactive GDP-bound (OFF) state, regulating multiple downstream effectors. Within the protein lies an intrinsic GTPase, which leads Ras proteins to hydrolyze GTP to GDP, thus allowing the cycling of GTP and GDP to continue [7]. Point mutations in *KRAS* effectively inhibit productive interactions of Ras with GTPase-activating proteins (GAPs), leading to the attenuated ability to

hydrolyze bound GTP to GDP, resulting in a constitutively active protein. For many decades, Ras was notorious as a "undruggable" target in cancer due to the inability to identify small molecules that bind with high affinity into the altered binding pocket of the mutant protein. As a result, clinically facile efforts to target Ras signaling in cancers were focused on downstream effectors, such as MAP kinase and Akt pathways, with mixed success [8,9].

One of the most welcome advances in oncologic drug development of the past five years has been the development of direct covalent inhibitors of mutant KRAS protein [10]. The initial class of agents that have advanced to the clinic binds to the cysteine protein encoded by the mutated *KRAS*^{G12C} allele, with the first two small molecule inhibitors – sotorasib (Lumakras) and adagrasib (Krazati) approved for use in non-small cell lung cancer by the US Food and Drug Administration [11–13]. Of note, the *G12C* allele only accounts for ~1.6% of all mutant *KRAS* cases in PDAC, and therefore there is considerable anticipation for the next series of inhibitors undergoing preclinical development that either target the more common mutant *KRAS*^{G12D} allele or bind to KRAS protein agnostic to the specific allelic variant [14–16]. Most of these inhibitors bind with the "off" state of KRAS (GDP-bound), although a few bind with the GTP-bound "on" state as well [17].

Despite the low frequency of *KRAS*^{G12C} alleles in PDAC, several patients have been accrued on early-phase clinical trials and treated with single agents, demonstrating objective responses, albeit transient in nature [18]. This suggests that inherent and/or adaptive mechanisms of resistance are likely to emerge on monotherapy, mandating the requirement for combinations. In fact, studies in lung and colorectal cancer patients have shown that the rapid emergence of genomic and nongenomic adaptive mechanisms is common in the face of targeted therapy against KRAS [19–22]. Such resistance mechanisms tend to be multiple in the same patient (for example, secondary mutations in *KRAS* itself or genes located within effector pathways) and heterogeneous across patients, underscoring both the immense selective pressure on cancer cells to sustain Ras signaling in the face of inhibition, and the challenges of targeting KRAS in the clinic for long-term benefit. With that said, combination therapies against these adaptive mechanisms are already under way [23–25] and for the first time in four decades, the concept of targeting this "undruggable" oncogene with small molecules has become a reality.

While small molecule inhibitors against KRAS have emerged as one of the most exciting new developments in targeted therapies, it is important to note that several other strategies are being evaluated to target mutant KRAS directly in solid cancers, including PDAC. For example, genetic extinction of mutant $KRAS^{G12D}$ using siRNA loaded with inhibitory exosomes (iExosomes) is currently under way in early-phase trials in advanced pancreatic cancer [26,27]. Similarly, immunologic approaches to target mutant KRAS as a neoantigen, either using peptide or nucleic acid vaccines or engineered T cells expressing a mutant epitope specific T-cell receptor (TCR), are all under way [28,29].

Targeting of *KRAS* Wild-type Pancreatic Cancers

While *KRAS* mutations are by far the dominant oncogenic event in PDAC, approximately 8–10% of cases are *KRAS* wild type [4,5]. *KRAS* wild-type tumors tend to be more frequent in "young-onset" PDAC, defined as cases occurring prior to 50 years of age [30,31]. A number of alternative drivers are present in *KRAS* wild-type PDAC, including fusions of *ALK*, *RET*, *NTRK1*, *MET*, *FGFR2*, *BRAF*, and *NRG1*, amplifications of *EGFR* or *ERBB2*, and other driver events. From a targeted therapy standpoint, many of these alternative drivers are considered "actionable" due to the availability of small molecule inhibitors which are approved and used in other solid cancers where such drivers are more common (for example, *ALK* fusions in lung cancer) and can be used off-label in PDAC patients, or because of a "tissue agnostic" approval across multiple cancer types [32–36]. Of note, young-onset PDAC also tends to be enriched in patients harboring pathogenic germline mutations in cancer-predisposing genes and represents a subset that should be particularly encouraged to receive both somatic and germline sequencing [30,31].

Targeting DNA Damage Repair Defects in Pancreatic Cancer

Beyond KRAS and aforementioned alternative drivers, DNA damage repair defects have emerged as an important subset of PDAC cases for which therapies can be tailored based on a defined molecular alteration [37]. Approximately ~8–10% of tumors harbor germline and/or somatic pathogenic variants in genes that encode for proteins involved in repair of DNA damage, most commonly double-strand break repair, including *BRCA1*, *BRCA2*, *PALB2*, and *ATM* [38,39]. A minor subset (~1%) harbor germline and/or somatic mutations in genes encoding proteins that repair DNA mismatch repair (including *MLH1*, *MSH2*, *MSH6*, and *PMS2*). Both of these distinct DNA damage repair defects are actionable, albeit with somewhat different strategies. PDAC with biallelic loss of function defects in *BRCA1*, *BRCA2*, and *PALB2* is unable to deploy a mode of repair known as "homologous recombination repair" in response to DNA double-strand breaks, resulting in profound chromosomal instability and genome-wide structural defects (for example, unbalanced translocations) [40]. These tumors are exquisitely susceptible to platinum agents (cisplatin and oxaliplatin), which further exacerbate DNA double-strand breaks, and to inhibitors of PARP, an enzyme that provides an alternative avenue for DNA repair in the absence of homologous recombination repair.

This therapeutic approach of leveraging a tumor-specific molecular defect by shutting off the available "escape hatch" (in this case, PARP-enabled DNA repair when tumor cells already lack homologous recombination repair) is known as "synthetic lethality," a paradigm that was first described in unicellular yeast but has emerged as a well-established avenue for discovery of targeted therapies in oncology [41].

PARP inhibitors are now approved for use in patients with germline *BRCA1*, *BRCA2*, and *PALB2* mutations, in the so-called "maintenance setting" following a favorable initial response to platinum-based therapy [42]. While the pivotal phase III POLO trial that led to approval of the first PARP inhibitor as monotherapy in PDAC was focused on germline mutations in DNA repair genes and in an advanced disease setting [43], several PARP inhibitors are now being investigated in tumors with somatic mutations of these genes, in additional settings (such as adjuvant therapy following surgical resection), and in combination with immunomodulatory agents [44,45]. Of note, although ATM also encodes for a protein that is engaged in the response to double-strand breaks, the response of PDAC harboring these mutations to PARP inhibitor monotherapy is less obvious [46,47]. Instead, ATM-defective tumors appear to depend on sustained function of the related ATR protein, which has led to initiation of trials using ATR inhibitors, including trials combined with PARP inhibitors [42,48].

Finally, PDAC with mismatch repair defects typically manifests with microsatellite instability and significantly higher tumor mutational burden (TMB) compared to mismatch repair-proficient cancers [49,50]. These tumors respond favorably to immunotherapy with immune checkpoint inhibitors, and mismatch repair-defective PDAC are included in the "tumor agnostic" approval of the use of immunotherapy [51].

Targeting the Altered Transcriptome in Pancreatic Cancer

While the genomic landscape of PDAC has been pivotal in the development of new and emerging targeted therapies, we have also come to recognize that there are transcriptomic subtypes in PDAC, which can correlate with responses to therapies [52]. The existence of transcriptomic subtypes based on RNA profiling of neoplastic epithelial cells in PDAC was first described in 2011 [53], and since then several distinct classification schemes have been proposed, which incorporate epithelial specific RNA profiles, stromal RNA profiles, or a combination of both [4,54–56].

Of the various RNA-based classification schemes proposed, the one most commonly adopted currently is a two-tier system that dichotomizes PDAC as "classical" and "basal-like" [52], phenocopying the four-tier Consensus Molecular Subgroups (CMS) classification used in colorectal cancers [57]. Retrospective data demonstrate that the "classical" and "basal-like" transcriptomic subtypes of PDAC are both predictive of response to cytotoxic chemotherapy, as well as prognostic in terms of outcomes [58,59]. Emerging data also suggest that the two transcriptomic subtypes are not static but display plasticity in response to ongoing therapy, tumor evolution, and *ex vivo* propagation [60,61]. Multiple clinical trials are now under way that take into consideration the transcriptomic subtype of PDAC at baseline to assign patients to various therapeutic regimens, including trials like PASS-01 and PREDICT-PACA, amongst others [62,63].

Targeting the Pancreatic Cancer Stroma

Pancreatic ductal adenocarcinoma is characterized by a profound host stromal response ("stromal desmoplasia") that is a *sine qua non* of this cancer. The PDAC stroma is composed of both cellular elements, most importantly fibroblasts, but also vascular and neural elements, as well as extracellular (acellular) matrix components [64]. The traditional viewpoint on the PDAC stroma has been that it is a barrier to the influx of both chemotherapeutic agents and a productive immune response, with the overarching premise being that depletion of the stroma will enable improvements in therapeutic responses and disease outcomes [65]. This simplistic premise of the stroma as a "monolith" has been intensely challenged in recent years, with several clinical trials targeting the PDAC stroma, both cellular elements (hedgehog inhibitors) and extracellular matrix components (hyaluronic acid), resulting in failure to improve overall survival compared to chemotherapy alone [64,66–68].

Over the past few years, and especially with the advent of single cell profiling approaches, we have come to appreciate the considerable heterogeneity and plasticity inherent in the PDAC stroma, particularly in terms of fibroblasts that form the pivotal stromal cellular component [69]. It is now widely accepted that the PDAC stroma is composed of both "tumor promoting" and "tumor restraining" fibroblast components, with prevalent identities such as "inflammatory cancer associated fibroblasts" (iCAFs) ascribed to former and "myofibroblastic cancer associated fibroblasts" (myCAFs) ascribed to the latter [70–72]. The existence of hybrid fibroblast transcriptomic features (based on single cell profiling approaches) suggests that the aforementioned dichotomy in fibroblast identity is not stable, and likely to be influenced by both tumor intrinsic factors, like the genetic makeup, and extrinsic factors, such as administration of chemotherapy and targeted agents [72,73]. In autochthonous preclinical models, genetic or pharmacologic depletion of tumor-restraining myCAFs (or myCAF-generated collagen 1 [74]) leads to more aggressive disease and shortened survival [75,76], mimicking the findings observed in the clinic with indiscriminate stromal targeting.

An improved understanding of stromal fibroblast heterogeneity and diversity in function has led to more recent trials being geared towards reprogramming of activated tumor fibroblasts towards a normal or resting state, such as with vitamin D receptor agonists, or all-trans retinoid acid, amongst others [77,78]. Ultimately, targeting the PDAC stroma will require strong pairing of underlying biology with translation, in order to prevent the missteps of the prior decade in this arena.

Targeting the Immune Microenvironment in Pancreatic Cancer

Amongst solid cancers, the resistance of PDAC to immunotherapy is notorious [79]. In contrast to melanoma or lung cancers, the administration of immune checkpoint inhibitors targeted against PD-1 and CTLA-4 has produced minimal response [80,81], with the exception of PDAC cases harboring DNA mismatch repair defects (see above). Similarly, adoptive cellular therapies like infusion of chimeric antigen receptor (CAR)-expressing T cells targeted against PDAC tumor antigens such as mesothelin have thus far been largely ineffective [82,83]. While whole-cell vaccines targeted against PDAC (with or without attenuated *Listeria*-expressing mesothelin as an added immunogen) have undergone extensive clinical trials, these too have demonstrated at most modest effect in advanced cases [84,85], with more sustained responses demonstrated in subsets of patients in the adjuvant setting [86].

The reasons for these failures of various immunotherapy modalities in PDAC are manifold and include the profound immune suppressive tumor microenvironment, composed of both cellular elements like tumor-associated macrophages, regulatory T cells and neutrophils, as well as cytokines like TGF-β and interleukins IL-6 and IL-1β, which attract immune suppressive cells to the peritumoral milieu and dampen effector T-cell function [3,87]. Further, the relatively modest tumor mutation burden and neoantigen load in most microsatellite stable PDAC [50], paired with defects in antigen presentation [88,89], underscore the challenges of generating a productive immune response in this disease.

The principal lesson learned from the clinical failures of immunotherapy has been the understanding that any immunotherapy modality cannot be deployed in isolation but needs to target multiple aspects of the cancer immunity cycle [90], such as pairing activation of effector T cells with disruption of immune suppressive myeloid cells, preferably in conjunction with chemotherapy to reduce tumor volume and release tumor antigens within the tumor milieu. In fact, some of the recent encouraging signals that have emerged in PDAC immunotherapy trials have been those that embraced this concept of combining multiple modalities (chemotherapy, immune checkpoint inhibitor, and myeloid/macrophage targeting agent) to overcome the profound barriers to immune rejection that exist in this disease [91–93].

Conclusion and Future Directions

Despite the considerable therapeutic nihilism and reluctance to conduct somatic molecular profiling in PDAC, several studies have now shown that a substantial minority of cases (~15–20%) harbor mutations that would be considered clinically actionable, even prior to the widespread availability of agents targeting mutant *KRAS* [30,94]. Biospecimens used to generate molecular profiles include not only tissues, which can sometimes be challenging to procure in advanced PDAC, but also noninvasive liquid biopsy approaches that can serve as a reliable surrogate for identifying actionable mutations in a clinically meaningful time frame [95]. Further, germline mutation profiling can identify patients who might benefit from PARP inhibitor or immune checkpoint-based immunotherapy. Moreover, in patients who harbor a germline pathogenic variant, cascade genetic testing can be extended to asymptomatic family members who might benefit from surveillance for PDAC [96]. Based on these mounting lines of evidence, guidelines bodies like the American Society of Clinical Oncology (ASCO) and National Comprehensive Cancer Network (NCCN) in the USA have recommended that all PDAC patients undergo targeted somatic profiling of their tumors and receive universal germline testing using a multigene panel [97,98].

Increasingly, clinical trials in PDAC are incorporating biomarkers as an inclusion criterion, whether these be genomic alterations, transcriptomic subtype, or aberrantly expressed proteins or epitopes. The benefits of established and emerging targeted therapies in PDAC (be it with small molecule inhibitors, antibodies or antibody–drug conjugates, vaccines or engineered adoptively transferred T cells) can only be leveraged if the molecular landscape of the tumor is accurately known. Further, the benefits of these emerging and exciting therapeutic approaches should not be restricted to the "ivory towers" of specialized cancer centers, but need to be extended to the community at large, including diverse populations that are often at the epicenter of health disparities in PDAC [99,100]. Only through such extrapolation will we make *bona fide* progress in this recalcitrant disease.

Introduction

In the 20 years since the human genome was first sequenced, genomics has developed into the more refined, patient-centered approach of precision medicine. Tumor sequencing has become the standard of care for many cancers as using genetic alterations and a patient's unique tumor biology guides diagnosis and treatment, resulting in the adoption of trastuzumab for *HER2*-positive breast cancer and vemurafenib and dabrafenib for $BRAF^{V600E}$ mutated melanomas as examples. More recently, precision medicine is being applied to pancreatic ductal adenocarcinoma (PDAC), a cancer that is difficult to treat. Over the past several years, molecular analyses have identified patients with PDAC harboring *BRCA1/2* mutations or microsatellite instability that benefit from novel therapeutics [1,2]. However, the vast majority of patients with PDAC do not exhibit these "actionable" mutations. With most PDAC patients presenting with advanced disease and a overall survival rate of 11% [3], improved therapies for PDAC patients are needed, and the molecular features of a patient's tumor should be leveraged in this approach.

Pancreatic ductal adenocarcinoma sequencing efforts have uncovered key mutations in aberrant molecular programs driving pancreatic carcinogenesis along with distinct molecular subtypes and epigenetic plasticity, which may contribute to therapeutic resistance [4–10]. Research has also revealed therapeutic vulnerabilities conferred by disrupted DNA repair mechanisms, and several large-scale studies demonstrated real-time feasibility and clinical benefit of genomic sequencing to guide targeted therapy [1,11–14]. In this chapter, we outline how the current understanding of PDAC's mutational landscape directs the clinical practice of precision cancer medicine while reviewing targeted therapies currently under investigation.

Mutational Landscape of Pancreatic Adenocarcinoma

In 2008, the genome-wide mutational landscape of PDAC was characterized for the first time by Sanger sequencing [15]. As next-generation sequencing (NGS) technologies evolved, additional whole-exome (WES) and whole-genome sequencing (WGS) studies emerged, including those from the multicenter consortiums the Cancer Genome Atlas (TCGA) and International Cancer Genome Consortium (ICGC). Today, our resolution of PDAC's genomic landscape has sharpened as each study has augmented our knowledge of tumorigenesis and disease progression while defining a rationale for more personalized treatment.

Four key driver genes (the oncogene *KRAS* and tumor suppressors *TP53*, *CDKN2A*, and *SMAD4*) largely shape the molecular events underlying tumorigenesis [4,16]. *KRAS* is the most commonly mutated gene in PDAC, with more than 90% of tumors harboring a pathogenic mutation [4]. In the stage-wise progression model of PDAC development, early premalignant lesions (pancreatic intraepithelial neoplasia or PanIN) harbor *KRAS* mutations, thus representing an early event in pancreatic carcinogenesis. A small percentage of cases present with multiple *KRAS* mutations, indicating convergent evolution of tumor clones [17].

Mutations in the tumor suppressor genes *TP53*, *CDKN2A*, and *SMAD4* occur in 50–75% of patients [4].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

During PDAC tumorigenesis, these alterations accumulate in a stepwise fashion with *CDKN2A* inactivation occurring after *KRAS* activation and *TP53/SMAD4* lost in advanced PanIN stages [7]. Moreover, a large number of additional recurrent mutations are present at a low frequency (<5–10%). Mutational combinations vary widely between tumors, making PDAC a highly heterogeneous disease. Not surprisingly, therapeutic strategies utilizing an unselective approach may limit the opportunity to identify effective avenues of treatment for individual patients.

Next, we highlight the genetic alterations and accompanying aberrant signaling pathways that are beginning to be exploited clinically.

DNA Damage Repair Pathways

DNA damage accumulates in cells due to endogenous factors (e.g., errors in replication, oxidative stress) and exogenous factors (e.g., chemotherapy, ionizing radiation). The ability to reliably repair DNA breaks is essential to genomic integrity, with multiple overlapping pathways dedicated to lesion repair [18]. Altogether, over 400 genes make up the DNA damage repair (DDR) signaling pathways, with each component susceptible to genomic and functional alterations. Thus, DDR deficiency poses a therapeutic vulnerability in malignant cells, and recent studies demonstrate that loss of function in one or more of these genes sensitizes PDAC to certain DNA-damaging chemotherapies, including platinum-containing agents [1,16].

To leverage the vulnerability DDR deficiency confers, drugs targeting DDR have been developed based on the concept of synthetic lethality. Specifically, a PDAC-associated DDR mutation forms a synthetic lethal pair with another DDR gene targeted by a therapeutic drug. One classic example is poly-ADP-ribose polymerase (PARP) inhibitors which treat tumors defective in homologous recombination (HR) repair [18]. Upon DNA damage, PARP1 binds to unrepaired single-strand breaks (SSBs) and double-strand breaks (DSBs) to recruit downstream effectors [19]. PARP inhibitors thereby "trap" PARP1 on DNA strands, leading to unrepaired damage that promotes genomic instability and cell death in the absence of functional HR [19].

Recent molecular analyses reveal that approximately 25% of PDAC patients harbor mutations in DDR pathway genes (e.g., *BRCA1*, *BRCA2*, *PALB2*, *ATM*). In one study, Waddell et al. examined genomic data from 100 PDAC tumors and identified four subtypes: stable, locally rearranged, scattered, and unstable [16]. Notably, tumors with unstable genomes harbored mutations in DDR genes. Among this cohort of patients, the BRCA mutational signature predicted response to platinum-based chemotherapy.

Several small retrospective studies demonstrated survival benefit when patients with PDAC and germline *BRCA1/2* mutations were treated with platinum-based chemotherapies [1,13,20]. Clinical trials utilizing PARP inhibitors in HR-deficient (HRD) breast and ovarian cancer also significantly improved outcomes, leading to a randomized phase II trial in which the combination of the PARP inhibitor veliparib with gemcitabine and cisplatin therapy was compared to gemcitabine and cisplatin only in patients with PDAC and a germline *BRCA1/2* or *PALB2* mutation [13]. Concurrent veliparib did not improve outcomes compared to gemcitabine and cisplatin alone, and increased hematologic toxicities were noted in the group that received triple therapy.

In an alternate approach, the Pancreas Cancer Olaparib Ongoing (POLO) trial evaluated the efficacy of PARP inhibition when used sequentially with chemotherapy [1]. This randomized, double-blind, phase III trial investigated olaparib as maintenance therapy among patients with metastatic PDAC and germline *BRCA1/2* mutation without disease progression on first-line platinum-based chemotherapy. The study's primary endpoint of progression-free survival (PFS) was significantly prolonged with olaparib compared to the placebo (7.4 vs 3.8 months; $P = 0.004$). This led to the US Food and Drug Administration's (FDA) approval of olaparib as maintenance therapy in this disease setting, and the POLO trial notably became the first successful phase III trial targeting a specific biomarker in PDAC.

Unfortunately, not all patients with *BRCA1/2* mutation respond to PARP inhibition or platinum-containing regimens, and some who initially respond eventually progress on treatment. Biallelic inactivation of DDR genes occupies a crucial role in PDAC's therapeutic response [21]. BRCA-mutated tumors may also acquire therapeutic resistance through reversion mutations or secondary mutations restoring the BRCA reading frame and thereby functional HR repair [21]. As such, the need for improved biomarkers to predict who will respond to DNA damage agents is apparent.

Current markers to identify patients who may benefit from these therapies are defined by genomic hallmarks such as an unstable genome, single-base signature 3, and HRDetect score [16,22,23]. However, emerging data suggest that these modalities testing germline alterations do not wholly capture patients with an elevated HRD score. Parallel somatic profiling identified an additional 10% of patients who exhibit a BRCA-like phenotype with an elevated HRD score, expanding those who may benefit from DNA damage agents [21]. Improved predictive biomarkers may also

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. help define patients beyond those with germline *BRCA1/2* mutations who may respond to other DDR inhibitors, including *ATM*, *ATR*, *WEEI*, and *CHK2* inhibitors, which are currently under clinical evaluation [24].

Recent evidence suggests that accumulated DNA damage from DDR deficiency also induces changes in the tumor microenvironment (TME) that may affect therapeutic response. The PD-1/PD-L1 axis, a target for immune checkpoint blockade, is upregulated by DSBs or PARP inhibition in cancer cells [25,26]. DNA damage also activates immune signaling by introducing genomic double-stranded DNA (dsDNA) into the cytosol and inducing the cGAS/STING signaling pathway [27]. Cytosolic cGAS activates STING along with downstream effectors interferon regulatory factor 3, nuclear factor κB, and STAT6 signaling to induce a type I interferon inflammatory response. In a *BRCA1*-deficient breast cancer model, treatment with PARP inhibition *in vivo* augmented DNA damage and the cGAS/STING pathway, increasing intratumoral CD8+ T-cell infiltration [28]. This led to the combination of DDR inhibitors with immunotherapy in multiple clinical trials [29,30].

A small but significant group of patients with PDAC (1–2%) exhibit defects in mismatch repair (MMR), another pathway for DNA repair. Defects in one of four MMR genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) leads to dysfunctional identification and repair of mismatched DNA base pairs. Unrepaired replicative errors in repetitive DNA sequences, called microsatellites, increase levels of microsatellite instability (MSI-H) among patients with biallelic inactivation of DDR genes, as in Lynch syndrome, and in MSI-H tumors [2]. Elevated tumor mutational burden in MSI-H tumors results in higher neoantigen expression, enhancing tumor immunogenicity and rendering tumors susceptible to immune checkpoint blockade (ICB). As a result, inhibiting PD-1 in tumors with MMR deficiency (dMMR)/MSI-h significantly improved outcomes.

In 2017, the FDA approved pembrolizumab for dMMR/MSI-H PDAC following the phase II KEYNOTE-158 study, which demonstrated a PFS of 4.1 months and OS of 23.5 months [2].

Oncogenic *KRAS* Mutations

Given its mutational frequency and role in tumorigenesis, *KRAS* is a promising therapeutic avenue in PDAC. Until recently, targeting oncogenic *KRAS* directly has proven particularly challenging due to the RAS protein's lack of druggable pockets to which small molecule inhibitors can directly bind [31]. However, a shallow pocket within the $KRAS^{G12C}$ mutant allele has recently been identified, leading to the first selective $KRAS^{G12C}$ inhibitor [32]. Although most PDAC tumors harbor mutations at G12D (40%) or G12V (33%), the significant responses seen with non-small cell lung carcinoma and the $KRAS^{G12C}$inhibitor sotorasib demonstrate the gene's potential as a therapeutic target [32,33]. Early-phase clinical reports in the 1–2% of PDAC patients harboring $KRAS^{G12C}$ mutations are promising. Sotorasib's success depends on a stable covalent bond with the mutant cysteine component unique to $KRAS^{G12C}$ [32]. Efforts are under way to develop direct inhibitors against other *KRAS* variants [33].

Downstream of *KRAS*, activation of the RAF/MEK/ERK pathway contributes to PDAC proliferation, and previous efforts targeting this signaling have been largely unsuccessful due to pathway reactivation by a complex network of feedback loops [33,34]. However, several MEK inhibitors combined with novel inhibitors are currently delivering promising results. One exciting strategy targets the protein-tyrosine phosphatase SHP2, which is critical to KRAS activation by regulating SOS1-dependent RAS-GTP loading [35]. In preclinical studies, SHP2 and MEK inhibition prevented adaptive resistance in multiple cancer models expressing mutant *KRAS* [36]. Consequently, SHP2 inhibitors are under investigation in phase I clinical trials. The small molecule SOS1 inhibitor BI-3406 also decreases RAS-GTP loading, thereby attenuating feedback reactivation by MEK inhibition [35]. When combined, BI-3406 and trametinib caused tumor regression in *KRAS*-mutated mouse models, leading to testing in phase I clinical trials.

In addition to downstream effectors, KRAS-dependent metabolic targets such as autophagy present a therapeutic target. *KRAS*-mutant tumors with upregulated cellular proliferation meet increased nutritional demands with elevated levels of autophagy [33]. Preclinical models demonstrated that autophagy inhibition synergizes with MEK inhibition to suppress PDAC growth, and this combination is being studied in phase I clinical trials [37].

Transcriptional Subtypes and Epigenetic Heterogeneity

Parallel to deciphering genomic mutations driving PDAC, the transcriptomic landscape has also emerged as a key contributor to PDAC heterogeneity. In 2011, Collisson et al. analyzed differential expression of 62 genes to first report three transcriptomic subtypes with prognostic significance: classical, quasimesenchymal, and exocrine-like [6]. Later, Moffitt et al. recognized the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

complex nature of the TME, role of desmoplastic stroma, and variability in malignant epithelial cellularity [8]. They analyzed whole transcriptomes to describe two subtypes, basal and classical, where basal tumors resemble the quasimesenchymal subtype proposed by Collisson et al. Since then, multiple studies have validated the basal and classical subtypes in both primary and metastatic tumor samples [17]. Basal-like tumors are associated with worse prognosis, higher pathologic grade, and poorer chemotherapy response compared to classical tumors [5,10].

To analyze molecular subtype in the clinical setting, immunohistochemistry markers distinguish between transcriptional subtypes. Basal-like tumors display elevated nuclear GLI1 and KRT17 while GATA6 expression identifies classical tumors [10,38,39]. However, recent findings reveal that while bulk tumors classify as basal-like or classical, varying proportions of these cells at the single cell level place tumors along a continuum between the two subtypes [5].

Molecular subtype plasticity has been documented in response to chemotherapy, highlighting a dynamic transcriptional landscape regulated by epigenetic reprogramming [9]. Defining these subtypes identified master regulators of basal-like (e.g., ΔNp63, EZH2) and classical tumors (GATA6-centered regulatory network) [40–42]. Additionally, the epigenetic landscape holds potential as a therapeutic target in PDAC. Dhara et al. recently isolated malignant epithelial cells from 54 treatment-naïve, resected tumors to describe a tumor cell-intrinsic epigenetic signature [43]. This signature correlated with up to a seven-fold improvement in disease-free survival (DFS), and over 700 putative gene-regulatory elements were silenced in patients with poor prognosis after resection and adjuvant gemcitabine/abraxane. In light of these discoveries, efforts to define clinically relevant transcriptional and epigenetic subtypes seek to determine potential targets at these new levels of molecular profiling.

Precision Medicine for Pancreatic Cancer

The past decade's genomic and transcriptomic analyses identifying biologically significant PDAC subtypes have built the foundation for larger studies examining real-time feasibility and the clinical benefit of molecular profiling. These multidisciplinary studies (e.g., IMPaCT, COMPASS, PancSeq, Know Your Tumor) rapidly returned results to clinicians (<30 days) with feasibility >90% in most cases [11,12,14,44]. This suggests that prospective molecular profiling can produce therapeutically relevant results within the time frame to aid clinical decision making.

In these studies, actionable genetic alterations were identified in 26–48% of patients, although the number and criteria used to define these targets varied [11,12,14,44]. On a larger scale, the Know Your Tumor program examined 677 patients and uncovered actionable mutations in 189 [14]. Of these, 46 (24%) received matched therapy guided by genomic results while 488 patients (72%) did not. Although the number of patients who received matched therapy was small, they experienced significantly longer survival compared to those without actionable genetic alterations (2.58 years vs 1.32 years; $P < 0.0001$).

Executing molecular profiling, efficient turnaround of results, and application guiding therapeutic decisions require coordination across multiple disciplines. Several challenges facing the implementation of precision medicine in PDAC are discussed later in this chapter along with the role of platform trials, such as Precision Promise, in breaking down these barriers. Despite the challenges, these studies indicate that molecular analysis to target genomic alterations is both attainable and critical in improving outcomes among patients with PDAC (Fig. 152.1).

With increased genomic profiling and the development of therapeutic agents, molecularly targeted therapy for PDAC has grown over the last several years and established several exciting therapeutics in the clinical setting. As previously discussed, olaparib is approved for maintenance therapy for patients with *BRCA1/*2 mutation following the POLO trial, and the KEYNOTE-158 study proved pembrolizumab's benefit in MSI-H tumors [1,2]. Tumors harboring neurotrophin receptor kinase (NTRK) gene fusions are now targeted by the TRK inhibitors larotrectinib and entrectinib (FDA approved in 2018 and 2019, respectively) [45,46]. More recently, a phase I/II study demonstrated significant radiologic regression when *NRG1*+ tumors were treated with zenocutuzumab [47]. Although current opportunities for therapy benefit a fraction of patients with PDAC (Table 152.1), ongoing research continues to identify new targets against this disease.

Challenges to Precision Medicine

Despite numerous studies exemplifying their promise, precision oncology-driven programs face multiple challenges, from identifying actionable results to delivering targeted therapies. These hurdles emphasize that only through a multidisciplinary approach and collaboration can we improve survival among patients with PDAC.

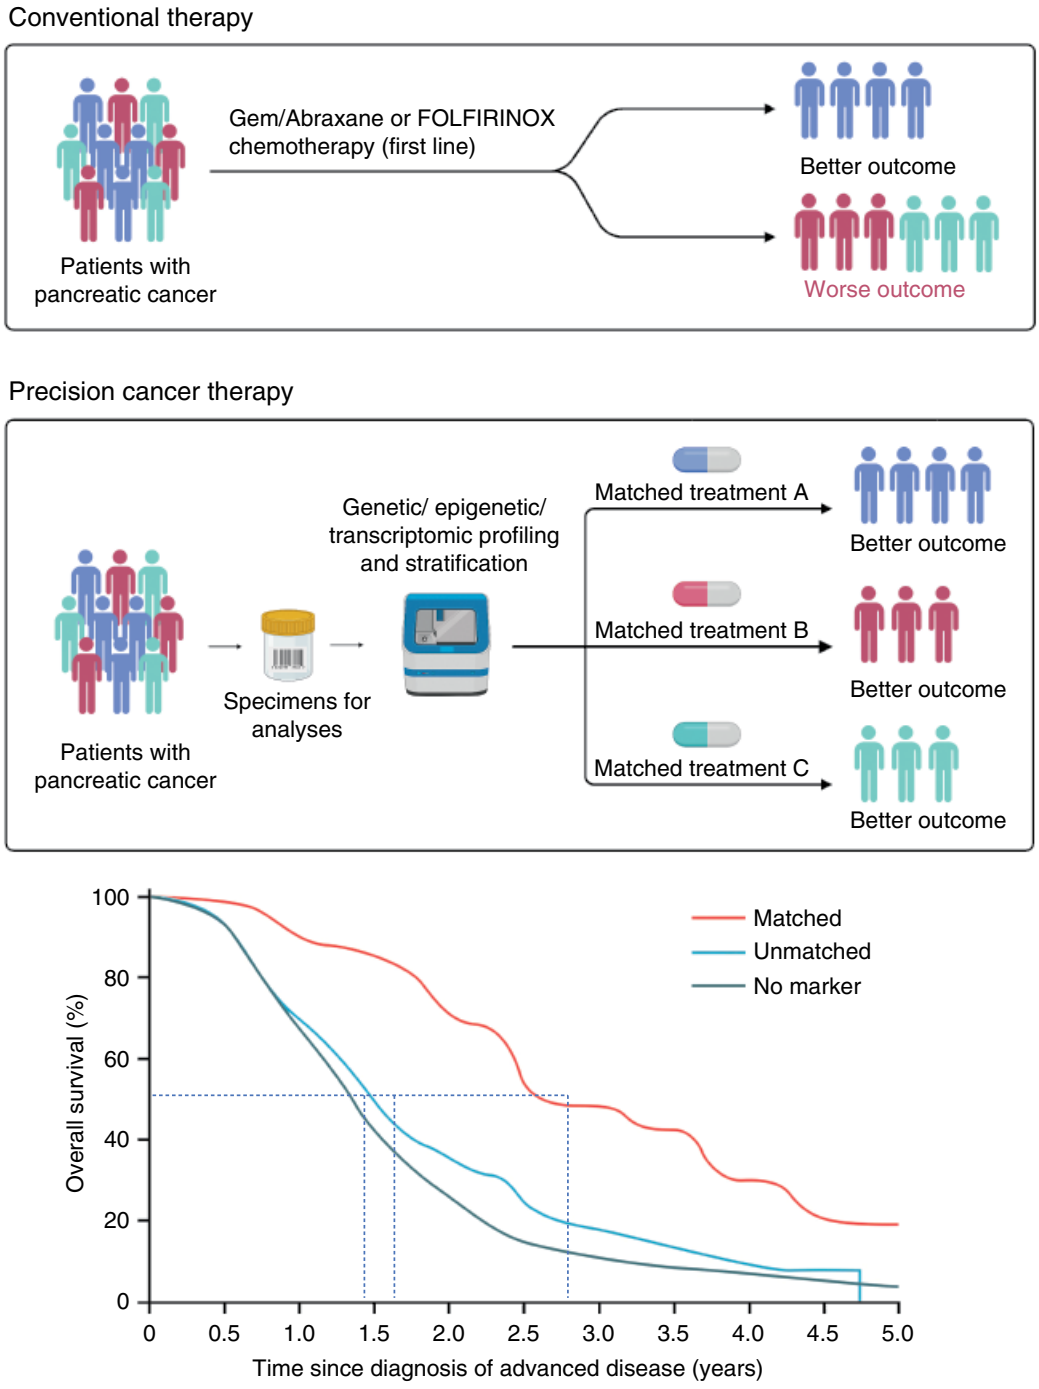

Figure 152.1 Precision medicine in pancreatic cancer. (Top) Schematic diagram comparing traditional and precision medicine in patients with PDAC. (Bottom) Improved survival among patients with PDAC who receive matched therapies via a precision medicine approach.

Tumor Biology

Molecular tests require adequate quantity and quality of tumor tissue to successfully identify tissue-specific markers for targeted therapies. Biopsy via endoscopic ultrasound fine-needle aspiration (EUS-FNA) may not obtain adequate tissue, as data suggest that core needle biopsy is more effective for molecular analysis [12]. Specimens may also not be optimal for genomic testing due to difficult anatomic location for acquisition, low cellularity, and abundant stroma [48]. Additionally, tumor biology challenges the clinical timeline as disease progression demands efficient turnaround for molecular analysis and application.

Table 152.1 Actionable mutations in PDAC.

Genetic alteration (target)		FDA-approved agents: Agent	FDA-approved agents: Trial	Targeted therapies in clinical trial
DDR	*BRCA1/2*	PARP inhibitor (olaparib), platinum-based chemotherapy	2019, NEJM (POLO trial)	Yes; other PARP inhibitor agents, combination therapy (PARP inhibitor with ICB)
	PALB2	None	–	Yes; other PARP inhibitor agents, combination therapy (PARP inhibitor with ICB)
	ATM	None	–	Yes; novel ATR inhibitors, combination therapy (PARP inhibitor with ICB, PARP inhibitor with AKT inhibitor/WEE1 kinase inhibitor/ATR inhibitor, ATR inhibitor with chemotherapy)
	MMR-d/MSI-h (*MLH1, MSH2, MSH6, PMS2*)	PD-1 inhibitor (pembrolizumab)	2020, JCO (KEYNOTE-158)	Yes; novel ICB agents, combination therapy (ICB with radiation therapy)
KRAS	*G12C*	G12C inhibitor (sotorasib)	2020, NEJM	Yes; other novel G12C inhibitors, combination therapy (G12C inhibitor with ICB/SOS1 inhibitor/SHP2 inhibitor)
NTRK Fusion		TRK inhibitors (larotrectinib, entrectinib)	2020, Lancet Oncology; 2020, Lancet Oncology	No novel agents
NRG1 Fusion		HER2/HER3 inhibitor (zenocutuzumab)	2021, JCO	Yes; other HER2/HER3 inhibitors

ICB, immune checkpoint blockade; DDR, DNA damage repair; MMR-d, mismatch repair deficient; MSI-h, high microsatellite instability.

Access to Precision Medicine

Clinical providers must also be educated on molecular test options, the timing of testing, optimal tissue collection, and actionable results [49]. Molecular tumor boards, composed of clinical personnel and research coordinators, provide guidance in developing and implementing personalized treatment plans. Improving access to these multidisciplinary meetings may represent one strategy to reduce disparities in access to precision oncology. Patient education in precision medicine opportunities is also essential to its success. Access to genetic counseling, given evolving guidelines for germline genetic testing in all PDAC patients, may be challenging in the community setting, and how to optimize patient outreach is still under investigation [50].

Organizational Barriers and Next Steps

As effective precision medicine spans multiple clinical and research entities, program organization poses additional challenges. Precision oncology is implemented primarily at academic tertiary care centers. However, patients treated at these facilities represent only a small fraction as 80% of patients with cancer in the US are treated in the community setting. Additionally, enrollment into precision medicine trials depends on molecular criteria. These challenges have given rise to innovative platform trials, including Precision Promise (US) and PRECISION-Panc (UK), which integrate molecular data from clinical trials to identify therapeutic biomarkers and match an effective treatment plan. Increasing access to these types of clinical trial platforms across the pancreatic community may lead to significant advances in drug development in PDAC.

Conclusion

As its incidence rises, PDAC poses a significant and continued clinical challenge. Hope to improve survival among those affected resides in early detection and more effective treatment. Over the last decade, precision cancer medicine has emerged as a promising avenue, and its application is revolutionizing the approach to PDAC. Recent molecular studies highlight the challenges that PDAC tumor heterogeneity and biology pose. As our understanding grows, it becomes more apparent that PDAC cannot be treated with a single approach. Only through collaborative effort among scientists, clinicians, patients, and community organizations can we expand our understanding of the disease's biology and develop the novel, molecularly driven therapeutics that will be effective in the years to come.

Palliative Chemotherapy for Advanced Pancreatic Cancer: Treatment Modalities, Side-effects, and Benefits of Survival

Christoph Springfeld[1] *and Thomas Seufferlein*[2]

[1] *Department of Medical Oncology, Heidelberg University Hospital, Heidelberg, Germany*
[2] *Department of Internal Medicine I, Ulm University Hospital, Ulm, Germany*

Introduction

Pancreatic ductal adenocarcinoma (PDAC) not only has the worst five-year survival of all common malignancies but also the smallest increase in overall survival during the last 40 years [1]. Surgery can cure some patients with early disease, but most patients are diagnosed with locally irresectable tumors or metastatic disease [2,3]. Current guidelines recommend chemotherapy for every PDAC patient if performance status and comorbidities permit it [4,5]: after curative resection, adjuvant therapy can improve recurrence rate and prolong survival (see Chapter 148). In patients with locally advanced disease, induction chemotherapy may convert the tumor to resectability and therefore still offer a chance for cure (see Chapter 147). In metastatic disease, chemotherapy can improve quality of live and prolong survival.

The unfavorable PDAC prognosis is caused by an aggressive tumor biology with early systemic spread and a relative resistance against systemic therapy. In contrast to some other cancers like seminoma, chemotherapy alone does not offer a chance for cure, and the gained survival benefit is short compared to other cancers like breast cancer or colon cancer. Even with the best currently available chemotherapy, stage IV patients have a median overall survival of less than a year [6]. Immunotherapy, although very successful in many other cancers, has so far been largely ineffective (reviewed in Chapter 150).

Targeted therapy, a very valuable option in many malignancies, has, with a few exceptions, not been successfully used in pancreatic cancer, mainly because about 95% of tumors harbor KRAS mutations that are usually not yet druggable. However, the approval of olaparib as maintenance therapy after platinum-based chemotherapy for patients with germline BRCA mutations [7], the occasional druggable alterations in patients with KRAS wild-type tumors [8], and the development of strategies to inhibit KRAS, e.g., with mutant-specific inhibitors for KRAS G12C [9], offer some hope that there will be further advances soon (reviewed in Chapters 151 and 152). For now, outside clinical trials, classic chemotherapy remains the mainstay of treatment for patients with advanced pancreatic cancer.

First-line Chemotherapy

The first chemotherapy with broader use in pancreatic cancer patients was 5-fluorouracil (5-FU) monotherapy in various dose regimens. Early trials testing combinations with drugs like carmustine, streptozocin, or mitomycin C did not show a consistent survival benefit [10,11]. In a landmark randomized phase III study published in 1997, Burris et al. showed that gemcitabine monotherapy (1000 mg/m^2 weekly for seven weeks, one week of rest, followed by weekly gemcitabine for every three out of four weeks) was superior to weekly 5-FU (600 mg/m^2) in patients with locally advanced or metastatic PDAC [12]. Patients in the gemcitabine arm had a median overall survival of 5.65 months compared to 4.41 months in the 5-FU arm. Gemcitabine treatment also resulted in better quality of life: 23.8% versus 4.8% of patients achieved a "clinical benefit response" that was a composite measurement of pain, Karnofsky performance status, and weight status.

Subsequently, several gemcitabine combinations with different chemotherapeutic partners, including cisplatin, oxaliplatin, and capecitabine, were tested but not found superior to gemcitabine monotherapy in randomized

phase III trials [13]. Metaanalyses showed a small benefit for gemcitabine combinations with platinum analogues or fluoropyrimidines, especially in patients with good performance status [14–17]. Gemcitabine was also combined with the EGFR tyrosine kinase inhibitor erlotinib in a randomized phase III study with 569 patients with locally advanced, irresectable or metastatic PDAC [18]. Median overall survival (OS) in the gemcitabine plus erlotinib group was statistically significantly longer than in the gemcitabine group (6.24 months vs 5.91 months, $P = 0.38$). The effect of erlotinib was more pronounced in patients who developed the typical skin rash caused by EGFR inhibition. It has been controversially discussed whether the survival benefit is clinically meaningful, especially when quality-of life aspects are also considered, and erlotinib was not included in the control arm of the major subsequent phase III studies (Table 153.1).

Gemcitabine monotherapy remained the standard of care until 2011, when Conroy et al. reported the results of the pivotal randomized phase III ACCORD11/PRODIGE4 study [6]. In this study, 342 patients with stage IV PDAC received either FOLFIRINOX, a combination therapy of bi-weekly oxaliplatin (85 mg/m^2), irinotecan (180 mg/m^2), and 5-FU (400 mg^2 as bolus and 2400 mg/m^2 as continuous infusion) or gemcitabine monotherapy. Median OS was increased from 6.8 months in the gemcitabine group to 11.3 months in the FOLFIRINOX group (hazard ratio for death 0.57, P <0.001). Objective response rate (31.6% vs 9.4%) and one-year survival (48.4% vs 20.6%) also clearly favored the FOLFIRINOX group. The study had strict inclusion criteria and only admitted patients with an Eastern Cooperative Oncology Group (ECOG) performance status of 0 or 1, younger than 76 years, without significant cardiac disease, and with near normal bilirubin. Combination therapy with FOLFIRINOX resulted in a higher rate of grade III/IV toxicities including neutropenia, diarrhea, and peripheral neuropathy. Quality of life was still better in the FOLFIRINOX group than in the gemcitabine group, because FOLFIRINOX better improved cancer-related symptoms and delayed quality of life impairment due to progression [19].

Several groups have reported small studies using modified versions of the FOLFIRINOX protocol, and a modified version of FOLFIRINOX (mFOLFIRINOX) with lower irinotecan dose and omission of the 5-FU bolus has also been used in an adjuvant study [20]. The case series suggest that mFOLFIRINOX is similarly effective as the original protocol [21], and although this has not been proven in a phase III study, mFOLFIRINOX can be considered when there are doubts if a patient is fit enough for the therapy.

Table 153.1 Selected randomized trials of palliative chemotherapy for pancreatic cancer.

Name	Line of treatment	Stage	n	Treatment regimen	Overall survival (months)	*P*-value	References

Finally, in 2013, a positive randomized phase III study was published that demonstrated a superior overall survival with a gemcitabine-based combination chemotherapy versus gemcitabine alone. In the MPACT trial, 861 patients with stage IV PDAC were randomized to receive either gemcitabine (1000 mg/m^2 weekly for three out of four weeks) plus nab-paclitaxel (125 mg/m^2 weekly for three out of four weeks) or gemcitabine alone [22]. Nab-paclitaxel is an albumin-bound, solvent-free, and water-soluble formulation of paclitaxel that does not require antiallergic premedication like previous castor oil-based formulations [23]. Patients had to have a Karnofsky performance status of at least 70% and a normal serum bilirubin level. Combination treatment increased overall survival from 6.7 months to 8.5 months (P <0.001) and objective response rate from 8% to 23% (P <0.001). The addition of nab-paclitaxel increased the rate of grade III/IV neutropenia (38% vs 27%), fatigue (17% vs 7%), and peripheral neuropathy (17% vs 1%).

The choice of first-line chemotherapy depends on the patient's fitness, comorbidities, and preferences. In a recent retrospective European observational study, 35.6% of patients were treated with mFOLFIRINOX, 25.7% with gemcitabine/nab-paclitaxel, and 20.5% with gemcitabine monotherapy [24].

Currently, there is no biomarker used in routine clinical practice that will predict success of a certain chemotherapy in an individual patient, but there is increasing evidence that patients with BRCA mutations should be treated with platinum-based chemotherapy [25–27]. For these patients, very high response rates have also been reported for the combination of cisplatin/gemcitabine [28], but it is uncertain whether this combination should be preferred to FOLFIRINOX. Patients with germline BRCA mutations can also receive olaparib maintenance therapy if there is at least stable disease after four months of platinum-based first-line chemotherapy [7].

Apart from the BRCA mutations, it is now clear that subtypes of pancreatic cancer exist that respond differently to different chemotherapies, and it is likely that predictive biomarkers will be developed in the coming years [29] (see Chapter 152).

Second-line Chemotherapy

After progression under first-line chemotherapy, second-line therapy can be considered provided the patient's performance status is still sufficient. After gemcitabine-based first-line therapy, 5-FU in combination with either oxaliplatin or nanoliposomal irinotecan (nal-irinotecan) can be used.

The CONKO-003 multicenter phase III study first randomized patients with failure of gemcitabine-based therapy to best supportive care or therapy with oxaliplatin and 5-FU [30]. Oxaliplatin (85 mg/m^2) was administered on days 8 and 15 of a six-week cycle, 5-FU (2000 mg/m^2 intravenously over 24h) with leucovorin on days 1, 8, 15, and 22 (OFF protocol). The study had to be terminated early due to slow recruitment, but median OS was increased from 2.30 months to 4.82 months (P = 0.008). After an amendment, the control arm was changed to 5-FU monotherapy [31]. The OFF protocol was also superior to 5-FU with an overall survival of 5.9 vs 3.3 months (P = 0.010). Surprisingly, the combination of oxaliplatin and 5-FU was inferior to 5-FU alone in the Canadian PANCREOX trial that used a different regimen (mFOLFOX6), probably due to increased toxicity in the combination arm [32]. Therefore, if oxaliplatin and 5-FU are used as second-line therapy, the OFF protocol should be preferred.

In the phase III NAPOLI-1 trial, nal-irinotecan and 5-FU (N = 117) were compared to 5-FU alone (N = 149) in stage IV patients with progression under gemcitabine-based first-line therapy [33]. Patients in the nal-irinotecan/5-FU group had a survival of 6.1 months compared to 4.2 months in the 5-FU only group (P = 0.012). Since many patients now receive first-line therapy with gemcitabine plus nab-paclitaxel and therefore suffer from taxane-induced polyneuropathy, nal-irinotecan is often the preferred choice for second-line therapy. For patients not fit enough for second-line combination therapy, 5-FU monotherapy can be considered.

After first-line therapy with FOLFIRINOX, gemcitabine-based second-line chemotherapy is reasonable and most commonly used [24], although there are no randomized trials defining the optimal protocol. In a French prospective cohort with 57 patients receiving second-line gemcitabine plus nab-paclitaxel, a response rate of 17.5% and OS of 8.8 months have been reported [34].

Future Perspectives

Despite some advances in recent years, namely the success of combination chemotherapy regimens and the approval of nab-paclitaxel, nal-irinotecan, and olaparib, the outlook for patients with metastatic pancreatic cancer is still dire. It seems unlikely that significant further progress will be made by novel chemotherapy combinations, but molecular markers predicting the success of currently available chemotherapies might improve outcome and save patients from unnecessary toxicities.

Pancreatic cancer is one of the last cancer entities without approved immunotherapy drugs; novel drugs, combination treatments with chemotherapy or radiation, and insights into the molecular resistance mechanisms

will hopefully also pave the way for this important treatment modality [35–37]. Targeted therapies that are already improving the prognosis of rare patients with druggable lesions might be extended to more and more subgroups; the early results of the KRAS G12C inhibitors are encouraging, and the development of inhibitors for other KRAS mutations and combination treatments, e.g., with EGFR inhibitors, is under way [38]. Taken together, these advances will hopefully make pancreatic cancer less fearsome in the future.

Management of Pain in Pancreatic Cancer

Annie W. Hsu[1], *Ayodeji Omosule*[1], *and Michael Erdek*[2]

Anatomy and Physiology of Pancreatic Cancer Pain

The pancreas is divided into four main segments as it extends from the midline laterally: the head (including the uncinate process), neck, body, and tail. While pancreatic cancer pain varies by tumor location, extension, and stage, it is typically abdominal, with referral to the epigastric region, upper abdominal quadrants, and less frequently lower abdominal quadrants, or it can be diffuse in nature [1–3]. Back pain in the T10–12 region, often misattributed due to its prevalence in the age group most affected by pancreatic cancer, is not only very common but is also the presenting symptom in many cases [4,5].

Visceral nociceptive signals, generated by tissue damage, inflammation, ductal obstruction, and glandular infiltration associated with pancreatic cancer, are transmitted along afferent sympathetic fibers to the celiac plexus (T12–L2). Here, they synapse with the splanchnic nerves (greater, lesser, and least) on their way to the T5–T12 dorsal root ganglia. Metastatic disease reaching other upper abdominal solid organs shares these pathways. Tumor extension into nonorgan surrounding tissues such as the peritoneum, retroperitoneum, and bones results in localized somatic pain [6]. Neuropathic pain may also be present as the result of perineural invasion (PNI) of cancer cells into the lumbosacral nerve plexuses, intrapancreatic nerve fiber destruction, and epidural spinal cord compression [7,8].

A variety of physiologic factors contribute to the generation and continuation of pancreatic cancer pain. Histologically, pancreatic cancer is characterized by extensive infiltration of inflammatory cells [9]. This inflammatory state, particularly the increased presence of macrophages, is associated with upregulation of nerve growth factor (NGF), the overexpression of which is correlated with both the extent of PNI and pain intensity [10]. Additionally, in the early stages of pancreatic cancer, NGF induces sprouting of calcitonin gene-related peptide (CGRP)-expressing sensory fibers, which increase in density with disease progression [11]. In later stages of disease, the central pancreas, now densely innervated with new sensory fibers, gradually becomes necrotic [12]. This results in the destruction of the distal ends of the sensory and sympathetic nerve fibers that had innervated the now necrotic tissue, resulting in a significant neuropathic pain state.

Pharmacologic Management of Pancreatic Cancer Pain

The principal philosophy behind chronic cancer pain management focuses on maximizing analgesia while minimizing unnecessary risk and patient side-effects. In order to achieve this balance, a gradual, stepwise approach is recommended, beginning with escalating pharmacotherapeutic treatments before progressing to more invasive interventions. The succession is paused for as long as satisfactory pain control is achieved. As 70–80% of cancer patients can be successfully managed with pharmacotherapy alone, analgesic medications, predominantly nonsteroidal antiinflammatory drugs (NSAIDs) and opioids, are considered to be the first line of chronic cancer pain management [13,14].

In 1987, the World Health Organization (WHO) published guidelines for the pharmacologic treatment of cancer pain. These guidelines, updated in 1997 and validated by multiple prospective studies, have served as the foundation upon which cancer pain pharmacotherapy

has been based for nearly four decades [15,16]. The guidelines outline a treatment strategy that is based upon five principles.

1) By mouth: Oral (least invasive) administration of analgesic medications should be chosen whenever possible.
2) By the clock: Analgesics should be given at regular intervals, titrated against the patient's pain such that pain is relieved by a given dose and does not return before the next dose is due. Additional rescue dosing may be given for incident and breakthrough pain.
3) By the ladder: Analgesics should be prescribed according to pain intensity as evaluated by a standardized scale.
4) For the individual: While there are toxicity-limited doses for some medications, there are no standard doses for opioid class medications, and doses should be tailored to the individual needs of each patient.
5) Attention to detail: Each patient's medication regimen should be meticulously planned out over a 24-hour period and written out in full for the patient/family.

Principle three, "by the ladder," proposes that the first medication used in the treatment of cancer pain be a nonopioid (Fig. 154.1). Though not specified, "nonopioid" has been interpreted to mean acetaminophen, acetylsalicylic acid (ASA), or an NSAID. These medications have the advantage of being widely available, familiar to patients, efficacious for a wide variety of etiologies, and easy to administer. Disadvantages include adverse side-effects such as hepatotoxicity with acetaminophen and gastrointestinal bleeding and renal toxicity with NSAIDs. The latter two can largely be avoided with the use of selective cyclooxygenase (COX)-2 inhibitors.

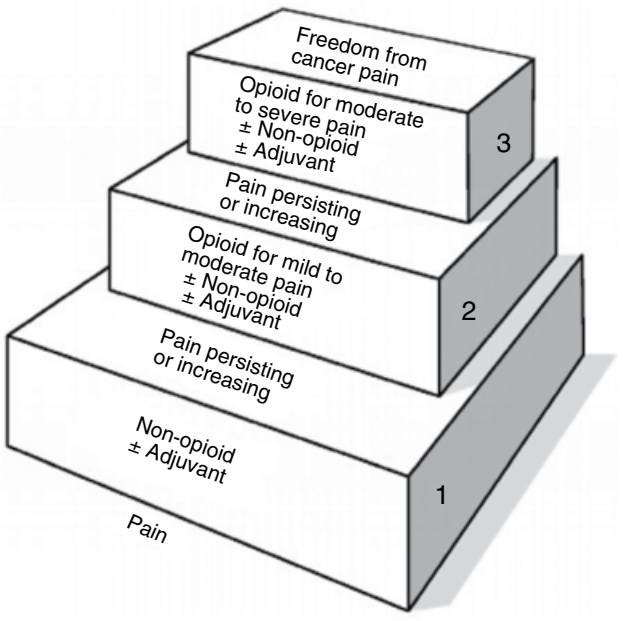

Figure 154.1 WHO pain ladder.

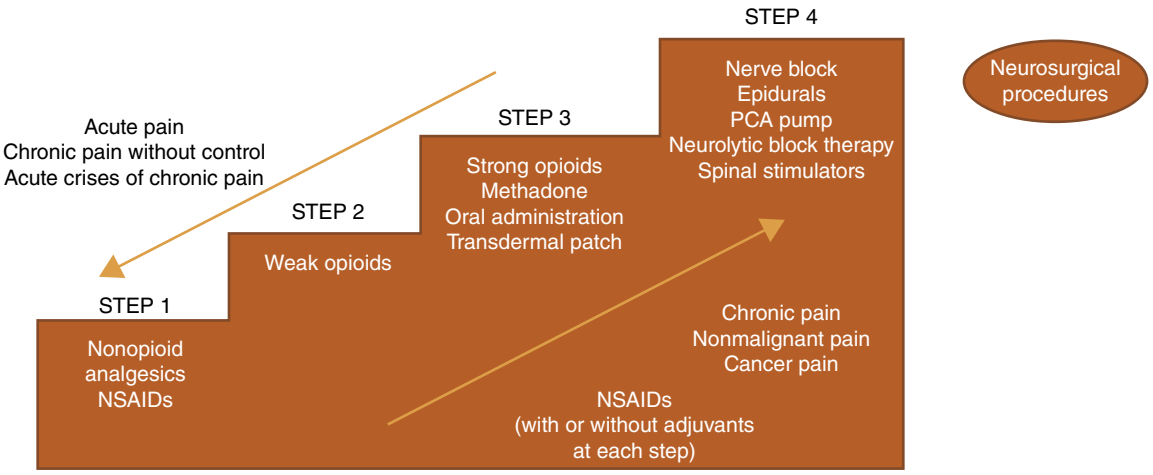
If pain is not adequately controlled with one of these medications, an opioid for mild to moderate pain should be added. This step has been controversial, as disagreement exists as to whether the addition of a "weak" opioid (with "ceiling" effects) to an NSAID decreases the necessary dose of either medication. The utility of this step seems to exist when either the ceiling effect or maximum safe dose of the nonopioid medication has been reached. If satisfactory pain control has not been achieved with the addition of a weak opioid, step three recommends the addition of a strong opioid (i.e, morphine, hydromorphone, oxycodone, etc.). The WHO guidelines state that only one drug from each group should be used at the same time.

Despite, or perhaps as a result of, its widespread use, the WHO analgesic ladder has been the source of much debate [17]. Multiple adaptations have been proposed, including elimination of the second step, accounting for acute and chronic noncancer pain, and including a fourth step representing interventional treatments (Fig. 154.2) [18–21]. Though imperfect, when combined with sound clinical judgment, such guidelines can serve as a foundation for the initial management of pancreatic cancer pain.



Interventional Management of Pancreatic Cancer Pain

Chemical Ablation of the Splanchnic Nerves or Celiac Plexus

Systemic analgesic therapy, per the WHO guidelines, is widely regarded as the standard of care for treating cancer pain. Unfortunately, not all cancer pain patients will achieve a satisfactory outcome by adhering to this algorithm, which has prompted some to challenge the clinical framework of the WHO guidelines for cancer pain [22]. A subset of patients with unresectable pancreatic cancer will suffer from medically refractory pain or develop intolerable side-effects from opioids, which preclude their continued use. For these patients, a variety of minimally invasive techniques have been developed since the early 20th century, the majority of which involve ablation of either the splanchnic nerves or celiac plexus, as these structures play a key role in the transmission of visceral pain from the pancreas.

A discussion of the various technical approaches to ablate either the splanchnic nerves or celiac plexus is beyond the scope of this chapter. Broadly, however, these

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. NSAID, nonsteroidal antiinflammatory drug; PCA, patient-controlled analgesia.

Figure 154.2 New adaptation of the analgesic ladder.

procedures can be subdivided into endoscopic and percutaneous techniques, with the latter consisting of anterior and posterior approaches. A common theme in all of these approaches is image-guided placement of one or more needles in close proximity to the targeted nerves and the use of a neurolytic solution, either phenol or concentrated alcohol. The former destroys nerves via protein denaturation, whereas the latter induces Wallerian degeneration. In either case, the nerves will ultimately regenerate in a process that takes several months. In the interim, patients can experience profound pain relief with a reduced dose of systemic opioids and resultant side-effects.

Regardless of the technical approach, chemical ablation of these nerves tends to be quite effective in the setting of pancreatic malignancy. In the most recent systematic review of the literature by the Cochrane Group, the pooled experimental data on celiac plexus neurolysis reveal statistically significant reductions in reported pain scores, persisting for at least eight weeks post procedure, and markedly reduced overall opioid consumption, persisting until the day before death. As a corollary to the observed reduction in systemic opioid usage, patients randomized to celiac plexus neurolysis tended to experience far fewer opioid-induced side-effects such as constipation. Of note, the overall likelihood of successful neurolysis is variable, but the published success rates generally range from 70% to 90% [23,24].

Although on metaanalysis ablation of the celiac plexus is clearly effective regardless of technical approach, the approach with the highest efficacy and lowest risk of patient harm remains quite controversial, especially with the advent of newer, endoscopic approaches to celiac plexus neurolysis [25–27]. Endoscopic ultrasound-guided celiac plexus neurolysis (EUS-CPN) may be theoretically safer than posterior percutaneous approaches, as it allows more targeted deposition of neurolytic agent in the vicinity of the celiac ganglia, real-time visualization of arterial vasculature in the targeted areas via Doppler, and a potentially reduced risk of anterior spinal artery syndrome. However, these theoretical advantages have not been definitively established in the literature. Furthermore, an endoscopic approach may be limited in effectiveness if the tumor is encasing the celiac trunk, a situation where a percutaneous splanchnic approach might be preferred.

There are very limited data comparing endoscopic to percutaneous approaches for chronic pancreatitis pain, with available literature showing no difference in pain relief and complications between the two approaches [28]. And there are no experimental data thus far comparing the two approaches for treatment of pancreatic cancer pain. Randomized controlled trials are needed to determine the relative efficacy and safety of endoscopic versus percutaneous approaches in the treatment of severe pain due to pancreatic cancer [26,29].

The indications for chemical ablation of the celiac plexus (or splanchnic nerves) for pancreatic cancer pain are relatively straightforward. Given the palliative efficacy of surgical resection and the risks associated with chemical ablation of the splanchnic nerves or celiac plexus, these procedures have traditionally been reserved for a subset of pancreatic cancer patients with unresectable disease. More specifically, good candidates are patients with neoplasm-related pain that is either unresponsive to systemic analgesic medications or associated with intolerable opioid-induced side-effects [30,31]. Absolute contraindications include uncorrectable coagulopathy, lack of adequate resources for patient resuscitation, and local infection in the anticipated

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

trajectory of the needle(s). Markedly impaired cardiac reserve or inability to lie in the prone position are relative contraindications, as these conditions could increase the risk of ischemic or direct chemical injury to the spinal cord, respectively. Another key consideration is anatomic distortion from the pancreatic malignancy. In some cases, the distortion is so pronounced that certain approaches are not feasible. In other cases, severe tumoral invasion or displacement of the celiac plexus may increase the risk of technical failure [32,33]. For this reason, cross-sectional imaging study is recommended prior to the procedure itself.

There are a variety of complications associated with neurolysis of the splanchnic nerves or celiac plexus, but major complications from these procedures are rare. Temporary back pain, abdominal pain, hypotension, and diarrhea are fairly common occurrences, but are generally self-limited and respond quite well to supportive measures. Injury to the kidneys or ureters may occur, which can result in hematuria. Given the close proximity of various approaches to the diaphragmatic crura, pneumothorax is a described complication. There are some case reports in the medical literature of rare complications from celiac plexus neurolysis, including hemorrhagic gastritis/duodenitis, gastroparesis, and aortic dissection. These reported complications are so rare that their actual incidence remains unknown [34–36].

The most feared complication from celiac plexus neurolysis is permanent neurologic injury, with the incidence of permanent paraplegia with posterior approaches being described as 0.15%. Bowel and bladder incontinence can also occur. Although one would expect inadvertent posterior migration of alcohol into the spinal canal to result in permanent neurologic injury, the advent of image guidance has minimized these mechanisms of neurologic injury. Some have posited that the mechanism of neurologic injury stems from alcohol-induced vasospasm of arteries feeding the spinal cord, resulting in infarction of the spinal cord, a theory supported in part by basic science research involving the direct effects of alcohol and local anesthetics on vasomotor tone. If, in fact, neurologic injury from celiac plexus neurolysis stems from a vasospasm phenomenon, this risk would be very difficult to prevent [37–40].

Radiofrequency Ablation of the Splanchnic Nerves or Celiac Plexus

Radiofrequency (RF) ablation of the splanchnic nerves and celiac plexus has been shown to be an effective treatment for chronic abdominal pain in patients with pancreatic cancer, liver cancer, and chronic pancreatitis. RF ablation uses a high-frequency, alternating current to heat tissue around an electrode, inducing focal thermal necrosis. Unlike conventional neurolytic methods with phenol and alcohol, it produces more predictable lesions, which may reduce the risk of inadvertent spread and tissue injury.

Radiofrequency ablation of the bilateral splanchnic nerves was first described by Raj et al, with lesioning performed at 80° C for 90 seconds [41]. Two small studies have since found that percutaneous RF ablation of the splanchnic nerves significantly reduces pain scores for pancreatic cancer pain and chronic pancreatitis for several months [42,43].

An endoscopic approach to RF ablation of the celiac ganglion has recently been described as well. A randomized controlled trial comparing EUS-guided celiac ganglion RF ablation to EUS-CPN showed significantly lower pain scores at four weeks post procedure in the RFA group compared to the CPN group. Mean scores for several quality-of-life measures were also significantly improved in the RFA group after adjusting for baseline pain scores, patient demographics, symptom duration, and chemoradiation therapy. However, there was no significant difference in opioid analgesic use between the two groups at the end of follow-up [44]. Further research is needed comparing RF ablation with traditional chemical ablation of the celiac plexus and splanchnic nerves in the management of pancreatic cancer pain.

Surgical Management of Pancreatic Cancer Pain

Thoracoscopic Splanchnicectomy

Thoracoscopic splanchnicectomy consists of the surgical interruption of the sympathetic chain via a thoracoscopic approach. Kang described 21 patients with unresectable upper abdominal malignancy and pain refractory to opioid analgesics who underwent bilateral thoracoscopic splanchnicectomy [45]. Baseline Karnofsky performance scale was greater than 60, and 71% of patients suffered from pancreatic cancer. Pain scores using a numerical rating scale decreased from an average of 8.5 preoperatively to 1.7 postoperatively, and patients required bilateral chest tubes for an average of three days postoperatively.

In another study, Johnson reported 65 patients (58 with pancreatic cancer) with unresectable upper abdominal malignancy who required opioid analgesia and were randomized to medical management, celiac plexus block, or thoracoscopic splanchnicectomy [46]. In this study, however, no significant differences were appreciated between the groups in pain scores or opioid consumption at two months. Potential limitations of this study

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

include a failure to identify the presence of carcinomatosis in patients, use of only a drop in systemic blood pressure to identify successful celiac plexus block, and a change in sample size from a calculated 324 necessary for analysis to only 65 due to slow recruitment.

Intrathecal Drug Delivery Systems

Intrathecal drug delivery systems (IDDS, i.e, intrathecal pumps) are an option for the treatment of patients with moderate to severe, chronic, refractory pain. Their use has led to improved quality of life, reduced pain, and increased satisfaction in those who have failed other therapeutic options. IDDS have been shown to provide significant pain relief and statistically significant control of analgesic toxicity in cancer patients in a randomized study when compared with standard analgesic therapy, as well as a trend toward increased survival at six months [47].

The Polyanalgesic Consensus Conference (PACC) of the International Neuromodulation Society offers guidelines on intrathecal drug therapy. Since the initial publication in 2012, an updated best practices guideline on intrathecal drug delivery was published in 2017 [48]. Algorithms for nociceptive and neuropathic pain (cancer pain may involve both) were issued, as were recommendations for starting dose ranges, bolus trial ranges, and maximum daily dose and concentration ranges. Available intrathecal (IT) analgesic medications for infusion include opioids (morphine, hydromorphone, fentanyl, sufentanil), local anesthetics (bupivacaine), clonidine, and ziconotide. IT therapy at the end of life is best weighed against surgical and infectious risk, as well as nursing care of externalized systems for those with a very limited life expectancy. Concentration and daily dose limitations are important to help prevent the development of an intrathecal granuloma at the catheter tip, and these are included in the aforementioned guidelines. Additional potential complications of IT therapy include respiratory depression and peripheral edema.

A detailed discussion of intrathecal drug trialing, surgical implantation, and intrathecal pump programming is beyond the scope of this chapter. Broadly, trialing of IT analgesic medications has been described by both bolus dosing and continuous infusion, although some have argued a bolus trial is less representative of the long-term effects of IT therapy [49]. Decrease in pain score by greater than or equal to 50% is a commonly used criterion for success of the trial. There exists debate regarding whether to continue, decrease, or eliminate existing systemic opioids prior to and during IT trial. Typically, catheter trials may last between three and seven days, placed at a spinal level corresponding to the vicinity of the patient's pain. Trials may consist solely of an opioid, but there is also the practice of adding an adjuvant agent such as bupivacaine and/or clonidine to the trial. Some have advocated for the possibility of foregoing IT trials in cancer patients due to the reported high success rates of IT therapy among cancer patients.

Complications may occur with implantation, pump management, drug reactions, side-effects, device malfunction, and human error in programming or refilling the pump [50]. High concentrations of opioids and high daily doses predispose to the risk of intrathecal granuloma, while the addition of adjuvant agents may lessen the risk by an opioid-sparing effect (although some carry their own risk of granuloma at high doses). Additional risks include infection, respiratory depression, peripheral edema, pump failure, and catheter obstruction or migration.

Ultimately, the use of IDDS is based on an analysis of safety, efficacy, and appropriateness for the patient, with a goal of respect for economic neutrality.

Management of Cancer Recurrence

Oliver Strobel[1], *Martin Loos*[2], *and Markus W. Büchler*[2]

Introduction

Management of pancreatic ductal adenocarcinoma (PDAC) recurrence is a highly relevant topic, because even after complete tumor resection with curative intent and adjuvant therapy, the majority of patients will experience local or systemic tumor recurrence. Most patients eventually die from local, metastatic, or combined tumor recurrences, resulting in median survival and five-year survival rates of only 20–25 months and 20% after resection, respectively [1].

Several factors are thought to contribute to the high failure rate and poor prognosis. The most obvious reason for local recurrence is incomplete tumor resection with positive margins. The introduction of stringent margin assessment revealed substantially higher R1 resections than initially anticipated and published in earlier studies [2–5]. An even more relevant problem is systemic failure with metastatic recurrence, most frequently involving peritoneal carcinomatosis and liver metastases. Undetected micrometastatic disease at the time of resection is responsible for early systemic failure, providing a clear rationale for the administration of systemic neoadjuvant and/or adjuvant therapies. However, results from randomized controlled trials showed that systemic therapy can significantly delay, but not prevent, systemic recurrence (Table 155.1).

With significant improvements in surgical therapy and systemic treatment options, the long-lasting controversy on the role of surgery in resectable PDAC has been resolved [1]. High-volume centers have reported actuarial survival rates after resection and adjuvant therapy of approximately 20% overall and of up to 60% in patient subgroups with a favorable combination of prognostic factors [5–10]. Interestingly, although PDAC recurrence is a highly relevant problem affecting the majority of patients, its management remains poorly studied and highly controversial, and is far from being evidence based. Part of the underlying problem is a certain therapeutic nihilism towards PDAC recurrence that is reflected by the fact that current treatment guidelines do not even clearly endorse structured surveillance programs after resection due to a lack of evidence for effective treatment options or a survival benefit by regular follow-up examinations [11,12].

This chapter gives an overview of current treatment options for PDAC recurrence with a focus on isolated local recurrence. We also give an overview of several aspects that are relevant in this context, including incidence and pattern of recurrence after resection, and the potential value of structured surveillance after resection.

Incidence, Timing, and Pattern of Recurrence

Due to the lack of structured surveillance programs after resection for PDAC, our knowledge of the true incidence, timing, and pattern of PDAC recurrence is limited. The best information stems from randomized controlled trials on resection and adjuvant therapy (see Table 155.1) [13–20], from autopsy series [21,22], and from some observational studies dedicated to the topic of recurrence [23,24].

Data from randomized controlled trials (RCT) give the best reference with respect to the "clinical" pattern of recurrence that we would expect to see based on structured follow-up programs with assessment of patient history, physical examination, cross-sectional imaging (usually

contrast-enhanced computed tomography), and serum values of tumor markers, especially carbohydrate antigen (CA) 19-9. The follow-up results of selected clinical trials published since 2000 are summarized in Table 155.1.

Data on disease-free survival from previous RCTs comparing adjuvant therapy with observation show that without adjuvant therapy, more than 50% of patients develop clinically detectable cancer recurrence within 5–10 months [13,15,16], and chemotherapy with gemcitabine or 5-fluorouracil (5-FU) monotherapy can delay this to 11–15 months. The introduction of more aggressive multiagent chemotherapy regimens has been shown to substantially improve disease-free survival rates after curative-intent resections [25–27]. Data from the PRODIGE RCT comparing modified FOLFIRINOX and gemcitabine as adjuvant therapy in patients with resected PDAC show a median disease-free survival of 21.6 months and 12.8 months, respectively [28].

Although the pattern of recurrence of PDAC reported in the literature is somewhat heterogeneous, most studies reported isolated local recurrence rates of 20–35%, while the majority of patients present with systemic disease. The highest local-only recurrence rate of 50% was reported from a secondary analysis of the ESPAC-4 randomized adjuvant chemotherapy trial. [20]. The reasons for the differing rates of local and systemic recurrences in the latter studies are unclear as well as the reasons why in patients with systemic disease progression, metastatic spread may be limited in some cases only to the liver, lung or peritoneum, and why other patients develop isolated local recurrences.

Neoadjuvant therapy has become the standard approach in patients with locally advanced PDAC and several RCTs are ongoing to assess its role in borderline and resectable PDAC. Whether neoadjuvant therapy affects the recurrence pattern after resection of PDAC has yet to be elucidated. A recent comprehensive metaanalysis of 26 studies, including 4986 patients, found neoadjuvant therapy to be associated with lower overall weighted locoregional recurrence of 12% compared to 27% after upfront surgery [29].

In summary, the data on recurrence from RCT show that even with modern aggressive adjuvant therapy, most patients develop recurrence within two years after resection. The data also suggest that based on structured surveillance programs, it may be possible to identify a subgroup of 20–50% of patients who first develop isolated local recurrence. While the RCTs and observational clinical studies give us a notion of the clinically detectable pattern of recurrence, the few available autopsy series demonstrate the "true" pathologic pattern of recurrence and the relevance of the sites of recurrence for death. In a Japanese autopsy study of 24 patients who died after resection of pancreatic cancer, 75% had local recurrence, 75% had distant metastases (50% hepatic), and local recurrence was the cause of death in 17% [21]. Another autopsy study in patients with PDAC included 22 patients after resection [22]. At autopsy, three patients (14%) had isolated local recurrence, four (18%) had only metastatic recurrence, and 13 (59%) had both local and systemic recurrence. These autopsy studies confirm that after resection and adjuvant therapy for pancreatic cancer, most patients die of systemic disease, but a subgroup of patients develop and die from isolated (or predominantly) local recurrence.

Surveillance After Resection for Pancreatic Cancer

Current evidence-based clinical guidelines on PDAC therapy do not clearly endorse structured surveillance programs after resection and completion of adjuvant treatment, mainly because there are no available data showing that earlier detection and treatment of recurrence lead to better patient outcomes [11,12]. Population-based or single high-volume center studies from the United States demonstrated no significant survival benefit but increased costs from regular surveillance computed tomography (CT) scans [30,31]. While the German guidelines do not recommend a structured follow-up at all [12], the American NCCN guidelines recommend history and physical examination every 3–6 months for two years, then annually and, as category 2B recommendations (lower-level evidence), CT scans and CA 19-9 measurements every 3–6 months for two years after surgical resection based on the consensus that earlier detection of recurrence may facilitate patient eligibility for investigational studies or other forms of treatment [11].

It has to be acknowledged that such clinical guidelines have to be based on current evidence and have to include socioeconomic considerations and that there is currently little evidence for any of the treatment options for pancreatic cancer recurrence discussed later (Table 155.2). But how should such evidence ever be generated if not based on structured surveillance for early detection of PDAC recurrence? Even with the limitations of cross-sectional imaging and serum levels of tumor markers in detecting metastatic disease known from the primary diagnosis of pancreatic cancer, the aforementioned data from RCTs suggest that a structured follow-up program based on these tools would allow for earlier detection of localized recurrence.

Heye et al. demonstrated that the comparison of sequential follow-up CT scans allows for early detection of local recurrences by observation of subtle but progressive changes at typical predilection sites for perivascular and lymphatic local recurrences (Fig. 155.1) [32]. In an analysis of 940 postoperative follow-up visits of 618

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 155.2 Treatment options for recurrent pancreatic cancer.

Treatment	Potential indications	Intention	Comments
Chemotherapy	Systemic recurrence	Palliation	Most frequently used for pancreatic cancer recurrence irrespective of pattern. No evidence based on randomized controlled trial (RCT) in the setting of recurrence. Choice for best regimen has to be based on previous chemotherapy, performance status, etc. (see Chapters 153 & 164). Similar rationale as for neoadjuvant and adjuvant therapy in primary pancreatic cancer. No evidence based on RCT.
In multimodal setting with re-resection	Isolated local recurrence	Medium- to long-term control Potential cure	Data from retrospective studies in selected patients with recurrence available (see Table 155.3b)
Chemoradiation	Isolated local recurrence	Palliation Local control Pain therapy	Preferred for isolated local recurrence in many centers, especially in a setting of unresectable perivascular recurrence. No evidence from RCT. Data from retrospective studies in selected patients with recurrence available (see Table 155.3a)
In multimodal setting with re-resection	Isolated local recurrence	Medium- to long-term control Potential "cure"	May be used in a "neoadjuvant" setting and in a multimodal concept involving external and intraoperative radiotherapy. Data from observational studies in selected patients with recurrence available (see Table 155.3b)
Surgery • *Local re-resection* In multimodal setting with chemotherapy or chemoradiation	Isolated local recurrence	Medium- to long-term control Potential "cure"	Performed by only a few specialized surgical centers. No evidence from RCT. Data from retrospective studies in selected patients with recurrence available (see Table 155.3b)
• *Metastasectomy* In combination with chemotherapy	Oligometastatic systemic recurrence	Medium- to long-term control	Literature restricted to case reports and small retrospective studies with mixed cohorts including synchronous metastases. Several small series with favorable survival after resection of isolated lung metastases.
Locally ablative therapies	Isolated local recurrence (in combination with chemotherapy)	Palliation Local control	Different modalities (radiofrequency ablation, irreversible electroporation, etc.) are currently evaluated in some centers. Literature restricted to case reports and retrospective studies with mixed cohorts of primarily unresectable tumors and local recurrences.

patients over a one-year period, recurrence was detected in 74 (40%) of 184 patients after PDAC resection, of whom only 26% had symptoms [33]. In all of these patients, cancer-directed therapy was initiated. Of 16 patients with isolated local recurrence, 12 (75%) were without symptoms and 11 were referred for re-resection.

These data have important implications, because they show that most recurrences are at first asymptomatic but will be detected earlier with regular surveillance including cross-sectional imaging, offering the opportunity for earlier initiation of oncologic therapy. In line with the latter data, Halle-Smith recently published a systematic review and metaanalysis on the clinical benefit of surveillance after PDAC resection [34]. Metaanalysis of five studies including 1596 patients showed that patients with active surveillance programs were more likely to have recurrence detected at an asymptomatic stage. These asymptomatic patients were more likely to receive treatment for

recurrence and had longer overall survival than those with symptoms at time of recurrence.

With advances in treatment options and diagnostic tools, the potential of structured surveillance programs will have to be reevaluated in the future. Novel analytic targets such as exosomal markers and cell-free DNA that are currently being evaluated in the early detection of PDAC may also be promising tools for postresection surveillance [35,36].

Treatment of Systemic Recurrence of Pancreatic Cancer

The treatment options for systemic recurrence of PDAC after resection are based on little evidence. The literature is restricted to mostly small retrospective studies in selected patients and multiple case reports, suggesting a considerable publication bias. Table 155.2 provides an overview of the available armamentarium for treatment of systemic PDAC recurrence. Based on common sense, the appropriate treatment options depend on multiple parameters, including the pattern and localization of recurrence, the clinical performance status and comorbidity of the patient, previous treatment, and timing (i.e., interval between resection and recurrence).

Clearly, systemic chemotherapy is the appropriate palliative therapy for the majority of patients with systemic PDAC recurrence, because they present with systemic disease. There is little evidence from the literature as to the best regimen in this situation. However, this is a palliative situation and depending on the time of recurrence (during or after adjuvant therapy), previous therapy, and performance status, the same principles as outlined for second-line adjuvant and palliative chemotherapy (Chapters 148 and 153) may be recommended. While metastastectomy for systemic PDAC recurrence is highly controversial, favorable survival has consistently been reported after resection of the rare cases of isolated lung metastases [37–39]. With respect to quality of life, adequate pain therapy and supportive care are very important aspects of palliative therapy in patients with PDAC recurrence (Chapter 154).

Treatment of Isolated Local Recurrence of Pancreatic Cancer

While the current NCCN guidelines recommend inclusion in a clinical trial (preferred), chemoradiation (if not previously performed), switch to an alternative systemic chemotherapy, or best supportive care for local recurrence [11], the German S3 guidelines recommend the evaluation of local therapy options for isolated local recurrence based on the retrospective studies available [12]. Available treatment options for local recurrences include chemoradiation, re-resection, and locally ablative therapies (see Table 155.2). In the following, we will focus on chemoradiation and re-resection. Data on feasibility, safety, efficacy, and long-term outcome of locally ablative therapies for local recurrence are limited and include mostly single-center series of small sample sizes [40].

Rationale for "Local" Therapy Options

Pancreatic ductal adenocarcinoma is a systemic disease and most patients will eventually die from metastatic disease. This notion has led to a long-lasting debate as to the value of resection even in resectable PDAC. Based on good evidence and with advances in both surgery and systemic therapy, resection in combination with systemic therapy has now been established as the only therapy with the potential for long-term survival or cure [1]. With further advances, the limits for surgery are today being pushed towards extended resections and resections after aggressive neoadjuvant therapies, with promising results for locally advanced PDAC [27,41,42]. Strategies of neoadjuvant treatment have the advantage that patients with early systemic progression who will have no benefit of surgical resection are selected out before surgery. Together with the pattern of recurrence and survival, data from molecular studies suggest that patients with isolated local recurrence may have biologically distinct PDAC subtypes of a less aggressive phenotype with slower systemic progression [22,43].

Groot et al. analyzed the pattern of disease recurrence after pancreatectomy in 877 patients from a single-center cohort. Six-hundred sixty-two (76%) of the 877 patients had disease recurrence [44]. Patients with multiple-site (4.7 months) or liver-only (7.2 months) recurrence had significantly worse median survival after recurrence compared to patients with lung- (15.4 months) or local-only (9.7 months) recurrence [44]. This notion provides a good rationale to test localized treatments such as re-resection and chemoradiation in this biologically selected subgroup of patients. However, the majority of patients presenting with suspected isolated local recurrence may also have micrometastatic disease and develop systemic progression later. Therefore, as for primary pancreatic cancer, local therapies for recurrence have to be embedded in multimodal treatment strategies that include systemic chemotherapy.

Chemoradiation for Isolated Local Recurrence

Chemoradiation is discussed by many as the main alternative to merely palliative chemotherapy for treatment of local recurrence. The evidence for chemoradiation is based on retrospective series of limited size (Table 155.3a). The actuarial overall median survival reported for chemoradiation is around 16–18 months,

Table 155.3a Retrospective series of chemoradiation for local recurrence of pancreatic cancer.

Author	Year	N	Radiotherapy	Chemotherapy	Oncologic outcomes
Wilkowski [48]	2006	18	45 Gy	5-FU (N = 4) 5-FU, Gem (N = 6) Cis, Gem (N = 8)	OS: 17.5 months PFS: 14.7 months CR: N = 6 (33%)
Wild [47]	2013	18[a]	SBRT 25 (20–27) Gy	28% (N = 5)	OS: 8.8 months
Habermehl [45]	2013	41	39.6–54 Gy + IORT (15 Gy) in N = 15	Gem (90%) 5-FU or Cap (10%)	OS: 16.1 months PFS: 6.9 months CR: N = 6 (15%)
Nakamura [46]	2014	30	54 (39–60) Gy	Gem (N = 18) S-1 (N = 7)	OS: 15.9 months PFS: 6.9 months

Included are studies with >5 patients undergoing chemoradiation.
[a] Study includes N = 3 patients after definitive chemoradiation (no resection) for locally advanced disease.
SBRT, stereotactic body radiation therapy; OS, overall survival; PFS, progression-free survival; CR, complete remission (clinical).

Table 155.3b Retrospective series of re-resection for local recurrence of pancreatic cancer.

Author	Year	N operated	N resected	Resection rate	Mortality	Other cancer-directed therapy	Oncologic outcome
Lavu [40]	2011	NA	8	NA	0	NA	OS: 17.5 months
Thomas [39]	2012	NA	7	NA	0	NA[b]	OS: NA[b] DFS: 9 months
Strobel[a] [43]	2013	97	41	42.3%	1 (1.8%)	In cases with re-resection: Chemoradiation: N = 22 IORT: N = 22 Chemotherapy: N = 21 NA: N = 4	Re-resection: OS: 26.0 months Exploration (ILR): OS: 10.8 months Exploration (mets.): OS: 9.4 months
Boone[b] [51]	2014	NA	10	NA	0	NA	OS: 31.8 months
Miyazaki [52]	2014	NA	11	NA	0	Chemotherapy: N = 8 None: N = 3	Re-resection: OS: 25.0 months No re-resection: OS: 9.3 months
Shima [53]	2015	NA	6	NA	0	Chemotherapy: N = 1	OS: 27.5 months
Kim [49]	2019	197	48	24.4%	0	Chemotherapy: N = 35	OS: 14.7 months (all 197 patients) OS: 36.5 months (after resection of isolated lung mets.) OS: 28.0 months (after resection of isolated remnant pancreas recurrence)
Yamada [54]	2018	114	90	78.9%	1 (1.1%)	Chemotherapy: N = 15	OS: 26.0 months

Included are studies with >5 patients undergoing re-resection.
[a] The cohort by Kleeff et al. is from the same center and included in the follow-up study by Strobel et al.
[b] Mixed cohort of local and distant recurrence. Only data of patients with local recurrence included here.
OS, overall survival; DFS, disease-free survival; ILR, isolated local recurrence without evidence of systemic disease confirmed by surgical exploration.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. with median progression-free survival of 6.9 months in the two larger out of four studies [45–48]. A poorer median overall survival of only 8.8 months in the only series with a low reported rate of systemic therapy (28%) [47] supports the notion that any local therapy for recurrence has to be accompanied by systemic chemotherapy in order to achieve favorable survival results. Using stereotactic body radiation therapy in combination with chemotherapy, almost comparable outcomes have been reported with a median survival after stereotactic body radiation therapy of 12–16 months.

Re-resection for Isolated Local Recurrence

Although the evidence for re-resection for the treatment of local PDAC recurrence is mainly based on retrospective series of limited sample size (Table 155.3b) [39,43, 49–54], there is an increasing body of evidence suggesting that resection of isolated local PDAC recurrence can be safely performed and that re-resection may offer a survival benefit compared to palliative treatment in selected patients. The reported outcome with median overall survival rates of 25 to >30 months after re-resection in the most recent series [43,50–54] appears to be superior to the outcome reported after chemoradiation. It should be noted that these differences may in part be explained by selection bias due to the exclusion of patients with radiologically undetected metastatic disease prior to reoperation in the re-resection series. The summarized results demonstrate that re-resection was safe with 0–2% mortality and associated with very encouraging survival outcome at least in the selected patients who underwent re-resection. It should be emphasized that these results originate from specialized referral centers for pancreatic surgery and may not be commonly applicable.

We have reported our initial experience with re-resection of isolated local PDAC recurrence [43]. Analysis in this series allowed for several relevant observations. Of 97 patients with preoperatively suspected isolated local recurrence and histologic proof of recurrence, 57 (59%) had isolated local recurrence by surgical exploration, while distant metastases were identified in 40 (41%) patients. This again highlights the necessity of better diagnostic tools to detect small metastatic deposits, a problem known from primary PDAC staging. Of 57 isolated local recurrences, 41 (72%) were resected while 16 (28%) were locally unresectable. Median postoperative survival was 16.4 months in isolated local recurrence versus 9.4 months in metastatic recurrence, confirming the better prognosis of isolated recurrence that had been described previously [55]. Importantly, median survival in isolated local recurrence was significantly longer after resection (26.0 months) versus exploration for local unresectability (10.8 months). This observation in isolated local recurrence points to a potential survival benefit from re-resection. R0 re-resection was achieved in 18 patients and resulted in 30.5 months median survival. In accordance with our findings, a metaanalysis of surgical treatment for isolated local recurrence of PDAC showed an overall survival almost twice as long in patients with re-resection compared to patients with nonsurgical treatment. The median survival benefit for patients who underwent re-resection was 28.7 months [56].

Groot et al. recently performed a systematic review on the treatment of isolated local recurrence of PDAC after surgical resection and analyzed different treatment options including re-resection, chemotherapy, and stereotactic body radiation therapy (SBRT) [57]. The authors found 18 studies with a total of 313 patients. Comparison of the three different treatment options of isolated local recurrence showed median survival of 32, 19, and 16 months after re-resection, chemoradiotherapy, and SBRT, respectively.

While a true benefit of re-resection can only be demonstrated by RCT, these results suggest that selected patients with suspected isolated local PDAC recurrence may benefit from re-resection.

Conclusion

Pancreatic cancer recurrence is a pressing concern affecting the vast majority of patients even after complete tumor resection and completion of systemic therapy. While the majority of patients develop metastatic recurrence, a significant subgroup of patients (20–30%) first develop isolated local recurrence. These patients may have tumors of less aggressive subtypes with slower systemic progression and may therefore benefit from a multimodal treatment strategy that includes local therapy. As most recurrences are at first asymptomatic, structured follow-up programs are needed to identify these patients.

Although the literature provides little evidence with respect to the management of PDAC recurrence, both chemoradiation and surgical re-resection have been suggested to be safe and effective by several retrospective series. The best “standard” management for cancer recurrence can only be determined based on RCT, which will be difficult to conduct for this indication. More likely, the therapy for PDAC recurrence will remain a matter of interdisciplinary, personalized decision making. Novel effective treatments for PDAC therapy and novel biomarkers for early diagnosis will hopefully also advance the fields of surveillance after resection, and result in earlier detection and more effective management of isolated and systemic PDAC recurrence.

Survival and Late Morbidity after Resection of Pancreatic Cancer

Avinoam Nevler and Charles J. Yeo

Department of Surgery, Jefferson Pancreas, Biliary and Related Cancer Center, Thomas Jefferson University, Philadelphia, PA, USA

Introduction

Pancreatic ductal adenocarcinoma (PDA) is the third leading cause of cancer mortality in the US, and is expected to become the second leading cause of cancer-related deaths in the US by 2030 [1]. Advances have been made in the treatment and management of pancreatic cancer. Enhanced diagnostic capabilities, improvements in surgical care, and new oncologic treatment regimens have been widely adopted. These have led to a near two-fold increase in overall five-year survival rates, from 6% to 12% [1,2], over the course of the last decade. A large proportion of this increase in survival can be attributed to the improvement in outcomes for patients following surgical resection, and to adjuvant therapy, which resulted in an increase in five-year postresection survival rates to almost 40%. However, despite these advances, pancreatic cancer remains a challenging disease, characterized by marked resistance to chemotherapy and radiotherapy, underscoring the urgent need for better therapies.

In this chapter, we will review the long-term survival of patients with resected PDA, and examine the oncologic outcome data from key clinical studies in PDA cancer care. We will summarize the literature on delayed post-operative complications of pancreatic resection, looking at pooled data from pancreatic resection for malignant and benign indications.

Survival after Resection for Pancreatic Cancer

Review of key studies involving adjuvant and neoadjuvant therapy in patients with PDA reveals the profound progress that was made during the past few decades in terms of a shift in treatment paradigms. Early large randomized, controlled studies such as ESPAC-1 [3] and CONKO-001 [4] proved the beneficial value of adjuvant therapy compared with observation only. Later studies such as ESPAC-3 [5] and RTOG 9704 [6] have reported postresection median survival of 23.2 months and 20.0 months, respectively. With the utilization of multidrug combination adjuvant therapies in studies such as ESPAC-4 [7], PRODIGE-24 [8], and APACT [9], the accumulating data tend to suggest an improved survival, reaching up to a median overall survival of 54.4 months in the modified FOLFIRINOX arm of the PRODIGE-24 trial. Similarly, early results from the ESPAC-5F [10] neoadjuvant study for borderline resectable tumors show a clear improved survival with neoadjuvant therapy (42% vs 77% one-year survival), with FOLFIRINOX-based treatment yielding the best survival outcomes (87% one-year survival rates).

It is important to note, however, that interpretation of these data needs to be done with caution, as possible confounding factors include strict selection criteria for participation in the study, often excluding patients with aggressive cancers, serious comorbidities, or extreme frailty. It is also important to consider that multidrug therapy is associated with greater toxicity and a higher study dropout rate, thereby possibly enriching the group with healthier participants.

Recurrences typically occur around 13 months after resection for patients who receive adjuvant monotherapy [7], compared to around seven months for patients without therapy [4]. The results of the APACT and PRODIGE-24 studies suggest a longer disease-free period with multidrug adjuvant therapy (16.6 months and 21.6 months, respectively). Unfortunately, these positive results are primarily encountered in patients who manage to complete the full treatment protocol.

Retrospective single-institutional experiences provide real-world survival data compared to prospective clinical trials, in which study-specific selection biases may be mitigated in part. In a large, single-institution study of 1175 PDAs resected at the Johns Hopkins Hospital (JHH) over 25 years, the median survival was just 18 months; one-year, two-year, three-year, and five-year overall survival rates were 65%, 37%, 27%, and 18%, respectively [11]. More recent data published from the Moffitt Cancer Center, detailing 309 pancreatic cancer patients (2008–2015) [12], show that completion of adjuvant therapy resulted in a median survival of 28 months compared with only 14 months in patients who did not complete adjuvant therapy. Valuable real-world data can also be extracted from an analysis of Surveillance, Epidemiology and End Results (SEER) data. Shi et al. analyzed SEER data on 10 097 pancreatic cancer patients (2004–2016), showing that overall survival in patients receiving adjuvant chemotherapy was 22.0 months and very similarly, survival in patients who received adjuvant chemoradiotherapy was 23.0 months [13].

Neoadjuvant treatment of locally advanced or borderline resectable tumors prior to surgery has been shown to be an effective course of therapy over recent years. The advantages of neoadjuvant therapy include early systemic oncologic treatment, which addresses possible tumor dissemination and micrometastases at an earlier stage; potential tumor downsizing and increased resectability; and providing a functional biologic assessment of tumor response to oncologic therapy, which informs on tumor aggressiveness and helps to select out patients who would not benefit from surgical resection.

Several large randomized studies have assessed neoadjuvant and perioperative chemotherapy in pancreatic cancer. Preliminary results from the ESPAC-5F study [10], assessing neoadjuvant treatment of borderline resectable PDA, indicate that all neoadjuvant treatment arms (gemcitabine + capecitabine/FOLFIRINOX/chemoradiation) resulted in increased survival rates compared with immediate surgery (a surgery first approach). Interestingly, the data seemed to show that FOLFIRINOX neoadjuvant treatment yielded relatively higher survival rates. Data from the PREOPANC study [14], which assessed neoadjuvant gemcitabine and radiation therapy versus upfront surgery followed by gemcitabine-based adjuvant therapy for resectable and borderline tumors, show a small improvement in overall and disease-free survival, increased R0 resection rates and a significant improvement in locoregional control rates in the neoadjuvant arm. These results are concordant with previous, smaller scale studies in which neoadjuvant treatment resulted in R0 resection rates above 90% [15,16].

It is important to acknowledge potential confounding factors when interpreting data from prospective and retrospective neoadjuvant studies. A substantial portion of patients in the intent-to-treat neoadjuvant group fail to undergo resection, due to either disease progression or poor performance status. As a result, the neoadjuvant treatment paradigm enriches the study cohort (i.e., patients undergoing subsequent resection) with more favorable patients. For example, Kurahara et al. have published their results with S-1 or gemcitabine-based neoadjuvant treatment in 165 pancreatic cancer patients (2010–2014) [17]. Survival analysis of the patients who were successfully resected demonstrated a remarkable benefit of neoadjuvant therapy with median overall survival of 53.7 months, compared with just 17.8 months for upfront surgery followed by adjuvant therapy. However, an intention-to-treat analysis revealed no clear differences in overall survival.

In 2016, Christians et al. published results from their retrospective analysis of 69 patients with resectable PDA treated with neoadjuvant chemoradiotherapy from 2009 to 2013 at a single institution [18]. The reported median survival from this relatively small cohort was an impressive 44.9 months for patients who completed the neoadjuvant course and successfully recovered from pancreatic resection. However, the intention-to-treat analysis for the whole cohort was 13.5 months shorter (31.5 months), albeit still impressive. The survival of the nine patients (15%) who failed to advance to surgical resection was just 8.1 months, and on par with patients having advanced disease. Importantly, patients included in this study satisfied strict inclusion criteria of having 'resectable' PDA, which comprised a relatively favorable group compared to large institutional series of patients receiving adjuvant therapy. Similarly, in a prospective study from the Massachusetts General Hospital assessing total neoadjuvant FOLFIRINOX treatment for borderline pancreatic cancer [19], R0 resection rates were 97% among the patients taken to surgery. However, when accounting for the entire patient cohort, including patients who progressed or were found to be unresectable, the R0 resection rate decreased to 65%.

We eagerly await results from ongoing studies, such as the PANDAS-PRODIGE44 (NCT02676349) assessing neoadjuvant treatment with mFOLFIRINOX with or without concomitant chemoradiotherapy, the ALLIANCE A021806 study (NCT04340141) assessing perioperative FOLFIRINOX compared with immediate surgery and adjuvant chemotherapy, and the PREOPANC-2 study assessing total neoadjuvant FOLFIRINOX vs perioperative gemcitabine with chemoradiotherapy.

How Common are Patients Cured of PDA by Resection?

The survival rates one year following pancreatic resection for PDA are estimated to be in the 75–82% range [11,13,20]. While this suggests surgical resection may not be beneficial for some proportion of cases, there is still no question that surgical intervention provides the best opportunity for long-term survival for many patients. Data from the latest adjuvant and neoadjuvant studies that show median survival durations of over 50 months [8,17] offer hope that biological cure of patients with PDA is realistic and achievable. Several studies shed light on this question with impressive survival outcomes reported out to 10 years and beyond (Table 156.1).

Generally, past studies assessing survival after pancreatic resection for PDA report five-year survival rates around 18–20%. However, more recent studies suggest that the rates are actually closer to 30%, and in some groups up to 40%. The data also indicate that overall survival 10 years after resection is roughly half the five-year survival rate, or 10–14%. The largest study to date on this subject was published by Seppänen et al., where the authors reported on the long-term survival of 853 patients with PDA [21].

While the 10-year survival rate presents a fairly good estimate of cure rate of PDA, the actual rate of true, biological cure (i.e., the permanent lack of imaging and biochemical findings suggestive of cancer) is hard to ascertain. This is mostly because metrics such as five-year survival rate fail to account for late recurrences, which have been shown to occur even after five years following surgery [22,23]. It is also important to note that there are varying interpretations of "cure" from PDA across different stakeholders. While many clinicians use the five-year survival benchmark as a definition for cure, patients and their caretakers prefer to interpret cure as renormalization of life expectancy or the persistent lack of any biological evidence of disease [24]. Therefore, in light of these differences in definitions and viewpoints, clinicians should be mindful when discussing long-term prognosis and PDA cure rates and remember that the meaning of cure may be neither fully understood nor consistent between patients and caretakers.

Prognostic Risk Factors

Prognostic factors are key aspects to any discussion of survival, mainly due to the information they provide regarding the natural history of the disease. When possible, prognostic information can be used to guide treatment decisions. Certain prognostic features have been consistently validated in patients with PDA. However, it is important to note and discuss with patients that these factors make only a partial contribution to estimating long-term survival, and that patients with unfavorable

Table 156.1 Five- and 10-year survival rates for patient with pancreatic cancer after surgical resection.

	Study period	N	Five-year Survival	Ten-year Survival
CONKO-001 (Adjuvant Group)	1998–2004	168	20.7%	12.2%
Shimada et al. [25]	1990–2013	229	17%	10%
Kimura et al. [26]	1988–2012	149	13.40%	3.60%
Ferrone et al. [22]	1985–2006	499	19%	10%
Dusch et al. [27]	1972–2004	360	19.20%	6.10%
Schnelldorfer et al. [28]	1981–2001	357	18%	13%
Adham et al. [23]	1983–2000	30	–	30% of 5 yr survivors had ≥10 yr survival
Riall et al. [29]	1970–1999	564	17%	9%

features can achieve long survival after resection, just as patients with favorable features may suffer an unfortunate early recurrence and death.

Pathologic features that have been reproducibly found to be associated with worse long-term survival include increased tumor diameter, regional lymph node metastases (including alternative metrics of lymph node burden such as lymph node ratio) [31–37], poorly differentiated histology, positive resection margin, and perineural invasion [29,38–40]. In multivariate models, each of these features was shown to have only modest impact (with associated hazard ratios below 2.0), reflecting their weak prognostic capabilities and their limited utility for treatment-related decisions. Indeed, in a study that contrasted 137 patients with short survival (<12 months, N = 58) and long survival (>30 months, N = 79) after resection for PDA, no pathologic features proved to be significant predictors for the long-term survival group. Interestingly, 65% of the long-term survivors and 17% of the short-term survivors had regional lymph node metastases, respectively [41].

Aside from conventional pathologic features, the only other validated prognostic marker is the serum-based carbohydrate antigen (CA) 19-9. This protein is a secreted sialylated Lewis-A (sialyl Le^A) antigen that is produced in high amounts by pancreatic cancer cells. Elevated postresection levels are associated with early recurrence and worse overall survival [42–44]. In fact, an *ad hoc* analysis of patients enrolled in the RTOG 9704 adjuvant trial [6,42] revealed that a postresection CA 19-9 level >180 U/mL is associated with an adjusted hazard ratio of 3.6 (which is substantially more powerful than conventional pathologic features). This finding has also been replicated in multiple studies [43–46].

Other prognostic and predictive markers include several molecular features of tumors. *BRCA1* and *BRCA2* mutations (and associated mutations resulting in "BRCAness") are associated with improved response to platinum therapy and a sustained response to PARP inhibitor therapy [47–49]. The existence of *KRAS* mutation and its specific subtype has been shown in several studies to be an important predictor of overall survival. For example, wild-type *KRAS* status seems to confer a more favorable prognosis compared to G12D, G12C, and G12V mutants [50,51]. Furthermore, not all KRAS mutations share the same phenotype (e.g., G12R mutation is associated with PI3K pathway impairment [52]), suggesting a possible future role for mutation-specific treatment protocols.

While the clinical benefit of routine complete next-generation sequencing (NGS) of PDA tumors is still being evaluated, data from the Know Your Tumor (KYT) initiative of the Pancreatic Cancer Action Network (PanCAN) strongly suggest that identification of actionable mutations and tailored therapy based on these mutations can improve survival rates in PDA patients. In the KYT study, which assessed patients with metastatic, locally advanced or recurrent pancreatic tumors, researchers identified 189 patients with actionable mutations (i.e., mutations resulting in a unique therapeutic susceptibility). After randomization to standard care versus specific mutation-matched therapy, overall survival in the mutation-matched therapy group was substantially greater than for the control group (2.6 years, 95% confidence interval [CI] 2.4 to not reached, vs 1.5 years, 95% CI 1.3–1.9 years).

Many studies have attempted to identify molecular factors that impact long-term prognosis. However, very few molecular factors have been proven to offer greater accuracy or utility than the clinical, biochemical, and radiologic factors used today. Tatarian et al. [53] noted that cytoplasmic HuR expression was predictive of favorable response to 5-FU therapy based on data from the ESPAC-3 trial [5]. Smith et al. performed a metaanalysis of several immunohistochemical prognostic markers (P16, SMAD4, VEGF, EGFR, bax, and bcl-2) in resected pancreatic cancer patients (11 eligible studies) and found vascular endothelial growth factor (VEGF) to be the most informative prognostic marker [54]. In another multigene signature study, Chen et al. [55] described a prognostic 15-gene signature in early-stage PDA (hazard ratio 3.3) which was also validated in the Stratford cohort [56].

Currently, these findings have not been adopted into routine clinical practice and decision making. Newly emerging technologies, however, present greater hopes in terms of robustness of data, reproducibility, and external validation. A newly evolving potential biomarker is the existence of circulating tumor cells [57] and circulating cell-free tumor DNA [58]. Recent metaanalyses have shown circulating cell-free tumor DNA measurement (of high yield mutations such as KRAS [59,60]) to be a prognostic marker before and after therapy [59,61,62]. Repeated measurement of KRAS expression in circulating cell-free DNA has even been suggested to offer greater value than CA 19-9 in relation to long-term prognosis and response to therapy [63].

Long-term Morbidity

Pancreatic surgery is associated with a high rate of postoperative morbidity. Immense efforts and continuing research have gone into developing ways to minimize and mitigate these early complications (which are detailed elsewhere in this book).

Late morbidity after pancreatic surgery, however, is composed of a quite different set of complications. Naturally, since some of these complications develop as

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

very late sequelae of pancreatic or duodenopancreatic resection, most of the data available are derived from patients who have undergone resection for benign or premalignant lesions. The most common late complications that have been observed include gastrectomy-associated complications (e.g., dumping syndrome, bile reflux gastritis, marginal ulcers, bleeding, gastric remnant cancer), biliary-related complications (bile duct strictures, recurrent cholangitis, pyogenic liver abscesses), pancreas-related complications (pancreatic duct strictures, pancreatogenic diabetes mellitus, pancreatic exocrine insufficiency), nonalcoholic fatty liver disease (NAFLD), and incisional hernias.

Gastrectomy-associated Complications

A classic pancreaticoduodenectomy (a Whipple operation which includes a distal gastrectomy) may carry a risk of delayed complications typically associated with a distal gastrectomy (Table 156.2). These include afferent limb syndrome, efferent limb syndrome, bile reflux gastritis, marginal ulcers (associated with bleeding, stricture, or perforation), dumping syndrome, delayed gastric emptying (discussed elsewhere in this book), and gastric remnant cancer.

Some early studies suggested that the rates of reflux gastritis, marginal ulcers, and dumping syndrome may be lower with a pylorus-preserving pancreaticoduodenectomy compared to those with the classic pancreaticoduodenectomy [69,70]. However, other studies have shown no clear difference in the risk for marginal ulcers or bile reflux gastritis [64]. The principle etiology of late afferent limb syndrome after pancreaticoduodenectomy is tumor recurrence, followed by radiation-induced stricture [68] and routine postsurgical adhesions.

The risk of gastric remnant cancer in patients undergoing a Whipple resection for pancreatic adenocarcinoma is extremely small. A recent case series and review of the literature published by the MD Anderson Cancer Center [71] reviewed 11 patients who underwent classic pancreaticoduodenectomy and subsequently developed gastric cancer. The median time to develop gastric cancer was 111.5 months and the overall survival post diagnosis of gastric remnant cancer was 61 months. Although this complication is very rare in patients with pancreatic cancer, data extracted from large cohort studies suggest that the incidence of gastric remnant cancer after gastrectomy for benign causes such as peptic ulcer disease is around 7% [72–74] and the average latency is about 20 years [74]. Most gastric remnant cancers occur at or near the gastroenterostomy, and the cause is believed to be related to the combined reflux of bile and pancreatic secretions. While this complication has been rarely documented after a classic pancreaticoduodenectomy, the purported mechanism of pancreatobiliary reflux is nonetheless exacerbated when the pylorus is resected. The relevance of this complication is likely low with the present survival rates for PDA (roughly 5% of patients, or less, will survive to 20 years), but may become an increasingly common issue for the current generation of hepatopancreaticobiliary surgical trainees as treatments and patient outcomes improve. Data from patients undergoing gastric resections for peptic ulcer disease suggest that endoscopic surveillance should be performed in appropriately selected patients starting five years after their distal gastrectomy [72].

As a case in point, Dr James J. Mezhir (1973–2016) suffered this very fate [75]. He was an accomplished pancreatic surgeon and scientist, and in fact reported the largest series of gastric remnant cancers as a surgical oncology fellow at the Memorial Sloan Kettering Cancer Center [72]. He underwent a pancreaticoduodenectomy as a teenager for the management of non-Hodgkin lymphoma causing bile duct obstruction [75,76]. Sadly, he developed an aggressive gastric remnant cancer 25 years after the index operation, and died after a two-year battle with the disease [75].

Table 156.2 Gastrectomy-associated complications for patients post pancreatoduodenectomy.

Complication	Prevalence
Bile reflux gastritis	11–25% [64,65]
Marginal ulcer	1–9% [64–66]
Perforated ulcer	2.3% [67]
Afferent limb syndrome	13% [68]
Dumping syndrome	10% [69]

Biliary Anastomotic Strictures

Biliary strictures occur in 3–8% of patients following pancreaticoduodenectomy [77-82], with the median time to stricture formation being just over one year. The occurrence of this complication is associated with an increased risk for cholangitis and it is best managed initially, when possible, by nonoperative interventions including endoscopic or percutaneous balloon dilation and deployment of plastic or metal biliary stents [83,84]. Surgical revision is appropriate in cases where these interventions fail (approximately 5–24% of the time). Reported risk factors for biliary strictures include small bile duct diameter at the time of the index resection (<5 mm) [82], preoperative biliary stenting, preoperative radiotherapy, continuous suturing of the anastomosis, postoperative occurrence biliary fistula, and postoperative biliary stenting [77,85,86].

Pancreatic Anastomotic Strictures

Pancreatic duct strictures after pancreatic anastomosis occur in 2–7% of patients after pancreaticoduodenectomy [81,87,88]. The etiology of these strictures may be benign or neoplastic in nature (e.g., as part of a locoregional recurrence). This complication typically presents as abdominal pain in the setting of pancreatitis, and manifests within 1–4 years after the index operation [87]. Magnetic resonance cholangiopancreatography (MRCP) or computed tomography (CT) can provide visual clues to secure the diagnosis [88]. Pancreatic anastomotic strictures are best managed initially by endoscopic stenting (guided by endoscopic retrograde pancreatography [ERP] or endoscopic ultrasound [EUS]) in selected cases [89–91]. However, a definitive operative revision is at times required. Effective options include a revision of the pancreaticoenterostomy or, more commonly, a lateral pancreaticojejunostomy [88].

Pancreatogenic Diabetes Mellitus

Pancreatogenic diabetes mellitus (type 3c) refers to diabetes mellitus in which the etiologic cause was neither autoimmune nor peripheral insulin resistance, but rather damage or loss of pancreatic tissue. Notably, this form of diabetes is unique in that glucagon (α-cells), pancreatic polypeptide-producing cells, and exocrine acinar cells are also damaged or lost. The development of pancreatogenic diabetes mellitus (pDM) is dependent on many factors, most notably on pancreatic endocrine reserves in the islets of Langerhans. Greater resection volume, history of chronic pancreatitis, and hyperlipidemia appear to be important risk factors for the development of new-onset pDM after pancreatic resection [92,93]. Furthermore, the density of pancreatic β-cells in the islets increases from the pancreatic head towards the pancreatic tail [94,95], which underscores why distal (left-sided) resection is often associated with a greater impact on the pancreatic endocrine reserve. These notions are supported by clinical evidence which indicates that distal pancreatectomy is associated with greater rates of new-onset pDM [92,93,96–98].

Diabetes mellitus and PDA have a close "reverse causality" relationship [99]. While diabetes mellitus has been associated with increased risk for pancreatic cancer, PDA has also been associated with inciting new-onset diabetes mellitus both through pancreatic tissue destruction (type IIIc), as well as through a paraneoplastic phenomenon that results in the inhibition of insulin secretion and the exacerbation of peripheral insulin resistance [100] (type II-like DM).

Table 156.3 shows the reported prevalence of new-onset pDM after pancreatectomy across multiple studies. Exacerbation of existing diabetes is also observed in a large proportion of these patients. Paradoxically, resection of the pancreatic tumor occasionally leads to resolution of DM in a small number of patients (although the etiology is unclear, this may be related to the nearly universal weight loss of 10–15% after pancreatectomy) [101,102]. As the development of DM is very common following pancreatic resection, it is important to discuss it with patients prior to surgery and offer specific guidance and education.

Table 156.3 Prevalence of pancreatogenic diabetes mellitus after pancreatectomy.

	N	Pancreaticoduodenectomy	Distal pancreatectomy
Burkhart et al. [103]	267	New onset: 18% (N = 135) Exacerbation of DM: 48% (N = 44)	New onset: 31% (N = 55) Exacerbation of DM: 26% (N = 23)
Hirata et al. [104]	167	New onset: 22% (N = 58) Exacerbation of DM: 57% (N = 42)	New onset: 27% (N = 33) Exacerbation of DM: 77% (N = 34)
Wu et al. [101]	3914	New onset: 16% (N = 3914)	
Fang et al. [105]	42	New onset: 12% (N = 42)	
White et al. [106]	100	New onset: 11% (N = 79)	New onset: 9.5% (N = 21)
DiNorcia et al. [93]	49		New onset: 37% (N = 38) Exacerbation of DM: 82% (N = 11)
Wu et al. [92]	1410 without DM 570 with DM		New onset: 22% (N = 310) Exacerbation of DM: 60% (N = 173)
Kang et al. [107]	101		New onset: 25% (N = 25)

Percentage of patients with pancreatogenic diabetes mellitus (total study population size in parenthesis).
DM, diabetes mellitus.

Pancreatic Exocrine Insufficiency

Pancreatic exocrine insufficiency (PEI) has been described as an immediate and long-term complication of pancreatic resection. Though described after any pancreatic resection, exocrine insufficiency is more frequently encountered after pancreaticoduodenectomy [96]. PEI occurs in roughly 30–70% [67,105,108–110] of patients undergoing pancreaticoduodenectomy.

The main mechanism is parenchymal loss of exocrine cells, which is similar to the mechanism of pDM, and in fact, exocrine insufficiency is one of the major criteria used to make the diagnosis of type IIIc DM [99]. Additionally, PEI can occur from failure of pancreatic enzymes to reach the jejunum. Symptoms may include abdominal distention; abdominal pain; pasty, floating and foul-smelling stools; and fat-soluble vitamin deficiency (vitamins A, D, E, and K).

Reported risk factors for postpancreaticoduodenectomy exocrine insufficiency include preoperative pancreatic endocrine impairment, history of chronic pancreatitis, preoperative decreased pancreatic parenchymal thickness, hard gland texture, postoperative imaging showing decreased pancreatic parenchymal thickness and postoperative dilation of the main pancreatic duct [109–112]. The type of pancreatic anastomosis performed has also been suggested in several studies to contribute to PEI occurrence, with pancreaticogastrostomy more commonly associated with PEI than pancreaticojejunostomy [113,114]. However, these findings were not reproduced in the RECOPANC study at 12 months follow-up (though the PEI endpoints were only assessed by questionnaire) [115]. A summary of reported rates and risk factors of pancreatic exocrine insufficiency is provided in Table 156.4. This complication, although not fatal or debilitating, is associated with a significant reduction in quality of life [116].

The treatment of PEI consists of oral pancreatic enzyme replacement with meals. Recommended doses are in the range of 18 000 to 30 000 USP units of lipase per meal. Of note, gastric pH should be maintained above 4.0 to prevent enzyme inactivation by acid [117].

Nonalcoholic Fatty Liver Disease

Increased hepatic fat deposition is a newly reported complication after pancreaticoduodenectomy [118]. In some cases, it can progress to nonalcoholic fatty liver disease (NAFLD). NAFLD attributable to pancreaticoduodenectomy is defined as hepatic steatosis (proven by imaging or histology) without other causes for secondary hepatic fat accumulation, such as significant alcohol intake, steatogenic medications or genetic disorders [119]. As this chronic condition progresses, the functional reserve of the liver diminishes and hepatic insufficiency may ensue [120]. This may assume increased relevance in patients with PDA who receive chemotherapy, which itself carries an independent risk of hepatotoxicity [121,122].

The prevalence of postpancreaticoduodenectomy NAFLD has been estimated at 8–40% [13–126], although the exact mechanism of this complication remains unknown. Sato et al. evaluated postoperative imaging studies in 110 patients who underwent a pancreaticoduodenectomy over a six-month period, and observed that decreased pancreatic volume was associated with NAFLD [125]. Tanaka et al. studied the physical and biochemical profiles in patients with NAFLD after pancreaticoduodenectomy [126]. They noted that unlike patients with conventional nonalcoholic steatohepatitis

Table 156.4 Prevalence of postpancreatectomy pancreatic exocrine insufficiency.

	N	PPPD-PG	PPPD-PJ	Risk factors identified
Lemaire et al. [112]	19	16/17 (94%)		Decreased postoperative pancreatic parenchymal thickness, postoperative dilation of the main pancreatic duct
Rault et al. [113]	33	12/23 (52%)	8/10 (80)%	Type of pancreatic reconstruction (PEI in PG more than PJ)
Fang et al. [105]	42	12/19 (63%)	10/23 (43%)	
Nakamura et al. [109]	61	38/61 (62%)		Preoperative endocrine impairment, hard gland texture, postoperative dilation of the main pancreatic duct
Nakamura et al. [111]	52	34/52 (65%)		Decreased pancreatic parenchymal thickness (preoperative and postoperative)
Hirono et al. [110]	199	59/90 (66%)	38/99 (38%)	Type of pancreatic reconstruction (PEI in PJ > PG), hard gland texture
Roeyen et al. [114]	186	51/68 (75%)	54/118 (46%)	Type of pancreatic reconstruction (PEI in PG more than PJ)

PPPD, pylorus-preserving pancreaticoduodenectomy; PEI, pancreatic exocrine insufficiency; PG, pancreaticogastrostomy; PJ, pancreaticojejunostomy.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. (NASH), patients with postpancreaticoduodenectomy, *de novo* NASH demonstrated significant decreases in body mass index and lower levels of serum albumin, cholesterol, and apolipoprotein B, and were noted to have decreased insulin resistance [127]. Since these findings are consistent with PEI, an increased dosage of oral pancreatic enzyme supplements was evaluated as a possible therapy, and the intervention indeed reversed these metabolic derangements in albumin, cholesterol, and lipoprotein levels in a number of patients. Additionally, treatment with increased oral dosing of pancreatic enzyme supplements improved the liver steatosis upon follow-up imaging.

These findings were reproduced by Nagai et al. in a separate study which prospectively treated 30 patients who developed NAFLD post pancreatic resection [128]. Treatment with oral pancreatic enzyme supplements resulted in improvement of liver function, near normalization of NAFLD imaging metrics, and laboratory improvement of total protein, albumin, and total cholesterol levels. Therefore, it may be advisable to initiate or augment oral pancreatic enzyme supplementation in patients with postpancreaticoduodenectomy NAFLD.

Future studies are needed to determine if enzyme supplementation should be recommended indefinitely in all patients (or in those at highest risk) in order to prevent this complication in the long term.

Incisional hernia

Available literature regarding the incidence of incisional hernia post pancreatic surgery is scarce, yet in our experience, the complication is not uncommonly encountered after open pancreatic surgery. In a recently published single-institution analysis of 678 long-term survivors after pancreaticoduodenectomy, the incisional hernia rate was reported to be 17.7% [79]. Similarly, a series of 205 pancreatic resection patients were reported to have an incisional hernia rate of 11.6% [129]. Risk factors for incisional hernia after abdominal surgery include obesity, history of smoking, previous abdominal surgery, and postoperative wound complications [130–132]. The incisional hernia rate following pancreatic resection is expected to improve when minimally invasive approaches like laparoscopic or robotic surgery are utilized [133,134].

Cholangitis and Pyogenic Liver Abscess

Biliary–enteric anastomoses result in chronic colonization of the biliary tract with enteric flora (bactibilia) due to the absence of the sphincter of Oddi. Though this bactibilia is generally of no clinical consequence because of continuous biliary drainage and decompression, there is a reported risk of cholangitis of 8–10% in the setting of biliary–enteric anastomosis [79,135]. Cholangitis, as well as colonized bile ducts, place patients with infarcted, injured, or necrotic liver parenchyma at risk for pyogenic liver abscesses. This can occur due to liver infarction from a retractor injury at the time of pancreaticoduodenectomy, or as a result of parenchymal injury related to liver-directed therapies used to treat hepatic metastases, such as hepatic arterial embolization or ablative procedures. Of note, these therapies are rarely performed for patients with conventional PDA at this time, and are more relevant for patients with metastatic neuroendocrine carcinoma.

In a large study from the Memorial Sloan Kettering Cancer Center, the liver abscess rate in patients undergoing hepatic arterial embolization was 33% for patients with prior biliary–enteric anastomosis, but just 0.05% in other patients [136]. The risk of a liver abscess with any liver directed therapy after pancreaticoduodenectomy was observed to be around 10% in a separate large multi-institution study (137). Patients found to have zones of infarct identified after pancreaticoduodenectomy, either from retractor injury or accessory hepatic arterial ligation, should be vigilantly monitored for potentially life-threatening liver abscesses that can develop with immunosuppression related to adjuvant chemotherapy. Extra caution is necessary for patients who developed liver abscesses in the early postoperative period. Most liver abscesses can be managed effectively with antibiotics and percutaneous drainage if diagnosed in a timely manner.

Conclusion

Long-term survival following pancreatic resection for cancer has slowly improved over the recent decade. However, this progress is most notable in patients with early-stage cancer, amenable to surgical resection that can also complete some form of chemotherapy. The possibility of tumor recurrence persists, even after many years. New treatments with multidrug combination regimens offer improved long-term survival. As more patients experience longer survival, the above-mentioned late complications will become increasingly important. Pancreatic surgeons should be mindful of the rates and risks of each of these complications and discuss them with their patients. Future studies aimed at reducing these risks are needed.

Periampullary Tumors: Clinical Presentation and Diagnostic Strategies

Jon M. Harrison and Keith D. Lillemoe

Department of GI and General Surgery, Massachusetts General Hospital, Harvard Medical School, Boston, MD, USA

Introduction

Periampullary tumors include several benign and malignant pathologies arising in proximity to or directly from the ampulla of Vater. Named for its bulbous appearance, the ampulla of Vater is 1–8 mm in length and originates at the confluence of the pancreatic duct of Wirsung and common bile duct before emptying into the second portion of the duodenum at the level of the major papilla [1,2]. The mechanism through which digestive fluids are secreted from the major papilla is regulated by the sphincter of Oddi, a muscular apparatus surrounding the ampulla. Importantly, substantial anatomic variability of these structures does exist and should be considered when evaluating pathology in this anatomic region [1].

Periampullary lesions comprise an important subset of hepatobiliary neoplasms, which often require pancreatoduodenectomy for treatment. From several large pancreatoduodenectomy series, the proximal pancreatic head represented the majority of periampullary tumors (56–66%) followed by the ampulla (16–25%). The distal common bile duct (12–15%) and duodenum (4–6%) were seen at lower frequency in resected specimens (Table 157.1) [3,4]. Relative to pancreatic ductal adenocarcinoma, nonpancreatic periampullary tumors tend to have more favorable prognosis, which is in part due to earlier detection and lower rates of nodal, perineural, and microvascular involvement [5,6].

Notably, ampullary adenocarcinoma has two dominant histologic subtypes: the more common intestinal and the more aggressive pancreatobiliary [7,8]. Important biohistochemical markers of the intestinal type include CDX2 and COX2 and cytokeratins (CK7 and C17) in pancreatobiliary tumors. Mucins (MUC1 and MUC2) are variably expressed in both histologic variants [9].

Inherited Syndromes

Inherited syndromes such as familial adenomatous polyposis syndrome (FAP), Gardner syndrome, Peutz–Jeghers disease, hereditary nonpolyposis colon cancer (HNPCC, formerly Lynch syndrome), and *MUTYH*-associated polyposis (MAP) are associated periampullary adenomas, which importantly can undergo malignant transformation. Periampullary adenocarcinoma is therefore a leading cause of morbidity and mortality in patients with these hereditary conditions [10–12]. Some common mutations and the rates of periampullary malignancy associated with each syndrome are listed in Table 157.2 [13,14]. Notably, only 33–37% of duodenal and ampullary adenocarcinomas harbor a *KRAS* mutation [15].

Upper endoscopic screening begins at a young age for patients with these hereditary syndromes. To prevent the risk of malignant transformation, duodenal and ampullary adenomas are removed if endoscopically feasible (Fig. 157.1) [16]. Larger, sessile, ulcerated, and dysplastic lesions, however, are surgically resected by way of ampullectomy, sleeve/segmental duodenectomy, or pancreatoduodenectomy [17,18].

In addition to the more common polyposis syndromes, patients with neurofibromatosis 1 (NF1) can develop small periampullary somatostatinomas, carcinoids, neural tumors, and GI stromal tumors (GISTs), which are less aggressive and more amenable to local resection than periampullary cancers [19].

Lastly, it is critical to rule out benign causes of obstructive jaundice such as choledocholithiasis, choledochocele, and pancreatic duct stricture from paraduodenal (groove) or autoimmune pancreatitis when evaluating patients for suspected periampullary neoplasms [20,21].

Table 157.1 Location and relative frequency of periampullary tumors.

Location	Relative frequency
Pancreatic head	60%
Ampulla of Vater	20%
Distal common bile duct	15%
Duodenum	5%

Table 157.2 Hereditary syndromes associated with periampullary neoplasms.

Hereditary syndrome	Gene mutation	Lifetime risk of periampullary malignancy
FAP and Gardner	*APC* (tumor suppressor)	12%
Peutz–Jeghers	*STK11* (tumor suppressor)	13%
HNPCC	*MLH1, MSH2* (DNA mismatch repair)	6%
MAP	*MUTYH* (DNA repair)	5%

HNPCC, hereditary nonpolyposis colon cancer; MAP, *MUTYH*-associated polyposis.

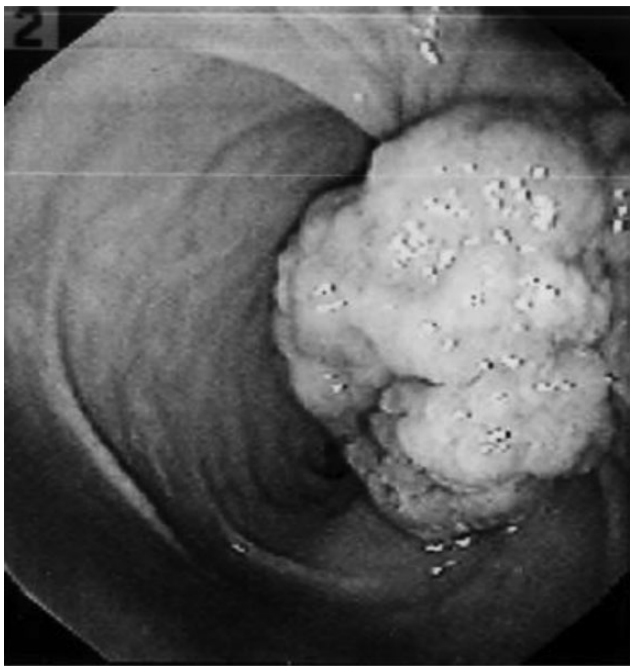

Figure 157.1 Endoscopic view of a periampullary villous adenoma.

Clinical Features

More than two-thirds of patients with periampullary tumors present with painless jaundice and its sequelae, including pruritus, dark urine, and acholic stools [22]. Other clinical findings such as upper gastrointestinal tract bleeding, epigastric pain, early satiety, and gastric outlet obstruction may also be present [23]. Although less common, pancreatitis and steatorrhea from pancreatic insufficiency can lead to fat-soluble vitamin deficiencies and coagulopathy [24,25]. In addition to the stigmata of a jaundice seen on physical exam, Courvoisier's sign and hepatomegaly can also be appreciated.

Laboratory Work-up

Laboratory studies including liver function tests are likely to reveal a hyperbilirubinemia, elevated alkaline phosphatase, and possibly a transaminitis. For patients with hematemesis or melena, anemia may also be present. Prolonged prothrombin time (PT)/international normalized ratio (INR) is another important lab abnormality that may be seen in patients with long-standing biliary obstruction.

Tumor markers including carbohydrate antigen (CA) 19-9 and carcinoembryonic antigen (CEA) can also aid in the diagnosis and management of periampullary neoplasms. In one large study comparing tumor markers in patients with periampullary tumors, higher CA 19-9 levels correlated with larger tumor size and positive lymph node status. In addition, patients with CA 19-9 levels above 26.6 U/mL had a decreased overall survival (25 months vs 56 months, $P = 0.003$) [26]. Similarly, CEA levels greater than 4.6 ng/mL were associated with decreased overall survival, although this was not statistically significant (25 months vs 43 months, $P = 0.077$). Another study investigating tumor markers in cases of resectable or unresectable periampullary cancer found CA 19-9 to be more sensitive for detecting tumors and predicting unresectable disease than CEA [27]. A final study evaluating tumor markers in ampullary cancers showed that elevated levels of CA 19-9 and CEA were predictive of decreased overall survival in both the intestinal and pancreatobiliary histologic subtypes, but a normal CEA level in intestinal-subtype ampullary cancers had improved survival [28].

It is important to note, however, that biliary obstruction may also produce an elevated CA 19-9 level, and this must be considered during the evaluation of patients with obstructive jaundice [29].

Diagnostic Modalities

Common diagnostic strategies in the work-up of periampullary tumors include axial imaging and endoscopy. Transabdominal ultrasonography is useful for ruling out cholelithiasis and identifying common bile duct dilation but only has an accuracy of 15% for diagnosing periampullary tumors [30]. By contrast, dual-phase (arterial and venous), thin-cut computed tomography (CT) scan of the abdomen and pelvis or magnetic resonance cholangiopancreatography (MRCP) are more accurate studies for detecting periampullary lesions and have the added benefits of assessing vascular abutment/involvement as well as detecting ascites and metastatic foci (>1 cm) to the liver, omentum, or peritoneum (Fig. 157.2) [31–36].

When determining which imaging modality to utilize, clinicians must be mindful of cost, institutional availability and experience, and the potential for contrast reactions and acute kidney injury.

On imaging, characteristic findings for periampullary tumors include a filling defect at the level of the major papilla and the classic "double-duct" sign, a radiographic feature found in over half of periampullary tumors in which the main pancreatic and common bile duct are

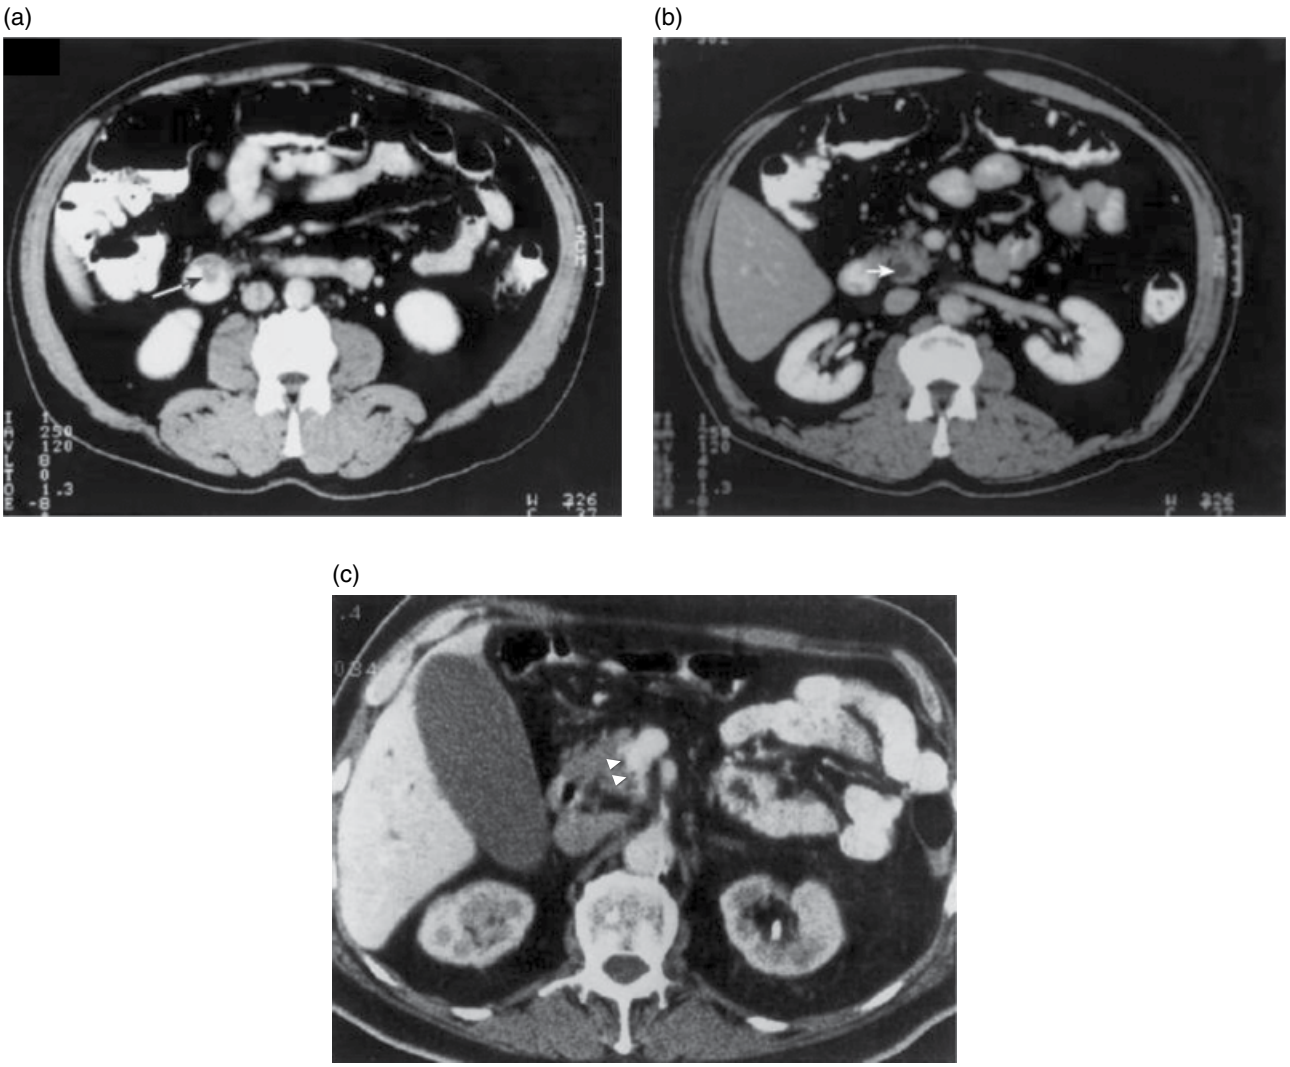

Figure 157.2 CT demonstrating an ampullary carcinoma causing obstructive jaundice. (a) Radiographic appearance of a small ampullary mass. (b) Appearance of distal common bile duct dilation caused by an ampullary lesion. (c) Superior mesenteric vein involvement in addition to abnormal enhancement of the medial border of the head and uncinate process of the pancreas.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. dilated [20,37]. By contrast, isolated common bile duct dilation with an "apple core" appearance may be seen in distal cholangiocarcinoma, whereas a dilated main pancreatic duct with abrupt caliber change is more suggestive of a pancreatic lesion. Note that intrapancreatic lesions can also cause extrinsic compression of the common bile duct and subsequent dilation.

Endoscopic techniques including endoscopic ultrasound (EUS) and endoscopic retrograde cholangiopancreatography (ERCP) are other adjuncts used in the work-up of periampullary tumors. EUS is an effective modality for determining tumor (T) and nodal (N) stages as well as vascular invasion in small periampullary lesions [38–42]. Furthermore, tissue sampling either through direct biopsy of mucosal lesions or fine needle aspiration can be performed with this endoscopic technique (Fig. 157.3) [36,43]. EUS findings can also influence clinical management. Specifically, adenomas or mucosal-based (T1) lesions may be candidates for endoscopic or surgical ampullectomy whereas higher tumor stage or tumors with positive lymph nodes should be considered for pancreatoduodenectomy [44–46]. EUS is also valuable for obtaining a tissue diagnosis of cancer prior to initiating neoadjuvant treatment in cases of borderline resectable or locally advanced disease. Importantly, rates of false-negative endoscopic biopsies can be found in up to 25% of patients, and extirpation should be considered to rule out malignancy in an otherwise benign lesion [47,48].

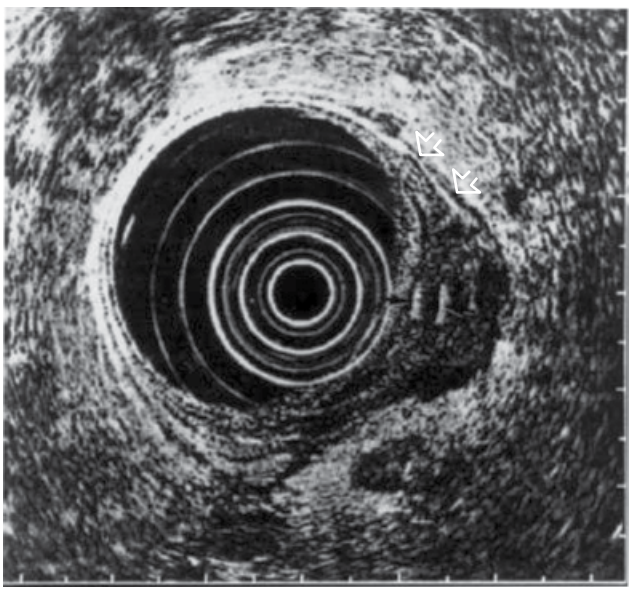

Figure 157.3 EUS of an ampullary tumor, represented by the hypoechoic region on the right. An endoprosthesis (small black arrows) is seen running through the tumor, which infiltrates beyond the muscularis propria (open arrows) and into the pancreas.

Like EUS, ERCP is another endoscopic tool used in the management of periampullary neoplasms. Unlike EUS, however, ERCP allows for characterization of biliary tree anatomy and therapeutic decompression in patients with long-standing biliary obstruction or planned neoadjuvant therapy (Fig. 157.4). ERCP can also be used to perform biopsy or brushings of suspicious or indeterminate biliary strictures. While valuable, surgeons must use ERCP selectively given the increased risk of infectious complications following biliary stenting in addition to the periprocedural risks of pancreatitis, perforation, or hemorrhage, all of which may delay operative intervention or increase operative case complexity [49–51].

In the last decade, another endoscopic adjunct, SpyGlass^{TM} direct visualization cholangioscopy, has been developed and used in the diagnosis of periampullary neoplasms and cholangiocarcinoma. Two studies examined the utility of this emerging technology and found it to be both safe and more efficacious in diagnosing indeterminate biliary strictures compared to conventional ERCP or EUS [52,53]. Additionally, SpyGlass can be used to treat benign biliary pathologies including choledocholithiasis by way of either stone extraction or lithotripsy.

Diagnostic Laparoscopy

While diagnostic laparoscopy has been used in the past for ruling out occult metastatic disease in patients with periampullary tumors, it is less commonly used in contemporary practice [54,55]. Specifically, two studies evaluated the added benefit of laparoscopy for patients with upfront resectable nonpancreatic periampullary lesions but only identified surreptitious metastases in 10% of patients [54,56].

As such, a cost-effective work-up for most patients with a suspected periampullary tumor includes liver function tests, blood counts, serum chemistries, coagulation studies, tumor markers, a dual-phase CT or MRCP, and EUS or ECRP, if tissue diagnosis or biliary stenting is indicated.

Conclusion

In summary, periampullary tumors consist of malignant lesions arising from the head of the pancreas, ampulla of Vater, distal common bile duct, and duodenum. Presenting symptoms include painless jaundice and, in rarer instances, bleeding, gastric outlet obstruction, pancreatitis, and nutritional deficiencies. Further characterization with axial imaging and endoscopic techniques is important for ruling out benign etiologies, establishing

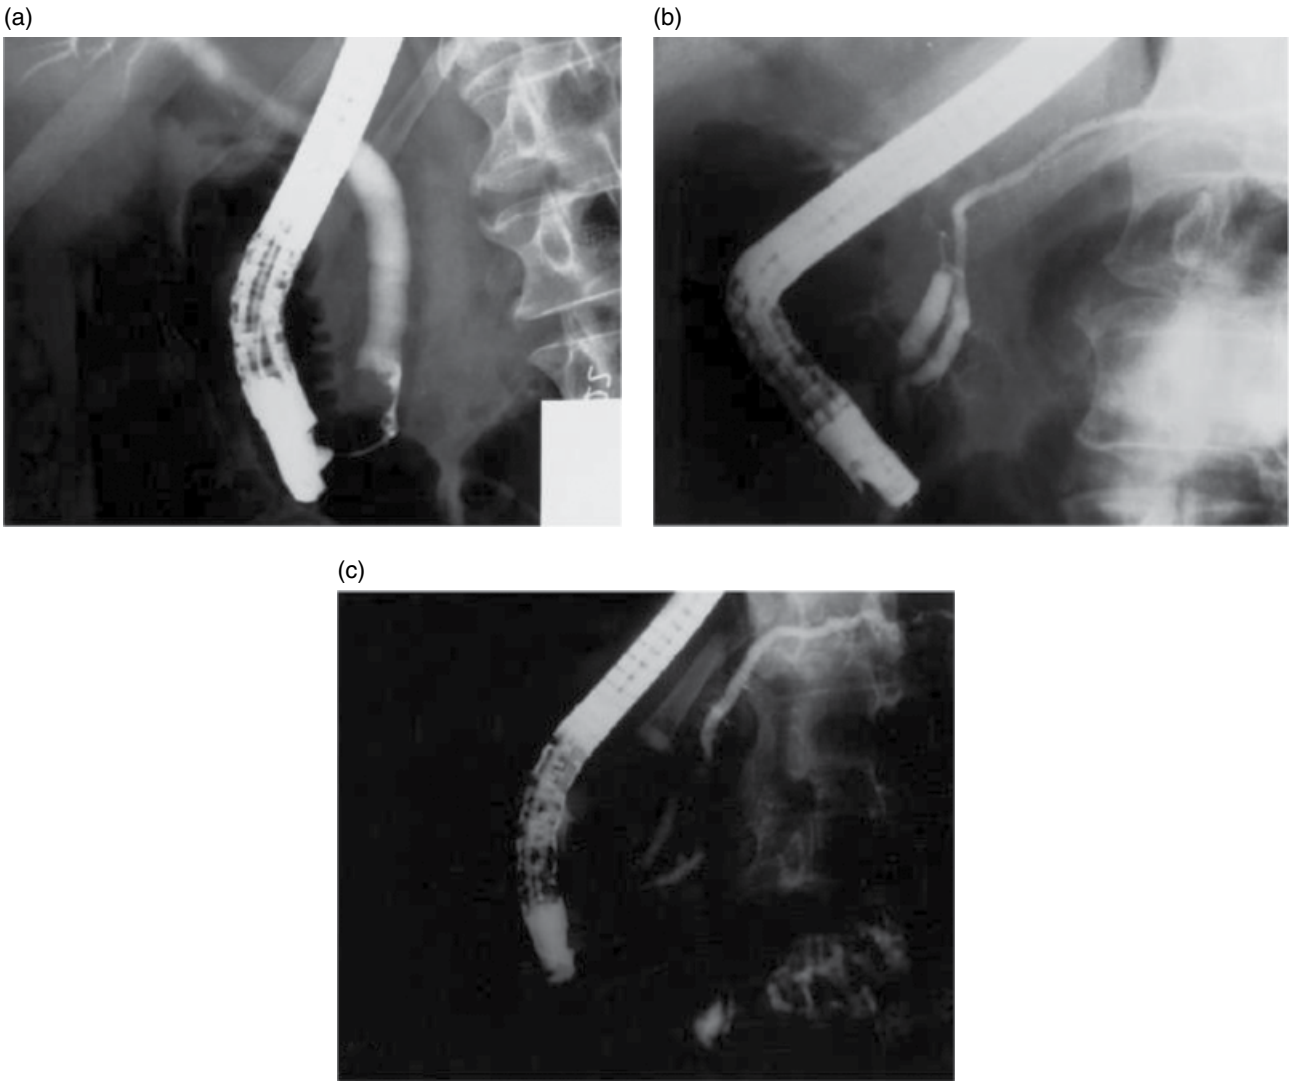

Figure 157.4 ERCP images of three periampullary lesions. (a) A periampullary carcinoma causing obstruction of the distal common bile duct. (b) A distal common bile duct carcinoma with dilated common bile duct and normal-appearing main pancreatic duct. (c) A pancreatic carcinoma, with partial obstruction of the main pancreatic and common bile duct causing a "double-duct" sign.

tissue diagnosis in the setting of preoperative therapy, and providing therapeutic interventions such as biliary stenting. These modalities can also influence clinical decision making and inform providers on whether to pursue a radical or more limited resection of the periampullary lesion.

Histology and Genetics of Cancer of the Papilla, Distal Common Bile Duct, and Duodenum

Carcinoma of Papilla (Ampulla of Vater)

The ampulla of Vater is a complex anatomic and histologic structure. Histologically, it consists of four compartments featuring transitional-type epithelia.

- The distal common bile duct (CBD) and pancreatic duct are lined by pancreatobiliary-type epithelium, a simple mucinous epithelium.
- The mucosa of the papilla of Vater (the duodenal protuberance surrounding the ampullary orifice) is covered by a specialized epithelium with features that resemble gastric-foveolar epithelium with scattered goblet cells.
- The duodenal surface of the papilla is virtually identical to the duodenal mucosa elsewhere.
- On the wall of the ampulla is the Oddi musculature within which are pancreatobiliary-type ductules lying individually and in clusters.

These different compartments not only have distinct histologic and functional properties but also their own chemical milieu which makes this small region highly complex and challenging. Thus, it is not surprising that there are vastly different impressions regarding the characteristics of the cancers of this region. Recently, careful analysis of tumors of this area processed with more standardized grossing protocols [1,2] has led to refined classification and elucidated the specific characteristics of tumors arising from different compartments [3–5].

Preinvasive Neoplasms

A significant proportion of the ampullary cancers (estimated at more than a third) arise from adenomatous lesions, i.e., preinvasive mass-forming neoplasia, which are also called tumoral intraepithelial neoplasms [6–9]. By location, these can be regarded in two groups.

- Those arising from the ampullary duodenal surface and thus presenting as obvious mass lesions endoscopically in the ampullary region, appearing as polypoid masses or ulcero-vegetating lesions in the duodenal lumen; almost all of these prove to be intestinal-type adenomas.
- Some arise within the ampullary channel and are termed intraampullary papillary-tubular neoplasm, which are essentially intraampullary counterparts of pancreatic intraductal papillary mucinous neoplasms (IPMNs), and while some are very similar to intestinal-type adenomas, many are hybrid type or pancreatobiliary or gastric lineage [6].

Adenomas of the Ampullary Duodenum

Adenomas with all the characteristics of colonic adenomas also arise from the duodenal surface of the ampulla. They can be sporadic or associated with familial adenomatous polyposis (FAP) syndrome. In fact, the ampulla is a common extracolonic site to be involved by FAP [10–14].

Adenomas of the ampullary duodenum are more likely to harbor an invasive carcinoma than similarly sized colorectal adenomas. Invasive carcinomas that arise in

adenomas are often hidden in the deep creases of the tumor at the base of the polyp and are difficult to detect in surface biopsies. Microscopically, adenomas of the ampullary duodenum are similar to those that occur in the large intestine but present some challenges in their diagnosis at the pathologic level. For example, reactive changes can mimic adenomas closely [7,8]. More importantly, an underlying invasive carcinoma of the pancreas or bile duct involves the ampullary epithelium by colonization ("cancerization") of the mucosal basement membrane, which simulates *in situ* disease [15,16].

Intraampullary Papillary-Tubular Neoplasms

Intraampullary papillary-tubular neoplasms (IAPNs) are adenomatous (tumoral intraepithelial) lesions that occur almost exclusively within the ampulla [6,17]. They represent the intraampullary counterpart of intraductal neoplasms of the pancreas and biliary tract. Papillary or polypoid tumors can fill the ampullary channel and distal segment of the common bile duct or main pancreatic duct. By definition, involvement of the ampullary duodenum and intramucosal extension into the proximal aspect of the common bile duct and main pancreatic duct is minimal (<25%) [6,9]. The mean age of affected patients is 64 years, with male predominance [6,9].

Gross examination of the ampullary duodenum (the view from the luminal aspect of the duodenum) typically reveals a hemispheric elevation of intact mucosa, often with a patulous papilla orifice from which nodules of friable granular material protrude into the duodenal lumen [1]. Ulceration may be evident, but overt mucinous discharge, characteristic of pancreatic intraductal neoplasms, is seldom encountered. On sectioning the ampullary wall, the tumors are characterized by a prominent exophytic growth pattern in the dilated distal bile duct and pancreatic duct.

Microscopically, IAPNs show various degrees of papillary or tubular growth (Fig. 158.1). Most have a mixture of these patterns. They exhibit a spectrum of dysplasia, and most cases show a mixture of low-grade (the criteria are the same as those used for adenomas of ampullary duodenum) and high-grade dysplasia which is defined as substantial cytologic atypia and architectural complexity. Unlike adenomas of the ampullary duodenum, approximately 50% of IAPNs show mixed (intestinal, gastric, pancreatobiliary) differentiation [6]. Approximately 75% of IAPNs are associated with invasive carcinoma at the time of diagnosis, but the invasive component is usually less than 1 cm in diameter [6]. Invasion is mostly tubular and often shows a mixture of intestinal and gastropancreatobiliary features. These tumors are easily missed and since the invasive carcinoma is often small, proper sampling and examination become crucial. This also pertains to ampullectomy for these cases.

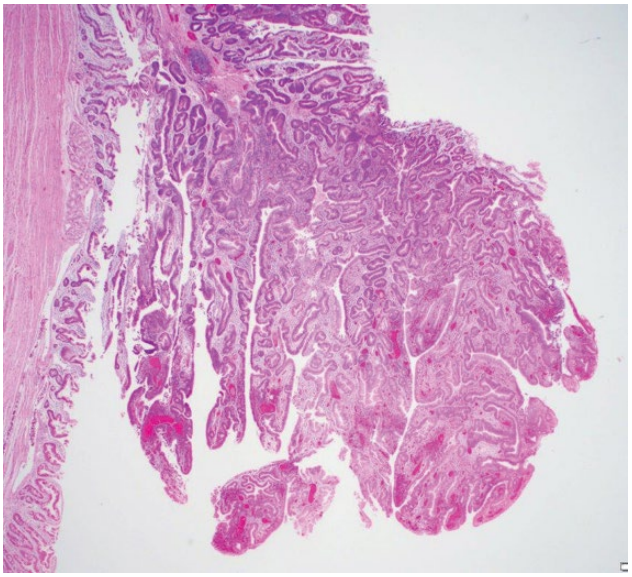

Figure 158.1 Intraampullary papillary tubular neoplasm (IAPN). (a) Grossly, an exophytic mass is located in the dilated distal bile duct and pancreatic duct. (b) Microscopically, IAPNs show various degrees of papillary or tubular growth.

It should be noted here that, because of the complexity of this site, it becomes very difficult to distinguish histopathologically true invasive carcinoma from adenomatous (preinvasive) cells pagetoidly extending into complex glandular units in a pseudoinvasive pattern.

The hybrid cellular nature of these lesions is also reflected in their immunophenotype. More than 50% of cases coexpress CK7 and CK20 [6]. Immunostaining for MUC2 and CDX2 is positive in cases with intestinal differentiation; immunostaining for MUC1, MUC5AC, and MUC6 is positive in cases with gastropancreatobiliary differentiation. However, overlaps are very common, and a significant proportion of the cases reveal mixed immunophenotype [6].

Noninvasive cases have an excellent prognosis. However, cases with extensive high-grade dysplasia can recur and this recurrence can be seen many years after resection [6]. Therefore, long-term follow-up is warranted, even in noninvasive cases. Cases with invasive carcinoma are associated with better survival than conventional (invasive) ampullary carcinomas unaccompanied by an IAPN (three-year survival of 69% versus 44%) [6]. This survival advantage is likely attributable to early detection of invasion but also reflects differences in tumor biology [3,18].

Invasive Adenocarcinomas

Until recently, the definition of ampullary cancer lacked uniformity, which has led to the vastly different impressions expressed regarding their characteristics. Many of

the studies on the topic have been presented to the literature under the heading of "periampullary cancers" and seemed to have included, on one hand, cases that are noninvasive carcinomas (adenomatous lesions with carcinoma *in situ* [CIS]), and on the other, tumors that arise in neighboring sites including the pancreas and secondarily invading the ampulla. Nonstandardized and limited pathologic evaluation seems to have been the biggest contributor to this variation. Recent refined definitions were provided and have been adopted by the College of American Pathologists (CAP) and American Joint Committee on Cancer (AJCC) [19,20], which currently serve as the main guide for the documentation of ampullary tumors in the United States. Accordingly, four categories are recognized in the section of "ampulla of Vater" cancers and their corresponding clinicopathologic characteristics are as follows [21].

- Ampullary-duodenum cancers arise from the duodenum-facing surface of the ampulla that is lined by intestinal epithelium normally, and typically form bulky ulcero-vegetating lesions readily observed in the duodenal lumen, in which the ampullary orifice is often eccentrically located (Fig. 158.2a). They typically have a prominent adenoma component and their invasive component is most commonly intestinal or mixed mucinous-intestinal phenotype. Although they are usually very large (>4 cm) and produce lymph node metastases (~60%), their behavior is often significantly better than expected.
- Intraampullary papillary-tubular neoplasm-associated carcinomas are characterized by preinvasive nodules located within the ampullary channel (i.e., distal portions of the common bile duct and main pancreatic duct). These can be viewed as an ampullary counterpart of IPMN/ITPN-associated invasive carcinomas. Because by definition they are predominantly intraampullary, these tumors are less impressive from the duodenal perspective; they show a dilated orifice, from which granular material may protrude into the lumen of the bowel. Upon sectioning the ampullary wall, the main bulk of the tumor is elucidated and typically reveals light tan, friable nodules (Fig. 158.2b). Probes placed into the common bile duct and pancreatic duct typically exit into the center of the lesion. They are by default rich in adenomatous components and microscopic examination often reveals only a small invasive carcinoma, and thus, not surprisingly, the prognosis is relatively good (median survival of >10 years), especially if invasion is limited.
- Ampullary duct carcinoma is the other category that can be regarded as an "intraampullary" tumor but they are biologically very different from the intraampullary papillary-tubular neoplasm-associated carcinomas discussed above. In essence, they are the intraampullary counterpart of pacreatic ductal adenocarcinomas (PDACs) and distal common bile duct carcinomas (DCBCs). Ampullary ductal cancers by default do not have a significant adenomatous (preinvasive neoplasm) component, and instead form circumferential scirrhous lesions that constrict the distal end of the common bile duct and pancreatic duct, with preservation (or minimal alteration) of the papilla of Vater and ampullary duodenal mucosa. Therefore, from the duodenal perspective, these tumors are fairly underwhelming, and typically show a button-like elevation of mucosa or a small, subtle ulcerating lesion (Fig. 158.2c) such that endoscopists are not sure if there is a lesion. If proper dissection approaches are not employed, ampullary-ductal carcinomas can easily be missed because they are small and subtle. Microscopically, they often prove to be pancreatobiliary-type carcinomas. Although these tumors are usually less than 2 cm in diameter, they have a high rate of lymph node metastasis (57%) and an aggressive behavior (median, 38 months), the worst among the ampullary carcinoma subtypes but nevertheless significantly better than PDACs.
- Ampullary carcinomas not otherwise specified (ampullary-NOS) include two subsets of tumors. The first is presumed to arise from the papilla of Vater (i.e., the edge of mucosa where the CBD and main pancreatic duct merge into the duodenal mucosa) (Fig. 158.2d) and thus does not qualify for one of the three categories discussed above. The second is those that cannot be confidently placed into one of the above categories because of inadequate processing. In our archival database, this group constituted >50% of the cases, but with improved grossing and classification, currently <10% are placed into this category.

Microscopically, ampullary adenocarcinomas are highly versatile in their morphologic appearance, demonstrating various types, as opposed to pancreatic and DBD carcinomas, the vast majority of which are pancreatobiliary type. Most ACs are tubular type, characterized by glandular arrangement. Some are intestinal-type tumors that are similar to conventional colonic adenocarcinomas (Fig. 158.3a). They are commonly associated with intestinal-type adenomas. An extensive mucinous component (>50% of the tumor volume) justifies a diagnosis of mucinous adenocarcinoma [9]. Those that resemble pancreatic or bile duct adenocarcinomas are called *pancreatobiliary-type adenocarcinomas* (Fig. 158.3b). Most ACs that have an ampullary duct origin prove to be of this type. A significant proportion of ampullary carcinomas (>40% in our experience) have a mixed phenotypic appearance and are difficult to place into one of the

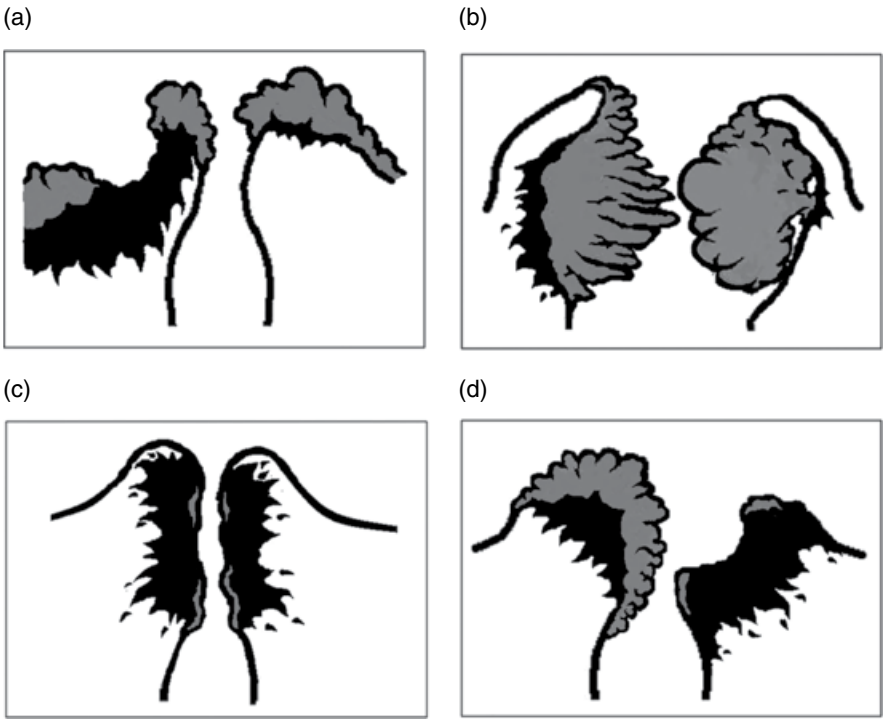

Figure 158.2 Site-specific classification of ampullary carcinomas. (a) (Peri)ampullary-duodenal: these tumors are characterized by substantial exophytic component on the duodenal surface of ampulla, while mostly sparing or only minimally involving the intraampullary segment. Often this vegetating tumor grows distally and leaves the ampullary orifice as an eccentric hole. (b) Intraampullary papillary-tubular neoplasm (IAPN) associated: invasive carcinomas arise from an IAPN. (c) Ampullary-ductal type: these tumors are quite underwhelming, showing mucosa-covered button-like elevations with a central dimple-like depression, or ulceration. (d) Ampullary-NOS type: these tumors are localized in the ampulla, mostly centered in the papilla region of the Vaterian complex, and not showing any of the specifications identified in other subtypes.

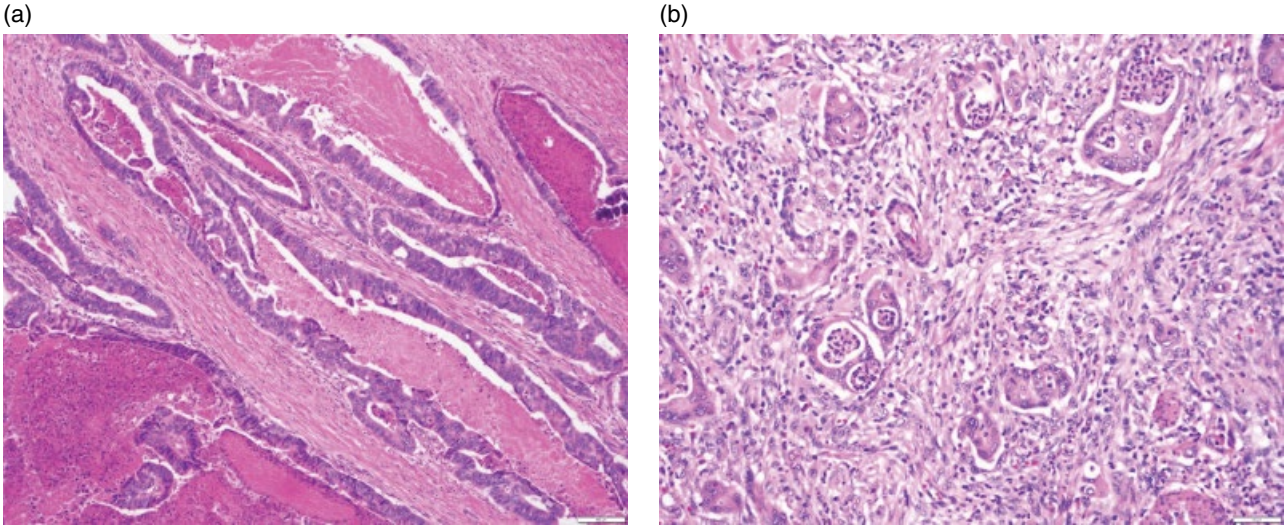

Figure 158.3 Histologic types of ampullary adenocarcinoma. (a) Intestinal type: similar to conventional colonic adenocarcinomas. (b) Pancreatobiliary type: small branching glands surrounded by a desmoplastic reaction.

categories as intestinal or pancreatobiliary [22]. If noninvasive carcinomas and carcinomas of neighboring sites (pancreatic and CBD) are excluded carefully and the true ampullary carcinomas with the refined definition are analyzed separately, the survival advantage of the intestinal type over pancreatobiliary type adenocarcinomas proves to be much less significant than previously reported [23–29].

Recently, immunohistochemically (IHC)-based classifications of ampullary carcinomas have been proposed [30,31] and are now being utilized by oncologists in management protocols. These panels are based on observations that the intestinal phenotype tends to stain for MUC2, CK20, and CDX2, whereas the pancreatobiliary phenotype stains positively for MUC1. However, in carefully selected cohorts analyzing true ampullary carcinomas with the refined definitions, the putative lineage markers MUC1/MUC2/CK20/CDX2 and their corresponding panels fail to show direct/significant prognosis [32]. There is emerging evidence that MUC5AC, the gastric marker, may prove to be a significant prognosticator of ampullary carcinoma [32].

The frequency of DNA mismatch repair (MMR) deficiency (i.e., immunohistochemical evidence of microsatellite instability) in ampullary cancers is comparable to, if not higher than, that in colon carcinomas [33–36]. MMR-deficient ampullary carcinomas are associated with medullary or pushing-order patterns, peritumoral inflammation (including lymphocytes, neutrophils, and eosinophils), or focal mucin production [33]. They appear to be less aggressive (lower rates of both lymph node metastasis and perineural invasion) and have a significantly better progress compared to MMR-intact ampullary carcinomas [33].

Recently, the introduction of checkpoint immunotherapies has revolutionized the oncologic targeted therapy paradigm in various organs. In ACs, PD-L1 expression appears to occur in the MMR-deficient group, specifically in tumors with medullary-type morphology [33]. Therefore, this subset of ACs may be targets for immunotherapy.

Since ampullary carcinomas are highly heterogeneous, it is difficult to ascertain the validity of molecular alterations identified in subsets [37]. *KRAS* mutations are found in approximately 40% of cases [38–42] and increased expression of p53 is detected in 70% [42–44]. Sixty-four percent of ampullary carcinomas that arise in FAP contain *APC* gene mutations, but only 17% of sporadic ampullary carcinomas carry this type of mutation [45]. Mutations of the β-catenin gene (*CTNNB1*) and alterations of the *SMAD4* (*DPC4*) gene are rare in ampullary carcinomas [46,47]. Like colorectal cancer, intestinal-type ACs show mutation of *APC* in greater than 50% of cases, whereas pancreatobiliary-type ACs show predominant *KRAS*, *TP53*, and *SMAD4* mutations, of similar frequency to PDAC [48–50]. In addition, *ELF3* has been implicated as a novel driver gene in AC [48,49] and, along with *KRAS* and *TP53*, may be mutated in all histologic subtypes, suggesting shared biologic mechanisms in development. *ERBB2* amplification has been shown in up to 23% of ACs and is mutually exclusive with downstream *KRAS/NRAS/BRAF* mutations that are responsible for resistance of therapies targeting *ERBB2* [51].

Ampullary carcinomas have an overall survival rate far better than pancreatic and distal common bile duct cancers. The five-year survival rate is approximately 45% [3,52]. Even the ampullary-duct carcinomas which are mostly pancreatobiliary type adenocarcinomas (i.e., ampullary counterparts of CBDC and pancreatic ductal adenocarcinomas) have a much better prognosis than ordinary PDACs. Invasion size may be an important factor. Ampullary carcinomas often arise from a precursor (adenomatous) lesion, and the mean size of the invasive component is usually significantly smaller than primary pancreatic carcinomas [52]. For instance, IAPN-associated invasive carcinomas often have only a small invasive component (mean 1.5 cm) [6]. Not surprisingly, they have a better prognosis [6]. Positive margins occur in less than 5% of ampullary carcinomas, compared with at least 35% of pancreatic tumors [52]. The carcinomas arising from the four distinct compartments of the ampulla have different biologic behavior, as discussed above.

Other factors associated with prognosis include tumor budding, perineural and lymphovascular invasion [18,53–57]. Among these, tumor budding is increasingly being recognized as an important prognosticator (and possibly stratified) as its value in the remainder of the GI tract is appreciated. In fact, in our study, we found it to be independent prognostic factor.

Uncommon Carcinomas in the Ampulla

There are other carcinoma types that occur in the ampulla, such as poorly cohesive carcinoma (with or without signet ring cells), medullary carcinoma, and mucinous (colloid) carcinoma [9]. These have some specific associations. For example, poorly cohesive carcinomas are usually diagnosed at an advanced stage and behave aggressively [58]. In contrast, medullary carcinomas are closely associated with microsatellite instability, and despite their large size and poorly differentiated appearance, their clinical behavior appears to be similar to, if not better than, that of other ACs [59]. Mucinous carcinomas are often ampullary-duodenal in origin and often present as advanced tumor and with a higher lymph node metastasis rate but their prognosis does not seem to be significantly worse [60]. Unlike their lower GI counterparts, they do not show association with MSI [60].

Distal Common Bile Duct Carcinoma

Distal common bile duct carcinoma (DCBC) is relatively uncommon and thus poorly characterized. Established risk factors for these tumors include parasites and congenital/anatomic variations such as choledochal

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cyst [61,62] and pancreatobiliary maljunction [63–65]. Recently, it was elucidated that DCBC is commonly associated with low (intrapancreatic) union of cystic and common hepatic ducts which suggests a chemical milieu alteration in bile as a factor in their etiopathogenesis [66].

One of the biggest challenges regarding DCBC has been in definition as to what really qualifies for this category. Common bile duct involvement is extremely common in pancreatic ductal adenocarcinomas if careful sampling is performed [67], and can even show focal circumferential involvement. Additionally, ampullary-ductal carcinomas discussed above are often classified as distal CBD carcinoma. Therefore, many studies have included cases from these secondary sites into the analysis of DCBC and vice versa. Careful dissection of the resection specimens and correlation of the findings with the imaging and clinical findings are crucial in establishing the true primary site in many cases [5].

A recent study reported that intrapancreatic tumors symmetrically/concentrically involving the common bile duct are likely to be DCBCs, which are frequently associated with high-grade biliary dysplasia, lack *KRAS* mutations, and have a superior prognosis with an actual five-year overall survival of 35%, whereas asymmetric/eccentric involvement generally implies pancreatic ductal adenocarcinoma, which are commonly associated with high-grade PanIN, *KRAS* mutations, and a poor five-year overall survival of 17% [68]. Microscopically, DCBCs commonly exhibit a small tubular pattern, sharing the similar morphology with pancreatic ductal adenocarcinoma. In addition, intraglandular neutrophil-rich debris is often seen [69]. Median survival is better than for pancreatic ductal adenocarcinoma, but worse than for ampullary carcinoma; however, the survival advantage over pancreatic carcinoma may be less when the tumors are size matched [69,70]. Poor prognostic indicators include node metastasis, lymphovascular invasion, size of invasion, and margin positivity [69]. T-staging of tumors based on depth of invasion or size is shown to be much more applicable and prognostically relevant [65,69].

The vast majority of biliary tract cancers are adenocarcinomas of the pancreatobiliary type. These are very similar to ordinary pancreatic ductal adenocarcinomas and are often histologically indistinguishable from each other except for subtle differences [69].

Incipient Cancers

Biliary intraepithelial neoplasia (BilIN) is defined as microscopic flat or micropapillary lesions of atypical bile duct epithelium. These flat lesions cannot be detected by preoperative image analysis or macroscopic examination. In the current WHO (5th edition), the BilIN classification scheme employed a two-tiered approach as low- and high- grade dysplasia, based on nuclear to cytoplasmic ratio, and loss of cellular polarity [71]. Since BilIN is most commonly detected incidentally in association with invasive carcinoma, its biological behavior and natural history have been difficult to evaluate. There are no data regarding the risk of progression of BilIN in the absence of invasive carcinoma. Low-grade dysplasia is largely believed to be clinically inconsequential; however, high-grade dysplasia is believed to be a significant lesion that may be associated with (or progress into) invasive carcinoma with relatively high risk, and thus warrants careful clinical attention [71]. BilINs are detected in >10% resected choledochal cysts, with or without an accompanying invasive carcinoma component [62].

An estimated 10% of biliary tract carcinomas arise in mass-forming preinvasive neoplasms (tumoral intraepithelial neoplasms [TIN]). Just as in the pancreas [4,72], ampulla [6], and gallbladder [73], the carcinomas arising from tumoral intraepithelial neoplasm, namely intraductal papillary neoplasm of the bile duct (IPNB) [74,75] and intraductal tubulopapillary neoplasm (ITPN) [76], show highly distinctive characteristics.

Intraductal papillary neoplasm of the bile duct (IPNB) shows a papillary proliferation of atypical epithelium that fills the bile duct and may lead to a fusiform or cystic dilation of the affected duct segment [74]. IPNB can be detected by imaging and gross examination. The degree of cytologic atypia is graded with the criteria used for BilIN. Similar to intraductal papillary neoplasm of the pancreas, IPNB is classified into gastric, intestinal, pancreatobiliary, and oncocytic types [74]. When the pancreatobiliary type becomes invasive, it usually shows the pattern of a tubular adenocarcinoma; intestinal-type IPNB, if invasive, often produces a mucinous (colloid) adenocarcinoma; the gastric and oncocytic-type IPNBs, if invasive, have a tubular type-associated carcinoma [71].

Intraductal tubulopapillary neoplasm is now recognized as a distinct group in the bile ducts as in the pancreas. ITPNs are distinguished from IPNBs by their tubular growth pattern with only minimal, if any, papilla formation [76]. Another important defining characteristic of ITPN is the mucin-poor nature of the cells. On gross examination, the bile ducts are filled with nodules. Foci of invasion are typically represented by firm, white scirrhous lesions with irregular borders [76]. Punctate or geographic foci of necrosis can be present. At the microscopic level, all ITPNs are characterized by large, smooth-contoured nodules composed of prominent, relatively small, back-to-back tubular units. In addition to their typical tubular pattern, solid areas or abortive papillae are seen. Necrosis is common, predominantly focal and with a "comedocarcinoma-like pattern" [76].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. ITPNs show a pancreatobiliary epithelial phenotype with MUC1 (80%) and MUC6 (30%) expression and negativity for MUC2 and MUC5AC [76]. Most ITPNs are associated with invasive carcinomas.

Overall, these have a more indolent behavior, partly attributable to the early detection of invasive carcinomas that are tagged by the massive intraductal component that leads to obstruction and early symptomatology. However, there is also evidence that even when stage matched, these invasive carcinomas arising from TINs behave better than those arise from BilINs, which indicates a different biology. This is also supported by the molecular alterations seen in these tumors [76]. Of note, as in the pancreas, those arising in oncocytic examples are currently classified as oncocytic variant of IPNB, but are increasingly being recognized as a separate entity of intraductal oncocytic papillary neoplasm (IOPN) as in the pancreas [77,78]. IOPNs have been shown to have a distinct molecular phenotype with rearrangements of PRKACA and PRKACB [79,80].

Nonampullary Duodenal Carcinoma

Nonampullary duodenal carcinomas (NADCs) are rare, and frequently have been grouped with jejunoileal adenocarcinoma. However, they have several distinctive characteristics. The distal duodenal carcinomas can be associated with intestinal-type adenomas; however, especially the proximal examples often form plaque/ulcero-plaque-like lesions arising from large vegetating adenomatous lesions [81]. Mismatch repair protein deficiency was found in 13% of NADCs overall, and more commonly in those with the plaque-like growth and pushing-border infiltration [81]. Proximal examples closer to the stomach also appear to be closer to gastric cancer in their nature, maybe arising from Brunner glands or metaplastic gastric-like epithelium. Additionally, NADCs, similar to ampullary carcinomas, are seldom pure "intestinal" type, and instead often exhibit a striking degree of morphologic versatility, with the gastropancreatobiliary being the predominant type and also unusual carcinoma types not described in the remainder of the GI tract [81,82]. This is reflected also in the frequency of the hybrid immunophenotype with less than 50% expressing "intestinal lineage markers" MUC2, CDX2, and CK20 [81]. The presence of gastric-pancreatobiliary histology appears to be associated with more aggressive behavior [82] and thus it is important to attempt to recognize and report this lineage (no matter the quantity) in any NADC case.

The prognosis of NADCs is fairly similar to ampullary-duodenal cancers and better than the ampullary-ductal cancers discussed above (five-year survival 29% vs 57%) [81]. More importantly, the prognosis of NADC is incomparably better than that of pancreatic ductal adenocarcinoma [81]. This is important because, for NADC that occurs close to the pancreas, pancreatic ductal adenocarcinoma with secondary invasion into duodenum becomes an important and highly challenging differential and the latter has been shown to have highly aggressive behavior.

Pathologic Staging of Cancers of This Region

The current eighth edition (2017) of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual and updated CAP Cancer Protocol for Carcinoma of the Ampulla of Vater [19,20] are based on the invasion of cancer into different compartments of this complex area. Into Oddi (T1a), duodenal submucosa (T1b), duodenal muscularis propria (T2), superficial pancreas (≤0.5 cm) T3a, peripancreatic soft tissue or duodenal serosa (T3b); or involvement of the celiac axis, superior mesenteric artery, and/or common hepatic artery (T4).

Lymph node (pN) staging is subdivided into N1 (1–3 positive nodes) and N2 (±4 positive nodes). A minimum of 12 regional lymph nodes is required for optimal staging in a pancreatoduodenectomy specimen, although with careful dissection typically more than 15–20 lymph nodes are harvested. A recent analysis of the AJCC classification system showed that the two-tier reclassification of positive lymph nodes was linked to significant differences in survival (including recurrence-free survival) between T3a and T3b tumors (but not between T1b and T2 or between lymphatic/venous invasion/node metastases) [83]. These results raise the question of the need for a size-related staging.

Neuroendocrine Neoplasms and Related Tumors

Neuroendocrine neoplasms should be regarded in two distinct groups: well-differentiated neuroendocrine tumors (NETs) and poorly differentiated neuroendocrine carcinomas (PDNECs). Well-differentiated neuroendocrine tumors constitute a heterogeneous group of neoplasms [9], including what were previously called ordinary carcinoids (often showing serotonin production), "ampullary somatostatinomas" (glandular psammomatous carcinoids with somatostatin positivity at the cellular level), gastrinomas and other hormonal types as well as nonfunctional tumors [84,85].

Ampullary somatostatinomas merit specific mention because they seem to be fairly unique to the ampulla, and conversely, a significant proportion of NETs in the ampulla prove to be of this type. These can be associated with neurofibromatosis and gastrointestinal stromal tumors. Although they are low-grade tumors, they are often infiltrative and show lymph node metastasis in close to half of the cases, but seem to behave in a very protracted fashion nevertheless [86–88]. Neuroendocrine tumors are graded based on the mitotic activity and Ki67 index. Accurate counting of Ki67 can be challenging. Eye-balling is discouraged. We find manual count performed on camera-captured printed images of tumor hot spots to be the most practical approach [89].

A distinct but related entity is duodenal gangliocytic paraganglioma, a neoplasm that combines features of a well-differentiated neuroendocrine tumor with those of a nerve sheath tumor admixed with ganglion cells [90–93]. This is a very peculiar entity that is almost unique to the ampulla and duodenum in the vicinity of the ampulla. The vast majority of cases seem to be benign with only rare cases showing lymph node metastasis, and even those seem to have benign behavior.

Poorly differentiated neuroendocrine carcinomas of this region need to be distinguished from the well-differentiated neuroendocrine tumors. They often occur in association with adenocarcinomas or glandular preinvasive neoplasms (adenomatous lesions). They are typically high-grade carcinomas, recognizable as such by morphology, showing highly atypical cytology (with differential diagnosis of other poorly differentiated carcinomas) as well as brisk mitotic activity and necrosis. Ki67 labeling index is typically higher than 50%. Retinoblastoma gene alteration is common, represented as loss of nuclear expression at the immunohistochemical elevel. Recent studies suggest that such tumors warrant cis-platinum treatment, as opposed to the well-differentiated NETs which grow slowly and not only do not require cis-platinum but also do not benefit much from it. They have a highly aggressive behavior.

Pseudotumors That Commonly Mimic Cancer

One of the most common types of pseudotumor in this region is paraduodenal ("groove") pancreatitis. This type of pancreatitis has been described under various names in the literature; here we use the term paraduodenal pancreatitis [94,95]. This particular pancreatic inflammation is found predominantly in male patients (40–50 years) with a history of alcohol abuse [96,97]. Grossly, there is either thickening and scarring of the duodenal wall, particularly in the area corresponding to the minor papilla, that extends to the adjacent pancreatic head tissue, and/or sieve-like cystic changes in the duodenal wall. Most cysts contain clear fluid, but others may have more granular white material and even stones. Microscopically, the chronic inflammatory process resides in the duodenal submucosa, the duodenal wall, and the adjacent pancreatic tissue. Typically, there are several small foci of necrosis surrounded by dense proliferation of myoid cells, which show all the features of myofibroblasts and are positive for muscle markers. A common finding associated with the inflammatory changes is Brunner's gland hyperplasia, which contributes to the thickening of the duodenal mucosa.

Fibroinflammatory biliary stricture (FIBS) is a rare benign tumor-like myofibroblastic lesion of the extrahepatic bile duct of unknown etiology that masquerades as cholangiocarcinoma. It is unrelated to autoimmune pancreatitis, primary sclerosing cholangitis, cholangiocarcinoma, prior bile duct injury or repair, and choledocholithiasis [98]. Histologically, the FIBS lesion is composed of spindle cells, fibroblasts, and myoblasts with varying degrees of fibrosis and lymphoplasmacytic inflammatory infiltrate [98]. If a defined mass is present, it is firm and lacks a capsule. By comparison with patients having bile duct cancer, FIBS patients present at a significantly younger age, are more likely to be female, and have a high incidence of coexisting autoimmune diseases [98]. The malignant potential of FIBS remains unknown due to the rarity of this disease. These lesions can masquerade as cholangiocarcinoma due to reactive epithelial hyperplasia, perineural extension, and involvement of vascular structures and adjacent organs. These features can be particularly misleading when examining intraoperative frozen sections due to the limitations of sample processing and the time constraints of immunohistochemistry. A subset of these cases appear to represent IgG4-related sclerosing cholangitis, which is a part of the autoimmune pancreatitis spectrum. Because preoperative cytology is not diagnostic of FIBS, surgical resection remains the mainstay of diagnosis and treatment, while immunosuppression may reduce the risk of recurrence.

Secondary Tumors

Virtually every malignant neoplasm described in the body can also occur in this region. These include melanomas, lymphomas, sarcomas, and germ cell tumors, all of which can mimic primary cancers and thus ought to be considered in the differential diagnosis of more common adenocarcinomas, at both clinical and pathologic evaluation.

Introduction

Ampullary neoplasms refer to a family of periampullary tumors, which arise from the ampulla of Vater. The significant premalignant potential and a unique anatomic location of ampullary neoplasms make them special. Typically, ampullary tumors are classified as benign and malignant. Benign tumors account for less than 10% of periampullary tumors [1], and ampullary carcinomas are the second most common periampullary carcinomas (after pancreatic adenocarcinoma) [2]. Although ampullary adenomas are classified as benign, they tend to progress to malignant transformation. True ampullary cancer is usually difficult to distinguish from other periampullary malignancies. It is generally diagnosed at an earlier stage, meaning that it has a better prognosis than periampullary cancers originating from the bile or pancreatic duct [3]. An aggressive diagnostic and therapeutic approach is therefore warranted for these tumors.

Epidemiology and Biologic Behavior

In autopsy studies, periampullary neoplasms prevalence is reported to be 0.04–0.12 [3,4]; however, the prevalence increases with the widespread availability of flexible endoscopy and screening programs. Currently, periampullary malignancies account for 5% of all newly diagnosed gastrointestinal tumors [5]. The incidence of ampullary carcinomas is 4–6 cases per million population, representing 0.2% of all gastrointestinal tumors and accounting for approximately 20% of all periampullary cancers [6,7]. Caucasian people are most affected, there is a male predominance, and the peak incidence is in the seventh decade [8]. Both benign and malignant ampullary tumors can occur in the setting of a genetic syndrome or, more commonly, sporadically.

Familial adenomatous polyposis (FAP) is the most common genetic predisposition [9], and most patients with FAP manifest some degree of dysplasia in the ampulla [10]. Periampullary cancers have become a leading cause of death in patients with FAP since prophylactic colectomy became the standard of care [11]. Gardner syndrome, Lynch syndrome, neurofibromatosis type 1, and Muir–Torre syndrome are the other reported genetic predispositions for ampullary carcinoma [12–15]. Ampullary adenomas progress to cancer through an adenoma to carcinoma sequence, similar to what is known with colon polyps. This interval allows a lead time for investigation and excision of these lesions before carcinoma development [16].

Thankfully, screening and early resections of these lesions have become more common worldwide. The current European Society of Gastrointestinal Endoscopy guideline recommends starting endoscopic surveillance at the age of 25 and continuing at intervals determined by the characteristics of previously found lesions [17]. The effective use of a side-viewing duodenoscope with random biopsies has increased duodenal and ampullary adenoma detection rates [17]. On the other hand, local factors play an essential role in sporadic tumors. The earliest histopathologic changes are seen in the common pancreaticobiliary channel, followed by the pancreatic duct. Concentrated bile produces mutagenic effects on ductal epithelium, resulting in epithelial apoptosis promoting malignant transformation [18]. Also, chronic liver fluke infection is a risk factor for ampullary carcinoma [19].

Histologic Features

Ampullary neoplasms are macroscopically classified as (i) intraampullary (intramural protruding), (ii) periampullary (extramural protruding), or (iii) ulcerating ampullary (19). Ulcerating ampullary lesions have a high lymph node metastasis rate and are mostly diagnosed at an advanced stage. Adenocarcinoma accounts for 75% of all ampullary neoplasms, followed by benign adenomas (20%) (Fig. 159.1) and neuroendocrine tumors (5%) [2]. Villous and tubulovillous adenomas are the most common benign lesions; the others include hemangioma, lipoma, leiomyoma, lymphangioma, and leiomyofibroma [1,9].

Histologically, Kimura and colleagues classified ampullary carcinomas into two subtypes: intestinal and pancreaticobiliary [20]. The intestinal type classically arises from an adenoma; however, a premalignant precursor lesion is often absent in the pancreaticobiliary type [19]. In 2010, the World Health Organization revised this classification, adding mixed as a third subtype [21]. Currently, histologic ampullary carcinoma classification includes three subtypes: intestinal, pancreaticobiliary, and mixed [21,22]. Typically, intestinal-type carcinomas have fewer invasive components and a less frequent perineural and lymphovascular invasion, which has been related to a better prognosis than the pancreaticobiliary type [23,24]. The mixed type overlaps with intestinal and pancreaticobiliary subtypes, ranging from 20% to 40% of ampullary carcinomas, showing features not attributable to a single phenotype [25].

Immunohistochemical stains can potentially distinguish between intestinal and pancreaticobiliary types. Intestinal epithelium expresses intestinal markers such as cytokeratin 20 (CK20), mucin 2 (MUC2), and caudal-related homeodomain transcription factor 2 (CDX2) plus or minus cytokeratin 7 (CK7), whereas pancreaticobiliary adenocarcinoma is positive for CK7 and mucin 1 (MUC1). Other potentially useful immunohistochemical stains to differentiate the subtypes include mucin 5AC (MUC5AC) and S100 calcium-binding protein (S100P) [26] (Table 159.1).

Genetic Features

Most ampullary neoplasms occur sporadically; however, the presence of FAP has been associated with a 200-fold higher risk of ampullary cancer compared with the general population, similar to colorectal cancer [27]. Several recent studies have provided an impressive amount of molecular information about hepatobiliary-pancreatic tumors, including ampullary cancers (ACs) [28,29]. Two landmark studies reported by Yachida et al. and Gingras et al. emphasized the presence of specific mutations, such as *KRAS*, *APC*, *TP53*, and *SMAD4*. Moreover, these two studies investigated putative associations between gene mutations and histologic subtypes [30,31]. Similar to colorectal cancer, intestinal-type ACs show APC gene mutations, whereas pancreaticobiliary-type ACs show *KRAS*, *TP53*, and *SMAD4* gene mutations, predominantly. In addition, the tumor suppressor gene *ELF3* has been implicated as a novel driver gene in ampullary cancer due to its role in the regulation of epithelial differentiation [30,32].

It seems that molecular profiling can drive therapeutic decisions since some features have been suggested to have a putative prognostic value. A study conducted by Mafficini et al. recently linked the presence of *KRAS* and *TP53* mutations with a more aggressive clinical course, regardless of histology [33]. However, few data are currently available, and further studies are warranted to make clinical decisions based on molecular features.

Table 159.1 Immunohistochemical classification and genetic mutations of ampullary cancer.

Histologic type	Positive stains	Other stains	Reference
Intestinal	MUC2, CK20, CDX2, ± CK7	-	[26]
Pancreaticobiliary	MUC1, CK7, ±MUC5AC	S100P+, SMAD4 loss	[26]
Mixed	Might show a combination of the above stains		[26]
	Gene mutations		
Intestinal	APC (49%), TP53 (39%), KRAS (39%), CTNNB1 (26%), ARID2 (18%)		[30]
	TP53 (64%), KRAS (46%), APC (41%), PIK3CA (26%), SMAD4 (20%)		[31]
Pancreaticobiliary	KRAS (67%), TP53 (67%), SMAD4 (20%), CTNNB1 (15%), ERBB3 (14%)		[30]
	TP53 (71%), KRAS (65%), SMAD4 (18%), CDKN2A (16%), PIK3CA (13%)		[31]
Mixed	KRAS (49%), APC (50%), TP53 (41%), SMARCA4 (27%), PIK3CA (23%)		[31]

Clinical Features

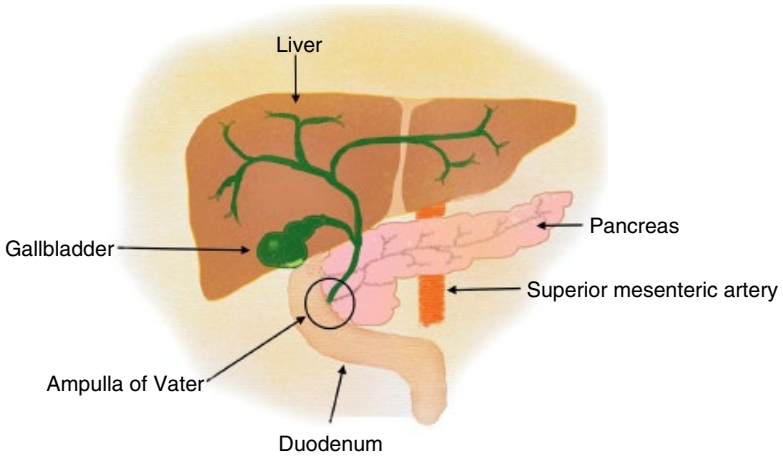
As with ampullary adenomas, the presenting symptoms and signs of ampullary adenocarcinomas are nonspecific, as frequently observed in pancreatic adenocarcinoma and extrahepatic cholangiocarcinoma (the most common symptom is painless obstructive jaundice, which is seen in two-thirds of patients) [34,35]. Occult gastrointestinal bleeding, diarrhea, fatigue, weight loss, and duodenal obstruction may be the symptoms associated with ampullary cancer. Due to cholestasis, 25% of ampullary adenomas develop common bile duct stones [36]. Furthermore, small distal intraductal benign tumors can mimic an ampullary malignancy and cause significant biliary obstruction [37]. Physicians should keep these lesions in mind when seeing a patient with atypical abdominal symptoms since there are no specific symptoms that are pathognomonic for ampullary lesions.

Diagnosis and Staging

The primary concern in evaluating ampullary lesions is to rule out malignancy risk, since ampullary adenomas have a premalignant potential. Also, an occult focus of carcinoma may be present within an adenoma [38,39]. Diagnosis is usually established by combining radiology, endoscopy, and histology, similar to evaluating ampullary adenoma and carcinoma. However, it is generally challenging to differentiate between them without complete resection.

Ampullary carcinomas are frequently diagnosed with a macroscopic appearance on endoscopy and histopathologic examination of the obtained biopsy specimens. Most ampullary lesions are apparent endoscopically. Ulcerated masses, lesions >3 cm, ampullary rigidity, and nonlifting of the periampullary component with submucosal injection are highly suspicious features for malignancy. However, the ampulla is best examined and biopsied with a side-viewing duodenoscope. Endoscopic retrograde cholangiopancreatography (ERCP) does not only help obtain biopsies, but it also excludes an associated stricture or stone and allows evaluation of the extension of the tumor into the pancreatic or biliary duct (Fig. 159.2). As a general rule, negative endoscopic biopsy for malignancy does not entirely exclude a malignant focus in an adenoma. Therefore, the diagnostic accuracy of biopsies can be increased by obtaining at least six biopsies, preferably at least 48 hours following sphincterotomy [40,41], and by complete resection of ampullary adenomas (endoscopic ampullectomy). Therefore, endoscopic ampullectomy is considered an integral part of the diagnostic process and may also be curative in highly selected cases, such as *in situ* carcinoma, low-grade dysplasia, and early adenocarcinoma [42–44].

In terms of differential diagnosis, primary ACs must be distinguished from other cancer types, including pancreatic cancer, distal cholangiocarcinoma, and small bowel cancers [45,46]. Endoscopic ultrasound (EUS), ERCP, and fine-needle aspiration cytology (FNAC) are the major diagnostic modalities. On the other hand, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET/CT) of the chest, abdomen, and pelvis are the basic tools for the staging of ACs [44,47]. In patients with obstructive jaundice, transabdominal ultrasound (TUS) is the first choice of imaging to rule out other causes such as choledocholithiasis and pancreaticobiliary tumors; however, it rarely reveals the neoplasm itself.



The complex and strategic anatomic structure of the ampulla of Vater, a crossroads of the three different

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 159.2 (a) Ampullary adenoma on forward-viewing endoscopy. (b) CT image of the same lesion. (c) Endoscopic retrograde cholangiopancreatography of the same patient showing distally complete obstruction of bile duct.

Figure 159.3 Schematic representation of the ampulla of Vater.

epithelia (intestinal, ductal pancreatic, and biliary), makes tumor staging highly difficult [45,46] (Fig. 159.3). The American Joint Committee on Cancer (AJCC)/ Union for International Cancer Control (UICC) updated the TNM staging system in 2018 (8th edition) [46,48]. According to the last edition, the T stage is subclassified based on the depth of duodenum and pancreas invasion, and the N classification has been splatted into N1 (1–3 lymph nodes) and N2 (four or more) (Table 159.2).

Cross-sectional techniques and EUS are usually preferred in staging and preoperative evaluation, as well as differentiating an ampullary adenoma from carcinoma [44]. With its ability to place an ultrasound transducer close to the ampulla, EUS is superior to CT, MRI, and TUS for tumor staging and is as sensitive as duodenoscopy in detecting small ampullary tumors [49] (Fig. 159.4). EUS and intraductal ultrasonography provide detailed information about the endoscopic appearance, tumor size, localization, tumor extension, and the existence of metastatic lymph nodes. These data help the preoperative staging of ampullary malignancy [50,51]. Furthermore, EUS-guided fine needle aspiration (EUS-FNA) can provide tissue from the ampulla, lymph nodes, and surrounding deeper structures. However, it does not rule out a malignant focus within an adenoma [52,53]. EUS is the best modality for T-staging ampullary carcinoma and vascular invasion, while the accuracy for N-staging is lower [53,54].

Although CT is superior to TUS in evaluating ampullary lesions, it is not sensitive enough for staging and detecting small lesions. On the other hand, CT is highly accurate in detecting distant metastasis, which usually involves lymph nodes, peritoneum, liver, bone, and lungs. However, MRI can provide more detailed images of the ampulla and periampullary tissue [55]. Ampullary cancers are usually hypodense distinct masses on MRI with magnetic resonance cholangiopancreatography (MRCP). A "double-duct" sign (dilation of both pancreatic and bile duct) or only the dilated bile duct can be observed mainly; however, single dilation of the pancreatic duct is rare [56].

Another staging modality is PET/CT, which has not been well studied in detecting ampullary malignancies; it

Table 159.2 The 8th edition of the TNM staging system by AJCC/UICC.

TNM stage	Criteria
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1a	Limited to sphincter of Oddi
T1b	Invasion into duodenal submucosa
T2	Invasion into duodenal muscularis propria
T3a	Invasion into pancreas ≤0.5 cm
T3b	Invasion into pancreas >0.5 cm
T4	Involvement of celiac or superior mesenteric artery
NX	Lymph nodes cannot be assessed
N0	No lymph node involvement
N1	Metastasis in 1–3 lymph nodes
N2	Metastasis in 4 or more lymph nodes
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
Stage group	
Stage 0	Tis N0 M0
Stage IA	T1a N0 M0
Stage IB	T1b 2 N0 M0
Stage IIA	T3a N0 M0
Stage IIB	T3b N0 M0
Stage IIIA	T1a,1b,2,3a,3b N1 M0
Stage IIIB	T4 AnyN M0 or AnyT N2 M0
Stage IV	AnyT AnyN M1

is highly sensitive in detecting distant metastasis [57]. In a recent study comprising 44 patients, Watanabe et al. assessed the usefulness of fluorodeoxyglucose PET (FDG-PET) for preoperatively predicting tumor invasion in ampullary cancer, retrospectively. They reported that PET performance correlated with tumor invasion and lymph node metastasis and speculated that FDG-PET could be a helpful modality for preoperative staging and treatment strategy [47]. In another study, Chuang et al. investigated the effectiveness of preoperative dual-phase 2-[18F] FDG PET-CT for poor survival in 54 patients with ampullary carcinoma receiving pancreaticoduodenectomy. They reported that dual-phase PET scan with bowel distention could better delineate the ampulla of Vater and characterize tumor physiology. Therefore, 2-[18F] FDG PET-CT offers good survival prediction before surgery in primary malignant neoplasms at the ampulla of Vater, providing better preoperative risk stratification along with improved treatment planning [58].

Management and Treatment

Endoscopic Management and Surgery

It can be difficult to differentiate an ampullary adenoma involving a carcinoma focus and true ampullary carcinomas from other periampullary cancers. Furthermore, there is no consensus regarding the optimal management of patients with ampullary adenomas. It is not clearly defined who requires endoscopic or surgical excision and who should be followed up with surveillance endoscopy. However, American Society for Gastrointestinal Endoscopy (ASGE) guidelines for the role of endoscopy in ampullary and duodenal adenomas attempt to make it easier and update the recommendations for management. The ASGE guideline recommends ERCP before resection attempts. The initial assessment in diagnosis is looking for a sign of malignancy with ERCP, which is also helpful in the differential diagnosis. These guidelines also recommend EUS before resection, as EUS is superior to other imaging modalities for the accuracy of primary tumor staging [16,59]. However, CT/PET and MRI should be completed before

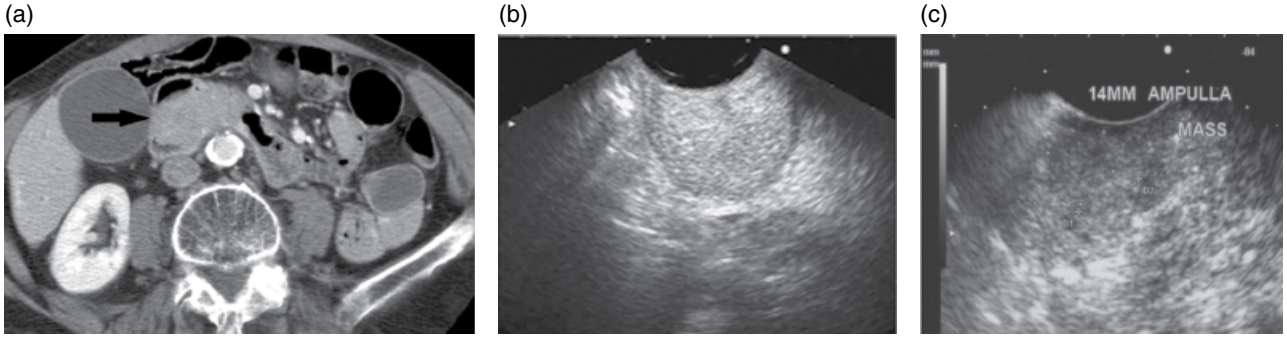

Figure 159.4 (a) A large soft tissue mass consistent with ampullary cancer in duodenal wall on CT. (b) Ampullary adenoma on endoscopic ultrasound (EUS). (c) 14 mm ampullary cancer on EUS.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

resection attempts since these modalities have been shown to be superior for detecting small, distant metastases and nodal metastases [57,60].

Removal of the adenoma is suggested in cases with sporadic adenoma, especially those that have high-grade dysplasia or are causing any symptoms. Endoscopic surveillance with biopsies every 6–12 months may be advised when a patient declines excision of the lesion. In cases with FAP, excision should be suggested since the prognosis seems better compared with sporadic cases. On the other hand, removing ampullary adenoma does not eradicate cancer risk because multiple upper intestinal adenomas are usually present in patients with FAP.

There are three excision options for ampullary neoplasms: endoscopic ampullectomy (Fig. 159.5), surgical ampullectomy (local surgical excision), and Whipple's procedure (pancreaticoduodenectomy). The decision is made based on the degree of surgical risk, life expectancy, stage of malignancy, and patient preference. Although there are no definite criteria on which approach is best for a random case, especially in centers that are not experienced in advanced endoscopy, patients with large lesions, adenomas containing carcinoma, lymph node involvement, and adenoma ingrowth into the bile duct or pancreatic duct on EUS should be referred to surgery. Endoscopic ampullectomy should only be attempted in patients with adenocarcinoma staged as Tis, while other stages should be referred for surgical resection [16].

There are comparable reports in the literature on the size of the lesion for endoscopic removal. The current recommendations suggest that removing ampullary adenomas <4–5 cm in maximal diameter is judicious. Resection of Tis ACs can be curative, although the most recent ASGE guideline does not endorse it in routine management [16,59]. Certain endoscopic features, including nonlifting with injection, ulceration, firmness, and presence of depression, suggest a possible malignancy, which are indications to refer for surgical resection [42,43].

The only curative treatment of carcinoma which eliminates histologic progression to carcinoma and eradicates a malignant focus within an adenoma is R0 (margin-negative) resection. Although pancreaticoduodenectomy (PD) has been associated with higher morbidity and mortality rates compared to surgical ampullectomy, it achieves curative excision for ampullary adenomas with almost no local recurrence risk, and has 90% successful resection rates for carcinomas. Curative surgery is deemed possible in approximately 50% of cases [61,62]. Moreover, surveillance endoscopies are not recommended after curative surgery. On the other hand, since a higher proportion of complications frequently burdens the postoperative course, several minimally invasive approaches have been explored, including robot-assisted and laparoscopic surgery; however, the real benefit of these modalities remains unclear [63–65].

Patients with evident malignancy on an adenoma should be referred for pancreaticoduodenectomy rather than endoscopic or local surgical excision. Although some studies report that endoscopic ampullectomy has lower morbidity and similar efficacy rates (46–93%) compared to surgical ampullectomy (0–30%), the role of endoscopic ampullectomy is still controversial [66]. Complete removal of the neoplasm is the aim of the procedure, and *en bloc* excision is the preferred method since occult carcinoma and also negative margins should be ensured entirely. However, due to the frequent local and locoregional lymph node involvement, this technique should be used in selected patients with noninvasive forms [67].

The quoted technical success rate for complete resection varies significantly from 42% to 92%, depending on individual endoscopists' experience with ampullectomies. Literature also reports comparable recurrence rates

Figure 159.5 (a) Ampullary adenoma in a patient with familial adenomatous polyposis. (b) Endoscopic appearance of the lesion two weeks after endoscopic ampullectomy. (c) Endoscopic appearance of the lesion three months after endoscopic ampullectomy.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. ranging from 2% to 33% following resection [42,68,69]. Patient and lesion features play a significant role in technical success, and therefore patient selection is critical. Predictors of success include male sex, age >48, lesion diameter <24 mm, and absence of FAP [3].

Postprocedure Surveillance

Patients with ampullary adenoma who have been treated with either endoscopic or surgical ampullectomy are at risk of recurrence and require endoscopic surveillance. In contrast, surveillance is not recommended after pancreaticoduodenectomy except for patients with FAP. All patients who undergo ampullectomy are invited for a follow-up diagnostic endoscopic procedure with side-viewing scopes in one week to one month. If this first endoscopy shows no residual lesion, routine endoscopic follow-up is suggested for surveillance at either three-month or six-month intervals for two years. After two years, some institutions may continue surveillance for much more extended periods [16]. Since patients with FAP are at risk of developing upper intestinal polyps other than ampullary adenomas, they require regular endoscopic surveillance according to the Spigelman classification [70]. In patients with ampullary cancer who undergo local surgical excision, endoscopic surveillance may be recommended, similar to endoscopically resected ampullary adenomas, although no guidelines are available.

This topic requires further study to identify the optimal interval and duration of postprocedural surveillance.

Medical Treatment

Although radical surgery is known as a curative modality for early-stage AC, tumor recurrence is still high (up to half of the patients). Therefore, the effectiveness of the postoperative approaches, including chemotherapy, radiotherapy, or chemoradiation, have been investigated over the years [71,72]. In a recent retrospective study comprising 4190 patients with ACs from the National Cancer Database, Nassour et al. highlighted that adjuvant chemotherapy and adjuvant chemoradiation therapy were associated with improved survival [73]. On the other hand, Ecker and colleagues reported that adjuvant chemotherapy is not associated with improved clinical outcomes, neither for intestinal nor for the pancreaticobiliary types of ACs [74].

There is a need for randomized controlled trials (RCTs) on this topic; however, conducting RCTs in AC patients is difficult because of several reasons, including the rarity of the disease and frequent misclassifications. Given the lack of RCTs supporting the use of adjuvant chemotherapy and chemoradiotherapy, the optimal regimen for ACs in both adjuvant and metastatic settings remains to be explored.

Recently, in a retrospective cohort study including 214 patients, Bolm et al. reported that pancreatobiliary-type ACs that received adjuvant therapy had an improved median overall survival (adjuvant treatment 85 months versus no adjuvant treatment 65 months); moreover, adjuvant therapy was found to be an independent prognostic factor in multivariate analysis. In contrast, there was no benefit of adjuvant therapy in intestinal-type AC patients, suggesting that adjuvant treatment might be indicated in pancreaticobiliary or mixed-type ACs [75].

Systemic chemotherapy represents the gold standard in patients with advanced AC with distant metastases. Some landmark studies conducted in biliary tract cancers might be guidance for this purpose, supporting the increase of median overall survival [76–79]. Studies focusing their attention on the molecular features of ACs may also be helpful to translate the results obtained in other biliopancreatic malignancies. For example, WNT pathways and PI3K alterations have been reported in more than 30% of all ACs regardless of histologic subtype. The anticancer agents found to be effective in the case of PI3K mutations, such as everolimus and temsirolimus, are also under evaluation in ACs [33,80]. Large-scale, prospective randomized clinical trials are still warranted to identify the role of systemic treatment in this setting.

Introduction

Tumors of the ampulla of Vater are relatively rare and arise from the duodenal papilla. Symptoms of an ampullary tumor include biliary colic, obstructive jaundice, recurrent cholangitis, and pancreatitis. These symptoms arise due to obstruction of the bile or pancreatic ducts. Occult bleeding is relatively common. However, most ampullary tumors are asymptomatic and are often found incidentally by screening endoscopy. Ampullary tumors are thought to develop either from the intestinal epithelium or the epithelium covering the pancreaticobiliary ducts. Most ampullary tumors are adenomas or adenocarcinomas [1]. The results of familial adenomatous polyposis (FAP) surveillance suggest that an ampullary adenoma is associated with the progression of adenoma to carcinoma and is recognized as a premalignant lesion, such as colonic adenoma [2–4]. Although the natural history of ampullary adenoma has not been well investigated in sporadic lesions, many endoscopists advocate resecting ampullary adenomas [1].

Indications for Endoscopic Papillectomy

Endoscopic papillectomy was first documented by Suzuki et al. in 1983 in Japanese [5] and by Binmoeller et al. in 1993 in English [6]. It involves resecting the mucosa and submucosa of the duodenal wall in the area of the anatomic attachments of the ampulla of Vater, including the tissues around the bile duct and the pancreatic duct orifices [7].

Surgical resection (pancreaticoduodenectomy or transduodenal ampullectomy) is recognized as the gold standard for treating ampullary tumors. However, no prospective study has compared endoscopic papillectomy with surgical resection. Surgical resection has a low recurrence rate but is too invasive for cases of localized ampullary adenoma. Endoscopic papillectomy has been accepted as a less invasive alternative to surgical treatment and is increasingly performed in cases of adenoma [8].

The indications for endoscopic papillectomy have not been established. The European Society of Gastrointestinal Endoscopy guidelines recommend endoscopic papillectomy for patients with ampullary adenoma without intraductal extension [9]. The 2015 American Society for Gastrointestinal Endoscopy guidelines did not provide specific criteria for endoscopic papillectomy [8]. Intraductal involvement of the lesion is considered a noncurative lesion, or one with a high risk of recurrence [10]. Additionally, surgical transduodenal ampullectomy is suitable for cases of large (>40 mm) lesions and a periampullary diverticulum for technical reasons. Endoscopic resection is not recommended for ampullary cancer because of the risk of lymph node metastasis. In contrast, high-grade dysplasia or carcinoma restricted to the mucosal layer is reportedly suitable for endoscopic papillectomy, but there is a rare risk of lymph node metastasis [11].

Preprocedural Evaluation

The purpose of the preprocedural evaluation is to evaluate extension to the bile duct or pancreatic duct after apparent advanced adenocarcinoma is excluded. The preprocedural diagnosis of ampullary tumor is based on endoscopic appearance, biopsy, endoscopic ultrasound (EUS), and endoscopic retrograde cholangiopancreatography (ERCP) with intraductal ultrasonography (IDUS).

Endoscopic Appearance and Pathologic Diagnosis

A side-viewing endoscope (duodenoscope) is generally used to visualize or treat ampullary tumors. Cap-assisted endoscopy is suggested when the ampulla is not observed by forward-viewing endoscopy [12]. The typical endoscopic finding of ampullary adenoma is a villous tumor. The characteristic features distinguishing adenoma and adenocarcinoma are the presence of ulceration, spontaneous bleeding, depressed area, friability, and rigidity, which have often been observed in patients with malignancy [13]. The fold convergence of the duodenum wall around the ampulla indicates invasion of the tumor into the duodenal wall.

However, ampullary adenomas cannot always be distinguished from ampullary adenocarcinomas based on endoscopic appearance alone. Observing the ampullary tumor with dye and narrow-band imaging is reportedly helpful for providing endoscopic images of microvessels and the surface structure of tumors [14] or to enhance tumor margins [15]. A biopsy is very important for differentiating adenoma from carcinoma and other tumors. However, the accuracy of biopsy is reportedly low, at approximately 70% [16–19]. It is thought that severe atypism is observed in the ampullopancreatobiliary common duct rather than in the ampulla–duodenum. Therefore, the biopsy must be taken from the deep portion of the orifice. Some reports have suggested that biopsy followed by endoscopic sphincterotomy has better accuracy when adenocarcinoma is suspected [20]. However, the sensitivity of biopsy does not change after sphincterotomy [21].

Tissue sampling by EUS-guided fine needle aspiration (EUS-FNA) is one of the options for pathologic confirmation when the tumor is not exposed to the surface of the duodenum. EUS-FNA is suitable when an invasive adenocarcinoma is suspected that has a negative histopathology initially. In one retrospective study of 35 patients, the accuracy of EUS-FNA for suspected primary ampullary lesions was 88.8% [22]. Thus, endoscopic papillectomy is occasionally performed as a diagnostic treatment or as a major biopsy before surgery, as the preoperative confirmation of the histopathologic diagnosis is not always accurate.

Endoscopic Retrograde Cholangiopancreatography, Intraductal Ultrasonography, and Endoscopic Ultrasound

Endoscopic retrograde cholangiopancreatography, including an evaluation of the biliary and pancreatic ducts, should be performed at the time of endoscopic resection to assess evidence of extension into either ductal system. IDUS is performed via the working channel of the duodenoscope and into the bile and pancreatic ducts after cholangiopancreatography. IDUS may be useful for imaging the detailed anatomy of the ampulla. EUS is essential for deciding whether or not endoscopic resection is indicated. It provides information on the presence of invasion into the muscularis propria, intraductal extension of the lesion, and metastasis to regional lymph nodes. EUS is superior to computed tomography (CT), magnetic resonance imaging (MRI), and transabdominal ultrasonography as diagnostic modalities [23,24]. A metaanalysis showed that the pooled sensitivity and specificity of EUS for the diagnosis of T1-stage tumors were 77% and 78%, respectively [25]. The combination of EUS and IDUS improves the accuracy of preprocedural diagnosis [23]. It is uncertain whether all cases of ampullary adenoma require EUS before endoscopic resection. Some experts suggest that EUS is not required when the tumor is ≤1 cm in diameter, or when no obvious endoscopic signs of malignancy are present [26].

Techniques

In general, endoscopic papillectomy is performed using a duodenoscope in the same manner as polypectomy using a snare, followed by stenting of the pancreatic duct for prophylaxis of postprocedural pancreatitis. Although no data have compared the safety or recurrence rates between *en bloc* and piecemeal resection, achieving *en bloc* resection without complications is fundamental when performing endoscopic papillectomy (Fig. 160.1). Piecemeal resection is performed for large lesions, aiming to decrease complications and recurrence. However, a complete pathologic evaluation is important to evaluate the resected margins or malignant foci with invasiveness, as the previous pathologic diagnosis is often incomplete. *En bloc* resection can potentially shorten the procedure time, requiring less cautery time. A large retrospective study concluded that *en bloc* resection is strongly associated with a higher rate of complete resection (odds ratio [OR] 4.05, 95% confidence interval [CI] 1.71–9.59, P <0.001) [27]. Balloon catheter-assisted papillectomy has been documented to facilitate *en bloc* resection in a few case reports [28,29].

Submucosal Lifting

Submucosal injection with epinephrine diluted in saline solution and indigo carmine before endoscopic papillectomy has been reported [30,31]. The mucosal tissue at the ampullary lesions does not lift because of tethering by the biliary and pancreatic ducts. After lifting the submucosa, the central lesion becomes comparatively depressed by the elevated mucosal tissue around the papilla, which makes snaring difficult.

A randomized control trial compared papillectomy with submucosal injection and simple papillectomy for small lesions [32]. Among 50 patients with papillary adenomas, the complete resection rates were 80.8% (21/26) in the simple papillectomy group (12 mm mean tumor size) and 50.0% (12/24) in the submucosal injection group (9.29 mm) ($P = 0.02$). No differences were observed among postprocedural bleeding, delayed bleeding, and pancreatitis. The authors concluded that simple papillectomy may be a recommendable technique. Therefore, mucosal injection is not routinely suggested for small lesions. However, it may be useful for cases with predominantly lateral periampullary extension [33]. Underwater ampullectomy without lifting of the submucosa has been reported for lateral spreading tumors rather than submucosal injection [34].

The effectiveness of these techniques is still under investigation.

Snaring and Transection

Electrosurgical snare resection is the most common snaring and resection technique. There is no specific type or size of snare for endoscopic ampullectomy. The snare is often placed with the tip on the oral side of the lesion. The snare is closed at the base and the lesion is resected. Although no general recommendations regarding the optimal current and power output have been provided, there are reports of both pure cutting and blended cutting. Many endoscopists prefer the "blended" or Erbe Endocut® mode, which decreases bleeding by coagulation. In a pilot randomized controlled trial (N = 60), Iwasaki et al. reported that both pure cutting current (Autocut® mode) and blended cutting current (Endocut mode) have similar efficacy and safety for endoscopic papillectomy, and that the Endocut mode may prevent immediate bleeding of large tumors. The incidence rates of delayed bleeding (13.3% vs 16.7%, $P = 1.00$) and pancreatitis (27% vs 30%, $P = 0.77$) were similar between the Autocut and Endocut procedures. Immediate bleeding in the resection of tumors >14 mm in diameter was more common in the Autocut than in the Endocut group (88% vs 46%, P = 0.04) [35].

A novel "hybrid-ESD papillectomy" technique has been introduced recently. This involves a circumferential incision with partial submucosal dissection and subsequent snare resection. The *en bloc* resection and complete resection rates were 100% (N = 8) and 63%, respectively. A clear lateral margin was achieved in all cases [36]. This may be a treatment option when the lateral margin of a tumor is difficult to confirm by grasping with snare forceps. Another study reported the effectiveness of submucosal dissection for recurrent laterally spreading papillary lesions [37].

Retrieval of Resected Tumors

Retrieving a specimen is very important for accurately evaluating and staging the tumor. Immediately after transection, the specimen is grasped with a snare and removed from the body to avoid intestinal migration. A basket catheter or net forceps should be used for large specimens. It is important that the tissue is not collected by aspiration through the endoscope, as this will cause the specimen to fragment, making it impossible to evaluate the cut end histopathologically.

Sphincterotomy/Pancreatic and Biliary Stent Placement

Cannulation and sphincterotomy of the bile and pancreatic ducts are occasionally performed during papillectomy. Cholangiography and pancreatography are performed before papillectomy to rule out intraductal extension and to ensure easy recannulation after resection. Some experts have included methylene blue in the contrast injected into the pancreatic duct to assist in identifying the pancreatic orifice and preserve access to the pancreatic duct [38]. Sphincterotomy is often performed using the Delphi process after papillectomy according to an expert consensus [39].

Placing a pancreatic stent is strongly recommended to prevent postprocedural pancreatitis [8,9]. Pancreatic stenting aims to maintain the pancreatic duct orifice and prevent obstruction of the pancreatic duct. However, pancreatic damage caused by thermal ablation cannot be prevented.

The only prospective, randomized, controlled trial to evaluate the role of prophylactic pancreatic duct stenting to reduce the rate of post-ERCP pancreatitis after endoscopic papillectomy was conducted by Harewood et al. [40]. That study enrolled 19 patients who underwent *en bloc* papillectomy, 10 of whom were randomized to placement of a pancreatic stent. A significant decrease in the rate of postprocedural pancreatitis was observed in the stent group compared with the conventional group (33% vs 0%, $P = 0.03$). A systematic review of 23 retrospective cohort studies demonstrated a nonsignificant reduction in the rate of postpapillectomy pancreatitis (OR 0.71, 95% CI 0.36–1.40, $P = 0.325$) [41]. A metaanalysis by Spadaccini et al. showed that the only factor affecting acute pancreatitis as an outcome was the placement of a same-session prophylactic pancreatic stent (OR −1.72, 95% CI −2.95 to −0.50, $P = 0.006$) [42]. In general, a 5 Fr or 3 Fr diameter pancreatic stent is used after papillectomy. A metaanalysis of the size of the pancreatic stent after ERCP showed superiority of a 5 Fr pancreatic stent [43].[43] A long (7 cm) pancreatic stent is more useful than a short (5 cm) stent to decrease the incidence of pancreatitis [44].

Other than the conventional method of placing a pancreatic stent after papillectomy, the techniques of biductal sphincterotomy with placement of a pancreatic duct stent before resection [45], pancreatic duct wire-guided endoscopic papillotomy, or retrieval of an intraductal migrated pancreatic stent after endoscopic papillectomy [46,47] have been introduced. Apart from the risk of postprocedural pancreatitis, obstructive cholangitis does not frequently occur except when caused by a clot obstruction due to major bleeding.

Treatment of Remnant Tissue/Intraductal Extension

Snares, biopsy forceps, and thermal ablation, such as argon plasma coagulation, are used to treat remnant tissue. Argon plasma coagulation is the most common technique and is useful for ablating remnant tumor as well as for hemostasis or prophylaxis of postprocedural bleeding. However, it must be applied carefully to the tissues around the pancreatic and bile duct orifices because it may induce a bile duct obstruction or pancreatitis due to the thermal effect.

Treatment of intraductal extension has not been well discussed. Several studies have reported the efficacy of endobiliary radiofrequency ablation (RFA) for intraductal residue after papillectomy [48]. Rustagi et al. reported the results of RFA for intraductal extension of ampullary tumors in 14 patients [49]. Additional modalities (thermal probe, argon plasma coagulation, and/or photodynamic therapy) were used in seven patients, and prophylactic stents were routinely placed. Treatment success was 92%, including 100% of those treated with RFA alone. Adverse events occurred in 43% of patients and included ductal strictures (five patients) and a retroduodenal abscess (one patient), which were successfully treated endoscopically. RFA should be used selectively in patients for whom treatment of an intraductal lesion is appropriate, as other endoscopic modalities are likely to be insufficient.

Clinical Results

Curative resection by endoscopic papillectomy is reportedly achieved in 52–92% of cases [6,16,18,30,50–53]. Multiple procedures may be required to completely remove all adenomatous tissue. Larger lesions are more likely to be incompletely excised during the initial endoscopic procedure. Jaundice, intraductal extension, occult adenocarcinoma in the resected specimen, and piecemeal resection are associated with lower rates of complete resection [27]. The recurrence rate of ampullary adenoma after endoscopic papillectomy ranges from 0% to 33%, over a median follow-up period of 19–65 months. Recurrence of benign lesions occurred in up to 33% of patients depending on the tumor size, final histology, presence of an intraductal tumor, coexistence of familial adenomatous polyposis, and endoscopist experience [16,18,27,51–53].

Complications

Endoscopic papillectomy is considered a less invasive option than surgery but is a high-risk endoscopic procedure. Therefore, the procedure requires the expertise of a specialist. Careful observation after the procedure is important to detect acute complications. Endoscopic papillectomy is associated with an increased risk of postprocedural pancreatitis, which is reported to occur in 3–25% of cases [16,18,51,52]. A systematic review with a pooled analysis by Spadaccini et al. reported that the overall adverse event rate was 24.9%. The most common adverse event reported after endoscopic papillectomy was postprocedural pancreatitis in 11.9%, followed by bleeding in 10.6%. Perforations and cholangitis were reported in 3.1% and 2.7% of cases, respectively. Long-term adverse effects of papillary stenosis occurred in 2.4% of cases. The mortality rate was 0.3% [42].

Pancreatitis occurs due to an obstruction of the pancreatic duct and thermal damage to the pancreatic parenchyma. As described earlier, a pancreatic stent should be placed, although it does not prevent pancreatitis in all cases. Postprocedural bleeding is a serious complication. The duodenal papilla is a hypervascular area, and bleeding is often observed on the anal side of the resected margin [54]. Postprocedural bleeding is treated with adrenaline injection, argon plasma coagulation, or clipping. Hemostatic procedures may cause a perforation or pancreatitis; therefore, excessive hemostasis should be avoided.

Perforations usually occur in the retroperitoneal area. The patient may not have signs of peritoneal irritation. However, pancreatitis or bleeding is often observed concurrently with a perforation. CT evaluation is informative for suspected perforations. If a perforation occurs, surgery may be considered, but select patients can be treated conservatively with antibiotics [16,18,30].

Late adverse events include the development of pancreatic or papillary stenosis [16,18,30,52,53,55], which can be treated endoscopically by stenting or balloon dilation.

Postprocedural Surveillance

Although there is no consensus, postprocedural surveillance is important for detecting local recurrence. The European Society of Gastrointestinal Endoscopy guidelines recommend long-term monitoring of patients.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Postprocedural surveillance is recommended within the first three, six, and 12 months and yearly thereafter for at least five years after endoscopic papillectomy or surgical ampullectomy, based on duodenoscopy with biopsies of the scar and any abnormal area [9].

Some reports indicate that there is a higher risk of developing colorectal neoplasia in sporadic cases of duodenal adenoma including ampullary adenoma [56]. Screening colonoscopy should be performed in patients with duodenal or ampullary adenomas [8].

Conclusion

Endoscopic papillectomy has been established as the first-line treatment for ampullary adenoma without ductal extension. The indications have expanded due to the development of endoscopic techniques and devices. The management of complications and the treatment of remnant or recurrent lesions have also made significant progress. No consensus exists on preprocedural assessment, endoscopic papillectomy technique, management of complications, or postprocedural surveillance.

Surgical Treatment of Papillary and Ampullary Tumors: Management and Long-term Results

Norbert Hüser, Volker Aßfalg, and Helmut Friess

Department of Surgery, Klinikum rechts der Isar, Technische Universität München, Munich, Germany

Introduction

If papillary and ampullary tumors are examined from a surgical point of view, it is important to achieve a sustainable treatment success for the patient through the operation. This is a crucial contribution in an interdisciplinary concept, as the surgeon chooses between local excision of the tumor in the sense of a papillectomy or ampullectomy and the oncologically radical procedure of partial pancreatoduodenectomy. In this respect, ampullary carcinomas must be distinguished from pancreatic head carcinomas near the papilla and distal bile duct carcinomas. The ampulla of Vater represents a special challenge for every surgeon because in this very circumscribed region, there are a large number of anatomic variants in the confluence, course, and joining area of the main bile duct and main pancreatic duct.

Although "carcinoma of the papilla" and "ampullary carcinoma" are usually used synonymously in clinical practice, the technical terms "ampulla" and "papilla" must be clearly distinguished from each other. They describe different depths of penetration of tumorous lesions within the duodenal wall to the head of the pancreas. This chapter outlines the surgical approach, strategically and surgically and against the background of macroscopic appearance and growth form of the tumor, and postoperative long-term results.

Surgical Management of Papillary and Ampullary Tumors

The indication for circumscribed operations of the ampulla is adenomas with missing or varying degrees of histologically proven dysplasia, in which endoscopic removal is not possible. The surgical presentation of these patients is therefore often prompted by gastroenterologists. Their often expressed fear that surgical intervention represents overtherapy of the relatively small lesions must be refuted within the framework of intensive cooperation. Even small lesions must be removed *in toto*. It is undisputed that radical tumor resections come to the fore with increasing T-stage ampullary neoplasms.

Anatomic Variations of the Periampullary Region

Figure 161.1 illustrates the main variant of the ampulla of Vater present in about 85% of all cases with prepapillary union of bile duct and pancreatic main duct and subsequent common channel with or without ampullary dilation. The papilla itself forms only the small elevation above the ampulla with a sphincter (M. sphincter of Oddi). It can protrude a few millimeters into the duodenum and can thus be easily identified either endoscopically or surgically after duodenotomy on the posterior wall of the pars descending about 8–10 cm distal of the pylorus. In about 10%, there is the possibility of a separate mouth of bile and pancreatic main duct. In 5% of cases a common mouth is formed by a single papilla even though the ducts are separated by a septum. In this case a proper ampulla does not exist [1].

Detailed knowledge of these evolutionary variations is particularly important because intraoperatively the ducts must be explored via their confluence points. In this context, it is also essential to obtain information by previously performed duodenoscopy about the formation of a papilla minor, which is usually located proximally. This is where the ductus Santorini ends, which embryonally drains the dorsal bud of the pancreatic

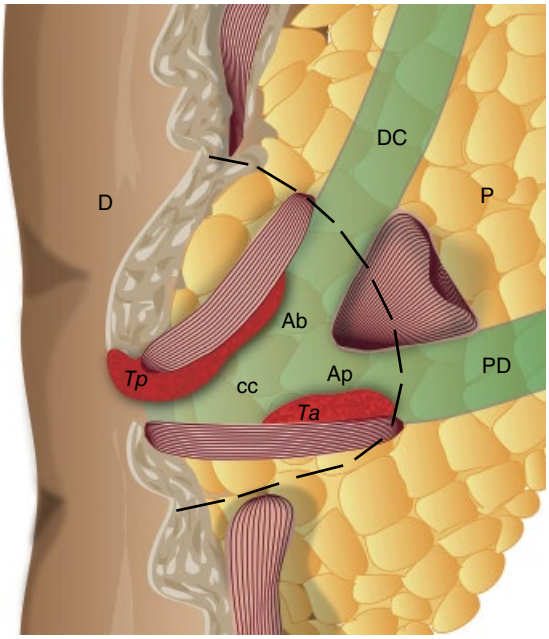

Figure 161.1 Schematic depiction of tumors in the area of the ampulla of Vater. Confluence of ductus choledochus (DC) and pancreatic duct (PD) via an ampullo-biliary (Ab) and ampullo-pancreatic (Ap) segment to a common channel (cc); P, pancreas; D, duodenum; dotted line, ampullectomy. Based on the macroscopic appearance, tumors of the papilla surface (*Tp*) and ampullary tumors (*Ta*) with intramural or intraductal growth can be differentiated. *Source:* Fischer and Zhou [3].

system and can be of varying size. Studies on resectates show that the accessory duct mostly ends blind in the papilla minor, which is then covered by duodenal mucosa [2]. If a lumen can be detected, this must also be intubated with a probe during the operation.

Indications for Surgical Papillectomy/Ampullectomy

In adenomas of the papilla of Vater, malignant tumor cells are frequently detectable. The dysplasias appear to follow an adenoma–carcinoma sequence analogous to colorectal cancer [3]. Biopsies histopathologically confirmed carcinomas in small adenomas in over 20% of cases and in up to 60% in villous adenomas [4]. It is therefore recommended to biopsy lesions even in the presence of endoscopic benign criteria such as soft consistency and sharp limitation, if necessary also in several places and repeatedly, so as not to miss components of a carcinoma located in deeper layers [5,6]. However, biopsy shows poor diagnostic accuracy with a high rate of false-negative results [7].

According to their localization, the following entities can be discriminated (see Fig. 161.1).

- Exposed tumors with polypous growth on the papilla or through the papilla's orifice.
- Intramural, ampullary tumors with polypous growth.
- Intraductal tumors that grow polypously into the lumen of the common channel.

Due to increasing expertise and technical developments, endoscopic removal of adenomas has now come to the fore even in this not always easily approachable region of the gastrointestinal tract [8]. In general, endoscopic papillectomy is considered demanding due to the complex anatomy, thin duodenal wall and very well-perfused tissue layers and is complicated in untrained hands, which is why it should be performed at a center with experience [9]. This makes interdisciplinary cooperation all the more important, as most lesions are discovered incidentally, as part of the further clarification of (endo)sonographically proven pancreatic or bile duct dilation or within a screening program (e.g., familial adenomatous polyposis or a hereditary nonpolyposis-associated colorectal carcinoma).

In the case of a carcinoma finding (bioptic or after endoscopic ablation), it is necessary to initiate a full oncologic TNM staging. Despite modern diagnostics, such as intraductal ultrasound which seems to be superior to endoscopic ultrasound [10], the exact diagnosis of early cancer and particularly the distinction between Tis and T1 remain extremely difficult. Data from a metaanalysis on endoultrasound show a sensitivity (95% CI) and specificity (95% CI) of 77% (0.69–0.83)/78% (0.72–0.84) for T1, 72% (0.65–0.80)/76% (0.71–0.83) for T2, 79% (0.71–0.85)/76% (0.71–0.83) for T3, and 84% (0.73–0.92)/74% (0.63–0.83) for T4 carcinomas [11]. However, this differentiation is important insofar as studies of T1 carcinomas already show locoregional lymph node metastases in up to 9% [12]. Therefore, intraductal tumors, which are often incompletely resected by endoscopy and have a high probability of recurrence [13] and carcinomas, remain clearly a domain of surgery.

The European Society of Gastrointestinal Endoscopy (ESGE) recently presented a corresponding guideline. According to this, for a lesion size of 20–30 mm with high-grade dysplasia or generally a size >40 mm, a surgical procedure is favored. This also applies to carcinomas (starting from carcinoma *in situ*) and a bile or pancreatic duct progression >20 mm [14,15]. However, it is difficult to endoscopicallyremove an adenoma which grows up to 20 mm along the bile or pancreatic duct. Therefore, we strongly favor a surgical approach in these cases. The American Society for Gastrointestinal Endoscopy no longer recommends endoscopic papillectomy in the case of a diagnosed carcinoma [16]. On the other hand, there

Table 161.1 Indications for surgical papillectomy/ampullectomy.

Functional pathology
• morphologic sphincter Oddi dysfunction / *endoscopic failure or technically unfeasible*
Inflammatory pathology
• inflammatory / fibrotic stenosis of Papilla of Vater or common channel of bile / pancreas duct / *endoscopic failure or technically unfeasible*
• stenosis of minor papilla (e.g. pancreas divisum) / *endoscopic failure or technically unfeasible*
Neoplasia
• villous and tubulovillous adenoma / *endoscopic failure or technically feasible,* or >40mm or 20-30mm and high grad dysplasia [14]
• adenoma with intraampullary / intraductal extension 20mm [14]
• carcinoma in situ [14]
• (T1a, N0, M0, G1/2 carcinoma) [15]
• severe co-morbidities (making pancreaticoduodenectomy not feasible)

are no clear recommendations for adenoma recurrences after endoscopic removal. In this context, however, it should be pointed out that the risk of recurrence increases more than tenfold if the lesion cannot be removed in one session [17].

Finally, a surgical ampullectomy may also be indicated in the case of inflammatory stenosis in the area of the common course of the bile/pancreatic duct or its orifice into the duodenum (Table 161.1).

Essential Surgical Steps of Papillectomy/ Ampullectomy

The head of the pancreas and the duodenum must be prepared as far as technically possible to be assessed manually from all sides in order to exclude a locally advanced tumor manifestation. This can be achieved by an extensive Kocher maneuver. In most cases, the papilla region can be palpated and if necessary, for example, a catheter can be pushed antegrade to the papilla via an incision of the bile duct (e.g., by cholecystectomy or choledochotomy).

After sufficiently extensive longitudinal incision of the duodenum in the pars descendens, the papilla is now *exposed* (Fig. 161.2a). Holding threads may help to mark the resection area around the tumor region. In the case of a large or villous adenoma, probing of the bile duct should be carried out for orientation. The actual *papillectomy* defines the separation and circumferential detachment of the sphincter after incision of the mucosa (Fig. 161.2b). This can also be performed in case of large-scale but superficial lesions. The a*mpullectomy* also includes sharp dissection of the bile and pancreatic ducts in their common course and muzzle area with subtle coagulation of mucosal bleeding. These structures should also be stretched with retaining threads to avoid retraction into the parenchyma of the pancreas. Intraductal tumor expansion determines the extent of excision of both the bile and pancreatic duct. A tumor-free resection margin is important, which is why a frozen section procedure is done during the operation. The reinsertion of both ducts into the duodenal wall is usually carried out as a common ostium. For this purpose, both structures are adapted with simple interrupted stitches (Fig. 161.2c), and the existing holding threads are now circumferentially used for the so-called "duct-to-mucosa" anastomosis with the duodenal wall (Fig. 161.2d). It is important to check the resistance-free opening of both ducts with a probe. Finally, the duodenum is closed with a continuous double row suture.

Besides postoperative bleeding, complications include local abscess formation, bile or pancreatic duct leakage, and sometimes severe pancreatitis. Pancreatic fistulas, which appear in less than 10% after local excisions and in about 16% after radical partial pancreatoduodenectomy, must be treated as serious complications. Overall, the surgery-related complications rate for ampullectomy is lower than for partial pancreatoduodenectomy, which is reported to be between 30% and 50% [18]. However, ampullectomy is an infrequently performed operation compared to partial pancreatoduodenectomy and therefore should be limited to one or two surgeons in an appropriate center. Complications after ampullectomy rarely require surgical revision.

Considerations of Ampullectomy Versus Partial Pancreatoduodenectomy

The aim of the surgical procedure is the complete removal of the papilla/ampullary tumor. Well-established surgical procedures are available for this purpose: local excision of the tumor by papillectomy/ampullectomy or oncologically radical, partial pancreatoduodenectomy. The latter procedure is explicitly discussed elsewhere in this book. It is considered the standard procedure for periampullary pancreatic head and distal bile duct carcinomas and is performed in ampullary carcinoma starting at least at tumor stage T1b or detection of lymph node metastases [19]. It includes resection of the duodenum (possibly with antrum of the stomach), distal bile duct, gallbladder, and pancreatic head as well as an oncologic lymph node dissection. Occasionally, alternative

options such as pancreatic head resection in combination with a segmental duodenectomy or a complete resection of the extrahepatic common bile duct and the ampulla are also indicated [20,21].

Due to their exposed location, papilla/ampullary carcinomas can become evident with obstructive jaundice at an early stage. Nevertheless, only about 40% of patients qualify for a surgical procedure after diagnosis [22]. General recommendations for or against local resection of an ampullary tumor have not been published in any surgical guidelines. While patients with a carcinoma *in situ* benefit from limited intervention, there are different views on the extent of surgery in case of a T1a staged cancer. Although isolated reports describe a combination of local lymphadenectomy and ampullectomy [15,23], it must always be taken into account that the initial surgical intervention sets the course for the patient's prognosis. Remaining tumor tissue or affected lymphatic tissue *in situ* is at least associated with a possibly harmful time delay of the subsequent, oncologically radical second intervention. In addition, it must be borne in mind that a local excision procedure cannot provide a reliable lymphadenectomy, especially in the pancreatic head area.

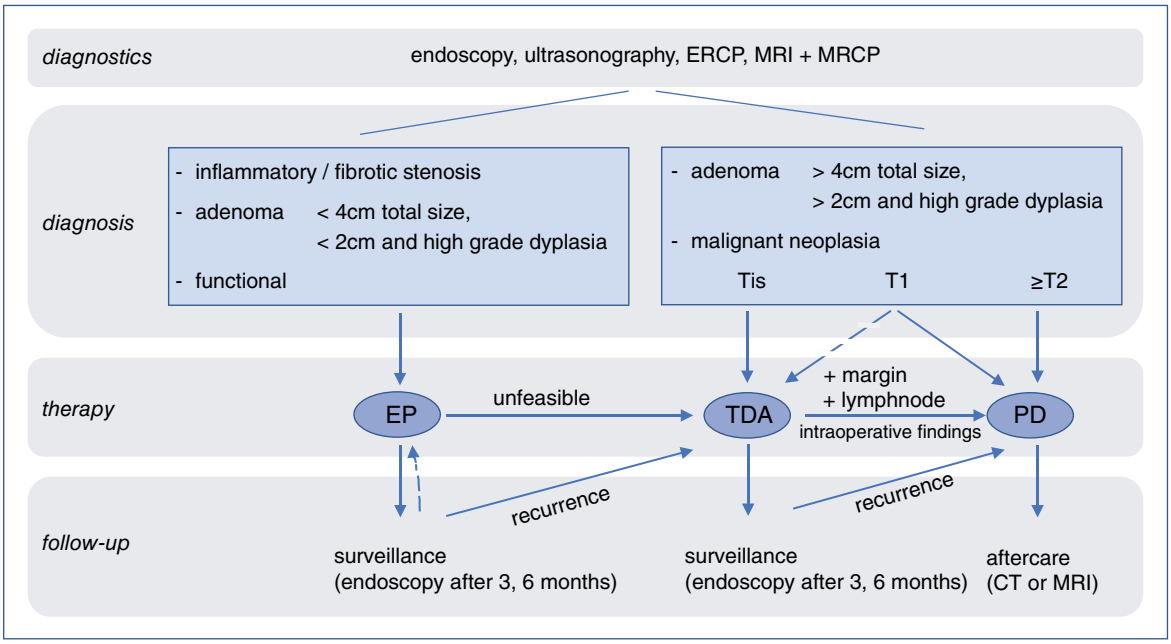
From the curative point of view, there must be no compromises in the choice of surgical procedure, although ampullectomy is a less invasive procedure and is associated with lower morbidity and mortality compared to partial pancreatoduodenectomy [24,25]. In this regard, it has been shown that the age of the patient alone has no influence on morbidity after partial pancreatoduodenectomy and therefore must not be the limiting factor in therapy decision making [26].

The risk for postoperative complications is clearly associated with the texture of the pancreatic parenchyma (soft, firm) and the diameter of the pancreatic duct (≤3 mm, >3 mm). However, these two parameters influence morbidity after ampullectomy or partial pancreatoduodenectomy in the same way.

Whenever a positive lymph node status or a tumor-affected resection margin is revealed during ampullectomy, a change of strategy (if possible intraoperative) towards a partial pancreatoduodenectomy must be determined. In order to avoid this method of therapy escalation in patients with Tis or T1a carcinomas who qualify for a local surgical procedure, attempts have been made in recent years to define preoperative tumor characteristics (such as size, histologic differentiation, or morphology) as predictive factors for lymph node metastases or deeper infiltration of pancreatic parenchyma and common bile duct. These approaches have not succeed.

Winter et al. studied the ampullary tumor size of 450 patients and showed an even more circumscribed growth pattern for adenocarcinomas compared to adenomas (median 2.0 versus 2.9 cm) [27]. In addition, another study revealed lymph node metastases and ductal involvement in 5% and 10% for early carcinomas (Tis, T1, <1 cm), respectively [12]. Therefore, it must be noted again that the procedure of ampullectomy as described in this chapter must be considered as an exception after diagnosis of ampullary carcinoma.

Surgical experience shows that there is often an advanced intraoperative tumor finding that could not be adequately determined in preoperative imaging, hence disqualifying for a local procedure. In many centers, therefore, the detection of a tumor that exceeds carcinoma *in situ* stage (by definition limited to the mucosa) is the indication for partial pancreatoduodenectomy. Postoperative morbidity and surgery-related lethality are comparable to the results after partial pancreatoduodenectomy for pancreatic cancer [12,27]. In contrast to the latter tumor entity, ampullary carcinomas are much less likely to develop portal venous or arterial infiltration [28]. This finding and a frequently observed lower mediodorsal tumor infiltration depth may explain the high R0 rate of over 95% [29].



Currently, there is no evidence for the benefit of neoadjuvant therapy with a curative approach of ampullary carcinoma if surgical resection is possible [30]. Analogous to pancreatic head carcinomas, there is also no indication for preoperative drainage of the bile duct system from the surgical point of view. A timely operation should be sought, as the operation's outcome is not improved by a stent insert [31]. Figure 161.3 outlines a potential algorithm for the treatment of ampullary tumors.

Extension of Lymphadenectomy

As one of the first lymph node stations, the posterior pancreatoduodenal group is affected by lymphogenic metastases [32]. The potential extent of lymph node dissection along the superior mesenteric artery allows the distinction into three levels. Level I leaves the lymphatic tissue surrounding the artery with separation of the mesopancreas, level II additionally includes radicular resection of the inferior pancreatic duodenal artery, the first jejunal artery, and an *en bloc* resection of the mesopancreatic lymph nodes, and level III further includes dissection of the periarterial nerve tissue. Due to the potential involvement of the pancreatoduodenal lymph node groups, radical surgical resection of an ampullary carcinoma should include level II dissection [33].

The classic Whipple procedure and the pylorus-preserving variant of partial pancreatoduodenectomy are presented in detail elsewhere in this book. It should be noted that both methods should be regarded as equivalent both oncologically as well as with regard to

Figure 161.3 Algorithm of endoscopic or surgical approach of pathologies of the ampulla of Vater.

morbidity and postoperative quality of life [34] if the bulb or pyloric region is proven to be free of tumor.

Long-term Results After Operative Therapy

In the presence of benign adenomas, the endoscopic papillectomy, which found its way into the clinic in the 1980s [35,36], has prevailed with a low morbidity rate and good feasibility. To date, however, there are no randomized controlled trials that compare endoscopic procedures and transduodenal ampullectomy surgery in terms of outcome, recurrence, and reintervention rate in both benign and malignant processes. Morbidity is roughly comparable for both procedures (28.3% for ampullectomy versus 24.7% for endoscopic resection) [37,38].

A recently published metaanalysis presents at least an indicative comparison of both therapeutic approaches (surgical ampullectomy or partial pancreatoduodenectomy versus endoscopic papillectomy) for noninvasive lesions, carcinoma *in situ*, and T1 lymph node-negative adenocarcinoma. However, the study comments on the enormous difficulties with regard to meaningful analyses that arose in the course of heterogeneous patient populations, different dysplasia or tumor stages (low grade versus high grade versus T1 with intact or nonpreserved submucosal layer) and various histopathologic tumor entities (intestinal versus pancreaticobiliary) [37].

Overall, there is an obvious superiority of surgery over endoscopy in terms of complete resection (pooled R0 rate 96.4% for ampullectomy versus 76.6% for endoscopic resection versus 98.9% for partial pancreatoduodenectomy). The recurrence rate of benign neoplasms after endoscopic intervention is about 20%, which is higher than after surgical ampullectomy, which is reported to be less than 10% [39].

The postinterventional and surgical control of patients is important, all the more in those cases where a local excision procedure was done despite a malignant lesion. CT scans or MR tomographic cross-sectional imaging, ERCP, and endosonography are limited with regard to accurate statements about the involvement of the distal common bile duct and pancreatic duct beyond the periampullary region. Moreover, despite the lack of evidence of lymphadenopathy, lymph node metastases cannot be excluded in cases of tumor stage of T1a or higher [12]. In the literature, there are only small numbers of cases of endoscopic therapy of T1 adenocarcinomas [40]. The medical societies reflect on these circumstances and accordingly derive their recommendations for surgical therapy of malignant lesions of the ampulla. However, even transduodenal ampullectomy cannot be a standard treatment for T1 carcinomas. When using this local procedure, it is essential to achieve a tumor-free resection margin and negative lymph node status, which was proven by the data of Beger et al. [15]. During a mean

follow-up period of nearly three years, especially those patients with R1 tumor resection showed tumor recurrence. Particular emphasis must be placed on the potential risk of a generalized tumor manifestation at the time of recurrence diagnosis with involvement of other organs, particularly the liver [41].

After partial pancreatoduodenectomy (performed with curative intent), the five-year survival rate across all tumor stages is about 45% [42]. Compared to periampullary carcinomas of the head of the pancreas and distal bile duct, ampullary carcinomas postoperatively show a comparatively favorable prognosis with a longer survival time. This was the result of the evaluation of the American National Cancer Institute database. Within AJCC stages, median survival is 55 months (stage I and II), 26 months (stage III) and 21 months (stage IV) respectively [43,44]. Besides tumor stage, positive lymph node status and perineural sheath invasion, histopathologic differentiation and thus the subtype of ampullary carcinoma play essential roles in the long-term postoperative course [44,45]. The five-year survival rates are below 30% for the pancreatobiliary subtype and over 60% for intestinally differentiated ampullary cancer [46]. The added value of adjuvant chemotherapy seems to be given (if at all) for pancreatobiliary ampullary carcinoma [47].

Conclusion

Ampullectomy and partial pancreatoduodenectomy are standardized surgical procedures for ampullary tumors and carcinomas. Strictly speaking, it makes no sense to compare both operations in terms of long-term outcome from an oncologic point of view because they do not replace each other, but they represent the appropriate treatment concept at different times of a periampullary tumor disease. Ideally, the operation achieves the least invasive but at the same time sufficiently radical procedure, as a fundamental prerequisite for sustainable treatment success for the patient. Of course, in addition to this important decision, surgically independent factors, such as tumor biology and subtype of ampullary carcinoma, play an essential role in long-term prognosis. Both surgical procedures are demanding, so it is essential that they are performed at a center with pancreatobiliary surgical expertise.

Surgical Treatment of Duodenal Cancer

Fuyuhiko Motoi

Department of Surgery I, Yamagata University Faculty of Medicine, Yamagata, Japan

Duodenal cancer is a rare disease. Primary, nonampullary duodenal adenocarcinomas account for about 0.5% of all gastrointestinal cancers. The incidence of duodenal cancer is 5.4 per 1 000 000 people [1]. It accounts for 60–100% of all duodenal malignancies and 30–45% of all small intestinal malignancies. Besides sporadic duodenal adenocarcinoma, other causes of adenocarcinoma include gastrointestinal polyposis syndromes with a genetic background, such as familial adenomatous polyposis, Peutz–Jeghers syndrome, and duodenal polyposis. Early duodenal cancer, which is classified into mucosal and submucosal types, is usually asymptomatic and is typically diagnosed on endoscopic check-ups. Although mucosal tumors with no lymph node metastasis could be treated by endoscopic complete resection [2], feasibility of endoscopic resection for duodenal lesion depends on location, depth, and size of tumor [3].

Long-term survival with submucosal or more advanced tumors, however, requires complete surgical resection. The standard surgical procedure for the disease is pancreatoduodenectomy (PD) with regional lymph node dissection (lymphadenectomy) [4]. The regional lymph nodes include nodes along the inferior pancreatoduodenal artery and first jejunal artery, infra- and suprapyloric nodes, nodes along the common hepatic artery, and nodes on the posterior and superior surface of the pancreatic head. Since these pancreatoduodenal lymph node stations are commonly involved in duodenal adenocarcinoma [4], *en bloc* regional node dissection requires total mesoduodenum excision. Segmental resection (limited resection: LR) of the duodenum can be performed in some cases, depending on the location and extent of the tumor. Partial segmental resection can achieve negative margins in tumors in the proximal (first part) or distal part (distal third or fourth part) of the duodenum, and the long-term survival outcome of LR for selected patients with such tumors, especially those located in the third or fourth portion of the duodenum and those with T1a/T1b stage cancers, is comparable between PD and LR [5–7].

The most significant prognostic factor for duodenal cancer is resectability. In the absence of distant metastasis, curative resection (R0 resection) determines the outcome in patients with duodenal cancer. Since the year 2000, the five-year survival rate after curative surgery has been reported to be 17–74% (Table 162.1) [1,4,8–18]. The results obtained are 40–60% reproducible, as reported by a large (more than 100 cases) series [10,12,13,15–17]. In another report, the TNM stage was higher in patients with nonampullary duodenal cancer than in patients with ampullary duodenal cancer [14]. Deep extension of the primary tumor (T), presence of nodal metastases (N), margin-positive resection (R), large size of tumor, poor histologic grade, and higher age are reportedly associated with a poor prognosis after resection [6,16,19]. However, after adjusting for TNM stage, no significant difference in survival was observed between ampullary and nonampullary duodenal cancer [14].

Database analysis of the largest series of stage I–IV cancers [19] showed five-year survival rates of 65.9%, 50.4%, 31.4%, and 11.9%, respectively, for the four cancer stages. The common recurrence sites were locoregional, intraabdominal distant organs, including the liver and peritoneum, and extraabdominal distant organs, including the lungs.

Systemic chemotherapy or chemoradiotherapy is administered after resection of advanced disease to prevent relapse in the setting of good postoperative performance status. However, the role of adjuvant therapy and/or neoadjuvant therapy for patients with duodenal cancer has not yet been established [6,20,21]. Additionally, survival outcomes after resection of duodenal cancer

Introduction

Extrahepatic bile duct tumors have been conventionally classified into perihilar and distal tumors from a surgical standpoint. The standard procedures are major hepatectomy for the former and pancreaticoduodenectomy for the latter. According to the 8th edition of the American Joint Committee on Cancer (AJCC) staging manual, tumors with their center located between the confluence of the cystic duct and common hepatic duct and the ampulla of Vater are considered distal bile duct tumors [1]. The TNM staging system of distal tumors is separate from perihilar tumors because their pathologic features, surgical approach, and prognosis are different.

Distal cholangiocarcinoma is a relatively uncommon disease, comprising approximately 30% of all cholangiocarcinomas [2]. Although pancreaticoduodenectomy is commonly selected as a surgical procedure for pancreatic head cancer and distal cholangiocarcinoma, a minor procedure for each type of tumor is necessary as biologic behavior is different. Because the prevalence of distal cholangiocarcinoma is lower than that of pancreatic head carcinoma, a limited number of publications focus solely on the clinicopathologic features of distal cholangiocarcinoma. Hospital mortality after resection in high-volume centers for distal cholangiocarcinoma is 0–7% (Table 163.1) [3–11]. The most common surgery-related complication is pancreatic fistula (7–53%) (see Table 163.1) [3,5,8,9,12] because patients have a normal soft pancreas with a thin main pancreatic duct in most cases of distal cholangiocarcinoma.

The five-year overall survival after resection of distal cholangiocarcinoma ranges from 24% to 50% (see Table 163.1) [3–13]. Lymph node metastasis is commonly observed (22–68%) (see Table 163.1), and this is a major factor that determines prognosis after surgery [3–14]. Other important prognostic factors are depth of invasion [6,8,10,12], pancreatic invasion [3,4,6–10,14], perineural invasion [3,4,6–8,14], tumor histology [4–6,8,9], and resection margin status [4–7,9–12,14]. Therefore, the surgical approach for distal cholangiocarcinoma should be carefully modified depending on tumor location, longitudinal or extramural tumor extension, lymph node status, and perineural involvement.

Pyloric Ring Preservation Versus Resection

Pylorus preservation or resection is a major option in pancreaticoduodenectomy. One of the merits of removing the pyloric ring is the removal of lymph nodes in the perigastric region. However, perigastric lymph node metastasis is not frequently involved in distal cholangiocarcinoma [15]. Based on these observations, pylorus-preserving pancreaticoduodenectomy is indicated in almost all patients with distal cholangiocarcinoma. Randomized controlled trials comparing the clinical outcome between pylorus-preserving pancreaticoduodenectomy and conventional pancreaticoduodenectomy (thus removing perigastric lymph nodes) for patients with periampullary carcinoma showed no significant difference in long-term survival between the two procedures [16,17]. However, this concept is not applicable in patients with a tumor in the middle region of the extrahepatic bile duct because the tumor is generally proximate to the duodenal bulb. Therefore, removal of the duodenal bulb together with the pyloric ring may be the method of choice for obtaining a safe surgical margin.

Maeta [4]	2017	453	57	–/52/42	4	68	–

This procedure is necessary for a case with severe extramural tumor growth.

Lymph Node Dissection

Lymph node metastasis is one of the most important factors affecting survival of patients with distal cholangiocarcinoma [3–6,8,10–14]. The five-year overall survival after resection is 4–36% in patients with nodal involvement and 30–73% in those without [3,4,6–12,14]. In addition, the number of involved nodes works as a determinant of cancer progression in distal cholangiocarcinoma 7,11,13,14,18–21]. In a report by Kiriyama et al. analyzing 370 patients with distal cholangiocarcinoma [6], the median survival time shortened with increasing number of involved lymph nodes: 2.2 years in patients with 1–3 metastatic nodes and 1.3 years in those with four or more (Fig. 163.1).

The total lymph node count (TLNC), defined as the total number of lymph nodes examined histologically, is another important predictor of survival because inadequate assessment of lymph nodes, due to either an insufficient extent of resection or pathologic examination, results in understaging of cancer [22,23]. It should be noted that TLNC substantially differs depending on the extent of lymphadenectomy and additional organ resection. In particular, TLNC can vary depending on

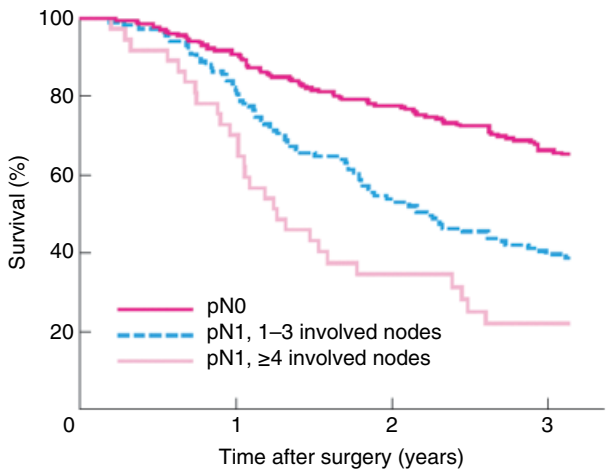

Figure 163.1 Overall survival according to the number of involved nodes in 370 patients. $P < 0.001$ (pN0 versus pN1, 1–3 involved nodes; pN0 versus pN1, 4 or more involved nodes) (log-rank test). *Source:* [6]/Oxford University Press.

the extent of lymphadenectomy for the perigastric and mesenteric lymph nodes. The AJCC recommends a "12-node minimum" for distal cholangiocarcinoma to prevent inadequate staging [1], but the supporting evidence for this number is ambiguous. Kiriyama et al. reported that TLNC considerably affected survival among 206 patients with pN0 disease who underwent R0 resection, who were divided into three groups according to TLNC (less than 10, 10–19, 20 or more). The three-year survival rates were 50%, 68%, and 71%, respectively [6]. Hence, a minimum of 10 nodes may be sufficient for pathologic nodal assessment in distal cholangiocarcinoma.

The total lymph node count also changes the lymph node ratio (LNR) results, calculated as a ratio between the number of lymph node metastases and TLNC because the greater the TLNC is, the lower the LNR. According to the report by Kiriyama et al., the median (range) TLNC was 19 (3–59) [6]. Nodal metastasis occurred in 157 patients (42.4%); the median (range) number of involved nodes was 2 (1–19), and the LNR was 0.11 (0.02–0.80). An LNR lower than 0.17 was associated with a significantly shorter median survival (1.3 vs 2.2 years). Another report by Kawai et al. indicated that an LNR >0.2 is an important factor for predicting survival after resected distal cholangiocarcinoma [14].

For distal cholangiocarcinomas, the location of nodal involvement differs among tumor locations, according to the report by Kayahara et al., which compared the lymph node stations between the middle third (N = 14) and lower third (N = 36) of cholangiocarcinomas [12]. In the former tumor, nodes along the common hepatic artery, in the hepatoduodenal ligament, and in the posterior pancreatoduodenal region were frequently involved with an incidence of 7%, 50%, and 7%, respectively. Interestingly, there was no lymph node metastasis in nodes around the superior mesenteric artery. In contrast, there was less nodal involvement in nodes along the common hepatic artery and more involvement in posterior pancreatoduodenal nodes in patients with lower-third cholangiocarcinoma. Notably, in 28% of patients with lower-third cholangiocarcinoma, there was lymph node metastasis in nodes around the superior mesenteric artery, with the highest frequency in nodes at the origin of the inferior pancreatoduodenal artery.

These differences in the state of cancer spreading through lymphatic vessels and lymph nodes should be considered preoperatively when planning a surgical approach for distal cholangiocarcinoma. Lymph node dissection along the superior mesenteric artery is recommended for the lower-third cholangiocarcinoma rather than the middle tumor. A thorough lymph node dissection along the superior mesenteric artery requires combined resection of the mesentery along the first jejunal artery and vein.

Skeletonization of the Hepatoduodenal Ligament and Dissection of Pancreatic Head Neural Plexus

Neural plexus invasion is a potential prognostic factor in cholangiocarcinoma ([4,6]. According to the recent extensive study by Maeta et al. (N = 453), the overall incidence in distal cholangiocarcinoma was 67% [4]. The five-year survival rate for patients with perineural invasion was significantly lower than those without (56% vs 33%) [4]. Neural invasion was observed more frequently with tumor progression [24]. Therefore, skeletonization of the hepatoduodenal ligament, including removal of the neural plexus around the hepatic artery and portal vein, is recommended for the treatment of advanced distal cholangiocarcinoma.

In this procedure, the proximal bile duct was transected basically at the level of the right hepatic artery or more proximally, as needed. Regional lymph node dissection was undertaken as far as possible (Fig. 163.2) [25].

Bile Duct Cut Margin

It is now widely recognized that margin status is one of the robust predictors of long-term survival in cholangiocarcinoma [26]. After surgical resection for extrahepatic cholangiocarcinoma, invasive carcinoma at ductal resection margins appears to have a substantial adverse effect on patient survival. Superficial spreading, defined as a noninvasive cancer extension of more than 20 mm, is sometimes observed in cholangiocarcinoma, accounting for approximately 15% of all tumors, according to Igami

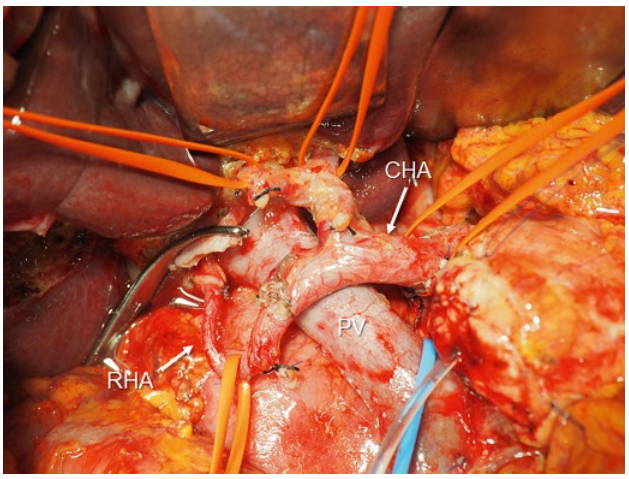

Figure 163.2 Skeletonization of the hepatoduodenal ligament. RHA, right hepatic artery; CHA, common hepatic artery; PV, main portal vein.

et al. [27]. Histologically, superficial spreading is more commonly observed in papillary and well-differentiated adenocarcinomas than in other types of carcinoma [27]. Because superficial spreading has a high risk at positive ductal margins, the extent of superficial spreading from the main tumor should be carefully examined using cholangiography, intraductal ultrasonography, and/or biliary biopsy. It is also important to examine the proximal bile duct cut margin by intraoperative frozen section histology.

Nonetheless, extensive spread of cancer beyond the macroscopic tumor mass is often observed in cholangiocarcinoma. Ebata et al. proposed that a 10 mm margin for invasive cancer and 20 mm margins for noninvasive components are required on the ductal stump to accomplish R0 resection [28].

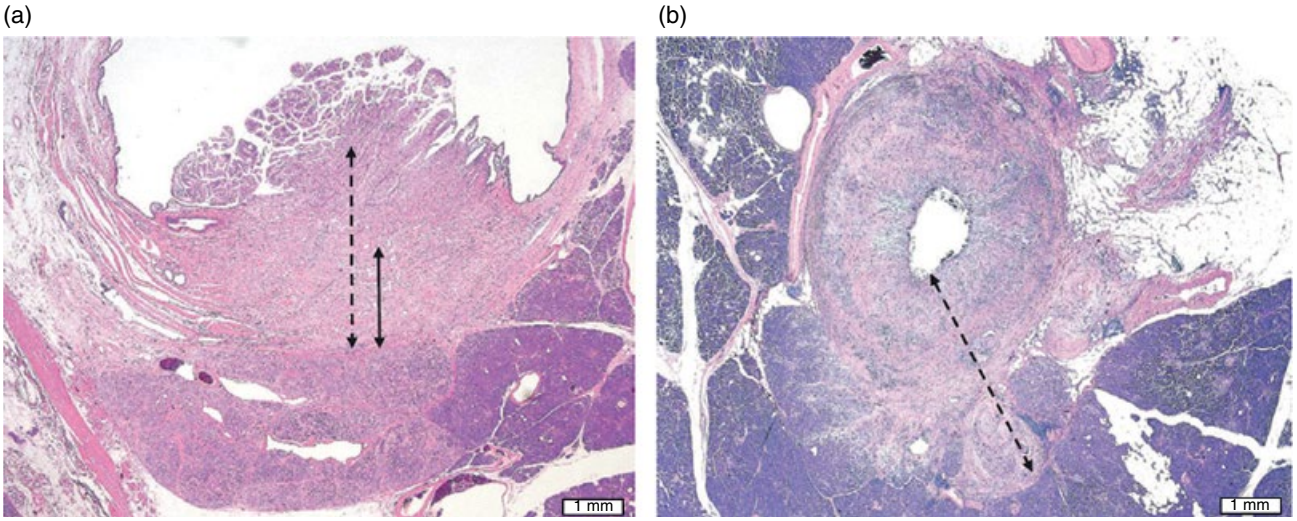
Notably, the clinical significance of residual carcinoma *in situ* at the bile duct cut margin is controversial. Several reports have indicated that residual carcinoma "*in situ*" in the proximal cut margin of the bile duct does not have an impact on survival [27,29,30]. However, a positive margin with "invasive" carcinoma is an independent risk factor for poor survival after surgery for distal cholangiocarcinoma [6,11,12]. Importantly, residual carcinoma "*in situ*" in the ductal stump potentially progresses to local recurrence and shortens postoperative survival in patients with early-stage cholangiocarcinoma. However, this prognostic effect was less severe than that of residual "invasive" carcinoma. Residual carcinoma "*in situ*" should be avoided as much as possible in surgery for early-stage cancer [31].

Tumor Depth

The T classification is used exclusively for pathologic staging, but it cannot be used to determine local unresectability and subsequent surgical procedures. However, because it is commonly associated with several prognostic factors, a preoperative assessment of T classification is needed.

In the eighth edition of the AJCC cancer staging classification [1], the T system for distal cholangiocarcinoma has been revised from a layer-based to a depth-based approach. Hong et al. first proposed a depth-based approach for the T system using the measured depth of invasion (DOI), with cutoff values of 5 and 12 mm [32]. DOI was defined as the vertical distance between the basal laminae of the adjacent normal/dysplastic bile duct and the advancing infiltration of cancer cells (Fig. 163.3). However, DOI was measurable in less than half of the patients because it is necessary to observe the clear basal lamina bounding the tumor with the most extensive cancer infiltration on the same histologic slide for accurate measurement of DOI [24]. Cancer infiltration, associated cholangitis, and catheter placements evoke fibrosis inside and outside the bile duct wall, often precluding clear visualization of the basal lamina.

The low frequency of measurability of DOI in bulky tumors and the high frequency in papillary tumors suggest that DOI cannot easily be measured in advanced tumors. In this regard, invasive tumor thickness (ITT), defined as the maximal vertical distance of the invasive cancer component, was measured (see Fig. 163.3).



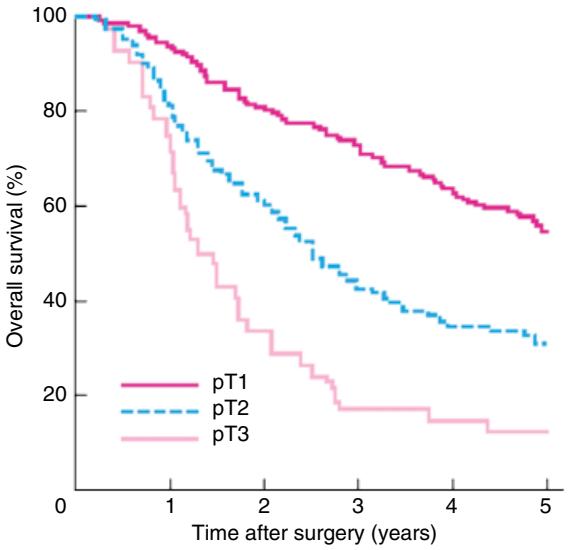


Figure 163.3 Depth of invasion (solid line) and invasive tumor thickness (dotted line) in (a) papillary and (b) nonpapillary tumor morphology. Both specimens were sectioned axially to the bile duct. Depth of invasion is not measurable in (b) because the basal lamina of the bile duct is not observed in the circumferentially thickening tumor (hematoxylin and eosin stain; scale bar 1s>mm). *Source:* [24], John Wiley & Sons.

In 222 patients with a missing depth of invasion (DOI), invasive tumor thickness (ITT) was used as an alternative to DOI for T assignment. $P < 0.001$ (pT1 versus pT2), $P = 0.001$ (pT2 versus pT3) (log-rank test). *Source:* [24]/Oxford University Press.

Survival curves according to T classifications of the AJCC eighth edition stratified by ITT are shown in Figure 163.4.

Portal Vein Resection

Pancreaticoduodenectomy combined with portal vein (PV) resection is an extended procedure that is often undertaken for pancreatic head cancer but is rarely performed for distal cholangiocarcinoma. Maeta et al. investigated the clinicopathologic features associated with PV resection using 453 patients who underwent pancreaticoduodenectomy, which is the largest series of PV resections in patients with distal cholangiocarcinoma [4]. Of these, 31 (6.8%) had combined PV resection. Postoperative morbidity and mortality were not different in those with or without PV resection. Portal vein invasion is associated with locally advanced disease. Consequently, the incidence of R1/2 resection was higher in this group (32% vs 12%). Survival among the patients with PV resection was worse than for the patients without PV resection (15% vs 42% at five years) (Fig. 163.5).

Considering the poor survival of patients with PV resection, distal cholangiocarcinoma with suspected PV invasion may be categorized as a borderline resectable tumor,

No. at risk

No PV resection	422	352	274
PV resection	31	22	7

and the establishment of neoadjuvant chemotherapy and adjuvant chemotherapy for such patients seems urgently needed [4].

Surgery-Related Complications of Pancreaticoduodenectomy

The morbidity and mortality rates after resection of distal cholangiocarcinoma are 17–69% and 0–7%, respectively (see Table 163.1) [3–12]. Patients generally have a normal soft pancreas with a small main pancreatic duct. Therefore, the rate of pancreatic fistula is higher in patients with distal cholangiocarcinoma (7–53%; see Table 163.1) than in patients with pancreatic head cancer [3,5,8,9,12]. Other common complications include biliary fistula (0.1–3%) [8,9], delayed gastric emptying (0.1–7%) [5,8,9], and bleeding (3–11%) [5,8,9,11].

Bile Duct Resection as a Minimally Invasive Surgical Procedure

Bile duct resection can be considered an alternative approach in high-risk patients with middle-third distal cholangiocarcinoma but provides a worse long-term outcome [25,33]. Jikei et al. reported a detailed surgical comparison between bile duct resection and pancreaticoduodenectomy [25]. Bile duct resection was characterized by shorter operation time, less blood loss, less

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

frequent complications, and lower mortality. However, the incidence of positive surgical margins was 26.3% in bile duct resection, in contrast to 5.6% in pancreaticoduodenectomy. The survival rate after bile duct resection was significantly worse than that after pancreaticoduodenectomy (38.8% versus 54.8% at five years). Meanwhile, "tumor length <15 mm" and "ductal margin length ≥10 mm" were favorable factors in bile duct resection. Therefore, it was proposed that a clinical guide for optimal candidates for bile duct resection included either or both of these favorable factors [25].

Conclusion

When a surgeon performs a pancreaticoduodenectomy for distal cholangiocarcinoma, dissection of the pyloric ring (pylorus-preserving, subtotal stomach-preserving, or conventional pancreaticoduodenectomy), the extent of lymph node dissection (dissect lymph nodes along the superior mesenteric artery or not), skeletonization of hepatoduodenal ligament, and the proximal cut line of the bile should be carefully designed based on tumor location as well as tumor extension.

Adjuvant and Palliative Chemotherapy of Periampullary Cancers

Arachchige D.N.R. Ponweera[1], Paula Ghaneh[1], and John P. Neoptolemos[2]

[1] *Department of Molecular and Clinical Cancer Medicine, University of Liverpool, Liverpool, UK*
[2] *Department of Surgery, University of Heidelberg, Heidelberg, Germany*

Introduction

The term "periampullary cancer" encompasses three pathologically distinct tumor subtypes which are in close anatomic proximity to the pancreatico-ampullary apparatus, including tumors arising from the distal common bile duct, ampulla of Vater, and duodenum. The incidence of these tumors remains low, with European figures ranging between 0.3 to 0.84 per 100,000 population, placing them within the European Union definition of rare cancers [1,2]. These tumors possess different biologic and molecular characteristics, but they are often grouped together as their curative surgical approach would usually mandate a pancreaticoduodenectomy [3,4]. Occasionally, the true pathologic origin of the malignant process is difficult to establish until full histologic assessment of the specimen is performed [5]. The heterogeneity of the histologic and biologic profiles has profound implications for their long-term survival rates and response to available chemotherapy regimens [5,6].

Periampullary tumors demonstrate a higher resectability rate, in contrast to pancreatic tumors. The ideal treatment is surgical resection, which offers a chance of cure and prolonged survival in 60–80% of patients with resectable disease on presentation [7]. The remainder usually present with manifestations consistent with locally advanced disease or evidence of distant widespread metastasis. The mainstay of therapy in this setting is palliation of symptoms, with relief of jaundice, alleviation of pain, and provision of nutritional support [8]. The focus on prolonging survival by the use of adjuvant and palliative treatments should not overlook the psychologic and emotional aspects for patients affected with this debilitating disease.

At present, the overall prognosis remains bleak despite adequate tumor clearance by surgical resection as the locoregional and distant relapse incidence rates are known to be high in these tumors [9]. Surgical resection alone is associated with five-year survival rates of 20–30%. The worst prognosis is associated with positive local lymph nodes and involved surgical margins [5,10,11]. Given the above, attempts to improve long-term survival by the addition of adjuvant chemotherapy have been tested in various clinical studies.

Most of the evidence in published literature on the use of adjuvant and palliative chemotherapy is limited to institutional retrospective case series and often contains a mixture of periampullary and pancreatic tumors with limited randomized controlled trials. The heterogeneity and quality of the evidence can lead to conflicting results about the genuine value of chemotherapy in periampullary cancers. The inherent rarity of these tumors has governed the paucity of published useful data that could be translated into effective clinical and oncologic management paradigms.

Distal Cholangiocarcinoma

Adjuvant Therapy

Patients with distal cholangiocarcinoma have the worst prognosis among periampullary cancer patients. The long-term survival figures resemble those achieved in pancreatic adenocarcinoma. Tumors arising within the intrapancreatic portion of the distal bile duct account for approximately 27%–40% of all cholangiocarinomas cholangiocarcinomas [12,13]. These are closely linked to tumors arising in the proximal pancreatic duct as they

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

share the same embryologic origins with common phenotypic and functional characteristics. This supports the hypothesis that they should be considered as a congruent disease entity [14].

Takada et al. [15] conducted one of the first phase III randomized controlled trials in Japan with adjuvant 5-fluorouracil (5-FU) and mitomycin C in 508 patients with resected pancreaticobiliary tumors (including 139 patients with cholangiocarcinomas) compared to surgery alone and concluded that adjuvant chemotherapy compared to surgery alone did not have an impact on the five-year survival rate (26.7% vs 24%).

Following this, the European Study Group for Pancreatic Cancer 3 (ESPAC-3) periampullary trial was designed to explore the benefit of adjuvant chemotherapy on overall survival in patients with resected periampullary cancer [16]. In this study, 428 patients (of whom 96 had cholangiocarcinomas) were randomized to either fluorouracil or gemcitabine-based chemotherapy versus surgery alone. The use of adjuvant treatment was associated with a potential survival advantage that did not reach statistical significance (median 43 months vs 35 months; hazard ratio [HR] 0.86; 95% confidence interval [CI] 0.66–1.11) but on multivariable analysis and after adjusting for prognostic variables, a statistically significant survival benefit was demonstrated with adjuvant chemotherapy with HR 0.75 (95% CI 0.57–0.98; $P = 0.03$). The median survival of patients with cholangiocarcinoma assigned to observation, fluorouracil plus folinic acid, or gemcitabine arms was 27.2, 18.3, and 19.5 months, respectively.

More recently, the BILCAP study [17] was a phase III randomized controlled trial conducted within the UK, primarily assessing survival outcomes between adjuvant capecitabine or observation alone following resection for confirmed cholangiocarcinoma or muscle-invasive gallbladder cancer. In this trial of 447 patients (of whom 156 had distal cholangiocarcinomas), no statistical significance was noted on overall survival in the intention-to-treat analysis. However, sensitivity analyses in this population proved a statistical significance following adjustment for prognostic factors (nodal status, grade of disease and sex, and minimization factors resulting in an overall survival HR of 0.71 (95% CI 0.55-0.92; $P = 0.010$). A statistically significant advantage was demonstrated for overall survival in the per-protocol analysis population in which median overall survival was 53 months and 36 months for capecitabine and observation respectively (HR 0.75; 95% CI 0.58–0.97; $P = 0.028$).

Concurrent with the BILCAP study, the PRODIGE 12-ACCORD 18 (UNICANCER GI Group) study [18] was a randomized phase III trial conducted in 33 centers in France with a total of 194 patients, to investigate beneficial outcomes with adjuvant gemcitabine and oxaliplatin chemotherapy (GEMOX) over observation following resection of biliary tract cancers (of whom 55 had distal cholangiocarcinomas). This study primarily investigated disease-free survival (DFS) following adjuvant GEMOX or observation and no statistically significant result was noted (median 30.4 months vs 18.5 months; HR 0.88; 95% CI 0.62–1.25; $P = 0.48$). No significant result was noted with overall survival either (median 75.8 months vs 50.8 months; HR1.08; 95% CI 0.70–1.66; $P = 0.74$).

These studies have demonstrated evidence for the use of adjuvant therapy (Table 164.1). Horgan et al. [11] conducted a large metaanalysis of 20 studies, which included a randomized trial of chemotherapy, two registry, and 17 institutional series. The treatment protocol contained chemotherapy alone in three studies, radiotherapy only in nine, while eight studies contained radiation and chemotherapy combinations. There was a total of 6712 patients, of whom 1797 received some form of adjuvant treatment during the course of their disease and 4915 in the surgery-only group. In this metaanalysis, the improvement in five-year survival with any adjuvant therapy was not statistically significant (pooled odds ratio [OR] 0.74; 95% CI 0.55–1.01); however, the survival benefit from adjuvant therapy was statistically significant when the data from the two large registry series (N = 1233 patients) were excluded (OR 0.53; 95% CI 0.39–0.72). Pooled data extracted from the studies confirmed a statistically significant overall survival advantage for any adjuvant therapy in node-positive disease (OR 0.49; 95% CI 0.30–0.80) and patients with margin-positive disease (OR 0.36; 95% CI 0.19–0.68).

These studies have demonstrated survival benefit for the use of adjuvant treatment in patients with cholangiocarcinoma, especially in those with poor prognostic indicators [22,23]. Currently, there are two randomized controlled trials under way of adjuvant therapy in patients with resected cholangiocarcinoma. The ACTICCA-1 trial compares adjuvant combination therapy with gemcitabine and cisplatin against the standard treatment of capecitabine and is due to publish it's findings by 2024. The ASCOT trial, which compares adjuvant S-1 chemotherapy versus observation alone, has completed recruitment and the results are due to be published.

Palliative Therapy

The benefits of systemic chemotherapy in addition to best supportive care in patients with metastatic and recurrent distal cholangiocarcinoma are well established. Patients treated with chemotherapy were noted to have a significantly better median overall survival of more than six months with a better quality of life. The reported high incidence of local relapse and distant recurrence would

advocate early referral for palliation treatment in patients with satisfactory performance status [22,24].

Eckel and Schmid [25] performed a pooled analysis of 104 trials examining the role of chemotherapy in advanced biliary tract cancer, which showed combination treatment to have a better effect compared to monoagent therapies. The gemcitabine- and platinum-based combinations demonstrated the greatest benefit in the pooled analysis.

The randomized phase III ABC-02 study [26] of up to six months of gemcitabine versus gemcitabine and cisplatin recruited 410 patients (73 distal cholangiocarcinomas) with unresectable, recurrent, or metastatic biliary tract carcinoma (Table 164.2).This trial demonstrated a significant overall survival advantage with the combination arm versus the gemcitabine arm (11.7 months vs 8.1 months; HR 0.64; 95% CI 0.52–0.80) and a median progression-free survival of 8.0 months versus 5.0 months (HR 0.63; 95% CI 0.51–0.77), respectively. Patients who received the combination therapy were 36% less likely to die at any time compared to those who received gemcitabine alone (HR 0.64; 95% CI 0.52–0.80). Grade 3 and 4 toxicities occurred with similar frequency in both study arms without any substantial difference. The combination of gemcitabine and cisplatin is the first-line treatment of choice recommended by

the European Society of Medical Oncology (ESMO) [31] in patients with favorable performance status (PS 0–1). Patients with PS 2 should be considered for gemcitabine monotherapy while oxaliplatin could be substituted for cisplatin in patients with impaired renal function.

Following the findings of the ABC-02 trial, the ABC-06 study [30] was completed recently. This was a phase III randomized controlled trial that compared second-line chemotherapy consisting of FOLFOX and active symptom control (ASC) versus ASC alone in patients with advanced or metastatic biliary tract cancers who had already undergone first-line chemotherapy with cisplatin and gemcitabine. A total of 162 patients were analysed (out of whom 45 had extrahepatic cholangiocarcinoma) and a statistically significant outcome was observed in overall survival. Median overall survival of 6.2 months and 5.3 months was noted in adjuvant FOLFOX and ASC and ASC-only cohorts respectively (HR 0.69; 95% CI 0.50–0.97; P = 0.031). Grade 3 and 5 toxicities were 69% in the FOLFOX and ASC cohort and 52% in the ASC-only cohort, with the most frequently reported adverse event being neutropenia.

Duodenal Adenocarcinoma

Adjuvant Therapy

Complete surgical resection with regional lymphadenectomy confers prolonged survival for patients with duodenal cancer. Important prognostic factors include the degree of tumor differentiation and local lymph node involvement. Several studies have shown no survival benefit for the routine use of adjuvant chemotherapy in completely resected, nodal disease-free duodenal adenocarcinoma [33,34].

The global low incidence of duodenal adenocarcinoma and challenges in conducting adequately powered future studies were reflected in the ESPAC-3 trial which contained only 10 patients with duodenal adenocarcinoma in addition to 25 nondescriptive periampullary tumors out of the original study cohort (see Table 164.1). The eight patients who were assigned to observation in this group survived a median of 28.7 months (95% CI 4.7–∞ months); 12 patients in the fluorouracil plus folinic acid group survived 22.4 months (95% CI 9.6–54.6 months), and 15 had high but not estimable survival with gemcitabine therapy [16].

There is currently no agreed regimen as a first-line therapy but many centers would advocate the use of adjuvant oxaliplatin-based chemotherapy in patients with high-risk features (e.g., nodal metastasis) similar to the recommendations for resected colonic adenocarcinoma. Other regimens which demonstrated disease-related activity are capecitabine and oxaliplatin (CAPOX), 5-FU and leucovorin with oxaliplatin (FOLFOX), and 5-FU and leucovorin with irinotecan (FOLFIRI) [28,29,35]. To date, there are no randomized controlled trials testing the superiority of any of these combinations.

Chemoradiation has been tested in the adjuvant setting and showed improvement in locoregional control but this did not translate into any survival benefit [36]. In a retrospective series published by Poultsides et al. [21] from a single institution, 122 patients with local lymph node involvement showed no difference in overall survival with adjuvant chemoradiotherapy compared to patients who underwent surgery alone (five-year survival 47% vs 48%; P = 0.82) [37].

An international collaboration for the study of rare tumors has launched an open-label, randomized controlled multicenter trial (BALLAD) to assess the efficacy of six months of adjuvant chemotherapy compared to observation only in stage I–III resected small bowel adenocarcinoma. The study will also compare fluoropyrimidine monotherapy versus fluoropyrimidine plus oxaliplatin. Recruitment into the study is currently ongoing and is expected to finish by 2022.

Palliative Therapy

A number of studies support the use of palliative chemotherapy in patients with recurrent and metastatic duodenal adenocarcinoma (see Table 164.2) as it adds a clear survival benefit over best supportive care [33,38,39]. The Eastern Cooperative Oncology Group (ECOG) published one of the early studies on 31 patients with locally advanced and metastatic small bowel tumors who received combination treatment 5-FU, doxorubicin, and mitomycin C with a median survival of eight months [27].

Zaanan et al. [28] published results of a retrospective study of 99 patients with advanced and metastatic small bowel adenocarcinoma (55 duodenal) comparing first-line treatments with FOLFOX, leucovorin–FU, FOLFIRI, and leucovorin–FU–cisplatin. In the report, 48 patients with advanced cancer who received FOLFOX as front-line therapy had a median progression-free survival of 7.4 months and median overall survival of 17.8 months. A study by Overman et al. [29] conducted at the M.D. Anderson Cancer Center evaluated the combination of capecitabine and oxaliplatin (CAPOX) in 30 patients with either metastatic or locally advanced small bowel or ampullary adenocarcinoma. In the 18 patients who had small bowel adenocarcinoma, the response rate was 61%, with a median time to progression of 9.8 months and median overall survival of 20.4 months. Of note, 10% of treated patients had a complete radiographic response to CAPOX therapy. The treatment combination of fluoropyrimidine and oxaliplatin was also reported to have a better disease activity in phase II randomized con-

trolled trials. Three studies, including that by Overman et al., combining fluoropyrimidine with oxaliplatin have shown similar activity, with response rates of 42–50% and a median time to progression ranging from 7.8 to 9.8 months [29,40,41].

Other studies have tested different agents, including irinotecan- and gemcitabine-based treatments which were found to have some disease activity in a small number of patients [28]. Targeted therapies such as antivascular endothelial growth factor receptor (VEGFR) or antiepidermal growth factor receptor (EGFR) therapies have not been evaluated in any formal study as yet and therefore there is currently no evidence to support their use outside the context of experimentation in a clinical trial.

Ampullary Carcinoma

Adjuvant Therapy

Ampullary carcinomas constitute 0.2% of the tumors arising in the gastrointestinal tract. These tumors show different immunohistochemical differentiation and molecular characteristics, including alterations of *KRAS*, *SMAD4*, and *APC* genes. The intestinal subtype mimics behavioral and oncogenic responses similar to duodenal adenocarcinoma, while the pancreaticobiliary subtype tends to be more aggressive, resembling pancreatic ductal adenocarcinoma with poor prognosis and unfavorable outcomes [42–45].

One of the earliest randomized controlled trials was published by Bakkevold et al. in 1993 [20]. This study demonstrated a median survival of 23 months versus 11 months ($P = 0.02$) using adjuvant combination chemotherapy agents 5-FU, doxorubicin, and mitomycin C in 61 patients (14 ampullary, 47 pancreatic tumors) who underwent a radical resection versus observation but with limited five-year survival (4 vs 8 years, respectively) and increased treatment-related toxicity.

ESPAC-3 [16] remains the landmark study in evaluating the role of adjuvant chemotherapy in periampullary carcinomas (see Table 164.1). There were 297 patients with ampullary adenocarcinoma who were randomized to observation, 5-FU/leucovorin, or gemcitabine. The use of adjuvant chemotherapy demonstrated a trend toward improved overall survival, favoring the chemotherapy group versus observation (median overall survival 43 vs 35 months; $P = 0.25$). Moreover, when the analysis was limited to patients with ampullary cancer, those treated with gemcitabine had a remarkable survival that was almost double that in the observation group (median 71 vs 41 months). Subsequent analysis did not show different treatment responsiveness between intestinal and pancreaticobiliary subtypes.

The ESPAC-4 trial [46] randomized 730 patients with resected pancreatic cancer between gemcitabine and combination therapy with gemcitabine and capecitabine (GemCap). The median survival was 25.5 months (95% CI 22.7–27.9) for gemcitabine and 28.6 months (95% CI 23.5–31.5) for GemCap. The hazard ratio was 0.82 (95% CI 0.68–0.98; $P = 0.032$) with a substantial difference in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

five-year survival of 28.8% versus 16.3% in the combination group. The ampullary arm of ESPAC-4 (comparing adjuvant gemcitabine with gemcitabine plus capecitabine) is currently recruiting and has a target of 346 patients and is anticipated to complete follow-up and report by 2022.

A number of retrospective series examined the benefit of chemoradiotherapy as an adjuvant treatment [47,48]. In a study coordinated by the European Organisation for Research and Treatment of Cancer (EORTC), 218 patients with resected pancreatic and periampullary cancers were randomized to postoperative radiotherapy plus concurrent 5-FU (25 mg/kg per day by continuous infusion) or observation. There were 104 patients with periampullary cancers (which included cancers of the ampulla, distal common bile duct or duodenum), and there was no difference in the two-year survival rate (67% radiotherapy vs 63% observation) or in the incidence of locoregional recurrence in the postoperative radiotherapy group compared to controls. This was contrary to the findings from another series at the Mayo Clinic of 29 out of 125 patients with ampullary cancer who underwent curative surgical resection in addition to 5-FU and concurrent radiotherapy with a median total radiation dose of 50.4 Gy (range 45.0–54.0 Gy) while the remainder underwent surgery alone. The five-year survival figures of 48% vs 11% were in favor of the adjuvant chemoradiation group [19].

Results from the ESPAC-4 ampullary trial will help inform future adjuvant therapy options for this patient group.

Palliative Therapy

Systemic chemotherapy remains the mainstay to halt disease progression and prolong survival in unresectable and metastatic ampullary carcinoma. Survival figures beyond 3–6 months are dismal without additive palliative therapy. Most of the existing evidence is extrapolated from large studies that contained a mixture of periampullary tumors, with ampullary tumors forming a subset. Agents that have been examined in this disease include antimetabolites (fluoropyrimidine and/or gemcitabine) with or without a platinum compound (cisplatin or oxaliplatin) with variability in response rates ranging from 10% to 40% [49,50]. A phase II study evaluating CAPOX in patients with advanced adenocarcinoma of the small bowel or ampulla reported a response rate of 33% with improved overall survival (20.4 vs 15.5 months in patients with metastasis). The primary site of disease was the ampulla of Vater in 12 out of 30 patients [29].

In the ABC-02 trial (see Table 164.2) which randomly assigned 410 patients with locally advanced or metastatic biliary tract cancer to receive combination cisplatin and gemcitabine versus gemcitabine alone [26], there were 206 patients in the gemcitabine group (ampullary: 11 cases) and 204 patients in the cisplatin plus gemcitabine group (ampullary: nine cases). The median progression-free survival was eight months in the cisplatin plus gemcitabine versus five months in the gemcitabine-only cohort. The overall median survival was 11.7 months vs 8.1 months, respectively. The ABC-06 trial [30] analysed 162 patients (of whom 11 were ampullary carcinoma) in which second-line chemotherapy, FOLFOX with ASC was compared to ASC alone in patients who had advanced or metastatic biliary tract cancer treated initially with first-line gemcitabine and cisplatin. A statistically significant benefit to median overall survival was proven in the ASC plus FOLFOX group (6.2 months), when compared to ASC alone (5.3 months) with an adjusted hazard ratio of 0.69 (95% CI 0.50–0.97; $P = 0.031$).

Conclusion

Periampullary tumors constitute a diverse group of tumor subtypes. Despite the advances in diagnostics and clinical cancer care, their treatment remains challenging for clinicians and oncologists worldwide. The rarity of these tumors, in addition to disparity of the published data, has slowed the advances made in the field. There is a high unmet need for these patients. Future randomized trials should be of high quality and use efficient novel study designs to ensure that the best clinical evidence is available for these patients.

Introduction

Periampullary cancers are grouped as heterogeneous malignant lesions arising from anatomic sites around the ampulla of Vater. They consist of pancreatic head cancer, ampullary region cancer, distal bile duct cancer, and duodenal cancer. Because of their anatomic proximity, periampullary cancers share similar clinical presentations. In addition, when they invade surrounding tissue, it is often hard to distinguish between then. On the other hand, the treatment strategy is similar and surgical resection is the most effective treatment for all diseases. Pancreaticoduodenectomy represents the most applicable surgical procedure, although limited resection, such as pancreas-preserving duodenectomy, is indicated for some patients.

The incidences and long-term survival rates after surgical resection are very different according to the type of cancer. This chapter mainly focuses on long-term survival after surgical resection in patients with periampullary cancers other than pancreatic cancer, especially presenting recent studies. We elucidate the incidence and survival of periampullary cancer, then describe current data regarding survival and factors indicating long-term survival in each disease.

Incidence and Survival of Periampullary Cancer

As mentioned above, periampullary cancer contains different types of tumors. However, it is often hard to distinguish between them. Pomianowska et al. reported that pathologic reevaluation changed the diagnosis in 55 cases (27%) within 207 resected periampullary adenocarcinomas [1]. Several reports have shown the incidence and survival of periampullary cancers by comparing each disease.

Hester et al. reported the incidence and survival of these diseases by analyzing the National Cancer Database in the United States [2]. This analysis included 116705 patients over 18 years with the histologic diagnosis of adenocarcinoma characterized by four anatomic subtypes. Pancreatic head adenocarcinoma was the most frequent (82%), following ampullary adenocarcinoma (9%), duodenal adenocarcinoma (6%), and distal cholangiocarcinoma (3%). Resection was performed in 73% cases of ampullary adenocarcinoma, 52% duodenal adenocarcinoma, 44% distal cholangiocarcinoma, and 42% pancreatic head adenocarcinoma. Reflecting the high resection rate, patients with ampullary adenocarcinoma showed the most prolonged median survival of 26.3 months. Although the other three diseases showed similar resection rates, the pancreatic head adenocarcinoma patients showed the worst median survival of 8.1 months, compared with duodenal adenocarcinoma (13.3 months) and distal cholangiocarcinoma (11.5 months). Within surgically resected cases, tumors originating from the pancreatic head showed a more aggressive character with a higher incidence of lymph node metastasis and a higher rate of positive microscopic margins than other tumors. The multivariate analysis showed that duodenal adenocarcinoma was associated with improved survival compared with other sites. The resected ampullary, pancreatic head, and duodenal adenocarcinoma within the study period demonstrated significantly improved survival with increasing receipt of adjuvant therapy. These results showed the different biologic characteristics of periampullary cancer in various sites.

Shmuck et al. also showed different characteristics of periampullary cancer by detailed analysis [3]. They analyzed the clinicopathologic factors of 472 patients with

surgically resected periampullary cancer located within 2 cm from the ampulla of Vater. Patients were divided into three groups: distal cholangiocarcinoma, pancreatic adenocarcinoma, and ampullary carcinoma. The study showed that pancreatic cancer had larger tumor sizes, more frequent R1 resection, and a higher rate of nodal and perineural invasion compared to other tumors. Ampullary cancer showed a much longer median survival at 31.9 months, compared with distal cholangiocarcinoma (19.9 months) and pancreatic cancer (17.2 months). Other studies have also described the more prolonged survival of ampullary cancer and duodenal cancer than other cancers [4,5].

These reports emphasize that periampullary cancer includes heterogeneous tumors, and patients should be treated considering the characteristics of each disease.

Distal Bile Duct Cancer

Overall Survival (Table 165.1)

Few reports describe the clinicopathologic data of patients with distal bile duct cancer. According to the Biliary Tract Cancer Registry in Japan [6], 4091 patients with distal duct cancer were registered from 2008 to 2013. Of these patients, 3800 (92.9%) underwent surgical resection. Based on the Japanese classification of biliary tract cancers, T3a disease, which invades the gallbladder, liver, pancreas, duodenum, or other adjacent organs, was the most frequently seen (53.4%), followed by T2 disease, which invades beyond the bile duct wall to the surrounding tissue (28.6%). In this patient population, the five-year survival rate was 39.1%. The following report demonstrated, by analyzing the same database, that the five-year survival rate of 1748 patients who underwent curative surgery with pancreatoduodenectomy was 47.4% [7].

A retrospective multicenter study from five German and Russian academic centers showed that the five-year survival rate of 228 patients with distal bile duct carcinoma was 27% and the median overall survival was 29.3 months [8]. The Nagoya Surgical Oncology Group from Japan [9] and the French group [10] also reported the five-year survival rate of patients with surgically resected distal bile duct cancer as 40.8% and 34%, respectively.

In high-volume single-center studies, a report from Heidelberg University Hospital in Germany described that the five- and 10-year survival rates and median overall survival time of patients with bile duct cancer who underwent pancreatoduodenectomy were 40.3%, 30.5%, and 36.8 months, respectively [11]. A report from the University of Verona Hospital in Italy described that the median survival time of 54 patients with resected distal bile duct cancer was 35 months [12]. Previous reports from the Johns Hopkins Medical Institution, USA [13], and the Samsung Medical Center in South Korea [14] also stated that the median survival/five-year survival rates of those patients were 18%/20.3 months (147 patients) and 48.3%/73.0 months, respectively. Our institutional experience showed similar rates: five-year survival rate and median survival time were 38.2% and 46.0 months (173 patients). According to these reports, the five-year survival rate and the median survival time of patients with resected distal bile duct cancer were approximately 40% and 40 months. No significant change was found in the last five years.

Prognostic Factors (Table 165.2)

The most critical factor for the long-term survival of distal bile duct cancer is surgical resection with a negative cancer margin. The Heidelberg University group showed the importance of complete tumor clearance [11]. Among 196 patients who underwent pancreaticoduodenectomy for this disease, R0 resection with more than 1 mm surgical margin (R0 >1 mm) was achieved in 113 patients (58%). The median overall survival of R0 >1 mm was significantly longer (77.5 months) than that of R1 (≦1 mm) (24.2 months) and R1 (direct) (21.9 months). Interestingly, there were no differences between R1 (≦1 mm) and R1 (direct). Surgical resection with absolute negative margin status is one of the most important prognostic factors for distal bile duct cancer.

Several studies revealed prognostic factors for distal bile duct cancer by multivariate analyses: age >70, ASA III, operative blood loss (>1000 mL), lymph node metastasis, perineural invasion, tumor grade, occurrence of postoperative pancreatic fistula, and grade C complication, in addition to margin status [8,9,11,12,15,16].

Most of the studies indicated lymph node metastasis as a prognostic factor. The number of lymph node metastases was also important. Analysis of Japanese registration cases of biliary surgery revealed that the five-year survival rates of N0, N+(1 or 2), N+(3 or more) were 61.2%, 29.5%, and 21.7%, respectively. Another study also reported similar results regarding the number of lymph node metastases [17].

The Nagoya University group emphasized the importance of cancer invasion depth as a prognostic factor [16]. They showed that invasion depth of 8 mm beyond the bile duct was the only independent prognostic factor determined by multivariate analysis of 121 surgically resected cases.

On the other hand, adjuvant treatment did not show a survival benefit. Analysis of the Japanese registry [7] and a metaanalysis including 2063 patients [15] did not show a significant difference between patients treated with or without adjuvant therapy. This might be because the regimen was not standardized and did not have enough power to prevent cancer spread. This problem should be dissolved by future prospective studies with current chemotherapy protocols.

Several recent reports included inflammatory parameters as prognostic factors, such as platelet-to-lymphocyte ratio, neutrophil-to-lymphocyte ratio, lymphocyte-to-monocyte ratio, and systemic immune-inflammation index determined by platelet count and neutrophil-to-lymphocyte ratio [18–20]. These results may indicate the involvement of inflammation and immune status in spread of distal bile duct cancer.

Recurrence

A few studies have reported on cancer recurrence after pancreaticoduodenectomy. Recurrence occurred in 39–67% of patients. The time to recurrence was 13–21 months. The most frequent form of recurrence was distant metastasis (mainly liver metastasis) and local recurrence [11,14,21,22].

Ampullary Cancer

Overall Survival (Table 165.3)

Survival in patients with ampullary cancer is favorable compared with other diseases of periampullary cancer. A population-based study in the Netherlands, including all patients with newly diagnosed malignancies, reported

Table 165.2 Published series of prognostic factors after surgical resection of distal bile duct cancer.

Authors	Reference	Study period	No. of patients	Prognostic factors (multivariate)

MST, median survival time; ND, not determined

the incidence, treatment, and survival of ampullary cancer [23]. The median overall survival of 3840 patients with ampullary cancer was 16.1 months. Within these, most patients (87.1%) had nonmetastatic disease. This may lead to a high resection rate of this disease. The five-year survival rate of nonmetastatic disease was improved from 19.8% in 1989–1995 to 29.1% in 2010–2016. The resection rate also increased from 49.5% to 63.9% in these two periods. Meanwhile, the prognosis of 463 patients with metastatic disease did not change between the two periods (median overall survival 4.4 months in 1989–1995, 5.9 months in 2010–2016).

In the database of the Surveillance, Epidemiology, and End Results (SEER) national cancer registry from the United States, 3292 patients were registered from 1998 to 2003. The resection rate was 40% and the five-year cancer-specific survival after resection was 47.3% [24]. According to the Biliary Tract Cancer Registry in Japan [6], 2161 patients were registered from 2008 to 2013, and 2053 patients (95.0%) underwent surgical resection. This high resection rate might be because the resected cases were mainly enrolled in this registry. Based on the Japanese classification of biliary tract cancers, T2 disease was the most frequently seen (38.5%), followed by T1a (17.5%), and tumor stage was most commonly classified as Stage IA (29.1%), followed by Stage IB (27.2%). The five-year survival rate was reported to be 61.3%.

In a multicenter study from Europe, a total of 887 patients who underwent pancreaticoduodenectomy for ampullary adenocarcinoma in nine tertiary referral centers (UK, Netherlands, Italy) were included, and the median overall survival and five-year survival rate of these patients were favorable with 64 months and 52%, respectively [25]. The authors emphasized that ampullary cancers had morphologic heterogeneity based on the epithelium of origin: intestinal, pancreaticobiliary, or mixed type. The pancreaticobiliary subtype was most frequently seen (53%), followed by the intestinal subtype (39%) and mixed subtype (8%). Patients with the pancreaticobiliary subtype showed worse overall survival than the other subtypes.

In high-volume single-center series, the Moffitt Cancer Center, USA, group reported that the median overall survival and five-year survival rate was 49.3 months and 43%, respectively, in their analysis of 106 resected ampullary cancer cases between 1996 to 2015 [26]. The group from the Mayo Clinic reported a study of 121 patients who underwent pancreaticoduodenectomy for ampullary cancer between 2006 and 2016 [27]. The median overall survival time was exceptionally long at 91.8 months, and the five-year survival rate was 57.9%.

Overall, the five-year survival rate for ampullary cancer was approximately 30% in all cases and 40–60% in resected cases.

Prognostic Factors (Table 165.4)

Many reports including multivariate analysis have revealed several prognostic factors for patients who underwent surgical resection. They include age,

Table 165.4 Published series of prognostic factors after surgical resection of ampullary region cancer.

Authors	Reference	Study period	No. of patients	Prognostic factors (multivariate)
Moekotte et al.	29	2006–2017	1007	Age, margin status, tumor differentiation, AJCC T3/4 stage, nodal involvement
Feretis et al.	28	2002–2013	110	Vascular invasion, lymph node ratio
Jin et al.	27	2006–2016	121	Performance status, adjuvant therapy, disease stage
Doepker et al.	26	1996–2015	106	Lymph node count, tumor differentiation, histologic subtype
Moekotte et al.	25	2006–2017	887	Nodal metastasis, perineural invasion, adjuvant chemotherapy
Bourgouin et al.	10	2001–2011	55	Loss of BMI ≥4%, nodal metastasis, UICC stage
Winter et al.	48	1970–2007	347	Blood transfusion, perineural invasion, nodal metastasis

AJCC, American Joint Committee on Cancer; BMI, body mass index; UICC, Union for International Cancer Control.

performance status, margin status, lymph node metastasis, lymphovascular invasion, perineural invasion, histologic grade, lymph node-positive rate, T stage, pathologic stage, and adjuvant therapy [25–30]. In most studies, lymph node metastasis has been identified as the most substantial prognostic factor, as for other types of periampullary cancers.

Moekotte et al. developed a prediction model for survival in patients with resected ampullary adenocarcinoma in their international multicenter study, including 27 centers from 10 countries. They established a nomogram, including age, margin status, tumor differentiation grade, T stage, and lymph node metastasis, by analyzing the derivation cohort consisting of 1007 patients. Four groups divided by points of this nomogram showed a stratified survival curve in the Kaplan–Meier analysis. They confirmed the prediction accuracy of this nomogram using a validation set including 462 patients [29].

The role of adjuvant therapy in the survival of patients with resected ampullary cancer remains controversial. Several studies identified adjuvant therapy as a favorable prognostic factor [25,27], while others did not [26,30]. In their international cohort study, including 887 patients, Moekotte et al. described adjuvant therapy as a favorable predictor, especially in pancreatobiliary type [25]. The Mayo Clinic group also showed that adjuvant therapy was a favorable prognostic factor only in patients with Stage IIB or above [27]. These results may indicate that adjuvant therapy can improve survival, especially in advanced-stage disease patients. Limitations of these retrospective studies were the difference in patients' backgrounds and the lack of standard protocol for adjuvant therapy due to its retrospective nature. A prospective study will reveal the effect of adjuvant therapy on ampullary cancer.

As described, several recent reports have revealed that histopathologic subtype correlated with survival. The pancreatobiliary subtype was found in about 55% of cases, while the intestinal type was found in 35–37% [29,30]. Nappo et al. reported on the influence of histologic subtypes. Pancreatobiliary subtype was correlated with advanced T stage, lymph node metastasis, and perineural and vascular invasion. The five-year survival rate of the pancreatobiliary subtype was 42.1%, while that of the intestinal subtype was 75.5% (P <0.05). However, survival of the pancreatobiliary subtype was better than that of pancreatic ductal adenocarcinoma [30].

Recurrence

A few studies have reported on cancer recurrence after surgical resection. The median time of recurrence-free survival was 27–65.5 months [26,27,31]. Most of the recurrence was distant metastasis (73.5–87.5%), while locoregional recurrence was found in 12.5–26.5% of resected cases. The liver is the most frequent site of distant metastasis.

Duodenal Cancer (Adenocarcinoma)

Overall Survival (Table 165.5)

Duodenal cancer can originate from any part of the duodenum. In most studies, therefore, duodenal cancers arising in the periampullary duodenum, which have not been clearly defined yet, and in other parts of the duodenum (extraampullary duodenum) have been grouped. These two groups, periampullary and extraampullary duodenal cancers, were reported to have similar long-term survival after resection. The group from the Mayo Clinic reported their analysis of 124 patients who had an operation for duodenal cancer [32]. Twenty-five patients had tumors originating from the periampullary duodenum while 99 patients from the extraampullary duodenum. The five-year survival rate was 37% in the extraampullary group

Cecchini et al.	44	Massachusetts General Hospital, USA	1982–2010	103	42%	44

MST, median survival time; ND, not determined; SEER, Surveillance, Epidemiology and End Results database.

and 38% in the periampullary group. From this report, it is reasonable to analyze both groups together.

The overall survival from database analysis showed more prolonged survival in resected than in nonresected cases. A population-based study in the Netherlands, including 1026 duodenal cancers, described that the median overall survival of all cohorts was 13–14 months, and five-year survival rate was 25%. Surgical resection was performed in 58% of these patients. The median overall survival was 25 months in patients with locoregional disease, 48 months in surgically resected cases, and 66 months in cases treated with neoadjuvant therapy and surgical resection. In comparison, that of metastatic cases was only 4–5 months.

A population-based study from Denmark also demonstrated that cases with metastasis (Stage IV) showed poor survival [33]. The median survival time of patients with Stage IV duodenal cancer was only eight months, while those of Stage I/II and III were 25 and 29 months, respectively. In a multiinstitutional study in the UK analyzing 178 cases who underwent surgical treatment, the median survival times of all cases, resected cases, and palliative treatment were 44 months, 84 months, and eight months, respectively [34]. Several single-center studies also showed the importance of surgical resection for long-term survival [35–37]. No significant improvement in survival was obtained during this decade. Recent metaanalysis including 26 studies and 6438 patients demonstrated that the five-year survival rate was 46% after curative resection, both segmentectomy and pancreaticoduodenectomy, compared with 1% in palliative treated patients [38].

Prognostic Factors (Table 165.6)

Curative surgical resection is an important prognostic factor. Several reports performed a multivariate analysis of prognostic factors of overall survival after surgical resection. Recently reported prognostic factors are older age, advanced pathologic grade, TNM stage, lymph node status, pathologic perineural and lymphovascular invasion, and resection margin status, while gender and size of tumor have not been consistently associated with outcome [37,39–41]. Most of these studies demonstrated that lymph node metastasis is one of the most significant prognostic factors. The metaanalysis showed that lymph node involvement remained an independent prognostic factor in most studies after correction for other clinicopathologic factors. The pooled five-year survival rate was 65% for N0 cases, compared with 21% for N+ cases (odds ratio [OR] 0.17, 95% confidence interval [CI] 0.11–0.27, P <0.0001) [38]. It is noteworthy that there is a relationship between an increased number of involved nodes and poor survival [34,40,42].

Recently, many studies have showed the benefit of adjuvant therapy for pancreatic-biliary tumors, and it has become standard therapy, especially for pancreatic cancer. However, its usefulness is still controversial for duodenal cancer [35,36,43]. The metaanalysis also did not support its benefit. Within six studies investigating

Table 165.6 Published series of prognostic factors after surgical resection of duodenal cancer.

Authors	Reference	Study period	No. of patients	Prognostic factors (multivariate)
Nitta et al.	41	2002–2018	86	Pancreatic invasion, lymph node status
Mann et al.	37	1997–2015	53	Resection margin status, tumor stage III or above
Legue et al.	39	1999–2013	1026	Favorable factors: locoregional disease, age < 60, low tumor stage, diagnosis in 2009–2013
Solani et al.	34	2000–2013	143	N category, lymphovascular invasion
Poultsides et al.	42	1984–2006	112	Nodal metastasis
Cecchini et al.	44	1982–2010	103	Perineural invasion

the five-year survival of patients treated with adjuvant therapy, there was no difference in the pooled five-year survival for the adjuvant therapy group and control group (48% vs 46%, respectively; OR 1.14, 95% CI 0.60–2.15, I^2 = 40%) [38]. This might be because there is no standard chemotherapy regimen for duodenal cancer. A future prospective study is required to disclose its benefit.

Recurrence

Median time from surgical resection to recurrence showed a wide variety between reports (14.5–53 months) [34,44]. The frequent form of recurrence was distant metastases, followed by locoregional recurrence. Among distant metastases, the liver is the most frequent site of recurrence [34,35].

Transplantation of Pancreatic Islets

Joseph Sushil Rao, Melena D. Bellin, and Bernhard J. Hering

University of Minnesota Medical School, Minneapolis, MN, USA

Introduction

Transplantation of allogeneic islets has evolved as an effective treatment for patients with difficult-to-control type 1 diabetes (T1D) [1] and is now available as a less invasive alternative to vascularized whole pancreas transplantation [2]. The first successful islet transplant in an experimental model was reported in 1972 [3] and the first transplant of deceased donor human islets was performed shortly thereafter in 1974 [4].

After decades of clinical research, health authorities in several countries have provided regulatory approval for use of transplantation of human pancreatic islets in the treatment of T1D. The current era of clinical investigation focuses on the evaluation of stem cell-derived islet products [5–7]. Here we provide an overview of approaches to human islet isolation and infusion, selection of patients with a favorable benefit/risk ratio, clinical efficacy and safety outcomes, the regulatory status of transplantation of allogeneic islets, and research priorities in islet β cell replacement.

Manufacturing, Release Testing, and Infusion of Allogeneic Human Islets

The preeminent procedures involved in transplantation of allogeneic human islets in T1D are illustrated in Figs 166.1 and 166.2. Selection of deceased pancreas donors is a critical factor in determining the yield of islets available for transplant [8]. Based on characteristics of 1235 deceased pancreas donors and islet yields obtained from their pancreases, a scoring system has been developed to predict postpurification islet yields of >400 000 islet equivalents (IEQ). Adherence to validated principles of donor pancreas procurement [9,10] and utilization of optimized enzyme blends for pancreatic tissue dissociation [11] increase the yield and transplant rate of human islet products.

To advance allogeneic islet products toward licensure in the United States, eight manufacturing facilities participating in the National Institutes of Health-sponsored Clinical Islet Transplantation (CIT) Consortium jointly developed and implemented a harmonized process for the manufacture of allogeneic purified human pancreatic islet (PHPI) product for evaluation in a phase III trial in subjects with T1D [12]. Manufacturing was controlled by a common master production batch record (MBPR), standard operating procedures (SOP) that included acceptance criteria for deceased donor organ pancreases and critical raw materials, PHPI product specifications, certificate of analysis and test methods. The process was compliant with current Good Manufacturing Practices and Good Tissue Practices.

The quality systems and regulatory and operational strategies developed by the CIT Consortium yielded product lots that met the prespecified characteristics of safety, purity, potency, and identity and were successfully transplanted into participating subjects. No adverse events attributable to the product and no cases of primary nonfunction were observed. The CIT MPBR and SOPs are publicly available (referenced in [12]). The most commonly used islet implantation site is the liver, with islets being infused intraportally. The portal vein is accessed by percutaneous transhepatic catheterization or minilaparatomy.

Progress on the manufacturing and transplantation of stem cell-derived islets is discussed below.

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

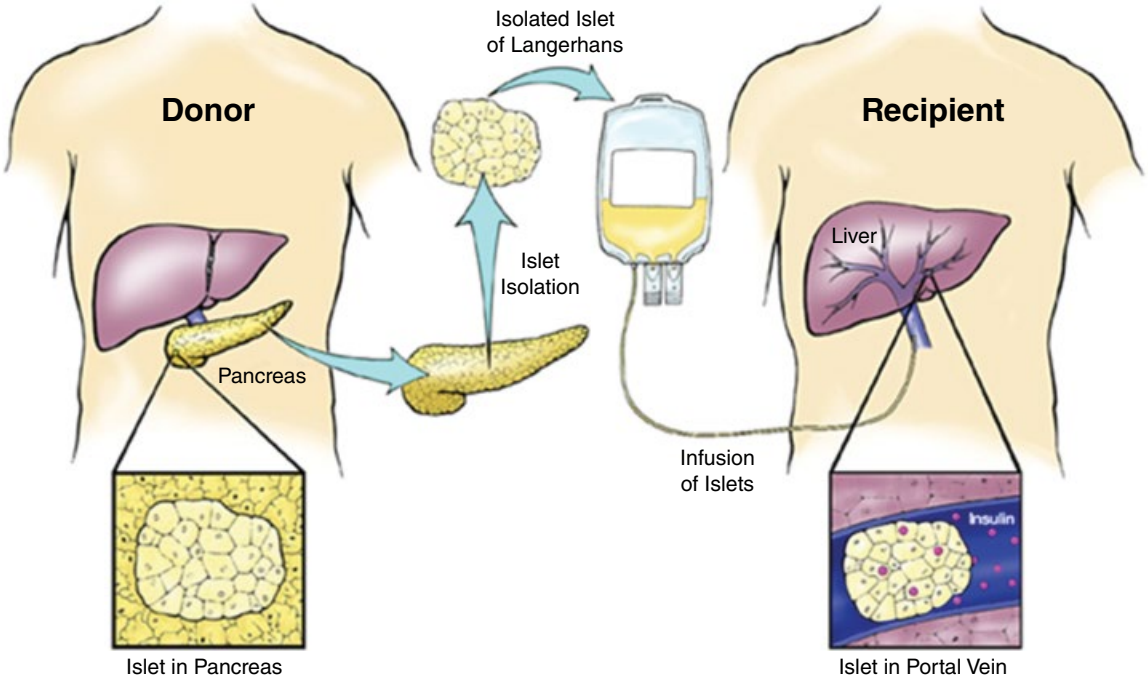

Figure 166.1 Diagram depicting the standard approach to transplantation of human allogeneic islets. A pancreas is retrieved from a suitable deceased donor. Islets are isolated from the donor pancreas, transferred to a transfusion bag, and infused through the portal vein into a type 1 diabetic recipient.

Selection of Islet Allotransplant Recipients

Allogeneic islet transplantation has been performed in patients with T1D as islet transplant alone (ITA) in nonuremic recipients, as simultaneous islet kidney (SIK) transplant in uremic recipients [13], or as islet after (previous) kidney (IAK) transplant in posturemic recipients [14].

ITA recipients are exposed to generalized immunosuppression only for the purpose of protecting the islet graft. The morbidity of diabetes complications in ITA must be perceived to be more serious than the risks associated with immunosuppression and the expectation of benefit associated with the islet graft must be high. Most ITA procedures have been performed in patients in whom T1D is complicated by impaired awareness of hypoglycemia (IAH) and recurrent severe hypoglycemic episodes (SHEs) [15]. These greatly feared acute complications require the assistance of another person for recovery [16]. IAH is found in up to one-third of adult patients with T1D and increases their risk of SHEs six-fold [17]. Recurrent hypoglycemia can have a profound impact on people's confidence, careers, and personal relationships, disrupt many everyday activities such as driving, work performance, leisure pursuits, and sleep [15], and can cause embarrassment, social ostracism, and employment discrimination [18].

Although several new educational and technologic interventions have recently been developed and should always be employed as first-line therapy in patients with SHEs, not all patients with IAH benefit from these interventions [19]. Despite accepting elevated hemoglobin A_{1c} (HbA_{1c}) targets of 8.0% and having access to behavioral therapies and sensor-augmented insulin pumps at a specialist hypoglycemia service, only 50% of patients with T1D and recurrent SHEs experienced resolution of SHEs, and 30% required pancreas or islet transplantation because of persistent SHEs [20]. Evidence-informed clinical practice recommendations identify patients in whom T1D is complicated by IAH and recurrent episodes of SHEs as candidates for islet or pancreas transplantation under the following conditions: SHEs persist after completion of a structured stepped care approach or a formalized medical optimization period that provides access to hypoglycemia-specific education including behavioral therapies, insulin analogues, and diabetes technologies under the close supervision of a specialist hypoglycemia service [19]. CIT-07 demonstrated the effectiveness of islet transplantation in restoring near normoglycemia and protection from SHEs in T1D [13].

Recent reports of multicenter trials of ITA in T1D complicated by hypoglycemia provide additional information on patient selection and eligibility [13,14,21–23]. An ideal candidate for IAK would be a patient diagnosed with T1D ≥5 years with stable kidney transplant, absent stimulated C-peptide, IAH as determined by the Clarke score, and a history of SHEs in the last one year despite medical care provided by an endocrinologist or diabetologist or patients who are unable to achieve and maintain glycemic control without hypoglycemic episodes by targeting a HbA_{1c} level above 7.5% (58.5 mmol/mol). Patients with high body mass index (BMI) (>30 kg/m^2), glomerular filtration rate (GFR) ≤40 mL/min/1.73m^2 or a history for panel reactive antibodies >50% or presence of anti-HLA antibodies against kidney donor or significant comorbidities would not be ideal candidates for islet transplant [14].

Simultaneous islet kidney and IAK recipients are already obligated to immunosuppression because of their concurrent or previous kidney transplant. The risks in ITA recipients should be minimal by following well-defined precautions (as discussed later). The risk/benefit ratio of an added islet transplant could be favorable, especially in those SIK and IAK recipients with T1D, who cannot meet clinically appropriate glycemic goals or who continue to experience SHEs after completion of a formalized medical optimization program under the guidance of an expert diabetes care team [19]. These recipients may also include patients who are not surgical candidates for or willing to accept the risks of a pancreas transplant [19,24,25].

Outcomes of Islet Allotransplantation in T1D

One- and Two-Year Metabolic Efficacy Results in ITA and IAK/SIK Recipients

The achievement of insulin independence in all of seven nonuremic ITA recipients by Shapiro et al. in Edmonton in 2000 marked a breakthrough in the clinical development of islet transplantation [26]. All patients quickly attained insulin independence after transplantation of a mean ± SD islet mass of 11 547 ± 1604 IEQ/kg. All recipients required islets from two donor pancreases, and one required a third transplant from two donors to achieve sustained insulin independence. After a median posttransplant follow-up of 11.9 months (range 4.9–14.9 months), the mean glycosylated hemoglobin values were normal, and episodes of hypoglycemic coma were avoided in all recipients. The complications were minor. The high success rate of the Edmonton protocol in restoring insulin independence has been attributed to the infusion of a high islet mass from more than one donor pancreas and the use of a glucocorticoid-free, low-dose tacrolimus and sirolimus maintenance immunosuppressive protocol, which is considerably less diabetogenic than previous protocols [27,28].

The insulin independence rate in the subsequent international multicenter trial of the Edmonton protocol for islet transplantation was 44% (16 of 36 patients) at one year post transplant [23]. The trial confirmed that persistent islet function even without insulin independence provides both protection from SHEs and improved levels of glycated hemoglobin [29]. The lower insulin independence rate compared with the initial and follow-up single-center reports by Edmonton [26,29] was in large part explained by the highly variable results achieved among the nine participating centers [23].

Consequently, and as already discussed, the manufacture of islet products for testing in the subsequent CIT trials was controlled by a harmonized process using a common batch record. Adherence to prespecified batch release criteria was demonstrated in qualification runs at each of the selected participating centers [12]. The purpose of the CIT-07 phase III trial, conducted at eight centers in North America, was to demonstrate the safety and effectiveness of transplantation of allogeneic islets in T1D complicated by SHEs [13]. Forty-eight adults with T1D for >5 years and persistent IAH and SHEs were enrolled. The primary composite endpoint of the CIT-07 trial, i.e., HbA_{1c} <7.0% at day 365 and freedom from SHEs from day 28 to day 365 after the first of up to three islet transplants, was successfully met by 87.5% of subjects. At two years, 71% of recipients met the endpoint. The median HbA_{1c} level was 5.6% at both one and two years. There were no study-related mortalities or disabilities [13]. Using the same composite endpoint as CIT-07, comparable results were reported by the Australian multicenter trial [30] and the Integrated UK Islet Transplant Program in its multicenter trial [31].

The TRIMECO multicentric randomized controlled trial assessed the efficacy and safety of islet transplantation and compared it to insulin therapies in T1D patients with severe hypoglycemia [22]. In this open label trial, T1D patients were randomly assigned in 1:1 ratio at 15 university hospitals into two groups, that received either immediate islet transplants or intensive insulin therapy followed by delayed islet transplant. The patients ranged between 18 and 65 years and suffered from SHEs or IHA or had kidney grafts with poor HbA_{1c}. Islet recipients received 11 000 IEQ/kg in 1–3 infusions. The enrolled 50 subjects were randomly assigned to the two defined groups. The median follow-up duration was six months in both groups. At six months, 64% patients in the immediate islet transplant group had a significantly higher modified β-score compared to the insulin therapy group. The authors concluded that islet transplantation effectively improves metabolic outcomes.

The results of this first randomized controlled trial in islet transplantation showed that, compared with insulin therapy, at six months, islet transplantation was effective at achieving optimal glycemic control in patients with unstable T1D and in patients with T1D who had established kidney transplants and poor glycemic control, suggesting that islet transplantation should be integrated into the stepped care approach to treatment of these patients [22].

IAK and SIK transplantation have been studied in pilot clinical trials by single centers and the French–Swiss GRAGIL Network (Group de Recherche Rhin, Rhône-Alpes et Genève pour la Transplantation d'Ilots de Langerhans) using several immunosuppressive protocols and endpoints [1,21,25,27,28]. These studies also suggest that insulin independence and near-normoglycemia can be restored in IAK/SIK recipients at rates comparable to those for ITA recipients.

The CIT-06 trial, performed by the CIT Consortium, is the first phase III trial of transplantation of human islets in T1D patients with established kidney transplants [14]. Of the 24 participants, 62.5% achieved the primary endpoint of freedom from SHEs and HbA_{1c} ≤6.5% or a reduction in HbA_{1c} of ≥1% one year after the first islet transplant. Median HbA_{1c} declined from 8.1% before to 6.0% at one year and 6.3% at two and three years following transplant, with related improvements in hypoglycemia awareness and glucose variability. The improved metabolic control was associated with better health-related and diabetes-related quality of life. The procedure was safe and kidney allograft function remained stable after three years. The results of this phase III trial support the indication of islet transplantation in patients with T1D post kidney transplant in whom problematic hypoglycemia and poor glycemic control persist despite optimized medical therapy.

The prevalence rates for key clinical outcomes in ITA, IAK, and SIK recipients at one year after final islet transplant were analyzed by the Collaborative Islet Transplant Registry (CITR) (Table 166.1, Fig. 166.3). More detailed metabolic studies demonstrated that intraportal islet transplantation can restore partial glucagon secretion, improve epinephrine secretion, restore autonomic symptom perception, and normalize endogenous glucose production in response to insulin-induced hypoglycemia in patients with long-standing T1D and IAH enrolled in the CIT-07 protocol [32]. Minimal islet graft function is sufficient to abrogate hypoglycemia (<54 mg/dL) [33].

Long-Term Metabolic Efficacy Results in ITA and IAK/SIK Recipients

A minority (~10%) of patients transplanted under the Edmonton protocol maintained insulin independence for five years post transplant. Approximately 80% showed sustained partial islet allograft function associated with HbA_{1c} levels of <7.0% and protection from SHEs for at least four years [29].

Table 166.1 One- and five-year prevalence endpoints of HbA_{1c}, severe hypoglycemic episodes (SHEs), and insulin independence for islet transport alone (ITA), islet after kidney (IAK), and simultaneous islet kidney (SIK).

Clinical endpoints	ITA (N = 877)		IAK (N = 183)		SIK (N = 24)	
	1 year	5 years	1 year	5 years	1 year	5 years[a]
HbA_{1c} <7.0	75%	61%	67%	48%	83%	80%
SHEs	94%	91%	93%	90%	100%	100%
Insulin independence	52%	25%	43%	21%	62%	33%

[a] Only 5/24 SIK recipients' endpoints have been reported at five years.

An analysis of CITR revealed that refined peritransplant management, including more potent induction immunosuppression, was associated with an insulin independence rate of 50% at five years after the final islet infusion [34], suggesting that a higher engrafted islet mass [35] could improve the longevity of the graft [36]. These improved results match long-term insulin independence rates after vascularized pancreas transplantation alone in nonuremic recipients [37].

The five-year outcome analysis of the French–Swiss GRAGIL Network reported sustained benefits of islet transplants [21] with 26% of recipients remaining insulin independent and 60% meeting the composite endpoint of HbA_{1c} levels of <7.0% and absence of SHEs. See Table 166.1 for prevalence rates of key clinical outcomes in ITA, IAK, and SIK recipients at five years after the final islet transplant as analyzed by CITR.

In an independent study with more than seven years of follow-up, the Zurich group also showed improved glycemic measures after SIK/IAK transplantation compared with intensified insulin therapy [38].

At the 10-year mark, in the analysis on 31 patients by the GRAGIL Network, the median HbA_{1c} was 7.2% versus 8.0% before transplantation, 74% of recipients were free of SHEs, one was insulin independent and median C-peptide was 0.6 ng/mL. The insulin requirements were significantly lower after transplantation and 51.9% had a functioning graft. These findings demonstrate that islet transplantation provided sustained improvement of glycemic control with protection from SHEs in almost 75% of the recipients for 10 years [39].

In an analysis of islet transplants performed at the University of Lille, the Kaplan–Meir estimates of patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 166.3 Observed prevalence rates of primary outcomes in T1D ITA recipients reported to CITR. Rates are shown according to subgroups with all four "favorable factors": (i) induction immunosuppression with T-cell depletion and/or TNF-α inhibitor, (ii) maintenance immunosuppression with mTOR inhibitor and calcineurin inhibitor, (iii) number of islet equivalents transplanted ≥325 000, and (iv) recipient age ≥35 years (left panels), and less than four favorable factors ("Rest"; right panels). Top row: proportion of recipients with absence of SHE in both subgroups prior to the first islet transplant (Pre1) and at each of the first five years after the last islet infusion. Of the 610 recipients analyzed, N = 164 met all four favorable factors, whereas N = 446 recipients met less than four of the favorable factors ("Rest"). Of those meeting all four favorable factors (N = 164), 12% (20 of 164) were free of SHE prior to transplantation, whereas 97% (67 of 69) of recipients were free of SHE at five years post last islet infusion. Bottom row: proportion of recipients meeting the composite endpoint of HbA_{1c} < 7.0% and absence of SHEs prior to the first islet transplant and at intervals post last islet infusion. Of the recipients analyzed, N = 165 met all four favorable factors, whereas N = 496 recipients met less than four of the favorable factors ("Rest"). Of those meeting all four favorable factors (N = 165), 3% (5 of 165) met the composite endpoint prior to transplantation, whereas 71% (37 of 52) of recipients met the composite endpoint at five years post last islet infusion. *Source:* Courtesy of Elizabeth Payne, PhD, and Cassandra Ballou, MS, The Emmes Company and CITR.

remaining insulin independent with $HbA1_c$ ≤6.5% were 39% at five years and 28% at 10 years [40] and the Kaplan–Meier estimates of graft survival were 82% and 78% after five and 10 years, respectively. Graft function was associated with a marked decrease of SHEs. ITA and IAK recipients had similar outcomes, and the kidney allograft function did not show a significant decline in the latter group [40].

A 12-year follow-up on seven recipients of the Edmonton protocol demonstrated sustained islet function. One subject remained insulin independent without the need for diabetic medications or supplemental transplants and another was insulin independent for more than eight years and experienced graft failure 11 years after the first islet transplant. The median $HbA1_c$ was 6.3% and no patient experienced SHEs, opportunistic

infections or lymphoma, confirming the safety of islet transplantation in the long term [41].

Impact of Islet Transplantation on Chronic Diabetes Complications, Quality of Life, and Patient Survival

Very few studies have examined the effects of islet transplantation on chronic diabetes complications. The Milan group demonstrated in a cohort of IAK recipients followed for seven years that successful islet transplantation, when compared to controls, was associated with lower cardiovascular mortality and improved endothelial function, kidney graft function, and kidney graft survival rates [42,43]. In a prospective, crossover cohort study examining the effects of ITA and intensive medical therapy on the progression of microvascular diabetes complications, the rate of decline in GFR was slower and the rate of progression of retinopathy was lower after ITA than on medical therapy [44].

Quality of life (QOL) studies using existing questionnaires showed that islet transplants, although having no impact on overall health-related QOL, were associated with improved diabetes-specific QOL, less fear of hypoglycemia, a reduction in behaviors adopted in avoiding hypoglycemia, and attenuation in concerns about SHEs [45]. The CIT-07 subjects reported consistent, statistically significant, and clinically meaningful improvements in condition-specific health-related quality of life as well as self-assessments of overall health [46]. Similar results were observed in the CIT-06 trial; both the Diabetes Distress Scores and Hypoglycemia Fear Scores improved significantly over the three years after the islet transplant [14].

A patient survival analysis in islet transplant recipients with IAH and SHEs pretransplant showed survival of 100% at 10 years and >80% at 20 years after islet transplantation, and incidence rate of mortality was 3.28 per 1000 person-years, suggesting that islet transplantation is not associated with increased mortality regardless of the use of long-term immunosuppressive therapy [47].

Adverse Effects of Islet Transplantation and Immunosuppression

Procedure-related complications of intraportal islet infusion include portal venous thrombosis, transient increase in liver enzymes, perforation of the gallbladder, and bleeding. Portal thrombosis is a preventable complication, provided that therapeutic anticoagulation is maintained and the infused packed cell volume is limited to <5.0 mL [48]. Postprocedural bleeding can be avoided by effective obliteration of the intraparenchymal catheter tract in the liver [49,50] or by accessing a mesenteric vein via minilaparotomy for intraportal islet infusion.

Immunosuppression- and immunity-related complications in ITA recipients include nephrotoxicity and sensitization to donor human leukocyte antigen (HLA) antigens. Although the decrease in GFR is common and significant, the GFR typically remains in the normal range. The decline in GFR is explained by an acute CNI effect [51] and is possibly also associated with correction of hyperfiltration after restoration of near-normoglycemia [52,53]. Whether the decline in GFR is progressive or stable in ITA recipients, as demonstrated in kidney transplant recipients immunosuppressed with CNI [54], remains to be determined. Of note, the rate of decline in GFR was slower in CNI-treated ITA recipients than in control patients on intensive medical therapy [55]. The risk of HLA class I sensitization is significant in ITA recipients in whom immunosuppression is discontinued after complete graft loss; it can be reduced by minimizing the number of islet donors used per recipient and by repeating HLA class I mismatches with subsequent islet infusions [56,57]. In the CIT-07 phase III trial, six of 48 participants had positive panel reactive antibodies at two-year follow-up and donor-specific antibodies developed in two patients [13].

A total of 51 instances of neoplasms have been reported to CITR in 34 of 1086 islet recipients who collectively represent a total of 4583 person-years of observed follow-up. Neoplasms diagnosed were basal or squamous cell carcinoma (N = 35), breast cancer (N = 4), mucinous adenocarcinoma of the appendix (N = 1), thyroid cancer (N = 4), lung cancer (N = 2), and posttransplant lymphoproliferative disorder (PTLD) (N = 2). There were 33 reports of death in 1086 recipients to the Registry for islet allograft recipients, corresponding to 3.0% crude mortality over a mean of 4.4 years elapsed follow-up per patient (including periods after complete graft failure and loss to observed follow-up) [58].

Regulatory Status of Transplantation of Allogeneic Human Islets

Multiple countries recognize islet transplantation as standard of care or have provided regulatory approval for use, including selected provinces in Canada, the UK, several health authorities in continental Europe, Australia, and Japan [59]. The path to regulatory approval varies across the world. According to the regulatory framework in the United States, allogeneic pancreatic islets meet the definition of a biologic product and a drug

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and are considered a somatic cell therapy. As such, allogeneic islets will require approval of a Biologics License Application (BLA) before they can be marketed in the US for the treatment of patients with diabetes [60]. The National Institutes of Health sponsored the CIT-06 and CIT-07 licensure trials in the US, which demonstrated the efficacy and safety of purified human pancreatic islets in patients with T1D [13,14].

Nevertheless, and possibly related to the costly and onerous regulatory path, none of the participating academic centers have submitted a BLA since the completion of the trials. The single BLA for allogeneic islets, which has been submitted by a for-profit entity to the US Food and Drug Administration, remains under review [61]. For these reasons, the use of allogeneic islets for the treatment of T1D has remained investigational in the US. Regulatory approval of islets in additional countries including the US would facilitate patient access to β cell replacement through third-party medical reimbursement and improve outcomes through continued clinical research [62].

Research Priorities in Islet Transplantation

Optimizing donor pancreas procurement and transportation, refining islet isolation and release testing, establishing extrahepatic sites and novel islet delivery techniques for enhanced islet engraftment, developing CNI-free immunosuppressive protocols lacking islet toxicity, and incorporating islet imaging and donor-specific immune assays into monitoring will improve the outcomes and utilization of islet allotransplantation [63]. However, the three most impactful research priorities are the generation of an unlimited supply of islet cells for transplant along with effective islet banking technologies, optimization of islet delivery and implantation techniques, and the development of strategies that facilitate islet graft survival without the need for maintenance immunosuppression.

Facing the substantial shortage of suitable deceased donor pancreases, academia and industry developed an alternative, stem cell-derived source of insulin-secreting islet β cells for transplantation [64]. The recent refinements represent a monumental accomplishment, culminating in the restoration of insulin independence after intraportal infusion of what was considered a half dose of stem cell-derived islets into a type 1 diabetic recipient in a clinical trial conducted by Vertex Pharmaceuticals [7]. Progress has also been made in preclinical studies of transplantation of porcine islets as an alternative source of islets in immunosuppressed nonhuman primates [65].

Large-scale application of β cell replacement strategies in diabetes will require high-quality islets that are accessible in cell banks. Cryopreservation could solve islet supply chain challenges. The comprehensive optimization of cryoprotectant agent composition, its loading and unloading conditions, and methods for vitrification and rewarming of mouse, porcine, human, and stem cell-derived β cells allowed considerably improved transplantation outcomes [66]. Better islet delivery and implantation technologies would improve engraftment and functional survival of transplanted islets, thereby lowering the costs of curative islet products and their applicability in the treatment of diabetes.

Faleo et al. demonstrated that cotransplantation of parathyroid gland and stem cell-derived insulin-producing cells enhances graft survival through release of proangiogenic and prosurvival factors [67]. The intrahepatic milieu is considered inhospitable to transplanted islets. To promote the utilization of the subcutaneous space as an alternate, safe, and easily accessible site for islet transplantation, islets were admixed with a device-free islet viability matrix, resulting in long-term euglycemia in murine and nonhuman primate animal models and paving the way for clinical development of alternate sources of pancreatic islets [68].

Finally, strategies have been advanced for minimizing and eliminating maintenance immunosuppression in islet transplant recipients. A recent preclinical study demonstrated that two peritransplant infusions of apoptotic donor leukocytes under short-term immunosuppression with anti-CD40, rapamycin, sTNFR, and anti-IL-6R induced long-term (>1 year) immune tolerance to islet allografts in nonhuman primates [69]. Important improvements in islet micro- and macroencapsulation have been reported in the last decade. Transplanted human islets survived for more than 10 months without immunosuppression in an oxygenated and immune-isolating chamber [70]. Other refinements of the encapsulation approach include the incorporation of the chemokine CXCL12 into alginate [71], conformal coating of stem-cell derived islets [72], and a nanofibrous encapsulation device for safe delivery of insulin-producing cells [73].

Multiplex genome editing is used to mitigate the innate and adaptive immune response to stem cell-derived islet cell products with the ultimate goal of developing an immune-evasive cell replacement therapy for diabetes. Genes being targeted include the highly polymorphic HLA Class I and II, PD-L1, HLA-G, and CD47 [74]. CRISPR Therapeutics and ViaCyte, Inc. announced in February of 2022 that they have dosed their first patient in a phase I clinical trial of a novel gene-edited cell replacement strategy to treat T1D [75]. Gene editing of stem cell-derived islet products will likely become a

focus of academic and corporate research efforts in β cell replacement for diabetes.

Conclusion

Islet allotransplantation has become a viable treatment option for patients with T1D and IAH in whom optimized medical therapy has been ineffective in preventing SHEs. Islet transplantation should also be considered in patients with T1D and end-stage renal failure who cannot meet clinically appropriate glycemic goals or in whom SHEs persist. Despite superior efficacy in restoring normoglycemia and freedom from severe hypoglycemia compared with current diabetes technologies, transplantation of allogeneic human islets has remained an underutilized treatment option, presumably largely due to concerns related to the risks associated with immunosuppression.

Considering the substantial progress made in developing limitless sources of islet cells for transplantation, improving their delivery and engraftment, and averting the need for maintenance immunosuppression, it is fair to assume that transplantation of islets will soon play an increasingly important role in the care of patients with diabetes.

Transplantation of the Pancreas

Rainer W.G. Gruessner and Angelika C. Gruessner

Departments of Surgery and Medicine, State University of New York (SUNY), Brooklyn, NY, USA

Introduction

The medical, financial, and social consequences of diabetes mellitus are a global challenge to public health. According to the World Health Organization (WHO), at least 420 million people are affected worldwide, with rising prevalence and a 5% increase in premature mortality. Diabetes is a major cause of blindness, kidney failure, heart attack, stroke, lower limb amputation, and poor quality of life. It is the ninth leading cause of death (presumably underreported) with an estimated 1.5 million deaths per year directly caused by diabetes [1,2]. In the United States alone, the annual cost of diagnosed diabetes amounts to $327 billion, a 26% increase over a five-year period [3]. Insulin-dependent, autoimmune type 1 diabetes (T1D) affects 0.1–1% of the population, dependent on the country, with its highest incidence around 10–15 years of age. The incidence has increased over time, approximately doubling over the past 2–3 decades [4].

Conservative treatment options for diabetes mellitus include a wide spectrum of modalities ranging from diet and exercise to drugs and insulin pumps. However, all of these options have resulted in suboptimal disease management and intensive insulin therapy comes at the expense of potentially life-threatening iatrogenic hypoglycemia with an estimated incidence of 2–10% per year [5,6]. Due to these deficiencies, transplantation of β cells as an organ (pancreas) or cellular preparations (islets) have been performed in increasing numbers over the past decades.

Pancreas transplants are performed in patients who require administration of insulin because of T1D, type 2 diabetes mellitus (T2D) or after a total pancreatectomy. Successful pancreas transplants have also been performed after failed islet transplants [7]. A successful pancreas transplant is the only definitive long-term treatment for patients with insulin-dependent diabetes mellitus that consistently restores glycemic control without exposing patients to the risk of severe hypoglycemia, and prevents, halts or even reverses the development or progression of secondary complications of diabetes mellitus [1,8]. Early in the history of pancreas transplantation, such transplants between identical twins contributed to our understanding of T1D as being an autoimmune disease. In patients with T1D who received a pancreas graft from their identical twin, T1D returned within weeks in the absence of immunosuppressive therapy [9].

Pancreas transplants are performed in three different categories of patients with diabetes mellitus [1]. The first and most common category includes diabetic patients with uremia who require a simultaneous pancreas and kidney transplant (SPK). The second category includes patients who are diabetic and posturemic and who undergo a pancreas after a previous (living or deceased donor) kidney transplant (PAK). The third category consists of patients with brittle diabetes mellitus without uremia who undergo a pancreas transplant alone (PTA).

The first pancreas transplant was performed on December 16, 1966, by William Kelly and Richard Lillehei at the University of Minnesota, USA [10]. Since then and as of December 31, 2020, about 35 000 pancreas transplants from the United States and almost 29 000 from outside the United States have been reported to the International Pancreas Transplant Registry (IPTR) [11]. Outcome after pancreas transplantation has significantly improved over time due to advances in surgical techniques and immunosuppressive therapy: at one year post transplant, patient survival rates are now >96% and graft survival rates are almost 86% (see below) [11].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Evolution of Surgical Techniques

Advances in surgical techniques have been instrumental in improved outcome after pancreas transplantation. In fact, more so than with any other solid organ, the history of pancreas transplantation has predominantly revolved around the development and application of different surgical techniques. No other abdominal organ has seen such a wide variety of surgical techniques for the purpose of transplantation [12].

Since the first pancreas transplant in 1966, the surgical focus has been on determining the optimal management for drainage of pancreatic exocrine secretions and venous outflow. While enteric drainage and systemic drainage are now the two most common techniques used, portal vein and other forms of gastrointestinal drainage (via the duodenum or stomach) are viable options and are considered complementary, rather than competing, alternatives [13]. Hence, the surgical technique should be adapted to the individual circumstances of donor and recipient and to the individual surgeon's preference to achieve an optimal outcome.

A multitude of surgical techniques for diverting exocrine pancreatic secretions have been reported over time: enteric drainage (used in the first pancreas transplant) (Figs 167.1 and 167.2), cutaneous graft duodenostomy, open intraperitoneal duct drainage, duct ligation, duct injection, gastric drainage, ureteral drainage, bladder drainage, and duodenal drainage (in chronological order) [11–13]. Of those, enteric and bladder drainage have been the most common techniques. Bladder drainage was the most popular technique until the 1990s for two reasons. First, it enables timely diagnosis and treatment of rejection [14]. Since rejection of the exocrine pancreas precedes rejection of the endocrine pancreas by 5–7 days, a drop in urinary amylase indicates rejection and treatment can be successfully implemented when the recipient is hypoamylasuric but still normoglycemic. More than 90% of pancreas rejection episodes are reversible in the absence of hyperglycemia [14]. Second, bladder drainage avoids morbidity and mortality of bacterial contamination that occurs with enteric drainage leaks. However, bladder drainage is associated with unique metabolic and urologic complications, including hyperchloremic metabolic acidosis (secondary to bicarbonate loss through the urine), dehydration, recurrent urinary tract infections, dysuria, hematuria, and/or graft pancreatitis secondary to reflux of urine into the ductal system of the graft [12–14].

The introduction of tacrolimus (Tac) and mycophenolate mofetil (MMF) in the mid-1990s resulted in a significant reduction in pancreas rejection rates and led to a major change in the management of pancreatic exocrine

Figure 167.1 Whole-organ transplant with systemic vein and enteric exocrine drainage (caudad position): side-to-side two-layer duodenojejunostomy. The pancreas with its vascular anastomoses (donor Y-graft to recipient common iliac artery, donor portal vein to recipient common iliac vein) is implanted in the standard fashion on the right side of the pelvis. The arterial anastomosis is medial and proximal to the venous anastomosis. *Source:* [13]/Springer Nature.

secretions in that enteric drainage became the predominantly used technique worldwide in about 95% of transplants. For enteric drainage, the pancreas graft can be placed in either a caudad (see Fig. 167.1) or a cephalad (see Fig. 167.2) position. Enteric drainage has seen several modifications. Construction of a Roux-en-Y loop is rarely performed (in about 15% of all transplants) and has been all but abandoned in favor of a direct donor duodenum-to-recipient jejunum anastomosis. The anastomosis itself is usually hand-sewn rather than stapled.

Duodenal and gastric (rather than jejunal) drainage are being used at some centers because they afford direct access to the allograft duodenum and pancreas for biopsy and for surveillance endoscopies, including graft endoscopic retrograde cholangiopancreatography (ERCP). The main disadvantage of duodenal drainage is the surgical management of eventual leaks or graft pancreatectomies: closure of the native duodenum can be very challenging and is associated with morbidity and mortality. Enteric drainage into the recipient jejunum remains the most commonly used exocrine drainage technique [11,12].

Venous drainage of the pancreas graft into the systemic circulation, bypassing the liver, is less physiologic than venous drainage into the portal circulation (Fig. 167.3).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 167.2 Whole-organ transplant with systemic vein and enteric exocrine drainage (cephalad position). The donor portal vein (in this case with an extension graft) is anastomosed end-to-side to the recipient common iliac vein or infrarenal cava. The donor Y-graft is anastomosed to the recipient common iliac artery. A two-layer side-to-side duodenojejunostomy is constructed about 40–80 cm distal to the ligament of Treitz (inset). The arterial anastomosis is medial and distal to the venous anastomosis. *Source:* [13]/Springer Nature.

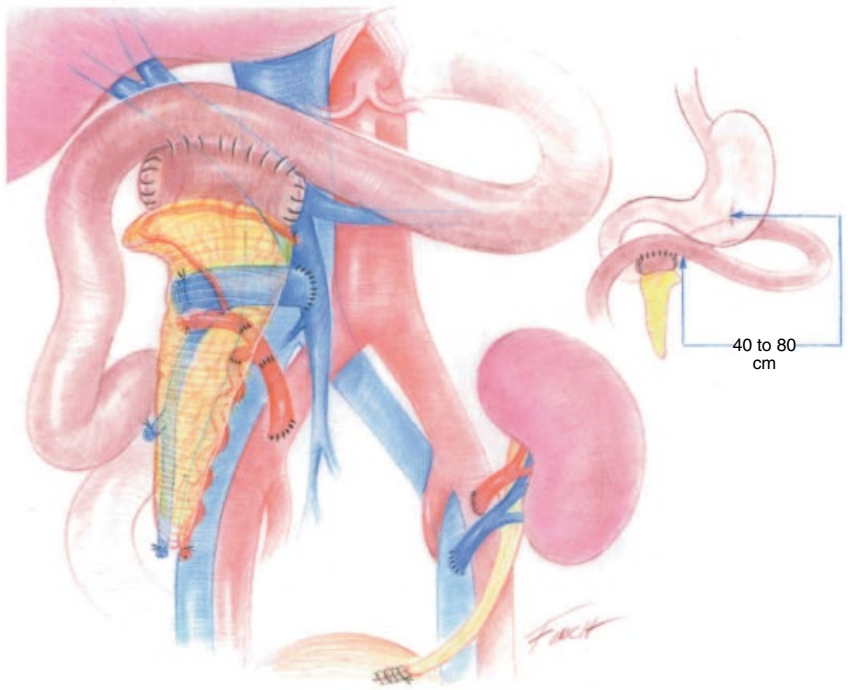

Figure 167.3 Whole-organ transplant with portal vein and enteric exocrine drainage using the intraperitoneal approach. The pancreas graft overlies the root of the small bowel mesentery, with the duodenal segment below the transverse colon. The donor portal vein is anastomosed end-to-side to the recipient superior mesenteric vein. The donor Y-graft (with an extension graft) is anastomosed to the recipient common iliac artery through a mesenteric tunnel. A two-layer side-to-side duodenojejunostomy is constructed about 40–80 cm distal to the ligament of Treitz. In the final position, the jejunal limb usually lies anterior to the donor duodenum. The simultaneously transplanted kidney is anastomosed to the recipient external iliac artery and vein. The ureter is implanted into the bladder using the extravesical ureteroneocystostomy (Lich) technique. *Source:* [13]/Springer Nature.

Systemic drainage was used in the first pancreas transplant due to its technical ease and has prevailed since. Portoenteric drainage was most popular in the 1990s [11–13]. Although systemic venous drainage causes peripheral hyperinsulinemia and portal hypoinsulinemia, serious metabolic consequences have not been reported. In fact, comparable metabolic control and graft outcome is achieved with portal vein and systemic vein drainage. As with enteric and bladder drainage, portal and systemic vein drainage should not be considered competing, but rather complementary, techniques. Obesity, thickened mesentery, and small mesenteric veins favor systemic vein drainage, whereas previous pelvic transplants or operations, severe iliac atherosclerosis, and short arterial grafts favor portal vein drainage. Systemic venous drainage is used in about 90% of all pancreas transplants [11–13].

Other, initially controversial technical issues have been resolved. They included pancreatic mass (whole organ is preferred over segmental transplant) and graft placement (intraperitoneal is preferred over extraperitoneal position); in SPK, bilateral is preferred over ipsilateral graft positioning.

According to the IPTR, an intraabdominal whole-organ pancreas transplant with enteric and systemic venous drainage (see Figs 167.1 and 167.2) is now the preferred technique worldwide [11]. However, the surgical technique may need to be adapted to the individual circumstances of donor and recipient to optimize outcome.

Lastly, from both a historical as well as a technical perspective, the pancreas was the first extrarenal organ to be successfully transplanted using a living donor and the first dual-organ transplant (SPK) from a living donor [15,16]. The (distal) pancreas was also the first extrarenal solid organ that was successfully procured, with spleen preservation ("Sutherland" technique), from a living donor using the minimally invasive (laparoscopic) technique [17].

In the United States, favorable changes in organ allocation policies have resulted in an adequate number of deceased donor pancreases in recent years. For that reason, a living donor pancreas transplant is rarely indicated (except for a highly sensitized patient, avoidance of high-dose immunosuppression or availability of a nondiabetic identical twin or a 6-antigen-matched sibling). In contrast, living donor pancreas transplants continue to be performed in moderate numbers in Asian countries (China, Japan, Korea) due to the lack of organ donation for cultural and religious reasons [18]. The evolution of strict metabolic criteria has diminished the risk for the donor to develop diabetes post donation [19]. Outcome after living donor pancreas transplantation is at least as favorable as for deceased donor transplantation [20].

Substantial improvements in immunosuppressive therapy and antimicrobial prophylaxis and therapy have added extra safety nets to the various surgical techniques and contributed to a significant decrease in technical complications and failures. From a technical perspective, pancreas transplants can be quite demanding and require solid skills in general and vascular surgery; graft pancreatectomies, pancreas retransplants, pancreas transplants after native pancreatectomy, living donor and split pancreas transplants, and pancreas transplants in combination with other extrarenal organs such as the liver or lung can be extremely challenging [11,21,22].

The evolution of pancreas transplantation with its many technical facets, including the introduction of robotic surgery for selected pancreas transplant recipients, has also greatly advanced the field of pancreatic surgery at large [23],

IPTR: Transplant Demographics

Between December 17, 1966, and December 31, 2020, a total of 63 871 pancreas transplants were reported to the IPTR; this total includes about 35 000 pancreas transplants from the US and almost 29 000 from outside the US [11,24]. The overall development of reported cases over the years for US and non-US cases is shown in Figure 167.4. The decrease in numbers in 2020 is due to the COVID-19 pandemic which impacted all pancreas transplant centers worldwide [11,24].

The following transplant demographics focus on the United States experience where reporting is mandatory. Of 34 998 US pancreas transplants, 96% were performed for diabetes mellitus and 4% as part of multivisceral transplants for technical reasons (i.e., elimination of a separate bile duct anastomosis).

Of all US pancreas transplants in patients with diabetes mellitus, 76.6% were in the SPK category, 15.2%, in the PAK category, and 8.2%, in the PTA category. Of those, 94% were primary transplants and 6% were retransplants. Until the late 1980s, pancreas transplants were performed almost exclusively in recipients with T1D. Between 1996 and 2000, only 4.6% of all recipients were reported to have T2D; the overall rate increased to 18.4% between 2016 and 2020. Most T2D recipients required an SPK transplant because of end-stage renal disease. About 60% of pancreas transplant recipients in the SPK and PAK categories were male, but in the PTA category more women (60%) were transplanted.

Pancreas transplants from donation after circulatory death (DCD) and living donors are rare. In the US, in contrast to many European countries, DCD donors were utilized in only 3% of all transplants, but the trend is slightly

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

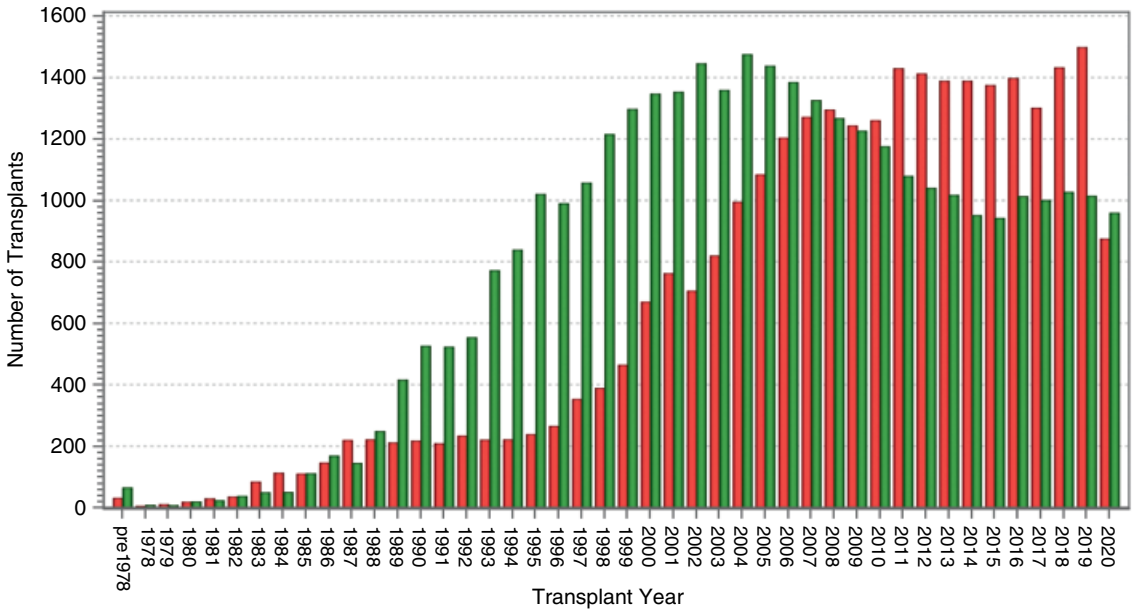

Figure 167.4 Annual number of US and non-US pancreas transplants reported to the IPTR between 12/17/1966 and 12/31/2020.

increasing. Living donor pancreas transplants account for less than 1% of all transplants in the United States.

Over time, the overall median recipient age for primary deceased donor pancreas transplants has significantly increased, from 32 (range 15–54) years in 1966–1985 to 42 (12–75) years in 2016–2020. In contrast, the median pancreas donor age has significantly decreased from 27 (range 4–62) years in 1986–1990 to 22 (4–53) years in 2016–2020. The most common cause of donor death was trauma and most deceased donors were of male gender. Preservation time of deceased donor pancreas also decreased significantly over time from 13.2 (1.5–50) hours in 1991-1995 for SPKs to 9.4 (1–46) hours in 2016-2020.

Little consideration is given any more to good HLA matching due to improvements in immunosuppressive therapy. In the SPK category, the median number of mismatches increased to five (out of a maximum of six) in 2016–2020; in the more immunogenic PAK and PTA categories, better HLA matching was achieved and "only" 57% of transplants were performed with a 5- or 6-antigen mismatch. Enteric and systemic vein drainage are the most commonly used surgical techniques (Fig. 167.5).

The mid-1990s saw a major change in immunosuppressive therapy after pancreas transplantation and led to significantly improved outcomes (see below). First, over 90% of recipients are now receiving induction therapy, in most cases with depleting antibodies. Second, the TAC-MMF combination is the most frequently used maintenance regimen, accounting for >80% in all three recipient categories. Third, the trend away from steroid avoidance and withdrawal continues; such protocols accounted for only 30% in all three categories for the 2016–2020 time period.

IPTR: Outcome

From 1966 through 2020, pancreas transplant outcomes in all three recipient categories improved significantly. The advancements were mainly due to better donor and recipient selection criteria as well as technical and immunosuppressive improvements which in turn resulted in a significant decrease in the rates of technical failures and immunologic graft losses [11,24].

The patient survival rate at one year for SPK recipients was 97% in 2016–2020 vs 58% in 1966–1985; for PAK recipients, 96% vs 81%; and for PTA recipients, 99% vs 75%. Long-term patient survival rates have paralleled short-term outcomes: five-year patient survival rate for 2016–2020 was >90% and the 10-year survival rate >70% in all three recipient categories.

Pancreas graft survival rates have even more impressively improved over time in all three recipient categories. The IPTR has always defined pancreas graft function as insulin independence. The pancreas graft survival rate at one year for SPK recipients was 91% in 2016–2020 vs 33% in 1966–1985 (Fig. 167.6); for PAK recipients, 86% vs 22%; and for PTA recipients, 87% vs 19% (Fig. 167.7). These pancreas graft survival rates are comparable to kidney graft survival rates. Long-term pancreas graft survival rates have paralleled short-term outcomes: five- and 10-year pancreas graft survival rates for 2016–2020

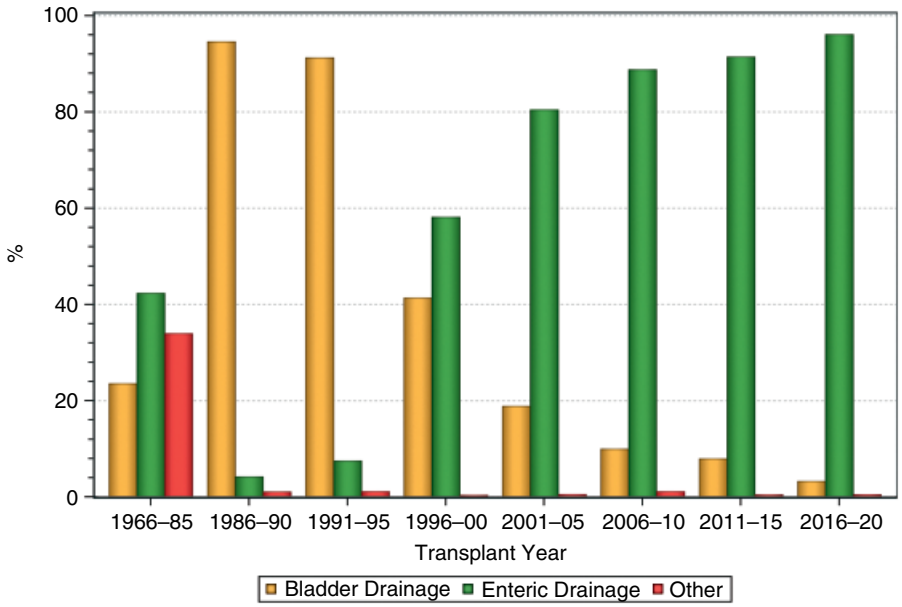

Figure 167.5 US duct management techniques in primary deceased donor pancreas transplants performed between 12/17/1966 and 12/31/2020.

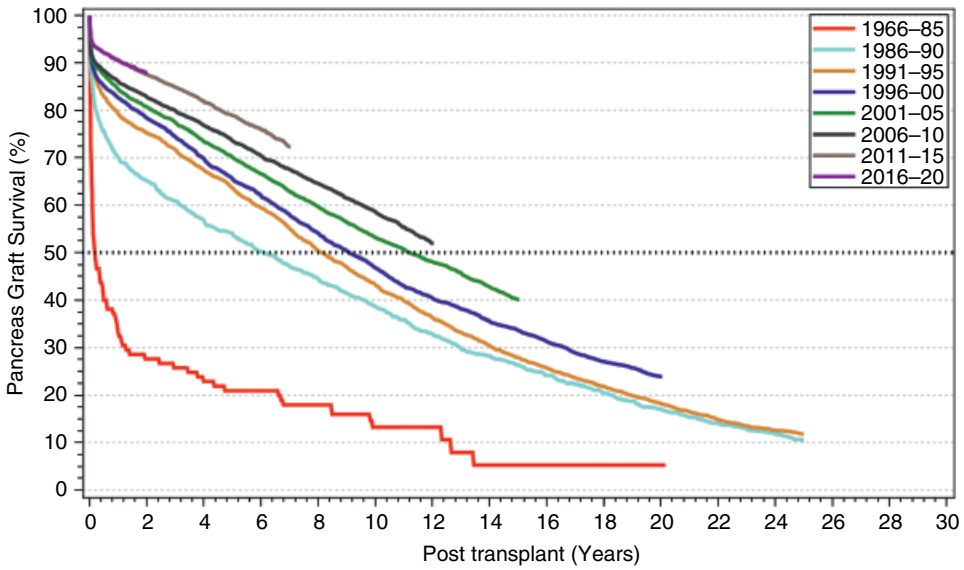

Figure 167.6 US pancreas graft survival by era after primary deceased donor simultaneous pancreas/kidney transplantation (SPK) performed between 12/17/1966 and 12/31/2020.

were 73% and 56% for SPK recipients; 64% and 38%, for PAK recipients; and 53% and 36%, for PTA recipients. Long-term graft survival paralleled improvement in short-term outcome. The half-life (50% graft function) for a SPK pancreas (kidney) graft increased from 73 months in 1986–1990 to 134 months in 2001–2005. Since 2005, more than 50% of all grafts are still functioning and therefore the half-life could not be computed (Table 167.1).

The most critical time period after a pancreas transplant remains the first year due to the risk of technical and immunologic complications. Not surprisingly, for grafts that survived the first year after transplantation, long-term outcome was significantly better. For SPK transplants which did not fail during the first year post transplant, pancreas (kidney) half-lives increased from 134 months (133 months) in 1986–1990 to 170 months (175 months) in 2001–2005 (see Table 167.1). SPK

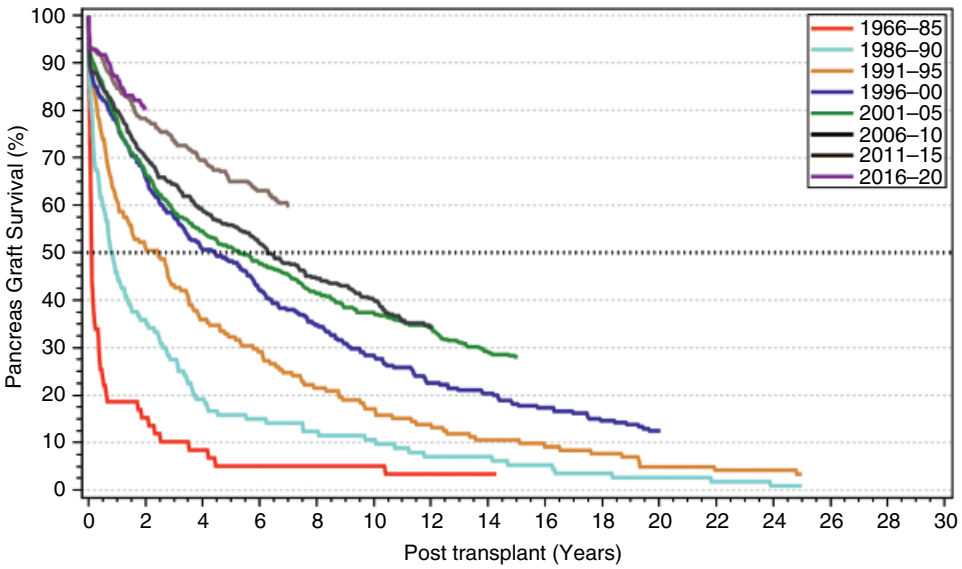

Figure 167.7 US pancreas graft survival by era after primary deceased donor pancreas transplantation alone (PTA) performed between 12/17/1966 and 12/31/2020.

Table 167.1 Pancreas and pancreas/kidney transplant half-lives for transplants performed between 1/1/1986 and 12/31/2005.

	SPK			
Transplant year	**Pancreas**	**Kidney**	**PAK**	**PTA**
1986–1990	73 (134)	92 (133)	6 (61)	10 (42)
1991–1995	98 (132)	115 (141)	23 (79)	29 64)
1996–2000	109 (140)	144 (163)	56 (89)	53 (80)
2001–2005	134 (170)	161 (175)	70 (113)	64 (107)

Brackets show conditional half-lives for txs that reached the one-year mark with functioning graft.
SPK, simultaneous pancreas and kidney transplant; PAK, pancreas after kidney; PTA, pancreas transplantation alone.

transplants performed after 2005 will have an even longer half-life. Similar improvements have been seen in the solitary transplant categories although not quite as marked, with half-lives of 113 months for PAK and 107 months for PTA recipients in 2001–2005 (Table 167.1).

At the time of this writing (January 2022), 7068 SPK pancreas transplants had reached the 10-year follow-up mark, and 1227 transplants the 20-year mark with a functioning pancreas. Important factors influencing long-term function were those that described the quality of the deceased donor. Pancreas transplants in younger, high panel reactive antibody (PRA) or black recipients showed an increased risk of early graft failure. Induction therapy with depleting antibodies had a significant positive impact on long-term survival.

Table 167.2 Early technical failures in enteric-drained primary deceased donor pancreas transplants performed in adult recipients between 1/1/2016 and 12/31/2020.

	SPK	**PAK**	**PTA**	**P**
N	**3397**	**194**	**234**	
Technical failure rate (%)	**5.5**	**6.2**	**6.4**	**0.79**
Graft thrombosis (%)	3.7	4.1	5.9	
Infection (%)	0.5	0.5	0.0	
Pancreatitis (%)	0.2	0.5	0.0	
Anastomotic leak (%)	0.4	0.0	0.2	
Bleeding (%)	0.3	0.5	0.0	
Technical/other (%)	0.4	0.6	0.3	

SPK, simultaneous pancreas and kidney transplant; PAK, pancreas after kidney; PTA, pancreas transplantation alone.

The rates of graft losses from technical and immunologic causes have significantly decreased over time in all three recipient categories. Technical failures (Table 167.2) include graft thrombosis (4%), infection (<1%), pancreatitis (<1%), anastomotic leakage (<1%), and bleeding (<1%); at one year, the overall technical failure rate in 2016–2020 was about 6% in all recipient categories vs 25% in 1966–1985. The rate of graft losses for immunologic reasons (mainly rejection; rarely, recurrent autoimmune disease) at one year was about 2% in the SPK category and about 5% in the PTA and PAK categories. Very few fields in all of solid organ transplantation have seen such improvement in reducing graft losses from

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

rejection: for solitary pancreas transplants (PAK, PTA) from 65% in 1966–1985 to 5% in 2016–2020. However, the long-term graft loss rates from rejection still remain higher in the solitary recipient categories (PTA and PAK) than in the SPK category; the transplanted kidney (serum creatinine levels) of SPK recipients frequently serves as an effective harbinger for the early diagnosis of rejection. Graft loss from rejection is also higher for younger (<30 years of age) vs older recipients and in nonuremic vs uremic patients.

Pancreas graft survival has not been different for T1D vs T2D recipients.

Multivariate analyses have provided further insight into outcome after pancreas transplantation. The factors with the highest impact on patient survival were functioning pancreas and kidney grafts. The loss of either organ increased the relative risk (RR) of death significantly (RR 15.98 for kidney graft loss, RR 3.3 for pancreas graft loss in the SPK category). Hence, maintenance of stable graft function is pivotal to patient survival. In the SPK category, recipients who were on dialysis before transplant had a higher risk of death, as well as patients over the age of 45; in the PAK category, recipients who had received a deceased donor kidney showed a higher RR of death compared to recipients of a living donor kidney.

The factors with the highest impact on patient survival were donor selection factors. Donor age >30 years of age and cold preservation time >12 hours significantly increased the risk of losing the pancreas graft. Older recipient age showed a slightly higher risk of pancreas graft loss in SPK recipients, but the risk was decreased in PTA recipients. A sensitization rate >60% increased the RR of graft failure. The COVID-19 pandemic has negatively impacted both pancreas and kidney graft survival [11,24].

IPTR: Survival Benefit

For a long time, the perception had persisted that a pancreas transplant is simply an alternative to insulin replacement therapy, despite evidence in the literature to the contrary [25,26]. Unlike liver and heart transplants, pancreas transplants are usually not immediately life-saving procedures. However, their life-saving nature becomes evident within several months post transplant by decreasing the recipients' risk of death from hypoglycemic unawareness, cardiocerebrovascular events, and other secondary diabetic complications.

Over a 21-year time period, from January 1, 2000, to May 31, 2021, the IPTR/UNOS collected information about listing and transplant outcome of diabetic patients. To determine the survival benefit of pancreas transplantation, patient survival on the waiting list versus after transplantation was defined as the primary outcome. Over the 21-year time period, pancreas and/or kidney transplantation in all four diabetic recipient categories saved a total of 273 843 life-years. On average, 11.7 life-years per patient were saved in the SPK category, 6.4 life-years in the PTA category, 6.3 life-years in the PAK category, and 6.6 life-years in the KTA category [8]. The survival benefit of pancreas and/or kidney transplant recipients in all three categories was highly significant compared to diabetic patients still waiting for transplantation (SPK category) [8,27]. The survival benefit was higher for patients with T1D vs T2D. The significant survival benefit of PTA recipients versus patients on the waiting list justifies the argument for preemptive pancreas transplantation, i.e., before the development of end-stage renal disease.

Given the survival benefit as evidenced by 273 843 life-years saved, pancreas transplantation should be more widely applied, specifically in the PTA category, and pancreas donation encouraged [8,28].

Impact on Secondary Diabetic Complications

A large body of literature clearly demonstrates the positive impact of pancreas transplantation on secondary diabetic complications in that a successful pancreas transplant can prevent, halt or even reverse the development and progression of these debilitating complications across many organ systems [29]. Primarily after SPK transplantation, functional improvements have been reported in diabetic nephropathy, neuropathy (autonomic and peripheral), gastroparesis, retinopathy, microvascular and macrovascular disease (including cerebral vasculopathy and morphology), cardiac function, and sexual function. In PAK recipients, improvements in graft function of a previously transplanted kidney have been demonstrated [30]. In PTA recipients, prevention or reduction in the progression of secondary complications have been reported despite the paucity of pretransplant symptoms in this category. This is most evident by the observation that long-term normoglycemia had reversed glomerular and cortical lesions of diabetic nephropathy with return to normal glomerular structure at 10 years post transplant [31]. Nevertheless, life-long exposure to calcineurin inhibitors and dehydration can still result in impaired kidney function.

Polyneuropathy also improved in recipients who achieved a normoglycemic state after a successful pancreas transplant, in contrast to the progression observed in the control group that was treated with insulin. Improvement was maintained over 10-year follow-up,

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

contributed to a higher level in general life activities, and correlated with a significant reduction in mortality in transplant recipients [32].

The positive impact of pancreas transplantation on secondary diabetic complications is primarily based on complete freedom from insulin and establishment of normoglycemia. A successful pancreas transplant completely normalizes and more effectively lowers the levels of HbA_{1c} when compared to intensive insulin therapy. Even 10 years post transplant, a successful pancreas transplant preserves almost normal insulin secretion and provides excellent glycemic control. Thus, restoration of β-cell secretory capacity, normalization in glucose counterregulation, and return to hypoglycaemia awareness are all achieved with a successful pancreas transplant [33].

Quality of Life After Pancreas Transplantation

One of the most pivotal factors in assessing quality of life issues after pancreas transplantation is graft function. In all three recipient categories, graft loss results in a marked reduction in quality of life whereas stable graft function significantly increases quality of life [34].

As the majority of pancreas transplants is performed in the SPK category, most available literature focuses on this population. Compared to remaining on the waiting list, SPK leads to greater improvements in general health and vitality, physical and mental health functions, social functioning and diabetes-related issues. Long-term follow-up studies clearly demonstrate that benefits to health and quality of life are not only present in the first year post transplant but are maintained and continue to increase in following years for as long as the graft functions. From the perspective of allocating healthcare resources, SPK provides a significantly greater number of quality-adjusted life-years than kidney transplants alone or dialysis. SPK is the therapy of choice for an increasing number of eligible diabetic patients.

As the number of SPK recipients with functioning grafts increases, more attention is now being placed on quantifying other quality of life issues such as the impact of psychologic and social support before and after surgery and in underrepresented groups. Due to the severity of established medical and psychologic impairment at the time of transplant, SPK does not fully return patients to the level seen in the general population. The impact of early referral for pancreas transplantation prior to end-stage organ damage is obvious and enforces the need for increasing the number of transplants in the PTA category.

There is a relative dearth of studies examining the impact on quality of life in the PAK and PTA categories due to the much smaller numbers of recipients. However, most recipients of these two categories find it easier to manage their immunosuppression on a daily basis than their diabetes mellitus. Future multicenter studies may better assess the impact of solitary pancreas transplants on patients' quality of life outcomes. Consistent with studies of heart, lung, kidney, and liver transplantation, pancreas transplantation clearly has a positive effect on quality of life [1,34].

pancreatic adenocarcinoma 366–372, 957, 958, 998–1005, 1007, 1009, 1131, 1137
pancreatic agenesis 23
pancreatic anomalies 23–29
pancreatic cancer 88, 91–94, 436, 437, 439, 480–484, 609, 611, 612, 738–742, 905–909, 921–926, 942, 943, 945, 946, 948, 982–987, 1033–1035, 1037–1043, 1047–1052, 1078–1089, 1093–1097, 1099–1104, 1113–1116, 1122–1128, 1131–1138, 1164–1174, 1180–1184, 1209–1215, 1218–1225
pancreatic cancer recurrence 1208–1215
pancreatic carcinoma 1021–1026
pancreatic cell culture 79
pancreatic cyst ablation 727–730
pancreatic cystic lesions (PCL) 617–619
pancreatic cystic neoplasms (PCNs) 619–621, 638–641, 654, 666, 670, 688, 693–698, 700–705, 744–747
pancreatic cysts 642–649, 680–685, 1014–1016
pancreatic diabetes mellitus 307, 445–449
pancreatic drainage procedures 501–504
pancreatic duct 48–50
pancreatic ductal adenocarcinoma (PDAC) 666–670, 934–939, 969, 1063, 1164, 1167, 1180, 1181, 1183, 1218
pancreatic ductal cells 398
pancreatic ductal stones 425–426
pancreatic enzyme replacement therapy (PERT) 430–434, 437–440, 447, 448
pancreatic enzymes 391
pancreatic evolution 99–100
pancreatic exocrine 447–449
pancreatic exocrine and endocrine function 715, 719
pancreatic exocrine function tests 352–354
pancreatic exocrine insufficiency (PEI) 303, 306, 445
pancreatic fibrogenesis 86–94
pancreatic fibrosis 461–463
pancreatic fistula 300–303, 725–727, 730
pancreatic fluid collections (PFC) 284, 294–298
pancreatic function 734
pancreatic imaging 595–598
pancreatic intervention 254–255
pancreatic intraepithelial neoplasia (PanIN) 969, 971, 1015
pancreatic ischemia 462
pancreatic islets 515, 517, 519
pancreatic microcirculation 222–225
pancreatic middle segment resection (PMSR) 715–720
pancreatic necroinflammation 107, 110
pancreatic necrosis 260–264
pancreatic neoplasms 1055–1060
pancreatic neuroendocrine carcinoma (PanNEC) 781
pancreatic neuroendocrine neoplasms (PanNENs) 763–768, 891, 892
pancreatic neuroendocrine tumor (PanNET) 781–788, 795, 796, 808–812, 820–826, 829–831
pancreaticoduodenectomy (PD) 690, 1078–1086, 1222–1225, 1284, 1288, 1289
pancreatic organogenesis 3–4
pancreatic pain 460, 464, 501–504
pancreatic protein synthesis 75–81
pancreatic pseudocysts (PPC) 211, 212, 214, 218, 284–286, 288–290
pancreatic regeneration 80, 81
pancreatic resection 723–726, 729, 744, 747, 1113, 1114
pancreatic screening 1012, 1014–1017
pancreatic secretion 65–71
pancreatic stellate cells (PSC) 86–94, 398–399
pancreatic stellate cells/carcinoma-associated fibroblasts 942, 943, 945, 947–948
pancreatic stent 1266–1268
pancreatic strictures 424–425
pancreatic surgery 418, 420, 421, 437, 439, 440, 501–502, 693–698, 718, 719
pancreatic tumors 366–368, 370, 791, 794
pancreatitis 146–151, 244–250, 266–269, 271–275, 284–286, 294–298, 326–331, 334–341, 523–531, 901
pancreatobiliary 1242–1248
pancreatobiliary cytology 652
pancreatoduodenectomy (PD) 885, 1047, 1055–1060, 1281
papillectomy 1272–1274, 1277
parasympathetic nervous system 69
parenchyma-preserving pancreatectomy 700, 704
parenchyma-sparing local head resection 709–711
parenchyma-sparing resection 694
parenteral nutrition 222–227
Partington 499
pathology, neuroendocrine neoplasm 763–768
pathology reporting 1066
pathophysiology 168
patterns of recurrence 1208–1210, 1213
Pavlovian concept 71
