The Pancreas

An Integrated Textbook of Basic Science, Medicine, and Surgery

Fourth Edition

Edited by

Hans G. Beger, MD, FACS (Hon.), JSS (Hon.), CSS (Hon.)
Founding Editor, Professor Emeritus of Surgery, University of Ulm, Ulm, Germany.

Markus W. Büchler, MD FACS (Hon.), FRCS (Hon.), FASA (Hon.)
Professor of Surgery, University of Heidelberg, Heidelberg, Germany.

Ralph H. Hruban, MD FACS (Hon.), FRCS (Hon.), FASA (Hon.)
Baxley Professor and Director, Department of Pathology, and Director of the Sol Goldman Pancreatic Research Center, Johns Hopkins University School of Medicine, Baltimore, USA.

Julia Mayerle, MD
Professor of Internal Medicine, Gastroenterology and Hepatology, Chair Department of Medicine II, LMU Klinikum, Ludwig-Maximilians-University, Munich, Germany.

John P. Neoptolemos, MA, MB, BCHIR, MD FRCS, FMEDSCI, MAE
Professor of Surgery, Department of Surgery, University of Heidelberg, Heidelberg, Germany.

Tooru Shimosegawa, MD, PhD
Professor Emeritus Department of Gastroenterology, Tohoku University Graduate School of Medicine, Sendai, Miyagi, Japan.

Andrew L. Warshaw, MD, FACS, FRCSEd (Hon.)
W. Gerald Austen Distinguished Professor of Surgery, Harvard Medical School, and Surgeon-in-Chief Emeritus, Massachusetts General Hospital, Boston, USA.

David C. Whitcomb, MD, PhD
Professor of Medicine, Cell Biology & Physiology, Human Genetics, Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh and UPMC, Pennsylvania, USA.

Yupei Zhao, MD, FICS (Hon.), FACS (Hon.), FRCS (Engl) (Hon.), FCSHK (Hon.)
Professor of Surgery, Department of General Surgery, Peking Union Medical College Hospital, Beijing, P.R. China.

Coordinating Editor

Christiane Groß
German Foundation for the Fight Against Pancreatic Cancer, c/o University of Ulm, Ulm, Germany

Preface

The fourth edition of *The Pancreas* presents the most comprehensive and latest knowledge about the genetic and molecular biological basis of embryology, anatomy, physiology, pathophysiology, and pathology for all disorders of the pancreas. Compared to the first edition, published in 1998, the fourth edition contains three newly addressed diseases of the pancreas: autoimmune pancreatitis, benign and premalignant cystic neoplasms, and neuroendocrine tumors. The understanding of the functions and dysfunctions of the exocrine and endocrine pancreas is derived from increasingly profound molecular biological data on the actions of compounds in subcellular compartments and intracellular transcription pathways. In the respective chapters, the presentation of the inflammatory (acute or chronic) and oncological diseases (benign, premalignant, or advanced cancer) is based on molecular biological understanding of pathomorphological processes and clinical phenomena. In clinical pancreatology, new and improved technical devices enable the gastroenterologist and the gastrointestinal surgeon to identify lesions by high-resolution imaging techniques, imaging of metabolic processes, and intrapancreatic ductal morphologic processes. The molecular profiling of pancreatic ductal adenocarcinoma has provided a deeper understanding of the genomic alterations that drive pancreatic ductal adenocarcinoma, including driver genes, actionable mutations, copy number alterations, patterns of genomic aberrations, structural variations, and mutational signatures. These findings have transformed our biological genomic understanding, but are still of limited clinical utility. Significant progress has been made in understanding the molecular pathogenesis of pancreatic cancer and identification of various molecular subtypes. However, this improved understanding has unfortunately not yet led to relevant progress for the patient's cure, although survival gain after radical cancer resection in addition with neoadjuvant chemotherapy is significant for selected groups of patients.

The synergistic interaction of basic scientists, pathologists, gastroenterologists, and gastrointestinal tract surgeons in the field of investigative and clinical pancreatology has led to a better understanding of pancreatic diseases through combining the knowledge of each to achieve the best management. Most importantly, the decision-making for patients with an option to be successfully treated for pancreatic disease is increasingly based on high-evidence data from clinical trials on treatment. New technical devices—endoscopic visualization of cellular abnormalities, laparoscopic minimally invasive surgical approaches, and robotic surgery—have led to significant clinical improvement. The establishment of local, parenchyma-sparing surgical approaches for the increasing number of benign tumors, cystic neoplasms, and neuroendocrine tumors have significantly improved the patient's outcome compared to classical pancreatic resections.

The goal of this fourth edition is to provide the clinician with the most current evidence-based synthesis of understanding of pancreatic diseases, functional assessment, diagnostic and technical devices, treatment options, and outcome results. All chapters are written by leading international experts on the topic. A major part of this edition has been contributed by international basic scientists, who provide an understanding of the molecular basis of pancreatic functions and dysfunctions. The editors acknowledge and are deeply indebted to all authors who have contributed to this edition. Their diligent efforts have provided state-of-the-art knowledge, particularly in regard to decision-making based on clinical evidence.

Contents

About the Companion Website *xvii*

Section 1 Anatomy of the Pancreas *1*

1 Development of the Pancreas and Related Structures *3*
Brian Lewis and Junhao Mao

2 Anatomy, Histology, and Fine Structure of the Pancreas *9*
Daniel S. Longnecker and Elizabeth D. Thompson

3 Congenital and Inherited Anomalies of the Pancreas *23*
Heiko Witt and Martin Zenker

Section 2 Physiology and Pathophysiology of Pancreatic Functions *33*

4 Physiology of Acinar Cell Secretion *35*
Ole H. Petersen

5 Physiology of Duct Cell Secretion *48*
Wei-Yin Lin, Paramita Sarkar, and Shmuel Muallem

6 Physiology and Pathophysiology of Function of Sphincter of Oddi *56*
Savio George Barreto and James Toouli

7 Neurohormonal and Hormonal Control of Pancreatic Secretion *65*
Chung Owyang and Matthew J. DiMagno

8 Regulation of Pancreatic Protein Synthesis and Growth *75*
Maria Dolors Sans and John A. Williams

9 Fibrogenesis in the Pancreas: The Role of Pancreatic Stellate Cells *86*
Minoti V. Apte, Romano C. Pirola, and Jeremy S. Wilson

10 Pancreatic Endocrine–Exocrine Relationship *98*
Kenichiro Furuyama and Yoshiya Kawaguchi

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Section 3 Acute Pancreatitis *105*

11 Epidemiology and Etiology of Alcohol-Induced Pancreatitis *107*
Jeremy S. Wilson, Romano C. Pirola, and Minoti V. Apte

12 Epidemiology and Etiology of Biliary Acute Pancreatitis *119*
Ippei Ikoma, Ko Tomishima, and Hiroyuki Isayama

13 Genetic Factors in Acute Pancreatitis *128*
Mitchell L. Ramsey and Georgios I. Papachristou

14 The Role of the Intestine and Mesenteric Lymph in the Development of Organ Dysfunction in Severe Acute Pancreatitis *138*
Alistair B.J. Escott, Anthony R.J. Phillips, and John A. Windsor

15 The Role of Neurogenic Inflammation in Pancreatitis *146*
Metrah Mohammad Nader and Jami L. Saloman

16 Molecular, Biochemical, and Metabolic Abnormalities of Acute Pancreatitis *155*
Ujjwal M. Mahajan, F. Ulrich Weiss, Markus M. Lerch, and Julia Mayerle

17 Histopathology of Acute Pancreatitis *164*
Günter Klöppel

18 Severity Classification of Acute Pancreatitis *170*
John A. Windsor

19 Clinical Assessment and Biochemical Markers to Objectify Severity and Prognosis *176*
Bettina M. Rau and Claus Schäfer

20 Acute Pancreatitis Associated with Congenital Anomalies *185*
Charlotte S. Austin, Christopher R. Schlieve, Andrew L. Warshaw, and Tracy C. Grikscheit

21 Acute Pancreatitis in Children *191*
Mark E. Lowe and Véronique D. Morinville

22 Acute Pancreatitis Associated with Metabolic, Infections and Drug-Related Diseases *199*
Ali A. Aghdassi, Mats L. Wiese, Quang Trung Tran, and Markus M. Lerch

23 Radiologic Diagnosis and Staging of Severe Acute Pancreatitis *208*
Yoshihisa Tsuji

24 Conservative Therapy of Acute Pancreatitis: Volume Substitution and Enteral and Parenteral Nutrition *222*
Steven M. Hadley, Jr. and Timothy B. Gardner

25 ICU Treatment of Severe Acute Pancreatitis *230*
Scott R. Gunn and David C. Whitcomb

26 Clinical Course and Medical Treatment of Acute Pancreatitis—Use of Antibiotics in Severe Acute Pancreatitis: Indications and Limitations *238*
Rainer Isenmann and Mathias Wittau

27 **Indications for Interventional and Surgical Treatment of Necrotizing Pancreatitis** *244*
Lily V. Saadat and Thomas E. Clancy

28 **Management of Infected Necrosis: Step-Up Approach** *254*
Hester C. Timmerhuis, Marc G. Besselink, and Hjalmar C. van Santvoort

29 **Management of Infected Pancreatic Necroses: An Endoscopic Approach** *260*
Todd H. Baron

30 **Minimally Invasive Debridement and Lavage of Necrotizing Pancreatitis** *266*
Kulbir Mann and Michael G.T. Raraty

31 **Open Surgical Debridement of Necrotizing Pancreatitis: Late Postoperative Morbidity and Outcome** *271*
Dongya Huang, Zipeng Lu, and Yi Miao

32 **Endoscopic Treatment of Acute Biliary Pancreatitis** *278*
Ichiro Yasuda, Tsuyoshi Mukai, and Toru Ito

33 **Strategies for the Treatment of Pancreatic Pseudocysts and Walled-Off Necrosis After Acute Pancreatitis: Interventional Endoscopic Approaches** *284*
Georg Beyer and Julia Mayerle

34 **Pseudocysts and Walled-Off Necrosis After Acute Pancreatitis: Surgical Approach** *288*
Naohiro Sata, Masaru Koizumi, and Alan Kawarai Lefor

35 **Management of Fluid Collection in Acute Pancreatitis** *294*
Georg Beyer, Simon Sirtl, Christoph Ammer-Herrmenau, and Albrecht Neesse

36 **Management of Pancreatic Fistula in Acute Pancreatitis** *300*
Marta Sandini, Thilo Hackert, and Markus W. Büchler

37 **Long-Term Outcome After Acute Pancreatitis** *306*
Christin Tjaden and Thilo Hackert

Section 4 Chronic Pancreatitis *315*

38 **Definition and Classification of Chronic Pancreatitis** *317*
David C. Whitcomb

39 **Molecular Understanding of Chronic Pancreatitis** *326*
Bomi Lee, Monique T. Barakat, and Sohail Z. Husain

40 **Natural History of Recurrent Acute and Chronic Pancreatitis** *334*
Rohit Das, Jorge D. Machicado, and Dhiraj Yadav

41 **Pediatric Recurrent Acute and Chronic Pancreatitis: Role of Pancreas Divisum** *344*
Jiri Snajdauf, Michal Rygl, Barbora Kucerova, and Natalia Newland

42 **Clinical and Laboratory Diagnosis of Chronic Pancreatitis** *349*
Georg Beyer, Markus M. Lerch, and Julia Mayerle

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. 43 Abdominal Imaging for the Diagnosis of Chronic Pancreatitis *357*
Atsushi Irisawa and Akira Yamamiya

44 Endoscopic Ultrasound for Diagnosis of Chronic Pancreatitis Versus Pancreatic Cancer *366*
J. Enrique Domínguez-Muñoz, Julio Iglesias-García, José Lariño-Noia, and Daniel de la Iglesia-García

45 Hereditary Pancreatitis and Complex Genetic Causes *375*
Celeste Shelton Ohlsen and David C. Whitcomb

46 Epidemiology and Pathophysiology of Tropical Chronic Pancreatitis *383*
Shailesh V. Shrikhande and Savio G. Barreto

47 CFTR-Associated Pancreatic Disease *390*
Chee Y. Ooi and Aliye Uc

48 Alcohol and Smoking in Chronic Pancreatitis *396*
Atsushi Masamune, Kazuhiro Kikuta, and Kiyoshi Kume

49 Idiopathic and Rare Causes of Chronic Pancreatitis *404*
Morihisa Hirota and Tooru Shimosegawa

50 Early Chronic Pancreatitis *412*
Kazuhiro Kikuta and Atsushi Masamune

51 Chronic Pancreatitis with Inflammatory Mass in the Pancreatic Head *418*
Ulrich F. Wellner, Kim C. Honselmann, and Tobias Keck

52 Structural Complications: Strictures, Stones, Pseudocysts, and Vascular Complications *424*
Xiaodong Tian, Xiaochao Guo, and Yinmo Yang

53 Nutritional Evaluation and Support: An Overview *430*
Sinead N. Duggan and Stephen J. O'Keefe

54 Exocrine Pancreatic Insufficiency *436*
Chris E. Forsmark

55 Bone Disease in Chronic Pancreatitis *442*
Sinead N. Duggan

56 Diabetes from Exocrine Pancreatic Disease *445*
Nao Fujimori, Tetsuhide Ito, and Yoshihiro Ogawa

57 Oxidative Stress and Antioxidants in Chronic Pancreatitis *451*
Soumya Jagannath Mahapatra and Pramod Kumar Garg

58 Pain Mechanisms in Chronic Pancreatitis *460*
Pierluigi Di Sebastiano, Fabio Francesco di Mola, Tommaso Grottola, and Rossana Percario

59 Pain Management in Chronic Pancreatitis *467*
Louise Kuhlmann, Søren S. Olesen, and Asbjørn M. Drewes

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. 60 **Adjunctive Therapy in Chronic Pancreatitis** *474*
Anna Evans Phillips

61 **Pancreatic Cancer Risks in Chronic Pancreatitis** *480*
Patrick Maisonneuve and Albert B. Lowenfels

62 **Evidence of Endoscopic and Interventional Treatment of Chronic Pancreatitis and Pseudocysts** *486*
Jörg Schirra, Simon Sirtl MD, Markus M. Lerch, and Julia Mayerle

63 **Major Pancreatic Resection for Chronic Pancreatitis: Indication, Goals, and Limitations** *496*
Faik G. Uzunoglu and Jakob R. Izbicki

64 **Pancreatic Drainage Procedures: Techniques and Results** *501*
Ulrich F. Wellner, Dirk Bausch, and Tobias Keck

65 **Duodenum-Preserving Pancreatic Head Resections for Chronic Pancreatitis: Techniques and Results** *506*
Hans G. Beger, Bertram Poch, Yang Yinmo, and Waldemar Uhl

66 **Total Pancreatectomy with Islet Autotransplant** *515*
Greg Beilman, Zachary Bergman, and Melena Bellin

67 **Minimally Invasive Surgical Management of Chronic Pancreatitis** *523*
Gilbert Z. Murimwa, Herbert J. Zeh III, and Matthew R. Porembka

Section 5 Autoimmune Pancreatitis *533*

68 **Epidemiology of Autoimmune Pancreatitis** *535*
Terumi Kamisawa

69 **Molecular Immunology and Pathogenesis of Autoimmune Pancreatitis** *540*
Yoh Zen

70 **Clinical Manifestation of Type 1 Autoimmune Pancreatitis** *546*
Tooru Shimosegawa

71 **Clinical Manifestation of Type 2 Autoimmune Pancreatitis** *554*
Nicolò de Pretis and Luca Frulloni

72 **Clinical Diagnostic Criteria for Autoimmune Pancreatitis** *561*
Tooru Shimosegawa

73 **Laboratory Diagnosis of Autoimmune Pancreatitis** *568*
J-Matthias Löhr and Miroslav Vujasinovic

74 **What is the Evidence Measuring Immune Markers** *573*
Shigeyuki Kawa, Takayuki Watanabe, and Norihiro Ashihara

75 **Autoimmune Pancreatitis and IgG4-Related Disease** *579*
Kazuichi Okazaki, Tsukasa Ikeura, and Kazushige Uchida

76 **Imaging Diagnosis of Autoimmune Pancreatitis** *595*
Kazuichi Okazaki, Makoto Takaoka, Tsukasa Ikeura, and Kazushige Uchida

Development of the Pancreas and Related Structures

Brian Lewis and Junhao Mao

Department of Molecular, Cell and Cancer Biology, University of Massachusetts Chan Medical School, Worcester, MA, USA

Anatomy of the Pancreas

The pancreas is a unique exocrine and endocrine organ located in the retroperitoneal region of the upper abdominal cavity. In humans, when fully formed, the organ has a distinct head, body, and tail, with the head of the pancreas contacting the duodenal region of the intestines (the main pancreatic duct drains into the duodenum) and the tail of the pancreas abutting the spleen. The greatest mass of the organ is present in the head, which is composed of tissue derived from two independent anlagen (see later). In other mammals, such as dogs and mice, the organ has a far less distinct structure and is identified as an amorphous pink tissue adjacent to the mesentery that runs along the upper intestinal wall.

The cells of the pancreas are arranged into distinct lobules composed primarily of the digestive enzyme-producing cells of the exocrine pancreas, which are arranged into acini (so-called acinar cells), the ductal structures that conduct these digestive enzymes to the intestines, and distinct clusters of endocrine cells, the islets of Langerhans, that secrete hormones and function to regulate glucose uptake and release and serum glucose levels. There are five recognized cell types within the islets, the α, β, δ, ε, and PP cells, which produce the hormones glucagon, insulin, somatostatin, ghrelin, and pancreatic polypeptide, respectively. The majority of the pancreatic tissue mass (more than 90–95%) is present within the exocrine compartment of the organ, with the islets of Langerhans, scattered throughout the tissue. The pancreas also has connective tissue, derived from the embryonic mesenchyme, which forms the septa that separate the many lobules of the organ. Mesenchyme-derived stromal cells are also present in the interlobular regions surrounding the pancreatic ducts, blood vessels, and nerves. In the following sections, we explore how these disparate cell types come together to form the pancreas.

Organogenesis in the Region of the Pancreas

Around day 14, the embryonic bilaminar germ disk is composed of a layer of epiblast and a layer of hypoblast. At this time, a faint groove appears along the longitudinal midline of the germ disk that develops into a structure called the primitive streak [1]. Around day 15, epiblast cells near the primitive streak undergo a morphologic change and migrate through the primitive streak into the space between the epiblast and hypoblast in a process known as gastrulation (Fig. 1.1). Some of the ingressing epiblast cells invade the hypoblast, which is eventually replaced by a new layer of epiblast-derived cells known as the definitive endoderm. Additional migrating epiblast cells occupy the space between the epiblast and the definitive endoderm to form a third layer of cells called the intraembryonic mesoderm (Fig. 1.1). As cells of the germinal disk migrate anteriorly to form a head process and lateral regions roll underneath to form an approximately cylindrical body shape, the endoderm is rolled into a tube that projects into the developing head region of the embryo surrounded by the mesoderm layer. This is the primitive digestive tube. The pancreas is specified by two separate outgrowths that arise on the dorsal and ventral surfaces of the primitive digestive tube. The epithelial cells of the pancreas originate from the interior lining of the primitive gut tube, which consists of a single layer of endoderm. A layer of mesenchyme, from which the muscle and

connective tissue of the gastrointestinal organs are derived, surrounds the endoderm.

The anterior regions of the endoderm form the foregut; regions posterior to the foregut form the midgut and hindgut. The most anterior regions of the foregut give rise to the esophagus and stomach. Just posterior to the foregut, the endoderm is continuous with the yolk sac, which extends outside the embryo, in a region known as the anterior intestinal portal. Endodermally derived cells close to the anterior intestinal portal specify the pancreas. The duodenum and liver are also specified by foregut endoderm in this region.

Thus, many gastrointestinal tissues are specified at the same time from a fairly restricted region of the gut endoderm. How are each of these organs specified in the appropriate anatomic location, and how do they differentiate properly into mature functional organs? The epithelial organs of the developing embryo originate as buds from the endoderm as the appropriate temporal and spatial cues are received. Thus, proper initiation and location of endodermally derived organs are regulated by the activation status of important signal transduction pathways involved in animal development, including the hedgehog, Notch, and fibroblast growth factor (FGF) signaling pathways.

Early Pancreatic Development

During the fourth week of gestation, two buds appear on the dorsal and ventral sides of the foregut near the anterior intestinal portal. These epithelial buds indicate the specification of the pancreas. These buds initially grow and differentiate independently, but later fuse to form a single organ. The anlage on the dorsal side, the dorsal pancreatic bud, appears first and gives rise to the dorsal pancreas. The cells of the dorsal pancreas will give rise to the head, body, and tail of the mature pancreas. The second pancreatic anlage appears shortly after the appearance of the dorsal pancreatic bud. This bud, which appears on the ventral side of the gut tube, is appropriately called the ventral pancreatic bud and develops into the ventral pancreas, which forms part of the head of the pancreas. Both pancreatic buds develop simultaneously, and the proliferating epithelial cells grow as projections into the surrounding mesenchymal tissue. During this time, the development of the intestines, and importantly the duodenum, continues. Rotation and asymmetric growth of the duodenum move the originally ventral part to a dorsal location, carrying with it the ventral pancreas and the primordial common bile duct. As the duodenum begins to rotate into its appropriate anatomic location, the ventral pancreas also rotates around the gut tube such that the ventral and dorsal pancreata lie adjacent to each other. These pancreatic rudiments then fuse to form a single organ. While both developing pancreatic buds independently form pancreatic ducts, the lumens of which are continuous with the lumen of the primitive gut, after they fuse their primary ducts anastomose to form the main pancreatic duct (Fig. 1.2). The region of the primary duct of the ventral pancreas proximal to the duodenum fuses with the primary duct of the dorsal pancreas and becomes the primary drainage into the duodenum, entering the duodenum immediately adjacent to the common bile duct. The proximal region of the primary duct of the dorsal pancreas sometimes

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 1.2 Contributions of the dorsal and ventral pancreas to the definitive organ. The ventral pancreas becomes most of the head. The dorsal pancreas becomes the remainder of the head, plus the body and tail. The duct of the dorsal pancreas contributes a large part of the main pancreatic duct plus the accessory duct. The duct of the ventral pancreas becomes the part of the main duct nearest the duodenum.

remains as an accessory drainage but often regresses. The ducts sometimes fail to fuse, in which event two independent duct systems drain into the duodenum.

Signaling Governing Early Pancreatic Development

Early pancreatic development and establishing pancreatic identity are governed by the interplay between several critical transcription factors and intercellular signaling pathways. PDX1 and PTF1A are among the earliest transcription factors expressed in the pancreatic progenitor populations, and their functions are critical for pancreatic development [2–5]. In mice, PDX1 expression is first detected in the primitive gut tube at embryonic day 8.5 (E8.5), which corresponds to ~25–27 days in humans. PDX1 expression demarcates the prospective pancreatic domain, which is then followed by PTF1A expression in pancreatic endoderm at E9.5 [5–7]. Mice lacking either transcription factor display pancreatic agenesis [2,3,5,8].

In addition to the transcription factors, several key intercellular signaling pathways between gut endoderm and mesenchyme, including the hedgehog, FGF, Notch and Hippo pathways, play important roles in establishing the pancreatic identity and controlling the expression of these transcription factors. Research studies have shown that sonic hedgehog (SHH), the ligand of the hedgehog pathway, is excluded from the prospective pancreatic region, but is present in the region of foregut that becomes the duodenum, and ectopic expression of SHH in the pancreas induces an intestinal fate, suggesting that SHH signaling may specify a duodenal versus pancreatic fate in the posterior foregut [9,10]. Another well-understood pathway mediating the mesenchymal–epithelial interaction is the FGF signaling pathway, in particular the FGF10–FGFR2 ligand-receptor pair. During early pancreatic development, FGF10 is highly expressed in the primitive mesenchyme, whereas its receptor FGFR2 is present in the pancreatic epithelium [11]. Mouse genetic experiments demonstrated that FGF10 provides the pro-proliferative signal to promote the expansion of the progenitor pool in the pancreatic epithelium [11]. In addition, FGF10 signaling from the mesenchymal cells is critical for maintaining the epithelial expression of SOX9 [12]. SOX9 is another transcription factor critical for early pancreatic development, and it exerts its function in part by controlling the expression of the FGF10 receptor FGFR2 [12,13]. Together, the complex regulatory loop between these signaling pathways and transcription factors in the epithelium and mesenchyme coordinates early organ growth and the establishment and maintenance of pancreatic identity.

Differentiation of Pancreas Cell Types

The acinar, ductal, and endocrine cells of the pancreas are all produced through the proliferation and differentiation of the epithelial cells of both pancreas primordia. The cells appear homogeneous during the early stages of development as they proliferate and grow into the surrounding mesenchyme as finger-like projections. The epithelial cells form undifferentiated tubules that branch and anastomose as they penetrate into the mesenchyme to generate a tubular network, which resembles an immature (and nonfunctional) duct system. The acinar cells appear as clusters of cells at the ends of branches of this tubular network. The endocrine cells appear as cells that delaminate from the tubular epithelium and reaggregate in isolated clusters embedded within the developing parenchyma. The existing cells within these small isolated endocrine clusters proliferate, and these clusters therefore expand to form the islets.

Apparent differentiation of pancreas epithelial cells into endocrine cells can be identified beginning at 12 weeks of gestation with the detection of endocrine granules. Most of the endocrine differentiated cells identified at this time express glucagon and are therefore believed to be α cells. Importantly, lineage-tracing experiments performed in mice demonstrated that these early α cells do not act as endocrine progenitors, as β cells, the predominant cell type in the mature islet, are derived from glucagon-negative cells [14]. Differentiation of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

acinar cells is detected at approximately 16 weeks, as identified by the appearance of zymogen granules. Interestingly, not all enzymes are elaborated at once—detection of trypsinogen does not occur until approximately 22 weeks. The digestive enzyme-positive cells arise as clusters from the undifferentiated tubules, the expansion of which is rapid such that the acinar cells become the dominant population within the organ. Although they are not yet mature acinar cells, the cells in the acinar clusters display some of their hallmark features, including basolaterally located nuclei. As differentiation continues, the cells become arranged in recognized acini and defined lobules surrounded by connective tissue. The ductal system arises after maturation of the immature tubular network. The specific morphologic changes that accompany this change are unclear, although some work suggests that Wnt signaling is involved in this transition [15].

Transcriptional Mechanisms Underlying Pancreatic Cell Fate Decision

Much information about pancreatic cell fate determination and cell type differentiation has been obtained from studies in animal models. Elegant genetic and cell-based experiments in mice have identified a gene regulatory network controlled by many transcription factors to specify different cell lineages in the developing pancreas.

Development of the Endocrine Lineage

Endocrine cell specification begins with the expression of NGN3, a bHLH (basic helix–loop–helix) transcription factor, in a subset of progenitor cells within the trunk region of the pancreatic bud [16–18]. The NGN3-expressing cells eventually give rise to all endocrine cell types: insulin-producing β cells, glucagon-producing α cells, somatostatin-producing δ cells, ghrelin-producing ε cells, and pancreatic polypeptide-producing PP cells [16–18]. NGN3 initiates endocrine lineage specification by inducing the expression of downstream transcription factors, including NeuroD, NKX2.2, PAX4, and ARX. Among them, NKX2.2, NeuroD, and PAX4 play key roles in the specification of β cells [19–21]. Mutant mice lacking any of these transcription factors display a phenotype of dramatic or total loss of β cells [19–21]. Further studies revealed that the opposing actions of PAX4 and ARX determine the fate choice between α and β cells. During endocrine differentiation, loss of ARX leads to a complete loss of α cells, but a concomitant increase in β and δ cells [22], whereas loss of PAX4 results in an opposite phenotype with loss of β and δ cells and expansion of α cells [20,22]. It is believed that this effect on cell fate choice is mediated by the reciprocal transcriptional repression between these factors.

Differentiation of Acinar Cells

Pancreatic acinar cells are primarily derived from precursor cells in the tip region, and their differentiation is coordinated by the transcription factor PTF1A, a master regulator of pancreatic development. Prior to exocrine differentiation, PTF1A forms a complex with the bHLH transcription factor RBP-Jk, and is required for activation of RBP-Jl, an acinar-specific paralog of RBP-Jk [23,24]. The more active RBP-Jl then replaces RBP-Jk to form the complex with PTF1A, thereby directly inducing the expression of many acinar-specific genes, including secretory peptides and digestive enzymes [23,24]. Interestingly, PDX1, another factor important for early pancreatic morphogenesis, is also involved in acinar differentiation. Although not essential for initial acinar specification, it appears that PDX1 is required for terminal differentiation of acinar cells [25]. Other transcription factors, such as NR5A2 and MIST1, are also required for acinar differentiation and homeostasis, likely through the interaction with the PTF1A/RBP-Jk/l complex [26,27].

Ductal Cell Differentiation and Lineage Plasticity

During development, NGN3-positive cells in the trunk region of the pancreatic bud give rise to endocrine cells, whereas NGN3-negative trunk epithelial cells contribute to the ductal system [28,29]. A number of transcription factors, such as SOX9, PROX1, HES1, and HNF6, are expressed in the ductal lineage and play various roles in ductal differentiation, including primary cilia formation in the ductal epithelial cells [30–33]. The Notch signaling pathway is the main determinant for promoting and maintaining the ductal cell identity [31]. Although the three lineages (endocrine, exocrine, and ductal) are specified during early development, the adult pancreatic cells from different lineages show remarkable plasticity and trans-differentiation capacity in pancreatic injury, pancreatitis, and tumorigenesis, which may shed light on the mechanisms underlying these pancreatic pathologies.

Development and Disease

Molecules important in the development of the pancreas are also causally associated with pancreatic disorders. Several of the signaling pathways involved in normal

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pancreas development, such as the Notch, hedgehog, Hippo/YAP and Wnt signaling pathways, are commonly dysregulated in pancreatic ductal adenocarcinomas [34–40]. Aberrant activation of Wnt signaling drives the development of other pancreatic tumor types such as acinar carcinomas, pancreatoblastoma, and mucinous cystic neoplasms [41–43].

In diabetes, mutation of the transcription factor PDX1, which is important for pancreas specification and for proper β-cell maturation and function, is a cause of maturity-onset diabetes of the young (MODY) [44]. Other transcription factors that are critical for β-cell development (as determined by genetic studies in the mouse), such as hepatocyte nuclear factor 1α (HNF1α), HNF1β, HNF4α, and NeuroD, are all also mutated in additional MODY complementation groups [44]. More recently, scientists have utilized our growing understanding of normal pancreas development to promote the differentiation of induced pluripotent stem cells into insulin-producing cells in a new potential therapeutic approach for diabetes [45–47].

Collectively, these findings illustrate the importance of key regulators of pancreas development and differentiation in pathologic disease states and how knowledge of normal pancreas development may drive new therapeutic strategies for pancreatic diseases.

Anatomy, Histology, and Fine Structure of the Pancreas

Daniel S. Longnecker[1] and Elizabeth D. Thompson[2]

[1] *Department of Pathology, Geisel School of Medicine at Dartmouth, Hanover, NH, USA*
[2] *The Johns Hopkins University School of Medicine, Baltimore, MD, USA*

Introduction

This chapter reviews the anatomy, histology, and ultrastructure of the pancreas, including both the exocrine and endocrine portions. The exocrine pancreas produces and secretes digestive enzymes (e.g., trypsin, chymotrypsin, amylase, lipase) into the duodenum. The exocrine portion includes acinar cells and ducts with associated connective tissue, vessels, and nerves that comprise more than 95% of the pancreatic mass. The endocrine pancreas (islets of Langerhans) makes and secretes insulin, glucagon, somatostatin, and pancreatic polypeptide into the blood. The islets comprise 1–2% of pancreatic mass.

When the anatomic terms *anterior* and *posterior* are used in this chapter, they pertain to relationships in the human, standing erect. Similarly, *superior* and *inferior* mean toward the head and toward the feet, respectively. We will adopt the convention that *right* and *left* (unqualified) indicate the subject's right-hand and left-hand sides. However, when describing the location of structures within an image, *image right* and *image left* are used to denote relationships without reference to the subject's right or left side.

The organization and content of this chapter are based in part on a recent Pancreapedia chapter on pancreatic anatomy and histology [1].

Gross Anatomy

The pancreas (meaning all flesh in Greek) lies in the posterior portion of the upper abdomen behind the stomach. It is largely retroperitoneal and is covered by peritoneum on the anterior surface of the head and body and is surrounded by fat in this region. It is customary to refer to various portions of the pancreas as head, body, and tail. The head abuts the C-shaped second portion of the duodenum in the right upper quadrant of the abdomen. The tail emerges into the peritoneal cavity (covered by peritoneal serosa) and extends toward the hilum of the spleen in the left upper quadrant. The pancreas weighs about 100 g and is 14–25 cm long [2]. Figure 2.1 shows a human pancreas that has been dissected to isolate it from surrounding fat and adjacent organs and Fig. 2.2 is a drawing depicting a pancreas that has been dissected to reveal the pancreatic and common bile ducts.

The pancreas is intimately associated with several adjacent organs. Relationships of the pancreas to surrounding organs and structures are depicted in Figs 2.3, 2.4, 2.5, and 2.6. As noted above, as the duodenum exits the stomach it loops around the head of the pancreas. The tail of the pancreas lies near the hilum of the spleen. The body of the pancreas lies posterior to the pyloric region of the stomach.

The portion of the pancreas that lies anterior to the aorta is somewhat thinner in the anterior–posterior axis than the adjacent portions of the head and body of the pancreas. This region is designated as the neck and marks the junction of the head and body (Fig. 2.1b). The proximity of the neck of the pancreas to major blood vessels posteriorly, including the superior mesenteric artery, superior mesenteric-portal vein, inferior vena cava, and aorta, limits the options for a wide surgical margin during pancreatectomy (Fig. 2.5).

There is no anatomic landmark for the junction between the body and tail of the pancreas [3]. Hellman defined the tail as one-fourth of the pancreas from the tip of the tail toward the head [4] whereas Wittingen and

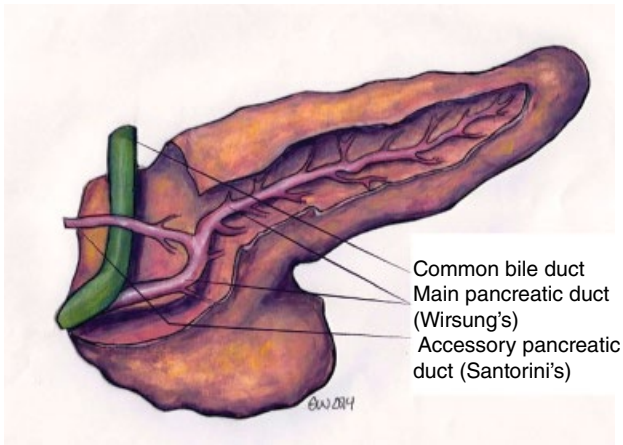

Figure 2.2 A pancreas dissected to reveal the pancreatic ducts and common bile duct as it traverses the head of the pancreas, ending as it joins the main pancreatic duct near the ampulla of Vater. Interlobular branches of the main duct are depicted but smaller ducts (intralobular ducts and ductules) are not. Eponyms identify the anatomist, embryologist, or physician who is credited with first describing a structure. Wirsung and Santorini were such scientists. *Source:* Drawing by Emily Weber.

Frey defined the junction between the body and tail as the point where the gland sharply narrows [5]. This point is difficult to define in some pancreases.

The common bile duct passes behind the upper portion of the head and then runs through the pancreas to join the main duct in the duodenal wall (Figs 2.2, 2.5, and 2.7b). The accessory pancreatic duct drains into the duodenum at the minor papilla in most humans, and the main pancreatic duct enters the duodenum at the major papilla (ampulla of Vater, Fig. 2.3). See Chapter 3 for discussion of pancreas divisum and other anomalies with possible clinical significance.

Typically, the bile duct and main pancreatic duct join into a "common channel" referring to the fused portion of the bile and pancreatic ducts proximal to its entry into the duodenal lumen. The common channel varies in length from a few millimeters to about 1 cm. A long common channel due to junction of the bile and pancreatic ducts proximal to the duodenal wall is regarded as an anomaly [6]. Less often, there is no common channel because the ducts open separately into the duodenum at the major

ampulla. The common channel has received much attention because stones in the biliary tract (gallstones) may lodge in the common channel, causing obstruction of both pancreatic and biliary duct systems. Such an obstruction is frequently the cause of acute pancreatitis.

The arterial blood supply to the pancreas is through branches of the celiac trunk and the superior mesenteric artery (Fig. 2.7). Both arise from the abdominal aorta and have multiple branches that supply several organs. Anastomosis of their branches provides collateral circulation that generally assures a secure arterial blood supply to the pancreas. Most of the arteries are accompanied by veins that drain into the superior mesenteric, portal, and splenic veins as they pass behind the pancreas, as shown in Fig. 2.7b. The superior mesenteric vein becomes the portal vein when it joins the splenic vein (Fig. 2.7b).

The typical locations of lymph nodes surrounding the pancreas are shown in Fig. 2.8. There is significant individual variation in the location of lymph nodes, so the locations shown are a generalization. In general, two systems of lymph nodes drain the organ: one surrounding the edges of the pancreas (Fig. 2.8a), and the other associated with the anterior surface of the aorta and celiac trunk (Fig. 2.8b). Various node groups have been assigned "station numbers" that may be used to designate their location [1,2,7]. These are rarely used in Western literature and are not illustrated here. Lymphatics arise in the interstitium of the pancreas and course with blood vessels and nerves draining to the nodes and then to the thoracic duct.

A rich plexus of autonomic nerves lies behind the head, neck, and body of the pancreas connecting to the celiac ganglia that lie along the aorta (Fig. 2.9).

Histology and Ultrastructure

Overview

The exocrine pancreas is a network of tubules composed of acinar and duct cells that synthesize, secrete, and carry digestive enzymes into the intestine. The small tubules in the lobular tissue are largely composed of acinar cells. The acinar tubules connect to the smallest terminal portions of the duct system that are commonly called ductules, although intercalated duct has also been used to denote these components of the duct system. In this chapter, we will use *ductule* to denote these small terminal portions of the duct system that link the acinar tubules to larger ducts, including small intralobular ducts. At the level of gross anatomy, the acinar tubules, ductules, and small ducts appear as solid lobular tissue as seen in Fig. 2.1c. The following descriptions include both histology and ultrastructure for each major cell type.

Acinar Tissue

An acinus is a cluster of acinar cells that contain zymogen granules, the storage compartment for pancreatic digestive enzymes. For many years, it was considered that acinar tissue was composed of clusters of acini arranged like grapes at the ends of a branching duct system. However, more recent studies have demonstrated that pancreatic acini and tubules are arranged as an anastomosing tubular network [8]. The duct cells at the interface of acinar tubules and ductules are referred to as centroacinar cells and these cells may also be interspersed within acini. An

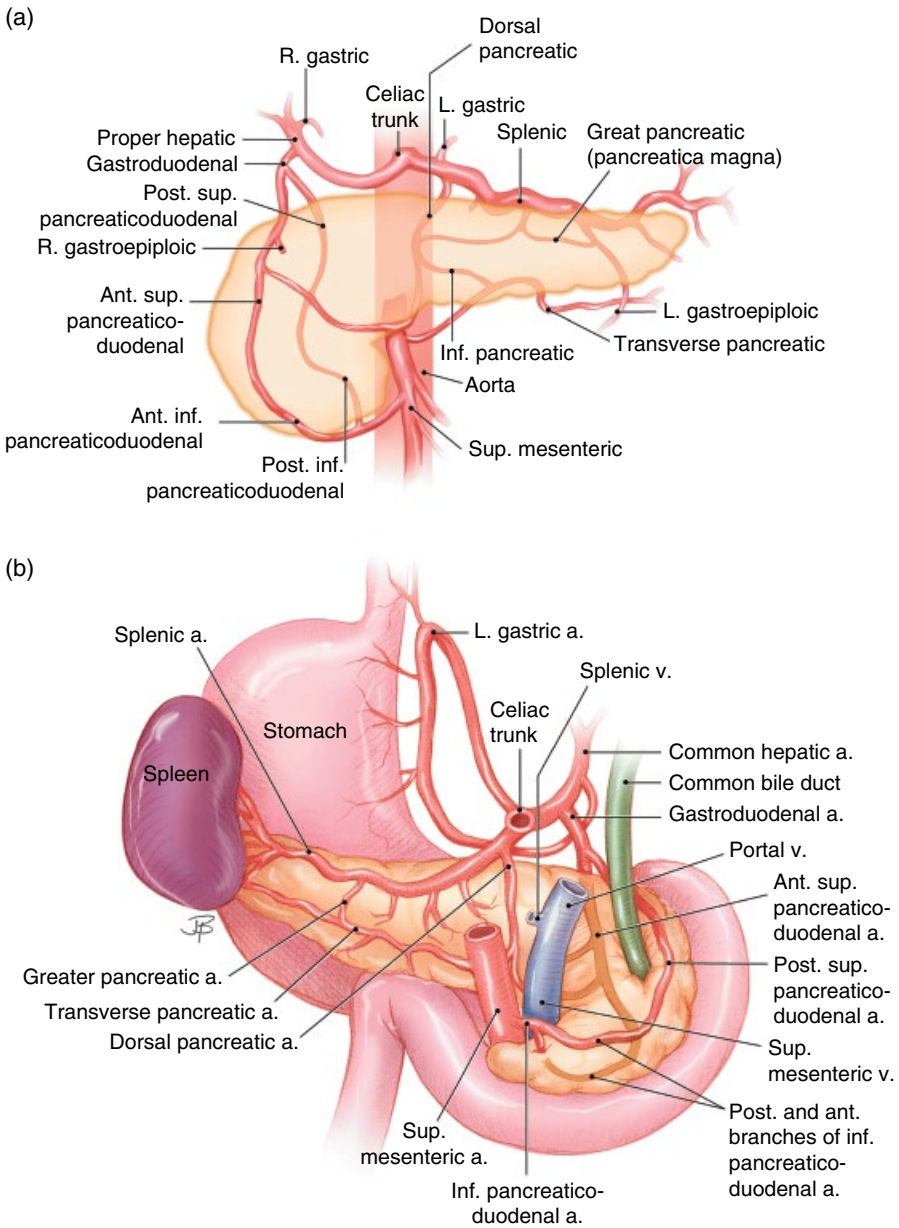

Figure 2.7 The arterial blood supply of the pancreas. Image (a) is visualized from the front (anterior) and (b) is seen from the back (posterior). *Source:* Drawing by Jennifer Parsons Brumbaugh, in Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology, 2007: Chapter 1. Reproduced with permission.

acinus may occur as a cul-de-sac at the end of a tubular network and also as an intermediate structure with ductules on either side. Recognizing this pattern provides a basis for understanding the changes that the pancreas undergoes with the development of cancer and pancreatitis [9,10]. The tubular complexes that are observed as a result of these diseases are contributed to by the transition of acinar cells into ductular-like cells, a process sometimes referred to as acinar to ductal metaplasia [11].

At the histologic level in sections stained with hematoxylin and eosin (H&E), individual acinar cells have bluish cytoplasm in the basal (perinuclear) region, reflecting the high content of RNA (Fig. 2.10). Central to the nucleus, the cytoplasm is eosinophilic (pink), reflecting the higher content of protein in the Golgi and zymogen granules. Many acinar cells are binucleate [12,13]. Although the detailed histologic characterization of binucleation is based on the rat pancreas, the observation

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 2.8 Lymph nodes draining the pancreas. There is considerable individual variation in the location and size of lymph nodes, so this drawing is somewhat schematic. Both (a) and (b) are anterior views; (b) includes some nodes that lie posterior to the pancreas. *Source:* Drawing by Jennifer Parsons Brumbaugh, in Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology, 2007: Chapter 1. Reproduced with permission.

also appears to pertain for the human pancreas but is of unknown significance.

The acinar cell ultrastructure reflects cell function, that is, the synthesis and secretion of digestive enzymes, and it will be described in the context of this function. The basilar cell membrane has an extracellular basement membrane that abuts the interstitial space where capillaries and nerve endings lie (Fig. 2.11). The lateral cell membranes are closely apposed to the cell membranes of adjacent acinar or centroacinar cells and these membranes are linked by linear tight junctions (Figs 2.12 and 2.13). The most distinctive feature of the luminal membrane is the formation of microvilli, which are narrow, finger-like extensions into the lumen of the acinus (Fig. 2.13).

The basilar and perinuclear cytoplasm of acinar cells contains abundant rough endoplasmic reticulum (RER) that forms flattened cisternae with a smooth luminal side, whereas the external surface is studded with ribosomes (giving rise to the "rough" designation). The RER is folded into stacks that generally lie in the plane of the adjacent cell membrane (Fig. 2.12).

Mitochondria are scattered throughout the cytoplasm of the acinar cells but their density is highest in the basal and central portion of the cell (Fig. 2.12). They are sparse in the cytoplasm adjacent to the luminal surface.

On the luminal side of the nucleus, small membrane-bound transport vesicles appear to bud from the RER and then to lie free in the cytoplasm. Central to this region are small stacks of flattened smooth-walled vesicles called the Golgi that appear to arise from the fusion of multiple transport vesicles. At the luminal side of the Golgi, the vesicles begin to round up and progressively to contain

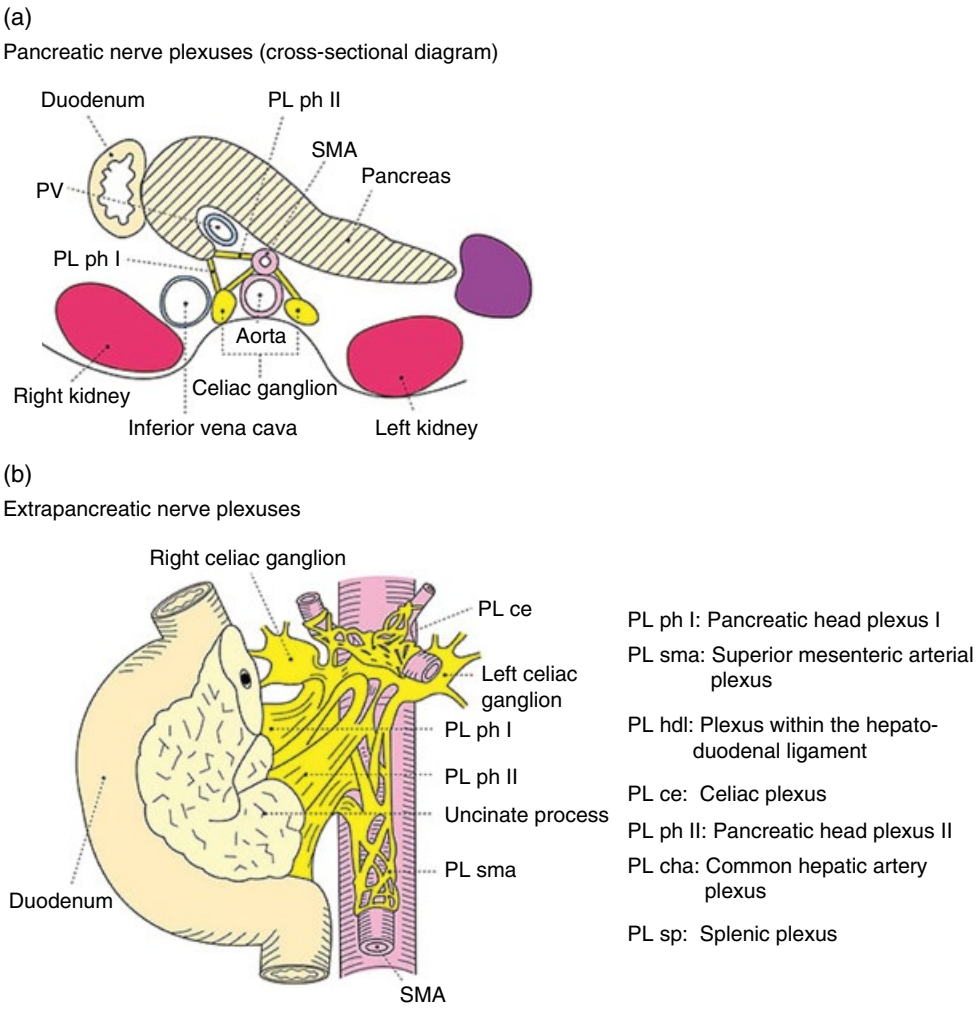

Figure 2.9 Nerves (yellow) serving the pancreas. The cross-sectional image (a) emphasizes the location of the celiac ganglia of the autonomic system lateral to the aorta while (b) emphasizes the rich nerve plexus that connects these ganglia to the pancreas. SMA, superior mesenteric artery; PL, plexus. *Source:* Classification of Pancreatic Carcinoma, 2003 [7]. Reproduced with permission of the Japan Pancreas Society.

homogeneous densities. These are nascent zymogen granules (also termed immature zymogen granules or condensing vacuoles) and they progressively lose membrane as contents condense to become mature zymogen granules.

The apical cytoplasm near the acinar lumen is occupied by variable numbers of mature zymogen granules. These are usually spherical (appearing round in cross-section) with a single bilayer membrane surrounding homogeneous dense content (see Figs 2.12, 2.13, 2.18, and 2.22). Fusion of the membranes of zymogen granules and adjacent lumenal cell membrane is observed prior to secretion of the zymogen into the lumen. See Longnecker [1] for additional electron micrographs that illustrate acinar cell ultrastructure.

Acinar cell cytoplasm may contain fat or autophagic vacuoles (sometimes called residual bodies) that are walled-off areas of damaged cytoplasm (Fig. 2.12).

Duct System

The components of the duct system are the main pancreatic duct (duct of Wirsung); its major branches, called interlobular ducts, that drain into the main duct throughout the pancreas as depicted in Fig. 2.2; smaller intralobular ducts; and ductules that link acinar tubules to the smallest intralobular ducts. The small intralobular ducts and ductules are ordinarily seen only at the level of light and electron microscopy. The accessory duct (duct of Santorini; Fig. 2.2) that connects the main duct to the duodenum at the minor papilla in some humans (Fig. 2.3) is of variable importance and is similar in structure to the main duct, although typically it is slightly smaller.

Enzymes from acinar cells are released into a bicarbonate-rich solution that is secreted by the centroacinar and ductal cells and flows from the acini and

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 2.10 Pancreatic lobular tissue with acinar cells, small duct, ductule, and small islet. This H&E-stained section is largely composed of acini and acinar tubules cut in cross-section or tangentially. A small intralobular duct (a) is shown image right and at its upper end it gives rise to a ductule (b) with virtually no connective tissue evident in its wall. Liquid content of the duct and ductule is homogeneous and pink (eosinophilic). Large, clear spaces are fat cells (c). A small vein (d) and artery (e) are at image right above center. A small islet is near the lower image right corner. *Source:* Hruban RH, Pitman MB, Klimstra DS. Tumors of the pancreas. AFIP Atlas of Tumor Pathology, 4th series, fascicle 6. Washington, DC: American Registry of Pathology; 2007. Reproduced with permission.

Figure 2.11 Pancreatic tissue with acinar, centroacinar, and ductal cells. The acinar cells are easily identified because of the darkly stained zymogen granules (ZG) and are larger than centroacinar and ductal cells. The basal portion (B) of the acinar cells lies next to the interstitial space that contains vessels (V), nerves, and connective tissue. Nuclei (N) with nucleoli (n) are in the basal portion of the acinar cells. The Golgi (G) lies at the junction of the basal (B) and apical (A) portions of the cell that borders the lumen (L) of the acinus. Centroacinar cells (CAC) have pale cytoplasm with no secretory granules. A small ductule (D) extends from image right to below center. Mitochondria (m) are identified at the top of the field. This is a 1 µm thick section of plastic embedded tissue prepared for electron microscopy that was stained with toluidine blue. *Source:* Micrograph contributed by James Jamieson.

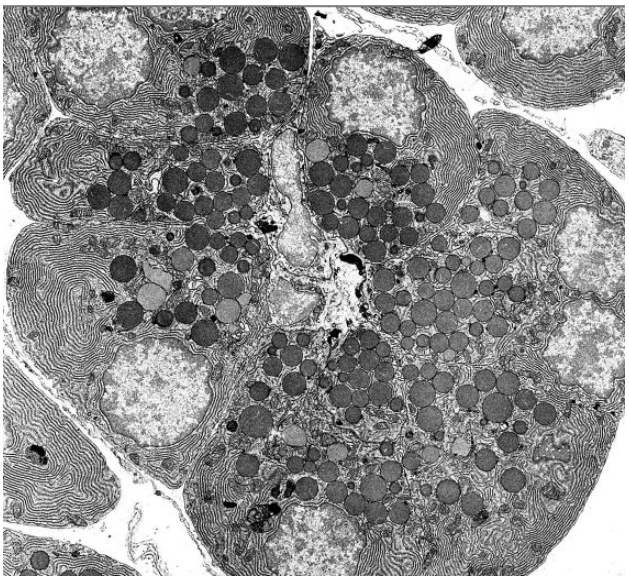

Figure 2.12 Acinar cells with RER, mature, and immature zymogen granules. Two centroacinar cells are near the center. The acinar cell at 3 o'clock, image right, is binucleate. Numerous mitochondria are present in the acinar cells. There are several electron-dense residual bodies in the acinar cells. It appears that two have been extruded into the interstitial space at the top of the image and others are being extruded into the acinar lumen near the center of the image. These pathways for clearing the cell of autophagic vacuoles and residual bodies have been documented in an animal model (rat) of acute pancreatitis [14]. *Source:* Micrograph contributed by James Jamieson.

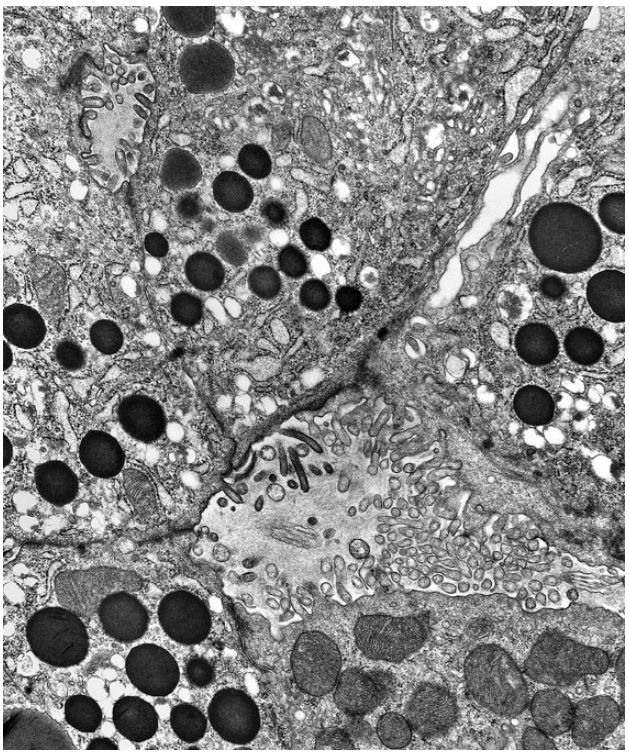

Figure 2.13 Apical portions of several acinar cells border two luminal spaces, lower image right and upper image left. A centroacinar cell with numerous mitochondria borders the lumen, lower image right. Microvilli protrude into the lumens from the luminal aspect of the acinar and centroacinar cells. Zymogen granules are prominent in all acinar cells. *Source:* Micrograph contributed by James Jamieson.

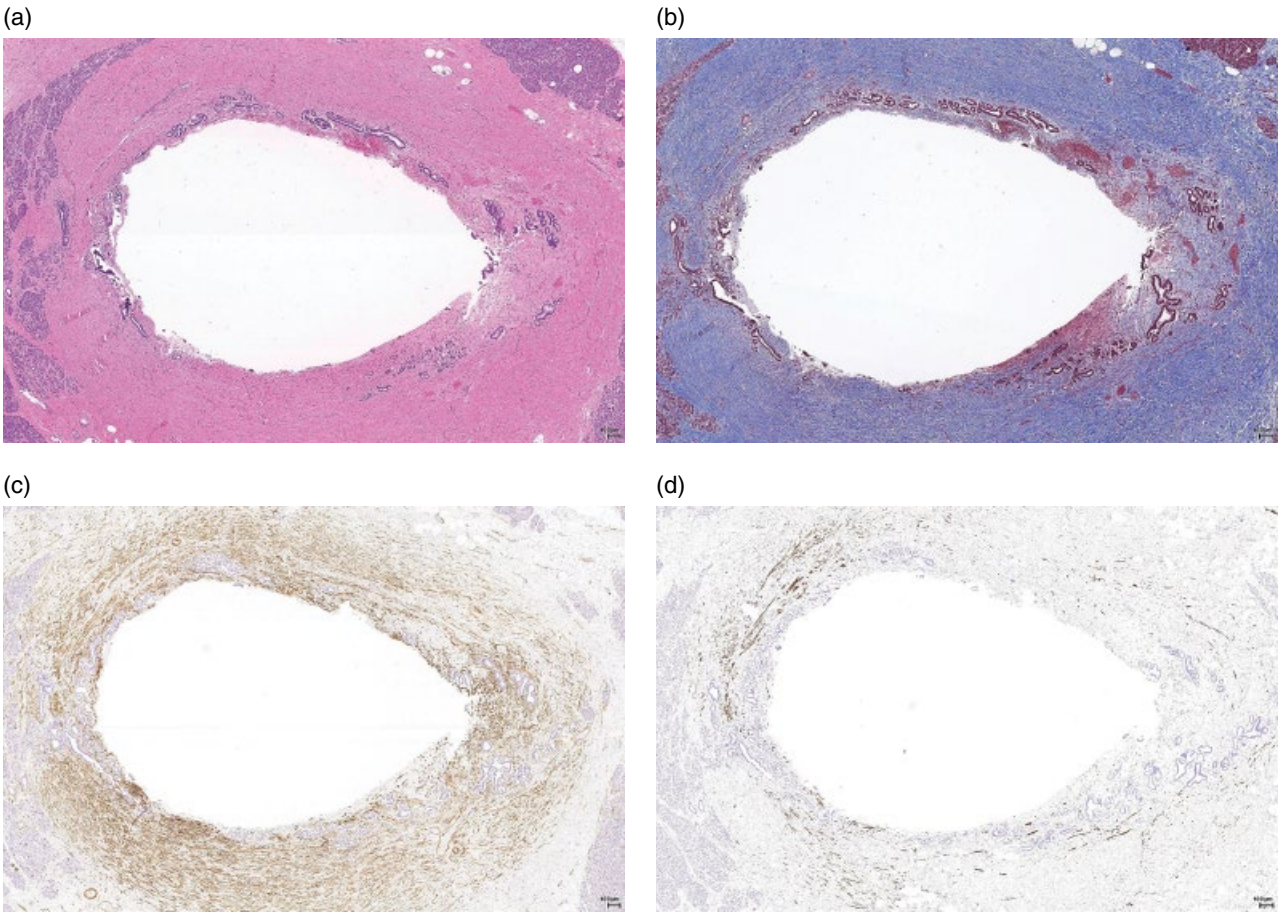

Figure 2.14 Serial cross-sections of main pancreatic duct (a) (H&E stain) stained to demonstrate collagen (b) (trichrome stain), myofibroblasts (c) (immunoperoxidase stain to demonstrate smooth muscle actin, a marker for myofibroblasts), and smooth muscle (d) (immunoperoxidase stain to demonstrate desmin, a marker for smooth muscle). The lining epithelium has been lost, probably reflecting preoperative ERCP and stenting of the pancreatic duct. The patient underwent a Whipple procedure because of chronic pancreatitis. There are many myofibroblasts and fewer smooth muscle cells in the wall of the main duct. *Source:* Micrographs contributed by Arief A. Suriawinata.

acinar tubules into the ductules that join to form the intralobular ducts, then into the interlobular ducts and main duct, and finally into the duodenum at the major or minor papillae. Ducts are illustrated in Figs 2.10, 2.11, 2.14, 2.15, and 2.16.

The integrity of the duct system is of key importance in preventing entry of the exocrine enzymes into the interstitial space, where they may be activated and cause tissue damage manifested as pancreatitis. As ductules anastomose to form intralobular ducts, the duct walls begin to develop a connective tissue wall (Fig. 2.10) that becomes progressively thicker as the smaller ducts join to form larger ducts and the main pancreatic duct. The main and interlobular ducts have thick, dense, collagenous walls that contain myofibroblasts and smooth muscle cells (Fig. 2.14). The connective tissue component of the duct wall becomes progressively thinner and contains fewer myofibroblasts and smooth muscle cells as the ducts branch and become narrower in the lobules (Fig. 2.15). The smallest intralobular ducts lack smooth muscle cells. Intercellular tight junctions, also called zonula occludens, between duct cells, centroacinar cells, and acinar cells play a major role in preventing leakage of the duct system. Kern provided excellent images and discussion of these tight junctions [15].

The lumen of the duct system is normally lined by a single layer of cuboidal epithelial cells that have a single nucleus and a smaller amount of cytoplasm than acinar cells (Figs 2.10, 2.15, and 2.16). The cytoplasm is pale pink and homogeneous in H&E-stained sections. The duct lumen may contain homogeneous material reflecting the protein content of the secretions (Figs 2.10 and 2.16). Sometimes epithelial cells may be shed into the lumen.

Ductal epithelium may undergo squamous metaplasia or mucinous metaplasia. In the latter process, the ducts are lined by tall columnar cells with abundant pale apical

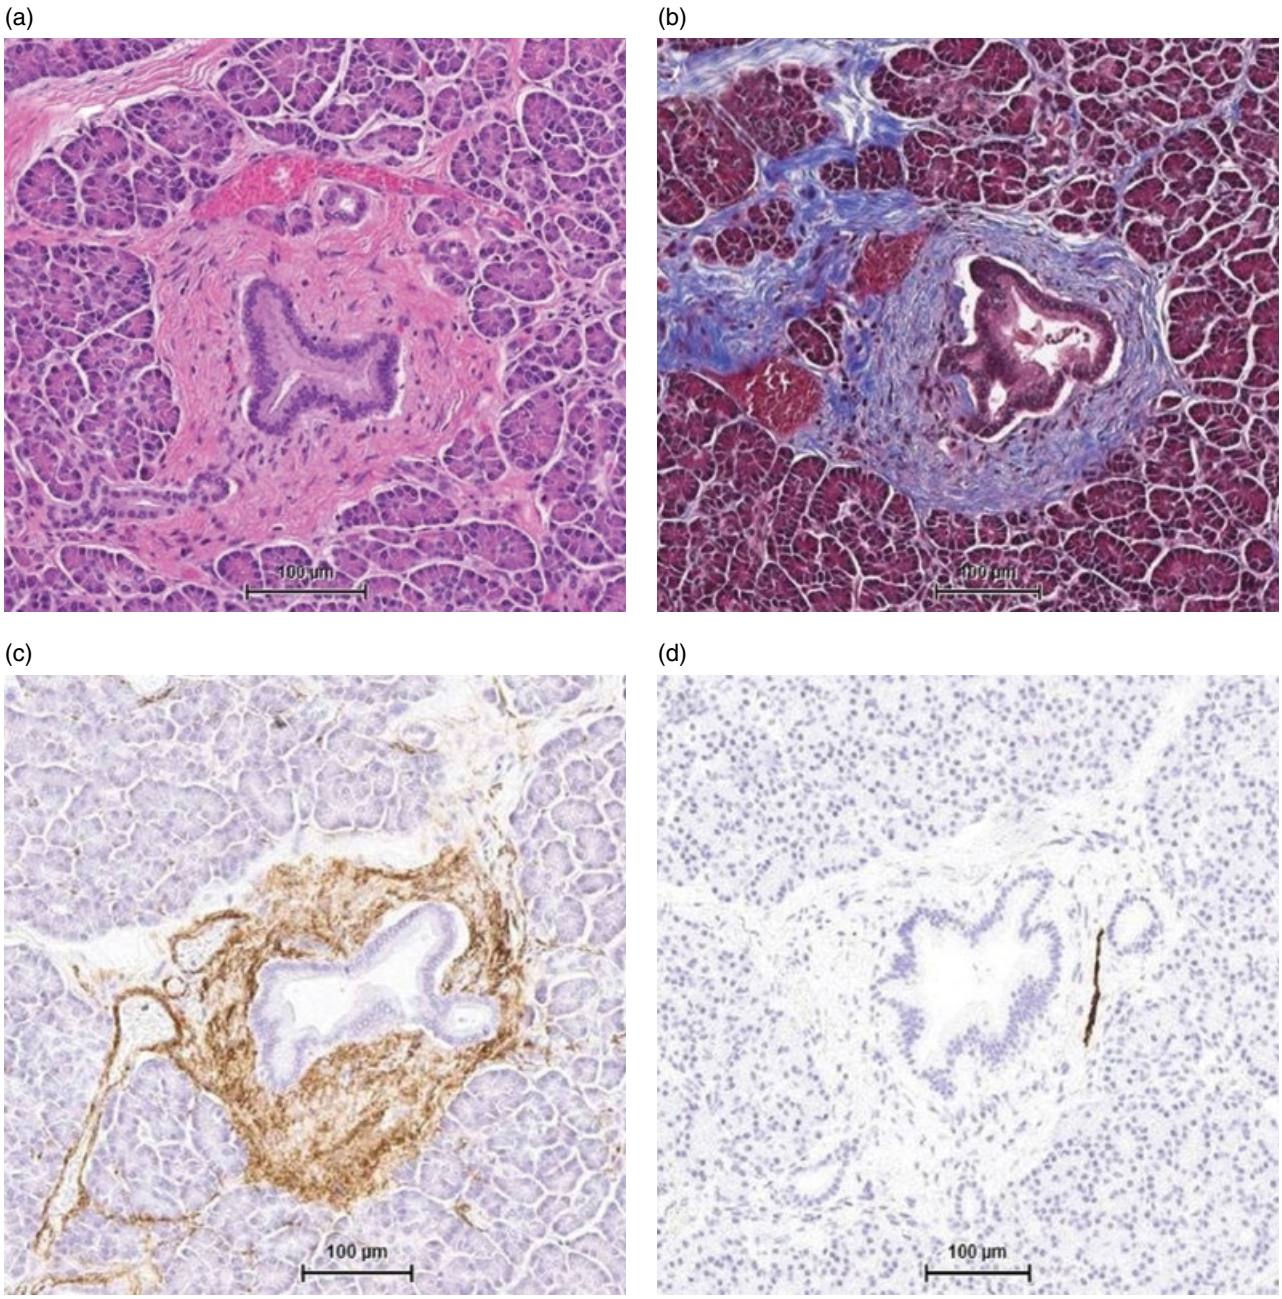

Figure 2.15 Serial cross-sections of a small intralobular duct surrounded by acinar tissue from the same patient as in Fig. 2.14. (a) H&E stain. Note the origin of a ductule branching into acinar tissue at 7 o'clock. (b) Trichrome stain with blue-staining collagen. There is fibrosis around acinar lobules (upper image left). (c) Immunoperoxidase stain with antibody to smooth muscle actin (SMA) to demonstrate the abundant myofibroblasts. (d) Immunoperoxidase stain with antibody to desmin to demonstrate smooth muscle cells. There is little staining. *Source:* Micrographs contributed by Arief A. Suriawinata.

cytoplasm that contains mucin. This type of change is characteristic of low-grade pancreatic intraepithelial neoplasia (PanIN) lesions and is possibly an early step in the development of PanIN.

At the ultrastructural level, duct cells have a simple structure compared with acinar cells. RER is sparse but mitochondria are numerous, and there are no secretory granules. The luminal surface gives rise to numerous microvilli, similar in appearance to those arising from acinar cells (Fig. 2.13). Ductal cells have single cilia, although they are difficult to detect without special tissue preparation and labeling [16].

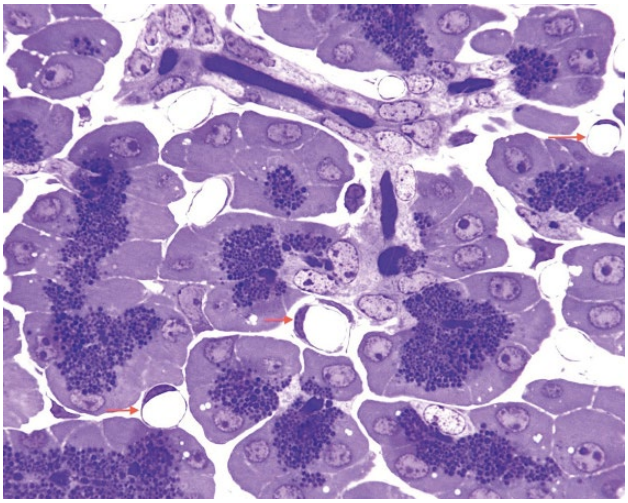

Figure 2.16 Pancreas ductule (top center) branches (upper image right) to reach several acini or acinar tubules (upper image right and near the center). Blue zymogen granules are conspicuous in the acinar cells and the liquid content of the ductule is also dark blue. Ductal and centroacinar cells have pale cytoplasm. The presence of numerous round empty capillaries (arrows) in the interstitial spaces indicates that the pancreas was perfused with fixative. Toluidine blue stain, 1 μm thick plastic embedded tissue. *Source:* Micrograph contributed by James Jamieson.

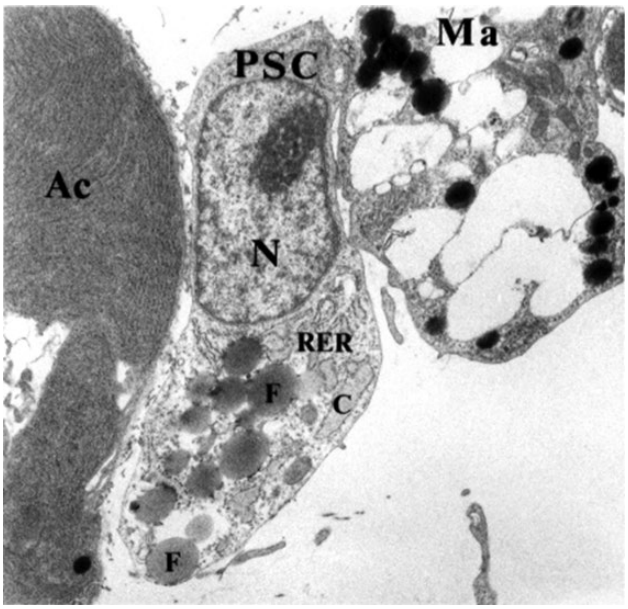

Figure 2.17 Pancreatic stellate cell (PSC) from a patient with acute pancreatitis. The PSC is near a macrophage (Ma), image right, and an acinar cell (Ac), image left. Fat droplets (F) and RER are conspicuous in the PSC cytoplasm below the nucleus (N). Original magnification 6000×. *Source:* Bachem et al. 1998 [17].

Interstitial Tissue

The interstitium contains capillaries, arteries, veins, lymphatics, nerve fibers, fat cells, and stellate cells. The stellate cells are undifferentiated connective tissue cells with characteristic structure (Figs 2.17 and 2.18) that are activated by inflammation to form fibroblasts and contribute to fibrosis associated with chronic pancreatitis and some neoplasms [17] (see Chapter 10).

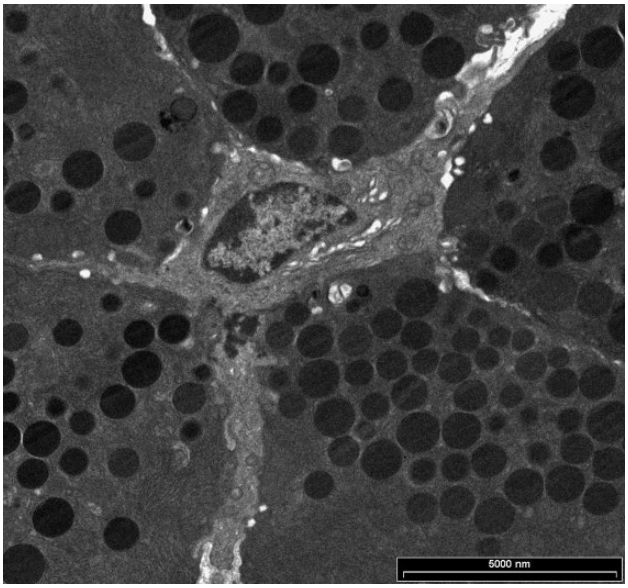

Figure 2.18 A pancreatic stellate cell (PSC) in situ is surrounded by multiple acinar cells containing zymogen granules. Extensions of PSC cytoplasm between acinar cells are conspicuous, upper image right and lower image left. The dark, irregular cytoplasmic inclusions at the origin of the latter interstitial extension may represent lipid droplets—a characteristic of PSC. *Source:* Contributed by the Pancreatic Research Group, UNSW, Australia, with special thanks to Dr. Murray Killingsworth.

Endocrine Pancreas

The pancreatic islets (islets of Langerhans) collectively comprise the endocrine pancreas that synthesizes and secretes insulin, glucagon, pancreatic polypeptide, and somatostatin. Most islets are too small to be seen by gross examination, hence they were not depicted in Figs 2.1 to 2.7. Islets vary greatly in size and ~70% are in the size range 50–250 μm in diameter in humans, with an average in the range 100–150 μm [18]. Small islets are dispersed throughout the acinar lobules (Fig. 2.19) and most larger islets lie along the main and interlobular ducts of the pancreas. Most islets are spherical or ellipsoid, but they can be irregular in shape—sometimes reflecting the presence of an adjacent structure, often a duct, or limitation by a tissue plane. Several reports provide support for the presence of a higher population

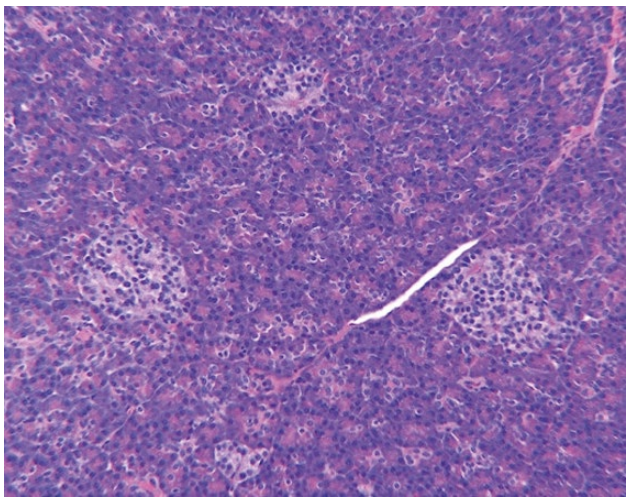

Figure 2.19 Pancreatic lobules with acinar cells and four islets at 12, 3, 6–7, and 9 o'clock. The islets are paler than the surrounding acinar tissue. The upper and lower islets are small and the lateral islets are medium size. H&E stain.

density of islets in the tail of the pancreas than in the head and body [5,19], although another study found no difference [20]. In adult humans, the number of islets is estimated to be 5×10^5–10^6 [21], whereas there are far fewer in smaller animals [22]. Islets comprise 1–2% of the pancreas in adults of most mammalian species. In addition to the islets, isolated islet cells may be found dispersed in the acinar lobules or in association with ducts.

Several of the images of islets are from sections that have been immunostained using antibodies to specific islet peptide hormones to demonstrate various islet cell types, including β cells (insulin), α cells (glucagon), δ cells (somatostatin) (Fig. 2.20), and pancreatic polypeptide (PP) (Fig. 2.21). In the portion of the pancreas derived from the dorsal pancreatic anlage, the majority of islet cells are β cells (75–80%), followed by α cells (about 15%), δ cells (about 5%), and very few PP cells. Most PP cells are in the portion of the pancreas derived from the ventral

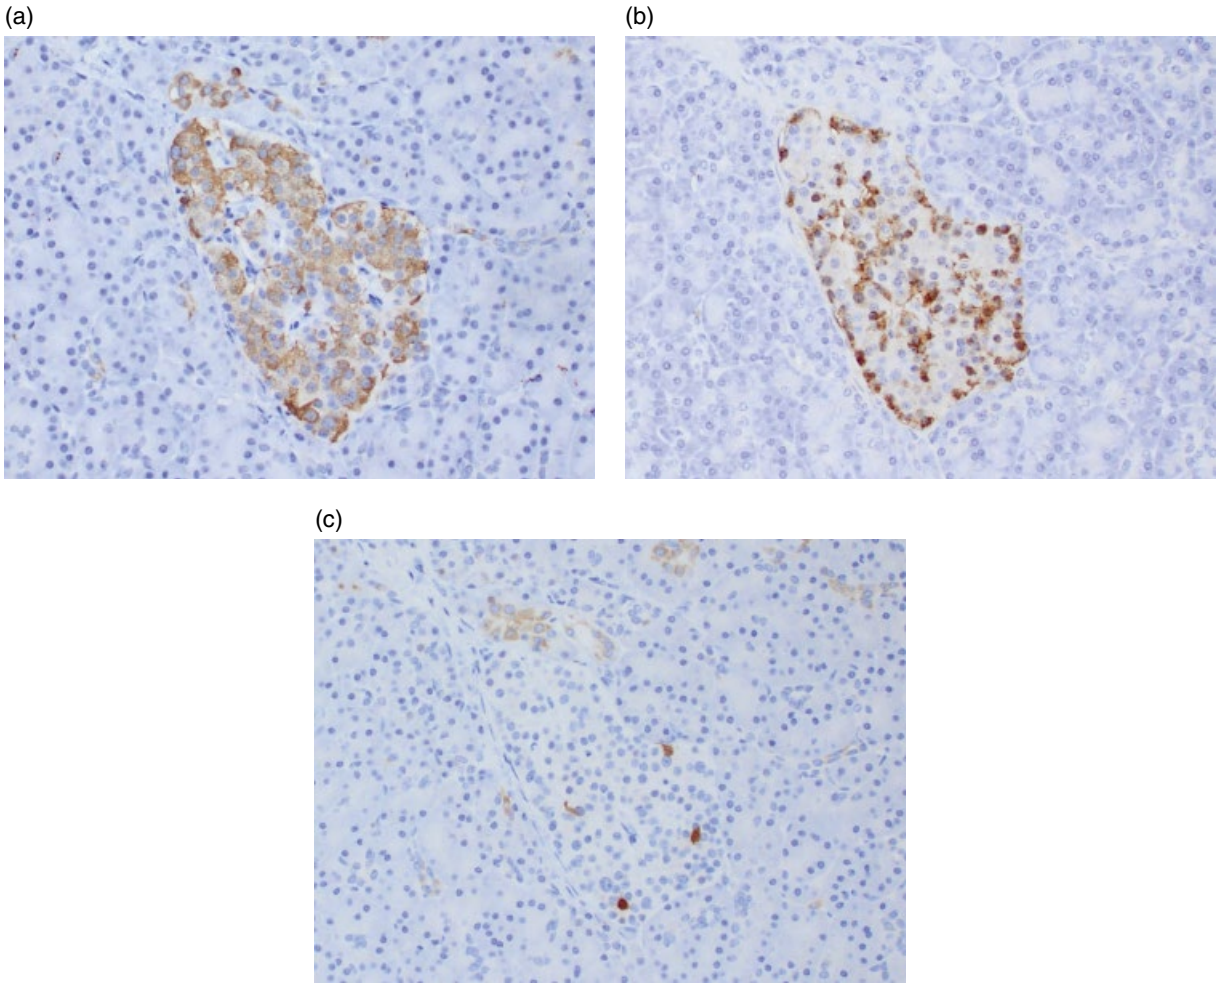

Figure 2.20 Serial sections of a human islet immunostained using antibodies to insulin (a), glucagon (b), and somatostatin (c). The presence of the hormones is indicated by brown staining. The predominance of insulin-secreting β cells is obvious. In (b) and (c), the location of α cells and δ cells is primarily at the border of groups of β cells. *Source:* Photos provided by Arief A. In murine species, β-cell granules have a wide halo surrounding the dense core. Acinar cell cytoplasm with zymogen granules, RER, and mitochondria is present (lower image right). *Source:* Micrograph contributed by Fred Gorelick.

pancreatic anlage, namely the uncinate process that is reported to comprise about 10% of the pancreas [23,24]. In the uncinate process, islets contain few α cells and many more PP cells. Stefan et al. presented data from a study of 13 nondiabetic human pancreases, showing that the PP cells comprise 54.3–93.7% of the volume of islets in the uncinate region, displacing most α cells and some

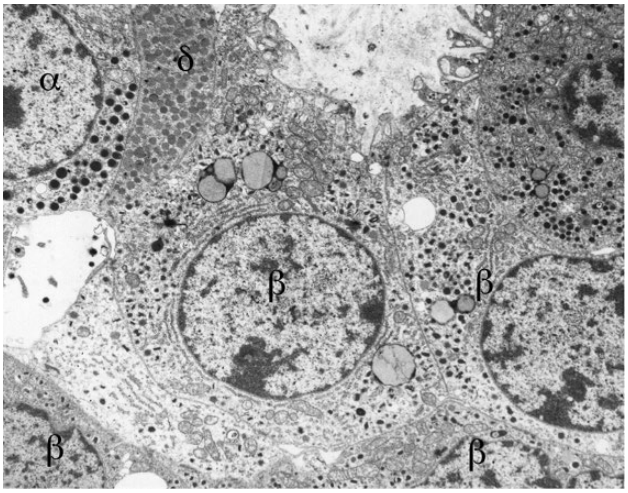

Figure 2.23 Human islet from transplant isolation with α, β, and δ cells labeled. The α-cell granules are typically slightly larger than β-cell granules; δ-cell granules are typically less densely stained than the granules in α and β cells. The cytoplasm of several islet cells contains lipid—most notably in the central β cell where lipid bodies lie at 4 and 11–12 o'clock around the nucleus. *Source:* Micrograph contributed by Susan Bonner-Weir.

β cells [24]. They provided data that indicated that PP cells were the second most prevalent endocrine cell type overall in the pancreases of their 13 subjects.

At the ultrastructural level, islet cells contain numerous mitochondria, a modest amount of RER, and small secretory granules (islet hormones). The granules vary in size and density with cell type and hormone and show some variation between species (Figs 2.22 and 2.23).

Capillaries in the islets connect with capillaries serving the adjacent acinar cells before draining into veins. These proximal acinar cells are exposed to higher concentrations of islet hormones than the majority acinar cells that are more distant from islets. The proximal acinar cells sometimes are larger and contain more zymogen than more distant acinar cells, and they form a halo around the islets. This unique feature of islet–acinar blood supply has been referred to as an insulo-acinar portal system [25].

Acknowledgments

The authors thank Fred Gorelick who contributed as a coauthor of this chapter in the previous edition of this book and Dale Bockman for reviewing the section that reflects his work on microanatomy of the acinar lobules. Congenital and Inherited Anomalies of the Pancreas

Heiko Witt[1] *and Martin Zenker*[2]

[1] *Pediatric Nutritional Medicine and Else Kröner Fresenius Center for Nutritional Medicine (EKFZ), Technical University of Munich (TUM), Freising, Germany*
[2] *Institute of Human Genetics, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany*

Introduction

Most congenital anomalies of the pancreas are attributable to disturbances in the three critical developmental steps: tissue differentiation, rotation, and fusion. Differentiation and rotation defects are usually rare, while defective fusion is common but mostly asymptomatic.

Primary Malformations

Pancreatic Agenesis

Complete (aplasia) or incomplete (hypoplasia) agenesis of the pancreas are very rare developmental disorders that can occur isolated or in combination with other defects such as polysplenia syndrome, congenital heart defects, or cerebellar agenesis. Their exact incidence is unknown. Partial agenesis is more common and is known as congenital short pancreas.

The clinical presentation is dependent on the degree of agenesis. Aplasia manifests clinically with neonatal diabetes mellitus, exocrine pancreatic insufficiency, and severe intrauterine growth retardation [1]. The last-mentioned appears to relate to the fact that insulin is a major intrauterine growth factor. Complete agenesis is incompatible with life, whereas the clinical presentation of hypoplasia varies from an asymptomatic course to endocrine and exocrine pancreatic insufficiency; pancreatitis may be an associated presentation. Pancreatic agenesis can be monogenic and half of the patients have heterozygous *GATA6* mutations [2]. The pancreatic phenotype ranges from aplasia to hypoplasia and most patients have cardiac malformations. Other features include gallbladder agenesis, biliary atresia, developmental delay, transient hypothyroidism, pituitary agenesis, and intestinal abnormalities. *GATA6* mutations have also been detected in a few patients with adult-onset diabetes with subclinical or no exocrine insufficiency [3].

In isolated families with autosomal recessive inheritance, defects in other genes have been described including pancreatic transcription factors *PDX1* (also known as insulin promoter factor 1, *IPF1*) and *PTF1A* [4,5]. Pancreatic agenesis appears to be isolated in *PDX1* mutated patients. Interestingly, heterozygotes are predisposed to maturity-onset diabetes of the young (MODY4); some patients show only subclinical or no exocrine insufficiency [4]. PTF1A plays a pivotal role in mammalian pancreatic development. *PTF1A* coding mutations cause pancreatic and cerebellar agenesis, whereas mutations in a *PTF1A* downstream enhancer cause isolated pancreatic agenesis [5,6]. Pancreatic agenesis associated with holoprosencephaly can be caused by defects in *CNOT1* [7].

In mice, a lack of hepatocyte nuclear factor-1-beta (Hnf1b) leads to pancreas agenesis [8]. In humans, heterozygous *HNF1B* mutations are associated with renal cysts and diabetes syndrome. Some of these patients show pancreatic atrophy/hypoplasia and exocrine insufficiency [9].

Partial agenesis of the pancreas mostly affects the dorsal part [10]. With this entity only a pancreatic head is seen on imaging. Dorsal pancreatic agenesis may be isolated or associated with polysplenia syndrome and can be accompanied by diabetes and pancreatitis [11]. It has been observed in patients with PDX1-MODY. Since most of the islet cells are located in the absent distal pancreas, the risk of diabetes mellitus is increased [12].

Ectopic Pancreas

In ectopic pancreas, also designated as heterotopic, aberrant or accessory pancreas, normally developed pancreatic tissue is anatomically separate from the gland and lacks ductal or vascular continuity. It can be found in various locations and can be made up of any cell found in the pancreas. Autopsy studies indicate that ectopic pancreas is quite common (0.5–15%), but its clinical manifestation is very rare [13]. In most cases, ectopic tissue is discovered in the submucosa of the stomach (particularly along the greater curvature of the antrum) and the duodenum (Fig. 3.1) as an incidental finding during endoscopy, where it appears as a 0.3–3 cm nodule. Other locations include the jejunum, ileum, a Meckel diverticulum, liver, spleen, biliary tract, mesentery, or umbilicus [12]. Although ectopic pancreas is primarily located in the submucosa, in some cases it is found in the muscularis or serosa.

The mechanisms leading to ectopic pancreas remain elusive. Misplacement of pancreatic cells into the developing gastrointestinal system, pancreatic metaplasia of other endodermal areas during embryogenesis, and an inaccurate differentiation of pluripotent endodermal stem cells are discussed.

Although ectopic pancreatic tissue can undergo similar changes as the orthotopic pancreas, particularly cystic degeneration, ectopic pancreatitis, and even pancreatic cancer formation, in most cases ectopic pancreas remains asymptomatic. If patients with ectopic pancreas become symptomatic, this may be due to the mass effect, which can cause either obstruction of the intestinal passage (mainly in the prepyloric localization) [14] or bowel intussusception, gastrointestinal hemorrhage secondary to mucosal ulcerations close to the pancreatic tissue [15], pain secondary to pancreatitis, and exceptional malignant transformation [16].

Diagnosis is made endoscopically or radiographically in antral localization. In other localizations, diagnosis is made at the time of surgery. The definite diagnosis relies on histology. The treatment is either surgical or endoscopic.

Annular Pancreas

In annular pancreas, the duodenum is completely, or rarer partly, surrounded by a ring-like band of pancreatic tissue. Early autopsy and surgical series reported an incidence of 3 in 20,000 but the increased use of imaging has raised the incidence to approximately 1 in 1,000.

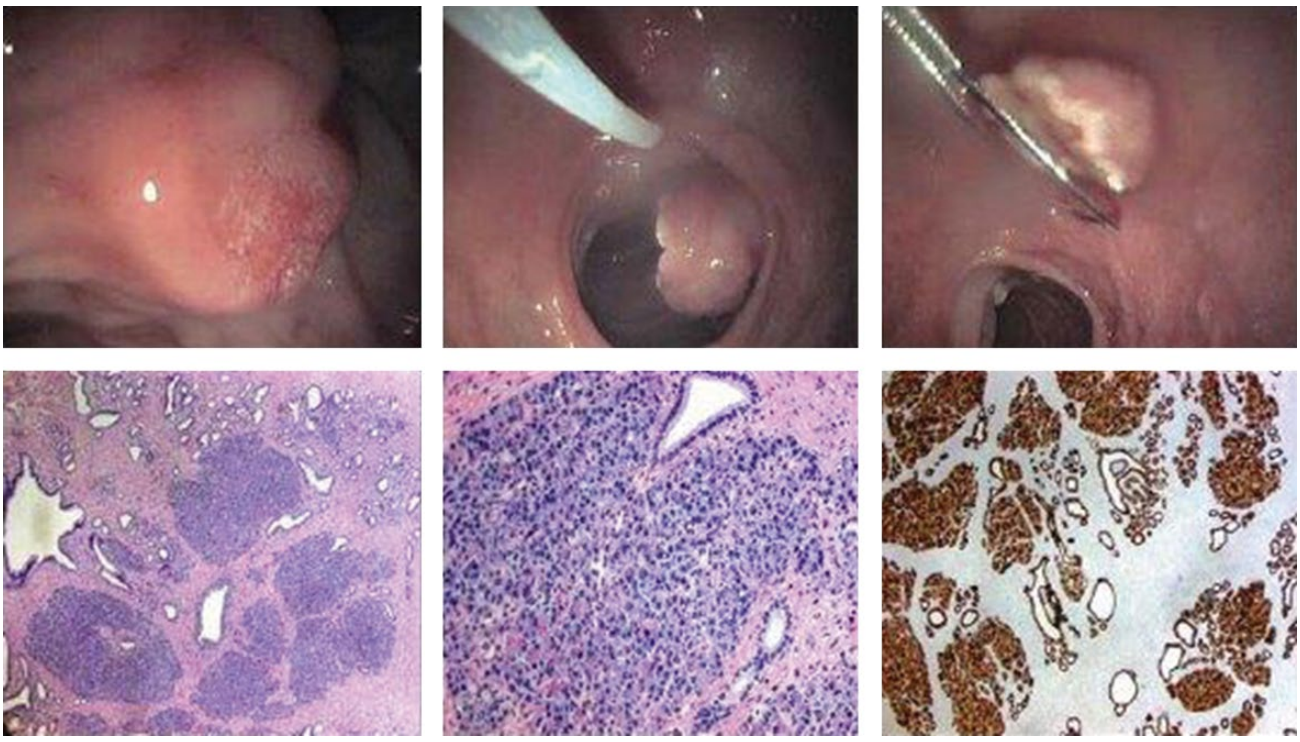

Figure 3.1 Ectopic pancreas under endoscopic vision and during endoscopic snare dissection (top images) and histologically (bottom panels, right cytokeratin staining). Note the complete absence of endocrine cells on histology, which corresponds to a type II ectopic pancreas according to Heinrich (1909). *Source:* Courtesy of M. Androshchuk and G. Lorenz, Greifswald.

Annular pancreas is frequently associated with other anomalies such as duodenal stenosis or atresia (40%), tracheoesophageal fistula (9%), congenital heart defects (7%), intestinal malrotation, and anal atresia [17]. A considerable number of affected individuals have chromosomal disorders, particularly Down syndrome (11–16%) [18]. This suggests that annular pancreas represents an early embryologic malformation. Agenesis of the dorsal pancreas may also be associated with annular pancreas [17].

Although most cases of annular pancreas are sporadic, there have been some cases of familial recurrence with different patterns of transmission. Annular pancreas can be found in Mitchell–Riley syndrome, in Martinez–Frias syndrome, and in congenital alveolar capillary dysplasia with misalignment of pulmonary veins [19].

Annular pancreas may manifest at any age or remain asymptomatic. The majority of symptomatic cases present in the first week of life as duodenal compression with bilious vomiting and feeding intolerance [18]. The diagnosis is suggested in >50% of cases during prenatal ultrasonography. A plain abdominal radiograph may demonstrate two large air filled spaces, the so-called "double-bubble" sign, if the obstruction is complete: Due to post-duodenal obstruction not only the stomach but also the upper duodenum is filled with gas.

Patients in whom annular pancreas becomes symptomatic later in life may suffer from recurrent vomiting, chronic gastric distension, pain resulting from pancreatitis, or peptic ulcers [20]. Upper gastrointestinal studies or a contrast-enhanced CT or MRI, which allow direct visualization of the ring, can aid the diagnosis.

Surgical therapy with duodenal bypass either in the form of a duodeno-duodenostomy or a duodeno-jejunostomy eliminates the obstruction with an excellent long-term prognosis [18]. Resection of the ring is not recommended because of the risk of pancreatic peritonitis, postoperative pancreatitis, fistulae, and late fibrosis. The prognosis depends on the age of onset and shows the highest mortality in the newborn period due to the high proportion of other coexisting organ malformations.

Pancreas Divisum

The fusion of the ventral and dorsal pancreas also merges the ducts of both parts of the gland. As a result, various anatomical variants of the pancreatic duct system can occur. In pancreas divisum, the most common anatomic variant, there is a separate outflow of the ventral part into the major papilla and the dorsal part via the Santorini duct into the minor papilla, which drains about 80% of the pancreatic juice [12]. Sometimes a small side branch connects both duct systems (incomplete pancreas divisum).

The estimated incidence varies from about 4–14% in autopsy series. Diagnosis relies on MRCP, especially secretin-enhanced MRCP. Endoscopic ultrasound and ERCP are invasive second-line investigations (Fig. 3.2).

The clinical significance of the pancreas divisum is disputed: while some consider it an insignificant normal variant, others postulate that the narrow opening of the minor papilla leads to a relative, functional stenosis and thus predisposes to obstructive pancreatitis. Since the prevalence in patients with chronic pancreatitis is similar to the frequency in the population, it is unlikely to cause pancreatitis alone [21]. Thus, other exogenous or genetic factors probably must be present. Interestingly, *PRSS1*, *SPINK1*, and *CFTR* mutations are more common in patients with chronic pancreatitis and pancreas divisum than in patients without this anomaly [22]. In chronic pancreatitis, the question arises whether endoscopic sphincterotomy and stent insertion at the minor papilla is beneficial and influences the natural course [23].

Anomalies of the Pancreaticobiliary Junction

The junction of the main duct of the pancreas with the bile duct is also very variable and most abnormalities are harmless variations in the norm and are incidental

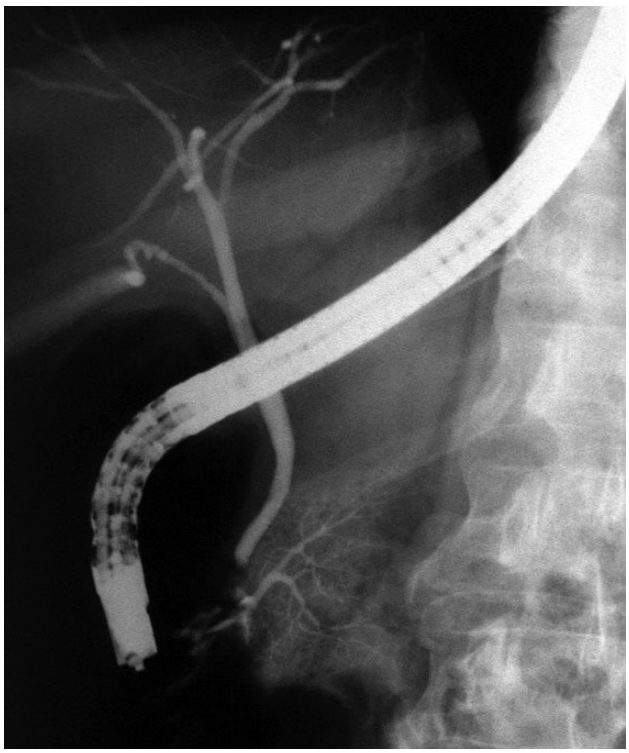

Figure 3.2 Pancreas divisum on ERCP. Whereas the intra- and extrahepatic bile ducts are of regular size and proportions, the pancreatic duct is short and tender (already overfilled with contrast medium) and supplies only the head of the pancreas.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

findings on endoscopy, ERCP, or MRI/MRCP [24]. Pancreaticobiliary maljunctions, in which the common bile duct and the ventral pancreatic duct unite outside the duodenal wall, result in a long common segment (long common channel) found in 1.5–3% of individuals [25]. This promotes the reflux of pancreatic secretions into the bile duct, as shown by dynamic MRCP after secretin stimulation. Reflux can lead to biliary duct inflammation and dilatation with choledochal cyst formation, pancreatitis, and, in the long term, malignant transformation resulting in biliary carcinoma. The incidence of pancreatitis is 3–31% in patients with pancreaticobiliary abnormalities [26]. The reflux of bile into the pancreatic duct system, conversely, is controversially discussed as a cause of pancreatitis and is less likely since pancreatic secretion pressure constantly exceeds the bile duct secretion pressure. Inherited choledochal cysts, which are often associated with pancreaticobiliary maljunctions, may manifest as acute or recurrent pancreatitis.

Congenital Cysts

Most pancreatic cysts are acquired pseudocysts of inflammatory origin and are found in the context of pancreatitis or cystic fibrosis (Fig. 3.3). In contrast, congenital pancreatic cysts are epithelial-lined and are rare, accounting for less than 1% of pancreatic cysts diagnosed in children. However, with improved radiological imaging, the diagnosis of incidental cystic lesions is on the rise. In a population-based MRCP study, small cysts (<1 cm) of unknown etiology were found in about a quarter of healthy volunteers (mean age 51.9 ± 13.4 years) [24]. In children, congenital cysts have a female predominance

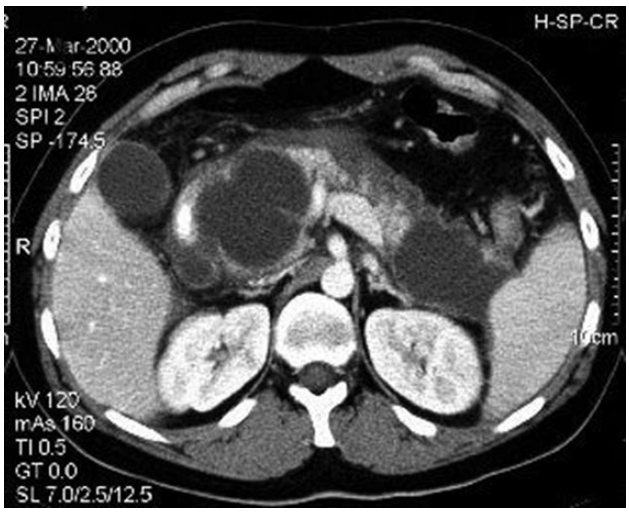

Figure 3.3 Large cysts in the pancreatic head and tail in a patient with chronic pancreatitis.

and may present as an asymptomatic palpable mass or with epigastric pain, jaundice, and vomiting by the compression of adjacent intestinal or biliary structures [27]. Symptoms often appear in the first two years of life. The cysts are more frequently located in the pancreatic tail or body than in the head, are more often unilocular than multilocular, and more often single than multiple [28]. Ductal communication is rare and, if present, suggests a pancreatitis-associated pseudocyst. The cysts are usually anechoic on ultrasound and are low attenuating structures without wall enhancement in CT or MRI studies. Associated anomalies may include renal tubular ectasia, polydactyly, anorectal malformations, polycystic kidneys, and asphyxiating thoracic dystrophy [28]. Multiple pancreatic cysts occur in about 10% of patients with polycystic kidney disease and in 30–70% of patients with von Hippel-Lindau disease (see below), but the cysts are rarely congenital in either disease.

Congenital Exocrine Insufficiency

Congenital exocrine pancreatic insufficiency is rare. Cystic fibrosis, which leads to progressive destruction of the pancreas and may result in clinical symptoms of secretory insufficiency from birth, account for the majority of cases with congenital exocrine pancreatic insufficiency. Cystic fibrosis and hereditary pancreatitis are discussed in dedicated chapters of this book.

Congenital exocrine pancreatic insufficiency, if complete, manifests from birth with loose and bulky stools, steatorrhea, failure to thrive, and hypoproteinemia leading to edema. Due to the large reserve capacity of the exocrine pancreas, clinical symptoms only appear when more than 90% of the exocrine cells are destroyed [29]. Pancreatic secretory insufficiency reflects either an isolated enzyme deficiency or early-onset degeneration of acinar cells resulting in fibrosis or lipomatosis of the gland.

Isolated Enzyme Deficiencies

Isolated inherited deficiencies of pancreatic digestive enzymes or duodenal enteropeptidase (enterokinase) are extremely rare. So far, isolated deficiencies of lipase, colipase, amylase, trypsin, and enteropeptidase as well as combined deficiencies of lipase and colipase have been reported [30]. Of clinical relevance are mainly deficiencies of trypsin and enteropeptidase, which manifest with failure to thrive, diarrhea, hypoproteinemia, and edema. In all deficiencies, enzyme replacement therapy is very effective.

When fat-digesting enzymes are affected, chronic diarrhea and steatorrhea are the leading symptoms, but failure to thrive is absent. Congenital deficiency of pancreatic lipase (PNLIP) is inherited in an autosomal recessive

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

manner and is caused by loss-of-function mutations in *PNLIP* [31]. Interestingly, *PNLIP* variants that lead to increased proteolytic degradation by trypsin are associated with early-onset chronic pancreatitis [32]. Colipase deficiency has been reported in two brothers and the combined deficiency of lipase and colipase in another family and in a single case. Pancreatic amylase deficiency may lead to diarrhea induced by a high-starch diet, but the functional capacity of the carbohydrate-digesting enzymes is quite high, and so the deficiency is mostly compensated. To date, two children with trypsinogen and about a dozen patients with enteropeptidase deficiency have been described [33]. Enteropeptidase (TMPRSS15) is a transmembrane serine protease that localized to the brush border of the intestinal mucosa. Although enteropeptidase is not a pancreatic enzyme, its deficiency manifests clinically as a trypsin defect, since it activates trypsinogen.

Shwachman–Bodian–Diamond Syndrome

After cystic fibrosis, Shwachman–Bodian–Diamond syndrome (SBDS) is the second most common inherited cause of exocrine pancreatic insufficiency with an estimated incidence of 1:50,000. SBDS is inherited in an autosomal recessive manner and is characterized by the triad exocrine pancreatic insufficiency, bone marrow dysfunction, and skeletal abnormalities. Histologically, there is hypoplasia of the acinar cells with replacement by adipose tissue (lipomatosis) (Fig. 3.4) [34]. The islet cells and the ductal architecture are preserved. In contrast to cystic fibrosis, water and bicarbonate secretion are not restricted. Exocrine insufficiency improves with age: while 90% of infants suffer from steatorrhea, around half of patients in the second decade of life are pancreatic sufficient. Neither diabetes nor pancreatitis are consistent features of SBDS.

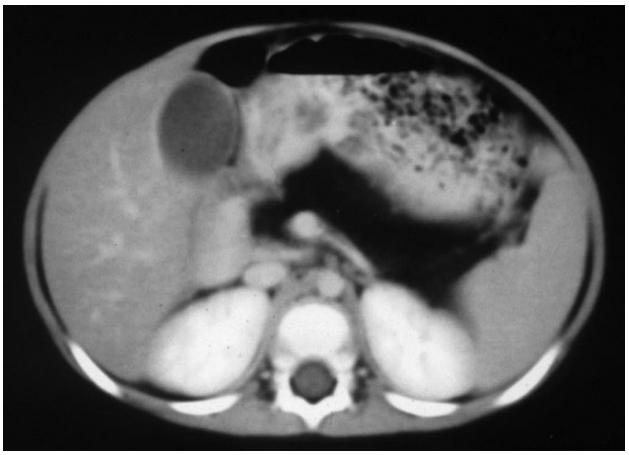

Figure 3.4 Fatty replacement of the entire pancreas (black central structure on the abdominal CT) in Shwachman–Bodian–Diamond syndrome. *Source:* Wilschanski M et al. (1994). Reproduced with permission of Wolters Kluwer Health.

The main hematological change is intermittent or permanent neutropenia, sometimes accompanied by anemia, thrombocytopenia, or pancytopenia. Infants in particular are at risk from serious bacterial infections. About 10–30% of patients develop myelodysplastic syndrome or acute leukemia [35].

Other manifestations include short stature, skeletal abnormalities (metaphyseal chondrodysplasia, shortened ribs), enamel defects with increased tooth decay, liver involvement with hepatomegaly and elevated transaminase levels, and often mild mental retardation [35].

In 90%, the syndrome is caused by gene conversion mutations in the *SBDS* gene [36]. Recently, the elongation factor-like 1 (*EFL1*) has been identified as second disease-causing gene [37]. Moreover, mutations in the genes encoding the DnaJ heat shock protein family (Hsp40) member C21 (*DNAJC21*) and the signal recognition particle 54 (*SRP54*) have also been associated with a SBDS-like phenotype [37].

Interestingly, all four genes are involved in ribosome biogenesis, reinforcing the postulate that the syndrome is a ribosomopathy. SBDS promotes by direct interaction with EFL1 the removal of the eukaryotic initiation factor 6 (eIF6) 60S subunit of the ribosome. This allows the 60S subunit to bind to the 40S subunit to generate a functional 80S ribosome. DNAJC21 is involved in the release of maturation factors from the pre-60S subunit. SRP54 recognizes the signal peptide of secretory proteins and mediates the targeting of the ribosome and the associated nascent polypeptide chain to the endoplasmic reticulum [37].

The diagnosis of SBDS is based on the clinical symptoms, imaging methods (skeletal X-ray, diffuse fatty degeneration of the pancreas in the MRI) and the corresponding laboratory parameters and should be confirmed by a mutation analysis. Because cytopenia can be cyclic, blood cell status should be measured repeatedly. Differential diagnoses include cystic fibrosis and other causes of neutropenia such as Diamond-Blackfan or Fanconi anemia, and congenital dyskeratosis.

Treatment is symptomatic. Because exocrine dysfunction improves with age, approximately 50% of patients in their second decade of life no longer require enzyme replacement therapy.

Pearson Marrow Pancreas Syndrome

Pearson syndrome is a rare multisystem mitochondrial disorder caused by deletions of mitochondrial DNA (mtDNA) [38]. Clinical characteristics are refractory

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. sideroblastic anemia with vacuolization of marrow precursors and variable exocrine pancreatic insufficiency [39]. Severe, transfusion-dependent, macrocytic anemia usually starts in infancy and may be accompanied by thrombocytopenia and neutropenia. Other features include lactate acidosis, renal tubulopathy, liver cholestasis and/or fibrosis, adrenal insufficiency, diabetes mellitus, cardiomegaly, and cardiac conduction defects [39]. Some patients have recurrent episodes of acute pancreatitis [39]. In contrast to the Shwachman syndrome, the pancreas in Pearson syndrome shows fibrosis instead of lipomatosis. The disorders also differ in bone marrow morphology. A phenotypic shift from a predominantly hematopoietic disorder (Pearson syndrome) to a disease with overt muscle dysfunction (mitochondrial myopathy) was repeatedly observed, up to a fully developed Kearns–Sayre syndrome [39].

In laboratory tests, a subset of patients show complex organic aciduria with 3-methylglutaconic aciduria. Therapy is symptomatic and in selected cases bone marrow transplantation can be considered. The prognosis is poor and patients usually die in early childhood from intractable metabolic acidosis, sepsis, or liver failure [39].

Figure 3.5 Aplasia of the nasal wings as a characteristic feature or Johanson–Blizzard syndrome.

Johanson–Blizzard Syndrome

Johanson–Blizzard syndrome (JBS) is characterized by congenital exocrine pancreatic insufficiency, a peculiar nasal malformation with hypo- or aplasia of the nasal wings (Fig. 3.5), and oligodontia of permanent teeth [40]. These three characteristics are present in virtually all patients [41]. The majority of patients also present with hearing impairment, scalp defects, varying degrees of cognitive impairment, and short stature. Hypothyroidism, microcephaly, intrauterine growth retardation, congenital heart defects, urogenital and anorectal malformations, renal anomalies, and diabetes with onset during adolescence are additional features of the syndrome [41].

The condition is inherited as an autosomal recessive trait and has an estimated incidence of 1:250,000 [42]. JBS is caused by *UBR1* mutations that lead to severe deficiency of the homonymous ubiquitin ligase of the N-end rule pathway [42]. As this pathway is responsible for degradation of intracellular proteins, it is likely that the excess or increased half-life of hitherto unknown proteins are involved in the pathogenesis of the pancreatic and other defects. While >95% of patients with a clinical diagnosis have UBR1 defects, *CAPN15* mutations may cause a phenotype overlapping with JBS.

Histologically, there is an almost complete absence of acinar cells, which are replaced by fat and connective tissue, whereas ductal architecture and islets are less affected. Thus, the ductular output of fluid and electrolytes is preserved, while the secretion of zymogens is decreased. The acinar cell loss is likely caused by intrauterine destruction, resembling pancreatitis of prenatal onset [43]. However, *UBR1* variants are not associated with chronic pancreatitis. *Ubr1* deficient mice have milder pancreatic dysfunction such as decreased zymogen secretion and increased susceptibility to experimental pancreatitis [42].

Diagnosis of JBS is based on the characteristic clinical picture and can be confirmed by *UBR1* sequencing. Therapy is symptomatic and consists of the substitution of pancreatic enzymes and, if necessary, of thyroid hormones as well as the provision of hearing aids and surgical correction of the malformations. The prognosis depends on the associated malformations. Lethal malformations such as bilateral renal dysplasia are rare. Mental retardation is variable, but about a third of those affected show normal intelligence.

Other Hereditary Disorders Affecting the Pancreas

Pancreatic abnormalities have been described in a number of congenital or inherited multisystem disorders, in which they are rarely a cardinal symptom or may even remain clinically inapparent.

Polycystic Kidney Disease

Multiple cysts of the pancreas can be present in autosomal recessive (ARPKD) and autosomal dominant polycystic (ADPKD) disease. Both diseases are genetically heterogeneous [44]. The estimated incidence of ARPKD is about 1 to 20,000 and of ADPKD about 1 to 400–1,000 [44]. The clinical presentation of ARPKD is highly variable. Newborns have markedly enlarged polycystic kidneys that can be associated with pulmonary hypoplasia. Liver involvement is evident in about half of infants and comprises cysts and periportal fibrosis. Pancreatic cysts and pancreatic fibrosis have been repeatedly reported on imaging or autopsy in children with ARPKD, but clinical significant pancreatic disease is exceptional. The same applies to ADPKD, in which sonographically detectable pancreatic cysts are much more frequent and are present in about 10% of adult patients but are rare in infancy. Occasionally, the cysts may lead to pancreatitis. Pancreatic involvement is typically less severe than renal and hepatic affection.

Von Hippel–Lindau Syndrome

Von Hippel–Lindau syndrome (VHL) is an autosomal dominant familial cancer syndrome with an estimated incidence of 1:36,000. It is caused by mutations in the *VHL* tumor suppressor gene [45], but genetic changes in cyclin D1 (*CCND1*) may further modify the phenotype. About 80% of cases are familial. Affected subjects are at risk of developing cerebellar, spinal, and retinal hemangioblastomas, renal cell carcinoma, pheochromocytoma, pancreatic neuroendocrine tumors, pancreatic and renal cysts, and epididymal cystadenoma [46].

About 35–70% of patients with VHL present with pancreatic findings. Pancreatic cysts are reported in up to 30% of patients on imaging studies but can be found in up to 72% of patients at autopsy; however, they are typically not congenital [27]. Involvement ranges from a single cyst to multiple cysts virtually replacing the pancreas. Usually the cysts are multiple but asymptomatic. These cysts may precede any other manifestation by several years. In about 12% of patients, pancreatic cysts are the only sign of the disease.

Serous cystadenomas and neuroendocrine tumors are other pancreatic manifestations. By replacing the pancreatic parenchyma, cysts and cystadenomas can compress adjacent structures and may cause exocrine or endocrine deficiency. Neuroendocrine tumors become malignant and metastatic in 8% of patients [46]. Pancreatic carcinoma and adenocarcinoma of the ampulla of Vater have also been reported.

Beckwith–Wiedemann Syndrome

The cardinal features of Beckwith–Wiedemann syndrome (BWS) are (asymmetric) macrosomia, macroglossia, and exomphalos in the neonate. Pancreatic hypertrophy is an imaging feature, and severe hypoglycemia due to transient hyperinsulinism occurs in 30–50% of neonates with BWS. Histology of resected pancreatic tissue shows an increase in the volume of endocrine relative to acinar tissue with expanded islets and preservation of lobular architecture [47]. Other clinical features include abdominal wall defects, ear anomalies, naevus flammeus, organomegaly, and nephroureteral malformations [48]. About 10% of patients develop embryonic tumors such as nephroblastoma, hepatoblastoma, and neuroblastoma during infancy [48]. Pancreatoblastomas have been described in a few cases and usually present in infants aged 3 months and younger. BWS is genetically heterogeneous. Loss or gain of methylation, paternal uniparental disomy, and *CDKN1C* loss-of-function mutations result in epigenetic or genetic defects on chromosome 11p15.5 with disrupted expression of imprinted genes [48]. About 85% of cases are sporadic.

Jeune Syndrome and Other Ciliopathies

Ciliopathies constitute a large group of multisystem disorders with considerable clinical and genetic heterogeneity, and pancreatic involvement is part of the phenotypic spectrum. Jeune syndrome (asphyxiating thoracic dystrophy) belongs to the skeletal ciliopathies and is a rare autosomal recessive osteochondrodysplasia with characteristic skeletal abnormalities, nephronophthisis, retinal abnormalities, pulmonary insufficiency, and hepatic fibrosis. It may be associated with pancreatic cysts and pancreatic fibrosis, leading to exocrine insufficiency [49].

Fibrotic and cystic changes of the pancreas may also be found in renal-hepatic-pancreatic dysplasia and in other ciliopathies [50].

Physiology of Acinar Cell Secretion

Ole H. Petersen

Cardiff School of Biosciences, Cardiff University, Cardiff, UK

Introduction

The acinar cell is the dominant cell type in the pancreas. In terms of percentage volume, the pancreas consists of 82% acinar cells, 4% duct cells, 4% blood vessels, 2% endocrine cells, and 8% extracellular matrix [1]. However, the acinar cell itself is not the functional unit in the exocrine pancreatic tissue because acinar cells are organized into acini consisting of up to several hundred acinar cells linked by numerous gap-junctional channels that allow both direct chemical and electrical intercellular communication [2,3]. There is an additional cell type that has not previously featured much in descriptions of acinar cell function, namely the pancreatic stellate cells (PSC). These very thin periacinar cells come very close to the acinar cells, but are nevertheless functionally isolated from the acinar cells [4–6]. The PSC play an important role under pathophysiologic conditions where they exert effects on the acinar cells [4–7], but it is unknown whether they have any physiologic role in the control of acinar cell secretion.

The principal function of the acinar cells is to secrete a potent mixture of digestive enzymes in response to food intake. This secretory response is mediated by vagal nerve stimulation, releasing acetylcholine (ACh) from nerve endings close to the acinar cells, and the circulating hormone cholecystokinin (CCK). The digestive (pro) enzymes are packaged into secretory vesicles called zymogen granules (ZG) and the secretion process itself occurs by exocytosis, that is, fusion of the granule membrane with the apical (luminal) cell membrane and subsequent opening of a pathway (pore) allowing direct movement of the zymogens from the granule interior to the acinar lumen [7]. In order to move the zymogens into the duct system and thereafter into the gut, there is also a need for fluid secretion. The acinar cells secrete a neutral Cl^--rich fluid, produced in response to stimulation with ACh and CCK [7,8]. Additionally, the small ducts secrete a HCO_3^--rich fluid when stimulated by the hormone secretin [7]. The aim of this chapter is to explain the cellular mechanisms underlying the very acute and finely controlled normal physiologic regulation of acinar fluid and enzyme secretion.

Composition of Pancreatic Acinar Juice

ACh or CCK activates acinar cells to secrete an isotonic NaCl-rich fluid (Fig. 4.1a) containing a multitude of enzymes and precursor enzymes. The protease precursors are trypsinogen, chymotrypsinogen, and procarboxypeptidases. These precursors are activated in the small intestine, initiated by conversion of trypsinogen to trypsin by the intestinal enzyme enteropeptidase. Trypsin then activates trypsinogen autocatalytically and also activates the other precursors. The acinar fluid also contains active α-amylase, lipases, and colipase as well as various other enzymes (e.g., collagenase, elastase, phospholipase A, and ribonuclease) [11]. The neutral NaCl-rich fluid containing these enzymes and enzyme precursors is delivered to the small ducts, where it is mixed with the HCO_3^--rich fluid produced by the duct cells in response to stimulation with secretin (Fig. 4.1b, c).

Acinar Fluid and Enzyme Secretion

There is separate control of acinar and duct secretion, as shown in experiments on the isolated perfused pancreas

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

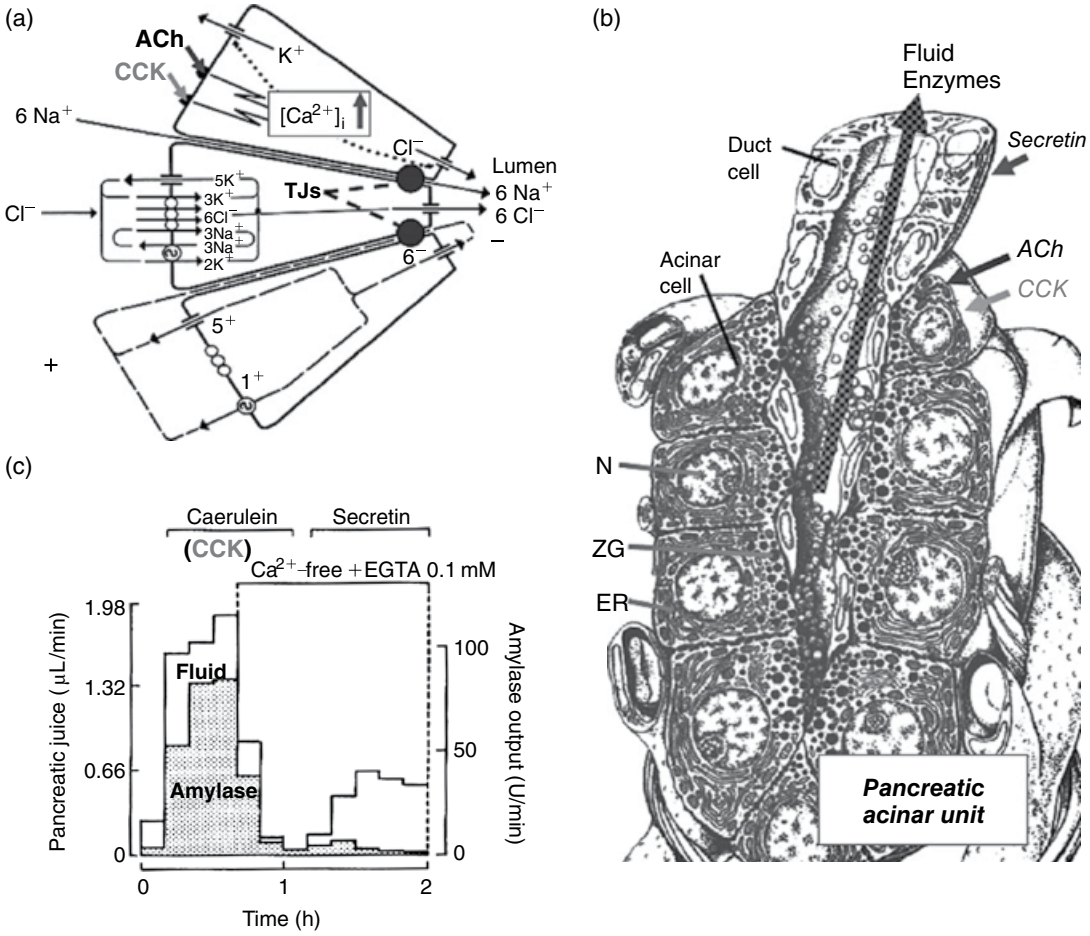

Figure 4.1 Fluid and enzyme secretion from acinar cells. (a) Acinar transport model illustrating the individual ion transport events that work together to produce an isotonic NaCl-rich fluid. For graphical convenience, different aspects of the processes are shown in separate cells. In the top cell it is shown that ACh or CCK binding to their respective specific receptors on the basolateral membrane elicits a rise in the cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$), which in turn activates Cl^+ channels in the apical (luminal) membrane and K^+ channels in the basolateral membrane (for graphical convenience all events in the basolateral membrane are shown only in the basal membrane). The middle cell illustrates transcellular Cl^- transport. The $Na^+/K^+/2Cl^-$ cotransporter, the K^+ channel, and the Na^+/K^+ pump are shown in the basal membrane and it is indicated that the net transport event is uptake of Cl^-, whereas at the apical membrane Cl^- exit into the lumen simply occurs through a Cl^- channel. The lower cell illustrates the overall electrical circuit and explains the transepithelial electrical potential difference. The $Na^+/K^+/2Cl^-$ cotransporter is electrically neutral, so the only electrogenic event at the basolateral membrane is the transport of cations (K^+ and Na^+) through the K^+ channel and Na^+/K^+ pump ($3Na^+$ pumped out for $2K^+$ taken in). This net outward (cation exit) current has to be matched by an inward (anion exit) current across the apical membrane and the completion of the circuit depends on the high conductance of the so-called tight junctions (TJs). *Source:* Adapted from [8] / With permission of American Physiological Society. (b) Model drawing of acinar unit with small duct segment attached. The polarity of acinar cells is shown with the nucleus (N) surrounded by endoplasmic reticulum (ER) in the basal part and zymogen granules (ZG) in the apical part. *Source:* Adapted from [9] / With permission of Springer Nature. (c) Fluid and amylase secretion from isolated perfused rat pancreas stimulated by the frog skin peptide cerulein (analog of CCK) and secretin. *Source:* Adapted from [10] / With permission of The Royal Society.

(Fig. 4.1c). Sustained fluid and enzyme secretion, due to stimulation with either ACh or CCK, is acutely dependent on the presence of Ca^{2+} in the extracellular solution, whereas the HCO_3^--rich fluid secretion evoked by secretin in the ducts occurs normally in the complete absence of external Ca^{2+} (Fig. 4.1c).

It is well established that exocytosis in general is activated by a rise in cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) [7,11]. In nerve and endocrine cells, exocytosis is normally activated by Ca^{2+} entering the cell interior via special voltage-activated Ca^{2+} channels in the plasma membrane, which open on membrane depolarization caused by action potentials [11]. However, the pancreatic acinar cell is electrically nonexcitable and cannot fire action potentials [12]. Ca^{2+} needed for stimulus–secretion coupling is therefore delivered to

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. the cytosol from intracellular stores [12]. It was established many years ago that the initial secretory response to stimulation with either ACh or CCK is independent of extracellular Ca^{2+} [13], whereas sustained secretion is acutely dependent on external Ca^{2+} (Fig. 4.1c). This is explained by the limited capacity of the intracellular Ca^{2+} stores and the fact that release of Ca^{2+} from stores into the cytosol inevitably activates Ca^{2+} pumps in the plasma membrane extruding Ca^{2+}, so that after a shorter or longer period of stimulation (depending on the intensity of stimulation) the contents of the intracellular Ca^{2+} stores have been exported to the extracellular solution [14]. A reduction of $[Ca^{2+}]$ in the intracellular stores activates a process known as store-operated Ca^{2+} entry. A signal is transmitted from the stores to the plasma membrane activating special Ca^{2+} channels (store-operated channels) that allow Ca^{2+} entry [15]. It is this Ca^{2+} entry process that sustains the secretory response during prolonged stimulation, after the stores have been emptied.

Ca^{2+} Signaling

It is well established that stimulation of acinar cells with either ACh or CCK elicits a rise in $[Ca^{2+}]_i$ (Fig. 4.2). At low, physiologically relevant, concentrations of neurotransmitter or hormone, the typical Ca^{2+} signal pattern consists of repetitive $[Ca^{2+}]_i$ spikes confined to the apical (granular) pole, as originally shown in 1993 [17]. Increasing the stimulating agonist concentration causes Ca^{2+} signal globalization, a process whereby a local Ca^{2+} signal initiated in the apical pole spreads as a wave from the apex to the base of the cell (Fig. 4.2).

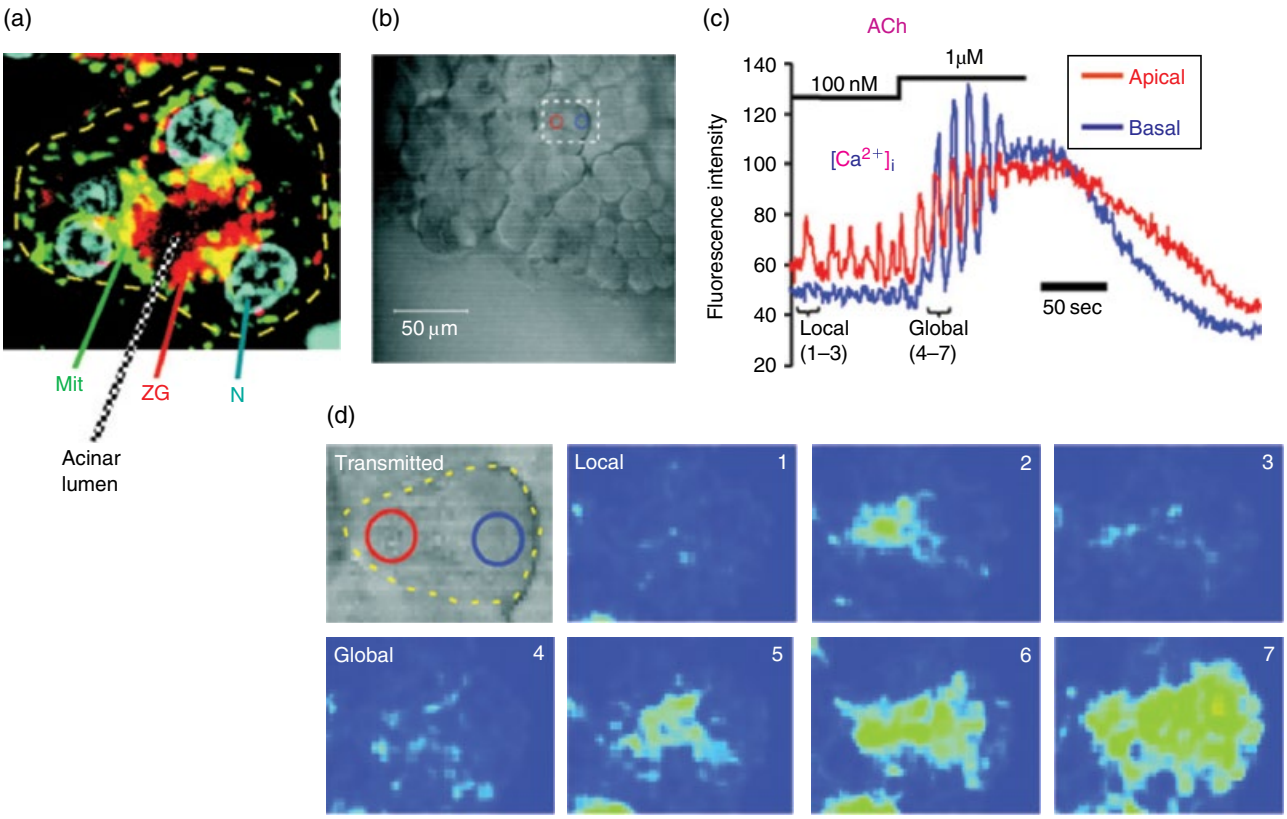

Figure 4.2 Ca^{2+} signaling and organelle distribution in the intact mouse pancreas. (a) Merged confocal images showing distribution of specific fluorescent markers for zymogen granules (ZG – red), nuclei (N – blue), and mitochondria (Mit – green). The optical slice goes through three cells (nuclei). The ZG are seen distributed around the lumen and are surrounded by mitochondria. Mitochondria are also located around the nuclei and close to the plasma membrane. (b) Confocal image of larger part of the pancreas showing many acinar units. One cell is highlighted by white dashed lines and in this cell apical (red) and basal (blue) regions of interest are signposted. The traces shown in (c) are from these two regions. (c) ACh-elicited cytosolic Ca^{2+} signals. At the low ACh concentration of 100 nM, repetitive Ca^{2+} spikes are seen exclusively in the apical pole. When the ACh concentration is increased to 1 µM, there is a rise in $[Ca^{2+}]_i$ in both the apical and basal regions. (d) Fluorescent images showing (upper row) a single local apical Ca^{2+} spike (numbers refer to time points in (c)) and (lower row) the initial Ca^{2+} wave generation following the increase in ACh concentration (numbers again refer to time points signposted in (c)). *Source:* Adapted from [16]/Elsevier/CC BY-4.0.

Organelles Important for Ca^{2+} Homeostasis

Early work in the 1970s on Ca^{2+} transport in exocrine glands indicated that ACh evokes Ca^{2+} signals in acinar cells by causing release of Ca^{2+} from the endoplasmic reticulum (ER) [7] but, for many years, the link between ACh occupation of muscarinic receptors on the cell surface and the outflow of Ca^{2+} from the ER was obscure. In 1983, Irene Schulz and Michael Berridge discovered that the intracellular water-soluble messenger inositol 1,4,5-trisphosphate (IP_3), generated inside the cell by receptor-activated phospholipase C action on a membrane phospholipid, phosphatidylinositol 4,5-bisphosphate (PIP_2), releases Ca^{2+} from the ER in permeabilized pancreatic acinar cells [18]. All subsequent work on many different cell types confirmed the generality of the concept that hormone- or neurotransmitter-elicited intracellular Ca^{2+} release is mediated principally via IP_3-evoked Ca^{2+} release from the ER [7,19]. Although the original discovery of IP_3-evoked Ca^{2+} release was made on pancreatic acinar cells [18], there are difficulties in applying this concept to these particular cells. The problem is that the physiologically relevant Ca^{2+} signals occur specifically in the apical granular pole (see Fig. 4.2), which contains mostly ZG and little ER. This difficulty was finally overcome by the results of the so-called Ca^{2+} tunnel experiments, in which it could be shown that Ca^{2+} taken up at the base of the cell into the ER could diffuse easily in the ER lumen and reach the apex via thin ER extensions penetrating deeply into the granular area between the ZGs (see Fig. 4.3). Upon stimulation, Ca^{2+} is released primarily from the ER elements in the apical pole due to the high concentration of ER Ca^{2+} release channels specifically in this part of the cell (Fig. 4.3) [20,22].

It was initially a surprise that cytosolic Ca^{2+} signals initiated in the apical pole could remain local in such a relatively small cell (~20 µm diameter). This could not be easily understood before it was discovered that the mitochondria in the acinar cell are distributed in a very specific manner [23]. The mitochondria are primarily

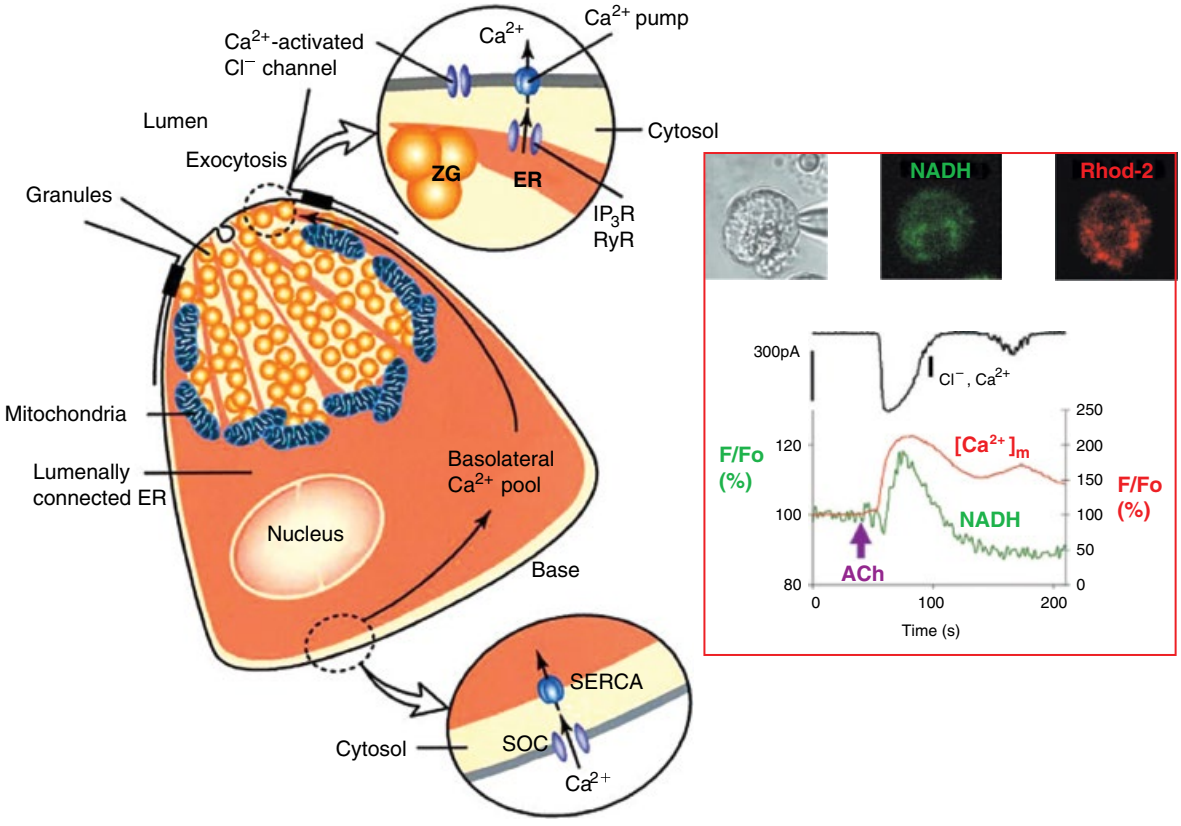

Figure 4.3 Organelle distribution and Ca^{2+} transport events in acinar cell. The main part of the figure shows a model cell with the distribution of organelles and Ca^{2+} transport pathways signposted. Insert (in red frame) shows triple measurements of Ca^{2+}-activated Cl^- current $\left(I_{Cl-,Ca^{2+}}\right)$, mitochondrial Ca^{2+} concentration ($[Ca^{2+}]_m$—measured by Rhod-2 fluorescence—and concentration of NADH (autofluorescence). It is seen that ACh evokes a rapid rise in $I_{Cl-,Ca^{2+}}$, which is followed immediately by a rise in $[Ca^{2+}]_m$ and, after a small delay, by an increase in the NADH concentration signifying activation of mitochondrial metabolism and therefore ATP production. *Source:* Adapted from [21] / John Wiley and Sons and [20] / With permission of Elsevier.

localized in a belt surrounding the ZG, separating the apical granular pole from the rest of the cell (see Figs 4.2 and 4.3). Due to their ability to take up Ca^{2+}, the mitochondria function as a Ca^{2+} diffusion barrier, effectively acting as a firewall preventing the spread of cytosolic Ca^{2+} signals from the apical pole into the basal part of the cell containing the nucleus (Fig. 4.3). The nucleus is well protected against Ca^{2+} signal invasion from the apical pole, since there is an additional mitochondrial belt surrounding the nucleus (Fig. 4.2). Finally, there is a concentration of mitochondria just beneath the plasma membrane (Fig. 4.2). The general concept that has emerged from studies of Ca^{2+} transport in the cytosol, ER, and mitochondria is that Ca^{2+} moves easily in the ER lumen, but with much more difficulty in the cytosol, due to the barriers created by the mitochondria [7,24].

The fact that the physiologically most important Ca^{2+} signals occur in the apical granular area has also prompted interest in the possibility that Ca^{2+} could be released from ZG and other acid pools in the apical pole. In studies on isolated ZG, it was shown that both IP_3 and another Ca^{2+}-releasing messenger, cyclic ADP-ribose (cADPR, derived from NAD) can liberate Ca^{2+} stored in this organelle (see Fig. 4.4). It has been clear for a long time that ACh causes intracellular Ca^{2+} release via generation of IP_3, acting primarily on the ER. It is now equally clear that CCK releases Ca^{2+} via generation of NAADP [7,26,27] and that NAADP primarily acts on acid stores (Fig. 4.4a). This may explain the somewhat different Ca^{2+} signal patterns that can be generated by CCK and ACh [28].

Mechanisms of Ca^{2+} Signal Generation

Figure 4.4 illustrates some of the most important steps. As already mentioned, there are two major signal transduction pathways, one initiated by hormonal (CCK) stimulation and the other by nervous (ACh) stimulation. CCK acts on high-affinity CCK1 receptors in the basolateral plasma membrane [29,30], whereas ACh acts on muscarinic M3 receptors, which are also localized predominantly in the basolateral membrane [16]. With state-of-the-art imaging technology, it is now possible to visualize some of the most important signal transduction steps.

Figure 4.5 demonstrates the ACh-elicited breakdown of PIP_2 in the basolateral membrane and the appearance of the water-soluble Ca^{2+}-releasing messenger IP_3 in the cytosol. The enzyme responsible for PIP_2 breakdown, phospholipase C, can in some cases be Ca^{2+} activated. However, the experimental result shown in Fig. 4.5 demonstrates that, at least in the pancreatic acinar cell, the disappearance of PIP_2 from the plasma membrane and the appearance of IP_3 in the cytosol are not secondary to Ca^{2+} signal generation, since a directly generated Ca^{2+} signal (via uncaging of Ca^{2+} in the cytosol) does not induce these effects, whereas ACh does.

Direct infusion of IP_3 into isolated cells elicits repetitive cytosolic Ca^{2+} spikes confined to the apical granular pole (see Fig. 4.6), in this way mimicking the effect of externally applied ACh (see Fig. 4.2). The importance of functional IP_3 receptors (IP_3R) for ACh-elicited Ca^{2+} signal generation and secretion in pancreatic acinar cells has been demonstrated very clearly by knockout experiments, in which it was shown that knockout of either type 2 or type 3 IP_3R had very little effect, whereas double knockout of both these receptors abolished ACh-elicited Ca^{2+} signal generation as well as secretion [34]. This directly confirms earlier data in which it was shown that intracellular infusion of the IP_3R antagonist heparin abolished both IP_3- and ACh-elicited Ca^{2+} spiking [35].

NAADP is a real intracellular messenger for CCK-induced activation of pancreatic acinar cells. Work from Galione's group in Oxford shows that physiologic CCK concentrations (1–10 pmol/L) evoke clear and dose-dependent increases in the cellular NAADP concentration. This effect is specific for CCK, since ACh has no effect on the NAADP level [26].

Intracellular infusion of NAADP, even at concentrations much lower (nanomolar) than those needed to obtain effects of IP_3 or cADPR, elicits repetitive cytosolic Ca^{2+} spikes in the apical pole that look very similar to those generated by IP_3 and cADPR [32]. The NAADP receptor has the interesting property that it can be inactivated by relatively high (micromolar) intracellular NAADP concentrations. Using such selective inhibition of the NAADP receptor, it has been shown that Ca^{2+} spiking evoked by physiologic CCK concentrations (<10 pmol/L) is blocked by a high intracellular NAADP concentration. This blocking effect is specific for the CCK response, since ACh-elicited Ca^{2+} spiking is unaffected [36]. Furthermore, the NAADP antagonist Ned-19 blocks CCK-elicited Ca^{2+} spiking, but has no effect on the action of ACh [27].

Although ACh and CCK initiate Ca^{2+} signaling via different pathways (see Fig. 4.4a), these ultimately converge and the measurable local apical Ca^{2+} transients are due to positive and negative feedback interactions between IP_3R and RyR on the ER (Fig. 4.4a). These Ca^{2+}-mediated positive and negative interactions are functionally important. For example, a Ca^{2+} signal initiated by an increase in the intracellular IP_3 concentration will subsequently activate RyR, inducing further Ca^{2+} release. This positive feed-forward effect explains the rising phase of the cytosolic Ca^{2+} spike. However, at a higher level of $[Ca^{2+}]_i$, a further $[Ca^{2+}]_i$ rise inhibits opening of both IP_3R and RyR. This explains the falling phase of the spike [7,37]. It has recently become clear that there is another class of channel involved in intracellular Ca^{2+}

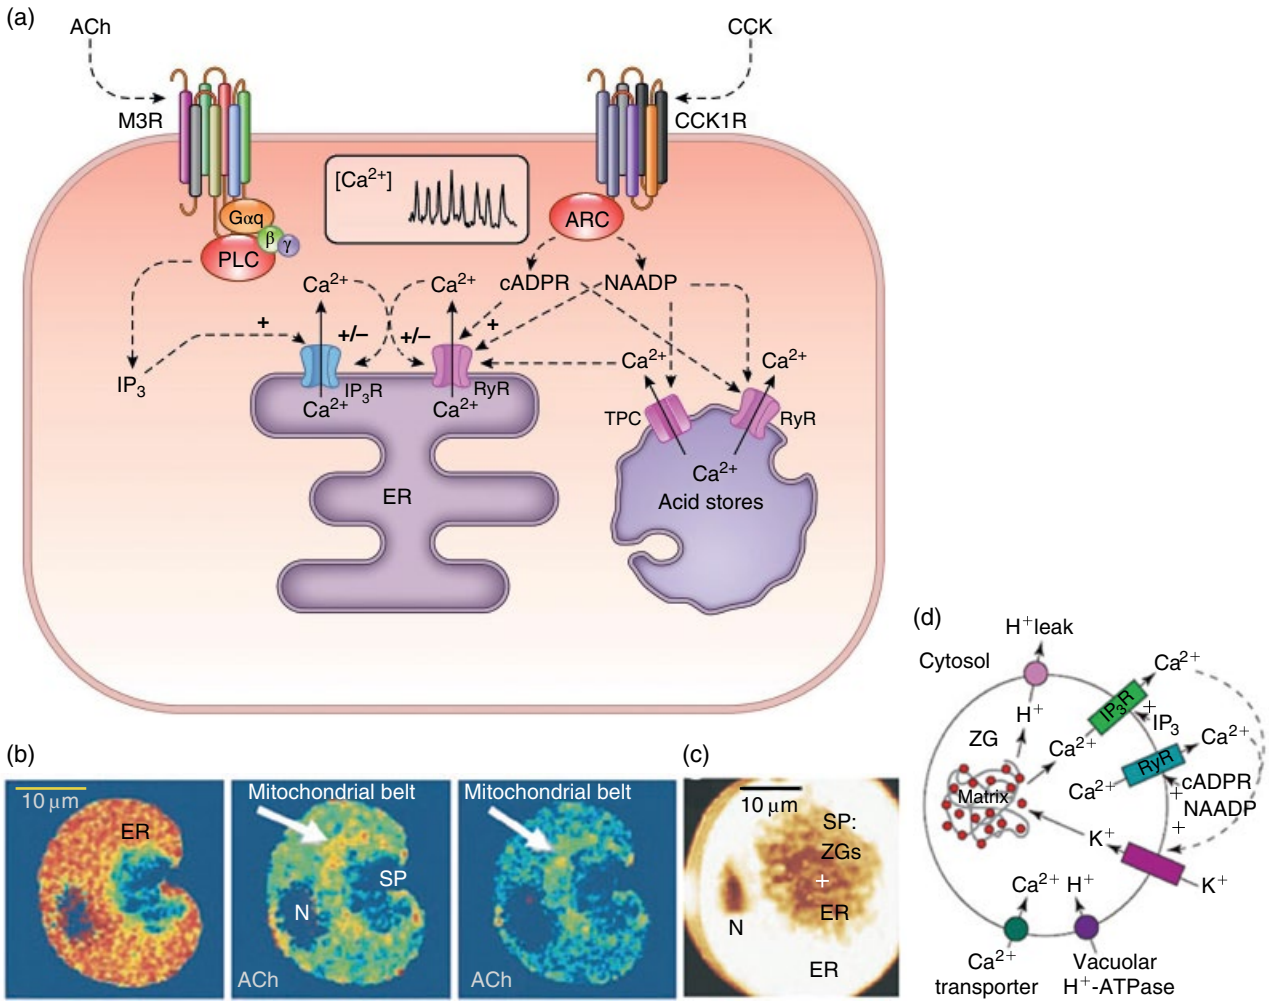

Figure 4.4 Ca^{2+} transport and signaling events in acinar cell. (a) Two receptor pathways are shown. ACh binding to muscarinic M3 receptors activates, via interaction with a classical trimeric G-protein, phospholipase C (PLC) generating the messenger IP_3 (as well as diacyl glycerol—not shown in diagram). CCK interaction with CCK1 receptors results in activation, via ADP-ribosyl cyclase (ARC), of two separate messengers, namely NAADP and cADPR. NAADP releases Ca^{2+} primarily from acid stores, via two pore channels (TPC). It also causes Ca^{2+} release from both acid stores and the ER via ryanodine receptors (RyR). cADPR releases Ca^{2+} via RyR from both acid stores and the ER. *Source:* Adapted from [7]. (b) Confocal fluorescent images illustrating changes in organellar [Ca^{2+}] following ACh stimulation. The left image shows the high resting [Ca^{2+}] in the ER (mostly in the basal (left) part of the cell). After maximal ACh stimulation, [Ca^{2+}] in the ER has been reduced markedly (shift from warm (red) to cold (green) color) and the perigranular mitochondrial belt is now clearly seen (yellow). This indicates that Ca^{2+} lost from the ER has been taken up in part by the mitochondria. The third image shows the almost complete loss of Ca^{2+} from the ER and the still elevated [Ca^{2+}] in the perigranular mitochondria. (c) Confocal image showing the distribution of fluorescent thapsigargin (white), a very specific marker for the ER Ca^{2+} pump. The optical slice goes through two cells (but only through one nucleus – N). It is seen that by far the highest ER Ca^{2+} pump density is in the basolateral parts of the cell, but it is important to note that there are some light elements in the darker granular (secretory pole – SP) areas signifying ER elements with Ca^{2+} pumps also in this part of the cell. (d) Schematic drawing of Ca^{2+}, H^+, and K^+ transports across the ZG membrane. *Source:* [25] / With permission of Elsevier.

release, namely the so-called two-pore channel (TPC) (Fig. 4.4a). In the pancreatic acinar cells, these channels are important specifically for the Ca^{2+} release evoked by CCK, which is mediated by NAADP. The sequence of events with regard to CCK-elicited Ca^{2+} signal generation is likely to be an initial release of a very small (trigger) amount of Ca^{2+} from endosomes/lysosomes, which is then amplified by a much more substantial liberation of Ca^{2+} from the ER and the acid stores occurring via RyR [7,27] (Fig. 4.4a).

Ca^{2+} Entry and Exit

Although the primary event responsible for activation of secretion by ACh or CCK is intracellular Ca^{2+} release, it

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universitat Bern, Wiley Online Library on [22/08/2023]. Figure 4.5 Acetylcholine (ACh)-induced breakdown of phosphatidylinositol 4,5-bisphosphate (PIP_2) in the plasma membrane (PM) and generation of inositol 1,4,5-trisphosphate (IP_3) in the cytosol (cyt). The green fluorescent protein (GFP)-linked PH domain of PLCδ1 binds with high affinity to both PIP_2 and IP_3. (1) Before stimulation, the main GFP fluorescence is seen in the basolateral membrane, indicating the presence of PIP_2 at this site. (2) Generation of a substantial rise in $[Ca^{2+}]_i$ by photolytic release of Ca^{2+} into the cytosol from caged Ca^{2+} does not cause any reduction in the PIP_2 concentration in the membrane. (3) ACh (1 µmol/L) causes a rise in $[Ca^{2+}]_i$ of similar magnitude to that seen after Ca^{2+} uncaging, but in this case there is loss of GFP fluorescence from the basolateral membrane, signifying loss of PIP_2, and appearance of fluorescence in the cytosol indicating appearance of IP_3. *Source:* Adapted from [31].

is also very important for both physiology and pathology to consider the overall cellular Ca^{2+} homeostasis, that is, Ca^{2+} entry and exit. All cells have to be protected against cellular Ca^{2+} overload, since it is well established that this causes cell death [38]. The plasma membrane must therefore be relatively impermeable to Ca^{2+} and there must be mechanisms for cellular Ca^{2+} extrusion. Ca^{2+} entry and exit across the plasma membrane of pancreatic acinar cells is controlled by specific transport mechanisms. Unlike many electrically excitable cells (e.g., cardiac cells), the acinar cells do not possess functional Na^+/Ca^{2+} exchangers, so that the only mechanism for extruding Ca^{2+} across the plasma membrane is via the plasma membrane Ca^{2+}-activated ATPase (PMCA) [25]. This pump is activated by increases in $[Ca^{2+}]_i$ above the basal level of 0.1 µmol/L, but has limited capacity. Interestingly, this pump is not uniformly distributed over the plasma membrane, but is specifically concentrated in the apical plasma membrane and therefore extrudes Ca^{2+} principally into the acinar lumen (see Fig. 4.7). The concentration of the pump in the apical membrane is functionally important, since the principal intracellular Ca^{2+} release sites are located in the apical pole (Figs 4.2 and 4.6), but carries the risk that Ca^{2+} overload, due to inappropriate Ca^{2+} entry across the basal membrane in pathologic conditions, cannot be dealt with adequately [25].

Physiologic stimulation of acinar cells does not primarily increase the permeability of the plasma membrane for Ca^{2+}, but after depletion of the ER Ca^{2+} store there is specific opening of the so-called store-operated Ca^{2+} channels in the basolateral membrane. This can most easily be visualized by measuring the uptake of Ca^{2+} entering the base of the cell into the peripheral mitochondria situated immediately beneath the plasma membrane, as shown in Fig. 4.7. In these types of experiments, the ER Ca^{2+} store is depleted by poisoning the Ca^{2+} pump in the ER very specifically with thapsigargin in the absence of external Ca^{2+}. Thereafter, Ca^{2+} is readmitted to the external solution and an increase in the Ca^{2+} concentration of those mitochondria situated very close to the plasma membrane can be visualized directly (Fig. 4.7). The nature of the store-operated Ca^{2+} channels

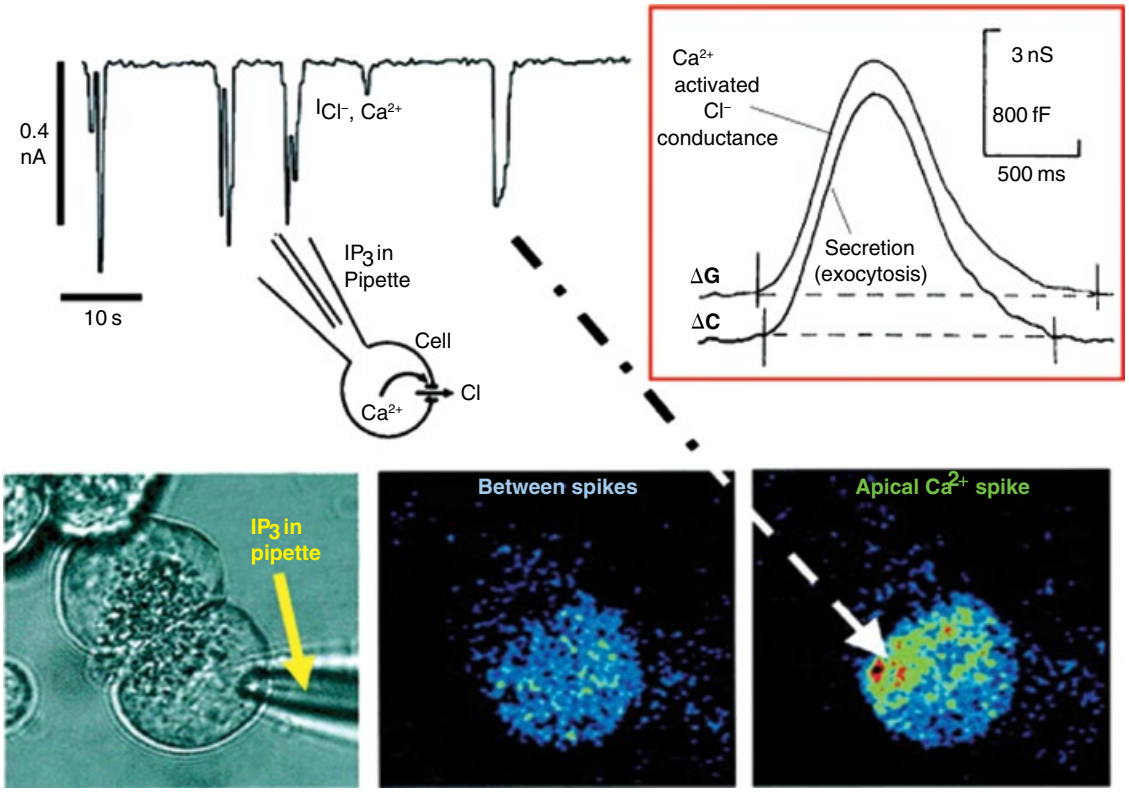

Figure 4.6 IP_3-elicited local apical Ca^{2+} spikes and exocytotic secretion. The main part of the figure shows the result from a patch clamp experiment with internal acinar cell perfusion. The trace shows the repetitive spikes of Ca^{2+}-dependent Cl^- current elicited by intracellular IP_3 infusion (10 μM). The images below illustrate the experimental configuration and the distribution of the elevated $[Ca^{2+}]_i$ during the height of a spike. It can be clearly seen that the Ca^{2+} signal occurs in the apical granular pole. *Source:* Adapted from [32]. The insert (in red frame) shows correlation between a single apical Ca^{2+} spike (during IP_3 infusion), recorded here as an increase in Cl^- conductance (ΔG), and the exocytotic response recorded as an increase in membrane capacitance (ΔC). It is seen that the increase in Cl^- conductance (a sensitive indicator of $[Ca^{2+}]_i$) slightly precedes the rise in capacitance and that the secretory response is completed just before $[Ca^{2+}]_i$ returns to the inter-spike level. *Source:* Adapted from [33] / With permission of Elsevier.

in the pancreatic acinar cells has been clarified by patch clamp studies, in which it has been possible to record directly the tiny Ca^{2+} currents flowing across the basolateral membrane upon depletion of the ER Ca^{2+} store. The biophysical properties of this current shows that the channels belong to the very Ca^{2+}-selective CRAC (Ca^{2+} release activated Ca^{2+}) channel type [41], which is also present in various immune cells [15]. These channels, including those in the acinar cells as well as other pancreatic cell types, can be blocked by very specific CRAC channel inhibitors [7,41–45].

During sustained stimulation with either ACh or CCK, one can usually observe a plateau of elevated $[Ca^{2+}]_i$, which represents a delicate balance of Ca^{2+} entry through store-operated Ca^{2+} channels in the basal membrane and Ca^{2+} exit mainly through Ca^{2+} pumps located in the apical plasma membrane [24]. Ca^{2+} extrusion is energy-dependent. Therefore, if intracellular ATP levels fall during pathologic conditions, for example when cells are exposed to nonoxidative alcohol metabolites [46], Ca^{2+} extrusion stops and dangerous Ca^{2+} overload occurs, resulting in necrosis [7,46].

Ca^{2+}-Mediated Control of Enzyme Secretion

It has been known for many years that intracellular Ca^{2+} is the main acute regulator of exocytosis [47]. In experiments on the isolated perfused pancreas, it has been demonstrated that during sustained stimulation with high concentrations of ACh or CCK, both fluid and enzyme secretion are acutely dependent on the presence of external Ca^{2+} (see Fig. 4.1). During this phase of the secretory response, the ER will have been partly depleted of Ca^{2+} and Ca^{2+} therefore has to be supplied by entry from the external solution through store-operated Ca^{2+} channels as described earlier. However, during physiologic stimulation, with low concentrations of CCK or ACh, there is not a sustained elevated $[Ca^{2+}]_i$ but rather a series of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 4.7 Overall Ca^{2+} homeostasis: Ca^{2+} entry and exit. The left part illustrates an experiment in which $[Ca^{2+}]$ is measured outside an isolated acinar cell by using a Ca^{2+}-sensitive fluorescent indicator linked to high molecular weight dextran, thereby limiting the indicator mobility. The morphology of the cell, with clear identification of the granular apical (Ap) pole is shown in (a). (b) to (i) are fluorescent images (taken at 3-s intervals) showing the distribution of the extracellular $[Ca^{2+}]$ rise immediately following stimulation with ACh (10 µM). It is clear that the Ca^{2+} extrusion from the cell occurs predominantly across the apical membrane. The right part of the figure illustrates the rise in $[Ca^{2+}]$ of mitochondria close to the basal plasma membrane during store-operated Ca^{2+} entry. Mitochondrial $[Ca^{2+}]$ ($[Ca^{2+}]_m$) was measured with a fluorescent probe and traces from three regions of interest (red, black, and green) are shown. The cell was initially poisoned with thapsigargin in the absence of external Ca^{2+} to deplete the ER of Ca^{2+}. During the time period indicated by the bar labeled 10 mM Ca^{2+}, Ca^{2+} was readmitted to the external solution and it is seen that there was a marked rise in $[Ca^{2+}]_m$ particularly in the red region of interest, very close to the basal plasma membrane. The image marked with a red arrow shows the distribution of the elevated $[Ca^{2+}]$ at the time indicated by a similar red arrow above the fluorescence traces. Clearly the elevation of $[Ca^{2+}]_m$ has essentially occurred in a region very close to the plasma membrane. The EM picture shows a mitochondrion (Mit) situated very close to the plasma membrane (PM). *Source:* Adapted from [39] and [40].

short-lasting Ca^{2+} spikes localized specifically in the critical apical region (Figs 4.2 and 4.6). These spikes are essentially independent of external Ca^{2+} and are due to repetitive release of small amounts of Ca^{2+} from the ER [7,48].

Can the short-lasting local Ca^{2+} spikes, evoked by low agonist concentrations or direct intracellular messenger infusion, control secretion? The most sensitive method for evaluating exocytotic secretion is measurement of membrane capacitance. When granules fuse with the plasma membrane, the surface area of the plasma membrane increases, but only transiently since the additional membrane inserted is subsequently removed by the process of endocytosis. As shown in Fig. 4.6 (inset), there is indeed a transient increase in the pancreatic acinar membrane capacitance during an individual short-lasting Ca^{2+} spike, which can most easily be recorded by electrophysiologic methods. Results, such as those recorded in Fig. 4.6, demonstrate clearly the very fine control exerted by the local apical $[Ca^{2+}]_i$ on exocytotic secretion.

Ca^{2+}-Mediated Control of Fluid Secretion

How is acinar fluid secretion regulated? The generally accepted model for isotonic fluid secretion by exocrine glands is illustrated in Fig. 4.1a. The principal step for activation of fluid secretion is Ca^{2+}-activated opening of Cl^- channels, which are specifically located in the apical plasma membrane [49]. This will cause Cl^- exit into the acinar lumen. The increased lumen negativity will attract cations and the principal extracellular cation, Na^+, will move through the very leaky junctions between the acinar

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cells, which are named (inappropriately!) tight junctions. These junctions sit very close to the apical membrane and separate the luminal fluid compartment from the basal and interstitial compartments, and also separate the very different properties of the apical and basolateral membranes (Fig. 4.1a). NaCl in the acinar lumen will osmotically attract water, which can pass through both the cell membranes (via aquaporins) and the tight junctions.

The principal activating step of acinar fluid secretion, namely the exit of Cl^- from the cell interior to the lumen through Ca^{2+}-activated Cl^- channels, only occurs if there is an electrochemical gradient favoring transport in this direction. The intracellular Cl^- concentration must be held above thermodynamic equilibrium and a Cl^--accumulating mechanism is therefore needed. As shown in Fig. 4.1a, a $Na^+/K^+/2Cl^-$ cotransporter is situated in the basolateral membrane (for graphical convenience shown in Fig. 4.1a only in the basal membrane). Energy for this process comes from the transmembrane Na^+ gradient established by the Na^+/K^+ pump, which is also situated in the basolateral membrane. Increased Cl^- secretion requires stimulation of the Na^+ pump, which occurs via the increased intracellular Na^+ concentration mediated by enhanced turnover of the $Na^+/K^+/2Cl^-$ cotransporter. This in turn requires additional K^+ cycling across the plasma membrane, which is mediated by Ca^{2+} activation of specific K^+ channels situated in the basolateral membrane (Fig. 4.1a).

As seen in Fig. 4.1a, it is the concerted Ca^{2+} activation of Cl^- and K^+ channels that controls the fluid secretion process. It is important to understand that the whole of the basolateral membrane is uniform with regard to distribution of surface membrane ion channels. Thus, the Ca^{2+}-activated K^+ channels are found not only in the basal membrane as illustrated in Fig. 4.1a, but also in the lateral membranes, up to the tight junctions. Therefore, local apical Ca^{2+} signals will be able to activate both Cl^- channels in the apical membrane and K^+ channels in the part of the lateral membrane close to the tight junctions. A limited amount of fluid secretion can proceed without special activation of K^+ channels, since rodent pancreatic acinar cells lack Ca^{2+}-activated K^+ channels [12]. If the resting K^+ permeability is sufficiently high, recirculation of K^+ can still occur. However, human pancreatic acinar cells, like all salivary and lacrimal glands in all species so far studied, do possess very sensitive Ca^{2+}-activated K^+ channels, which undoubtedly contribute to the fine regulation of human acinar fluid secretion [50]. In the human acinar cells, these Cl^- and K^+ channels will be activated by the short-lasting repetitive local Ca^{2+} signals in the secretory granule region, which have been directly demonstrated in response to stimulation with either ACh or physiologic concentrations (low pM) of CCK [51].

Dangers of Ca^{2+} Signaling

As described in this chapter, local Ca^{2+} signaling elicited by physiologically relevant agonist concentrations is a remarkably precise mechanism for fine regulation of pancreatic acinar secretion (Fig. 4.6). These Ca^{2+} signals also control the production of ATP (Fig. 4.3), which is required to fuel both fluid and enzyme secretion. However, Ca^{2+} signaling carries a risk of cellular Ca^{2+} overload, which has the capacity to kill cells [7]. This occurs when acinar cells are hyperstimulated with, for example, CCK. In this situation Ca^{2+} spiking is replaced by a sustained elevated $[Ca^{2+}]_i$ which, by a still poorly understood mechanism, activates the digestive proteases inside the cells [25]. The sustained elevated $[Ca^{2+}]_i$ is due to open CRAC channels and can be markedly reduced by CRAC channel inhibitors [7,41–43]. A sustained elevated $[Ca^{2+}]_i$, unlike repetitive short-lasting Ca^{2+} spikes, does not stimulate mitochondrial ATP production, but inhibits it [52]. The combination of a global and sustained high $[Ca^{2+}]_i$ with a low cytosolic ATP level is lethal [7,53].

Intracellular digestive enzyme activation is a hallmark of pancreatitis, which is mostly related to biliary disease or excessive alcohol intake. Both bile-related and alcohol-related acute pancreatitis are due to cytosolic and mitochondrial Ca^{2+} overload, which have been brought about by excessive opening of CRAC channels in the plasma membrane triggered by excessive release of Ca^{2+} from intracellular stores [7]. Both bile acids and the combination of ethanol and fatty acids (generating fatty acid ethyl esters) have the capacity to elicit excessive release of Ca^{2+} from intracellular stores [7]. The cytosolic Ca^{2+} overload leads to mitochondrial Ca^{2+} overload, which causes opening of the so-called mitochondrial permeability transition pore (MPTP) and this depolarizes the inner mitochondrial membrane resulting in loss of ATP production [7,46,52]. The dangerous effects of bile acids or fatty acid ethyl esters can be markedly inhibited by reducing the intracellular Ca^{2+} release via caffeine inhibition of IP_3 receptors [35,54], by reducing Ca^{2+} inflow via CRAC channels using specific CRAC channel inhibitors [7,41–43] or by inhibiting the MPTP [55]. The pancreatic acinar cell lives dangerously. It very effectively employs Ca^{2+} signaling as a finely coordinated mechanism for regulation of both fluid and enzyme secretion, but excessive intracellular Ca^{2+} release or Ca^{2+} entry has the capacity to cause necrosis.

The Ca^{2+}-mediated toxic actions on the acinar cells, initiated by bile acids or the combination of ethanol and fatty acids, are markedly amplified by interactions with the neighboring stellate cells as well as with the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 4.8 Ca^{2+}-dependent interactions, between acinar cells, neighboring stellate cells and resident macrophages in the acinar environment, drive the development of acute pancreatitis. Inhibition of Ca^{2+} influx in these three cell types through CRAC channels (denoted by red asterisks) would be a rational therapy against acute pancreatitis. For details, see text. *Source:* Adapted from [7].

macrophages that invade the pancreatic tissue in the early stages of acute pancreatitis (Fig. 4.8). Loss of kallikrein from the acinar cells that are most sensitive to the toxic actions will lead to generation of bradykinin (BK), which then acts on type 2 BK receptors on stellate cells, releasing Ca^{2+} from internal stores that in turn opens CRAC channels. The generation of Ca^{2+} signals in the stellate cells activates nitric oxide formation [6], which, via an unknown mechanism, promotes necrosis of the acinar cells, starting a vicious circle (Fig. 4.8). ATP and ADP released from dying acinar cells act on purinergic receptors on macrophages generating Ca^{2+} signals in these cells due to activation of CRAC channels [44]. This stimulates secretion of many cytokines, including interleukins and TNF-α, which in turn causes further necrosis of the acinar cells (Fig. 4.8). It is therefore these necrotic amplification loops, dependent on Ca^{2+} influx through CRAC channels that drive the development of acute pancreatitis (Fig. 4.8). The therapeutic and preventive effects of small molecule CRAC channel inhibitors [41–43] are therefore not only due to reduction of Ca^{2+} influx into acinar cells, but also due to inhibition of CRAC channel opening in the neighboring stellate cells and macrophages [4,7,44,45].

Physiology of Duct Cell Secretion

Wei-Yin Lin, Paramita Sarkar, and Shmuel Muallem

Epithelial Signaling and Transport Section, National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD, USA

Introduction

The cardinal function of the pancreatic duct is fluid and HCO_3^- secretion, which determines the volume and electrolyte composition of the pancreatic juice and guards the acinar cells against damage by various stressors. Indeed, ductal fluid and electrolyte transport is compromised in diseases such as cystic fibrosis and pancreatitis, which stress the pancreas [1]. Ductal secretion is coupled to acinar secretion that provides the small volume of isotonic, plasma-like fluid. The ducts then secrete the bulk of the fluid into the pancreatic juice making economical and recirculating use of the electrolytes in primary fluid secreted by acinar cells. Thus, for a better understanding of ductal secretion and physiology, first we have to understand the mechanism of acinar secretion and its regulation. Selective transporters in acinar and duct cells mediate vectorial transport of osmotically active ions to generate and secrete fluid of defined composition. Ductal and acinar cells secretion is highly regulated at both the resting and secreting states by multiple inputs that transmit their signals through the two main second messengers Ca^{2+} and cAMP. The Ca^{2+} and cAMP inputs are integrated into a final response with synergized high fidelity. Other important regulators of the entire secretory process are the transported ions. This is highlighted in the regulation of ductal transporters and secretion by intracellular Cl^- [2]. This chapter discusses the principles of ductal fluid and HCO_3^- secretion and its regulation and how they can be corrected in pancreatic disease states.

Sequential Secretion by Acinar and Duct Cells

Fluid and Electrolyte Secretion by Acinar Cell

Pancreatic fluid and electrolyte secretion is a two-step, sequential process. The acinar cells secrete a small volume of isotonic, NaCl-rich fluid. Whereas, the duct produces most of the fluid and determines the final ion composition of the pancreatic juice [3]. Understanding ductal secretion requires an understanding of acinar cells secretion. The key transporters and the mechanism of fluid secretion by acinar cells are modeled in Fig. 5.1. Vectorial ion transport depends on the Na^+ and K^+ gradients and the membrane potential that are set by the basolateral Na^+/K^+ ATPase pump [4]. The Ca^{2+}-activated K^+ channel at the basolateral membrane Kcnma1 sets the membrane potential near the K^+ diffusion potential of about −60 mV [5]. About 60–70% of acinar cells salt uptake is mediated by the ubiquitous basolateral $Na^+/K^+/2Cl^-$ cotransporter NKCC1 [3]. The remaining salt is absorbed by the basolateral Na^+/H^+ exchanger NHE1 and by a Cl^-/HCO_3^- exchange activity. It is generally assumed that the ubiquitous AE2 mediates the Cl^-/HCO_3^- exchange that supports fluid flux. However, in salivary glands, AE4, which functions as a cation-driven Cl^-/HCO_3^- exchanger [6], mediates part of the Cl^- influx necessary for fluid secretion [7]. NHE1 and AE2 also control the cytoplasmic pH (pH_{in}) to prevent large fluctuations in pH_{in} during the secretion [8,9]. Under resting conditions NKCC1, AE2, and AE4 maintain intracellular Cl^- (Cl^-_{in}) at 40–60 mM [10]. The importance of Cl^-_{in} is

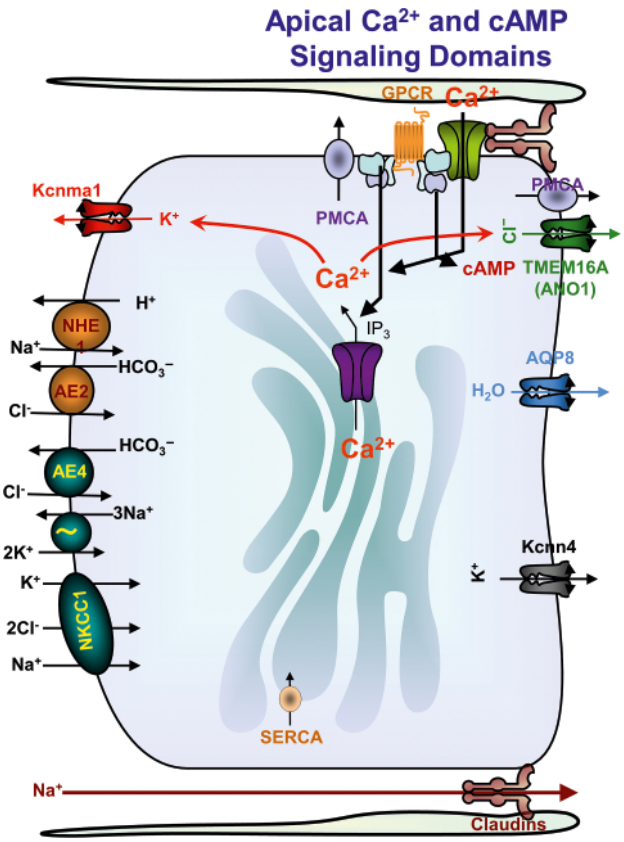

Figure 5.1 Mechanism of fluid and electrolyte secretion by acinar cells. The model shows the key transporters and the relationships between them that mediate the bulk of fluid and electrolyte secretion by acinar cells. Key regulation of acinar fluid and electrolyte secretion take place by assembly of Ca^{2+} and cAMP signaling complexes at the apical pole to control the function of ANO1 and K^+ channels.

discussed below in relation to regulation of the secretory process. Cl^- exits across the luminal membrane through the Ca^{2+}-activated Cl^- channel TMEM16A/Ano1 [11] and water flows through the water channel AQP8 [12]. The tight junction on acinar cells is the main route of paracellular Na^+ flux, which may be mediated by one of the acinar claudins [13].

Acinar cells fluid and electrolyte secretion is regulated by Gq-coupled receptors that increase free cytoplasmic Ca^{2+} ($[Ca^{2+}]_i$) and is enhanced by the cAMP/PKA pathway. To prevent Ca^{2+} toxicity by stronger stimulation, only 1–5% of the Gq pool evoke Ca^{2+} oscillations under physiological stimulation. The Ca^{2+} oscillations initiate and remain confined to the apical pole [14], although they can propagate to the basal pole [15,16]. Acinar cell secretion starts by an increase in apical $[Ca^{2+}]_i$ to activate Ano1 [11], and K^+ channels in the basal [17] and maybe apical poles [18]. This leads to Cl^- efflux into the luminal space and K^+ efflux into the interstitial space. Na^+ transport through the tight junctions results in the net secretion of NaCl and generation of an osmotic gradient that drives water flow through the water channel Aqp8, leading to cell shrinkage. Cell shrinkage reduces $[Ca^{2+}]_i$ and activates the volume-sensitive cotransporters NKCC1 [19], NHE1 [20], AE2 [21], and perhaps AE4 to recover cytoplasmic electrolytes and cell volume. The cycle of Ca^{2+}-regulated water flow is repeated with each Ca^{2+} spike making acinar cells function as a Ca^{2+}-driven ion and water pump.

Fluid and Electrolyte Secretion by Duct Cell

The main transporters mediating ductal fluid and HCO_3^- secretion are shown in Fig. 5.2. Transport is fueled by the Na^+ gradient and the membrane potential set by the Na^+/K^+ ATPase pump [22], the K^+ channels K(Ca^{2+})1.1 [23], and an unknown basolateral K^+ channel. HCO_3^- enters the ducts by basolateral $1Na^+–2HCO_3^-$ co-transport [24,25] mediated by the electrogenic NBCe1-B isoform [26] that accumulates cytoplasmic HCO_3^- and osmolytes. The basolateral Na^+/H^+ exchanger NHE1 [25] and Cl^-/HCO_3^- exchange, likely AE2, control pH_{in} and Cl^-_{in}, which is required for stimulated secretion [27].

The bulk of HCO_3^- exits across the luminal membrane by the interrelated activity of the cAMP-activated Cl^- channel cystic fibrosis transmembrane conductance regulator (CFTR) and the exchanger slc26a6 [3]. Slc26a6, an electrogenic $1Cl^-/2HCO_3^-$ exchanger [28,29], is essential for ductal fluid secretion because it mediates net solute transport in addition to HCO_3^- secretion. Fluid moves osmotically and exits the luminal membrane through AQP1, a process essential for ductal fluid secretion [30]. CFTR has finite HCO_3^- permeability [31] and CFTR-mediated HCO_3^- flux becomes important at the distal portion of the ducts when luminal and cytoplasmic Cl^- are low [3]. Other ductal transporters on the luminal membrane of note are Na^+/H^+ exchanger NHE3 [32] and H^+/K^+ ATPase pump ATP12A [33]. Luminal ATP12A may inhibit H^+ absorption [33], although ATP12A in the airway epithelium actually contributes to the pathology in cystic fibrosis [34], a disease that prominently affects the pancreas. Hence, the role of ATP12A in the pancreatic duct remains to be established. We have suggested that H^+-secreting transporters like NHE3 and perhaps ATP12A function to salvage HCO_3^- in the ductal resting state [32] (Fig. 5.2a).

Ductal secretion is stimulated by the Gs-coupled secretin receptor that transmits its signal by increasing cAMP to activate protein kinase A (PKA) [3]. PKA phosphorylates the R domain of CFTR to activate the channel. CFTR then activates the slc26a6 by interaction of CFTR R domain with the slc26a6 STAS domain [35]. In turn, this interaction further activates CFTR. At the same time, CFTR inhibits NHE3 to prevent H^+ secretion

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 5.2 Mechanism of fluid and electrolyte secretion by duct cells. The models show the key transporters and the relationships between them in the resting (a) and stimulated ducts (b). The resting duct can secrete H^+ by NHE3 and perhaps ATP12A to salvage HCO_3^-, while slc26a6 is away from CFTR and not active. In the stimulated state the H^+-secreting transporters are inhibited and slc26a6 and CFTR are mutually activated to cause fluid and electrolyte secretion. Osmotic flow of H_2O is through the water channel AQP1.

into the lumen [36]. CFTR recycles the Cl^- absorbed by slc26a6 to maintain HCO_3^- secretion through slc26a6. Net osmolyte secretion by slc26a6 in the form of HCO_3^- together with paracellular Na^+ flow drives osmotic water secretion to generate the final volume of the pancreatic juice.

Regulation of Ductal Secretion

Ductal secretion is dynamically regulated in both resting and stimulated states by kinase and phosphatase pathways and scaffolding proteins. In addition, Cl^-_{in} regulates the transporters that mediate ductal secretion by affecting their activity and selectivity [2]. The resting state is set by the WNK, SPAK/OSR1, and CAMKII kinases [37]. Pancreatic duct cells express CaMKII [38] and mammals have four WNKs [39], with WNK1, WNK3, and WNK4 expressed in the pancreas [3]. The WNKs regulate Na^+, K^+, Cl^-, HCO_3^-, and Ca^{2+} transporters in epithelia by determining their surface expression and activity [39]. SPAK and OSR1 are homologous stress-activated kinases that act downstream of the WNKs, with the WNKs serving as scaffolds to the SPAK/OSR1. The SPAK/OSR1 can affect surface expression, inhibit or activate the ion transporters [40]. Another level of regulation of the WNK kinases is through interaction with kelch-like 3 (KLHL3) and cullin 3 (CUL3), which regulate WNKs level by ubiquitination and degradation [41]. The role of CaMKII in epithelial transport is not well understood, although CaMKII affects the activity of many transporters and channels, such as Ca^{2+} channels [42] and the regulation of NBCe1-B by Cl^- [37].

In the pancreatic duct, the WNK and the SPAK/OSR1 kinases function in the same pathway with the WNKs acting as scaffolds for the SPAK/OSR1 kinases. The WNK/SPAK pathway regulates the ductal NBCe1-B [43], slc26a6 [31], and CFTR [43,44] by inhibiting surface expression and the activity of the transporters. Notably, knockdown of the WNK and of SPAK kinases enhanced stimulated ductal fluid secretion, indicating that the kinases exert tonic inhibition of the secretion [43] to set the basal non-secretory state (see model in Fig. 5.3a). Similarly, by modulating NBCe1-B inhibition by Cl^-_{in}, CaMKII limits HCO_3^- secretion to favor the resting state [37].

The multifunctional protein IRBIT (IP_3 binding protein released with IP_3) regulates the pancreatic duct stimulated, secretory state. IRBIT was discovered as a

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universitat Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

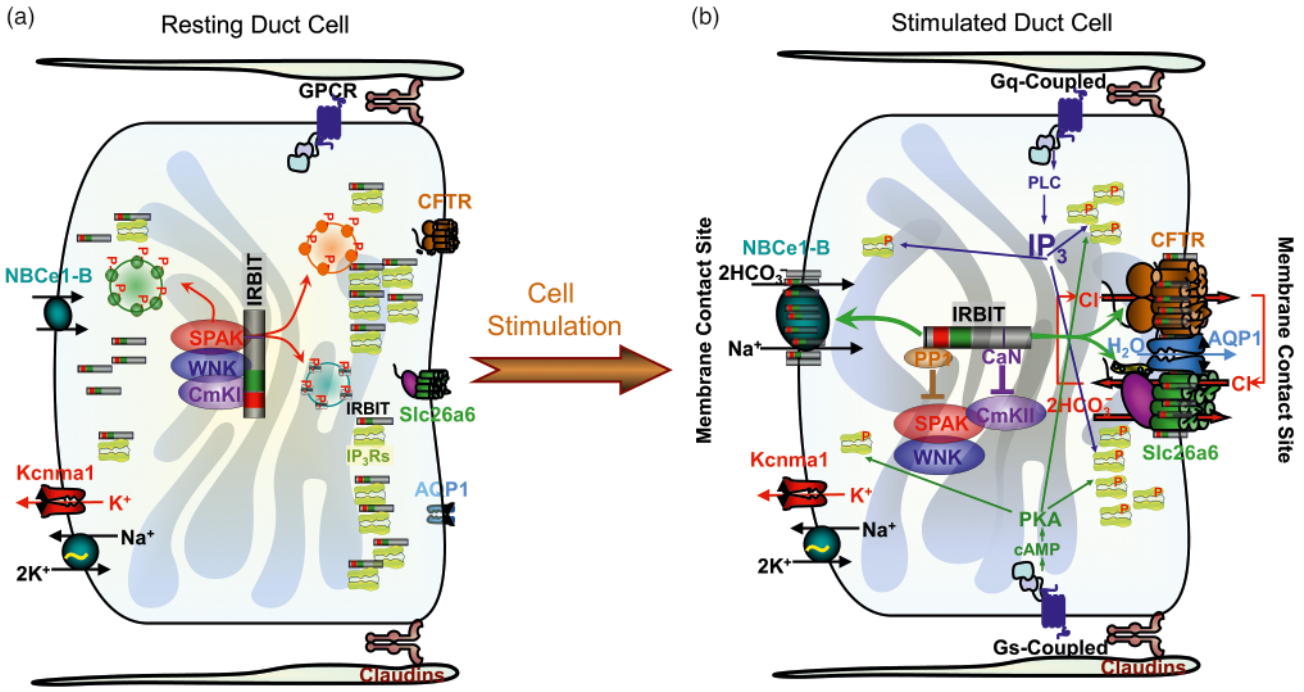

Figure 5.3 IRBIT mediates synergistic activation of the cAMP and Ca^{2+} signaling pathways at membrane contact sites. In the resting state (a), the WNK/SPAK and CaMKII kinases associate with the transporters and SPAK and CaMKII phosphorylate NBCe1-B AID, slc26a6, and CFTR to sequester most of them in intracellular organelles and modulate their regulation by Cl^-_{in}. IRBIT is sequestered by the IP_3 receptors but also aids in association of the kinases with the transporters. When the cells are stimulated (b) with physiological concentrations of IP_3 and cAMP generating agonists, PKA phosphorylates the IP_3R to facilitate release of IRBIT from the IP_3R by IP_3 and IRBIT localizes to membrane contact sites. IRBIT recruits PP1 and CaN to the transporters to dephosphorylate them at the SPAK and CaMKII phosphorylation sites and target them to the plasma membrane at membrane contact sites. IRBIT remains bound to the transporters' autoinhibitory domains and further activates the transporters and ductal secretion.

protein that binds to the IP_3 receptors (IP_3Rs) [45] and as an activator of NBCe1-B [46]. IRBIT has an N terminus protein phosphatase 1 (PP1) binding motif, a PEST domain, a coiled-coil domain, calcineurin (CaN) binding motif and a PDZ ligand at the end of the C-terminus [37,47]. The coiled-coil domain participates in activation of target proteins by IRBIT [48] and the PDZ ligand locates IRBIT close to the HCO_3^- transporters [43] and at membrane contact sites (MCS) [49]. IRBIT activates transporters by two mechanisms, increasing their surface expression and transport activity, and perhaps by assembling them into complexes at MCS. This is best understood with NBCe1-B. The first 85 residues of NBCe1-B form an autoinhibitory domain (AID) [50]. IRBIT interacts with the AID to prevent the NBCe1-B self-inhibition [46]. In addition, IRBIT reverses the inhibition of NBCe1-B by WNK/SPAK and by CaMKII through recruiting PP1 and CaN to the transporter, which dephosphorylates the SPAK phosphorylated Ser65 [37,51].

IRBIT also interacts with and potently activates CFTR [43,48] and slc26a6 [51] by interacting with a sequence similar to the NBCe1-B AID that is present in CFTR R domain and slc26a6 STAS domain [51]. Indeed, IRBIT similarly recruits the PP1 to NBCe1-B, CFTR, and slc26a6 [43,51]. The key role of IRBIT in ductal secretion was established by showing that knockout of IRBIT in mice markedly inhibits ductal fluid secretion. The reduced secretion due to IRBIT knockdown was partially recovered by knockdown of SPAK [43], showing the interplay between the IRBIT/PP1 and the WNK/SPAK pathways in modulating ductal secretion, as illustrated in Fig. 5.3b.

HCO_3^- secretion depends on strict regulation of both intracellular and surface membrane HCO_3^- concentrations that are determined by carbonic anhydrases (CA). CA are either cytoplasmic or membrane anchored with their active site at the extracellular cell surface [52]. The surface CA control the supply or the removal of HCO_3^- at the surface of the plasma membrane and the cytoplasmic CA buffer cytoplasmic HCO_3^-. The plasma membrane localized CA interact with many H^+ and HCO_3^- transporters [53]. We know very little about the role and molecular identity of the CA that are important in ductal secretion. Some information became available from human disease in which mutations in CA12 causes

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universitat Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

salt wasting [54,55]. CA12 is a critical activator of AE2 and ductal secretion. Deletion or mutation in CA12 inhibits its ductal secretion by about 50% and overexpression of CA12 markedly increases ductal secretion [27]. Hence, activation of CA12 is a potential treatment of ductal hypofunction.

Another prominent regulator of ductal function is Cl^-_{in}. Cl^-_{in} has a key role in ductal function by driving HCO_3^- secretion through slc26a6, controlling the luminal membrane potential through CFTR and of pH_{in} through AE2 (Fig. 5.2). Sensing Cl^-_{in} is therefore essential for tuning the secretory process. Cl^-_{in} regulates the function of multiple channels and transporters by functioning as a signaling ion [2]. Cl^- regulates the activity of at least two HCO_3^- transporters, NBCe1-B and CFTR. Cl^-_{in} controls HCO_3^- permeability of CFTR by affecting the function of WNK1 [31,56]. Once Cl^-_{in} is below 8 mM, CFTR becomes the HCO_3^- channel to increase HCO_3^- concentration of pancreatic juice from 120 to 140 mM [57]. A more dramatic regulation by Cl^-_{in} is seen with NBCe1-B. IRBIT-activated NBCe1-B is regulated between 5 and 20 mM Cl^-_{in} [58]. Ductal secretion starts when resting Cl^-_{in} is about 35 mM and decreases to 4 mM toward the latter phase of Cl^- absorption and HCO_3^- secretion [3,59]. At Cl^-_{in} above 20 mM, 70% of NBCe1-B activity is inhibited, which is sufficient to support HCO_3^- secretion at the proximal duct. As demand for cytoplasmic HCO_3^- increases in the face of accumulation of luminal HCO_3^-, Cl^-_{in} is reduced toward 4 mM to increase the activity of NBCe1-B threefold [58], which ensures continued HCO_3^- supply.

The Ca^{2+} and cAMP Pathways Synergize to Activate Ductal Secretion

Synergism between signaling pathways is a fundamental concept in biology that serves to prevent cell toxicity by overstimulation. Signaling pathways function at 1–5% of capacity and synergize to generate the maximal physiological response. The Ca^{2+} and cAMP signaling pathways synergize in a mechanism mediated by IRBIT [51]. At the resting state IRBIT is bound to IP_3 receptors. Physiological stimulation increases ductal cAMP to phosphorylate the IP_3R to increase their affinity for IP_3 and reduce their affinity for IRBIT [51]. A small increase in IP_3 by physiological stimulation with Ca^{2+}-mobilizing receptors releases IRBIT from the IP_3R that then binds to CFTR, slc26a6, and NBCe1-B to activate them and ductal secretion [51]. This important physiological mode of synergism is illustrated in Fig. 5.3.

Ductal Secretion-Associated Pancreatic Diseases

Ductal fluid and HCO_3^- secretion not only wash digestive enzymes to the intestine, but also protect the parenchyma from damage due to stresses to the pancreas. In addition, as a chaotropic ion, HCO_3^- is essential for solubilization of macromolecules like digestive enzymes and mucins and divalent ions in biological fluids [3,60]. The duct is the first line of defense of the pancreas that must be breached before damage to acinar cells takes place. Indeed, damage to ductal secretion occurs in several diseases of the pancreas, including cystic fibrosis (CF) and pancreatitis. CF leads to destruction of the pancreas and pancreatic insufficiency [61] due to inhibition of ductal fluid and HCO_3^- secretion [3]. Moreover, several studies have identified mutations in CFTR that are associated with chronic pancreatitis [62] and specifically inhibit CFTR-dependent HCO_3^- transport [56,63] and permeability [56], independent of Cl^- channel activity [56]. The importance of the duct in protection of the pancreas and of CFTR in ductal function [64] led to the examination of the state of CFTR in chronic autoimmune [65] and alcoholic pancreatitis [65,66], which revealed mislocalization of CFTR in these forms of pancreatitis. Notably, treatment of autoimmune pancreatitis with corticosteroids ameliorated the disease primarily by increasing ductal HCO_3^- secretion [65]. In animal models, induction of acute pancreatitis by cerulein stimulation, bile duct infusion, and alcohol treatment impaired ductal function [67]. Finally, the chronic pancreatitis model NOD mice and the autoimmune pancreatitis model of poly IC in MRL/Mp-Fas mice showed markedly reduced expression of CFTR. Notably, treatment with CFTR correctors restored CFTR expression, ductal function, pancreas integrity, and most notably, acinar cell functions [68]. Similarly, CFTR correctors and potentiators reduced the severity of pancreatitis in a cerulein acute pancreatitis model [69]. These findings suggest that CFTR correctors should be considered as a safe and effective treatment for pancreatitis.

The intimate involvement of the duct in the health of the pancreas and pancreatic diseases suggests that the duct should be a prime target for therapy. There are several potential targets. One could be activators of IRBIT together with inhibitors of the WNK/SPAK/OSR1 kinases. Because of their involvement in renal salt homeostasis and hypertension [41], such drugs may became available in the future. Another potential target is CA12 that affects ductal function [27] and is modified in several cancers [70]. Drugs affecting CA12 activity are being developed in the cancer field and

may become useful for the treatment of pancreatitis. A very promising option is the use of CFTR potentiators and correctors that are approved for the treatment of CF [71]. These drugs repair CFTR localization and increase ductal secretion to slow progress of the disease in animal models and further improve the function of acinar cells. These drugs are effective in humans and in CF patients by increasing pancreatic and acinar cells function, although they increased slightly the incidents of acute pancreatitis in pancreatic sufficient patients [72,73].

Physiology and Pathophysiology of Function of Sphincter of Oddi

Savio George Barreto[1,2] *and James Toouli*[2]

[1] *Division of Surgery and Perioperative Medicine, Flinders Medical Centre, Adelaide, South Australia, Australia*
[2] *College of Medicine and Public Health, Flinders University, Adelaide, South Australia, Australia*

Introduction

The presence of gallbladder and biliary tract was described in some of the earliest recorded observations of humans [1], but their role in digestion was not appreciated until much later. In the sixteenth century, a membrane near the distal end of the common bile duct thought to impede reflux of duodenal contents into the bile duct was described but it was not until 1887 that this structure was described as a sphincter and named after Rugero Oddi, who published a detailed description of its anatomy as a result of dissections undertaken while studying medicine [2]. The physiological role of the sphincter of Oddi was further appreciated after the hormone cholecystokinin (CCK) was shown to contract the gallbladder and reduce sphincter of Oddi resistance. These and subsequent studies firmly established that an intimate relationship existed between gallbladder contraction, sphincter of Oddi function, and the flow of bile and pancreatic juice into the duodenum.

Anatomy and Morphology

The terminal parts of the common bile duct and pancreatic duct, the common channel, and major duodenal papilla of Vater are invested by varying thickness of smooth muscle that together form the sphincter of Oddi segment (Fig. 6.1). The major part of the human sphincter of Oddi lies within the duodenal wall, and is anatomically and functionally independent of the duodenal muscle.

Distinct sphincters have been described at the terminal end of the common bile duct (sphincter choledochus), pancreatic duct (sphincter pancreaticus), and common channel (sphincter ampullae) [3]. However, studies using a combination of radiologic, duct cast techniques, and histologic sectioning methods did not distinguish separate sphincters [4], and human autopsy studies have concluded that the common bile duct and pancreatic duct become fused in a common connective tissue sheath outside the duodenal wall and pass together through a slit in the duodenal muscle known as the "choledochal window." However, the lumina do not join at this level but are separated by a thick muscular septum. In most subjects, fusion of the two lumina occurs in the submucosal layer of the duodenum to form a common channel that varies in length between 2 and 17 mm. Before entering the duodenum, each duct becomes completely surrounded by circular muscle, some of which forms a figure-of-eight pattern around the two ducts. The point at which the smooth muscle starts on each duct is readily identified radiologically as a notch. Distal to the notch each lumen becomes narrow as it traverses the duodenal wall, this narrowing being associated with a thickening of the duct wall due to smooth muscle, connective tissue, and mucous glands. As the ducts pass through the duodenal wall longitudinal muscle, fibers interdigitate between the circular ductular muscle fibers and the duodenal muscle. The ducts emerge from the duodenal muscle layers and pass through the duodenal submucosa for a variable distance before opening onto the papilla of Vater; throughout this submucosal course, the ducts are ensheathed by circularly oriented smooth muscle. Manometric studies in humans support Hand's description of the sphincter of Oddi in that separate sphincteric zones have not been identified [5].

The mucosa of the human sphincter of Oddi segment is lined by columnar epithelium and contains numerous

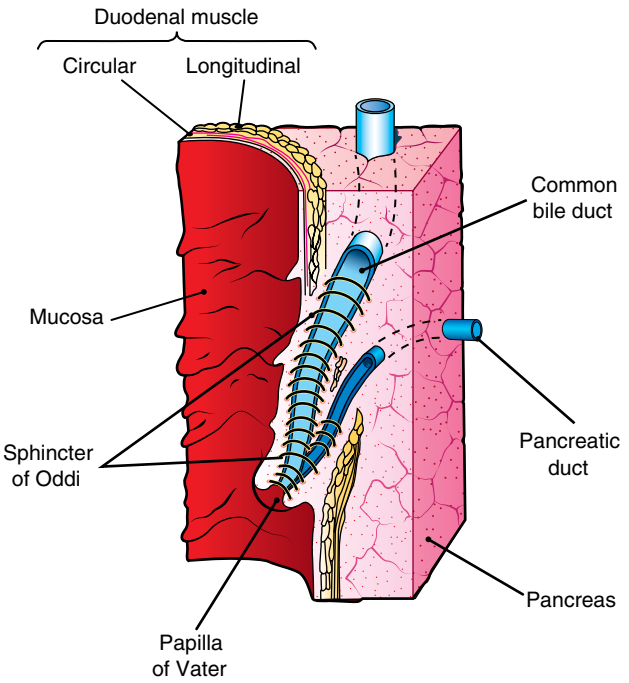

Figure 6.1 Anatomy of the human sphincter of Oddi at the junction of the bile and pancreatic ducts with the duodenum.

mucus-secreting glands. The mucosa is thrown into longitudinal folds likened to mucosal valvules [6]. These folds are least marked proximally and increase distally, becoming maximal in the common channel. The mucosal folds may occasionally be seen projecting through the orifice of the duodenal papilla.

Innervation

The extrahepatic biliary tract is innervated by dense networks of extrinsic and intrinsic nerves that regulate smooth muscle tone and epithelial cell function of the extrahepatic biliary tree. The celiac ganglia contribute both motor and sensory nerves made up of sympathetic fibers that originate in the T7–T10 spinal segments. The hepatic plexus is formed by nerve fibers from both vagi and supplies parasympathetic motor nerves to the extrahepatic biliary system [7].

The wall of the biliary tract is composed of three layers, namely serosal, muscularis, and mucosal. Ganglionated nerve plexuses are located in the subserosal and the subepithelial layers. The sphincter of Oddi has a rich ganglionic plexus. It has a predominance of cholinergic ganglia and a smaller number of adrenergic ganglia. Immunohistochemical studies from our laboratory have demonstrated the presence of a wide range of peptidergic neurons in the sphincter region, including galanin-, substance P-, and somatostatin-containing nerves. In addition, the inhibitory transmitter nitric oxide has been demonstrated in nerves to the sphincter and is thought to have an important function in modulating sphincter relaxation. It has been shown that the nerves in the sphincter region communicate with the proximal biliary tract, the gallbladder, and the duodenum [8,9].

Physiology

Bile reaches the sphincter of Oddi via the common hepatic and common bile ducts. The sphincter of Oddi not only regulates the flow of bile and pancreatic juice into the duodenum, it is also the regulatory structure that prevents reflux of duodenal contents into the pancreatobiliary passages. The role of the common bile duct in the control of bile flow has been confused due to anatomic differences in species studied. Histologic studies in humans have demonstrated only thin longitudinally oriented layers of smooth muscle within the walls of the common bile duct [10]. The major tissue component appears to be elastic fibers. However, in other species such as sheep, the common bile duct is invested with circularly oriented smooth muscle that exhibits peristaltic activity.

The weight of evidence suggests that the human common bile duct does not have a primary propulsile function. However, the elastic fibers and the longitudinally oriented smooth muscle provide a tonic pressure that may help overcome the tonic resistance of the sphincter of Oddi. The diameter of the human common bile duct before and after cholecystectomy has been the subject of controversy. Part of the disagreement is due to the methodology used in determining duct size. It has become evident that duct size as determined by ultrasonography and magnetic resonance cholangiography (MRC) cannot be equated to duct size determined by endoscopic retrograde cholangiopancreatography (ERCP) or intraoperative extraluminal measurements. Ultrasound and MRC record the nondistended lumen, whereas the contrast used during ERCP produces distension. Intraoperative measurements include wall thickness. In general, the normal diameter of the common bile duct as determined by ultrasound is less than 6 mm, by ERCP, less than 10 mm, and by intraoperative extraluminal measurements less than 12 mm. What has become clear is that the common bile duct does not increase in diameter significantly following cholecystectomy [11,12]. The major cause of dilated common bile duct is increased intraluminal pressure, which generally is produced by either primary or secondary obstruction at the sphincter of Oddi.

Motility of the Sphincter of Oddi

The primary function of the sphincter of Oddi is to control the delivery of bile and pancreatic juice into the duodenum. This is possible because of low pressure within the bile duct. Approximately 800–1500 mL of bile flows through the human sphincter of Oddi. Various studies in animals and humans have tried to evaluate the mechanism by which the sphincter of Oddi controls the flow of bile and pancreatic secretions. These studies have shown that there is anatomic variability between species and that sphincter of Oddi motility differs from one species to another. Thus, while many commonalities exist, one needs to be circumspect in comparing animal data directly with the motility and function of the human sphincter of Oddi.

Sphincter of Oddi Motility Studies in Animals

In vivo studies in dogs, cats, rabbits, and monkeys have demonstrated that the sphincter of Oddi exhibits muscle contractions that are independent of duodenal activity. The common bile duct and pancreatic duct proximal to the sphincter do not demonstrate spontaneous motor activity. Results from the dog studies have suggested that the sphincter of Oddi has a milking effect on bile, thus propelling small volumes of fluid from the common bile duct into the duodenum [13]. Manometric and electromyographic studies of the opossum sphincter of Oddi have demonstrated that the predominant mechanism of common bile duct emptying in the opossum is the antegrade sphincter of Oddi phasic contractions that propagate the entire length from the cephalic to the caudal end [14,15]. However, the frequency of the phasic contractions varies periodically during fasting. In cats, cholecystokinin (CCK) inhibits the sphincter phasic contractions and produces a fall in sphincter tone by stimulation of nonadrenergic noncholinergic inhibitory neurons—this effect overriding a lesser, direct smooth muscle stimulatory action of the hormone [16].

Recent studies have shown that the sphincter may act as a pump or a resistor and that bile duct pressure influences it [17]. This intrinsic activity is controlled by interstitial nerves of Cajal and is modulated by hormones [16], ATP and adenosine [18], and nitric oxide [19].

Neurohistochemical studies have demonstrated both adrenergic and cholinergic neurons within the sphincter of Oddi and experiments in animals have determined the pharmacologic effects of histaminergic, cholinergic, and adrenergic stimulation on the sphincter muscle [14]. However, the physiologic significance of these drug actions on the sphincter of Oddi requires further investigation.

The function of the vagus nerve in sphincter of Oddi physiology remains obscure. Sphincter of Oddi neurons likely receive vagal input and their activity is modulated by release of neuropeptides from sensory fibers, a significant source of excitatory synaptic input to these cells arising from the duodenum. This duodenum–sphincter of Oddi circuit is likely to play an important role in the coordination of sphincter of Oddi tone with gallbladder motility in the process of gallbladder emptying [20]. Studies in dogs have suggested that following vagal transection the resistance to flow across the sphincter of Oddi is decreased [21]. However, in the prairie dog increased resistance to flow through the sphincter of Oddi occurs after truncal vagotomy. Results from vagal stimulation studies have failed to define clearly the role of the vagus in biliary dynamics.

The Australian possum sphincter of Oddi demonstrates activity similar to that of the human sphincter. In this species, inhibition of sphincter phasic contractions promotes flow of bile. It has been shown that this inhibition is mediated by neural release of nitric oxide [16]. There is evidence that nitric oxide mediates the cerulein- and CCK octapeptide-mediated relaxation of the canine sphincter of Oddi [22]. The neuropeptide, galanin, selectively stimulates longitudinally oriented sphincter of Oddi smooth muscle via a direct mechanism, leading to a moderate reduction in trans-sphincteric flow [23]. Table 6.1 illustrates the effects of various bioactive agents on the sphincter of Oddi.

Table 6.1 Effects of various bioactive agents on the sphincter of Oddi.

Stimulators
Morphine met-enkephalin
Galanin
Substance P
Cholecystokinin
Neuropeptide Y
Nitric oxide
Inhibitors
Tramadol
Glucagon
Calcitonin gene-related peptide
Cholecystokinin
Peptide YY
Somatostatin

Sphincter of Oddi Motility in Humans

Cineradiographic studies of the human sphincter of Oddi exhibit rhythmic contractions that propel contrast into the duodenum [24]. Sphincter of Oddi pressure studies conducted at the time of biliary tract surgery have demonstrated variations in pressure thought to be the manometric equivalent of the cineradiographic contractions [25]. Resistance to outflow of fluid from the common bile duct into the duodenum has also been demonstrated by the intraoperative studies. This resistance was reduced after administration of CCK octapeptide or smooth muscle relaxants such as amyl nitrite [26].

Manometric recordings from within the sphincter of Oddi segment have been made via a pressure-sensitive catheter introduced into the sphincter of Oddi via a duodenoscope (Fig. 6.2) [27].

The manometric recordings have demonstrated that the human sphincter of Oddi is characterized by prominent phasic contractions superimposed on a basal sphincter of Oddi pressure 3 mmHg above the pressure in the common bile duct and pancreatic duct (Fig. 6.3). The amplitude of the phasic contractions is approximately 130 mmHg and the mean frequency is 4/min. Analysis of the direction of propagation of the phasic contractions during a continuous 3-min period demonstrated that the majority of contractions (60%) are oriented in an antegrade direction from the common bile duct toward the duodenum. A smaller number of contractions occurred either simultaneously (24%) or had a retrograde orientation (15%). Intravenous bolus injection of CCK octapeptide (20 ng/kg) normally produces inhibition of the phasic contractions and a fall in the basal sphincter of Oddi pressure.

Table 6.2 shows the pressures recorded from the sphincter of Oddi of normal subjects. Studies from patients with T-tubes inserted in the common bile duct following bile duct exploration [28] have shown that the frequency of sphincter of Oddi phasic contractions

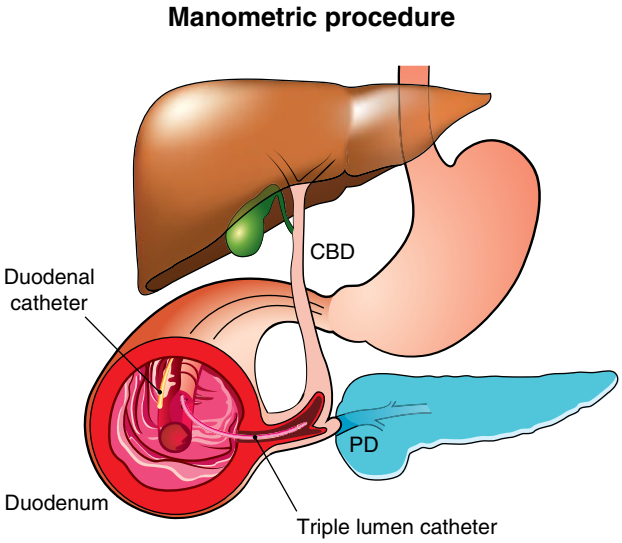

Figure 6.2 Manometric recording from the human sphincter of Oddi. A triple-lumen pressure-sensitive catheter is positioned in the sphincter via the biopsy channel of the duodenoscope. A separate catheter records duodenal pressure. CBD: common bile duct; PD: pancreatic duct.

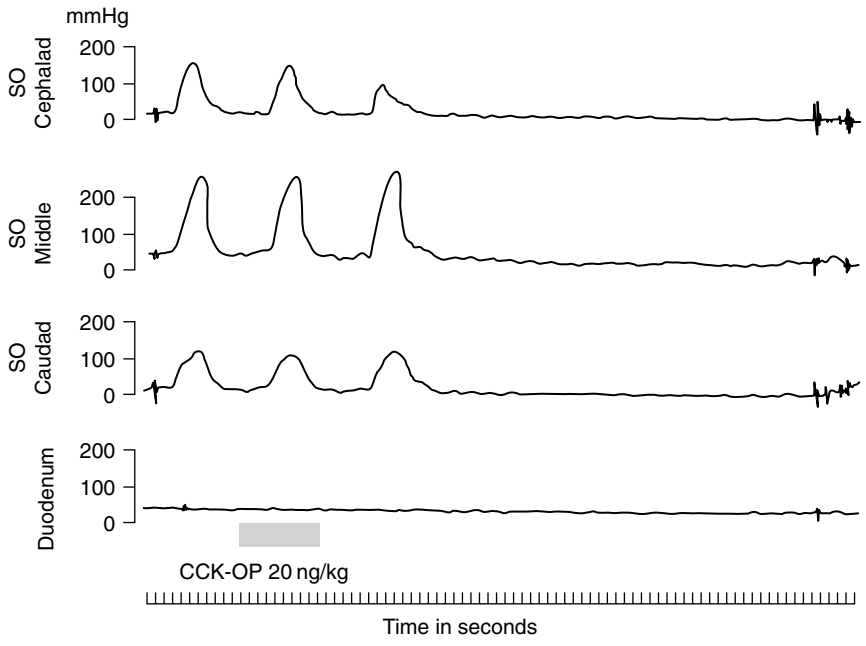

Figure 6.3 Manometric recording from the human sphincter of Oddi (SO) showing prominent phasic contractions, which are inhibited after injection of cholecystokinin octapeptide (CCK-OP).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. during fasting exhibits a periodicity in relation to duodenal migrating motor complexes, similar to that demonstrated in the opossum (Fig. 6.4).

Following the ingestion of a meal, bile flow across the sphincter of Oddi is promoted by inhibition or reduction in the amplitude of the phasic contractions and a fall in the sphincter of Oddi basal pressure. This effect on the human sphincter of Oddi is similar to that following intravenous injection of CCK octapeptide. In humans, bile flow occurs mainly between sphincter of Oddi phasic contractions during the period of diastole. The phasic contractions do propel small volumes of bile into the duodenum, but this is not the major means by which bile flow occurs. The phasic contractions in humans may function to prevent reflux of duodenal contents into either the bile or the pancreatic ducts, and to maintain the ducts free of small debris. In order to promote flow across the human sphincter of Oddi, inhibition or reduction of the phasic contractions and a fall in basal pressure is necessary.

Table 6.2 Pressures recorded from the sphincter of Oddi of normal subjects.

	Normal		
	Median	**Range**	**Abnormal**
Basal pressure (mmHg)	15	3–35	>40
Amplitude (mmHg)	135	95–195	>300
Frequency (/min)	4	2–6	>7
Sequences			
Antegrade (%)	80	12–100	
Simultaneous (%)	13	0–50	
Retrograde (%)	9	0–50	

Pathophysiology of the Sphincter of Oddi Dysfunction (SOD)

The terminology SOD implies motility abnormalities of the sphincter of Oddi associated with pain, elevations of liver or pancreatic enzymes, common bile duct dilatation, or episodes of pancreatitis. The most common presentations of this symptom complex include persistent or recurrent "biliary" symptoms postcholecystectomy (10–20%) [29] or features consistent with idiopathic recurrent acute pancreatitis (abnormal sphincter of Oddi manometry has been recorded in 30.5% [30]).

In 2016, the Rome IV expert consensus [31] updated the diagnostic criteria for sphincter of Oddi disorders [32]. For biliary pain, the Rome IV expert consensus [31] included the criteria listed in Table 6.3, as well as the presence of elevated liver enzymes or dilated bile duct (but not both), in the absence of bile duct stones or other structural abnormalities. The consensus statement also listed supportive criteria the presence of one or more of which, in association with the pain, may help in arriving at the diagnosis. These include abnormal amylase/lipase, abnormal sphincter of Oddi manometry, and abnormal hepatobiliary scintigraphy.

The clinical diagnostic system for SOD is the Modified Milwaukee Classification described for both biliary [33]

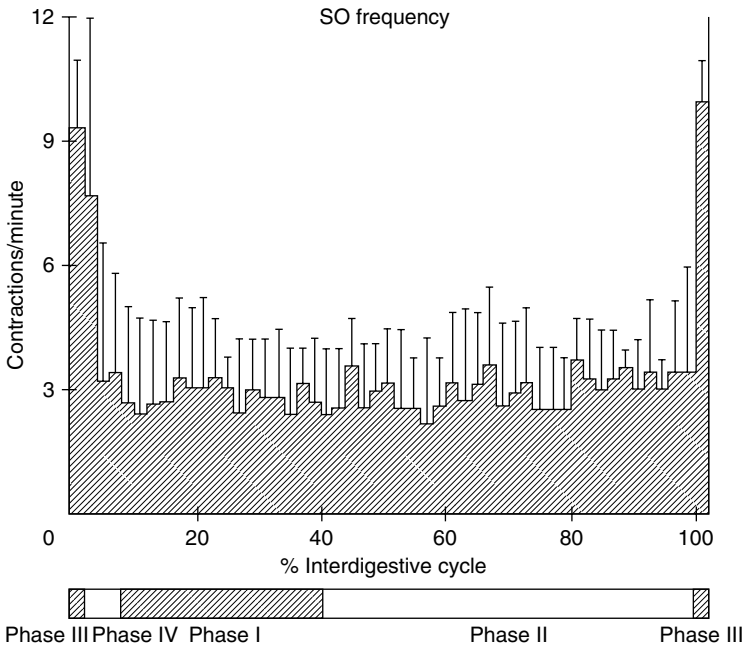

Figure 6.4 Manometric recordings of the human sphincter of Oddi showing changes in frequency of contraction in relation to the duodenal interdigestive motility pattern.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and pancreatic [34] disorders (Table 6.4). These have been modified from the original Milwaukee Classification proposed by Hogan and Geenen [35]. Pancreatic SOD may be considered in patients with documented acute recurrent pancreatitis, after exclusion of known etiologies for pancreatitis, and documenting elevated pancreatic sphincter of Oddi pressures on manometry [31].

An alternate classification of SOD may be based on manometric recordings. We have previously subdivided SOD into two groups [36], namely, those exhibiting a stenotic pattern (abnormally raised basal sphincter pressure >40 mmHg) and those displaying a dyskinetic pattern including paradoxical response to CCK injection, rapid contraction frequency, high percentage of retrograde contractions, or short periods of raised basal pressure [37]. These patients display an abnormal response to morphine or a fatty meal stimulus. In addition it has been postulated that SOD characterized by a manometric stenosis may contribute to the development of adult choledochal cysts [38,39].

The stenotic subtype of SOD is characterized by pathomorphological changes evident on histological examination of sphincter complexes resected at the time of transduodenal sphincteroplasty for patients with severe postcholecystectomy pain. The changes contributing to the high basal pressure include inflammation of the papilla and its transampullary septum or fibrosis with or without inflammation, papillary cholesterolosis [40], muscle hypertrophy, or mucosal edema [41]. These findings have been reported in 58% of patients undergoing transduodenal sphincteroplasty and transampullary septectomy for postcholecystectomy pain [40] and one possible cause has been postulated to be due to the chronic passage of small gallstones [40]. Another possible cause may be end-stage dyskinetic SOD. The stenotic subtype corresponds to the Modified Milwaukee type 1 and responds best to sphincterotomy (surgical or endoscopic). We have previously demonstrated that surgical sphincteroplasty and septectomy when performed for manometrically confirmed sphincter of Oddi stenosis in patients with recurrent pancreatitis resulted in a good clinical outcome in a majority of patients [42,43].

In a clinical setting, there is no need for manometry prior to ERCP and sphincterotomy for type 1 SOD of either biliary or pancreatic type presentation.

The dyskinetic subtype, conversely, is believed to be the result of a functional or neurohormonal disturbance in the absence of any pathological reproducible abnormalities [36]. Infections such as Cryptosporidium and HIV have also been shown to lead to features of SOD [44]. This subtype corresponds to the type 2 and 3 of the Milwaukee Classification. Sphincter of Oddi manometry is essential to arrive at the diagnosis. The paradoxical response to CCK injection noted by us [41] may be the result of a defect in the enteric nervous system akin to that described for achalasia of the esophagus [45]. While sphincterotomy relieves symptoms of type 1 SOD, it is less effective in alleviating symptoms of this subtype [46]

Table 6.3 Rome IV diagnostic criteria for biliary-type pain
Adapted from [31].

Pain located in the epigastrium and/or right upper quadrant and all of the following:

1) Builds up to a steady level and lasting 30 minutes, or longer
2) Occurring at different intervals (not daily)
3) Severe enough to interrupt daily activities or lead to an emergency department visit
4) Not significantly (<20%) related to bowel movements
5) Not significantly (<20%) relieved by postural change or acid suppression

Supportive criteria: Nausea and vomiting, radiation to the back and/or right subscapular region, and waking from sleep.

Table 6.4 Modified Milwaukee classification for biliary and pancreatic sphincter of Oddi dysfunction.

	Diagnostic criteria	
Classification	**Biliary**	**Pancreatic**
Type 1	A) Biliary-type pain B) Elevated ALT, AST, ALP >1.1 times the upper limit of normal on one occasion C) Bile duct diameter ≥9 mm	A) Pancreatic-type pain B) Serum amylase or lipase level of 1.1 times the upper limit of normal on one occasion C) Duct dilatation of >6 mm in the head and >5 mm in the body of the pancreas
Type 2	A) Biliary-type pain with either B or C in the criteria mentioned in Type 1	A) Pancreatic-type pain with either B or C in the criteria mentioned in Type 1
Type 3	A) Biliary-type pain only without other abnormalities	A) Pancreatic-type pain only without other abnormalities

ALT: alanine aminotransferase; AST: aspartate aminotransferase; ALP: alkaline phosphatase.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. and is associated with a risk of early recurrence of symptoms on follow-up [47]. Following clinical studies over the last decade there has been a change in our understanding of the SOD dyskinetic subtype.

The Rome IV consensus postulates that type 3 SOD is a disorder of "gut–brain interaction" [31]. This view was largely shaped by the findings of the clinical trial entitled "Evaluating Predictors and Interventions of SOD (EPISOD)" [48]. This multicentre randomized controlled trial conducted in seven centers involved the randomization of 214 patient with postcholecystectomy pain and without significant abnormalities on imaging or laboratory studies, with no prior sphincter of Oddi treatment or pancreatitis. Patients either had an endoscopic sphincterotomy or sham therapy irrespective of manometry findings. A significantly higher proportion of patients in the sham-treatment group experienced relief as compared to the sphincterotomy group (37% vs. 23%; $P = 0.01$). These findings persisted at 5-years' follow-up with patients who received a sphincterotomy faring worse-off based on the Patients' Global Impression of Change (PGIC) criteria [49]. The authors recommended that ERCP be undertaken only in patients with a dilated bile duct or significantly deranged liver function tests [50]. This recommendation has been supported by the results of the ERCP for Sphincter of Oddi Disorders (RESPOnD) study [51]. The latter was a prospective longitudinal cohort study that evaluated the benefit of ERCP with sphincterotomy when performed for SOD.

Type 2 SOD is considered a "functional biliary sphincter disorder" by the Rome IV consensus [31] statement and includes those patients who have biliary pain postcholecystectomy with either dilated ducts or elevated liver enzymes. Current data supports the performance of biliary manometry in these patients [46,52] and there remains a role for sphincterotomy in those patients who had demonstrable pre-procedure abnormalities in manometry [53]. The response to sphincterotomy in patients with type 2 SOD is not uniform but demonstrates benefit in a significant number of individuals.

Management of patients with type 3 SOD and those patients with type 2 SOD who do not benefit from a sphincterotomy or in whom manometry findings remain inconclusive is a challenge. Various pharmacologic agents have been used with varying success. These include hyoscine butyl bromide, nifedipine, nitric oxide, octreotide, gabexate mesylate, ulinastatin, trimebutine, amitriptyline, and duloxetine [54–57].

The treatment of pancreatic types 2 and 3 SOD remains speculative. We have elucidated various mechanisms by which galanin may be involved in the pathogenesis of acute pancreatitis [58]. Given the action of galanin on the sphincter of Oddi [23], its contribution to SOD-induced acute pancreatitis [59] is worthy of consideration. Use of galanin antagonists [60–63] may offer a potential therapy in this subgroup of patients.

The causes for pain in SOD remain conjectural. Mechanisms for production of pain may include relative obstruction of flow through the sphincter of Oddi resulting in bile duct or pancreatic duct distension, "ischemic" pain arising from spastic contractions, hypersensitivity of the papilla, and severance of nerves supplying the sphincter of Oddi during cholecystectomy. Other potential explanations may include duodenal-specific visceral hyperalgesia (in type 3 SOD) [64], continuous visceral pain (biliary pain) caused by local inflammatory/sensitizing processes or persistent hyperexcitability of the nociceptive neurons in the central nervous system [65], or other functional gastrointestinal disorders including intestinal dysmotility [66], irritable bowel syndrome (IBS), or non-ulcer dyspepsia.

Summary

The sphincter of Oddi is a small but important complex muscle that modulates flow of bile and pancreatic juice across one of the busiest anatomic junctions of the body. Its motor activity is controlled by an interaction of neuronal and hormonal modulators. In such a complex structure it is not surprising that at times disorders in motility arise and these disorders lead to significant clinical syndromes.

Neurohormonal and Hormonal Control of Pancreatic Secretion

Chung Owyang and Matthew J. DiMagno

Division of Gastroenterology, Department of Internal Medicine, University of Michigan, Ann Arbor, MI, USA

Introduction

The pancreas, one of the most important organs in the digestive tract, has both exocrine and endocrine functions. The exocrine pancreas secretes digestive enzymes and HCO_3^- to facilitate digestion and absorption of nutrients. The endocrine pancreas releases hormones that regulate metabolism and the disposition of the breakdown products of food.

The human pancreas secretes about 1 liter of juice daily, containing mostly water, electrolytes, and digestive enzymes. Mediation of postprandial pancreatic secretion has been ascribed mainly to the hormones secretin and cholecystokinin (CCK) and to vagovagal reflexes that activate cholinergic postganglionic neurons in the pancreas. In addition to these classical pathways, other regulatory peptide hormones and neurotransmitters may be involved.

Stimulation of Pancreatic Secretion

Hormonal Mechanisms

Secretin

Secretin is the most potent and efficacious stimulant of pancreatic fluid and HCO_3^- secretion in humans and all other species tested. It is synthesized by small intestine S-type enteroendocrine cells and is released postprandially. Duodenal pH is the major regulator of secretin release. A threshold pH of 4.5 triggers secretin release and stimulates pancreatic HCO_3^- secretion [1,2]. Below this pH, pancreatic HCO_3^- output is related to the total amount of titratable acid presented to the duodenum. Secretin levels in humans increase only a few picomolars postprandially because food buffers much of the gastric acid and pancreaticobiliary secretion neutralizes the remaining acid entering the duodenum by [3]. The mechanism by which acid stimulates secretin release is unclear. In rodents it was shown that H^+ may release a secretin-releasing factor into the proximal intestinal lumen to stimulate secretin release [4]. Secretin-producing cells appear to have acid-sensing ion channels belonging to the TRP (transient receptor potential) channel family. Hence, luminal acid likely stimulates secretin release by more than one mechanism.

Nonacid factors may influence postprandial secretin release. Nutrients such as oleic acid and other digestive products of fat can increase plasma secretin levels and pancreatic HCO_3^- secretion [3,5]. Bile in the upper gut can also stimulate secretin release [6]. However, the physiological importance of these nonacid factors in postprandial secretin release is questionable, as the postprandial plasma secretin level does not increase in achlorhydria or in health if meal-induced acid secretion is neutralized with $NaHCO_3^-$.

The pancreas appears highly sensitive to the small amounts of secretin released into the circulation postprandially [3,6]. *In vitro* animal models show that secretin stimulates HCO_3^- secretion by isolated ducts or duct fragments [7,8]. ^{125}I-labeled secretin and autoradiography revealed a secretin-binding site on pancreatic acini and duct cells [3], suggesting that secretin acts directly on the pancreas to stimulate pancreatic secretion. Conversely, *in vivo* studies have shown that the effect of secretin at physiological doses is highly sensitive to atropine [3]. Receptor autoradiography, immunocytochemistry, and electrophysiology demonstrate the presence of secretin receptors in vagal afferent fibers [3,9,10]. Vagal nodose ganglia also contain high-affinity CCK_1 receptors [3]. Injection of a subthreshold dose of CCK-8 (5 pM) significantly enhances the neural response to

5 pM secretin. This synergistic interaction helps to explain the robust postprandial pancreatic HCO_3^- and enzyme secretion despite a modest postprandial increase in plasma CCK and secretin.

Cholecystokinin

CCK is the other gut hormone that plays an important role in pancreatic secretion. It is synthesized in specific enteroendocrine I cells in the proximal intestine and released by hydrolytic products of digestion such as amino acids and fatty acids [11]. Undigested fat is ineffective, but products of lipolysis such as fatty acids are the most potent stimulants of CCK release [12]. The CCK response to fatty acids is influenced by chain length, saturation, concentration, and total load [13].

Fasting plasma CCK levels are low, averaging about 1 pM in humans [14–16]. Postprandially, plasma CCK concentration increases to 6–8 pM within 10–30 min, then gradually declines to basal levels during the ensuing 3 h [15,16]. Several molecular forms of CCK appear to be released into the circulation postprandially, including CCK-58, CCK-33, CCK-22, CCK-12, and CCK-8 [17]; CCK-58 being predominant in dogs and humans and the only form detected in rats [16–19].

Nutrients may stimulate CCK secretion by a number of mechanisms. In species such as the rat, in which feedback inhibition of pancreatic enzyme secretion occurs, CCK release is mediated by a trypsin-sensitive CCK-releasing peptide [20]. Duodenal peptone stimulates serotonin (5-HT) release from intestinal enterochromaffin cells, which in turn activates submucosal sensory substance P neurons. Signals are then transmitted to cholinergic interneurons and to epithelial CCK-releasing peptide-containing cells by way of cholinergic secretomotor neurons [20]. CCK release may be controlled by the level of active intraluminal proteases [16]. Protein, the major food stimulant of CCK secretion in rats, may bind or inhibit intraluminal endopeptidases, which would otherwise inactivate the CCK-releasing peptide [21] (Fig. 7.1). The mechanisms responsible for the actions of CCK-releasing peptide in humans are unclear, but may be similar to rats as feedback regulation of CCK release by proteases also occurs in humans. Study of CCK secretion from purified CCK-producing cells shows that amino acids stimulate CCK release by binding to the Ca^{2+}-sensing receptor [22], whereas fatty acids bind to specific G-protein–coupled fatty acid receptors [23]. Thus CCK secretion may be mediated by more than one mechanism.

CCK plays an important role in the stimulation of postprandial pancreatic enzyme secretion. The infusion of physiological doses of CCK produces the same level of pancreatic enzyme secretion as during the postprandial state [24]. Furthermore, administration of the potent CCK antagonist lorglumide or MK-329 produces a 50–60% inhibition of meal-stimulated pancreatic secretion in dogs [25] and humans [26]. CCK can also stimulate fluid and HCO_3^- secretion [27]. The effect on HCO_3^- secretion is weak but physiologically relevant because CCK potentiates the action of secretin on the pancreas [28]. In intact dogs and humans, CCK-stimulated pancreatic enzyme secretion is not potentiated by secretin [24,29,30]. The mechanisms by which CCK stimulates pancreatic enzyme secretion remain

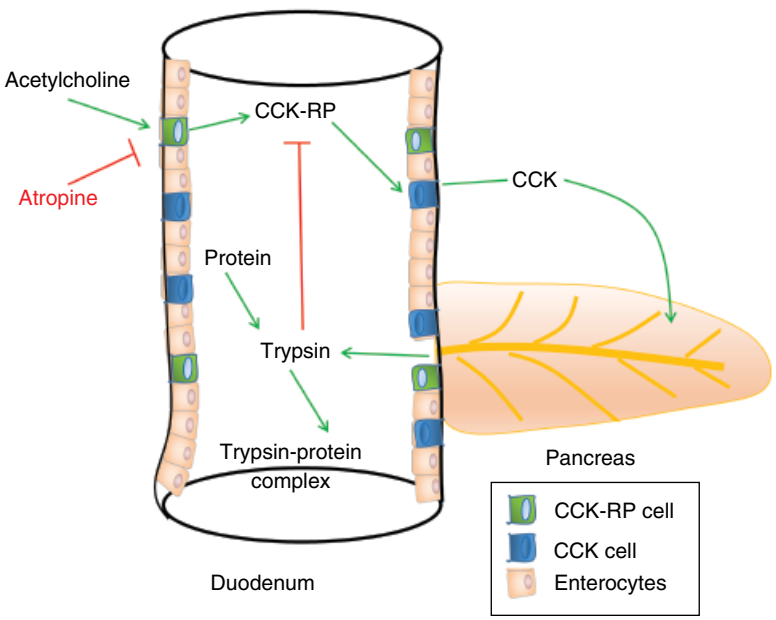

Figure 7.1 Cholecystokinin (CCK)-releasing peptide (CCK-RP) stimulation of postprandial secretion. CCK-RP is secreted into the proximal small intestine under the influence of cholinergic pathway and inactivated by trypsin. When food enters the duodenum postprandially, protein binds to trypsin and prevents the inactivation of CCK-RP. CCK-RP stimulates CCK cells in the duodenum to release CCK into the bloodstream. CCK, in turn, stimulates pancreatic enzyme secretion.

controversial. *In vitro* studies using dispersed rat pancreatic acini show that CCK-stimulated amylase release is insensitive to atropine or tetrodotoxin, indicating a direct action on pancreatic acini [31]. However, *in vivo* studies of humans and dogs have shown that atropine can block CCK-stimulated pancreatic secretion, implying involvement of cholinergic pathways [31]. Furthermore, enzyme output in response to low-dose CCK is reduced after vagotomy [31]. It appears that CCK can act through atropine-sensitive and atropine-insensitive pathways to stimulate pancreatic exocrine secretion. Human studies have shown that CCK-8 infusions at physiological doses can stimulate pancreatic enzyme output predominately in an atropine-sensitive fashion [31]. Furthermore, studies in rats indicate that physiological doses of CCK act through stimulation of vagal afferent pathways originating from the duodenal mucosa [31] (Fig. 7.2). CCK receptors have been detected in the rat vagus nerve using *in vitro* autoradiography [16]. Vagal CCK_1 receptors exist in high- and low-affinity states [16]. Under physiological conditions, CCK appears to act through high-affinity vagal CCK_1 receptors to mediate pancreatic enzyme secretion [16]. In contrast, the effect of CCK on satiety is mediated by low-affinity vagal CCK receptors [16]. These findings suggest that different affinity states of the vagal CCK receptors mediate different digestive functions. Under physiological conditions, CCK seems to stimulate postprandial pancreatic enzyme secretion through cholinergic pathways rather than through direct action on pancreatic acinar cells. M1 and M3 muscarinic receptors on pancreatic acini appear to mediate these responses [32,33] (Fig. 7.2). The molecular cloning of the CCK receptor gene and subsequent recognition that its expression is virtually absent in human pancreas [16,34] suggests that CCK acts at an extrapancreatic site. One study indicates that human acini do not respond to CCK agonists, although they respond to a muscarinic agonist [16]. In contrast, acini responded to CCK agonists after adenovirus-mediated CCK receptor gene transfer [16]. Quantitative reverse transcription–polymerase chain reaction showed that CCK_1 receptor mRNA expression was ~30-fold lower than that for CCK_2 receptors, and ~10-fold lower than for M_3 muscarinic receptors. In situ hybridization did not detect CCK_1 receptor mRNAs in adult human pancreas, supporting the concept that CCK acts at an extrapancreatic site to stimulate enzyme secretion. By contrast, a study of isolated human pancreatic acini showed that physiological levels of CCK induced Ca^{2+} signaling, activated mitochondrial function, and stimulated enzyme secretion [35]. The physiological relevance of these observations is unclear. CCK_1 receptors are expressed in human pancreatic stellate cells, which lie near acinar cells [36]. Low CCK concentrations (20 pM)

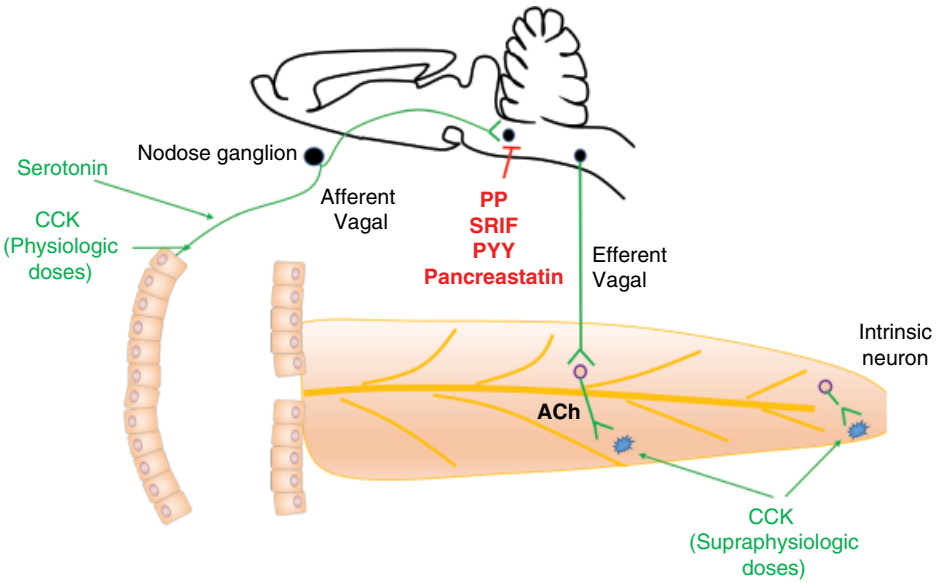

Figure 7.2 Sites and mechanisms of action of stimulatory and inhibitory hormones to modulate pancreatic enzyme secretion. Dosages of cholecystokinin-8 (CCK-8) that produce physiological plasma CCK levels act through stimulation of the vagal afferent pathway, which originates from the gastroduodenal mucosa. In contrast, dosages that produce supraphysiological plasma CCK levels act on intrapancreatic neurons and, to a lesser extent, on pancreatic acini. Serotonin (5HT) another stimulatory hormone also acts via vagal afferent pathway to evoke pancreatic enzyme secretion. In contrast, most of the inhibitory hormones such as PP, SRIF, PYY, and Pancreastatin act at a central vagal site to inhibit pancreatic secretion. ACh: acetylcholoine; PP: pancreatic polypeptide; SRIF: somatostatin; PYY: pancreatic polypeptide YY.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. stimulate acetylcholine release, which evokes enzyme secretion from pancreatic acini. Thus, it appears that CCK may regulate cholinergic stimulation of the pancreas through both neural and nonneural pathways.

Serotonin

Apart from CCK, intestinal serotonin (5-HT) appears to play an important role in mediating postprandial pancreatic enzyme secretion [16]. Although 5-HT is found in the myenteric plexus, the major source of 5-HT in the gastrointestinal tract appears to be mucosal enterochromaffin cells [37]. 5-HT is released in response to various stimuli [37], including duodenal acidification [37], instillation of hypertonic glucose, sucrose, or maltose solutions [16,38], vagal stimulation [39], and mechanical stimulation [40]. 5-HT may increase the discharge of vagal afferent fibers from the stomach and proximal intestine [41,42], which in turn can stimulate pancreatic secretion by way of a vagovagal reflex mediated by a cholinergic afferent pathway [16]. *In vivo* studies show that vagal responses to luminal osmolarity and the digestion products of carbohydrates depend on the release of endogenous 5-HT from mucosal enterochromaffin cells, which acts on 5-HT_3 receptors on vagal afferent fibers [16] (Fig. 7.2).

5-HT and CCK are the principal mediators of postprandial enzyme secretion. A CCK_1 receptor antagonist inhibited 54% of postprandial protein secretion in rats. CCK_1 receptor and 5-HT_3 antagonists combined almost completely abolished exocrine pancreatic secretion [16], suggesting that 5-HT–dependent pancreatic stimulants account for about 50% of postprandial pancreatic secretion. Vagal CCK and 5-HT receptors act synergistically to mediate pancreatic secretion [16], explaining how a small increase in the plasma CCK level is sufficient to produce a robust postprandial pancreatic secretion.

Other Hormones and Stimulatory Factors

Insulin plays a significant role in modulating exocrine pancreatic secretion [43]. Animal studies have demonstrated that insulin potentiates the secretory response of secretin plus CCK [44], and that ouabain, an inhibitor of Na^+,K^+-ATPase activity, abolishes the stimulatory action of insulin. Physiologically, the actions of insulin are important because immunoneutralization experiments in conscious rats showed that pancreatic secretion of water, HCO_3^-, and protein stimulated by a meal or by a combined intravenous infusion of physiological doses of secretin and CCK is markedly reduced when the circulating insulin is neutralized with a rabbit anti-insulin antibody [45]. It is well known that pancreatic enzyme secretion is often reduced in diabetes without overt pancreatic disease [46]. This may be mediated by enhanced activation of the TRESK K^+ channel in the nodose ganglia, observed in rats with diabetes [47] or fed a high-fat diet, reducing the excitability of the nodose ganglia and contributing to decreased pancreatic secretion mediated by the vagovagal reflex [47].

Bombesin (a gastrin-releasing peptide in mammals), a polypeptide isolated from the skin of frogs and also found in the human digestive tract, stimulates pancreatic secretions that contain small amounts of HCO_3^- and high concentrations of enzymes in humans [48,49]. Bombesin can act directly on the pancreas, or indirectly by promoting CCK release from the small intestinal mucosa [50]. In other systems, bombesin reportedly exerts its effect by way of a cholinergic pathway [51]. Hence, bombesin may act through different pathways to stimulate pancreatic secretion. However, the physiological importance of bombesin in pancreatic secretion is uncertain as bombesin receptor antagonists do not influence postprandial enzyme secretion in mammals [52].

Neurotensin appears to stimulate pancreatic enzyme secretion in humans and dogs. In rats, the stimulation appears to be neurally mediated, involving cholinergic vagal afferent pathways. Neurotensin is released by intestinal fatty acids, suggesting a role in mediating fat-stimulated pancreatic secretion. However, exogenous infusion of neurotensin in doses that stimulate pancreatic secretion results in a plasma level much higher than after a normal meal [53,54].

Ghrelin, found in gastric endocrine cells and in neurons of the hypothalamic arcuate nucleus, has been shown to stimulate pancreatic enzyme secretion. It acts as an endogenous ligand for the growth hormone secretagogue receptor, which is found throughout the body, including the hypothalamus and the pancreatic islet and acinar cells. Depending on the animal species, ghrelin acts directly on acinar cells or centrally through the vagal cholinergic pathways [60].

Nitric oxide (NO) is present in pancreatic neurons and vascular endothelium [61], and appears to play a significant role in regulating pancreatic secretion. In humans, L-NAME, an inhibitor of NO production, dose dependently reduces enzyme secretion stimulated by secretin and cerulein [62]. *In vitro*, NO synthase inhibition has no effect on amylase release or intracellular Ca^{2+} concentration in rat pancreatic acinar cells stimulated by carbachol and CCK-8 [63]. L-NAME also reduces CCK-stimulated pancreatic microvascular blood flow and at the same time decreases pancreatic fluid and protein output in rats [64]. This observation may have clinical importance because inadequate blood flow has been associated with clinical pancreatitis. Interestingly, treatment with NO donor L-arginine before and after cerulein injection increases pancreatic blood flow and reduces the severity of cerulein-induced hemorrhagic pancreatitis. These observations

suggest NO may protect the pancreas from injury, possibly because it increases pancreatic blood flow.

Other peptides with stimulatory effects on enzyme secretion include those with direct effects on acinar cells, including atrial natriuretic factor (ANF), fibroblast growth factor 21 (FGF21), and histamine. Other peptides stimulate pancreatic secretion through neural mechanisms, including C-natriuretic factor (CNP) and melatonin. The effect of amylin on enzyme secretion is unresolved.

Neural Mechanisms

Parasympathetic Nervous System

The pancreas is innervated by parasympathetic and sympathetic nerve fibers. The parasympathetic fibers pass through the pancreas directly through the vagus nerve and indirectly by the celiac ganglion, the splanchnic nerves, and perhaps through the intramural plexus of the duodenum. In humans, the vagus nerve appears to play an important role in mediating pancreatic secretion. Insulin-induced hypoglycemia, which is presumed to stimulate the vagus nerve centrally, augments secretin-stimulated pancreatic protein output [65]. Vagotomy reduces the HCO_3^- secretory response to exogenous hormones. Furthermore, vagotomy also reduces pancreatic enzyme responses to intestinal stimulants and food [31,66]. Exogenous cholinergic stimulation appears to primarily modulate the actions of gut peptides on pancreatic secretion but has no physiologically relevant effect on CCK or secretin release [67].

In humans, stimulation of duodenal volume receptors and osmoreceptors elicits a pancreatic enzyme response mediated by cholinergic neurons [31]. Increased firing in peripheral afferent vagal neurons and in central sites has been recorded after gastric distension and intestinal perfusion with amino acids and HCl [68,69].

Intrapancreatic postganglionic cholinergic neurons regulate enzyme and HCO_3^- secretion. These neurons are activated by central input during the cephalic phase and by vagovagal reflexes initiated by gastric- and intestinal-phase stimulation. Acetylcholine released by pancreatic neurons may act directly on acinar cells or potentiate the action of secretin on HCO_3^- secretion from duct cells *in vitro*. Acetylcholine and CCK interaction is additive. The enteropancreatic reflex may also play a role in mediating postprandial enzyme secretion [31]. This is especially important after chronic vagotomy [70].

Sympathetic Nervous System

Adrenergic innervation of the pancreas occurs mainly through the splanchnic nerves, which are distributed to blood vessels, with a few passing to acini and ducts [28].

Activation of splanchnic nerves usually inhibits exocrine and endocrine pancreatic secretion; splanchnic nerve stimulation decreases and splanchnicectomy increases pancreatic secretion in response to pancreatic stimulants [28,71]. These responses are likely mediated by vasoconstriction caused by stimulation of α-adrenergic receptors on blood vessels. Physiologically, the major role for adrenergic activation appears to be the inhibition of fluid and HCO_3^- secretion, which is mainly mediated by vasoconstriction.

Enteropancreatic Neural Reflex

Functional and anatomic enteropancreatic neural connections have been demonstrated by anterograde and retrograde tracing. Neurons in the ganglia of the myenteric plexus of the stomach and duodenum project directly to the pancreas [72]. Stimulation of duodenal myenteric neurons can influence endocrine and exocrine pancreatic functions in the rat. These enteropancreatic neural pathways have cholinergic and serotonergic components [72,73]. The cholinergic nerves from the duodenum stimulate intrapancreatic neurons through nicotinic synapses. In contrast, stimulation of enteropancreatic serotonergic axons inhibits pancreatic secretion through presynaptic 5-HT_{1P} receptors on cholinergic nerves [72]. The physiological role of the serotonergic enteropancreatic neural pathways is unclear.

Inhibition of Pancreatic Secretion

The regulation of pancreatic secretion depends on the balance between inhibitory and stimulatory influences exerted through hormones and the autonomic nervous system. The inhibitory phase of pancreatic secretion is mediated by many hormones.

Pancreatic polypeptide (PP) is localized in the islets of Langerhans and between the acinar cells of the exocrine pancreas [74]. PP secretion is regulated mainly by a cholinergic mechanism [75]. Postprandial PP release is mediated by a long vagovagal reflex and short local cholinergic pathways [75].

In humans and dogs, infusion of physiological concentrations of PP inhibits basal and stimulated pancreatic secretion [75,76]. *In vivo*, PP appears to act preferentially by inhibiting vagal stimulation [77]. *In vitro*, PP inhibits pancreatic enzyme secretion by way of presynaptic modulation of acetylcholine release [78]. Because its secretion is under cholinergic control and it acts by interfering with cholinergic transmission, PP is an ideal candidate to modulate pancreatic secretion stimulated by the cholinergic enteropancreatic reflex. PP may also act centrally, as suggested by the presence of PP receptors in discrete locations in the hypothalamus, limbic system, brain

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. stem, and other central locations [79]. Microinjection of PP into the dorsal motor nucleus (DMV) inhibits CCK-stimulated pancreatic secretion, suggesting that the DMV is an important site for neural feedback inhibition of pancreatic exocrine secretion [80]. Hence, PP acts at multiple brain stem sites to modulate vagal cholinergic efferent output to the pancreas [81].

Glucagon also inhibits pancreatic exocrine secretion stimulated by secretin and CCK or by ingestion of a test meal in dogs, cats, rats, and humans [82–84]. The inhibitory characteristics are reduced flow volume and decreased HCO_3^- and enzyme secretion. Currently, the sites of action are unclear.

Somatostatin, present in the pancreas as well as the upper gastrointestinal tract and central nervous system, may also play a role in the inhibition of pancreatic secretion. Research indicates that somatostatin does not act on peripheral vagal afferent or efferent pathways nor directly on pancreatic acinar; it exerts its inhibitory action at a central vagal site [85]. Somatostatin injected into the DMV significantly inhibits pancreatic exocrine secretion evoked by intravenous administration of CCK-8 or 2-deoxy-D-glucose, suggesting somatostatin acts through a central cholinergic mechanism [16].

Enteroglucagon is an intestinal hormone believed to mediate the inhibitory action of hypertonic glucose infusion into the jejunum. In animal studies, infusion of oxyntomodulin, a 37-amino acid glucagon-containing peptide isolated from porcine lower intestine, inhibits basal and cerulein-stimulated pancreatic secretion of HCO_3^- and enzymes [86]. The inhibitory action of enteroglucagon is 10-fold more potent than that of pancreatic glucagon.

Peptide YY (PYY) is a 36-amino acid peptide found in the distal intestine and colon of humans and experimental animals [87]. It is released by fat and, to a lesser degree, protein in the ileum or colon. PYY infusion in dogs significantly inhibits basal and meal-stimulated pancreatic HCO_3^- and enzyme secretion [88]. Physiological experiments demonstrate that intra-ileal, but not colonic, carbohydrate increases plasma PYY levels and decreases amylase secretion in dogs [89]. In humans, ileal carbohydrate perfusion inhibits exocrine pancreatic secretion. Therefore, PYY may represent a late postprandial event serving as a physiological signal to reduce exocrine pancreatic secretion after completion of digestion and nutrient absorption.

Glucagon-like peptide 1 (GLP-1) is another ileal hormone that is elevated in the circulation during ileal carbohydrate infusion. There is conflicting data on whether GLP-1 has inhibitory vs. stimulatory and direct vs. indirect effects on exocrine pancreatic secretion. Recent studies support a direct stimulatory effect on acinar cells through a cyclic AMP-dependent mechanism. Older studies suggest the opposite. In anesthetized pigs with cut splanchnic nerves, intravenous GLP-1 infusion inhibits hypoglycemia-induced pancreatic HCO_3^- and protein secretion, effects absent in vagally stimulated, isolated, and perfused porcine pancreas [90], suggesting that GLP-1 acts through a central mechanism. Studies in rats indicate GLP-1 inhibitory action depends on intact vagal nerves [91].

Other peptides. Although the list of peptides known to inhibit exocrine pancreatic secretion continues to expand, little is known about the mechanisms through which these and other hormones or neurotransmitters inhibit pancreatic enzyme secretion. Most of these peptides lack direct inhibition of pancreatic acinar cells and most suppress pancreatic enzyme secretion *in vivo* but do not act directly on acinar cells to reduce pancreatic enzyme release. Animal studies suggest that peptides such as PP, somatostatin, calcitonin gene-related peptide (CGRP), enkephalin, and pancreastatin inhibit pancreatic enzyme secretion by modulating cholinergic transmission, and most, if not all, act through a central vagal site [92–98]. Leptin also inhibits pancreatic enzyme secretion through a similar neuro mechanism, but paradoxically increases pancreatic protein output in rats when administered by duodenal perfusion through CCK activation of duodeno-pancreatic reflexes. Less clear are mechanisms of inhibiting pancreatic secretion by adrenomedullin and galanin.

Feedback Regulation of Pancreatic Secretion

A series of observations in rats suggest that intraluminal actions of pancreatic proteases play an important role in regulating pancreatic enzyme secretion [16,99]. It was demonstrated that diversion of pancreatic juice in the duodenum stimulates CCK release and pancreatic enzyme secretion [16]. Conversely, intraduodenal administration of trypsin or chymotrypsin inhibits CCK release and pancreatic enzyme secretion [16]. This phenomenon is specific for activated proteases, not with inactivated trypsin, amylase, lipase, or HCO_3^-.

Feedback regulation of pancreatic secretion by proteases appears to be mediated by a trypsin-sensitive substance secreted by the proximal small intestine, originally designated CCK–releasing factor (CCK-RF) [16,21]. When trypsin is present, this peptide is cleaved and inactivated. CCK-RF may mediate pancreatic enzyme secretion in response to dietary protein intake in rats. Dietary protein in the intestine competes for the trypsin that would otherwise inactivate CCK-RF [16]. The resulting increase of CCK-RF in the intestinal lumen stimulates CCK release and pancreatic enzyme secretion (Fig. 7.1).

Efforts to demonstrate a protease-sensitive feedback mechanism in humans remain controversial because of technical limitations in removing or blocking intraluminal protease activity. Using a different approach, investigators reported that intraluminal administration of trypsin or chymotrypsin in humans suppresses CCK release and partially reduces the CCK response to intestinal administration of amino acids or oral ingestion of a test meal [16,100]. These observations support the existence of feedback regulation of pancreatic enzyme secretion in humans. Liener and colleagues demonstrated that Bowman–Birk soybean trypsin inhibitor, an inhibitor of chymotrypsin and elastase, strongly stimulates pancreatic enzyme secretion in humans [101].

The existence of feedback regulation of pancreatic enzyme secretion in humans may have important clinical implications. In patients with chronic pancreatitis, decreased pancreatic enzyme secretion may result in elevated plasma CCK levels, reflecting a failure in the feedback modulation of CCK release. This may cause hyperstimulation of the pancreas and produce pain. Effective enzyme replacement therapy may reduce pancreatic stimulation, decrease intraductal pressure, and diminish pain. Large doses of pancreatic extract have reduced pain in some patients with chronic pancreatitis [102,103].

Conclusion

Under physiological conditions, in rodents and humans, cholinergic vagal afferent pathways rather than pancreatic acinar cells represent the primary targets on which CCK may act as a major mediator of postprandial pancreatic secretion. The vagal afferent pathways also transmit sensory information about the mechanical and physiological state of the digestive tract, mediated in part by 5-HT, which in turn influences pancreatic secretion. A synergistic interaction between CCK and 5-HT at the level of the nodose ganglia may explain the robust postprandial pancreatic enzyme secretion despite a modest increase in plasma CCK after a meal. Interestingly, most hormones such as PP, somatostatin, CGRP, and pancreastatin act through a central vagal site. This supports the Pavlovian concept that the neural system is the major regulator of pancreatic secretion.

Regulation of Pancreatic Protein Synthesis and Growth

Maria Dolors Sans and John A. Williams

Department of Molecular and Integrative Physiology, University of Michigan Medical School, Ann Arbor, MI, USA

Introduction

Regulation of pancreatic protein synthesis and growth allows the exocrine pancreas to provide an adequate supply of digestive enzymes for nutrient assimilation. In young animals, the pancreas grows along with general body growth and thereby provides an increasing amount of digestive enzymes. In the adult, digestive enzyme synthesis is regulated at both transcriptional and translational levels to match the need for both total and specific digestive enzymes. If the need for digestive enzymes is greater than can be met through these mechanisms, the pancreas can grow or regenerate [1]. This can occur either as a result of increased food intake, or because of decreased pancreatic mass due to disease. Some of the same systemic regulatory signals that regulate enzyme secretion, that is, the vagal nerve and gastrointestinal (GI) hormones, also participate in the regulation of pancreatic protein synthesis and growth, although the intracellular regulatory pathways involved are significantly different. An additional regulatory influence is provided by nutrients, especially amino acids, and islet hormones, particularly insulin, which do not directly affect secretion. The purpose of this chapter is to provide a brief overview of the regulation of pancreatic protein synthesis and growth. Not all areas can be covered in depth owing to page limitations. Areas of recent progress are featured with review articles being cited to cover the older literature.

Regulation of Protein Synthesis

Protein synthesis plays a central role in the maintenance of the pancreas and provision of digestive enzymes. Both the mRNA profile and autoradiographs of newly synthesized proteins are dominated by digestive enzymes. Whether the acinar cell can regulate digestive enzyme synthesis independent of the synthesis of cellular structural proteins is unclear. In general, the GI tract, including the exocrine pancreas, atrophies in the absence of food and protein synthesis that occurs in response to food intake helps to maintain normal function. Individual dietary components also regulate protein synthesis. In most cases, as reviewed in the following, this involves transcriptional regulation of digestive enzyme mRNA. By contrast, shorter term meal-stimulated protein synthesis is regulated primarily at the translational level. Finally, increased protein synthesis is necessary for pancreatic growth.

Long-Term Regulation by Diet

Since the original work by Pavlov, the adaptation of the exocrine pancreas to dietary changes has been observed in a variety of species [2,3]. The content and secretion of the major digestive enzymes, proteases, amylase, and lipases change in proportion to the dietary content of their respective substrates, protein, carbohydrate and fat, by stimulation of both, transcriptional and translational mechanisms [4–6]. Various hormones mediate many of these effects and in most cases their release is increased by the nutrients whose digestion they regulate. In some cases the genetic elements regulated in the promoter region have been identified although the full intracellular pathway leading to their regulation is not yet known [2].

Protein

Feeding a high-protein diet to rodents (typically 60–80% casein or other high-quality protein) increases the content of multiple proteases and the mRNA levels of

trypsinogen, chymotrypsinogen, and proelastase [2,7], with activation of the mTORC1 pathway and can occur independently of cholecystokinin (CCK) [8]. There are, however, differential effects on different isoforms of enzymes such as trypsinogen and this increase is not mimicked by feeding a mixture of amino acids [9–11]. Clinical studies have shown that a severe reduction of protein in the diet causes pancreatic injury, leading to nutrient malabsorption and a state of malnutrition [12,13], which can be especially critical in children and young adults [14]. The pancreas is extremely vulnerable to protein deficiency states, as seen in patients with the *kwashiorkor* syndrome, where the pancreas is one of the most severely affected organs, with reductions in size and secretory capacity [12,15,16]. In an experimental study, feeding mice a protein-free diet for 4 days resulted in a decrease in the relative pancreatic digestive enzyme content and secretion [17]. Other data showed that the stimulation of protease synthesis, by isolated pancreatic lobules following infusion of the CCK analogue caerulein, *in vivo*, was greatly increased compared with a small increase in translatable mRNA, suggesting a post-transcriptional locus for this regulation.

It has also been shown that a high protein (40%) diet can stimulate pancreas growth in mice, independent of CCK [8]. Individual amino acids can increase pancreatic trypsin levels and stimulate pancreas growth [9,18]. The amino acid leucine, specifically, modulates growth responses of pancreatic progenitors, involving mTORC1 [19], and changing the synthetic rates and messenger RNA (mRNA) levels during several days or weeks.

Carbohydrates

The level of carbohydrate in the diet has long been known to have significant effects on pancreatic amylase content and amylase mRNA [2,3]. This is seen when dietary carbohydrate replaces either dietary fat or protein, provided that dietary protein is adequate. Starch and sugars all similarly affect amylase, as does intravenous glucose. The effects of carbohydrate are believed to be primarily mediated by insulin. When animals are rendered diabetic, the amylase content and synthesis and mRNA levels fall dramatically, whereas lipase increases moderately [3,20]. Insulin restores the amylase synthesis and content and mRNA levels in diabetic rats. Similar decreases in amylase have been seen in obese rat and mouse models with insulin resistance. However, insulin administration to normal rats either decreases or does not change amylase, and other evidence suggests a more direct role for glucose in addition to effects on insulin. Amylase is also regulated by glucocorticoids [21], although this may not mediate dietary effects of carbohydrate. A dietary response sequence in the promoter of the amylase *Amy2.2* gene has been identified that mediates dietary adaptation and the effect of insulin [22].

Fat

In response to a high-fat diet (40–70% of calories as triglycerides), the content and synthesis of pancreatic triglyceride lipase increase [2]. This is accompanied by an increase in its mRNA [23,24]. Adaptation of other pancreatic lipases and colipase have been much less well studied. In neonate mice and rats, bile salt-stimulated lipase and pancreatic lipase-related protein 2 are the two predominant lipases [25]. Secretin has been proposed as a mediator of the effect of dietary lipid [26]. Fatty acids can stimulate secretin release and infusion of secretin in conscious rats led to an increase in the relative synthesis of lipase [2]. Gastric inhibitory peptide (GIP) has also been shown to increase pancreatic lipase and colipase content and mRNA levels [27]. Finally, ketones, metabolites of ingested fat, have also been proposed as a mediator of the increase in pancreatic lipase [2].

Meal-to-Meal Regulation of Translation by Hormones and Nutrients

Whereas long-term dietary changes in digestive enzymes may be mediated by changes in mRNA expression, short-term meal-to-meal control needs to be immediate, reversible, and flexible. Such control of protein synthesis is mainly at the translational level [28]. This section reviews the effects of food intake and hormones, especially CCK and insulin, on the exocrine pancreas translational machinery. Translation of mRNA into protein can be divided into three phases: initiation, elongation, and termination. For details on these three mechanisms, the reader is referred to reviews on translation [28–32]. Only a few studies have evaluated the immediate regulation of the pancreatic translational synthetic machinery after food intake. Early studies showed that fasting reduces total protein synthesis in the pancreas and refeeding stimulates it [33,34]. More recent studies showed that feeding a regular meal activates protein synthesis in the mouse pancreas at the translational level without an increase in the mRNA of the digestive enzymes [35]. In humans, feeding increases both the rate of secretion and synthesis of digestive enzymes, although the rate of turnover of zymogens remains fairly constant during feeding and fasting [36]. In rats and mice, feeding stimulates the protein kinase B (PKB/Akt)/mammalian target of rapamycin complex 1 (mTORC1) pathway and the phosphorylation of 4E-BP1 and ribosomal protein S6, downstream of mTORC1, in addition to the formation of the eIF4F complex [35,37] as illustrated in Fig. 8.1.

Dietary protein and amino acids have also been shown to be necessary to stimulate pancreatic protein synthesis

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

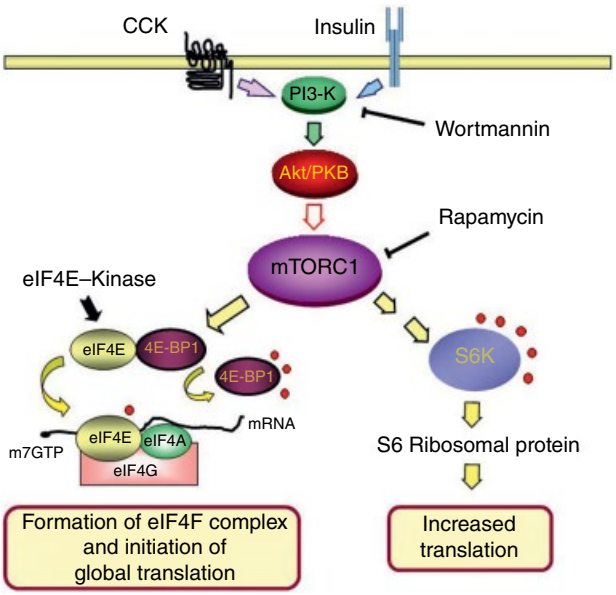

Figure 8.1 CCK and insulin stimulate translational initiation through the P13K-PKB-mTORC1 pathway. mTORC1, which can be inhibited by rapamycin, phosphorylates the eIF4E-binding protein (4E-BP1) that allows the release of eIF4E and the formation of the eIF4F complex necessary for a global increase in translation. mTORC1 also phosphorylates S6K1, which is responsible for phosphorylating S6, thereby increasing the translation of a specific subset of mRNAs. CCK also increases the activity of an eIF4EK, leading to phosphorylation of eIF4E. Together, these effects lead to an increase in protein synthesis Adapted from [28].

at the translation initiation level in mice after 2 h of feeding [38]. When protein or the amino acid leucine are removed from the diet, postprandial pancreatic digestive enzyme synthesis is strongly inhibited, and their deficiency could induce pancreatic insufficiency and malnutrition. The inhibition of protein synthesis and decreased polysomal fraction, caused by the reduction of protein, or only leucine in the diet, has a similar general effect, but it is induced by different mechanisms: protein deficiency causes a partial reduction of the activation of mTORC1 and the guanine nucleotide exchange factor eIF2B; whereas leucine deficiency causes an amino acid imbalance that activates the general controlled nonrepressed (GCN2) kinase, that, in turn, increases eIF2α phosphorylation that blocks protein synthesis [38].

Other studies have shown how dietary protein and amino acids stimulate pancreatic protein synthesis and pancreatic growth in rats [39] and mice [8] fed for several days. Branched-chain amino acids (BCAA), particularly leucine, also stimulate the phosphorylation of 4EBP1 and S6K and the formation of the eIF4F complex in mice and rats, without the need for an increase in the hormones CCK and insulin [40]. A mechanism has been described for a direct stimulation of protein synthesis by amino acids through mTORC1 [35,40–42], and it seems that amino acids are necessary both as a signal and as a substrate for pancreatic digestive enzyme synthesis after a meal [38].

The effects of food can also be mediated by GI and systemic hormones and neurotransmitters. Their stimulatory mechanisms have been mainly studied in isolated pancreatic acini [43]. CCK, carbachol, insulin, and bombesin all stimulate the synthesis of total protein, trypsinogen, chymotrypsinogen, lipase, and amylase in isolated rat acini [44–46]. These *in vitro* studies demonstrate that CCK and insulin, at their stimulatory doses, have an additive effect on protein synthesis after 30 min, and that this effect is mainly at the translational level because it occurs without a change in mRNA levels and in the presence of actinomycin D [46,47]. Increased synthesis of both digestive enzymes and structural proteins was observed, although differences between individual proteins suggested nonparallel translational effects [47].

CCK stimulates protein synthesis in isolated rat acini and in the whole animal [48–50], by increasing the rate of translation initiation [48–51] and elongation [52], at concentrations that stimulate digestive enzyme secretion. Additionally, CCK or its analogue caerulein, activates the S6 kinase (S6K) [53,54] and the phosphorylation of eIF4E [50,51] and activates the formation of the eIF4F complex by stimulating the release of eIF4E from its binding protein 4E-BP1 and increasing the association of eIF4E with eIF4G [35,51]. These actions are summarized in Fig. 8.1. The activation of S6K, the formation of the eIF4F complex, and the activation of the elongation processes and eEF2 appear to be regulated through a rapamycin-sensitive pathway and to be downstream of phosphatidylinositol 3-kinase (PI3K) [49,52,53]. The calcium–calmodulin-activated phosphatase calcineurin is also involved in the activation of CCK-stimulated pancreatic protein synthesis and the regulation of the translational machinery [50]. As mentioned earlier, insulin also stimulates protein synthesis in pancreatic acini *in vitro* [45] by activating the eIF4F complex formation, in a similar manner to CCK [49]. Insulin stimulates pancreatic digestive enzyme synthesis *in vivo*, after a meal. This has been demonstrated with the use of pancreatic acinar cell conditional insulin receptor (IR) knockout mice [54]. The activation of the Akt/mTORC1 pathway is reduced in the pancreas of these mice after 2 h of a meal feeding, and also the translational machinery and polysomal fraction. Additionally, the protein content of the stimulated pancreatic juice is reduced, but not the total pancreatic juice volume, compared with their littermate controls. This demonstrates that insulin is an important physiologic regulator of the pancreatic digestive enzyme synthesis and acinar cell homeostasis that could lead to pancreatic insufficiency during diabetes [28].

At concentrations of CCK and cholinergic analogues that inhibit secretion [43], protein synthesis is also inhibited [44,48,55]. In minced rabbit pancreas, however, only a decrease in protein synthesis was observed in response to CCK, and this was accompanied by a decrease in the number of polysomes [55].

Inhibition of Pancreatic Protein Synthesis. Endoplasmic Reticulum (ER) Stress and Unfolded Protein Response (UPR)

In vivo, inhibition of pancreatic protein synthesis occurs during the development of acute pancreatitis [56]. This inhibition is accompanied by a reduction in the activity of the guanine nucleotide exchange factor eIF2B, an increase in eIF2α phosphorylation, and a decrease in the formation of the eIF4F complex [48,50,56] (Fig. 8.2). Additionally, this inhibitory effect appears to be calcium related, because the incubation of isolated acini in calcium-free media or with A23187 and thapsigargin to release intracellular Ca^{2+} increases eIF2α phosphorylation and inhibits eIF2B activity. This suggests that pancreatic acinar cells adapt to short-term stress induced by reduction in calcium stores by inhibiting protein synthesis of pancreatic enzymes [48,55]. The ER-resident kinase (PERK) [57] mediates eIF2α phosphorylation in the exocrine pancreas [58,59] and activates the ER stress mechanisms. The inhibition of protein synthesis associated with high concentrations of CCK could therefore be an adaptive or protective mechanism in response to stress localized in the ER [48,56].

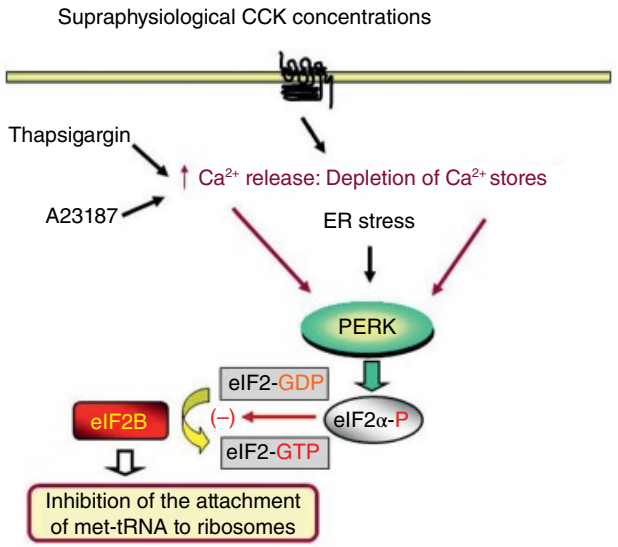

Figure 8.2 Mechanism by which high concentrations of CCK and induction of ER stress inhibit initiation of translation. Depletion of intracellular Ca^{2+} stores or other forms of ER stress activates a kinase (such as PERK), which phosphorylates eIF2α and thereby inhibits eIF2B. This inhibition results in a decrease in protein synthesis Adapted from [28].

ER stress mechanisms are protective cellular responses to stress in the ER, due to an accumulation of unfolded or misfolded proteins in this cellular compartment that trigger the UPR [59]. ER stress and UPR mechanisms have been described in some experimental models of acute pancreatitis [56,60], in pancreatic acinar cell damage *in vitro* [61], and in induced pancreatic acinar cell damage due to alcohol abuse *in vivo* [62].

Regulation of Pancreatic Growth

The pancreas arises embryologically as an outgrowth of the foregut that develops through a relatively undifferentiated duct-like state into acini, islets, and mature ducts under the influence of mesenchyme and a number of transcriptional regulators [63]. By birth, the pancreas has assumed its fully differentiated form and histology but continues thereafter to grow in parallel with body growth. Depending on the species, this can occur by hypertrophy or hyperplasia. A recent study showed that rodent pancreas grows predominantly by hypertrophy, and human pancreas by hyperplasia [64]. During this period, growth of the acinar cell mass is by self-duplication of acinar cells [65]. While all acinar cells can divide, some studies have shown a subset that divides faster in normal growth and regeneration [66]. In the adult animal, acinar and islet cells were originally assumed to be no longer dividing but in fact they both show a small but finite turnover that can be accelerated by hormones and diet. Hence the acinar and beta islet cells are considered to exist in the G_o phase of the cell cycle rather than being terminally differentiated. Whether undifferentiated stem cells remain in the adult pancreas or if small duct cells can function as stem cells remains controversial.

In the exocrine pancreas, enhanced growth in response to hormones or diet can take the form of cellular hypertrophy in which protein increases in excess of DNA resulting in larger cells, or cellular hyperplasia marked by an increase in DNA resulting in more cells. Normally in hyperplasia, protein increases in parallel with DNA, so the endpoint is normal-sized cells. In hypertrophy and hyperplasia, there is usually an increased total digestive enzyme content in the pancreas, although the concentration relative to DNA or total protein may or may not change. Although not as well studied, glandular atrophy can result from loss of cellular protein, as seen with protein-deficient diets [17], or from loss of cells, as seen with some forms of pancreatitis following apoptosis or necrosis. Two distinct types of *in vivo* growth to be discussed are adaptive growth in response to diet and

hormones and regeneration following the loss of functional cells. The use of cell culture as a model for pancreatic growth will also be reviewed.

Adaptive Growth in Response to Nutrients and Hormones

To ensure adequate nutrient absorption, the amount and composition of digestive enzymes secreted by the pancreas must complement the size and macronutrient composition of a meal. Although the synthesis and secretion of digestive enzymes can increase with consumption of larger and/or more frequent meals, this capacity is finite. Another mechanism whereby the pancreas can adapt to increased feeding is through growth of the acinar cells. Both a high-protein diet and hyperphagia that occurs with cold exposure, pregnancy, and lactation are associated with pancreatic growth [1].

GI hormones released after a meal may contribute to the growth-promoting effects of feeding on the exocrine pancreas as CCK, secretin, and gastrin have all been shown to induce pancreatic growth [67]. The effects of CCK have been studied extensively in rodents and have been reviewed previously [43,68]. Direct administration of CCK or caerulein induces acinar cell growth *in vivo* [1,67,69], and *in vitro* [70]. Feeding a high-protein diet and especially synthetic or naturally occurring trypsin inhibitors, such as those found in raw soy flour, prevents feedback regulation of CCK secretion and culminates in maintained high concentrations of circulating CCK [71], which also stimulates pancreatic growth [72]. Oral trypsin inhibitor-induced pancreatic growth is blocked by coadministration of CCK antagonists [73] and is absent in CCK [74] and CCK-A receptor-deficient mice [75]. In the rat, CCK-stimulated growth is primarily through cellular hypertrophy, but with some hyperplasia, whereas in mice it is primarily through hyperplasia. In both cases, the hyperplasia involves DNA synthesis and replication of mature acinar cells [76]. Although CCK can mediate adaptive growth, it does not appear to be essential for growth during development and CCK or its receptors are not necessary in most studies for maintenance of normal pancreatic size. In contrast to CCK, the hormone secretin had little effect by itself but can potentiate the action of CCK [67].

More recently, information has emerged on intracellular pathways mediating pancreatic growth (Fig. 8.3). CCK is known to activate a number of intracellular pathways potentially related to growth, including an increase in intracellular Ca^{2+}, three MAPK pathways, and the PI3K-mTOR pathway [43]. Most of these pathways are activated in the pancreas in response to endogenous CCK release following feeding of camostat [77]. Pharmacologic and genetic evidence exists for three major intracellular pathways, calcineurin–NFAT, mTORC1, and ERK1/2, playing nonredundant roles in adaptive pancreatic growth. The calcineurin–NFAT pathway can be blocked pharmacologically with the calcineurin inhibitors FK506 and cyclosporin A and genetically by overexpression of *Rcan1* [74,78,79]. The mTORC1 pathway can be blocked with rapamycin [80] or by acinar cell-specific deletion of Raptor, an essential component of mTORC1 (SJ Crozier, MD Sans, and JA Williams, unpublished data). The ERK pathway can be blocked with specific MEK inhibitors active *in vivo* such as PD-0325901 [81]. Blockage of each of these pathways blocks pancreatic adaptive growth induced by feeding camostat. These pathways are important regulators of mRNA transcription and translation, and it is likely through modulation of these processes that CCK affects pancreatic growth by activating the cell cycle.

Polyamines have also been studied as mediators of pancreatic growth induced by CCK and other hormones [82]. The naturally occurring polyamines putrescine, spermidine, and spermine are normal cell components involved in protein and DNA synthesis. Biosynthesis of polyamines is initiated by ornithine decarboxylase and its inhibitor difluoromethylornithine inhibits pancreatic growth in response to CCK. However, there is no clear role for polyamines in pancreatic growth and it may be that they are simply a cellular component necessary for pancreatic growth similar to their role in intestinal adaptation and liver regeneration.

Growth of the pancreas in response to CCK administration is greatly diminished in rats fed a low-protein diet [83]. Conversely, consumption of large amounts of protein induces pancreatic hypertrophy in rodents [84], even in the presence of a CCK receptor antagonist [18] and in CCK-deficient mice [85]. Therefore, it appears that dietary protein both potentiates the effects of CCK on pancreatic growth and also stimulates pancreatic growth via CCK-independent mechanisms. These CCK-independent mechanisms are undoubtedly mediated, at least in part, by amino acids. Purified amino acids do not stimulate CCK secretion, yet ingestion of large quantities of amino acids stimulates pancreatic growth [18]. This action is mediated in large part by the mTORC1 pathway, which is activated by amino acids [8]. Interestingly, growth of the pancreas in mice fed a high-protein diet occurs predominately via cellular hypertrophy [85] whereas that associated with supraphysiologic levels of CCK, such as direct CCK administration and trypsin inhibitor feeding, in mice is primarily hyperplastic [74]. It may be that a threshold level of CCK exists, above which signal transduction pathways are activated that permit cell division following cellular hypertrophy.

Other systemic hormones, including insulin [20], thyroid hormones, and glucocorticoids, can stimulate and regulate pancreatic growth in response to meal feeding [1,86].

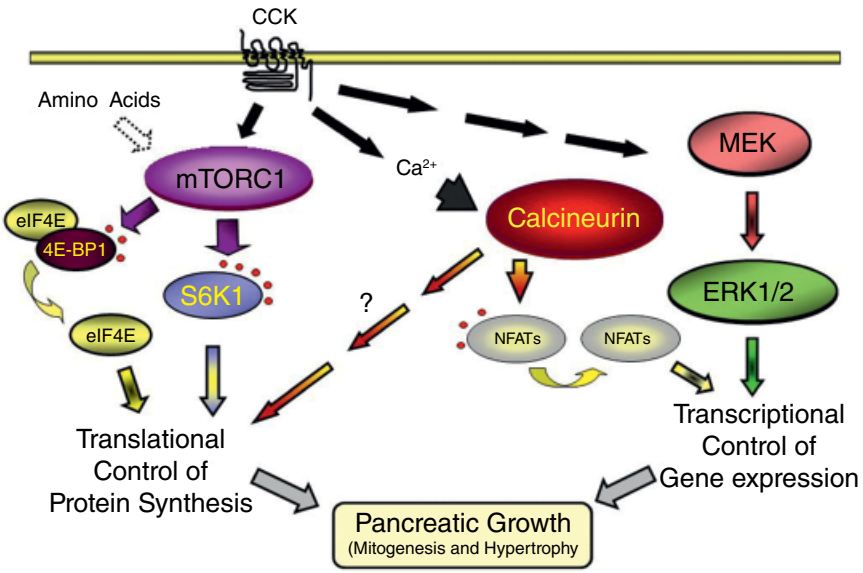

Figure 8.3 Intracellular pathways through which CCK stimulates pancreatic growth. At least three pathways involving calcineurin-NFAT, mTORC1, and ERK1/2 have been shown to be necessary for growth of rodent pancreas either *in vivo* or *in vitro*. Inhibitors of all three pathways can block growth Adapted from [1].

Activation of vagal nerve fibers to the pancreas during feeding stimulates the release of additional peptides associated with secretion of bicarbonate and digestive enzymes. Some of these neuropeptides may also play a role in the regulation of pancreatic growth and their effects have been reviewed previously [87]. In particular, vasoactive intestinal polypeptide (VIP) potentiates the effects of caerulein on pancreatic growth in a manner similar to secretin and gastrin-releasing peptide and bombesin stimulate pancreatic growth, although not as strongly as CCK.

Regeneration

Despite the low rate of cellular turnover normally observed in the adult pancreas, studies in rodents have demonstrated its ability to regenerate in response to tissue injury [88]. This has been studied both after pancreatitis and following surgical resection. Experimental pancreatitis induced by caerulein, arginine, bile salts, or ethionine leads to cell death by a combination of apoptosis and necrosis. The remaining acinar cells dedifferentiate and form tubular complexes that express both acinar and ductal characteristics and some markers of embryonic pancreas. These cells divide and grow and eventually differentiate back into mature acinar cells [89–91]. At present, there is little definitive evidence for regeneration from stem cells.

Following surgical resection of 50–90% of the rat pancreas, the remnant pancreas increases in size and protein and DNA content, with the increase being greater after more complete resection [92]. However, the pancreas never regains its normal size and islets appear to regenerate to a greater extent than exocrine tissue. In some reports differentiated acinar cells are said to incorporate thymidine or show mitotic figures, whereas in other studies regeneration is reported to occur in the injured margin and show tubular complexes and express embryonic markers [93]. In mice, a 75% resection was followed by growth of the remnant by 40%, with evidence for proliferation of differentiated acinar cells [94].

Similarly, to adaptive growth, dietary protein, CCK, and insulin play a significant role in the regeneration of exocrine cells following pancreatic injury. The pancreas is incapable of regeneration in rats fed a protein-free diet. Both exogenous and endogenous CCK enhance and CCK receptor antagonists slow the rate of pancreatic regeneration following pancreatitis [95]. There is also a significant decrease in the rate of pancreatic regeneration in mice lacking the CCK-A receptor in the pancreas [96]. The importance of insulin is shown by the fact that in diabetic rats, CCK administration fails to induce pancreatic regeneration following pancreatitis unless exogenous insulin is also administered [97]. Pertinently, it has been demonstrated that the expression of IGF-1 mRNA is significantly increased following pancreatitis and resection, indicating that both insulin and IGF may be important in pancreatic regeneration.

The expression of cellular oncogenes that regulate the cell cycle and thereby control cellular proliferation rates is significantly increased in models of pancreatic regeneration [98,99]. Many genes associated with embryonic development, and whose expression is normally repressed in the adult, are re-expressed during pancreatic regeneration following pancreatitis [90]. Only a little is known of signal transduction pathways that mediate these changes in gene expression. The p42/p44 MAPK pathway, which modulates the expression of cell-cycle

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. regulators, is activated in the regenerating pancreas [100]. Activation of the PI3K pathway has been shown to be necessary for pancreatic regeneration following resection, as inhibition of the pathway via pharmacologic inhibitors or siRNA severely diminished regeneration [94]. Moreover, the PI3K pathway activation in response to resection decreased with age and may contribute to the reduced regenerative capacity of the aged pancreas. Further identification of the signal transduction pathways, and also the factors modulating these pathways, will be important for improving our understanding of pancreatic regeneration.

Growth of Pancreatic Cells in Culture

In vitro culture of differentiated or immortalized cells can be used as models for cell growth. Most pancreatic cancer cell lines, however, are undifferentiated and will not be considered here. Primary dissociated pancreatic cells, although not dividing, can be maintained in suspension culture under conditions such that they retain the differentiated phenotype or where they dedifferentiate and adopt a more plastic phenotype. When isolated acinar cells or acini are placed on an extracellular matrix such as collagen or matrigel, the cells will initiate division and remain viable for several weeks but almost invariably lose their differentiated appearance. CCK or its analogue caerulein can stimulate cell division and growth, as do insulin, epithermal growth factor (EGF), and other growth factors [70,101]. This model has been applied to evaluating which intracellular pathways mediate growth, with evidence for participation by Ras [102], PI3K/Akt [94], and MAPK pathways [103]. The dedifferentiated phenotype of cultured acinar cells was originally reported as duct like [104,105]. Subsequently, they were characterized as similar to precursor cells that can transdifferentiate into insulin-containing islet cells [106] and that the dedifferentiated cells can simultaneously express acinar, ductal, or beta-cell proteins. Another report showed retention of acinar cell phenotype with an altered medium containing a high amino acid level [107]. In a similar manner, pancreatic duct cells have been grown in monolayer culture. They retain their ion-transporting phenotype and have been used to study duct function. Their growth in culture is stimulated by EGF, TGFα, and insulin, inhibited by TGFβ, but not affected by secretin or other GI peptides [108].

Although no real differentiated pancreatic acinar cell line exists, considerable research has been carried out with AR42J cells, a rat cell line derived from an azoserine-induced tumor which under the influence of glucocorticoids assumes a more acinar phenotype [109]. However, these cells were subsequently shown also to have neuroendocrine properties and can even be driven toward an islet phenotype such that they appear more like an undifferentiated ductal epithelium. Their growth can be stimulated by CCK, gastrin, PACAP, and other peptides, but only to 25–30% and not after exposure to dexamethasone, which induces acinar differentiation but inhibits growth [109].

In summary, all the cultured pancreatic cells studied to date, although dividing and regulated by hormones, possess a relatively undifferentiated phenotype. Hence, they are more a model for regenerating pancreas after pancreatitis than they are a model for diet- or hormone-driven acinar proliferation.

Fibrogenesis in the Pancreas: The Role of Pancreatic Stellate Cells

Minoti V. Apte[1,2], *Romano C. Pirola*[1,2], *and Jeremy S. Wilson*[1,2]

[1] *Pancreatic Research Group, South Western Sydney Clinical Campus, School of Clinical Medicine, UNSW Medicine and Health, University of New South Wales, Sydney, NSW, Australia*
[2] *Ingham Institute for Applied Medical Research, Liverpool, NSW, Australia*

Introduction

Fibrogenesis is defined as the development or production of fibrous tissue. In the healthy pancreas, fibrogenesis is a well-controlled, regulated process that is essential for regular turnover of extracellular matrix (ECM) in the parenchyma, thereby maintaining normal pancreatic architecture. In diseased states, however, this process is hijacked such that the fine balance between production and degradation of fibrous tissue is disrupted, leading to the deposition of excessive amounts of ECM proteins in the organ, eventually resulting in pathologic fibrosis.

Elucidation of the cellular and molecular mechanisms involved in pancreatic fibrogenesis began in earnest in 1998, when methods were developed to isolate and culture pancreatic stellate cells (PSC), now established as key cells in the fibrogenic process, from rodent and human pancreas [1–3]. Interestingly, the presence of these cells in the pancreas was first reported by Watari et al. [4] in Japan a decade and a half earlier (in 1982), and confirmed by Ikejiri [5] in 1990. However, little was known of their function at the time. It was the subsequent development of techniques to isolate viable PSC from the pancreas that provided the much-needed *in vitro* tool that enabled researchers to interrogate the functions of these cells both in health and in pancreatic disease.

Pancreatic Stellate Cells (PSC)

PSC in Health

PSC comprise 4–7% of total parenchymal cells in the normal pancreas. They are found around the basolateral aspects of acinar cells (Fig. 9.1a), blood vessels, and small pancreatic ducts [1,2] and also around pancreatic islets [6].

In their native, quiescent (non-activated) state, PSC store abundant vitamin A (retinoids) in their cytoplasm and belong to a larger "stellate cell system" in the body, comprising retinoid storing cells in several other organs, including the liver, lungs, intestine, kidney, spleen, and adrenal glands [7]. The specific density imparted by the stored lipid enabled Apte et al. [1] to develop the density gradient centrifugation method for the isolation of quiescent PSC from the pancreas. This method has since been refined and further customized by several groups to suit their experimental purposes. The presence of cytoplasmic vitamin A droplets (Fig. 9.1b), and the expression of selective markers such as the intermediate filaments desmin, glial fibrillary acidic protein (GFAP) and nestin, and the neuroectodermal proteins neural cell adhesion molecule and nerve growth factor differentiate PSC from fibroblasts. Due to the expression of neural markers, PSC were initially thought to be of neuroectodermal origin. However, lineage tracing studies with hepatic stellate cells (counterparts of PSC in the liver) have confirmed a mesenchymal origin for these cells [8]. The fact that a proportion of PSC are replenished from bone marrow further supports a mesenchymal origin for PSC [9].

Islet stellate cells (ISC) are similar to but differ in certain aspects from PSC. ISC have fewer vitamin A-containing droplets and undergo a more rapid activation than PSC. Upon activation, ISC express more α-SMA but have reduced rates of proliferation and migration compared with exocrine PSC [6].

Initial studies were focused on the ability of PSC to maintain normal extracellular matrix turnover in health, by not only synthesizing ECM proteins such as collagen,

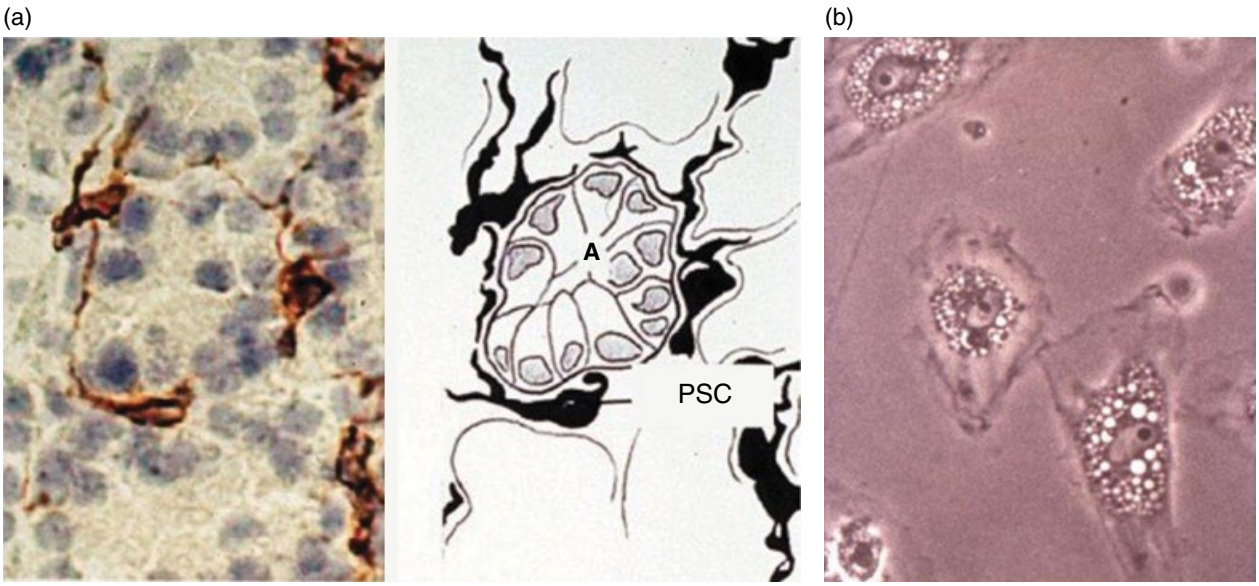

Figure 9.1 (a) Expression of the cytoskeletal protein desmin in pancreatic stellate cells (PSC): a representative photomicrograph of a normal rat pancreatic section immunostained for the stellate cell selective marker desmin is shown on the left with a corresponding line diagram on the right. Desmin-positive (brown) PSC with long cytoplasmic projections can be seen along the basolateral aspects of acinar cells. (b) PSC in early culture exhibiting a typical flattened polygonal shape. The nucleus is surrounded by numerous vitamin A-containing lipid droplets in the cytoplasm. *Source:* Apte et al. (1998) / Reproduced with permission from BMJ Publishing Group Ltd.

fibronectin, and laminin, but also the enzymes (matrix metalloproteinases [MMP] and their inhibitors [TIMP]) that degrade ECM [10]. Evidence has now emerged to indicate that PSC may serve several other functions in the healthy pancreas, including (i) a role in innate immunity and first-line defense (since they express toll-like receptors, TLR 2, 3, 4, and 5 [11], which recognize PAMPs, DAMPs, and alarmins), as well as their ability to phagocytose cell debris and neutrophils [12]; (ii) as mediators of cholecystokinin-induced pancreatic enzyme secretion (since they respond to CCK via CCK receptors by secreting acetylcholine), which in turn acts on muscarinic receptors on acinar cells to stimulate enzyme secretion [13]; and (iii) progenitor-like capabilities since they express several stem cell markers, including CD133, SOX9, nestin, and GDF3 [14,15]. They can differentiate into other cell types including insulin-secreting cells under the influence of relevant growth factors.

PSC in Disease

During pancreatic injury, PSC are activated, i.e., they transform from their quiescent state to a myofibroblast-like phenotype characterized by loss of vitamin A stores, expression of alpha smooth muscle actin (αSMA), fibroblast activation protein (FAP), fibroblast specific protein (FSP1), and fibrinogen [16] (Table 9.1). Activated PSC synthesize and secrete excessive amounts of ECM proteins, overwhelming their ability to degrade these proteins, eventually causing fibrosis of the gland. PSC can be activated by a wide range of factors, each of which is pertinent to pancreatic pathophysiology either as a factor that is upregulated/modulated during pancreatic disease

Table 9.1 Characteristics of quiescent and activated pancreatic stellate cells (PSC).

Characteristic	Quiescent PSC	Activated PSC
Vitamin A lipid-containing droplets	Abundant	Absent
Alpha smooth muscle actin	Not expressed	Expressed
Proliferation	Basic	Enhanced
Ability to migrate	No	Yes
Collagen production	Limited	Increased
Activity of matrix metalloproteinases (MMP) and tissue inhibitors of matrix proteinases (TIMP)	In equilibrium	TIMP > MMP
Cytokine production	Limited	Increased inflammatory cytokines (PDGF, TGFβ, CTGF, IL-1, IL-6, IL-15)
Ability for phagocytosis	No	Present (CD6-mediated)
Protein expression	Basal expression	Differential expression

Proteases

Table 9.3 Signaling pathways involved in pancreatic stellate cell (PSC) activation.

Factor	Pathway involved	Outcome
Oxidative stress	Nrf2 antioxidant pathway	PSC activation and pancreatic fibrosis
Nicotine	α7nAChR-mediated JAK2/ STAT3 signaling pathway	PSC activation, proliferation, α-SMA expression, and ECM formation
LPS	NLR family pyrin domain-containing 3 inflammasome	Activation of PSC
TGF-β1	SNHG/miR-34b/ LIF pathway	Proliferation, migration, and ECM accumulation
siRNA	Notch3	Inhibits the activation, proliferation, and migration of cancer cells
CCG-222740	Rho/MRTF pathway	Reduces PSC activation and modulates immune cells
Tissue injury/ pathogens	Sonic hedgehog/ Smo/Gli pathway	PSC activation and perineural invasion
Ethanol and growth factors	MAPK pathway	PSC activation and fibrosis
Thiazolidinediones	PPR γ pathway	PSC activation inhibition
IL-6	JAK2/ STAT3 pathway	PSC activation and immune modulation
siRNA	transcription factor NF-κB pathway	PSC activation, proliferation, apoptosis

or as a compound that is directly injurious to the gland (listed in Table 9.2). Notably, in addition to being activated by exogenous cytokines (released by surrounding acinar or inflammatory cells) via paracrine routes, PSC are capable of producing their own cytokines, which act on the cells via corresponding receptors (autocrine pathways) resulting in a state of perpetual activation thus further facilitating pathological fibrosis.

Signaling pathways that mediate activation of PSC are being increasingly identified (summarized in Table 9.3). Furthermore, close interactions between several of these pathways have now been characterized, implying that there is considerable redundancy when it comes to modulation of PSC activation [17–20]. Interestingly, several studies have shown that a number of the above signaling pathways converge to a common downstream mediator of PSC activation, namely a sustained increase in intracellular calcium [21]. In recent years, attention has been focused on microRNA, (small noncoding RNA) in PSC because they are now recognized as important factors in numerous cell functions including proliferation, differentiation, apoptosis, and protein synthesis. Several miRNA have been shown to be differentially expressed between quiescent and activated PSC [22]. MicroRNA 15b and 16 (reported to regulate PSC apoptosis) [23] and miR21 are postulated to be cofactors in connective tissue growth factor (CCN2)-mediated PSC activation [24]. MicroRNA are often transported by small extracellular vesicle (exosomes) secreted by a variety of cell types. A recent study has shown that exosomes from acinar cells carrying miR-130a-3p can fuse with PSC membranes, with consequent transport of miR130a into PSC where it binds to and inhibits PPARγ leading to PSC activation [25]. In addition to the identification of factors causing PSC activation, in recent times attention has been turned toward signaling pathways and factors that maintain PSC quiescence or reverse activated PSC to their quiescent state. These are discussed in more detail in the context of development of therapeutic approaches to inhibit/reverse pancreatic fibrosis under the section titled "Reversal of Pancreatic Fibrosis."

Over the past decades several major advances have been made in our understanding of the role of PSC in the diseased pancreas. It is clear that PSC are critical to the process of regeneration and repair in acute pancreatitis (usually a self-limiting inflammatory condition), but also play a central role in disease progression in recurrent acute and chronic pancreatitis as well as pancreatic cancer.

Acute Pancreatitis (AP)

In the majority of cases, acute pancreatitis is a self-limiting condition, with restitution of pancreatic structure and function to normal within a few weeks. Early in the disease process and in response to acinar cell-derived trypsin [26] as well as the chemokines/cytokines released by damaged acinar cells and the infiltrating inflammatory cells, PSC become activated and proliferate rapidly. While most of the increased PSC numbers comprise proliferating resident cells, a small proportion (7–18%) are derived from circulating bone marrow cells [9]. Activated PSC are thought to play a role in the progression of AP via synthesis of nitric oxide, which in turn further damages acinar cells [26,27]. However, they also play a major role in recovery from AP. The ECM proteins produced by these activated PSC provide a supportive lattice and a scaffold that supports the regeneration of acinar and ductal cells during recovery from acute pancreatitis. Notably, the ECM regulates the critical integrin-mediated interactions between cell membranes and the surrounding matrix, which in turn are important controllers of cell proliferation and differentiation. In the absence of integrin receptors (as demonstrated by studies using β1-integrin knockout mice [28], ECM synthesis by PSC is inhibited. This is associated with increased apoptosis and decreased proliferation of acinar cells, thereby delaying the process of pancreatic repair.

PSC also play an important role in aiding regeneration and remodeling after severe necrotizing acute pancreatitis. In a seminal study using pancreatic tissue from patients with severe acute pancreatitis, Zimmerman et al. [29] found outgrowth of "pilot ductules" from islands of granulation tissue (comprised of remnant acini, ductules, and stellate cells). These ductules exhibited a mantle of stellate cells which are thought to support growth and differentiation of ductal cells into mature duct and acinar cells. Thus, PSC may be critical to the reconstitution of pancreatic parenchymal cells after acute injury. Additionally, the MMPs and TIMPs secreted by the cells may help in the remodeling process by removal of excess ECM via fibrinolysis, while activated PSC are removed through processes such as apoptosis, senescence and/or reversion to quiescence.

Chronic Pancreatitis (CP)

Chronic necroinflammation of the pancreas (chronic pancreatitis) is characterized histologically by abundant fibrosis that surrounds islands of atrophied acini and distorted pancreatic ducts. Notably, fibrosis is also detected within and around pancreatic islets despite the absence of obvious necroinflammation of the islet cells [30]. Studies involving dual staining for collagen and the PSC activation marker αSMA (using Sirius Red stain and immunohistochemistry, respectively) combined with immunostaining for selective PSC markers have conclusively demonstrated the presence of activated PSC in fibrotic areas (Fig. 9.2) around acini and ducts as well as around islets; more importantly, dual staining for αSMA and procollagen mRNA has established that activated PSC are the predominant source of collagen I in the fibrotic pancreas [31]. As with AP, the increased numbers of PSC in CP are sourced mainly from the resident PSC population, with a small proportion being derived from pluripotent circulating bone marrow cells [32]. Interestingly, activated PSC are known to cause beta-cell dysfunction (decreased insulin secretion and apoptosis), and these effects are further aggravated by hyperglycemia [33]. These findings indicate that PSC-mediated islet cell dysfunction may be a factor in the diabetes of chronic pancreatitis.

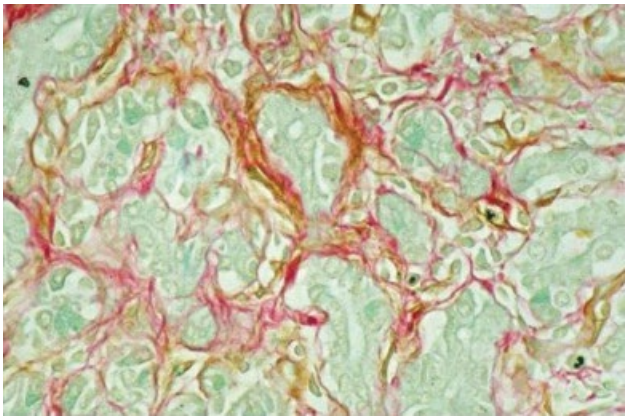

Figure 9.2 Activated pancreatic stellate cells (PSC) in chronic pancreatitis: a section from a patient with chronic pancreatitis showing colocalization of staining for the PSC activation marker alpha smooth muscle actin (αSMA, brown) and collagen using Sirius Red (red) (dual staining) in fibrotic areas of the pancreas. *Source:* Haber et al. (1999) / Reproduced with permission of Elsevier.

The role of PSC in CP has been studied using human CP tissue (which usually only allows point-in-time assessments) and experimental models of CP (which allow examination of chronological events during fibrosis development and progression). Space restrictions preclude a detailed discussion of the current (predominantly rodent) models of CP noted in Table 9.4. Each model has its advantages and deficiencies, but possibly the most physiologically relevant model (particularly for alcoholic chronic pancreatitis) involves chronic ethanol administration followed by endotoxin challenge (given the well-demonstrated increase in serum endotoxin levels in heavy drinkers) [34]. With the recent focus on the role of smoking in chronic pancreatitis and the knowledge that smoking aggravates alcoholic CP, models have been developed whereby alcohol-fed, endotoxin challenged rats or mice

Chronic alcohol administration with additional challenge/intervention
• Pancreatic duct ligation
• Free fatty acids
• Caerulein
• Endotoxin/LPS
• Smoke exposure

are exposed to tobacco smoke [35]. These studies support the concept that smoke exposure significantly increases the severity and progression of alcohol-induced pancreatic injury and fibrosis.

Mechanistic insights gained from the above work indicate that during CP, PSC are activated by numerous factors/pathways including (i) the profibrogenic growth factor TGFβ, which is found to be highly expressed in spindle-shaped cells and in infiltrating M2 macrophages within fibrotic areas and also in acinar cells adjacent to areas of fibrosis (but not in acinar cells away from fibrotic areas), supporting the notion that TGFβ induces PSC activation via paracrine and autocrine pathways [31]; (ii) platelet-derived growth factor (PDGF) acting via the PDGF receptor known to be upregulated in fibrotic areas, thereby providing a possible mechanism for the observed increase in proliferation and migration of PSC to injured areas during pancreatic necroinflammation [31]; (iii) nerve growth factor (NGF), demonstrated to be expressed in PSC in areas of fibrosis, and implicated in the pain of chronic pancreatitis via its ability to induce neurite growth [36]; (iv) oxidative stress, as evidenced by increased staining of oxidant stress marker 4-hydroxynonenal [37]; (v) cigarette smoke compounds (via activation of the α7nicotinic acetylcholine receptor [α7NACh receptor]) expressed on PSC [35]. Notably, a positive feed-forward loop is set up between PSC and macrophages, whereby the interleukins IL4 and IL13 produced by activated PSC promote further transformation of macrophages to the M2 phenotype, which, in turn secrete IL22, TGFβ, and PDGF to cause further PSC activation and progression of fibrosis [38].

Reversal of Pancreatic Fibrosis

Our improved understanding of the biology of PSC and their role in the fibrosis of chronic pancreatitis has led to a dramatic increase in efforts in the field to develop targeted therapies to prevent/inhibit/retard the fibrogenic process. It must be acknowledged, however, that the efficacy of most approaches has largely only been demonstrated in animal models and translation of these findings to clinical settings is awaited. The potentially useful strategies suggested by pre-clinical studies are itemized in Table 9.5 and include:

1) *Modulation of growth factors*: Inhibition or degradation of profibrogenic growth factors TGFβ and tumor necrosis factor alpha (TNFα) and their downstream signaling [38–43], histone deacytylase (HDAC) inhibitor [44], heat shock protein (HSP90) inhibitor [45].
2) *Antioxidants*: Vitamin E [46], ellagic acid, a plant polyphenol [47], salvianolic acid, a herbal medicine [48]; and irisin, an exercise-induced hormone [49], N-acetylcysteine [50].
3) Protease inhibitors [51].
4) *Modulation of signaling pathways*: Troglitazone and miR-130a-3p binding to the peroxisome proliferator receptor gamma, PPARγ [12,25]; retinoic acid-

Table 9.5 Reversal of pancreatic fibrosis.

Mechanism	Compounds
Modulation of growth factors	Inhibitors of TGFβ, TNFα, HDAC, HSP90
Antioxidants	Vitamin E, ellagic acid, salvianolic acid, irisin, N-acetylcysteine
Protease inhibitors	Camostat mesylate, dasatinib, CP734
Modulation of signaling pathways	Troglitazone and miR-130a-3p binding to PPARγ; Retinoic acid – Wnt–catenin pathway; miR-200a –TGF-β1/PTEN/Akt/mTOR pathway; 3-methyladenine (3-MA) – PI3K pathway
Inhibition of collagen synthesis	Collagen siRNA
Anti-inflammatory approach	Prostacyclin analogue ONO-1301; amygdalin; indomethacin; isoliquiritigenin
Behavioral modification	Alcohol withdrawal
Plant compounds	Rhein, apigenin, curcumin, saikosponin A, date palm fruit extract
Vitamins	Vitamin D – isoforms D2 and D3, vitamin A (retinol) or its metabolites such as retinoic acid
Induction of quiescence of activated PSC	Melatonin, bone morphogenic protein, troglitazone, kinase inhibitors – sorafenib, sunitinib, trametinib, dactolisib, and dasatanib, coenzyme Q10

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

induced PSC quiescence via suppression of the Wnt–catenin pathway [52]; miR-200a-mediated inhibition of TGF-β1-induced PSC activation and extracellular matrix formation through inhibition of the PTEN/Akt/mTOR pathway [53]; 3-methyladenine (3-MA), a PI3K inhibitor causing decreased fibrosis by decreasing autophagy in PSC [54].

5) *Inhibition of collagen synthesis*: Collagen siRNA [55].
6) *Anti-inflammatory approach*: A prostacyclin analogue ONO-1301, which inhibits proinflammatory and profibrogenic cytokine production [56]; amygdalin, which inhibits PSC activation and attenuates fibrosis by decreasing production of profibrotic cytokines in a rat CP model induced by injecting dibutyltin dichloride (DBTC) [57]; inhibition of cyclooxygenase by indomethacin, an anti-inflammatory drug that results in decreased activation of PSC [58]; isoliquiritigenin, a component of licorice which decreases macrophage infiltration and attenuates caerulein-induced pancreatic fibrosis [59].
7) *Behavioral modification*: Alcohol withdrawal in alcohol-induced pancreatitis [60].
8) *Plant compounds* exerting a range of effects that inhibit PSC activation: An anthraquinone derivative rhein and a flavonoid, apigenin; curcumin (a polyphenol found in turmeric) reported to inhibit activation of PSC through the inhibition of IL1β, which decreases TNFα-induced activation of activator protein-1 (AP-1) and mitogen-activated protein (MAP) kinases (ERK, c-Jun N-terminal kinase [JNK], and p38 MAP kinase) [61]; conophylline, a plant alkaloid, which decreases fibrosis through the inhibition of ERK1/2 in PSC [62]; resveratrol, a natural polyphenol, which decreases oxidative stress-induced activation and glycolysis in PSC, mediated by ROS/miR-21 [63]; genestein, a natural isoflavone, which decreases fibrosis in human PSC transfected with let-7d to express thrombospondin 1, a marker of fibrosis [64]; saikosponin A, the active component of the Chinese medicine chaihu, which decreases PSC activation, viability, proliferation, and migration, and promotes apoptosis by inhibiting autophagy and the formation of NLRP3 inflammasome via the AMPK/mTOR pathway [65]; date palm fruit extract, which decreases fibronectin-1 and αSMA, markers of fibrosis in PSC activated by TNF-α [66].
9) *Vitamin D* and its isoforms D2 and D3 decrease *in vitro* PSC activation by decreasing IL-6 [67]. Notably, *in vivo* studies with the vitamin D ligand calcipotriol have shown significant attenuation of the fibrosis of chronic pancreatitis in mice [68]. Based on these findings, a clinical trial is under way (NCT02965898, Laukkarinen J, Tampere University Hospital) to assess if vitamin D supplementation can prevent progression of recurrent AP to chronic pancreatitis. Since storage of vitamin A is associated with PSC quiescence, administration of vitamin A (retinol) or its metabolites such as retinoic acid, has been assessed in models of chronic pancreatitis. In this regard, vitamin A-containing liposomes combined with TLR4-silencing shRNA has been reported to inhibit pancreatic fibrosis in mouse models of chronic pancreatitis [69]. Interestingly, vitamin A deficiency was seen to promote islet stellate cell activation and dysregulation of glucose metabolism in mice, an effect that was mitigated by supplementation of vitamin A [70].
10) *Induction of quiescence of activated PSC*: Melatonin, the anthraquinone derivative rhein [71], bone morphogenic protein [72], troglitazone (a ligand for the peroxisome proliferator activated receptor PPARγ) [25,73]; kinase inhibitors (sorafenib, sunitinib, trametinib, dactolisib, and dasatanib), which have been shown to inhibit PSC proliferation and ECM synthesis [74–76]. Interestingly, trametinib also decreases the expression of two autocrine mediators of PSC activation, IL6 and TGFβ [75]. Coenzyme Q10 suppresses PSC activation by inhibiting autophagy through PI3K/ATK/mTOR signaling [77].

Pancreatic Cancer

It is now well established that the abundant collagenous stroma of pancreatic cancer is produced predominantly by PSC (discussed in more detail below). It is also increasingly clear that PSC play a much wider role to aid cancer progression via active crosstalk not only with cancer cells but also with other stromal cells. Consequently, the development of novel approaches to interrupt this crosstalk is considered a critical addition to currently available treatment strategies for pancreatic cancer.

The fibrotic stroma of pancreatic cancer comprises extracellular matrix proteins including collagen type I, fibronectin, and laminin, noncollagenous factors such as glycosaminoglycans (e.g., hyaluronan), glycoproteins, and proteoglycans, and several cell types, including stellate cells, endothelial cells, neural elements, and immune cells [78].

Studies with human pancreatic cancer sections, involving dual staining for PSC-selective markers and *in situ* hybridization for collagen mRNA, have established that PSC are the major source of the fibrosis of pancreatic cancer [79] (Fig. 9.3). Activated PSC have been identified surrounding the earliest (premalignant) lesions of pancreatic cancer, such as pancreatic intraepithelial neoplasms (PanIN) and intraductal papillary mucous

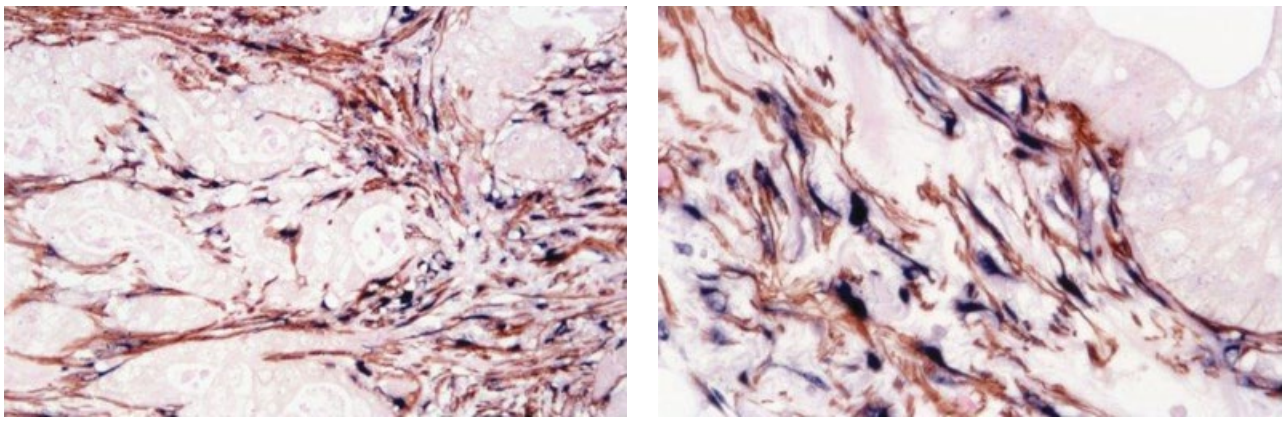

Figure 9.3 Low- and high-power views of a human pancreatic cancer section dual stained for alpha smooth muscle actin (αSMA) and collagen mRNA: immunostaining for αSMA (brown) combined with *in situ* hybridization for collagen mRNA (blue) reveals colocalization of the two stains in stromal areas of the section with no staining in tumor cells. This pattern of staining indicates that pancreatic stellate cells are the main source of collagen in pancreatic cancer stroma. *Source:* Apte et al. (2004) / Reproduced with permission from Wolters Kluwer Health.

neoplasms (IPMN), indicating that PSC activation is an early feature in carcinogenesis [80,81]. While PSC may act to restrain early-stage cancer growth, it is now widely accepted that eventually cancer cells subvert PSC function to their own benefit [82,83]. Indeed, a positive correlation has been reported between the extent of activated PSC in the stroma and poor clinical outcome as assessed by overall survival [84,85].

Recent studies have prompted a recognition of the significant inter- and intra-tumoral heterogeneity exhibited by PSC in pancreatic cancer tissue. Ikenaga and colleagues [86] first reported identifying two populations of PSC based on positive or negative staining for the membrane metalloproteinase CD10, with patients with CD10+ve PSC exhibiting worse outcomes. Subsequently, subtypes of cancer-associated fibroblasts (CAFs) were described by Ohlund et al. [87]—those at a distance from neoplastic cells showing an inflammatory phenotype (high expression of interleukin 6 [IL6] and relatively low expression of αSMA), termed inflammatory CAF or iCAF; and those adjacent to malignant cells showing a myofibroblastic phenotype (high αSMA expression) termed myofibroblastic CAF or myCAF [87]. Since then, a study by Neuzillet et al. [88] using transcriptomic analyses, has reported the presence of four subtypes of CAF (A, B, C, and D) in pancreatic cancer. Each of these subtypes demonstrates specific functional and molecular features and appears to exert different effects on disease prognosis. The authors found that PSC exhibited features mainly of subtypes B and C (prominent expression of myosin II and podoplanin, respectively).

As noted earlier, the role of PSC in pancreatic cancer extends well beyond merely producing the fibrotic stroma. Using *in vitro* (cocultured PSC and cancer cells) and *in vivo* (subcutaneous xenografts, orthotopic implants, genetically engineered models) approaches, a close bidirectional interaction between PSC and cancer cells has been identified, which facilitates local tumor growth and distant metastasis [82,89]. Pancreatic cancer cells induce PSC activation, as evidenced by increased proliferation, ECM production, and migration. In turn, PSC significantly increase pancreatic cancer cell proliferation, while at the same time inhibiting their apoptosis, thereby increasing cancer cell survival. PSC also stimulate cancer cell migration (an effect associated with enhanced epithelial–mesenchymal transition [EMT]) and stemness of cancer cells. Interestingly, cancer cells have been found to induce autophagy in PSC leading to release of alanine, which acts as an alternative carbon source for the TCA cycle and lipid synthesis in cancer cells, thus improving cancer cell survival in the nutrient-poor and hypoxic environment of PDAC [90]. The transport of alanine between PSC and cancer cells is reported to be mediated by the SLC1A4 transporter, which is upregulated on cancer cells and may serve as a novel therapeutic target to inhibit cancer cell metabolism [91]. The factors/signaling pathways that mediate the interactions of PSC and cancer cells are being increasingly elucidated. A detailed discussion of these is out of the scope of this chapter, but the major factors are summarized in Table 9.6. Interactions of PSC with other cells in the tumor microenvironment are covered in Chapter 123.

A known characteristic of pancreatic desmoplasia is its ability to interfere with the delivery of chemotherapeutic agents to cancer cells. Hessmann et al. [92] demonstrate that PSC/cancer-associated fibroblasts are not only resistant

Table 9.6 Signaling pathways mediating interactions between pancreatic stellate cells and cancer cells.

Mediator	Signaling pathway	Functional role
PSC-derived CXCL12 (SDF-1)	CXCL12 (SDF-1) signaling	Immunosuppression
PSC-derived SDF-1	Galectin-1	Proliferation of PSC and chemokine production facilitating PCC metastasis
Smo, Gli	Hedgehog pathway	PSC activation, ECM synthesis, migration, desmoplasia, angiogenesis; PCC proliferation, migration, and chemoresistance
HGF	HGF/c-MET pathway	PSC promote proliferation and metastasis of tumor cells
CCL2	Hypoxia inducible factor 1 (HIF-1)	PSC activation, Macrophage recruitment
IL-6	IL6/JAK/STAT	PSC activation and proliferation
Kindlin-2	Integrin	Cytokines production in PSC facilitating progression and migration of PCC
MAPK	Mitogen-activated protein kinase (MAPK) signaling pathway	PSC proliferation, TIMP-1 production
Periostin	Periostin pathway	Periostin secreted by PSC promoting PCC proliferation, EMT, and resistance to nutrient deprivation and hypoxia
PPAR-γ ligands	Peroxisome proliferator-activated gamma (PPARγ)	Inhibition of PSC activation, proliferation, and collagen synthesis Increased phagocytosis
PDGF	PI3-Kinase pathway	PSC migration and proliferation
Hyperglycemia	Protein kinase C	PSC proliferation, α-SMA, collagen-I production, angiogenesis
Suppression of miRNA-21	Reactive oxygen species (ROS)	PSC activation and induction of glycolysis
Rho-associated protein kinase	Rho-ROCK pathway	Activation of PSC, collagen I synthesis, and fibrosis
SMAD-2,3	SMADS	PSC activation, proliferation, ECM deposition, transdifferentiation, TGF-β1 expression
TLR9	Toll-like receptor (TLR) signaling	Immunosuppression; PSC-derived cytokine production
Vitamin D	Vitamin D receptor	PSC quiescence; decreased chemoresistance
β-catenin	Wnt/β-catenin signaling	Invasion of PCCs
Caveolin-1 (Cav-1)	Cav-1-ROS signaling	Promotes tumor growth and induces stroma–tumor metabolic coupling
NGF	PI3K/AKT/GSK signal pathway	Cancer cell proliferation and invasion

α-SMA: alpha smooth muscle actin; c-MET: tyrosine-protein kinase of Met; CCL: chemokine ligand; CXCL: chemotactic cytokine ligand; ECM: extracellular matrix; JAK/STAT: Janus kinase/signal transducers and activators of transcription; HGF: hepatocyte growth factor; NGF: nerve growth factor; PCC: pancreatic cancer cells; PDGF: platelet-derived growth factor; PSC: pancreatic stellate cells; SDF: stromal-derived factor; SMAD: small worm mothers against decapentaplegic.

to gemcitabine themselves but can convert gemcitabine into an inactive metabolite 2′,2′-difluorodeoxyuridine thus decreasing the availability of active agent to destroy tumor cells. PSC may also directly modulate the response of cancer cells to chemotherapeutic agents. In an autocrine response to stromal-derived factor 1α (SDF-1α) secreted by PSC, the cells secrete IL6, which in turn exerts a protective effect on cancer cells from the apoptotic effect of gemcitabine [93]. In addition, post-chemotherapy, PSC may facilitate proliferation of residual cancer stem cells leading to recurrence [94].

In view of the emerging strong evidence of the importance of the microenvironment to pancreatic cancer outcomes, there is general agreement in the field that targeting cancer cells alone will remain an inadequate treatment approach and that modulating the microenvironment in addition to chemotherapy represents an essential element of future novel therapies. New high-throughput screening

modalities have the potential to allow faster identification of potentially useful compounds that target stromal–tumor interactions [95].

Conclusion

In summary, it is now unequivocally established that the cells responsible for fibrogenesis in the pancreas are pancreatic stellate cells (PSC). In health, PSC maintain a fine balance between ECM production and degradation, thereby ensuring normal ECM turnover in the gland. PSC may also have additional roles in the healthy pancreas as progenitor cells, immune cells, and intermediary cells in CCK-regulated pancreatic exocrine secretion. In diseased states, PSC are transformed into an activated myofibroblast-like state, producing excessive amounts of ECM proteins. When the activation of PSC is limited, as in resolving acute pancreatitis, PSC can aid the regenerative/repair process. However, perpetuated activation of the cells, as seen in chronic pancreatitis and pancreatic cancer, ultimately leads to pathologic fibrosis. Notably, it is now becoming increasingly evident that PSC have functions beyond the fibrotic process in both chronic pancreatitis and pancreatic cancer. In chronic pancreatitis, PSC have been shown to facilitate acinar cell injury, interact with M2 macrophages and to promote islet (beta) cell dysfunction. In pancreatic cancer, PSC display heterogeneity facilitating both inflammation and fibrosis and they interact closely with cancer cells and other stromal cells such as endothelial cells, immune cells, nerve cells as well as the ECM itself to influence cancer progression. Understanding the biology of these multifunctional PSC will underpin the development of novel therapeutic approaches for difficult-to-treat fibrotic diseases of the pancreas such as chronic pancreatitis and pancreatic cancer.

Pancreatic Endocrine–Exocrine Relationship

Kenichiro Furuyama and Yoshiya Kawaguchi

Department of Life Science Frontiers, Center for iPS Cell Research and Application, Kyoto University, Kyoto, Japan

Introduction

The adult pancreas is composed of two functional tissue components. One is exocrine pancreatic tissue, in which acinar cell clusters are connected to the pancreatic ducts and secrete digestive enzymes into the duodenum. The other is the islet, an endocrine cell mass that secretes hormones into the bloodstream to maintain blood glucose homeostasis. Though the functions of exocrine and endocrine pancreas are separately conducted by independent functional tissues in mature pancreas, both tissues are anatomically in intimate contact. For example, a capillary microvascular network that connects islets and acini is reported in humans and other mammals. Until very recently, it has long been believed that arterial blood is separately supplied to the islets and acini but the outflow from the islet is drained into the surrounding acini through the microvascular network, known as the insuloacinar portal system. As a result, acinar cells are exposed to high concentrations of islet hormones and potentially receive signals from islet cells. It has been shown that insulin receptors are expressed in acinar cells and that insulin stimulates digestive enzyme secretion [1–4], leading to the concept of an insulin–pancreatic acinar axis. Similarly, other islet hormones are involved in regulating acinar function directly or indirectly, expanding the concept of the islet–acinar axis. For example, somatostatin from islets shows an inhibitory effect on exocrine pancreatic secretion [5,6]. Glucagon and pancreatic polypeptide also regulate exocrine function indirectly via insulin and somatostatin action [7–11]. Considering new information on intra-islet crosstalk among α, β, δ, γ, and ε cells [12], acinar function is regulated by orchestrated outputs from the heterogeneous cell types of the islet.

More recently, however, Dybala et al. performed real-time imaging of individual red blood cells *in vivo* and showed that blood flow in the microvascular network is bidirectional between islet and exocrine pancreas in mice, indicating that blood supply into the islet is not isolated from the microcirculation of exocrine tissue [13,14] (Fig. 10.1). Along with the microvascular network, the lack of capsule or basement membrane, which separates islets from the exocrine acinar compartment, enables intercellular communications between exocrine and endocrine tissues via secreted factors or direct cell-to-cell contact signals [14]. Indeed, the accumulation of abnormal proteins secreted by exocrine acinar cells impairs β-cell function in maturity-onset diabetes of the young type 8 (MODY8) [15]. Thus, endocrine and exocrine pancreas tissues are not only in anatomically intimate contact, they functionally regulate each other through bidirectional communications.

In this chapter, pancreatic endocrine–exocrine interactions are discussed by introducing clinical evidence, phylogenetic comparisons of the pancreas, and a brief overview of murine pancreas development. Further, new information on intercellular signals are reviewed, focusing on the regulation of embryonic islet development by acinar products and intra-islet crosstalk for regulating cell function and the maintenance of cell identity.

Clinical Evidence that Supports the Endocrine–Exocrine Relationship

Exocrine Dysfunction in Diabetic Patients

Exocrine dysfunction in diabetic patients was reported in studies that showed reduced amylase secretion by the secretion-pancreozymin test. Hardt et al. conducted a multicenter analysis and reported that 22.9% of 1021 diabetic patients showed lower concentrations of fecal elastase-1 and a higher prevalence of reduced elastase-1 in

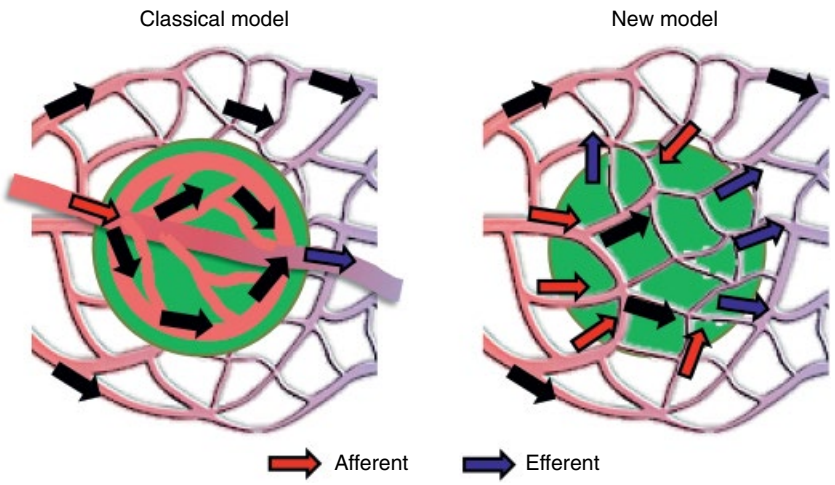

Figure 10.1 Islet microcirculation models. Left panel: the classical model, or "insulo-acinar portal system," assumes independent afferent vasculature (red arrow) to the islet and unidirectional blood flow Adapted from [1–4]. Right panel: the new model by Dybala et al. Adapted from [13] shows connecting capillaries and bidirectional blood flow between exocrine and islet tissues.

T1D than T2D patients (51% and 35%, respectively) [16]. Furthermore, fecal elastase-1 was reported to be inversely correlated with HbA1c levels and duration of the disease [17]. Andriulli et al. reported a meta-analysis of prospective studies involving 2891 patients (921 of them with T1D and 1970 with T2D) [18]. They showed that fecal elastase-1 was low in 921 patients (31.8%). The prevalence of the low elastase-1 level was 37.7% in T1D and 26.2% in T2D patients. Collectively, almost one in three patients with diabetes exhibited impaired exocrine function by testing for fecal elastase-1.

Despite exocrine dysfunction in the majority of diabetic patients being clinically mild, the pancreatic size in T1D patients is reported to be 45% smaller than healthy controls [19,20]. Because acinar cells constitute more than 90% of total pancreatic epithelial cells, this finding indicates the involvement of an endocrine–exocrine relationship, though no clear mechanism is known [19,20].

Diabetes in Patients with Chronic Pancreatitis

Seventy percent of patients with chronic pancreatitis have diabetes mellitus. It is naturally imagined that chronic inflammation in exocrine tissue affects islets and causes β-cell loss, but the pathogenesis has proven not to be so simple. While the majority of patients with chronic pancreatitis show insulin deficiency, only 16% show hypoglucagonemia [21]. Intriguingly, oral glucose intake stimulates glucagon secretion, resulting in hyperglycemia in patients. In addition, Larsen et al. reported that meal-induced somatostatin secretion was elevated in these patients and potentially suppresses insulin secretion [22]. Though the precise mechanism that causes the impaired secretion of these islet hormones in the patients is unknown, Pierzynowska et al. reported that the intravenous administration of amylase decreased insulin levels in a pig model [23]. Considering the leaked digestive enzymes into the pancreatic parenchyma in human chronic pancreatitis, a direct inhibitory effect of acinar products on β-cell function has been an attractive hypothesis.

Maturity-Onset of Diabetes of the Young Type 8 (MODY8)

More direct evidence on the acinar–islet axis was recently shown in the pathogenesis of MODY8 [15]. These patients develop juvenile-onset exocrine dysfunction, followed by glucose intolerance during young adulthood. The causative gene of this disease is carboxyl ester lipase (CEL), which is expressed specifically in pancreatic acinar cells. Mutant CEL protein, which is produced in the acinar cells of MODY8 patients, is up-taken by β cells via endocytosis, and accumulated mutant protein impairs the function of β cells and reduces their proliferation, resulting in glucose intolerance.

Endocrine and Exocrine Pancreas: Phylogenetic Comparison and Embryonic Organogenesis of Mammalian Pancreas

Evolution of Vertebrate Pancreas

To understand the molecular mechanisms functioning in the endocrine–exocrine crosstalk of human pancreas, an understanding of the evolution of vertebrate pancreas in the phylogenetic tree and the machineries of embryonic organogenesis of mammalian pancreas is useful. Invertebrates do not have a pancreas, but islet hormone-producing cells are dispersed within the gut epithelium of

Cephalochordate [24]. The first animal that showed an endocrine cell cluster, i.e., a primitive islet, is Lamprey, but its islet is not surrounded by exocrine tissue [25]. Interestingly, insulin-producing cells are first found in the gut of ammocoetes, a larva stage, and divided into two clusters in adults; one cluster expands in the gut subepithelial layer and the other enters the liver. Similarly, somatostatin-producing cells are detected first in the gut epithelium but then move to the subepithelial layer, where they form the islet structure with insulin-producing cells. Glucagon-producing cells exist within the gut epithelium throughout life and do not join the islet [26]. As evolution progressed, Gnathostomata acquired exocrine pancreas tissue [27]. The acquisition of a jaw, it seems, required a new digestive organ to meet increased masticatory substances. In Chondrichthyes such as sharks, the pancreas is detected as a solid organ that contains endocrine and exocrine tissue, but the pancreas of Osteichthyes is not uniform. In some fish, including eels and catfish, the pancreas is detected as an independent organ, but in others it exists in the liver as a hepatopancreas [27]. In other vertebrates, including amphibians, reptiles, birds, and mammals, the pancreas is basically detected as an independent solid organ that possesses endocrine and exocrine tissues [24]. Considering the tight connection between the digestion/absorption of nutrients and regulation of blood glucose levels, the coexistence of the two tissues in one organ and the mutual regulation of their function would be a purposeful change during evolution.

Organogenesis of Mammalian Pancreas during Embryonic Stages

As stated above, the pancreas originated from the gut and became an independent organ during vertebrate evolution. A similar process is conserved in the embryonic organogenesis of the mammalian pancreas. Previous studies showed both exocrine and endocrine cells originate from a pool of multipotent precursor cells in the pancreatic buds that evaginate from the primitive gut tube in mice [28]. Within the pancreatic buds, epithelial cells gradually form the ductal plexus and undergo remodeling to form a branched duct structure composed of a Cpa1- and Ptf1a-expressing tip domain and a Nkx6.1-positive trunk domain [28]. During segregation of the tip/trunk regions, the differentiation ability of epithelial cells is spatiotemporally regulated; $Pdx1^{+}Ptf1a^{+}c Myc^{high}Cpa1^{+}$ progenitor cells are multipotent at first but lose their ability for endocrine differentiation after embryonic days 13–14, whereas $Nkx6.1^{+}$ cells in the trunk region can differentiate into endocrine and duct cells [28]. In endocrine lineage, $Ngn3^{+}$ endocrine precursor cells bud out from the lining of the $Nkx6.1^{+}$ ductal trunk and differentiate into all cell types of the islet, including glucagon^{+} α cells, insulin^{+} β cells, somatostatin^{+} δ cells, and pancreatic polypeptide^{+} γ cells. Acinar cells are formed in the Cpa1- and Ptf1a-expressing tip domain [28].

Gene knockout studies have identified several crucial transcription factors in murine pancreas development. For example, *Pdx1* knockout results in pancreatic agenesis, while *Ngn3*-null mice lack differentiated endocrine cells [29]. The inactivation of *NeuroD* causes a significant reduction in endocrine cell numbers and impaired islet formation [30]. Further, *Ptf1a*-null mice completely lack exocrine acinar cells but have a small number of endocrine cells [31,32].

Regulation of Endocrine Development by Exocrine Cells during Embryonic Stages

Kodama et al. reported that the exocrine-specific inactivation of *Pdx1* by Elastase-Cre causes not only hypoplastic exocrine formation but also substantial endocrine defects resulting in a diabetic phenotype [33]. Defects in endocrine development include impaired tip/trunk patterning of the developing ductal structure, accelerated apoptosis, reduced number of Ngn3-expressing endocrine precursors, and ultimately fewer β cells. In addition, postnatal expansion of the endocrine cell content was extremely poor. These findings indicate the existence of several exocrine-driven factors that regulate proper endocrine development and function. Using microarray-based analysis of the same mutant mice and an *in vitro* explant culture of embryonic pancreatic tissue, Hirata et al. identified Trefoil factor 2 (TFF2) as a novel exocrine factor that supports the survival of endocrine cells in the multiple stages of organogenesis through distinct receptors: TFF2 prevents the apoptosis of insulin-producing cells and $Nkx6.1^{+}$ endocrine precursors via CXCR4 receptor and an unknown receptor for TFF2, respectively [34] (Fig. 10.2). Future study warrants the identification of other exocrine-driven factors that regulate endocrine development, and it may be possible that the same embryonic machinery is reactivated in the pathogenic situation in adult organ.

Intra-Islet Crosstalk for Cell Function and Identity

Recent advances in islet biology include the molecular mechanism of intra-islet communications that orchestrate hormone secretion and govern cell state plasticity.

Intra-Islet Communication in Hormone Secretion

Pancreatic islets are composed of five major cell types secreting different hormones: glucagon$^+$ α cells, insulin$^+$ β cells, somatostatin$^+$ δ cells, pancreatic polypeptide (PPY)$^+$ γ cells, and ghrelin$^+$ ε cells. Inside the islet, these endocrine cells have heterogeneous contacts with each other and establish intra-islet crosstalk via paracrine signals, and all play critical roles in the maintenance of blood glucose hemostasis in the body. It should be noted that not only major pancreatic hormones but also several proteins secreted from α and β cells are involved in transmitting intra-islet crosstalk. These transmitters include α-cell-derived glucagon-like peptide 1 (GLP-1) and acetylcholine (Ach), β-cell-derived serotonin (5-HT), and urocortin3 (UCN3) secreted from α and β cells in humans (Fig. 10.3).

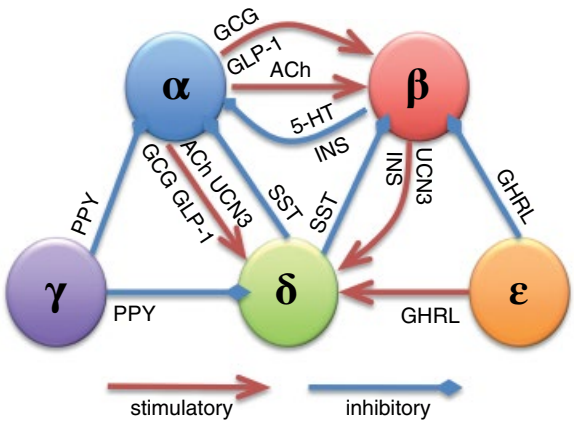

Figure 10.3 Intra-islet crosstalk regulates hormone secretion. Note the reciprocal regulation among endocrine cells to determine the amount of hormone secretion. Ach: acetylcholine; GCG: glucagon; GHRL: ghrelin; GLP-1: glucagon-like peptide 1; INS: insulin, PPY: pancreatic polypeptide; SST: somatostatin; UCN3: urocortin 3; 5-HT: serotonin.

In detail, signaling molecules from α cells, including glucagon and GLP-1, enhance insulin secretion through glucagon and GLP-1 receptors by increasing intracellular cyclic AMP levels [35–37]. Furthermore, ACh released from α cells regulates insulin secretion both positively and negatively; it directly acts on β cells to stimulate the secretion and indirectly suppresses the secretion via δ cells [38,39]. In turn, β-cell signaling molecules, including insulin and 5-HT, suppress α-cell secretion, establishing a paracrine feedback loop between α and β cells [40]. Delta cells are powerful inhibitory modulators of α- and β-cell signaling. Somatostatin secreted from δ cells predominantly functions as a paracrine suppressor to glucagon and insulin secretion in response to stimulatory cues from α or β cells (such as insulin, UCN3, glucagon, GLP-1, and ACh), providing negative feedback loops [38,39,41,42]. Additionally, PPY secreted from γ cells potentiates insulin secretion by inhibiting somatostatin secretion and directly suppressing glucagon secretion [10,11]. Recent studies showed that ghrelin secreted from ε cells suppresses insulin secretion directly and indirectly through enhanced somatostatin secretion [43,44].

The aforementioned mutual communication among islet cells seems to serve as a safety valve to maintain glucose homeostasis for the disease condition; however, intra-islet crosstalk itself is reported to be disturbed in diabetes. Accumulating evidence has shown that α-cell functions and gene expressions are compromised in T1D [45], indicating an impaired counterregulatory response to hypoglycemia [46]. Further, β-cell destruction in T1D decreases intra-islet UCN3 levels, which could lead to the attenuation of somatostatin inhibitory circuits and thus result in exaggerated hyperglycemia via α-cell-derived glucagon action [41]. Therefore, further investigation of impaired intra-islet signaling is required for developing new therapeutic strategies [47,48]. Of note, the islet microenvironment contains non-endocrine cells, including vasculatures, neurons, and immune cells, all of which play significant roles in controlling hormonal outputs from the islet [49,50]. The involvement of these cells in the impaired intra-islet crosstalk in diabetic patients should be clarified.

Intra-Islet Crosstalk for Cellular Identity

Previous studies showed that murine islet cells possess a plasticity to transdifferentiate into other cell types in response to cellular stress or cell death. Talchai et al. demonstrated that murine β cells stop insulin expression under severe metabolic stress and a subset of them dedifferentiate into neurogenin3-expressing endocrine precursor-like cells [51]. In addition, α cells can convert into insulin-producing cells upon near total β-cell loss in mouse diabetic models [52]. However, it was reported

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 10.4 Intra-islet crosstalk maintains cell identity. Murine α-cell identity is maintained by insulin and hedgehog signals secreted by surrounding β and δ cells, respectively.

that the percentage of α cells that can transdifferentiate is only 1–2%; thus, the majority of cells are refractory to the cell fate change.

Recent studies have shown that intra-islet crosstalk also plays important roles in maintaining the identity of islet cells (Fig. 10.4). Cigliola et al. revealed that, even without β-cell ablation, blockade of the insulin pathway in α cells, either by insulin receptor knockout or by treatment with insulin receptor antagonists, caused α-to-β-cell transdifferentiation [12]. In addition, the inhibition of δ-cell-driven hedgehog signaling in α cells promotes α-cell conversion into insulin-producing cells [12]. These findings clearly show that α-cell identity is maintained by paracrine permissive signals derived from proximate β and δ cells in mice. As to the plasticity of human islet cells, the first evidence was provided when α and γ cells were observed to transdifferentiate into insulin-producing cells upon Pdx1 and MafA overexpression *in vitro* [53]. However, it is still an open question if transdifferentiation to other cell types upon cellular stress occurs, or if similar intra-islet crosstalk functions to maintain cellular identity in human islets *in vivo*. Future study is warranted.

Epidemiology and Etiology of Alcohol-Induced Pancreatitis

Jeremy S. Wilson[1,2], Romano C. Pirola[1,2], and Minoti V. Apte[1,2]

[1] *Pancreatic Research Group, South Western Sydney Clinical Campus, School of Clinical Medicine, UNSW Medicine and Health, University of New South Wales, Sydney, NSW, Australia*
[2] *Ingham Institute for Applied Medical Research, Liverpool, NSW, Australia*

Introduction

Alcoholic pancreatitis represents a clinical paradox. On the one hand, the risk of developing the disease increases with the amount of alcohol consumed, suggesting direct toxic effects of alcohol on the pancreas. On the other hand, only a minority (5% or less) of heavy drinkers develop the disease, suggesting a role for individual susceptibility factors. (Note: In this text, the words "alcohol" and "ethanol" are used interchangeably.)

Epidemiology

In Western society, alcohol ranks with gallstone disease as a major cause of acute pancreatitis, and is the major cause of chronic pancreatitis. There has been variation in attribution rates amongst different studies [1–4]. This variation most likely relates to the background alcohol consumption of the population under study, the types of institutions surveyed (e.g., private facility vs. county or Veterans Affairs facilities in the United States), the difficulties associated with eliciting an accurate alcohol consumption history, and the growing awareness of possible cofactors in the disease (e.g., smoking). There is evidence that the incidence of acute episodes of alcoholic pancreatitis is rising in many Western countries [5].

For a long time, acute alcoholic pancreatitis and chronic alcoholic pancreatitis were considered separate diseases [6]. It is now generally recognized that they are a part of the same continuum. There is good clinical [7,8] and experimental evidence [9,10] that repeated attacks of pancreatic necroinflammation lead to chronic pancreatitis (the necrosis-fibrosis sequence).

With respect to the amount of alcohol consumption required to produce pancreatitis, there has been confusion. Episodic binge drinking or the isolated alcoholic debauch rarely, if ever, causes pancreatitis [11]. However, with regard to the common situation of chronic alcohol intake, an early study suggested that the risk of developing pancreatitis was linear, even at relatively low (social) levels of consumption [12]. Later studies have suggested that there is a threshold above which pancreatitis is more likely to occur [2,13,14]. A recent meta-analysis found that the risk of chronic pancreatitis increased 2.5-fold at 50 g/day consumption and approximately sixfold at 100 g/day consumption [15].

Most clinicians, basing their views on clinical experience, would agree that the diagnosis is not made in the absence of chronic heavy alcohol consumption (80–100 g of alcohol per day for at least 5 years). However, alcoholic pancreatitis is now emerging as a polyfactorial/polygenic disease, so that lesser amounts of alcohol consumed may also be responsible for the phenotype.

Pathogenesis

Large Duct and Small Duct Theories

Historically, studies of pathogenesis of alcoholic pancreatitis centred first on the sphincter of Oddi and the large pancreatic ducts and subsequently on the small pancreatic ducts. The "large duct" theories gradually lost support because of a failure of consensus on the effects of alcohol on sphincter of Oddi motility, the effect of alcohol on pancreatic secretion and other factors. The "small duct" theory lost support over failure to establish the primary role of protein plugs in small pancreatic ducts in the pathogenesis of the disease. These "duct" theories have been dealt with in greater detail elsewhere [16].

Direct Cellular Effects of Alcohol on the Pancreas

From the 1980s, attention focused on the direct effects of alcohol on pancreatic acinar cells; from around 2000, on pancreatic stellate cells and, most recently, on pancreatic duct cells. The results of these studies, conducted largely in rodents, are depicted in Fig. 11.1.

It should be emphasized that there is no satisfactory model of alcoholic pancreatitis. In experimental animals, alcohol by itself induces a number of changes that predispose the pancreas to autodigestion, acinar injury, and stellate cell activation, but which are insufficient to cause overt pancreatitis. However, co-administration of an additional "hit" such as bacterial endotoxin produces pancreatitis (necroinflammation and fibrosis) as delineated in greater detail below.

The recently described Gao-binge model [17] results in pancreatic damage but involves pair feeding of liquid diets followed by a single gavage of diet equivalent to 5 mg/kg ethanol, which equates to 35 standard drinks in a 70 kg male. Although the mortality of this model is reported to be zero, one must query whether the changes reported represent an effect of ethanol per se or perturbation of cardiovascular and other systems.

Metabolism of Alcohol by the Pancreas

Many of the direct effects of alcohol on the pancreas are a consequence of the metabolism of alcohol (ethanol) by the gland via oxidative and nonoxidative pathways.

The oxidative pathway of alcohol metabolism involves sequential oxidation by alcohol dehydrogenase (ADH) to acetaldehyde and then to acetate via acetaldehyde dehydrogenase (ALDH). Catalase in peroxisomes can also metabolize ethanol to acetaldehyde but its activity is thought to be low as it is determined by the availability of its substrate hydrogen peroxide (H_2O_2). Additionally, cytochrome P450 2E1 (CYP2E1) can metabolize ethanol, at high concentrations, to acetaldehyde and this is enhanced by enzyme induction following chronic ethanol exposure [18]. Both ADH and CYP2E1 have been identified in pancreatic tissue (catalase is ubiquitous) [19–21]. The oxidative pathway results in depletion

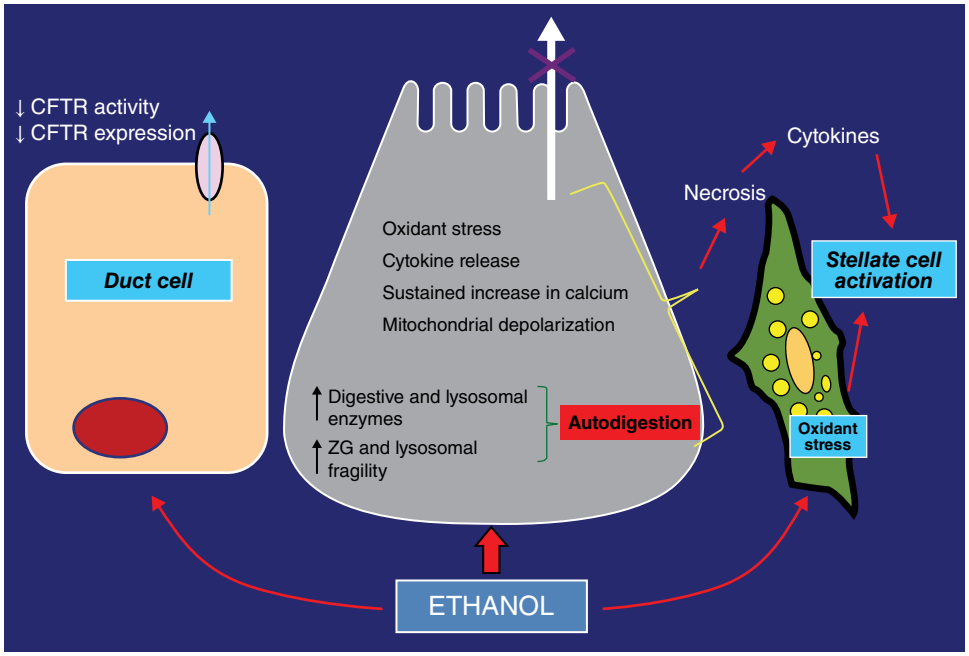

Figure 11.1 Effects of alcohol and its metabolites on the acinar cell, duct cell, and stellate cell of exocrine pancreas. Ethanol induces an increase in digestive and lysosomal enzyme synthesis in the acinar cell, while at the same time, decreasing exocytosis and impairing organelle stability. These effects predispose the cell to premature intracellular enzyme activation and autodigestion. Ethanol metabolism within the cell leads to oxidant stress which damages subcellular membranes, proteins, and nucleic acids. In addition, ethanol causes a sustained increase in intracellular calcium leading to mitochondrial depolarization and cell death. The ethanol-induced injury to the acinar cell also results in the release of cytokines by the cell, which can subsequently damage neighboring cells. Ethanol impairs duct cell function by decreasing CFTR expression and activity. With regard to the pancreatic stellate cell, ethanol and its metabolites and oxidant stress activate PSC leading to production of excessive amounts of extracellular matrix proteins. Cytokines released from acinar cells can also activate PSC via paracrine pathways, while cytokines synthesized by PSC themselves can further activate the cells in an autocrine manner, leading to progressive fibrosis, even in the absence of the initial trigger. *Source:* Pancreatic Research Group, UNSW Sydney.

of antioxidant defences (mainly glutathione) and the production of reactive oxygen species capable of disruption of membranes, proteins, and DNA.

The nonoxidative pathway involves esterification of ethanol with free fatty acids (FFA) to form fatty acid ethyl esters (FAEE). The enzymes catalyzing this reaction are fatty acid ethyl ester (FAEE) synthases. There appears to be no one enzyme responsible for this reaction, and carboxyl ester lipase (CEL) and triglyceride lipase have been implicated. It has been reported that the pancreas has the highest FAEE synthesizing capacity of any parenchymal organ [22].

FAEE are believed to exert toxicity via:

- direct perturbation of biological membranes following intercalation, and
- a transport shuttle mechanism with local release of FFA resulting in disturbance of intracellular membrane function with decreased lysosomal stability (*vide infra*) and altered intracellular calcium homeostasis with resultant calcium overload, mitochondrial dysfunction and cell death.

The pancreatic acinar cell possesses the enzymatic machinery for both oxidative and nonoxidative ethanol metabolism, with the former representing the major pathway for alcohol metabolism [19–21] in rats. Kinetic studies using rat pancreatic acini suggest that ethanol is metabolized in acinar cells predominantly by Class III (high Km) ADH [19,20]. However, Chiang et al. reported that the predominant class of ADH in human pancreatic acini is ADH I, with ADH III contributing little to pancreatic alcohol oxidation [23]. These disparate findings may reflect species differences and the relative magnitudes of the oxidative and nonoxidative pathways in human pancreatic tissue remain to be determined. However, even in rat pancreatic acinar cells, where oxidative metabolism of ethanol seems to dominate, the contribution of the nonoxidative pathway cannot be discounted because FAEE are produced in sufficient amounts to produce local injury [24]. Interestingly, pharmacological inhibition of the FAEE synthase CEL ameliorates alcohol-induced pancreatic damage in mice [25]. A recent study suggests that circulating FAEE levels may be useful as a specific biomarker for acute alcoholic pancreatitis (as distinct from nonalcoholic acute pancreatitis) [26].

Rat pancreatic stellate cells (PSC) can also oxidize alcohol to acetaldehyde via a pyrazole–sensitive (Class I) ADH [27]. These observations are well supported by a study reporting activity of an ADH Class I isozyme, namely ADH1C, in quiescent human PSC, which was inhibited by pyrazole [23]. Interestingly, this study also showed that the expression of ADH1C was increased in activated human PSC in chronic pancreatitis [23]. The capacity of PSC for nonoxidative ethanol metabolism is yet to be determined.

Effects of Ethanol on Pancreatic Acinar Cells

Chronic alcohol administration to rodents results in a number of changes in acinar cells which may predispose the cells to injury.

In vitro and *in vivo* approaches have now established that ethanol and its metabolites exert multiple effects on acinar cells including:

- an increase in intracellular levels of digestive enzymes (trypsin, chymotrypsin, and lipase) mediated, at least in part, by increases in their respective mRNA levels [28] and possibly also by decreased secretion secondary to acetaldehyde-induced apical microtubule disruption [29] and inhibition of binding of secretagogues to their receptors [30];
- an increase in lysosomal enzyme content [28,31];
- decreased stability of lysosomes mediated by accumulation of FAEE and cholesteryl esters (transesterification products of FAEE) in the cells [24,32];
- decreased zymogen granule (ZG) stability [33], possibly mediated by an ethanol-induced reduction of GP2 [34], the predominant protein in ZG membranes that is responsible for ZG shape and membrane stability.

Taken together, the effects of alcohol on lysosomes and ZGs create a situation whereby there is an increased potential for contact between trypsinogen and lysosomal hydrolases with subsequent generation of active trypsin, thus activating an intracellular digestive enzyme cascade and autodigestion.

- FAEE cause a sustained rise in intracellular calcium levels by (i) inducing calcium release from endoplasmic reticulum following stimulation of IP_3 receptors, and (ii) inhibiting Ca^{++}ATPase pumps in plasma membrane and endoplasmic reticulum (ER) resulting in defective clearance of cytosolic calcium. The sustained rise in calcium levels causes mitochondrial overload and cell death [35].
- Transcription factors NF-κB and AP-1 (which are important regulators of cytokine expression) are induced by alcohol and acetaldehyde as well as by FAEE [19].

The unfolded protein response/ER stress and autophagy are two homeostatic mechanisms for maintaining cellular integrity in all cells. Recent studies have demonstrated that chronic alcohol consumption induces ER stress [36,37] and impairs autophagy [17,38] in pancreatic acinar cells.

Effects of Ethanol on Pancreatic Stellate Cells

PSC are the principal source of collagen and other extracellular matrix proteins in the fibrosis of chronic alcoholic pancreatitis. PSC are directly activated upon exposure to

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. ethanol [27,39]. This activation is thought to be mediated via the metabolism of alcohol to acetaldehyde and the subsequent intracellular generation of reactive oxygen species [27].

PSC are also activated by inflammatory cytokines (released during pancreatic necroinflammation) and, in turn, produce their own inflammatory cytokines resulting in an autocrine loop allowing perpetuation of activation even after removal of the initial insult [40–44].

Effects of Ethanol on Pancreatic Duct Cells

Inspired by the original observations of Sarles et al. [6] on pancreatic intraductal abnormalities and sweat electrolytes in patients with chronic alcoholic pancreatitis, Maleth et al. [45] have recently examined the effect of ethanol on CFTR function. This was impaired (as determined by sweat chloride concentration) in recently abstinent alcoholics and in acutely drinking alcoholics with very high blood alcohol concentrations but not in normal individuals consuming alcohol acutely. In addition, it was found that in duct cells isolated from alcoholic pancreatitis tissue, CFTR expression was decreased at both mRNA and membrane protein levels, with evidence of impaired posttranslational processing. In *in vitro* experiments using duct cell lines and tissue from mice and guinea pigs, ethanol decreased CFTR mRNA as well as membrane CFTR levels and stability; these effects were reported to be mediated by nonoxidative metabolites of ethanol.

Regulation of Gene Expression in Alcoholic Pancreatitis

Chhatriya et al. [46] in a preliminary study involving analysis of serum from a small number of patients ($n = 4$) with alcoholic pancreatitis or alcoholics without pancreatitis ($n = 4$, controls "normal") and pancreatic tissue from patients with alcoholic pancreatitis (data from existing datasets) have identified 14 miRNA differentially expressed between index and controls, in both serum and pancreas. Network analysis was performed to identify the differentially expressed genes regulated by these miRNA as well as the transcription factors that influence the expression of the selected miRNA. The findings indicate that both inflammatory and anti-inflammatory pathways are modulated in alcoholic pancreatitis patients, but given the limitation of sample sizes and lack of experimental validation of the functional consequences of the miRNA/gene changes, the study does not provide any conclusive insights into the pathogeneis of alcoholic pancreatitis. Clearly, much more work is required in this area.

RNA Seq methodology has been employed using tissue derived fom human pancreatic transplantation involving subjects with idiopathic, hereditary, and alcoholic pancreatitis. With respect to alcoholic pancreatitis the number of patients ($n = 2$) is too small to draw meaningful conclusions [47].

Individual Susceptibility to Alcoholic Pancreatitis

Despite the substantial experimental evidence supporting direct toxic effects of alcohol and its metabolites on the pancreas, it is well established that only a minority of alcoholics develop clinically evident pancreatitis [48,49], suggesting that additional factors are required to induce the disease in heavy drinkers. The search for these cofactors has prompted many studies, as summarized in Table 11.1.

Ideally, studies into individual susceptibility to alcoholic pancreatitis should compare alcoholics *with* the disease and alcoholics *without* the disease so that the index and the control groups differ in only one variable, i.e., the presence or absence of pancreatitis. This has not always been the case, with several studies using only the healthy population as a control group.

Environmental Factors

Dietary Factors

There is no clear evidence that dietary factors play a role in individual susceptibility to alcoholic pancreatitis [50] especially with respect to macronutrients. Properly controlled studies of dietary micronutrients, antioxidants and other micronutrients are yet to be performed.

Beverage Type and Periodicity of Drinking

Similarly, there is no evidence that the type of alcoholic beverage consumed plays any part in susceptibility to alcoholic pancreatitis [50], although the congeners of alcoholic beverages have not been studied exhaustively.

Additionally, it has not been established that the periodicity of drinking is a susceptibility factor in this disease [50]. Although there have been occasional reports implicating binge drinking, most patients imbibe alcohol at high levels constantly, prior to the initial presentation.

Smoking

The role of smoking as a trigger factor for alcoholic pancreatitis has been a particularly contentious subject [51,52]. The vast majority of heavy drinkers are also smokers, making it difficult to demonstrate unequivocally an independent role for smoking in the initiation of pancreatitis. Law et al. [53] concluded that smoking is independently associated with chronic pancreatitis, after adjusting for alcohol and other risk factors. However, the retrospective nature of the study made it difficult to

stratify accurately the extent of smoking and alcohol use. Furthermore, the study population included patients with chronic pancreatitis with a variety of etiologies; only a small proportion of the study subjects were heavy drinkers.

While the role of smoking as an *initiating* factor in alcoholic pancreatitis remains uncertain, there is evidence to suggest that it may *facilitate the progression* of the disease as evidenced by the accelerated development of pancreatic calcifications and endocrine dysfunction in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

patients with alcoholic pancreatitis who smoke [54]. To study the possible mechanisms of this, Lugea et al. [55] exposed mouse and human acinar cell lines to cigarette smoke extract and/or ethanol. Cigarette smoke and ethanol, but neither agent alone, induced oxidative stress and cell death. The authors also reported that in a rat model of ethanol feeding plus LPS, exposure to cigarette smoke promoted cell death and features of pancreatitis by suppressing the adaptive unfolded protein response signaling pathway and increased ER stress pathways in acinar cells.

Obesity

Another putative risk factor for alcoholic pancreatitis is obesity. Using a prospectively recruited cohort of patients with alcoholic chronic pancreatitis and age- and sex-matched healthy subjects as controls, Ammann et al. [56] reported that obesity prior to onset of chronic pancreatitis, defined as body mass index greater than 30 was fivefold more frequent in patients with alcoholic chronic pancreatitis compared to healthy controls, but had no effect on disease progression. However, as obesity is highly prevalent in asymptomatic alcoholics compared to the general population [57], the lack of an appropriate control group (alcoholics without pancreatitis) in the Ammann study [56] precludes any definitive conclusions regarding obesity as a susceptibility factor for the development of alcoholic pancreatitis.

Lipid Intolerance

Alcohol abuse can cause hypertriglyceridemia and hypertriglyceridemia (at exceptionally high levels of serum triglycerides) is a known cause of acute pancreatitis. These facts have led to speculation that those alcoholics who develop pancreatitis do so via the development of hypertryglyceridemia. However, when postprandial lipid tolerance was studied in patients with alcoholic pancreatitis (index group) no difference was found compared with a control group comprising alcoholics without pancreatitis [58]. This study emphasized the importance of appropriate controls in studying susceptibility to alcoholic pancreatitis.

Endotoxin

Serum endotoxin levels are increased in alcoholics, even after a single binge, most likely due to an alcohol-induced increase in gut permeability permitting translocation of gram-negative bacteria (such as *E. coli*) across the mucosal barrier and decreased clearance of endotoxin by Kupffer cells in the liver [59,60]. Forsyth et al. [61] have shown that alcohol increases the permeability of Caco-2 intestinal epithelial cell monolayers via CYP2E1-induced oxidant stress, which in turn induces the circadian clock proteins, CLOCK and PER2.

Experimental studies support the concept of bacterial endotoxin (lipopolysaccharide, LPS) as a promising susceptibility factor for alcoholic pancreatitis. Vonlaufen et al. [62] reported evidence that endotoxin (LPS) challenge in alcohol-fed rats initiates overt pancreatic injury and also stimulates progression to chronic disease manifesting as acinar atrophy and fibrosis. Importantly, this effect was abrogated in TLR4 (Toll-like receptor 4, LPS receptor) knockout rodents [63], demonstrating the specificity of the effects of LPS on pancreatic cells). These studies were corroborated by the findings of Li et al. [64] of increased LPS levels in the portal blood of ethanol-fed rats accompanied by evidence of pancreatic injury, increased pancreatic expression of collagen I (mRNA and protein), increased expression of TLR4 (mRNA and protein), increased numbers of PSC and increased TLR4 protein expression in pancreatic macrophages and stellate cells.

Further work is needed to determine whether genetic polymorphisms pertinent to the alcohol-induced hyperpermeability/endotoxin paradigm may explain individual susceptibility to alcoholic pancreatitis (*vide infra*).

Hypophosphatemia

Recently, Farooq et al. [65] demonstrated that mice on a low phosphate diet and given alcohol developed pancreatitis reversible with phosphate supplementation. Hypophosphatemia impairs ATP production and mitochondrial function, and has been reported to occur in several acute illnesses including acute pancreatitis [66]. Acceptance of such a hypothesis would require a comparison of alcoholics with and without pancreatitis.

In summary, in terms of environmental factors, a clear and single susceptibility factor for alcoholic pancreatitis remains to be identified.

Hereditary Factors

There have been major advances in documenting hereditary factors in the pathogenesis of pancreatitis. However, these have not translated widely into the management of alcoholic pancreatitis. This may be because abstinence remains the mainstay of treatment and because of the current costs of genetic testing. A large study by Gurakar et al. [67] showed that the percentage of patients initially diagnosed as idiopathic pancreatitis can be reduced by genetic testing but the authors did not test their patients diagnosed as alcoholic pancreatitis.

Polymorphisms of Alcohol Metabolizing Enzymes

Alcohol toxicity is most likely to depend on its metabolism generating toxic metabolites such as acetaldehyde, FAEE, and reactive oxygen species. Increased or decreased activities of alcohol metabolizing enzymes (ADH, ALDH, CYP2E1, FAEE synthases) may result in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the accumulation of toxic metabolites and tissue damage (*vide supra*).

ADH and ALDH are the major enzymes of oxidative alcohol metabolism in the body. There are multiple ADH and ALDH enzymes encoded by different genes which can exist as several allelic variants. These variants can influence rate of metabolism and their distribution varies between ethnic groups as well as different tissues in the body [18].

Based on amino acid sequence and structural similarities, human ADH enzymes are now classified into five classes. The three Class I enzymes (ADH1A, ADH1B, and ADH1C) are the major contributors to ethanol clearance in the liver [18].

There are two main groups of ALDH enzymes, cytosolic ALDH 1 and mitochondrial ALDH2. ALDH2 is the major enzyme responsible for the oxidation of acetaldehyde to acetate [18].

Most attention to ADH-mediated metabolism/damage in alcoholic pancreatitis has been centered on the *ADH1B* gene. In Asian populations, the *ADH1B*2* allele predominates and encodes for the more active β2-ADH subunit that produces acetaldehyde at a much faster rate than the more common *ADH1B*1* allele (wild type) [68,69]. Several Japanese studies have demonstrated that the frequency of the *ADH1B*2* allele is increased in patients with alcoholic pancreatitis compared to alcoholics without pancreatitis [69–71]. In the Japanese population, a decreased frequency of the *ADH1B*1* allele has also been reported suggesting that this allele "reduces vulnerability" [71,72].

A recent meta-analysis of eight case-control studies evaluating the association of ADH1B, ADH1C, and ALDH2 variants in alcoholic pancreatitis found a higher risk for carriers of the *ADH1B*2* allele and a lower risk for the *ALDH2*2* allele (coding for a metabolically nearly inactive protein) in Asian patients [73]. In non-Asian subjects, the *ADH1C*2* allele was associated with decreased risk [73].

Genetic polymorphisms have been described in the promoter region as well as in intron 6 of the *CYP2E1* gene, some of which are associated with altered function [74]. However, no polymorphism has been associated with alcoholic pancreatitis, in studies of alcoholics without pancreatitis as controls.

Mutations of FAEE Synthase Enzymes

One study reported a positive association between the risk of developing alcoholic pancreatitis and a polymorphism of the gene for one of the candidate FAEE synthase enzymes, CEL, in Japanese subjects [75]. The investigators employed alcoholics without pancreatitis as controls. The functional significance of this polymorphism has not yet been elucidated, and the study findings have not been corroborated in a study involving European subjects [76]. A more recent study has reported an association between a hybrid allele of the CEL gene (*CEL-HYB*) and alcoholic chronic pancreatitis [77]; however, the controls used were healthy subjects and not alcoholics without pancreatitis. Based on *in vitro* studies using HEK293 cells, the authors report that the resulting CEL-HYB protein may cause cell injury by impairing autophagy [77].

Trypsinogen Gene Mutations

The landmark report of Whitcomb et al. [78] in 1996 implicating a mutation in the cationic trypsinogen gene (R122H) in hereditary pancreatitis greatly strengthened the notion that trypsin may be central to the pathogenesis of pancreatitis. Certainly this discovery inspired a great amount of work into the pathogenesis of hereditary pancreatitis with a number of other mutations subsequently described.

Using a similar candidate gene approach, studies in alcoholic pancreatitis largely have been negative. A protective variant (G191R) of the anionic trypsinogen gene *PRSS2*, resulting in an easily degraded form of trypsin, was reported to be significantly less common in patients with alcoholic chronic pancreatitis compared to healthy controls, but the prevalence of this variant in alcoholics without pancreatitis was not tested [79].

The results of two large genome-wide association studies (GWAS), one from North America [80] and the other from Europe [81] have been published. A significant association in the *PRSSI*/*PRSS2* locus at 7q34 was detected (rs10273639). This single nucleotide polymorphism (SNP) rs10273639 is located in the 5′ promoter region of *PRSS1* and may affect expression of the trypsinogen gene. Both investigating teams found a decrease in alcoholic pancreatitis risk with rs10273639. This association was not observed in nonalcoholic chronic pancreatitis nor in patients with alcoholic liver disease, although there was no control group of alcoholics without pancreatic or liver disease. The functional significance of rs10273639 awaits clarification.

Claudin 2 Mutations

A second association of alcoholic pancreatitis was revealed by the aforementioned GWAS [80,81], involving the *CLDN2-RIPPLY1-MORC4* locus (Xp23.3, SNPs rs7057398, and rs12688220). *CLDN2* encodes claudin 2, a tight junction protein. The authors again found a decreased risk of alcoholic pancreatitis associated with the *CLDN2* locus SNP rs12688220. The functional significance of this *CLDN2* SNP remains unclear.

In chronic pancreatitis tissue sections, claudin 2 is expressed in duct cells and acinar cells and there is aberrant expression along the basolateral membrane of acinar cells in the presence of the high-risk SNP [80]. There is an intriguing possibility that the SNP reported influences the function of claudin 2 in the intestine, influencing

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. intestinal permeability and the possibility of endotoxemia in those alcoholics susceptible to pancreatitis (*vide supra*). Upregulation of pore-forming claudin 2 has been implicated in increased intestinal permeability in Crohn's disease [82].

SPINK 1 Mutations

An association between mutated *SPINK1* and alcoholic pancreatitis has also been described. The N34S mutation, a c.101A>G transition leading to substitution of asparagine by serine at codon 34, was found in 5.8% patients with alcoholic pancreatitis, compared to 1.0% alcoholic controls without pancreatitis [83]. A more recent study on Romanian patients has reported that 5% of patients with ACP had the N34S mutation compared to 1% of healthy controls [84]. A meta-analysis found a significant association of the N34S mutation with alcoholic pancreatitis with an odds ratio of 4.98 (95% confidence interval: 3.16–7.85) but the association was the weakest among categories analyzed including tropical pancreatitis, idiopathic chronic pancreatitis, and hereditary pancreatitis [85]. Since the N34S mutated human *SPINK1* does not show any altered trypsin inhibitor capacity, the functional consequences of this mutation are unclear.

Chymotrypsin Gene Mutations

Chymotrypsin C (CTRC) is a minor isoform of chymotrypsin. In a German study, in individuals with idiopathic or hereditary chronic pancreatitis, various CTRC variants have been found and the two most frequent variants were detected in 3.3% of pancreatitis patients but only in 0.7% of controls [86]. In individuals with alcoholic pancreatitis both variants have been detected more often (2.9%) than in patients with alcoholic liver disease (0.7%) [86]. In a Chinese population more CTRC variants were detected in chronic pancreatitis patients but the overall frequency of mutations was 2.3% and thus lower than in the European study [87].

CFTR Mutations

CFTR mutations have been implicated in a subset of patients with idiopathic pancreatitis [88,89]. In addition, it has been demonstrated, in both animal and human studies, that CFTR expression and function are impaired by alcohol [45]. However, there is an overall lack of evidence implicating CFTR mutations in the pathogenesis of alcoholic pancreatitis. A small study from Brazil showed that patients with alcoholic pancreatitis showed a higher frequency of the T5/T7 genotype in the noncoding region of thymidines in intron 8, suggesting reduced transcription of the *CFTR* gene [90]. Clearly additional and larger studies are needed.

Other Hereditary Factors

A number of other hereditary factors have also been examined as possible triggers for alcoholic pancreatitis. These include blood group antigens [91,92], HLA serotypes [93], alpha-1-antitrypsin phenotypes [94], genotypes of the cytokines transforming growth factor beta (TGFβ) [95], tumor necrosis factor α (TNFα) [95], interleukin 10 [95], and interferon gamma [95], and genotypes of detoxifying enzymes such as UDP glucuronosyl transferase (UGT1A7) [96,97] and glutathione *S*-transferase [98], and calcium sensor receptor genotypes [99,100]. Most studies have failed to show any association with alcoholic pancreatitis, although one recent study has reported a positive association between the risk of developing alcoholic pancreatitis and fucosyl transferase (FUT2) non-secretor status as well as with ABO blood group B status [101]; further work is awaited.

Summary

Since the first association of alcohol excess with pancreatitis more than 200 years ago, understanding of the disease "alcoholic pancreatitis" has undergone considerable conceptual refinement. Although alcohol excess remains a central and definitional component of the disease phenotype, it is clear that the disease is multifactorial/polygenic and that further work is needed to tease out the various pathogenetic components and their inter-relationships.

Acknowledgment

The authors gratefully acknowledge the assistance of Craig Smith with the preparation of this manuscript

Epidemiology and Etiology of Biliary Acute Pancreatitis

Ippei Ikoma, Ko Tomishima, and Hiroyuki Isayama

Department of Gastroenterology, Graduate School of Medicine, Juntendo University, Tokyo, Japan

Introduction

Acute biliary pancreatitis (ABP) is caused by a primary common bile duct stone (CBDS) or a CBDS that has moved from the gallbladder. Common channel, duodenal reflux, and ductal hypertension hypotheses for the etiology of ABP are posited. CBDS passage or impaction at the common channel can cause ABP. The treatment strategies for ABP differ from those of other types of acute pancreatitis (AP).

Endoscopic biliary drainage may improve the outcome, and differential diagnosis is important for patients with AP. Abdominal ultrasound, CT, MRI/MRCP, and endoscopic ultrasound (EUS) can be used to diagnose CBDS. EUS has the highest detectability among these modalities but requires an expert endoscopist and is relatively invasive. The standard of care of ABP is treatment of AP with/without endoscopic treatment following cholecystectomy when gallstones are detected. The timing of endoscopic and surgical treatment of ABP is controversial. Here, we summarize recent advancements in the etiology, epidemiology, clinical features, diagnosis, and treatment strategies (including endotherapy and cholecystectomy) of ABP.

Etiology

Biliary pancreatitis is caused by stone passage from the common bile duct to the duodenum through the papilla, including the sphincter of Oddi and common channel. Acosta and Ledesma analyzed the feces of patients with gallstones and pancreatitis and found gallstone in the feces of 94%. By contrast, only 8% of patients with simple gallstone attacks without pancreatitis had gallstones in their feces [1]. Passage of a CBDS through the papilla may cause gallstone pancreatitis; however, the underlying mechanism is unclear. There are three hypotheses as to the mechanism by which gallstones cause acute pancreatitis: (i) common channel, (ii) duodenal reflux, and (iii) ductal hypertension.

Common Channel Theory

Opie et al. reported that a patient who died of acute pancreatitis had a stone lodged in the major duodenal papilla of the common duct of the bile and pancreatic ducts [2]. He proposed that the reflux of bile acids into the pancreatic duct caused the pancreatitis. Moreover, Opie injected bile acids into the dog pancreatic duct, which caused inflammation in the pancreas; other studies have yielded similar results [3]. It has become apparent, however, that no more than two-thirds of the population have such a common ductal channel [4,5] and, in many cases, this is so short that a stone obstructing the common bile duct would also obstruct the pancreatic duct.

The common duct is more frequently found in cases of acute biliary pancreatitis [6]. Passage of stones can cause stenosis of the major duodenal papilla, which may lead to functional obstruction of the common duct [7]. Because the pancreatic duct pressure is two- to threefold higher than that of the normal bile duct, pancreatic secretions flow into the bile duct more easily than bile flows back into the duct. The common channel hypothesis is supported largely by the results of the abovementioned studies [8,9].

Companion website: www.wiley.com/go/beger/thepancreas4e

Duodenal Reflux Theory

The second hypothesis is that pancreatitis is caused by the influx of duodenal contents into the pancreatic duct due to the passage of a stone. This mechanism was proposed in an animal study involving obstruction of the duodenum. Because ligation of the pancreatic duct did not cause pancreatitis, reflux of the contents was considered the main cause [10]. This phenomenon is rarely observed in humans and can cause acute pancreatitis due to obstruction after gastrectomy and duodenal or small bowel reconstruction [11,12].

However, the oblique course of the duct, the sphincter of Oddi, and the mucosal folds around the opening suggest that this is not the mechanism of pancreatitis. Although the sphincter may be injured immediately or shortly after the passage of gallstones, leading to reflux of duodenal contents, it is not thought that EST in ERCP (endoscopic retrograde cholangiopancreatography) causes gallstone pancreatitis or the development of pancreatitis due to reflux of duodenal contents [13]. In a study in rats, isotonic saline inflow into the pancreatic duct caused pancreatitis, suggesting that pancreatitis associated with duodenal obstruction may be related not only to reflux of duodenal contents but also to increased intestinal pressure.

Ductal Hypertension Theory

Learch et al., using opossums [14], compared the severity of pancreatitis in three groups: pancreatic duct alone ligated, pancreatic duct and bile duct separately ligated, and common duct ligated. The results showed no difference in disease severity among the groups, suggesting that bile reflux is not essential for the development or exacerbation of pancreatitis. Other studies have shown that continuous stimulation of secretion in the presence of pancreatic duct obstruction worsens pancreatitis [15]. When the obstruction of the pancreatic duct was released, the pancreatitis improved [16].

When pancreatic secretion is stimulated by obstruction of the pancreatic duct, it causes an increase in intraductal pressure. Although rare, increased intraductal pressure can also be caused by, for instance, duodenal papillary tumors, parasitic infections, and ERCP. Injections of various compounds into the pancreatic duct at high pressure can cause pancreatitis, and the injection pressure is more related to the development of pancreatitis than the absence of injected material [3]. The mechanism is thought to be rupture of the branched pancreatic duct and leakage of secretions into the interstitium or inhibition of secretion of pancreatic juice into the ductal lumen.

After ligation of the pancreatic duct, changes first occur within the glandular cells rather than in the stroma or around the pancreatic duct. High pressure in the lumen of the gland causes exocytosis of zymogens and inhibits the release of Ca ions from the gland cell membrane [17]. Disruption of the cell membrane and its transporter channels inhibits the recovery of Ca ion concentration that occurs after stimulation of CCK. An increase in calcium ion concentration in the entire glandular cell leads to intracellular activation of trypsin, which in turn activates various proteases, leading to self-digestion by pancreatic enzymes. CCK stimulation compounds the effect of ductal obstruction [16,18]. Disruption of acinar Ca^{2+} signaling is a key early event in the initiation of intra-acinar enzyme activation [19]. Experimentally, pancreatic duct obstruction causes inhibition of calcium ion signaling [20,21].

These three hypotheses are considered to be related in a complex way, as opposed to one being considered most likely. The development of acute pancreatitis may involve a combination of factors, because obstruction alone often causes biliary complications rather than pancreatitis. When gallstone passage occurs in patients with common ducts, pancreatitis is induced. However, once the stones are cleared, the activated pancreatic enzymes are drained and the pancreas recovers. As a result, only mild pancreatitis occurs clinically. Most cases will be mild, but in rare cases the flow of pancreatic juice, which is rich in digestive enzymes, may become obstructed, causing severe pancreatitis. Even if the stone is passed, severe disease typically develops.

Secondary obstruction may be due to edema of the pancreatic head or papillae after the passage of gallstones. Temporary obstruction of the pancreatic duct by multiple small stones has been reported. Large stones falling into the distal bile duct or papillary region can cause obstruction of the pancreatic duct. If this occurs in stages, it suggests that there is a possibility of preventing further obstruction in the early stages and preventing severe pancreatitis.

Epidemiology

Alcohol and gallstones are the two major causes of acute pancreatitis. In a 2016 survey in Japan, alcoholic was the most common cause (42.8%), followed by gallstone (19.8%) and idiopathic (16.2%) pancreatitis in males. In women, cholelithiasis was the most common (37.7%), followed by idiopathic (24.8%) and alcoholic (12.0%) pancreatitis. Alcoholic pancreatitis was more common among those in their 40s, and gallstone pancreatitis was more common among older adults [22]. Regarding the size of the stones, small stones have a higher risk of pancreatitis. Diehl et al. reported a fourfold increase in the incidence of pancreatitis if the stone diameter was less than 5 mm [23].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

In the Japanese report, about 60% of patients had passed stones and only about 25% had bile duct stones of 6 mm or more in diameter. Elevated serum pancreatic enzymes were common in patients with small stones. Also, about 70% of severe pancreatitis was due to naturally passed stones. These factors suggest that small bile duct stones are more likely to induce pancreatitis. Large stones are more likely to obstruct the bile duct before falling into the anatomically common duct, whereas small stones are more likely to fall into the common duct and cause pancreatic duct obstruction.

Clinical Features

It has been reported that 15% of acute pancreatitis develops into severe acute pancreatitis [24]. Gallstones and alcohol are the most common causes of acute pancreatitis, and there are various reports on the differences in severity and mortality. Gallstone pancreatitis is reportedly associated with more severe disease and mortality [25,26]. By contrast, ABP caused by alcohol is thought to be more severe, and the mortality rate is higher [27–29]. Some studies found no clear difference in clinical course between the two groups, and no definite conclusion has been reached [30–32]. In severe pancreatitis, intestinal bacteria migrate out of the intestinal tract at an early stage and cause pancreatic and peripancreatic infections. In the clinical course of acute pancreatitis, such complications of infection are thought to worsen the prognosis. Riity et al. reported differences in the bacterial flora of alcoholic and gallstone infections. A higher percentage of microbes is detected in gallstone pancreatitis, with Gram-positive bacteria being more common in alcoholic pancreatitis and gram-negative bacteria in cholecystic pancreatitis (80% vs. 20%) [33]. A case of severe acute biliary pancreatitis that progressed to walled-off necrosis is presented in Fig. 12.1 (Fig. 12.1a, b, c). This case required endoscopic drainage and necrosectomy because of infection.

Diagnosis of Acute Biliary Pancreatitis

Acute pancreatitis is treated differently depending on the etiology. ERCP improves the prognosis of ABP complicated by cholestasis/cholangitis, though ERCP is contraindicated for other types of acute pancreatitis. Therefore, it is important to distinguish ABP from other forms of pancreatitis because of the need for different treatment strategies.

Blood Tests

Bilirubin, AST, ALT, ALP, and gamma GTP levels should be measured in all patients to differentiate ABP from other-cause acute pancreatitis [34]. If the blood ALT level is more than 150 IU/L (sensitivity 48–93%, specificity 34–96%, positive Eudox ratio 1.4–12.0, negative Eudox ratio 1.8–4.9) [35,36], or if three or more of the five items (bilirubin, ALP, γGTP, ALT, and ALT/AST ratio) are abnormal (sensitivity 85%, specificity 69%, positive likelihood ratio 2.7, negative likelihood ratio 4.6), ABP is highly suspected. When combined with abdominal ultrasonography, it is possible to identify the cause of acute biliary pancreatitis with a sensitivity of 95–98%, specificity of 100%, positive likelihood ratio of ∞, and negative likelihood ratio of 20.0 to 50.0 [37].

Because trypsinogen 1 in blood is specifically elevated in acute biliary pancreatitis, the ratio of trypsin-2-alpha1-antitrypsin complex to trypsinogen 1 in blood is reportedly useful for identifying the etiology of ABP [38].

Abdominal Ultrasonography

If combined with blood tests, it is possible to diagnose the etiology of acute pancreatitis with gallstones in most cases. The probability of detecting a CBDS by abdominal ultrasonography varies from 20% to 90%. The absence of biliary stones or bile duct dilatation on abdominal ultrasonography does not rule out ABP [39–41]. If the initial examination does not reveal biliary stones but gallstone pancreatitis is suspected, it is necessary to perform repeatedly ultrasonography or MRCP.

Computed Tomography

In many cases, biliary stones are not detected by CT (sensitivity 40~53%), and CT is not suitable for the diagnosis of acute biliary pancreatitis [37,41]. Calcium bilirubinate gallstone is the most frequent CBDS, which cannot be detected by CT because of radiolucency. If the etiology is unclear, CT should be performed because pancreatic cancer or intraductal papillary mucinous tumor may be the cause of acute pancreatitis.

MRI/MRCP

The sensitivity of MRI/MRCP to detect CBDS is 80%, compared with 20% and 40% for abdominal ultrasonography and CT, and MRI/MRCP is recommended to determine the indication for endoscopic papillary procedure (ERCP/EST) [42]. Compared to ERCP, it can be used at an earlier stage of pancreatitis because it is noninvasive and does not require EST/EPBD, thus there is no risk of worsening

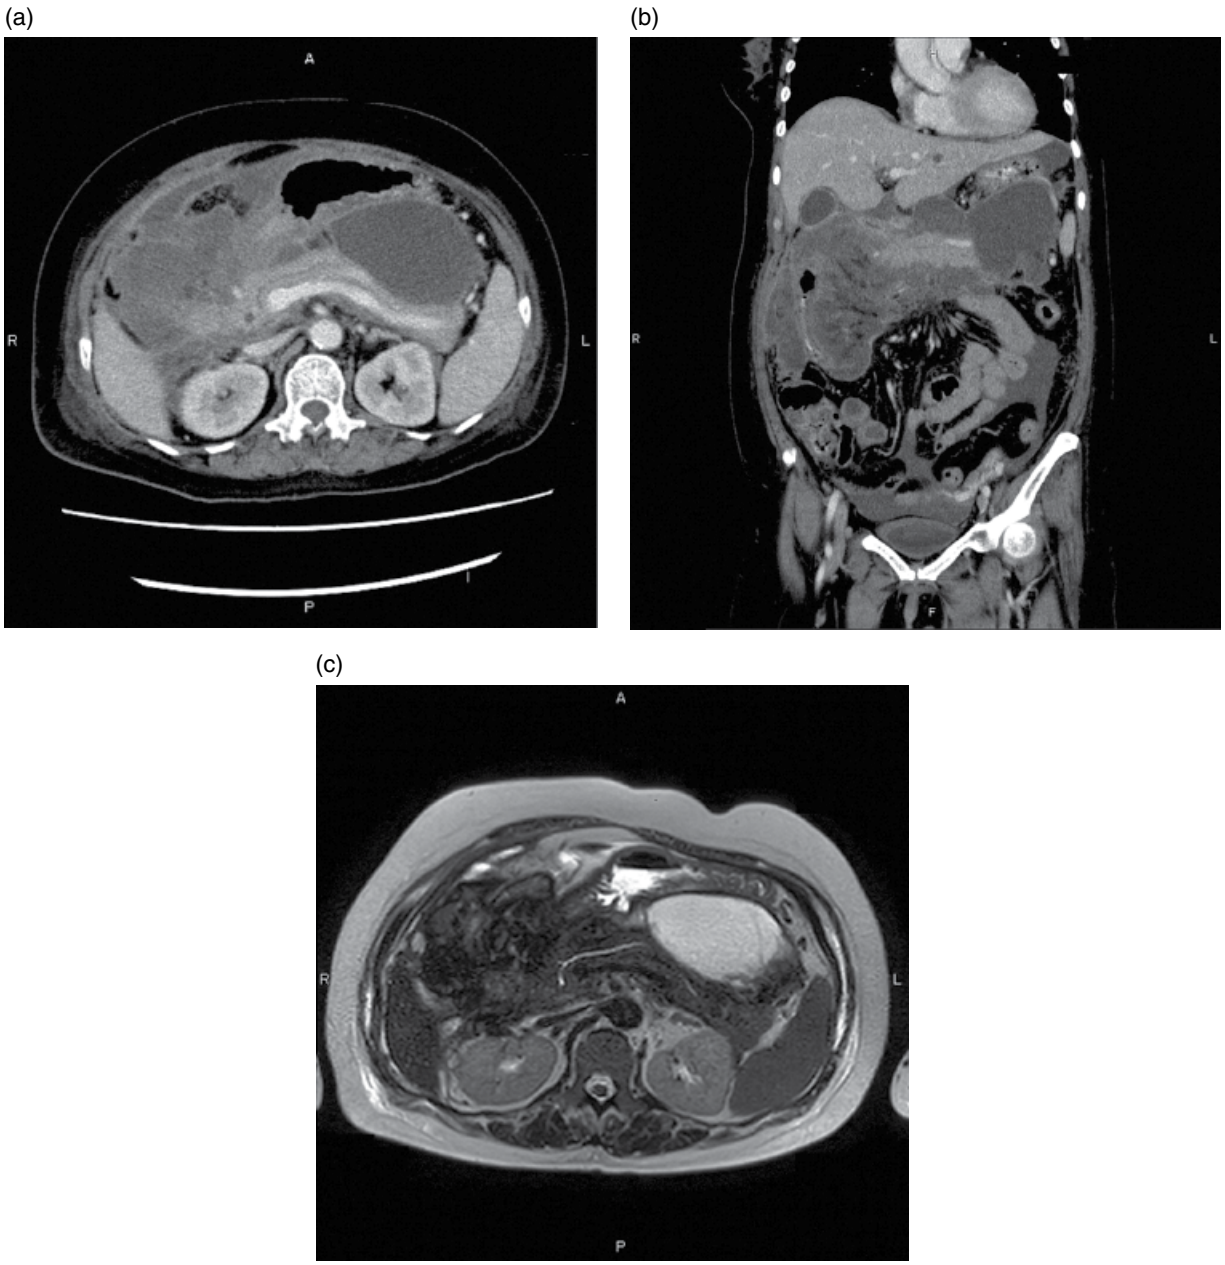

Figure 12.1 A 59-year-old woman presented with severe acute biliary pancreatitis. The inflammatory response remained high. Contrast-enhanced computed tomography (CT) showed an irregularly shaped fluid collection with a contrast-enhancing film (a, b), and MRI T2 showed a fluid collection with mixed high and low signals (c).

acute pancreatitis (Fig. 12.2). However, if the diameter of the bile duct is large, if there is ascites, or if the patient is not holding their breath well, the image quality may be low, and small stones of less than 5 mm may be missed.

Endoscopic Ultrasonography (EUS)

EUS is superior to abdominal ultrasonography in its ability to detect the common bile duct (Fig. 12.3). When the etiology is not clear on abdominal ultrasonography, EUS can detect common bile duct stones in 59–78% of cases [43–45]. Although ERCP and EUS are considered the gold standards for the examination of biliary stones, there is an RCT, which showed that ERCP sometimes failed to detect CBDS (14%), whereas EUS was able to detect CBDS in all patients [46]. In a prospective study of the simultaneous diagnostic performance of EUS, MRCP, and CT cholangiography for the detection of CBDS, their diagnostic sensitivity was 100%, 88%, and 88%, respectively [47]. ERCP during an attack of acute pancreatitis

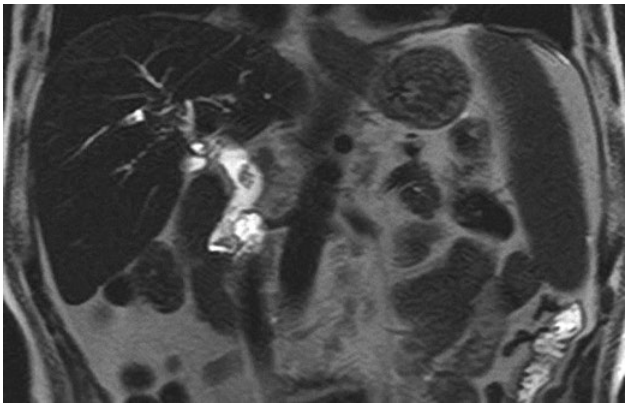

Figure 12.2 MRCP shows a shade defect in the dilated common bile duct that may be a stone.

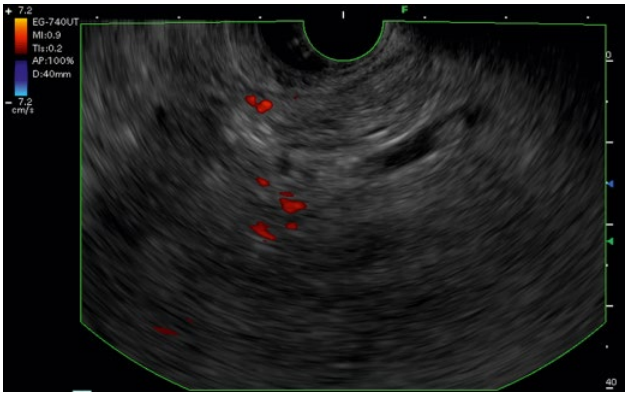

Figure 12.3 EUS shows a stone with acoustic shadow in the common bile duct.

may worsen the inflammation. In cases of suspected ABP, Liu et al. compared whether to perform EUS or diagnostic ERCP for the diagnosis of gallstones and CBDS. Although there were no statistically significant differences in mortality rate, complication rate, hospital stay, or need for intensive care, the complication rate was lower in the EUS group (7.1%) compared with the ERCP group (14.3%) [46]. Therefore, compared with diagnostic ERCP, EUS is safer because it avoids unnecessary ERCP. In addition, in mild-to-moderate acute pancreatitis, the detection rate of gallstones and CBDS does not differ between EUS and MRCP [48]. In terms of invasiveness, MRCP or CT cholangiography (MRCP is more noninvasive in terms of contrast media allergy) should be performed first. If no stone is found on MRCP/CT, confirmation of small stones by EUS may avoid unnecessary ERCP and contribute to a lower incidence of incidental disease.

ERCP

ERCP is not always necessary for diagnosis of ABP but is performed for its treatment. The British Society of

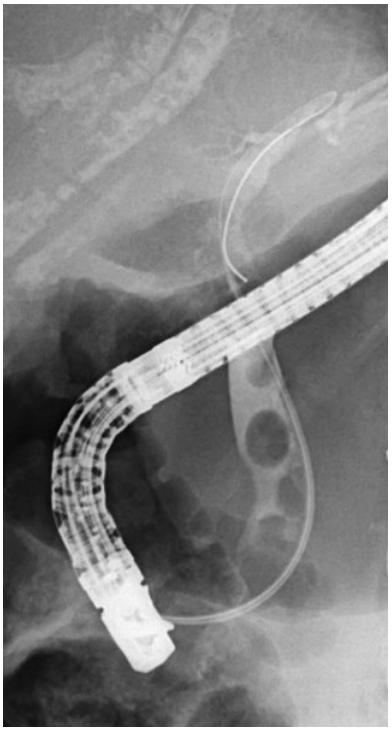

Figure 12.4 ERCP shows multiple shade defects in the common bile duct and common bile duct stones.

Gastroenterology guidelines recommend ERCP in the presence of jaundice, liver damage, dilatation of the common bile duct, and strong suspected presence of CBDS or repeated attacks of acute pancreatitis [49] (Fig. 12.4). Early ERCP in gallstone pancreatitis, which is expected to be severe, does not significantly affect the reduction of fatality, but does affect the reduction of complications of acute pancreatitis [50].

Other indications for diagnostic ERCP were aspiration and analysis of the bile juice to detect sludge/crystal in the bile juice. Biliary sludge/crystal was difficult to detect by other diagnostic imaging modalities including EUS and analysis of bile juice was mandatory. Biliary sludge is almost certainly not a cause of pancreatitis but is a common finding in patients with acute pancreatitis due to reduction in gallbladder motility. As with gallstones, the essential pathophysiologic mechanism is obstruction to the pancreatic duct at the level of the ampulla of Vater. Biliary sludge is a mixture of particulate matter that precipitates from bile, generally consisting of cholesterol monohydrate crystals, calcium bilirubinate, and other calcium salts embedded in mucin [51]. Biliary sludge often coexists with gallstones [52], and it is questionable whether the formation of sludge represents an early stage of gallstone formation. Biliary sludge has been reported as causing acute pancreatitis in 3.1% of cases [53], although whether this is due to sludge per se or to associated microlithiasis is difficult to judge.

Lee et al. assessed 86 patients diagnosed with idiopathic pancreatitis and found evidence of biliary sludge in the majority (67%). Although the presence of biliary sludge did not have a causal relationship with the pancreatitis, its presence was predictive of recurrent episodes of acute pancreatitis [54]. Bile aspiration by ERCP and microscopic observation may be diagnostically useful.

Treatment Strategy

ERCP is used to treat pancreatitis, prevent exacerbations, and improve cholangitis. The latter two uses are controversial. Therefore, the suitability of ERCP for ABP is determined by the presence or absence of cholangitis or biliary obstruction. However, we experienced marked improvement of ABP after ERCP. In such cases, the stone was impacted at the papilla, which required the precut technique to extract or push the impacted stone into the bile duct using a catheter.

In other words, after the diagnosis of acute biliary pancreatitis by the tests described above, if there is no cholangitis or biliary obstruction, a standby ERCP/EST should be performed after usual treatment for acute pancreatitis. If there is cholangitis or obstruction of the biliary duct, perform emergency ERCP/EST and then treat the acute pancreatitis and subsequently perform cholecystectomy.

ERCP

Gallstone pancreatitis is caused by bile duct stones or bile sludge in the common papillary duct, resulting in pancreatic duct obstruction and papillary edema. Pancreatitis severity was more than 80% in cases where pancreatic duct obstruction due to insufficiency persisted for more than 48 hours [55]. Therefore, early ERCP/EST may relieve pancreatic duct obstruction and papillary edema and prevent worsening of pancreatitis and cholangitis by pancreatic duct decompression and bile duct drainage. However, performing ERCP/EST at the extreme stage of acute pancreatitis may cause additional stress to, and thus worsen, the pancreatitis.

Several meta-analyses compare early ERCP with conservative treatment for acute biliary pancreatitis [56–60]. Excluding cases of complications of cholangitis, all reports showed no significant difference in mortality and complication rates between early ERCP and conservative treatment for cholelithiasis, irrespective of the degree of pancreatitis. In 2012, Tse et al. reported [59] that early ERCP significantly reduced the risk of mortality (RR 0.20, 95% CI 0.06~0.68), and local (RR 0.45, 95% CI 0.20~0.99) and systemic complications (RR 0.37, 95% CI 0.18~0.78). However, in RCTs only, excluding patients with cholangitis, early ERCP tended to increase mortality (RR 1.91, 95% CI 0.85~4.30) and the incidence of local (RR 1.15, 95% CI 0.69~1.92) and systemic complications (RR 1.02, 95% CI 0.44~2.36). In 2020, Nicolien et al. reported [61] an RCT of early ERCP vs. conservative treatment in severe cholelithiasis without cholangitis and found no significant difference in the risk of complications or mortality. Based on these results, routine early ERCP is not recommended for all ABP cases. Early ERCP is recommended for patients with or suspected of having acute cholangitis. For patients with uncomplicated acute cholangitis, priority should be given to treatment of acute pancreatitis.

Timing of Cholecystectomy following Acute Biliary Pancreatitis

Recurrent pancreatitis with gallbladder stones may cause ABP as a result of recurrent stone passage from the gallbladder to the duodenum. Cholecystectomy was performed even though CBDS were not detected by various diagnostic modalities.

To prevent its recurrence, cholecystectomy was performed after improvement of ABP. In a study using a Canadian database, the 6- and 12-month cumulative readmission rates for the cholecystectomy and non-extraction groups were 4.9%, 5.6%, 12.4%, and 14.0%. In a study using the Kaiser Permanente database (USA), the incidence of recurrent acute pancreatitis in the ERCP/EST group without cholecystectomy and the no-treatment group was 8.2% and 17.1%, respectively. By contrast, the recurrence rate in the cholecystectomy group was 5.4%. In cases of acute pancreatitis with gallbladder stones, cholecystectomy should be the first choice to prevent recurrence; however, the timing is controversial.

There are claims that early surgery is associated with a risk of perioperative complications [62]. By contrast, there are reports that surgery can be safely performed within 48 hours irrespective of abdominal symptoms and blood test findings, leading to shorter hospital stays [63,64]. The PONCHO trial, an RCT reported in the *Lancet* in 2015, compared a group who underwent cholecystectomy in the same hospital with a group who underwent standby cholecystectomy [65]. The mortality, gallstone-related complication, and rehospitalization due to recurrent pancreatitis rates were lower in the former group than in the latter. However, there was no difference in the rate of transition from laparoscopy to laparotomy. AGA recommend cholecystectomy in the same hospitalization.

There is a report of nine trials comparing early (within 48 hours) and late (after 48 hours) cholecystectomy in mild acute cholecystic pancreatitis [66]. Early surgery reportedly leads to shorter hospital stays without increasing the complication or mortality rate, and early surgical intervention

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

is desirable if the condition permits. By contrast, in the 2004 cohort, there were more infectious complications and more postoperative complications in surgeries performed within 5 days of severe acute cholangitis onset or during hospitalization for acute pancreatitis. In AGA, cholecystectomy is recommended in severe pancreatitis with fluid retention around the pancreas after the fluid retention has improved or after 6 weeks if a pseudocyst has formed.

Conclusion

The management of ABP is controversial. There are various disease presentations, and we could not fully classify the clinical features of each to establish treatment strategies. Therefore, well-designed large-scale clinical trials are required.

Genetic Factors in Acute Pancreatitis

Mitchell L. Ramsey and Georgios I. Papachristou

The Ohio State University Wexner Medical Center, Columbus, OH, USA

Introduction

Approximately 70% of acute pancreatitis (AP) in adults is attributable to alcohol use or pancreatic duct obstruction from choledocholithiasis [1]. However, it is increasingly recognized that these stimuli are modulated by other susceptibility factors such as trypsinogen activity, pancreatic ductal clearance, and endoplasmic reticulum (ER) stress. This observation is supported by the large number of patients with environmental exposures such as heavy alcohol use who never develop clinical AP [2]. Some predisposing factors are anatomic, such as pancreas divisum, while others are related to germline pathogenic variants leading to alterations in the structure or function of proteins integral to normal pancreas functions. Following alcohol and gallstones, the next most common AP etiologic group is unexplained or idiopathic [1]. With the increasing availability of germline genetic test panels, several studies have reported high rates of germline pathogenic variants among patients with idiopathic recurrent AP (IRAP) [3–5]. Pathogenic variants in pancreatitis-related genes are hypothesized to decrease the threshold to develop AP following exposure to an inciting event. In this chapter, germline pathogenic variants that are associated with increased susceptibility or increased severity of AP will be discussed. The pancreas is divided into different anatomic and functional compartments that are predisposed to distinct mechanisms of injury [6]. Certain genetic factors are directly linked to the proper function of either the acinar cell or duct cell compartments, and it is useful to consider them in context of these compartments (Table 13.1).

The clinical syndrome of pancreatic autodigestive injury, an acute inflammatory response, and a range of local and systemic complications defines AP [6]. Autodigestive injury is promoted by premature activation of pancreatic proenzymes within the acinar cells or within the pancreatic duct. This premature activation is mediated by trypsin and can be influenced by genetic variations. Indeed, the 1996 discovery of the gain-of-function mutations in the cationic trypsinogen gene (*PRSS1*) serves as the prototypical example [7]. Since that discovery, a variety of other susceptibility genes have been described that influence trypsin activity and ductal cell function thereby increasing the risk of AP. The most prevalent genes associated with AP are *PRSS1*, cystic fibrosis transmembrane conductance regulator (*CFTR*), pancreatic serine protease inhibitor Kazal-type 1 gene (*SPINK1*), and claudin 2 (*CLDN2*) [8,9]. Multiple genes have been associated with progression to chronic pancreatitis (CP), including variants in chymotrypsin C (*CTRC*) and calcium-sensing receptor (*CASR*), which are introduced here but are more completely discussed in Chapter 45. Lastly, severity modifying genes have been described, including monocyte chemotactic protein-1 (*MCP-1*), which increase the severity of AP [10].

Acinar Cell-Associated Susceptibility Factors

Calcium dysregulation appears to be the primary pathway for triggering AP within acinar cells [11,12]. In health, multiple protective mechanisms limit trypsinogen exposure to calcium, including trypsinogen packaging in zymogen granules, calcium sequestration in the ER, and numerous cytosolic calcium homeostasis processes [13]. When calcium occupies the calcium-binding domains of the trypsinogen molecule it results in both trypsinogen activation and prevention of its degradation [11]. Therefore, alterations in cellular calcium concentration, zymogen granule formation, or alteration to the calcium-dependent regulatory domains of the trypsinogen molecule can potentially increase the risk of

Proinflammatory cytokines	MCP-1: c.–2518G
	TNF-α: c.–1031C, c.–863A
	IL-8: c.–251A

CFTR^{sev}: severe pathogenic variants in CFTR; CFTR$^{m\text{-}v}$: mild or variable pathogenic variants in CFTR.

pancreatic autodigestion. Several pathogenic variants have been identified among subjects with AP that alter calcium and trypsinogen homeostasis, including variants in *PRSS1*, *SPINK1*, and *CLDN2*.

Cationic Trypsinogen: *PRSS1*

Hereditary pancreatitis is characterized by recurrent AP leading to CP, and is attributed to autosomal dominant inheritance of pathogenic variants in *PRSS1* (located on chromosome 7q35), the gene coding for cationic trypsinogen [7]. Cationic trypsinogen is the predominant trypsinogen found in human pancreatic secretions, followed by anionic trypsinogen (*PRSS2* on 7q35) and meso trypsinogen (*PRSS3* on 9p13) [14]. Trypsinogens are serine proteases synthesized in pancreatic acinar cells and are activated on cleavage of a short exposed peptide chain called trypsinogen activation peptide (TAP). Enterokinase or a second trypsin molecule can cleave TAP, allowing for the transformation of trypsinogen to active trypsin [15]. Once activated, trypsin activates other pancreatic proenzymes to initiate digestion of chyme. Trypsin can also inactivate trypsin at the arginine residue (codon 122) in the side-chain. Trypsin has two calcium-binding domains, one at the activation site and one at the autolysis site, and nearly all of the described variants identified among subjects with hereditary pancreatitis involve one of these two calcium-regulated sites [16].

The first *PRSS1* mutation to be identified was the c.365G>A substitution, replacing arginine with histidine at codon 122 (R122H) [7]. Arginine 122 is the initial site of hydrolysis of trypsin by other trypsin molecules. In the case of the *PRSS1* mutation, the arginine to histidine substitution renders trypsin resistant to fail-safe autolysis leading to prolonged activity of trypsin and pancreatic autodigestion. Over 50 variants of *PRSS1* have been reported, including gain-of-function variants with deleterious effects (R122H, N29I, A16V) and loss-of-function variants with beneficial effects (Y37X) [16]. Among kindreds, a wide variation in phenotype suggests that additional modifying environmental and/or genetic factors are involved in the pathogenesis of hereditary pancreatitis [17,18].

Hereditary pancreatitis due to variants in *PRSS1* has a high but variable disease penetrance (80% by age 20 years, 96% by age 50 years) and typically presents in childhood with recurrent AP [19–22]. After repeated episodes of AP, approximately half of patients with pathogenic variants in *PRSS1* progress to CP [20,23]. Additionally, the cumulative risk of pancreatic cancer approaches 40% of affected patients by age 70 [20,22]. There are no specific therapies directed at *PRSS1*, so the mainstay of treatment is avoidance of toxic exposures (smoking, alcohol), monitoring for pancreatic endocrine and exocrine insufficiencies, and screening for pancreatic cancer beginning at age 40 [24]. A pilot clinical trial investigated the use of amlodipine (dihydropyridine calcium channel blocker) in four subjects and showed a modest reduction in symptoms and analgesic use, but this has not been replicated [25]. Total pancreatectomy with islet autotransplant (TPIAT) is often considered for intractable CP-related pain in hereditary pancreatitis [26]. The indications and outcomes of TPIAT are discussed in Chapter 66.

Serine Protease Inhibitor Kazal Type 1: *SPINK1*

Serine protease inhibitor Kazal type 1 (SPINK1), also known as pancreatic secretory trypsin inhibitor (PSTI), is encoded by *SPINK1* on chromosome 5q32 and is packaged in exocrine granules along with trypsinogen. SPINK1 is a 56-amino-acid acute-phase protein that directly blocks the active catalytic site of trypsin, thus preventing trypsin from activating trypsinogen. The proportion of SPINK1 protein to its RNA has been shown to range from less than 1:1000 in the normal pancreas to at least 6:1 in the inflamed pancreas [18]. This indicates that *SPINK1* translation is rapidly increased *after* pancreatic injury, and therefore likely plays a role in limiting the extent and duration of an attack by inhibiting trypsin [27]. These findings also fit with the observation that SPINK1 is an acute-phase reactant [28].

Several loss-of-function pathogenic variants have been identified in *SPINK1* and the N34S haplotype is the most

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. prevalent throughout the world, found in 1–3% of the general population [29]. Pathogenic variants in *SPINK1* are identified in 7–10% of subjects with AP and in 25–50% of cases of early-onset idiopathic CP, including tropical fibrocalculous pancreatitis [30–34]. The N34S variant is more prevalent among alcoholics with CP than among alcoholics without CP, suggesting that loss-of-function of SPINK1 increases susceptibility to alcohol-related CP [35]. The risk and severity of pancreatitis appears to be similar between subjects with homozygous, heterozygous, or compound heterozygous genotypes, suggesting that the genetics underlying the disease state is complex and involves other susceptibility factors [31,32].

Among those who develop pancreatic disease associated with pathogenic variants in *SPINK1*, the phenotype is variable but generally presents in young adulthood [36,37]. Pathogenic variants in *SPINK1* increase susceptibility to recurrent AP and CP, but do not appear to be a major risk factor for sentinel AP [5,11,38]. These observations indicate that SPINK1 acts as a disease modifier, so the clinical phenotype of those with pathogenic variants reflects the etiologic agent of AP [27,35]. No specific therapy exists for patients with AP who have pathogenic variants in *SPINK1*, although a case report of a patient with familial hypocalciuric hypercalcemia and R67H variant in *SPINK1* describes abrogation of recurrent AP when treated with cinacalcet (a calcimimetic agent) [39]. This report demonstrates the disease modifier effect of SPINK1: when the underlying cause of AP (hypercalcemia) resolved, no further AP recurrences occurred. Pancreatic cancer screening is not currently recommended in this group [24].

Chymotrypsin C: *CTRC*

Another pancreatic secretory enzyme involved in trypsin regulation is chymotrypsin C, which is able to rapidly degrade trypsin in the absence of calcium through cleavage of the calcium binding loop [15]. Chymotrypsin C is encoded by *CTRC* (1p36.21) and is stored within zymogen granules until it is released into the pancreatic duct. The function of chymotrypsin C was initially described by Rinderknecht et al. in 1988 as the second line of defense against prematurely activated trypsin, following PSTI/SPINK1 [40]. Thus, it follows that loss-of-function variants in *CTRC* may produce a similar clinical phenotype as loss-of-function variants in *SPINK1*.

Several pathogenic variants have been described in *CTRC*, including the association of R254W and K247_R254del with idiopathic CP [41,42]. One group identified the G60G variant at higher rates among patients with AP than among healthy controls, but subsequent study in the North American Pancreatitis Study II cohort identified similar rates of G60G among subjects with recurrent AP and controls [43,44]. Lastly, an additional case series identified similar detection rates for pathogenic variants (V235I, I259V, K247_R254del) in *CTRC* among AP cases (1.8%) and controls (1.2%) [45]. Thus, similar to *SPINK1*, pathogenic variants in *CTRC* are associated with recurrent AP and CP, but do not appear to be risk factors for sentinel AP. Unlike pathogenic variants in *PRSS1* and *SPINK1*, the natural history and management of subjects carrying variants in *CTRC* has not been well described.

Claudin 2: *CLDN2*

Claudins are a family of transmembrane proteins that regulate paracellular permeability of ions and water [46]. Claudin 2 is encoded by *CLDN2* (Xq22.3), and, in health, localizes to the plasma membrane between pancreatic islet and duct cells [47]. Under stress, pancreatic acinar cells can express claudin 2, which may contribute to the development of pancreatic edema that is characteristic of interstitial AP [48]. Germline polymorphisms in the *CLDN2-MORC4* locus, including rs7057398 and rs12688220, have been associated with increased susceptibility to AP [49,50], IRAP (in homozygous females) [51], and CP [47,52]. In particular, homozygous females and hemizygous males are most susceptible to alcohol-related pancreatic injury, suggesting that variants in *CLDN2* act as a disease modifier in the setting of environmental exposure [47,52]. In contrast to PRSS1, SPINK1, and CTRC, claudin 2 does not appear to interact with the trypsin-dependent pathway of AP [47]. There is no specific therapy for subjects with AP and pathogenic variants in *CLDN2*, although strict abstinence from alcohol should be emphasized.

Endoplasmic Reticulum (ER) Stress-Associated Susceptibility Factors

An additional mechanism leading to AP is ER stress. Although this more commonly predisposes to CP, a brief discussion is included here due to the involvement of similar genes discussed above. For example, the *PRSS1* G208A variant leads to misfolding and accumulation within the cell rather than premature activation within the pancreatic duct [53]. Similarly, misfolded CTRC caused by the A73T and G61R variants precipitates within the cell, causing ER stress and altering microtubule function that ultimately leads to the development of CP [54]. In addition to these variants in *PRSS1* and *CTRC*, variants in carboxypeptidase A1 (CPA-1) also cause ER stress and contribute to the development of CP, but have not been associated with AP.

Carboxypeptidase A1: *CPA-1*

Carboxypeptidases are metalloproteases that cleave C-terminal peptide bonds from dietary polypeptides [55]. Among these carboxypeptidases is CPA-1,

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

which is secreted as a zymogen, procarboxypeptidase A1, and is activated by trypsin and chymotrypsin C in the duodenum [56]. Procarboxypeptidase A1 is a highly prevalent protein in pancreatic juice, and loss-of-function variants in *CPA-1* (located at 7q32.2) (N256K, R382W, and c.1073-2A>G) have been associated with early onset CP, but not with AP [56]. The mechanism of injury leading to CP is thought to involve ER stress, as reduced CPA-1 does not affect trypsin activity.

Duct-Associated Susceptibility Factors

Pancreatic ductal blockage is another factor that may contribute to premature zymogen activation within the pancreatic parenchyma. This is most clearly illustrated by gallstone pancreatitis; however, there are additional important duct-associated factors and susceptibility genes that can contribute to the development of AP.

The pancreatic duct cell differs from many other types of epithelial cells in its expression of a combination of ion channels and transporters. The primary apical (luminal) ion channel of the duct cell is CFTR [57], which is permeable to chloride and, to a lesser degree, bicarbonate [58,59]. The continuous entry of bicarbonate into the duct cell is facilitated by a sodium–bicarbonate cotransporter on its basolateral surface [60]. Simultaneously, minimal chloride permeability on the basolateral surface results in bicarbonate being the dominant diffusible anion within the duct cell. In this setting, a concentration gradient across the apical membrane favors bicarbonate secretion [61]. This ion secretion is dependent on CFTR, so any alterations in CFTR function can potentially limit fluid secretion into the pancreatic duct which increases the transit time of protein-rich acinar secretions to the duodenum. Maintenance of a high pancreatic duct pH and presence of trypsin inhibitors reduce the potential for activation of trypsinogen within the pancreatic duct. Failure to flush the pancreatic duct is a susceptibility factor for AP, and *CFTR* loss-of-function mutations represent the prototype genetic defect.

Cystic Fibrosis Transmembrane Conductance Regulator: *CFTR*

The epithelial cells of multiple organs (i.e., lungs, pancreas, intestine, bile ducts) contain the CFTR ion channel, and severe pathogenic variants in *CFTR* (located on 7q31.2) may lead to multiple organ dysfunction resulting in the clinical phenotype of cystic fibrosis (CF) [62]. In health, CFTR-mediated secretion of bicarbonate and chloride into the pancreatic duct dilutes the protein-rich fluid from the acinar cells and maintains a basic pH to prevent premature zymogen activation. Active transport of anions creates a gradient for osmosis, such that CFTR is primarily responsible for creating a fluid current that carries zymogens expediently to the duodenum [63]. The risk of AP among subjects with pathogenic variants in *CFTR* is dependent on the balance of ductal clearance and zymogen production (Fig. 13.1) [64]. Ductal clearance correlates with the activity of mutant CFTR in ductal cells, and zymogen production correlates with acinar cell function, which may be reduced by damage from recurrent AP [65].

The first pathogenic variant in *CFTR* was identified in 1989, and now more than 2000 variants in *CFTR* have been identified [62]. Although the functional role of many of these variants remains unknown, the more commonly identified variants have been categorized according to their effect on the CFTR protein, where classes IV and V are milder mutations ($CFTR^{m\text{-}v}$) and I, II, III, and VI are more severe ($CFTR^{sev}$) [62]. A number of online databases have been created to assist clinicians in interpreting identified variants, including CFTR2.org and

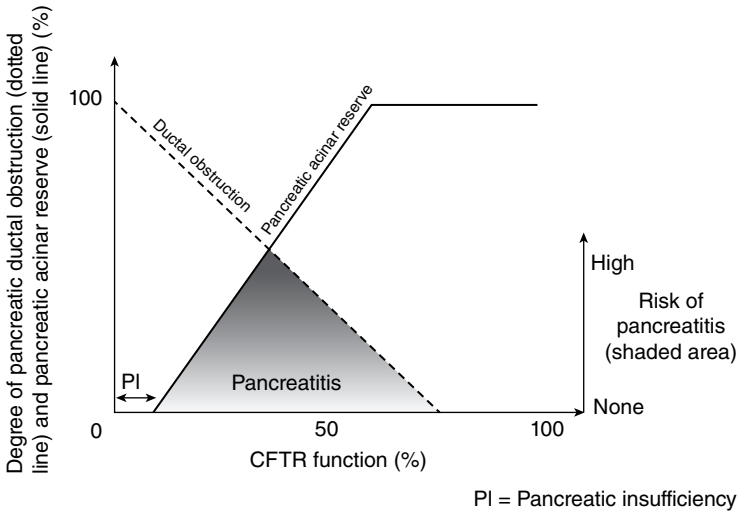

Figure 13.1 Relationship between percent of cystic fibrosis transmembrane conductance regulator (CFTR) function and risk of acute pancreatitis among subjects with cystic fibrosis. *Source:* [104] / With permission of Elsevier.

umd.be/CFTR, that include genotype and clinical details (i.e., sweat chloride, lung function, and pancreatic sufficiency) [66,67]. The prevalence of the *CFTR* pathogenic variant carrier state is 3–4% in Caucasians [68,69] and 1–2% among those of African descent [68,69]. CF has a prevalence of between 1/2500 to 1/6000 live births [62,70].

Severe pathogenic variants that are found among subjects with pancreas insufficient CF include F508del, the most prevalent variant in Caucasians, I507del, R33X, and G542X [64]. Patients who are homozygous for severe pathogenic variants (i.e., F508del/F508del) or have complex heterozygosity involving severe variants (i.e., F508del/G551D) present with typical CF at a young age, with impaired pulmonary function, exocrine insufficiency, and a low incidence of AP [62]. In contrast, class IV and V mutations reduce CFTR function to 10–49% of normal function and are identified among subjects with pancreas sufficient CF [71]. These pathogenic variants include R117H, R1162X, and c.2789+5G>A, among others [64]. Patients with homozygosity or complex heterozygosity for these milder mutations present with atypical CF, with milder pulmonary symptoms and pancreas sufficiency, and may experience recurrent AP [72,73]. It is increasingly recognized that carriers of *CFTR* mutations are also at heightened risk for CF-related conditions, including AP [74]. This is referred to as CFTR-related disorder (CFTR-RD), and includes subjects who have at least one pathogenic variant in *CFTR* but do not meet diagnostic criteria for typical or atypical CF [75]. In this category are a number of variants including R74Q, R75Q, R117H, R170H, L967S, L997F, D1152H, S1235R, and D1270N that have been associated with recurrent AP and CP without lung disease [76]. In summary, subjects with two milder mutations or a single severe mutation are at increased risk of AP while those with <2% of normal CFTR function have a very low risk of AP [75,77]. Furthermore, it is suggested that some variants of *CFTR* may augment the inflammatory response, predisposing to severe disease [78].

It has been estimated that approximately 20–30% of patients with IRAP or idiopathic CP carry a pathogenic variant of *CFTR*, and only a minority of these will meet criteria for a diagnosis of CF [75]. One of the earliest studies on this topic observed pathogenic *CFTR* variants in 10% of German subjects with alcohol-related CP and 21% of subjects with early-onset, idiopathic CP, but no pathogenic variants were identified in subjects with recurrent AP [79]. Similarly, an Italian cohort identified pathogenic *CFTR* variants in 20% of CP (majority of cases were alcohol-related) but only 6% of AP subjects [80]. These findings have been replicated in a Spanish cohort [81], an Austrian cohort [82], and pediatric and adult American cohorts [3,5,83]. A single cohort in Indian patients found a prevalence of pathogenic variants in *CFTR* of only 2.3% among children with IRAP, but the only CFTR variants used in their study were F508del, G551D, G542X, and A117H, while these other studies generally used *CFTR* panels assessing for over 20 different variants [4]. More recent studies include expanded gene panels and are able to identify *CFTR* pathogenic variants in 10–20% of subjects with alcohol-related recurrent AP and CP, and in nearly half of adult subjects with IRAP or idiopathic CP [84]. Thus, CFTR dysfunction appears to be a major susceptibility factor for alcohol-related or IRAP and idiopathic CP.

The majority of *CFTR* mutations identified among American patients with CF are now targetable by CFTR modulator therapy, including the CFTR potentiator ivacaftor and CFTR correctors elexacaftor, lumacaftor, and tezacaftor. Several observational studies have demonstrated a reduction in AP episodes among patients with CF during treatment with CFTR modulators. In particular, subjects with pancreas sufficient CF appear to have the greatest reduction in AP episodes during treatment [85,86]. The effect of CFTR modulators on AP risk among patients with pancreas insufficient CF is uncertain at this time [86,87]. Subjects with pathogenic variants in *CFTR* are not currently recommended to undergo pancreatic cancer surveillance [24]. Smoking and alcohol use may induce CFTR dysfunction, so abstinence should be emphasized for all subjects with a pathogenic variant in *CFTR* [88].

Calcium-Sensing Receptor: *CASR*

Integral to proper functioning of CFTR is the calcium-sensing receptor (CaSR), located in the apical membrane of ductal cells. CaSR monitors calcium concentration within the pancreatic duct, and may stimulate CFTR and other ion channels to maintain a low calcium concentration within the duct [89]. Gain-of-function and loss-of-function variants in *CASR* (located on 3q13.33) have been inconsistently identified in subjects with AP [5] and CP [90,91] but may contribute to pancreatitis when pathogenic variants in *SPINK1*, *PRSS1*, or *CFTR* are also present [92].

Multiple Genetic Defects and Susceptibility

It has been hypothesized that *SPINK1* could, in fact, act as a disease-modifier gene [93,94]. This is supported by the observation that the *SPINK1* N34S haplotype is relatively common, although there is no specific phenotype associated with this genotype. Furthermore, the severity of disease is similar between patients with homozygous and heterozygous genotypes. A small study of subjects with $CFTR^{sev}/CFTR^{m\text{-}v}$ genotypes with *SPINK1* mutations

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

led to the hypothesis that defects in these gene products may act synergistically to increase the risk of pancreatitis [95]. The risk of AP is increased 10-fold in individuals with a *SPINK1* mutation, 40-fold in individuals with *CFTR* compound heterozygosity, and 500-fold in individuals who have both [96]. Finally, pathogenic variants in *CASR* alter pancreatic calcium homeostasis but may require a second hit in pancreatitis-related genes in order to cause pancreatitis [92].

Severity Modifying Factors: Polymorphisms in Cytokines

In addition to modifying the risk of developing AP, genetic factors may also modify the severity of AP by altering the production of proinflammatory cytokines. The interplay of cytokines in the inflammatory response to AP includes TNF-α, IL-1, IL-8, and IL-10, and may involve others as well [97]. Several pathogenic variants have been identified at higher frequency among subjects with severe AP, including variants in the genes coding for MCP-1, IL-1ß, and IL-8.

The earliest pathogenic variant contributing to the development of severe AP was identified in *MCP*-1 [98]. MCP-1 is a key chemokine in the regulation of inflammation, released by mononuclear cells to attract additional monocytes, lymphocytes, mast cells, and eosinophils. A single-nucleotide polymorphism (c.-2518A>G) in the distal regulatory region of *MCP-1* results in a significantly greater MCP-1 response to inflammatory stimuli than the wild-type sequence, which leads to greater severity of AP [10]. The presence of the G allele significantly increased the risk of severe AP from any cause about sevenfold (~40%), whereas subjects with an AA genotype had a low risk of severe AP (~5%) [10].

The acute inflammatory response is a highly regulated process, with proinflammatory and anti-inflammatory factors interacting in sequential and coordinated ways. TNF-α, the earliest cytokine to be released in inflammation, is a principal mediator of immune responses to endotoxin. The c.–308G>A and c.–238G>A polymorphisms in *TNF*-α have not been consistently associated with the incidence or severity of AP [99]. In contrast, the c.–1031C and c.–863A polymorphisms significantly increase the risk of severe AP (odds ratio [OR] 2.7) [100]. IL-8 is produced by macrophages and attracts neutrophils to the site of inflammation. The c.-251T>A polymorphism in *CXCL8* (the gene coding for IL-8) is associated with an increased risk of developing AP (OR 1.4) [101,102]. A number of other candidate cytokines have been investigated, including IL-1ß, IL-6, and IL-18, and pathogenic variants in these genes marginally increase the risk of severe AP (OR 1.23, 1.22, 1.25, respectively) [103].

Future Directions

Since the discovery of pathogenic variants in *PRSS1* among subjects with hereditary pancreatitis, a number of genetic factors have been identified that modify the risk and severity of AP. These are most commonly encountered among subjects with recurrent AP and CP, but may be identified among subjects who have experienced a sentinel AP as well. Among subjects with recurrent AP and an identified genetic predisposition, integrating our understanding of the effect of the mutation with the therapeutic approach is necessary. This may take the form of environmental risk modification, such as cessation of smoking and alcohol use, but may also involve specific drug therapy, such as the case with CFTR modulator drugs in subjects with pancreas sufficient CF. Specific therapies for other predisposing variants are not yet available. Future studies to develop novel therapies to correct high prevalence pathogenic variants is necessary to halt the progression from recurrent AP to CP.

The Role of the Intestine and Mesenteric Lymph in the Development of Organ Dysfunction in Severe Acute Pancreatitis

Alistair B.J. Escott[1], Anthony R.J. Phillips[2], and John A. Windsor[3]

Introduction

Acute pancreatitis (AP) is a complex and challenging disease with an unpredictable course [1]. The severity and outcome of AP are primarily determined by local and systemic factors; the presence of infected (peri)pancreatic necrosis (e.g., "acute necrotic collections" and/or "walled off necrosis") and persistent end-organ dysfunction (e.g., cardiovascular, pulmonary and/or renal failure) [2]. Recent improvements in the management and outcomes of infected pancreatic necrosis means that it is less important in driving organ dysfunction/failure and impacting clinical outcome. This is evidenced by the marked diminution of the second (late) peak in the bimodal mortality profile of severe acute pancreatitis [3]. Organ failure is the leading cause of death from AP. The pattern of this organ failure is broadly similar across acute and critical diseases, suggesting common drivers for the "multiple organ dysfunction syndrome" (MODS) [4]. This pattern appears to be no different for severe acute pancreatitis [5,6].

The aim of this chapter is to review the role of the intestine in the development of MODS, the evidence for the gut–lymph concept in promoting MODS in acute pancreatitis and to discuss the potential to translate this to effective clinical treatments.

Role of the Intestine and Mesenteric Lymph in Multiple Organ Dysfunction Syndrome

The concept that the intestine drives critical illness was developed in the 1960s when bacterial endotoxin was demonstrated in the systemic circulation of patients with infective and noninfective severe diseases [7]. This gave rise to the *bacterial translocation hypothesis* where gut organisms were proposed to cross the intestinal barrier to create a "septic-like state" [8]. In the 1980s, the *gut motor hypothesis* expanded this concept to acknowledge the contribution of changes in the intestinal flora and the increased permeability of the gut barrier, postulating that bacterial pathogens and endotoxins enter the systemic circulation via the portal venous system [9]. This was largely discredited when it was not possible to prospectively demonstrate bacteria in the portal vein or systemic circulation in patients with major trauma [10]. A further concept was advanced where neutrophil priming occurred in the mesenteric circulation and that this contributed to both local gut injury and distant organ injury [11–13]. This was the basis of the *second-hit hypothesis*, which implicates the intestine but does not rely on a direct bacterial role.

Using experimental models of hemorrhagic shock and trauma Deitch and colleagues introduced the concept that organ failure might be promoted by gut-derived mesenteric lymph. They suggested that primed neutrophils and other intestine-derived toxic factors were the mediators of MODS, and that this occurred in association with increased gut permeability but independent of bacterial translocation [14]. Deitch went on to demonstrate that these intestine-derived factors were transported by thoracic duct lymph to reach the systemic circulation to promote systemic inflammation and organ dysfunction [14,15]. He termed this the "*gut–lymph hypothesis*" [16]. Demonstrating that lung injury mediated by hemorrhagic shock altered mesenteric lymph was key to validating this concept in the experimental

setting. Ligation of the mesenteric lymph duct before hemorrhagic shock prevented lung injury in a rodent model, while done after shock but before resuscitation only partially prevented lung injury [17]. It was found that mesenteric lymph from these rats was cytotoxic to endothelial cells and caused increased permeability to both a monolayer of endothelial cells and lung tissue while portal vein plasma did not [17,18]. The early failure of lung function [4–6] has also been demonstrated in experimental models of burns [19], shock [20], and sepsis [21] and AP [22]. Furthermore, ligation of the mesenteric or thoracic duct ligation in these different models has been shown to prevent neutrophil priming [23], reduce red blood cell deformity [24,25], reduce cardiac dysfunction [26–28], protect against renal injury [29], and increase ATP and ATPase renal activity [30].

The plausibility of the gut–lymph concept is enhanced by considering the anatomy of the mesenteric/thoracic duct lymphatics [31]. Gut and mesenteric lymph drains from the intestine and mesentery to the cisterna chyli and then ascends through the mediastinum in the thoracic duct. Almost 75% of thoracic duct lymph arises from the abdomen and pelvis [32]. The thoracic duct lymph drains into the internal jugular or subclavian veins on the left side of the neck, immediately upstream of the heart, lungs, and kidneys, the organs most often involved in MODS. It is noteworthy that this lymph bypasses the liver and its detoxification processes (Fig. 14.1).

While there has been considerable interest in how intestinal injury contributes to the severity of AP, the gut–lymph concept has only recently been considered of potential clinical relevance [33].

Intestinal Injury and Dysfunction Is Associated with Severe Acute Pancreatitis

There are several mechanisms of intestinal injury during acute pancreatitis. Splanchnic vasoconstriction is a key, but not sole, mechanism (Fig. 14.1), and is the reflex response to redistribute blood from the splanchnic region to vital organs. This splanchnic vasoconstriction can cause ischemic injury to the mucosa and wall of the intestine, as well as the pancreas. In the intestine the microanatomy of the intestinal mucosa makes it particularly prone to ischemic injury. The villus tip is most susceptible to ischemia due to the countercurrent flow of oxygen via the rich capillary network between the parallel artery and vein [34]. This ischemic injury can be compounded by the use of nonselective inotropes in persistently hypotensive patients [35]. Intestinal injury is also increased with fluid resuscitation and reperfusion injury [36]. Intestinal ischemia is related to the severity of AP [37] with a lower gastric intramucosal pH (pHi) in

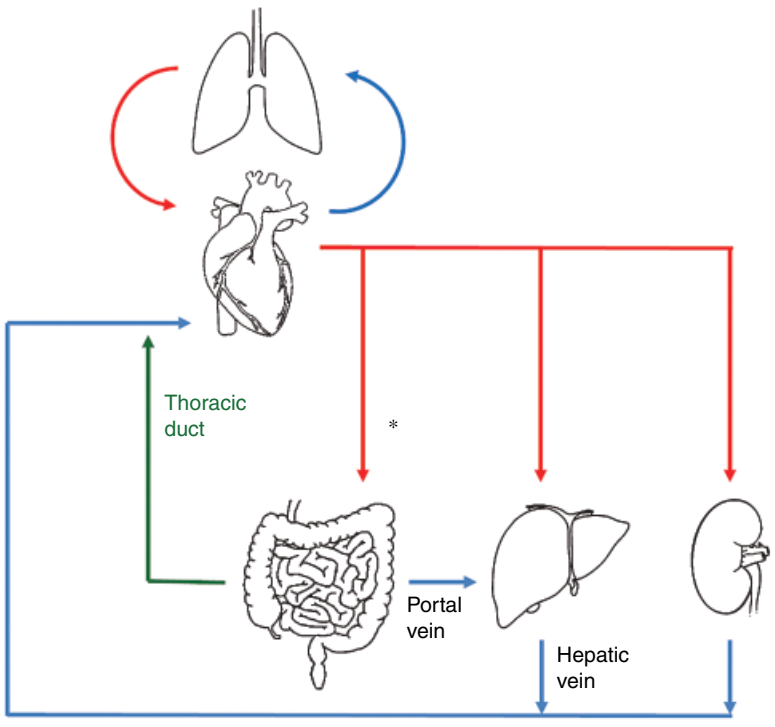

Figure 14.1 Schematic of the gut–lymph concept emphasizing that in acute pancreatitis (and other acute and critical diseases) the vasoconstriction (*) of the intestinal arterial supply to redistribute blood to vital organs results in intestinal ischemia. Drainage of lymph from the intestine via the thoracic duct, bypasses the liver, to enter the circulation proximal to heart, lungs, and kidneys, organs that fail most often.

patients admitted to intensive care than those that remain on the ward, and a low pHi is correlated with an increased risk of mortality [38,39]. Ischemic injury to the intestine is also known to contribute to the breakdown of protective mucus [40], which is compounded by the action of pancreatic proteases [41,42]. The ischemic environment also induces mucosal atrophy, mitochondrial dysfunction [43], oxidative stress, and cell death. Interestingly the mitochondrial dysfunction found early in AP appears to occur in the pancreas, lung, and jejunum with relative sparing of the liver, heart, and kidneys [43].

There is strong evidence for intestinal dysfunction in AP (Fig. 14.2), and it is estimated to occur in 60% of patients [44]. Clinically this dysfunction can be evident as an ileus (dysmotility) [45], feeding intolerance [46], and at the severe end of the spectrum, nonocclusive intestinal ischemia [47,48]. Although suspected, there is still no clear clinical evidence that increased intestinal permeability, as detected by enterally administered polyethylene glycol, is associated with an increased risk of MODS in AP [49]. Increased urinary intestinal fatty acid binding protein, a marker of intestinal mucosal injury, has been correlated with the severity of AP [37,50]. The depletion of IgG anti-endotoxin antibodies, indicative of exposure to endotoxin and "gut barrier failure," is strongly associated with the development of organ failure and death in severe AP [51]. The administration of enteral nutrition (rather than starvation or parenteral nutrition) has been associated with a reduction in infectious complications and mortality in patients with AP [52], giving rise to the concept of "gut rousing" and "gut protection" to maintain and improve intestine function [53] during AP and other acute and critical diseases.

Altered Gut–Lymph Composition in Acute Pancreatitis

There is a significant body of experimental evidence that mesenteric lymph undergoes significant compositional change during acute and critical diseases, such as hemorrhagic shock, sepsis, trauma, and burns [14]. Comparable experimental evidence is only now emerging for AP. A canine model of AP with thoracic duct cannulation demonstrated that a significant proportion of pancreatic amylase and lipase is transported via thoracic duct lymph compared with peritoneal absorption from pancreatic ascites [54]. A rodent model of acute pancreatitis revealed a profound change in the proteome of mesenteric lymph [55]. Of the eight proteins exhibiting a significant increase in mesenteric lymph seven were pancreatic proteases, and the increase was up to 40-fold. Despite this flooding of mesenteric lymph with pancreatic proteases there was no commensurate increase in the abundance of antiproteases. Lipase is also markedly elevated in

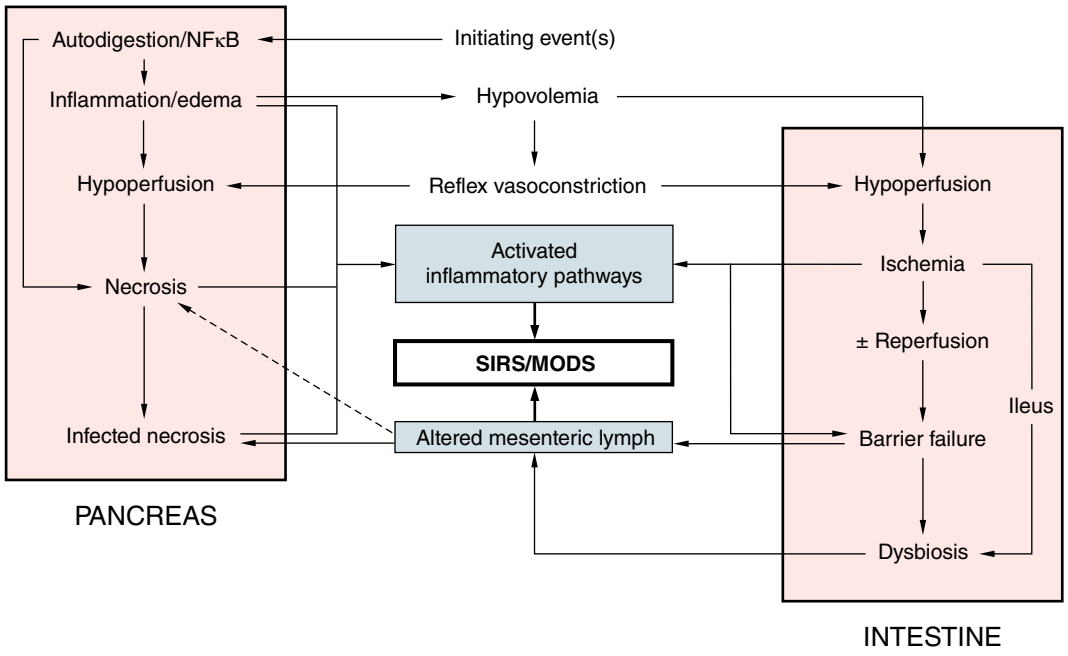

Figure 14.2 A summary of the complex interactions between the pancreas and the intestine in the development of systemic inflammation (SIRS) and multiple organ dysfunction (MODS) in the pathogenesis of severe acute pancreatitis. *Source:* Adams DB (2017)/ John Wiley & Sons.

mesenteric lymph during AP and generates free and unsaturated fatty acids in mesenteric lymph that are directly toxic to umbilical vein cells [56], exhibit systemic toxicity, and are associated with ARDS and MODS [57]. The gut lymph profile of noncoding microRNA is also altered in AP, in both the experimental and clinical settings [58]. Interestingly, there were seven miRNAs that were increased in intestinal lymph during experimental AP and their log abundance correlated with AP severity [58]. The clinical significance of these microRNA changes has yet to be determined, but these molecules can regulate gene expression, influence cell function in remote organs, and offer potential therapeutic strategies with designer antisense sequences. Other groups have demonstrated changes in mesenteric lymph composition in AP. For example, it has been found that the tryptophan metabolites kynurenine and 3-hydroxykynurenine are elevated in rodent mesenteric lymph and plasma during AP and this elevation correlated with disease severity [59].

One of the challenges in studying the role of mesenteric lymph in patients with severe AP is the difficulty in gaining access to thoracic duct lymph in the clinical setting. A pilot nontherapeutic study was conducted in post-esophagectomy patients which allowed serial sampling of thoracic duct lymph for several days following surgery [60]. While not in AP patients it did allow confirmation of compositional changes in human lymph similar to the rodent studies of AP. The effect of enteral feeding on TD lymph composition, and in particular on the markers of intestinal ischemia and injury, suggested that intestinal injury occurs with enteral feeding in these patients.

Gut–Lymph Toxicity in Acute Pancreatitis

The pathophysiologic and clinical significance of the profound compositional changes in mesenteric lymph in AP is still to be fully elucidated. Some progress has been made by testing the toxicity of the altered mesenteric lymph. In our own studies we have tested toxicity on four levels: organelle (e.g., mitochondrial function), cell (e.g., endothelial, cardiac), organ (e.g., isolated perfused heart and lung), and organism (e.g., rodent AP model). Mesenteric lymph from experimental AP incubated with either endothelial cells or cardiac fibers was toxic, causing increased cell death. In the case of cardiac fibers there was lymph-induced toxicity that induced mitochondrial complex dysfunction [61]. Experimental AP is associated with a reduction in cardiac output, contractility, and impaired relaxation, which can be replicated by infusion of mesenteric lymph collected from an experimental model of AP and then infused into an isolated and paced heart model [28]. Significantly, as further evidence of lymphatic toxicity, experimental work has shown that cardiac dysfunction can be prevented by thoracic duct ligation [28] (Fig. 14.3). In another critical study mesenteric lymph from a rodent model of ischemia-reperfusion injury was intravenously infused into other rats with AP [62] causing an increase in AP severity, augmented microcirculatory collapse and produced evidence of lung injury [62]. Other studies have shown that thoracic duct ligation [22] and lymph diversion [63] have been shown to ameliorate lung injury in AP.

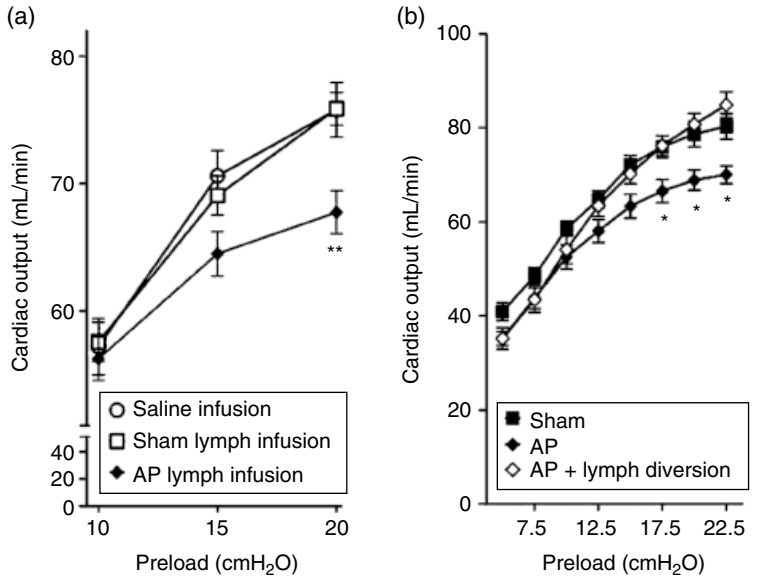

Figure 14.3 (a) Cardiac output is reduced in *ex vivo* working hearts by acute pancreatitis-conditioned gut–lymph when compared to saline or sham lymph. (b) Cardiac output is maintained in rats with acute pancreatitis when compared to sham rats or rats with acute pancreatitis in which the thoracic duct is ligated. $^{*}P < 0.05$, $^{**}P < 0.02$.

Translating the Gut–Lymph Concept to Clinical Treatments for Acute Pancreatitis

Open surgical drainage of thoracic duct lymph has previously been explored as a treatment for a number of diseases. There have been over 70 publications [64] in the English literature, but none since 2004. There is an even more extensive non-English literature from Eastern European countries [65]. The reasons for the discontinuation of this treatment is likely a combination of the invasive nature of the thoracic duct cannulation and the lack of compelling evidence due to the predominance of underpowered, nonrandomized and uncontrolled study designs. Within this seemingly forgotten literature there were four studies [66–69] in which external lymph drainage was used for the treatment of acute pancreatitis. One uncontrolled study of 10 patients reported an improvement in abdominal pain, peritonism, and shock in a "dose-dependent" manner related to the volume of lymph drained [66]. Three of these studies investigated the effect of thoracic duct lymph drainage on pulmonary function in the setting of AP-associated acute respiratory distress syndrome. One study noted that arterial oxygenation improved once drainage was instituted [67]. Another case series demonstrated elevated levels of pancreatic enzymes and cytokines in lymph and plasma but no clinical improvement [69].

With the evidence that proteases contribute to lung injury in acute pancreatitis [70] and the evidence that thoracic duct lymph is flooded by pancreatic proteases in AP [55] suggests that external drainage is a treatment strategy warranting more careful evaluation. A canine model of thoracic duct external drainage has shown that this is effective in reducing plasma amylase and lipase in AP [54].

One of the major barriers to advancement in this area has been the lack of a reliable, safe, and minimally invasive technique for sampling, monitoring, and draining thoracic duct lymph in patients with severe AP. The advent of innovative retrograde percutaneous radiological techniques for cannulating and externally draining the thoracic duct [71] is stimulating the conduct of more studies to evaluate external drainage of thoracic duct lymph to mitigate an important driver of MODS [72].

Another potential treatment strategy based on the gut–lymph concept is the design and delivery of treatments that target known toxic factors in mesenteric lymph [73]. In an experimental rodent model it was demonstrated that inhibition of tryptophan metabolites kynurenine and 3-hydroxykynurenine, which are elevated in mesenteric lymph of rats with AP, is protective against MODS [74].

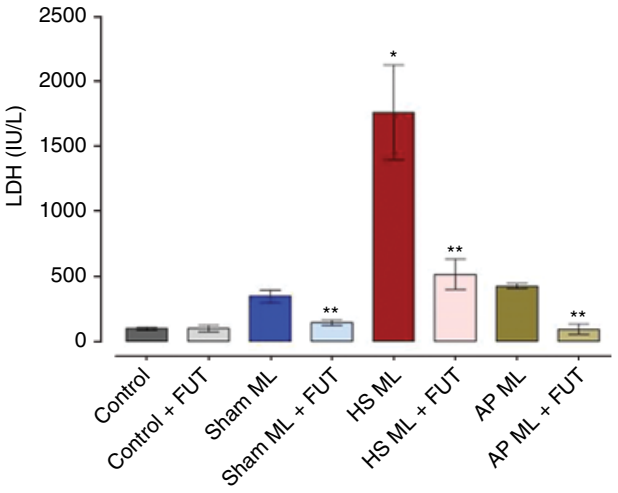

Figure 14.4 Cell death (LDH level) of endothelial cells (HMEC) was increased on treatment with hemorrhagic shock (HS) or AP-conditioned gut–lymph (ML) when compared to control media or mesenteric lymph (ML) from sham-treated rats (*$P < 0.05$). Cotreatment with the antiprotease nafamostat (FUT) reduced cell death (**$P < 0.05$) (unpublished).

In another experiment it was found that antiprotease treatment with nafamostat significantly reduced endothelial cell death when combined with mesenteric lymph from experimental hemorrhagic shock and AP (Fig. 14.4). This raises the possibility of delivering antiprotease treatment to mesenteric lymph by supplementing enteral nutrition with lipophilic transporters. In a similar manner it is possible to deliver anti-lipase treatment (i.e., orlistat) to mesenteric lymph to reduce the generation of toxic fatty acids, which are known to exacerbate organ dysfunction [75]. Enhanced delivery of oral orlistat to mesenteric lymph has been achieved in rodent models [76].

In order to translate the gut–lymph concept into effective clinical treatments, a more complete understanding the role of mesenteric lymph in the pathogenesis of the systemic inflammatory response and organ dysfunction will be required. These experimental studies are examples of potential new treatment strategies.

Conclusion

There is now compelling experimental evidence that altered mesenteric lymph contributes to the systemic inflammation and MODS that characterizes severe AP. The "gut–lymph" concept provides a new disease paradigm, a new field of research, and a long-awaited opportunity to develop new and specific treatments for MODS in severe AP.

Introduction

Pancreatitis is a clinical condition in which the main pathology is inflammation of the pancreatic tissue. It has multiple etiologies that include both genetic and environmental components. It also can be classified as acute or chronic pancreatitis. Acute pancreatitis typically resolves, but it is associated with acinar cell death and activation of subsequent inflammatory cascades [1,2]. Chronic pancreatitis, conversely, is a progressive destruction of the pancreas by repetitive insults. This leads to replacement of viable tissue by fibrotic tissue and subsequently alters pancreatic nerves around the area of inflammation [3–5]. Pathological activation of sensory neurons and the inflammatory sequelae are known as neurogenic inflammation. Neurogenic inflammation is the process by which substances released from sensory nerve terminals promote inflammation in their target tissue. The inciting factors that lead to pancreatic inflammation can be varied; however, the resulting pathology has a common histologic presentation, including edema, vasodilation, invasion of immune cells, and varying degrees of breakdown in the barriers between different tissue compartments within the pancreas.

The central and peripheral nervous systems (CNS and PNS, respectively) can adapt to an ongoing disease process in the gastrointestinal tract. A major role has been recognized for the PNS as a driver of inflammatory pancreatic responses, such that it is being investigated as both a prognostic biomarker as well as a therapeutic target. Experiments in animal models indicate that manipulation of the PNS can alter the course of the disease. Specifically, these manipulations have targeted sensory innervation of the pancreas in studies that go back to the early twentieth century, which found that activation of the primary sensory neurons produced vasodilation [6]. The studies by Bayliss [6] were the beginning of the recognition that sensory neurons have an "efferent" function through the peripheral release of small molecules that can act on blood vessels and immune cells to establish "neurogenic inflammation." Here we review the current state of our understanding of the role of neurogenic inflammation in pancreatitis and how this information might be translated into new treatments for human disease.

Innervation of Pancreas

The pancreas is innervated by two distinct neural pathways, vagal and spinal. Historically, they have been further divided into two distinct types of nerve fibers: afferent fibers conducting sensory information from the pancreas to CNS and efferent autonomic fibers (parasympathetic and sympathetic) conveying motor commands from the CNS to the pancreas (Fig. 15.1). The vagus nerve comprises both parasympathetic and sensory fibers. Pancreatic sensory afferents originate from the nodose ganglia (NG) [7]. They transmit information to the nucleus tractus solitarii (NTS) in the brainstem. Preganglionic parasympathetic neurons originate from the dorsal motor nucleus of the vagus (DMV) located in the brainstem and medulla [8]. These fibers activate parasympathetic postganglionic neurons located in the intrapancreatic ganglia [8,9]. The sympathetic efferent fibers of the pancreas consist of preganglionic and postganglionic neurons. Preganglionic

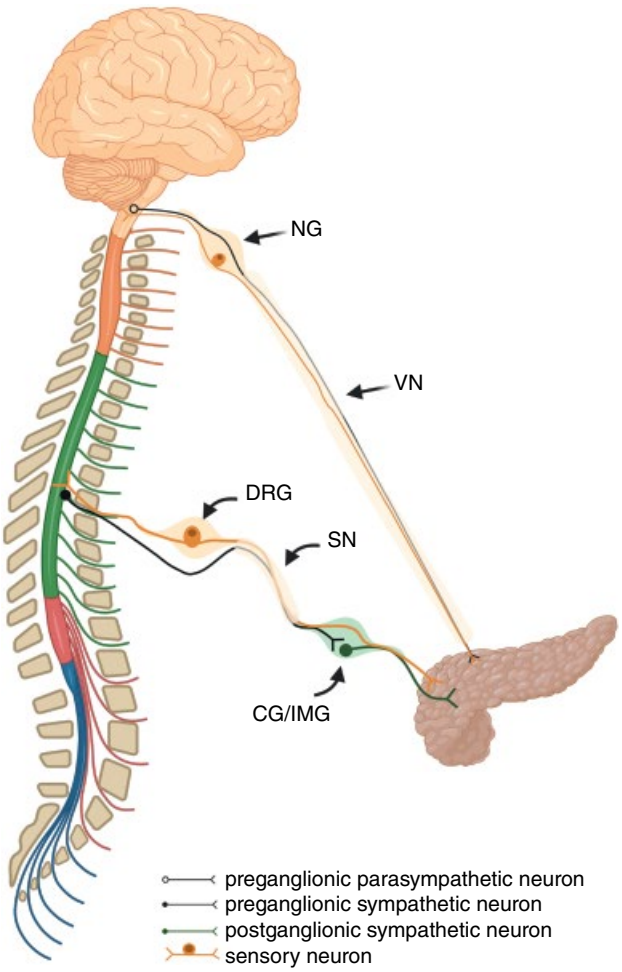

Figure 15.1 The pancreas receives sensory input from primary afferents whose cell bodies are located in the nodose ganglion (NG) and run in the vagus nerve (VN). Sensory innervation from dorsal root ganglia (DRG; also known as spinal ganglia) to the pancreas travels with sympathetic preganglionic axons in the greater splanchnic nerve (SN) and passes through the celiac ganglia (CG), which together with the IMG form the celiac plexus. The VN also contains axons from parasympathetic preganglionic neurons whose cell bodies are located in the brainstem (in the dorsal motor nucleus of the vagus, not shown). These axons synapse on parasympathetic postganglionic neurons (not shown) that are in the organ. Sympathetic innervation arises from sympathetic preganglionic neurons whose cell bodies are located in the spinal cord intermediolateral cell column (not shown) at T5–9 vertebral levels. Axons from these neurons innervate sympathetic postganglionic neurons in prevertebral ganglia found near the organ. The prevertebral ganglia include the CG, whose neurons innervate pancreas. Anatomy shown for human, but rodents are organized in a similar fashion, varying only in the details. Figure created with BioRender.com.

efferent sympathetic fibers project from cell bodies in the lateral horn of the spinal cord called the intermediolateral cell column (C8-L3). Information is transmitted to paravertebral and prevertebral sympathetic ganglia in the celiac plexus (celiac and superior mesenteric ganglia; CG and SMG, respectively). Preganglionic sympathetic neurons synapse on postganglionic sympathetic neurons in the CG and SMG [8,11]. The postganglionic sympathetic fibers subsequently project to intrapancreatic ganglia, islets, ducts, and blood vessels, and release neurotransmitters [12]. Parasympathetic and sympathetic efferent fibers release various neurotransmitters that directly affect blood pressure, pH, temperature, and metabolism of pancreatic tissues [9,12]. Spinal sensory afferent fibers originate from dorsal root ganglia (DRG) at (T6-L2) segments of the spinal cord. These afferent fibers, located in the splanchnic nerves pass through the celiac plexus and transmit information from the pancreas to the spinal cord [8,10].

Neuroimmune Signaling

Under healthy conditions, neurohormonal signaling pathways involving both autonomic (parasympathetic, sympathetic) and sensory nerves regulate the exocrine and endocrine functions of the pancreas [9]. However, given that the primary function of the exocrine pancreas is production of digestive enzymes (proteases), the pancreas is always on the edge of activating inflammatory cascades. Sensory fibers transduce chemical and mechanical stimuli to the CNS, but they also release neurotransmitters and neuropeptides into the parenchyma, which can recruit and activate immune cells, thereby promoting inflammation.

Twenty years ago, patients with AP were reported to have increased levels of circulating inflammatory cytokines [13]. Studies of models of AP established that in response to the initial insult, acinar cells produce and release a variety of inflammatory mediators that initiate the inflammatory response. More specifically, a feedback loop begins when damaged acinar cells release TNF-α, IL-6, IL-8, IL-10, and chemokines into the circulatory system. These mediators subsequently recruit neutrophils, and then macrophages, monocytes, and lymphocytes, to the pancreas. The recruited white cells cause the release of more proinflammatory cytokines, which leads to more edema and local inflammation suggesting that the initial inflammatory responses and signals that recruit leukocytes originate in injured pancreatic acinar cells [14]. It is not exactly clear how acinar cell injury leads to the induction of inflammatory mediators, but the process involves activation of specific transcription factors. NF-κB, in particular, is activated in experimental and human AP, and genetic and pharmacologic approaches have shown its important role in the cytokine storm [15].

In addition, interleukins and TNF-alpha cytokines released by innate immune cells during inflammation are directly sensed by nociceptors, which lead to increased membrane excitability. Nerve growth

factor (NGF) and prostaglandin E (2) are also major inflammatory mediators released from immune cells that act directly on peripheral sensory neurons to cause sensitization. An important effect of nociceptor sensitization by immune factors is an increased release of neuropeptides at peripheral terminals that further activate immune cells, thereby inducing a positive feedback loop that drives and facilitates inflammation [16]. Under pathophysiological conditions, this bidirectional communication promotes an autoamplification loop that underlies neurogenic inflammation and suggests that the nervous system plays a key role in inflammation and may be a potential therapeutic target.

Role of Neurotransmitters

Neuropeptides

The idea that the sensory nervous system, via neurogenic inflammation (Fig. 15.2), plays a role in pancreatitis has led a number of investigators to test this hypothesis by inducing pancreatic inflammation and manipulating pancreatic sensory input, either surgically or chemically in an effort to identify key neuronal proteins involved in pancreatitis pathology. Nathan et al. [17] hypothesized that sensory neurons were a "final common pathway" for neurogenic inflammation associated with pancreatitis. Using two experimental models of pancreatitis (repeated caerulein injections and common pancreaticobiliary duct ligation), they were able to show that sensory denervation (via neonatal capsaicin treatment) dramatically reduced multiple measures of pancreatic inflammation. Subsequent studies expanded on this concept by using pharmacologic approaches to block pancreatic afferent activity. Sensory nerve fibers innervating the pancreas contain a wide array of neuropeptides; however, substance P (SP) and calcitonin-gene related peptide (CGRP) are the most studies in relation to pain and inflammatory mediators. They not only signal the perception of pain to CNS via primary afferent synapses on spinal cord neurons, but also recruit leukocytes and activate surrounding cells' inflammatory signaling pathways [18]. The origin of SP is thought to be from extrinsic sources of sensory afferent neurons mainly in bilateral DRG [19] (Fig. 15.1).

However, recently, Shen et al. illustrated that pancreas is rich in SP-containing neurons inside intrapancreatic

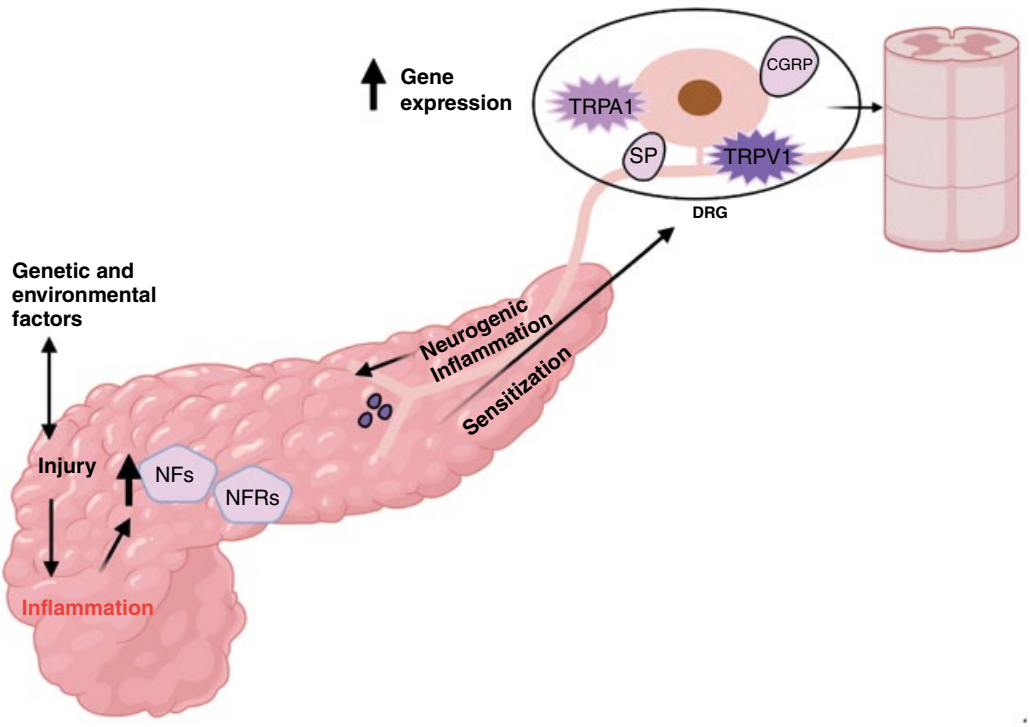

Figure 15.2 Pancreatic injury, exacerbated or induced by environmental and genetic factors, leads to pancreatic injury and inflammation. This inflammation is accompanied by an increase in neurotrophic factors (NFs, e.g., nerve growth factor and artemin) as well as neurotrophic factor receptors (NFRs, e.g., TrkA). The NFs produce sensitization of sensory fibers innervating the pancreas and this leads to an increase in sensory neuron gene expression for receptors/channels that detect noxious stimuli (e.g., TRPA1 and TRPV1) as well increased production and release of small molecules that produce neurogenic inflammation in the pancreas (e.g., substance P [SP], calcitonin gene-related peptide [CGRP]). This feed-forward loop, if not blocked, can lead to fibrosis and permanent damage associated with chronic pancreatitis, as well as setting the stage for cancer development. Figure created with BioRender.com

ganglia in rats. In their experiment, they surgically denervated posterior branches of bilateral T5 –L2 DRG, SP expression remained >60% in the pancreas. Moreover, after high doses of capsaicin were injected to destroy primary sensory afferents, the remainder of SP protein levels was still >50% in the pancreas. This suggested that half of SP origin were from intrapancreatic ganglia [20]. In the case of pancreatitis, intrinsic SP secretion could be a clue to an autoamplification loop that contributes to acinar cell death. SP executes its function by binding to neurokinin receptors (NK1). Among several inflammatory disease models, the association of SP/NK1R signaling and its contribution to AP through neurogenic inflammation has been well demonstrated. In a recent study, Tskuamato et al. also demonstrated anti-inflammatory action of the NK1R antagonist in a mouse model of AP. Their study results showed NK1R antagonist completely inhibited blood IL-6 levels and subsequently NK kappa B pathway in mast cells [21]. Reduction in IL-6 and a blockade of a potent inflammatory pathway could be promising in decreasing edema, microcirculatory dysfunction, and ultimately pancreatic tissue injury in patients with acute pancreatitis. Han et al. also confirmed a well-established idea that pancreatic SP-NK1R signaling pathways were markedly upregulated in patients with acute pancreatitis. In their experiment, the use of an herbal medicine (containing baicalin, emodin, maglol-immunomodulators, and analgesics) that is commonly used for the management of acute pancreatitis was shown to reduce both pain and the severity of AP via blocking neuron activation-mediated pancreatic SP-NK1R signaling pathways [22]. Reduced activation of SP-NK1R signaling reduces the downstream inflammatory pathway, which subsequently reduces acinar cell necrosis. Their study also emphasized the idea that inflammation and pain positively reinforce each other, therefore, minimizing pain is considered a potential strategy to mitigate inflammation [23]. Interestingly, Green et al. recently challenged our current understanding of the NK-1 receptor as the primary facilitator of SP-generated peripheral neurogenic inflammation and pain. Their study illustrated similar patterns of innate immune cell recruitment in *NK-1R*-deleted mice as that of WT mice, whereby injections of SP caused a significant influx of inflammatory cells. More specifically, the activation of the mast cell receptor Mrgprb2/X2 by SP lead to cytokine release and recruitment of immune cells contributing to inflammatory pain. The finding that SP promoted immune cell recruitment via Mrgprb2 rather than NK-1 receptor provides a novel target in treating inflammation and pain [24].

Many studies have also sought to understand the pathological role of CGRP in patients with pancreatitis. CGRP has been explored as a neuromodulating peptide in diverse painful conditions, due to its localization in unmyelinated sensory nerves that are activated by nociceptive and painful chemical stimuli [10]. Numerous studies have also indicated that CGRP induces vasodilation by the release of nitric oxide and subsequently mediates an inflammatory response by increasing of IL-1β and IL-6 expression [25]. Hu et al. illustrated that patients with acute pancreatitis had elevated trypsin and CGRP in their serum. They have hypothesized that serum CGRP could act as a new detection index of acute pancreatitis and serve as evidence of ongoing pancreatic inflammation [26].

TRP Channels and Protease Receptors

Transient receptor potential (TRP) cation channels, key regulators of nociception, have been implicated in both acute [27] and chronic [28] pancreatitis. Schwartz and colleagues used cerulein-treated mice to demonstrate that antagonists for the TRP vanilloid type 1 and ankyrin type 1 (TRPV1 and TRPA1, respectively) channels effectively block both pain and inflammatory markers, including upregulation of myeloperoxidase and neutrophil infiltration (acute pancreatitis), as well as fibrosis and nerve sprouting (chronic pancreatitis). The question then becomes what are the signals released by the damaged pancreas that produce abnormal activation of pancreatic afferents?

The majority of pancreatic afferents express receptors on their pancreatic terminals that can induce activation and calcium influx into the presynaptic terminal, which can contribute to the release of inflammatory molecules (Fig. 15.2). The receptors in sensory endings that have received the most attention in recent years are the transient receptor potential cation channel subfamily vanilloid type 1 and 4 (TRPV1, TRPV4), a related family member TRP ankyrin 1 (TRPA1) and protease-activated receptor 2 (PAR2). They can be stimulated by numerous endogenous molecules including anandamide (an endogenous cannabinoid), protons, leukotriene B4, hydrogen peroxide, and products of lipid peroxidation such as 4-hydroxynonenal [28–31]. Their activation triggers the release of proinflammatory neuropeptides like SP and CGRP, thereby initiating neurogenic inflammation both at the spinal cord and peripheral sites, thus causing pancreatic inflammation via neurogenic inflammation [32].

Numerous studies have demonstrated that TRPV1 is involved in peripheral inflammation, in the modulation of nociceptive inputs to spinal cord and brain stem centers, as well as the integration of diverse painful stimuli [32]. The role of TRPV1 phosphorylation by protein kinase A/C in the development of inflammatory hyperalgesia is well established [33]. During inflammation, protein kinases phosphorylate TRPV1 and thereby enhance its function, with consequent increases in nociceptor sensitization. Interestingly, a calcineurin inhibitor, Tacrolimus (an immunosuppressant drug) enhances TRPV1 function by reducing

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. the dephosphorylation of TRPV1. More specifically, calcineurin blockers increase TRPV1-dependent substance P release from cultured DRG neurons and induce a relapse of acute pancreatitis-related pain in a TRPV1-dependent manner in mice [34,35]. Conversely, dephosphorylation of TRPV1 by a phosphatase (calcineurin) decreases its function. This discovery suggests the involvement of calcineurin in the termination of pancreatic pain. In a recent study, Joseph et al. illustrated that by precisely removing a unique protein kinase phosphorylation site (TRPV1 S801) in mice through CRISPR/Cas9 editing can attenuate inflammatory pain and produce fewer side effects than more general TRPV1 inhibition. This unique observation raises the possibility of engineering novel TRPV1 antagonists that selectively interact at the phosphorylated TRPV1 site [36]. A similar study found that Tacrolimus also interacts with TRPA1 channels in primary sensory neurons. In a mouse model, injection of Tacrolimus evoked licking or biting behaviors and these behaviors were almost abolished in TRPA1 knockout mice. This result indicates that Tacrolimus might also cause pain sensations through TRPA1 activation and confirms the importance of calcineurin (a phosphatase) in pain termination [37].

In recent years, a growing body of studies illustrated that TRPV4 acted as a crucial regulator in neural and inflammatory cells, suggesting TRPV4 may be a potential therapeutic vehicle in inflammatory diseases. TRPV4 plays a significant role in disrupting the epithelial and endothelial barrier function, which suggests an important role in edema formation associated with inflammation and tissue injury [38]. A recent discovery unveils TRPV4 channel's unique interaction with Piezo1 (pressure sensing ion channel type 1). Studies have found that Piezo1 stimulation triggered TRPV4 channel opening, which subsequently led to a sustained elevation in intracellular calcium that caused intracellular organelle dysfunction in pancreatic tissues. Moreover, TRPV4 gene knockout mice were protected from Piezo1 agonist and pressure-induced pancreatitis. This study uncovers a calcium signaling pathway in which Piezo1-induced TRPV4 channel opening causes pancreatitis [39,40].

Moreover, the cooperative interaction between PAR2 and TRPV1, TRPV4 and TRPA1 has been established in hyperalgesia, inflammation, and edema [41]. In the pancreas, trypsin released from the injured pancreatic acinar cells directly activates PAR2, which subsequently sensitizes TRPV1. Their interaction causes neurogenic inflammation in pancreatic tissue [42]. PAR2 can also be activated via tryptase, a substance released from an activated mast cell. When mast cells degranulate and release tryptase, this produces nociception by binding to PAR2 on primary afferents [43–45]. In an experimental animal model Kido et al. illustrated that an agonist of PAR2 induced nociceptive pain behavior and a selective PAR2 antagonist reduced incision-induced guarding pain behavior in rats [46].

Studies have concluded that TRP channels are themselves upregulated by growth factors (NGF and ARTN) that are highly expressed in inflamed pancreata [47–50]. Many studies have attempted to explain the mechanism of NGF-induced pancreatitis pain on sensitization via modulation of TRPV1 [51–53]. Another hypothesized mechanism underlying pain in pancreatitis is the activation of the NGF/trkA pathway [51–53]. These studies indicate that for palliative care, a targeted therapy against TRPs could be essential.

Assuming that pancreatic sensory terminals are similar to other visceral nerve endings, they will express a wide range of receptors that allow them to respond in an autocrine/ paracrine fashion. These receptors could respond to molecules released by adjacent sensory fibers as well as to ATP and norepinephrine released from pancreatic sympathetic postganglionic neurons [54,55]. Many of these molecules may act locally on sensory endings to induce release in the absence of action potential generation. However, once an action potential is generated in a sensory fiber, this will trigger release of proinflammatory neuropeptides and excitatory neurotransmitters. Once this activity reaches the spinal cord it can rebound via a process known as a dorsal root reflex. This reflex produces a retrograde action potential that travels back out to the periphery and initiates release of inflammatory molecules [56–58]. The efficacy of this reflex is exaggerated by spinal cord inflammation, which has been shown to accompany pancreatitis [59,60].

Nerve-Targeted Interventions

Novel experimental models of vagotomy demonstrate contribution to neurogenic inflammation. Szklarczyk and coworkers have recently demonstrated in rat that bilateral vagotomy significantly reduced the severity of AP, which was manifested by decreased activity of serum lipase and improvement of pancreatic blood flow, as compared to the AP rats with intact vagal nerves. In addition, vagotomy caused the increase of anti-inflammatory IL-10 in the blood. Attenuation of AP was supported by the examination of the pancreatic tissue and the reduction of the morphological signs of inflammation such as edema, leucocyte infiltration, and vacuolization of the acinar cells [61]. Their follow-up study indicated that a unilateral vagotomy could also contribute to pancreatic protection. The strong reduction of inflammatory changes was observed in the rats with left vagus nerve removal compared to right vagus nerve removal. Perhaps due to the prevalence of left vagal nerve in pancreatic innervation and predominance of this vagal branch in the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

stimulation of pancreas exocrine function [62]. Since the vagus nerve contains both parasympathetic and sensory fibers, the specific anti-inflammatory mechanism remains unclear; however, these studies have demonstrated that manipulation of the vagus nerve (e.g., vagal inhibitor) could be a potential treatment for pancreatitis.

Moreover, Michalski and coworkers demonstrated that cannabinoid receptors were expressed in the pancreas (on both nerves and other cell types). In cerulein-induced acute pancreatitis, administration of cannabinoid agonists reduced inflammation and alleviated pain in mice [63]. Their follow-up research demonstrated that the addition of cannabinoids leads to a reduced inflammation and fibrosis [64]. To further expand on this idea, Utomo et al. illustrated a direct immune modulatory effect of THC on peripheral blood cell populations in both healthy volunteers and patients with CP. Their study illustrated an immunosuppressive effect of cannabis via deactivation of signaling through the proinflammatory p38 MAP kinase and mTOR pathways and a concomitant deactivation of the pro-mitogenic ERK pathway19 [65].

Although nerve-targeted interventions effectively reduce pancreatitis symptoms in preclinical models, in most experimental paradigms these interventions are applied either simultaneously with the disease-inciting stimulus (e.g., caerulein) or early in the disease process. Thus, their relevance for treatment of patients is unclear, especially for acute pancreatitis where the primary symptom of pain is treated medically with nonsteroidal anti-inflammatory drugs and opioids. Clinicians are reluctant to use more aggressive procedures that include injections into splanchnic nerves or celiac ganglia due to occasional adverse effects that can be severe and difficult to justify for a disease that in many cases resolves relatively quickly. However, for chronic pancreatitis, nerve injections are an important option. There are three primary techniques that are utilized to manage intractable pancreatic pain: celiac plexus block (CPB), celiac plexus neurolysis (CPN), and thoracoscopic splanchnic denervation (TSD). Importantly, there is little or no evidence that these treatments affect non-pain disease features (which would be difficult to assess in the absence of large controlled trials). TSD can effectively reduce adreno-medullary function, pain scores, and opioid use in patients with chronic pancreatitis [66,67]. A meta-analysis of 16 studies reveals that TSD significantly reduces pain and improves quality of life. However, the pain returns in half of those initially achieving relief after just 1.5 years [68,69]. There are many possible explanations for why TSD may not provide complete and lasting pain relief. During the surgical procedure, damage to nearby intercostal nerves or incomplete denervation of the thoracic splanchnic nerves (greater, lesser, least) may contribute to residual pain. However, the splanchnic nerves carry not only sensory fibers, but sympathetic fibers as well. Given that sympathetic activity suppresses pancreas function, the loss of this brake following denervation could result in hypersecretion of digestive enzymes that exacerbates inflammation and pain. Furthermore, some patients may have progressed to sensitization of the CNS meaning that they will continue to experience pain and hypersensitivity in the absence of peripheral input. Separately, the pancreas is still innervated by the vagus. While the role of vagal sensory afferents in pancreatic nociception has not been thoroughly investigated, it is possible that these fibers, which remain intact, are also contributing to the recurrence of chronic pain. Further studies will be needed to parse out the underlying cause for some patients to develop persistent pain following TSD.

Conclusion

The efficacy of silencing sensory neurons for patients with pancreatitis will be worth revisiting in the future with the development of new drugs that have been developed for pain and that act by blocking either sensory nerve function or the inflammatory molecules released by sensory fibers. For example, clinical trials are now under way for both anti-NGF and anti-CGRP antibodies and drugs [70–74]. These drugs may make it possible to conduct sufficiently powered clinical trials to determine if these types of therapies are both safe and effective for this difficult disease. Further studies are needed to clarify the interaction of inflammatory cells and nerves in AP as well as in chronic pancreatitis. A better understanding of the complex cellular and molecular mechanisms of neuroimmune interactions should offer possibilities for innovative therapy and long-term disease prevention.

Introduction

Pancreatitis is an inflammatory disorder of the exocrine pancreas caused, in most cases, by immoderate alcohol consumption or the passage of gallstones. Recent studies involving animal and isolated cell models have elucidated many of the pathophysiological, cellular, and molecular processes involved in the disease onset. More than 100 years ago it was proposed that pancreatitis is essentially a disease in which the pancreas falls prey to its own, prematurely activated digestive enzymes. Why and how digestive zymogens undergo activation within the pancreas early in the disease process has been the topic of extensive research efforts and debate. Premature activation of pancreatic zymogens results in biochemical and later metabolic alterations, the mechanisms of which will be reviewed in the following chapter. Regardless of the underlying etiology the natural course of pancreatitis, a primarily sterile inflammatory disorder, proceeds in three steps: (i) a local inflammatory reaction—caused by tissue edema or characterized by extensive necrosis, (ii) a systemic inflammatory response (SIRS), and (iii) eventually microbial superinfection of the pancreatic necrosis, which frequently results in multiorgan failure and is closely associated with a rise in mortality. Mortality in severe acute pancreatitis peaks at two different time points: patients either pass away during the first 7 days after the onset of pain from an overwhelming inflammatory response syndrome resulting in multiorgan failure (~30%) or they die late in the disease course facilitated by a compensatory anti-inflammatory response syndrome, which permits translocation of gut bacteria into pancreatic necrosis, resulting in uncontrollable sepsis. Frequently, however, a mixed picture of a systemic inflammatory response and a compensatory anti-inflammatory reaction, called MARS (mixed anti-inflammatory response syndrome), is observed. The pathogenesis of the inflammatory response in acute pancreatitis is indistinguishable from that of other traumatic or infectious immune reactions, but pancreatitis is often characterized by an overwhelming course. Thirty percent of all patients admitted to hospital suffering from acute pancreatitis display symptoms of a two-organ failure at admission. Outside the pancreas the most frequently affected organs are the lungs, kidneys, and the gut [1].

Molecular and Biochemical Abnormalities

Pathophysiological Significance of Digestive Protease Activation

Trypsinogen and other pancreatic proteases are synthesized by acinar cells as inactive proenzyme precursors and stored in membrane-confined zymogen granules. After activation in the small intestine, trypsin converts other pancreatic zymogens such as trypsinogen (*PRSS1*, *PRSS2*), chymotrypsinogen (*CTRC*), proelastase, pro-carboxypeptidase, or pro-phospholipase A2 to their active forms [2]. Although small amounts of trypsinogen are probably activated within the pancreatic acinar cell under physiological conditions, two protective mechanisms normally prevent cell damage from proteolytic activity: (i) Pancreatic secretory trypsin inhibitor (PSTI), the product of the *SPINK1* gene, is co-secreted with pancreatic zymogens. PSTI can inhibit up to 20 % of potential trypsin activity in humans [2].

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.
© 2023 John Wiley & Sons Ltd. Published 2023 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/beger/thepancreas4e

The fact that mutations in the *SPINK1* gene are associated with certain forms of human pancreatitis [3,4] indicates that this protective mechanism may play a role in pancreatic pathophysiology. The implications of SPINK1 overexpression in a disease model of pancreatitis have recently been reported [5]. (ii) Cell biological experiments using living rodent acini provided evidence that trypsin limits its own activity by autodegradation under conditions that mimic pancreatitis [6]. In humans, mesotrypsin has been labeled a candidate for autoactivation of trypsinogen. This minor trypsin isoform constitutes less than 5 % of total secreted trypsinogens. Interestingly, mesotrypsin is poorly inhibited by PSTI, which led to the suggestion that it might participate in degradation of other zymogens and proteases. Recently, the evolutionary signature mutation of human mesotrypsin was introduced into mouse cationic trypsinogen, to recapitulate salient features of human mesotrypsin. In these animals, no change in experimental pancreatitis severity was observed excluding a crucial role of mesotrypsin in the course of pancreatitis [7].

The suggestion that prematurely activated digestive enzymes play a central role in the pathogenesis of pancreatitis is based on the following observations: (i) The activity of both pancreatic trypsin and elastase increases early in the course of experimental pancreatitis. (ii) The activation peptides of trypsinogen and carboxypeptidase A_1 (CPA_1), which are cleaved from the respective proenzyme during the process of activation, are released into either the pancreatic tissue or the serum early in the course of acute pancreatitis [8]. (iii) Pretreatment with gabexate mesilate, a serine protease inhibitor, reduces the incidence of ERCP-induced pancreatitis [9]. (iv) Serine protease inhibitors reduce injury in experimental pancreatitis [9]. (v) Hereditary pancreatitis is often associated with various mutations in the cationic trypsinogen gene that could render trypsinogen either more prone to premature activation or may render active trypsin more resistant to degradation by other proteases. (vi) Triplication of the trypsinogen locus in humans, i.e., an assumed gain in the trypsin activity that is expressed in affected subjects leads to hereditary pancreatitis. (vii) Mutations in the *SPINK1* gene, which might render PSTI less effective, are associated with certain forms of chronic pancreatitis [3].

Certain mutations associated with human hereditary pancreatitis stabilize cationic trypsin against autolysis by blocking CTRC-dependent trypsinogen degradation or by increasing CTRC-mediated processing of the trypsinogen activation peptide [10]. However, it has been shown that decreased autodegradation, opposite to intracellular trypsin activity mediating autoactivation, outweighs in the course of pancreatitis [6]. Recently, *in vivo* studies employing trypsinogen-7 (T7) knockout animals, resembling human PRSS1, revealed a minimal effect on inflammation in acute pancreatitis, moreover a ~50% reduction of intrapancreatic trypsin activity was detected. Knockout of T7 did not exert a significant effect on chronic pancreatitis severity [11]. Recently, a humanized PRSS1 mouse model revealed that mice carrying a humanized PRSS1 p.R122H mutation did not exert spontaneous intracellular autoactivation; however, in conjugation with established risk factors led to more severe pancreatitis [12]. A similar approach of humanized PRSS1 p.K23R knockin showed severe pancreatitis driven by intracellular trypsin autoactivation [13].

In clinical and experimental studies that investigated the time course of pancreatitis it was detected that trypsinogen activation occurs very early in the course of acute pancreatitis, and is dependent on a pathological intracellular calcium signal. One study that employed the caerulein model of acute pancreatitis reported a biphasic pattern of trypsin activity that reached an early peak after one hour and a later second peak after several hours [8]. This observation is interesting because it suggests that more than one mechanism may be involved in the activation of pancreatic zymogens and the second peak may require the infiltration of inflammatory cells into the pancreas. Taken together these observations represent compelling evidence that premature, intracellular zymogen activation plays a critical role in initiating acute pancreatitis.

Clinical Evidence for Digestive Protease Activation

A number of recent studies involving patients have greatly contributed to understanding the role of zymogen activation in pancreatitis. In patients who underwent endoscopic retrograde cholangiopancreatography (ERCP), an interventional medical procedure that requires cannulation of the pancreatic duct and is associated with a significant complication rate for pancreatitis, the prophylactic administration of a small molecular weight protease inhibitor reduced the incidence of pancreatitis [14]. While protease inhibitors have not been found to be effective when used therapeutically in patients with clinically established pancreatitis, the result of the prophylactic study supports the conclusion that activation of pancreatic proteases is an inherent feature of the disease onset. Moreover, since reasonably specific antibodies have become available that detect the trypsinogen activation peptide (TAP) but do not cross-react with either active trypsin or inactive trypsinogen, the presence of TAP in serum and urine of patients with acute pancreatitis provides direct evidence for an activation of trypsinogen during

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pancreatitis. The amount of TAP released also appears to correlate with the disease severity [15].

Cathepsin B in Premature Digestive Protease Activation

Several lines of evidence have suggested a possible role for the lysosomal cysteine protease cathepsin B in the premature and intrapancreatic activation of digestive enzymes [9]. The largely circumstantial evidence for this "cathepsin B hypothesis" is based on the following observations: (i) CTSB has been shown to activate trypsinogen *in vitro*; (ii) during the initial phase of acute pancreatitis in several animal models a redistribution of CTSB into a zymogen granule-containing subcellular compartment was detected by density gradient centrifugation [16]; and (iii) experimental approaches to show an essential role of CTSB in premature zymogen activation by inhibition of this lysosomal enzyme with synthetic inhibitors rendered contradictory results either increasing or decreasing premature zymogen activation, or failing to improve the course of experimental pancreatitis [17]. To test the cathepsin B hypothesis more directly and to overcome the shortcomings of lysosomal enzyme inhibitors, which have only limited specificity for CTSB, a CTSB-deficient mouse strain that was generated by targeted disruption of the *ctsb*-gene was studied in experimental pancreatitis [6]. The results of these studies were unequivocal: 90% of intrapancreatic trypsinogen activation during pancreatitis depends on the presence of cathepsin B [6].

Human genetic studies excluded CTSB as a susceptibility gene for pancreatitis. An association with chronic pancreatitis was detected in the Indian population but the effect size was small and could not be replicated in other cohorts [18]. *In vitro*, the majority of hereditary-pancreatitis-associated cationic trypsinogen mutations that increased autoactivation had no effect or even diminished CTSB-mediated activation. Thus, a knowledge gap remains whether CTSB-mediated trypsinogen activation observed in rodent models is relevant to the human condition.

All the above data suggest that cathepsin B-induced protease activation is a critical component in the onset of pancreatitis and the time has finally arrived for evidence from human studies to emerge in support of this hypothesis. It has been recently shown that cathepsin D (CTSD) is expressed in pancreatic acinar and inflammatory cells, undergoes subcellular redistribution and activation during experimental pancreatitis, and regulates disease severity by potently activating CTSB. Its impact is only minimal and transient in the early, acinar cell-dependent phase of pancreatitis and much greater in the later, inflammatory cell-dependent phase of the disease [19]. However, a number of additional issues regarding the cathepsin-hypothesis of pancreatitis remain to be addressed: (i) the conditions under which two physiologically colocalized classes of enzymes begin to activate or degrade each other remain unknown and may have important therapeutic implications; (ii) the cellular basis of the subcellular redistribution phenomenon of lysosomal enzymes remains poorly understood and could involve either protein sorting or vesicular fusion events; (iii) if either the ratio of lysosomal cathepsins and digestive proteases, or the processing of lysosomal cathepsins itself, were to vary from one class of vesicular compartment to the next, or even within the same compartment, this may change the interpretation of the role of cathepsins in pancreatitis and therefore needs to be explored.

Conclusions

During the course of pancreatitis the extent of acinar cell necrosis is not proportional to intrapancreatic trypsin activity [16]. This lends to the hypothesis whether acinar cell damage beyond a certain threshold is irrelevant for the progression of pancreatitis, or whether only a given degree of trypsin activation is required to elicit activation of other digestive enzymes in a cascade inside the acinar cells to drive pancreatitis severity. To support the first assumption, trypsin must have other effects beside the protease activation cascade or even outside pancreatic acinar cells. One such cellular compartment where trypsin plays a role outside the exocrine pancreas is trypsin activation within macrophages, leading to macrophage activation [20]. Furthermore, extracellular trypsin affects the capacity of inflammatory cells to enter the pancreas and it activates protease-activated receptors (PAR) on pancreatic ductal epithelial cells.

Metabolic and Systemic Abnormalities

In the past, patients with acute pancreatitis have been categorized according to the presence or absence of complications and the definitions of severe disease and the Atlanta classification [21] has codified this concept. Complications include systemic organ failures as well as local disease manifestations. Recently, it has been shown that organ failure during the first week of admission is invariably associated with a high mortality rate of >50% [22]. An investigation of 290 patients with predicted severe acute pancreatitis showed that early organ failure was present in 60% of patients. When organ failure was

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

only transient clinical outcome was good (mortality below 1%), whereas persistent organ failure resulted in a mortality rate of 35% [1]. A better understanding of the pathogenesis of early multiorgan failure might therefore be essential for the development of new strategies for the prevention or treatment acute pancreatitis.

Pathogenesis of Pulmonary Failure

ARDS (acute respiratory distress syndrome), later termed ALI (acute lung injury) is a frequently occurring manifestation of organ dysfunction in an intensive care setting and can be the cause of death in critically ill patients. The exact incidence remains unknown but may be as high as 75 per 100,000 population in the USA [23]. Overall acute pancreatitis is a condition in which patients rarely develop ARDS (8%) of total, but severe attacks are frequently associated with acute lung injury (ALI) and respiratory failure (ARDS). The definition set in 1994 for ALI reads as follows: a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiological, physiologic abnormalities that cannot be explained by, but may coexist with, left atrial or pulmonary capillary hypertension [24]. The distinction between ALI and ARDS is the degree of hypoxemia. The incidence of pulmonary complications in acute pancreatitis varies between 15% and 55% and their severity ranges from mild hypoxemia without clinical or radiological signs to severe ARDS. The major cause of hypoxemia is ventilation/perfusion mismatch, which results in right to left pulmonary shunting. In ARDS the injured lung is believed to go through three phases: exudative, proliferative, and fibrotic but the course of each phase and the overall disease progression are variable. The pathophysiological features of the lung in ARDS arise from severe injury to the alveolo-capillary unit. The histological features are dense eosinophilic hyaline membranes and alveolar collapse. The endothelial cells swell, the intercellular junctions widen and pinocytic vesicles increase, causing capillary leak and edema formation. Approximately 10% of patients with acute pancreatitis show alveolar edema on chest radiographs and one third of patients develop progressive hypoxemia during the first week of hospitalization [45]. The cause for the development of alveolar edema is an increase in microvascular permeability in the context of SIRS. This was shown by applying labelled transferrin as an indicator for lung vascular permeability within 48 hours after hospital admission, which was found to be significantly increased in the lung tissue of patients who had later died in the disease process [25]. A similar observation demonstrated an increase in the gallium-transferrin pulmonary leak index strongly correlated with the mortality rate [26].

Lankisch and coworkers determined the incidence of pulmonary infiltrates in 140 consecutive patients with acute pancreatitis with 26% within 24 hours after admission to hospital [27] (see Fig. 16.1). The mortality rate of acute pancreatitis significantly correlated with the presence of pulmonary infiltrates and effusions. Logistic regression analysis showed that radiologic abnormalities were associated with a 15-fold increase in mortality rate. A reduced PaO2 on hospital admission has long been regarded as a prognostic factor for the severity of pancreatitis and is part of the Ranson Score, the Imrie Score, and the newly released UK guidelines, which recommend to hold peripheral oxygen saturation above 95% to prevent organ failure as a treatment goal [28].

With respect to the pathophysiology of ARDS in acute pancreatitis two case series showed that massive cytokine release may have a contributing role in SIRS. Especially IL-8 was reported to be significantly higher in patients at admission who later developed acute severe lung injury [29]. In pleural effusions TNF-α, IL-1, IL-6, and PMN-elastase were significantly higher in serum in ARDS patients, which may point to a direct impact of these cytokines on the development of ARDS but could also occur because of a diminished excretion of cytokines into pleural effusions [30].

Phospholipase A2 (PLA-2) has long been regarded as a major culprit for acute lung injury in acute pancreatitis. Out of numerous phospholipase A2 (PLA-2) subtypes, PLA-2 type I and PLA-2 type II, have been implicated in the pathogenesis of pancreatitis. PLA-2 type I is expressed by pancreatic acini (cytoplasmic PLA-2 type Ib). Data from Creutzfeldt and coworkers dating back to

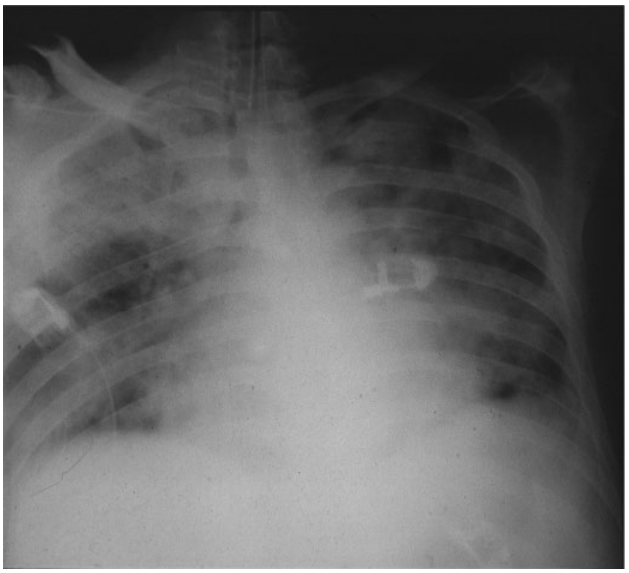

Figure 16.1 Severe adult respiratory distress syndrome in severe acute pancreatitis.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. 1969 suggested that PLA-2 type II is responsible for the cell necrosis in acute pancreatitis by converting its endogenous substrate lecithin (part of the lipid bilayer of cell membranes) into the more toxic compound lysolecithin. Thus PLA-2 could break down pulmonary surfactant which consists of phospholipids and could therefore impair oxygenation and increase vascular permeability. This notion was confirmed as elevated circulating plasma levels of PLA-2 correlated with more severe pulmonary changes in patients with gram-negative septic shock [31]. Furthermore, intratracheal application of nonpancreatic PLA-2 induced lung injury with interstitial edema and accumulation of inflammatory cells, but the concept that release of pancreatic PLA-2 from necrotic acinar cells mediates lung injury had to be abandoned. In addition to the hypothesis of a direct impact of PLA-2 other pancreatic zymogens and nitric oxide released from pulmonary macrophages have been implicated in contributing to pulmonary complications in acute pancreatitis. An experimental study testing this concept showed that intravenous application of elastase or trypsin resulted not only in pulmonary damage through NFκB activation and TNF-α release with subsequent transmigration of neutrophils but also in an increase in lung vascular permeability. Neutrophils have been implicated in mediating lung injury in acute pancreatitis and inhibition of neutrophil-derived serine proteases such as PMN-elastase seem to be promising treatment targets [32].

In conclusion, severe attacks of acute pancreatitis are frequently associated with acute lung injury. Arterial hypoxemia, pulmonary infiltrates, pleural effusions as well as ARDS may develop as complications of the disease. Within the first few days following the onset of severe acute pancreatitis lung injury develops because of acute pancreatitis. Sepsis is the predominant cause of lung injury in the later phase of the disease. Besides best supportive care, protective mechanical ventilation, hemodynamic monitoring as well as enteral nutrition and renal replacement therapy have been considered to be of potential benefit to treat pulmonary complications.

Pathogenesis of Renal Failure

Acute renal failure (ARF) occurs in 19% of patients with moderate sepsis, 23% with severe sepsis, and 51% with septic shock with positive blood cultures [33]. The cytokine-mediated induction of nitric oxide synthesis that occurs in SIRS and sepsis decreases systemic vascular resistance. This arterial vasodilatation predisposes patients with SIRS to ARF [34]. Patients who develop ARF in the setting of critical illness are more likely to die than dialysis-dependent patients admitted to ICU, suggesting that the bad outcome associated with the recent development of renal failure is due to SIRS, rather than merely due to renal dysfunction [35]. The clinical syndrome of ARF in the setting of critical illness, manifested by rising serum creatinine and decreasing urine output, results from injury to the tubular epithelial cells or acute tubular necrosis. In necrotizing pancreatitis renal insufficiency occurs in 21% of patients after a median time period of 8.3 days after the onset of pancreatitis. In analogy to the pathogenesis of ARF in critically ill patients suffering from SIRS a combined pathomechanism of prerenal failure due to extensive fluid loss into the third space together with a prolonged cytokine-mediated organ failure even after fluid resuscitation can be assumed to be operative. Simmons and coworkers showed that increased plasma proinflammatory cytokine levels (TNF-α, IL-1b, IL-6) predict the mortality in patients with ARF [36]. This finding is supported by the fact that in animal models infusion of high concentrations of proinflammatory cytokines can lead directly to the development of multiorgan system failure. Furthermore, patients with SIRS and associated ARF show signs of intense endothelial damage and hypercoagulability as indicated by increased vWF, thrombomodulin, t-PA, PAI-1, and D-dimer activity [37]. In conclusion, ARF is a frequent extrapancreatic complication of acute pancreatitis but studies on the pathogenesis of ARF are urgently needed to treat this potentially fatal complication.

Pathogenesis of Paralytic Ileus and Gut Permeability

Patients with acute pancreatitis often suffer from severe intestinal motility disturbances, which render them prone to bacterial translocation into the pancreatic necrosis due to bacterial overgrowth and increased gut permeability, which is then burdened with an increase in mortality (Fig. 16.2). Studies on CDE-diet fed mice revealed that acute necrotizing pancreatitis inhibits gastric emptying and intestinal transit *in vivo*. The global reduction in jejunal contractility is explained by the disruption of the intestinal motor function at the postreceptor level, which plays an important role for the development of an intestinal ileus during acute pancreatitis [38].

In an animal model of acute pancreatitis Ryan and coworkers reported a significant increase in intestinal permeability to macromolecules that correlated with disease severity. The pathogenesis of gut barrier failure can be attributed to local (intestinal) factors namely: mucosal ischemia, disruption of mucosal epithelial integrity, reperfusion injury, disruption of intestinal bacterial ecology, as well as impaired mucosal immunity. Thoracic epidural analgesia for pain also augments ileal mucosal capillary perfusion and improves survival in severe acute pancreatitis [39].

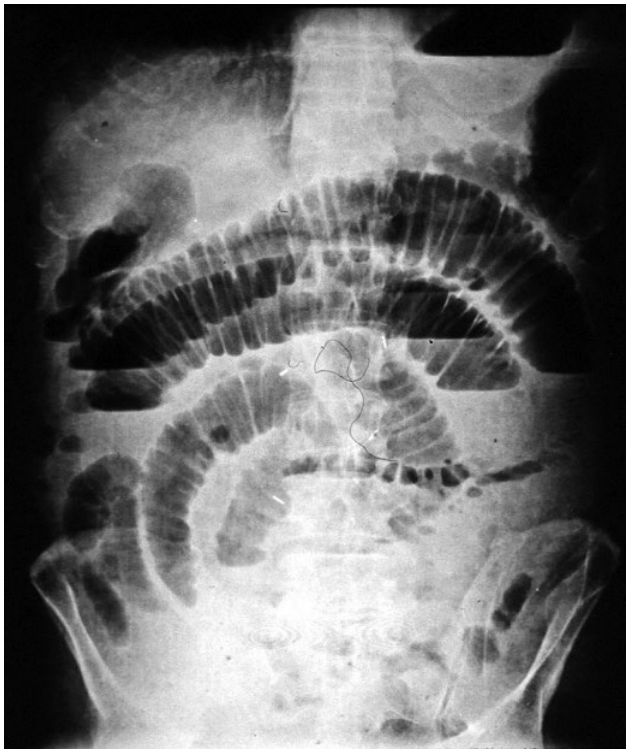

Figure 16.2 Paralytic ileus in severe acute pancreatitis.

Pathogenesis of Coagulopathies

The systemic inflammatory reaction and the development of organ failure in acute pancreatitis share similarities with a complicated course of sepsis, major trauma, or burns [40]. Ranson and coworkers noted abnormalities in coagulation factors during severe acute pancreatitis. They concluded from a prospective analysis of 35 patients in which they correlated amylase levels with respiratory, renal, and hepatic dysfunction that enzyme-related intravascular coagulation is involved in the pathogenesis of these coagulation complications during acute pancreatitis [41]. In systemic inflammation a rapid activation of coagulation may turn into a global or selective exhaustion of physiological anticoagulant systems. The interactions between coagulation and inflammatory pathways are essential for the pathogenesis of disseminated intravascular coagulation. For example, the proinflammatory cytokines TNF-α, IL-1, and IL-6 upregulate thrombin formation and downregulate physiological antithrombotic defence mechanisms, especially the protein C pathway [42]. The protein C pathway is both a major physiological anticoagulant system and a central link between inflammation and coagulation. The zymogen protein C is converted to activated protein C (APC) by thrombin bound to thrombomodulin on the endothelial surface. While the underlying mechanism is incompletely understood, recombinant APC decreased the levels of IL-6 and D-dimer and reduced mortality in severe sepsis patients. Investigating levels of APC, PC, and D-dimer in 31 patients with severe acute pancreatitis showed that PC deficiency and decreased APC generation contributed to a compromised anticoagulant- and anti-inflammatory defence, which subsequently aggravated multiorgan failure. Clinical trials evaluating treatment with PC are warranted in severe acute pancreatitis. In addition to the therapeutic impact of restoring coagulation in severe acute pancreatitis a recent clinical study has shown that signs of disseminated intravascular coagulation are also of high prognostic value. The aggravated coagulation parameters predict a fatal outcome in patients with acute pancreatitis. An AT-III level <69% was the most accurate marker for poor outcome of acute pancreatitis at admission [43].

Electrocardiographic Abnormalities in Acute Pancreatitis

Acute pancreatitis has been reported to be associated with electrocardiographic abnormalities including arrhythmias, bradycardia, T-wave changes, intraventricular conduction disturbances, and ST-segment elevation termed "pseudoinfarction" (Fig. 16.3). The clinical relevance and causes of such electric abnormalities are poorly understood. However, experimental studies performed on a murine model of acute pancreatitis have reported ultrastructural disturbances including interstitial edema and cardiomyocyte hypoxia, myofiber overcontractility, intracellular edema between cardiomyocytes, and cardiomyocyte hypertrophy with collagenization of myocardial stroma [44]. Albrecht and Laws proposed a direct cardiotoxic effect of proteolytic pancreatic enzymes as a cause of ST-segment elevation and myocardium specific enzyme increase (particularly phosphokinase MB fraction). Other mechanisms that have been proposed to explain electrocardiographic abnormalities appearing during AP are those associated to metabolic disturbances, hemodynamic instability, vasopressor drug use, pericarditis, myocarditis, exacerbation of underlying cardiac disease, coagulopathy, and coronary artery spasm [45]. Patients with acute pancreatitis have a high risk to develop metabolic abnormalities. The consequences of low or high serum electrolyte levels on cardiac electric activity include changes in the T-wave morphology, bundle branch blocks arrhythmias, QT-internal shortening or prolongation, asystole, prominent U-wave, ST-segment depression or elevation, ventricular fibrillation [46]. Recently two prospective studies have reported abnormalities on ECG and correlated these changes to the severity of acute pancreatitis.

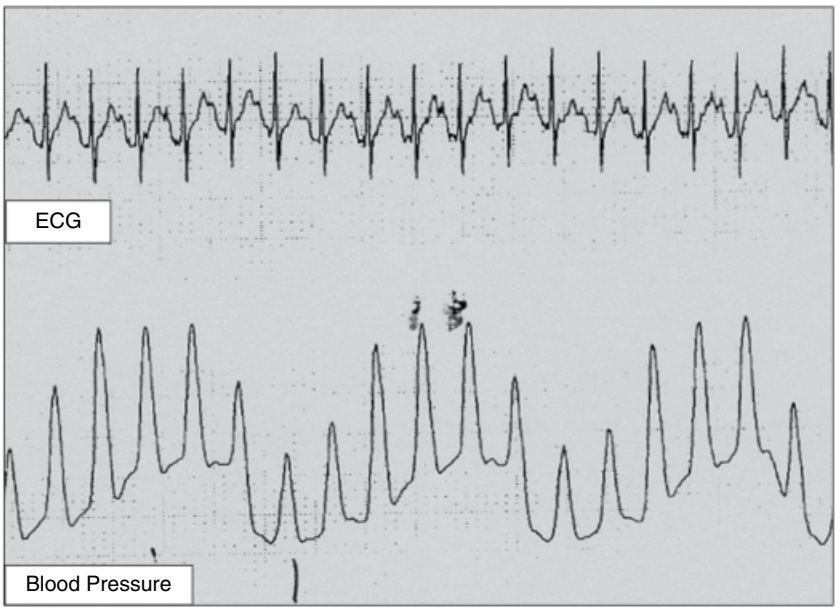

Figure 16.3 ECG changes in severe hypovolemia and hypopotassemia.

The Role of Hypocalcemia and Hypomagnesemia

Hypocalcemia is a frequent finding in patients with severe acute pancreatitis and has been implicated to be of prognostic value by the Ranson scoring system [47]. It has been demonstrated that hypocalcemia is more frequent in severe attacks as compared to mild attacks of pancreatitis (86% vs. 39%) [48]. Prevalence of hypocalcemia ranges between 15% and 88% in critically ill patients. Several pathogenetic mechanisms contribute to the development of hypocalcemia and need to be considered in evaluating hypocalcemia: (i) Serum calcium levels reflect only part of the physiologically active ionized calcium. More than half of the circulating calcium is bound to albumin and serum calcium levels need to be corrected for serum albumin levels as albumin is lost to the third space. When calcium levels are corrected for albumin, the majority of patients display normocalcemia, which explains the absent symptoms of hypocalcemia like arrhythmias and tetany. (ii) In response to decreased serum calcium levels circulating parathyroid hormone levels (PTH) are increased. This subsequently leads to calcium mobilization from bone and calcium reabsorption in the kidneys is increased. In a prospective study by McKay PTH levels were determined to be invariably elevated in response to hypocalcemia in acute pancreatitis but significantly increased concentrations were found in patients with a complicated course of the disease [49]. Inadequate mobilization of calcium from bone indicating end-organ failure could offer an alternative explanation for hypocalcemia. However, patients suffering from acute pancreatitis were shown to react with an adequate rise in serum calcium levels and urinary cyclic adenosine monophosphate upon infusion of exogenous PTH. These findings had been previously substantiated by data from animal experiments [25]. Hypomagnesemia together with hypocalcemia can inhibit PTH secretion as well as peripheral action of PTH. Intracellular magnesium levels in patients with acute pancreatitis are thus believed to be decreased [50]. Patients with acute pancreatitis and hypocalcemia commonly also show intracellular magnesium deficiency despite normal serum magnesium concentrations. Magnesium deficiency could therefore play a significant role in the pathogenesis of hypocalcemia in acute pancreatitis. It has been reported that bivalent cation Mg^{2+} counteracts the intracellular calcium signaling and thereby ameliorates the deleterious effect of intracellular premature zymogen activation. Moreover, in preliminary experiments we were able to show that Mg^{2+}-therapy readily administered as a food supplement in an animal model of acute pancreatitis has a beneficial effect on the course of the disease. Currently we are conducting a multicenter, multinational, randomized, placebo-controlled phase II trial to investigate the efficacy of oral magnesium for the prevention of painful acute episodes of hereditary and idiopathic pancreatitis (EUROPAC-2) [3]. The role of increased free fatty acids (FAA) in the pathogenesis of hypocalcemia in acute pancreatitis has not been clearly elucidated and different pathophysiological mechanisms have been proposed. Circulating lipase and phospholipase released from necrotic pancreatic acinar cells may cleave triglycerides and hereby lead to elevated serum FAA. Warshaw determined the effect of FFA on

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. serum calcium levels in an animal model. His findings suggested that (i) changes in the concentration of FFA occur spontaneously but may have an impact on calcium levels; (ii) the observed depression of calcium may be due to intravascular sequestration of calcium by FFA-albumin, but increased flux of circulating calcium-FFA complexes into extravascular and intravascular sites may also be important; and (iii) the markedly increased FFA concentration in some patients with acute pancreatitis may contribute significantly to hypocalcemia and calcium flux [51]. In conclusion, hypocalcemia is a frequent finding in severe acute pancreatitis.

Histopathology of Acute Pancreatitis

Günter Klöppel

Department of Pathology, Consultation Center for Pancreatic and Endocrine Tumors, Technical University Munich, Munich, Germany

Introduction

In this chapter, the histopathology of acute pancreatitis is reviewed and the various patterns of tissue damage that have been described so far are related to the known etiologic factors and the discussed pathogenetic mechanisms. Finally, an attempt is made to correlate the histopathologic findings with the clinical and radiologic criteria of the 2012 Atlanta Classification of Acute Pancreatitis [1] that revised the 1992 Atlanta classification [2].

Definition

Acute pancreatitis is in most cases a necroinflammatory autodigestive damage that initially involves the intrapancreatic and extrapancreatic fatty tissue and is caused by noninfectious factors. Rarely acute pancreatitis has an infectious cause and shows initially an acinar cell necrosis [3]. Clinically and histologically, it can be classified into a mild form called acute interstitial edematous pancreatitis affecting 90–95% of patients, and a severe form called acute necrotizing pancreatitis affecting only 5–10% of patients. The mild form of acute pancreatitis is often associated with gallstone disease, while the severe form is usually linked to alcoholism.

Histopathologic Patterns of Tissue Necrosis

Fatty tissue necrosis within and outside the pancreas is the most frequent histologic lesion that can be seen during the initial phase of most cases of acute pancreatitis based on an autodigestive process (type 1 necrosis pattern) (Fig. 17.1). The necrotic process that emanates from fat cells in the interlobular spaces of the pancreas and in the peripancreatic area, and the later inflammatory reaction, are very variable in degree and extent. Another, but rare, pattern of tissue damage is characterized by necrosis of the duct epithelium which becomes the starting point of a ductal and periductal inflammation. In the third pattern, which is also rare, the acinar cell necrosis is the key lesion that is followed by a perifocal intralobular inflammation [4].

Acute Pancreatitis with Fatty Tissue Necrosis Pattern

Most cases of mild and severe acute pancreatitis are characterized by the fatty tissue necrosis pattern. The degree and extent of this necrosis pattern determines the severity and the course of acute pancreatitis and its classification into mild/interstitial edematous or severe/necrotizing pancreatitis [1] (Table 17.1).

Initial Phase

Interstitial pancreatitis leads commonly to an edematous swelling of the pancreas, but the pancreas may also be normal in size. In addition the pancreas displays tiny white disseminated spots of fatty tissue necrosis on its surface and also in the interlobular fatty tissue [5] (Fig. 17.2). Because this form of pancreatitis has a mild nonlethal course, the study of the described histologic changes is nowadays largely limited to rare resected pancreatic tissue specimens, in which an interstitial pancreatitis developed, either in association with long-term operations or in conjunction with preoperative investigations.

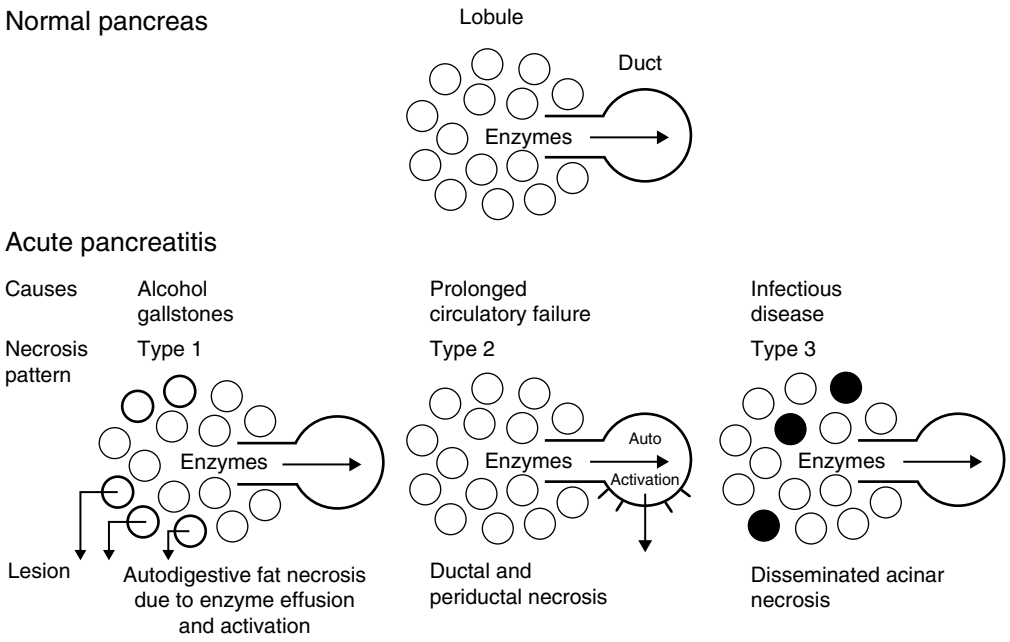

Figure 17.1 Schematic presentation of three necrosis patterns observed in human acute pancreatitis related to potential causative factors.

Table 17.1 Atlanta classification 2012 of acute pancreatitis: type and severity correlated with complications, imaging findings and histopathologic features.

Type and severity	Complications and imaging findings	Histopathologic features
Interstitial edematous pancreatitis		
Mild	None	Parenchymal edema with tiny fat necroses Peripancreatic fat necrosis
Moderately severe	Transient organ failure and/or acute peripancreatic fluid collection (APFC)	
	Pseudocyst (deriving from unresolved APFC)	Pseudocyst (without debris)
Necrotizing pancreatitis		
Severe	Acute necrotic collection (ANC) with persistent organ failure and systemic complications	Large peripancreatic fat necrosis with or without parenchymal necrosis and hemorrhage
	Walled-off necrosis (deriving from ANC)	Well-demarcated pseudocyst emerged from peripancreatic and pancreatic necrosis

Necrotizing pancreatitis is characterized by numerous large and confluent areas of fat necroses extending into the peripancreatic tissue (Fig. 17.3). In addition, the pancreas shows parenchymal necrosis, although it is usually much less extensive than the peripancreatic necrosis. The extent of fat necrosis correlates roughly with the amount of interlobular fatty tissue present in the individual pancreas. This means that the pancreas of obese subjects may show more extensive necrosis than the pancreas of normal weight individuals. Where large fat necrosis involves blood vessels, especially veins, the necrosis becomes hemorrhagic, because of vessel wall damage followed by thrombosis or rupture. Arteries, because of their thick walls, are more resistant to necrosis, but if also affected, can develop thrombosis, resulting in panlobular ischemic necrosis. Another important complication of large fat necrosis that involves the surrounding tissues, is the destruction and thus opening of interlobular ducts that lead to duct leakage of secretions. Surprisingly, acinar cells adjacent to fat necrosis seem to be well preserved for a long time. The only change may be a widening of acinar lumina, which have PAS-positive secretions. The islets are not affected, unless they are lying in lobules that are largely or entirely necrotic. In the course of the disease, the necrotic foci are

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 17.2 Acute interstitial pancreatitis: tiny fatty tissue necrosis within the pancreas. Note the preservation of the adjacent acinar cells.

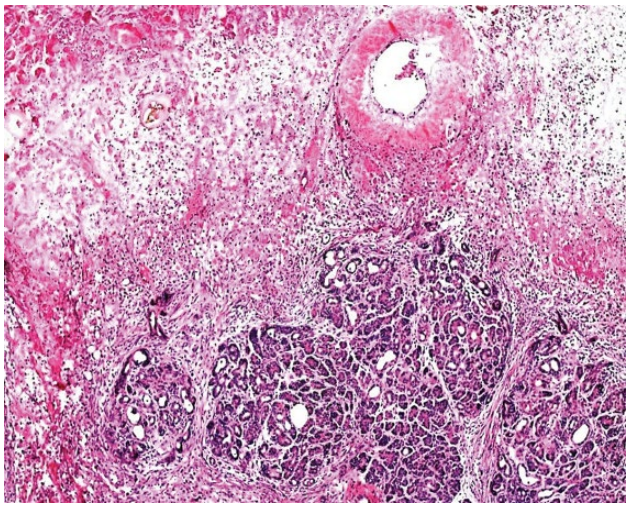

Figure 17.3 Acute necrotizing pancreatitis: extensive peripancreatic fat necrosis with hemorrhage involving the wall of a duct (top) and extending into the interlobular spaces of the pancreatic tissue below.

delimited by a collar of foamy macrophages intermingled with granulocytes that later are increasingly replaced by myofibroblasts to build up a wall of granulation tissue separating the necrosis from intact tissue.

Outcome

In *interstitial pancreatitis*, the edema, which is probably rich in pancreatic enzymes, is usually resolved by macrophages within a few days and leaves no changes behind. The same happens to the tiny foci of fat necrosis. Since the diameter of these fat necroses are usually smaller than 10 mm, they are barely detectable by imaging. Larger liquefied foci of peripancreatic fat necrosis, which probably correspond to the radiologic lesion called "acute peripancreatic fluid collection," are rare. If such a rare lesion does not resolve and gets encapsulated by granulation tissue (see later), it may become a pseudocyst.

In *necrotizing pancreatitis*, the large fat necroses liquefy. Follow-up studies by imaging have shown that necroses not exceeding 2–5 cm in diameter, can be slowly reabsorbed by macrophages. Larger necrotic areas (usually >5 cm), especially when they also involve pancreatic parenchyma, may not resolve spontaneously and their liquefied and hemorrhagic content is then lined by macrophages that, together with some granulocytes and lymphocytes, form a thin layer of granulation tissue within 10–20 days of the onset of the disease. This change may correspond with an "acute necrotic collection" as described by the radiologist (Table 17.1) [6]. Often the macrophages in the granulation tissue contain hemosiderin as a sign of the phagocytosis of hemorrhagic tissue. After 20–30 days, the granulation tissue starts to be replaced by fibrosis with collagen type 1 and 3. If the fibrotic demarcation is fully developed the change is radiologically called "walled-off necrosis" that corresponds to the old term "pseudocyst associated with necrosis" (Table 17.1). Most of these advanced lesions are found outside the pancreas, particularly around the head of the pancreas [7,8]. The fact that walled-off necroses/pseudocysts contain amylase suggests communications with the pancreatic duct system. This may be particularly the case in those pseudocysts which, in time, increase in size and by growing compress or erode such structures as the bile duct, duodenum, stomach, vessels, or peritoneum. The involvement of vessels may also lead to sudden hemorrhage.

Another severe complication is a colonization of the necrotic areas with (mostly gut-derived) bacteria or fungi. This usually takes place during the period (days 4–20) when the demarcation of the liquefied necrotic area still consists of only a small rim of granulation tissue.

The resolution of necrotic tissue within the interstitial spaces of the pancreas is usually followed by the development of interlobular fibrosis replacing the necrotic tissue (Fig. 17.4) [9,10]. If this necrosis-fibrosis process [11] takes place repeatedly because of recurrent attacks of necrotizing acute pancreatitis, and also involves the large interlobular ducts and the main duct, relapsing acute pancreatitis may evolve into chronic pancreatitis [12,13].

Acute Pancreatitis with Duct Epithelium Necrosis Pattern

Initial Phase

Disseminated duct cell necrosis of small to medium-sized interlobular ducts as initial key lesion is accompanied by intraductal aggregates of granulocytes mixed

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 17.4 Acute necrotizing pancreatitis 6 weeks after onset. Development of cell-rich interlobular fibrosis induced by the resorption of a fat necrosis (center). H&E, ×125.

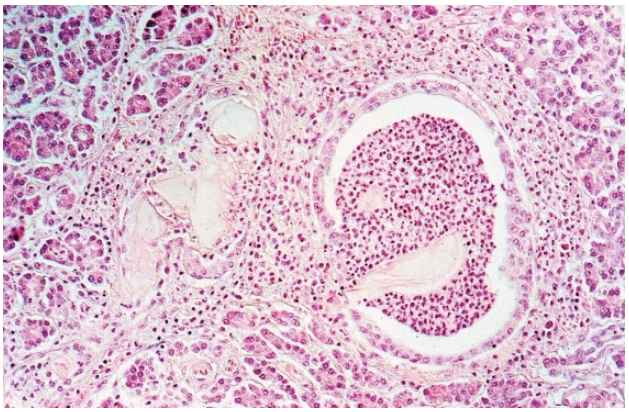

Figure 17.5 Acute pancreatitis with duct epithelium necrosis pattern. Interlobular duct filled with aggregated neutrophilic granulocytes and secretions. Rupture of the duct epithelium with granulocytes infiltrating the periductal interstitial space. H&E, ×120.

with precipitations of eosinophilic secretions. There is also duct rupture and extension of the necrotic process and the granulocytic process into the periductal area (Fig. 17.5). This may be a solitary change, but is also observed in association with foci of fat necrosis elsewhere [14–16]. The ensuing acute pancreatitis seems to be usually mild.

Outcome

The outcome of acute pancreatitis with duct epithelium necrosis is largely unknown because the patients in whom this necrosis pattern has been observed and described all died from prolonged circulatory failure that was usually not caused by acute pancreatitis, but by various extrapancreatic diseases such as hepatic failure. Our only observation of type 2 necrosis so far, made in a pancreatic resection specimen from a patient with hereditary pancreatitis [16], could suggest that in this setting the initial necrosis of the duct-lining cells, followed by an inflammatory involvement of the surrounding interstitial tissue, may result in structural changes such as irregular dilatations and periductal scarring of the affected pancreatic ducts.

Acute Pancreatitis with Acinar Type Necrosis Pattern

Initial Phase

Scattered intralobular foci of acinar cell necrosis are the key lesions of this type of necrosis in acute pancreatitis (Fig. 17.6). It is accompanied by a perifocal inflammatory infiltrate consisting of single neutrophil granulocytes and macrophages. Fat and ductal necrosis are absent. These changes are indicative of a pancreatitis caused by an infection.

Outcome

In acute pancreatitis with acinar necrosis the outcome seems to be favorable in most cases, since the cases that have been reported so far showed a mild pancreatitis [17].

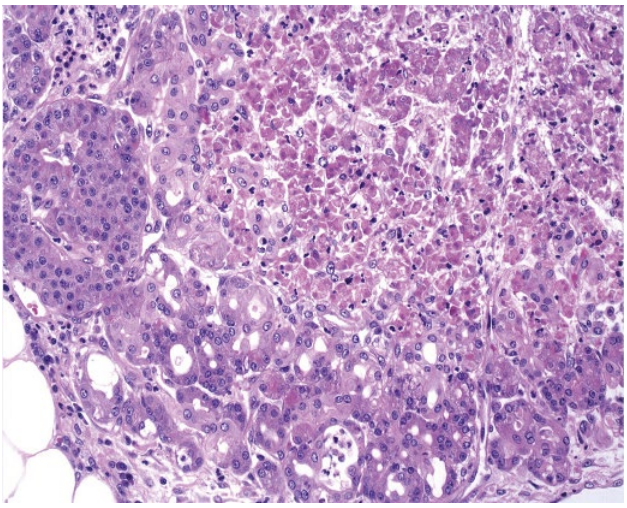

Figure 17.6 Acute pancreatitis with acinar cell necrosis pattern. Intralobular focus of acinar necrosis surrounded by few granulocytes and macrophages.

Histopathology Related to Etiologic Factors and Pathophysiologic Mechanisms

Acute pancreatitis with *a fat necrosis pattern* is most often associated with alcohol abuse and gallstone disease. The only difference between the two etiologic factors on the resulting morphologic changes seems to be the disease severity, since biliary pancreatitis usually follows a mild course as compatible with interstitial pancreatitis, while alcoholic pancreatitis is a severe necrotizing disease. Rare causative factors are metabolic or drug-associated processes, and familial-hereditary or circulatory failure-related conditions.

The pathophysiologic mechanisms that lead to sudden autodigestive fat necrosis in the human pancreas are still unidentified or hypothetical. Based on findings in experimental pancreatitis it has been suggested that disruption of intracellular compartmentalization leads to an intracellular enzyme activation by lysosomal hydrolases with subsequent acinar cell damage [18,19]. However, acinar cell necrosis has not yet been convincingly proven as the initial histologic lesion in acute human pancreatitis caused by the most common etiologic factors [20]. It must therefore be assumed that etiologic factors such as alcohol abuse and gallstone disease lead to a functional rather than a structural acinar cell damage, which results in a sudden and uncontrolled release of digestive enzymes from the acinar cells into the adjacent interstitial tissue [20]. It is possible that among the released proenzymes lipase plays an important role, because it is one of the few pancreatic enzymes that does not require activation [21,22] and may therefore directly cause the liquefaction necrosis of interstitial fat cells. Whether fat necrosis depends on the action of lipase alone or the combined action of lipase plus other enzymes, such as phospholipase A_2, is not known, but it is likely that several proenzymes as well as cytokines become activated by fat-cell necrosis and may then help to destroy adjacent tissues and trigger the inflammatory process that determines the severity of the clinical course.

Another pathophysiologic theory related to the fat necrosis pattern, which rests on the frequent association of gallstone disease with pancreatitis, is the duct obstruction–bile reflux theory (based on Opie's common channel theory) [23]. It postulates that temporary obstruction of the common bile duct and the main pancreatic duct by a gallstone (or tumor tissue or inspissated secretions as in cystic fibrosis) [24] causes increased intraductal pressure and/or ampullary incontinence, with duodenopancreatic and bile reflux. This in turn activates pancreatic proenzymes, which leak from small ducts into the interstitial space. However, despite the obvious clinical association between gallstone migration and pancreatitis, definite functional and histologic proof of the ductal-obstruction pathogenesis is, thus far, lacking in human acute pancreatitis.

Acute pancreatitis with necrosis of the duct epithelium is associated with prolonged circulatory failure. In this case the tissue hypoxia in the pancreas seems to injure especially the medium-sized interlobular ducts and cause its necrosis. In addition, there could be an autoactivation of trypsinogen within the duct lumen, as the ducts are found to be filled with dense pancreatic secretions and neutrophil granulocytes [14]. This could be due to a stasis of pancreatic juice, which became viscous and sluggish because of a general slowdown of secretory processes in the exocrine pancreas, because of a severe circulatory failure. Since we saw a comparable picture in a case of familial pancreatitis, it may be speculated that a similar duct damage as in prolonged circulatory failure may occur due to mutation-related changes of the trypsinogen molecule (e.g., by *PRSS1* mutations) allowing its uncontrolled premature activation [25].

In acute pancreatitis with acinar cell necrosis and without any significant autodigestive interstitial necrosis, there seems to be a direct cytotoxic damage to the acinar cells by microorganism such as mumps virus or bacterial agents.

Unsolved Questions

There are several unsolved questions in acute pancreatitis, but the most important one concerns its pathogenesis and pathophysiology. It is not known how etiologic factors such as alcohol abuse, gallstone disease, hypercalcemia, or circulatory failure lead to premature digestion in the pancreas. Moreover, the pathophysiologic concepts currently discussed usually refer to experimental pancreatitis models [18,26,27]. Although these models have markedly improved our knowledge on pathogenetic mechanisms in acute pancreatitis, it must be emphasized that none of these models is fully comparable to what is seen in humans.

Another question that is still to be solved relates to the severity of acute pancreatitis. It is not yet known which factors govern the mechanisms that decide the extent of autodigestion and thus lead either to a mild or severe course of the disease.

A final question is how the criteria that define the Atlanta 2012 classification [1] and are solely based on radiologic [6] and clinical features relate to the morphologic findings in acute pancreatitis? Table 17.1 therefore tries to summarize and correlate the most important criteria of the Atlanta 2012 classification with the histopathologic changes that can be seen in conventional acute pancreatitis.

Severity Classification of Acute Pancreatitis

John A. Windsor

Surgical and Translational Research Centre, University of Auckland, Auckland, New Zealand

Introduction

The accurate classification of acute pancreatitis severity is important because it will "improve communication and advance our understanding of the disease and its management" [1]. When specific treatments become available for clinical trials in acute pancreatitis "an inclusive clinical classification system will assume increasing importance" [2]. Systems for classifying severity will continue to evolve with new scientific knowledge and for this reason they are best considered "working" classifications. The aim of this chapter is to outline the reasons for classifying severity, review the systems currently available, and identify aspects for further improvement.

Reasons for Classifying the Severity of Acute Pancreatitis

Classification systems are valuable in clinical and research settings, to assist communication between clinicians, patient monitoring and allocation to clinical studies, auditing of clinical outcomes, and comparison between centres (Table 18.1). Some of these reasons are best met by predicting severity, rather than by classifying severity, although these are sometimes confused [3–5]. When the ultimate disease severity needs to be anticipated ahead of time, prediction of severity is required. When the severity needs to be defined at a particular time point, classification of severity is required. In this way prediction is about the future and classification is about the present and the past. Prediction is usually required early in the disease course, whereas classification can be useful at any time during the disease course.

Severity Classification Systems

The first severity classification system for acute pancreatitis was published in 1983 [6], followed by the widely used original Atlanta classification in 1993 [7], which was a clinically based classification system that defined a binary approach: mild and severe disease. While there has never been difficulty in identifying patients with mild and uncomplicated acute pancreatitis, this is not so for severe disease. Nor is it so for patients with non-mild acute pancreatitis who represent a heterogenous group with varying severity and outcomes that were not captured by the original Atlanta classification.

Two systems for classifying the severity of acute pancreatitis were introduced about a decade ago and have replaced the original Atlanta classification (Table 18.2): the "determinant-based classification" (DBC) in 2012 with four categories of severity [8] and the "revised Atlanta classification" (RAC) in 2013 with three grades of severity [9]. It has been suggested that DBC and RAC are "equivalent" and "comparable and complementary" [3,4], but there a "few differences" [10] worth noting (Table 18.3). There have also been questions about which is the more valid, which has higher utility, and which should be used [11]. A number of studies have compared the validity of the DBC and RAC classification systems (Table 18.4). Most of the studies have been from single tertiary centers and subject to selection bias.

The DBC defines severe AP on the basis of either persistent organ failure (without infected pancreatic necrosis) or infected pancreatic necrosis (without persistent organ failure). The RAC defines severe AP on the basis of persistent organ failure alone, with infected pancreatic necrosis a diagnostic criterion for the moderately severe grade [9]. The explanation given for this was that "infected necrosis without persistent organ failure . . . has a lesser

Table 18.1 The reasons for classifying the severity of acute pancreatitis.

Related to clinical decision-making	Triage of patients regarding initial treatment intensity[a]
	Transfer of patients to specialist unit or intensive care[a]
	Tracking trajectory of patient's clinical course
	Treatment (e.g., ERCP, enteral nutrition)[a]
Related to research decision-making	Audit of outcome
	Allocation of patients to trial arm[a]
	Analysis of interventions

[a] Denotes reason that is more appropriate for prediction than classification systems.

Table 18.2 Classifications for the severity of acute pancreatitis.

Determinant-based classification [8]	
Mild	No (peri)pancreatic necrosis and no organ failure
Moderate	Sterile (peri)pancreatic necrosis and/or transient organ failure
Severe	Infected (peri)pancreatic necrosis or persistent organ failure
Critical	Infected (peri)pancreatic necrosis and persistent organ failure
Revised Atlanta classification [9]	
Mild	No organ failure and no local or systemic complications
Moderately	Severe transient organ failure and/or local or systemic complications or exacerbations of preexisting comorbidities
Severe	Persistent organ failure (single or multiple)

Table 18.3 Key differences between the DBC and RAC classification systems.

	Severity classification systems	
Criteria	**DBC category**	**RAC grade**
Exacerbation of comorbid disease	Not included	Moderately severe
Infected (peri)pancreatic necrosis without persistent organ failure	Severe	Moderately severe
Infected (peri)pancreatic necrosis with persistent organ failure	Critical	Severe

DBC: determinant-based classification; RAC: revised Atlanta classification.

mortality rate than infected necrosis with persistent organ failure." Thus, the principle difference between the DBC and RAC is the importance attributed to infected pancreatic necrosis. In some studies patients with infected pancreatic necrosis without persistent organ failure have been shown to have a similar outcome to those with severe acute pancreatitis [12,13]. These findings are consistent with the meta-analysis of 14 studies which was the basis for the DBC [14]. This demonstrated that infected (peri)pancreatic necrosis and persistent organ failure were independent and virtually equivalent determinants of mortality. It was for this reason that the DBC included infection of pancreatic necrosis in the severe category.

Given the significant advances in the management of infected pancreatic necrosis, fueled by technology developments and the seminal randomized trials from the Dutch Acute Pancreatitis group [22], it is reasonable to ask how important infected necrosis still is as a determinant of mortality. Open necrosectomy, which is responsible for new-onset organ failure and increased mortality, has been superseded by the "step-up approach." The original meta-analysis [14] has recently been repeated using data from the modern era and it has confirmed that infected pancreatic necrosis has become less important as a determinant of mortality (publication pending). This change has virtually abolished the second peak of the bimodal mortality curve, which was previously attributed to infected pancreatic necrosis [23]. In the nationwide prospective cohort study from 26 hospitals in Spain it was found that infected pancreatic necrosis correlated with high morbidity and had a mortality comparable to sterile necrotizing pancreatitis [24].

Approach to Severity Classification Depends on the Setting

In a peripheral hospital the incidence of severe and critical acute pancreatitis is low and the fundamental clinical decision is whether the patient is going to develop sufficiently severe acute pancreatitis to warrant transfer to a tertiary center. In this setting a binary classification system (non-severe vs. severe) might well suffice. In a tertiary center the requirements are different and the incidence of severe and critical acute pancreatitis higher. In this setting there is value in having more than two categories of severity. With different

Table 18.4 Studies that compared the determinant-based classification (DBC) and revised Atlanta classification (RAC) systems from the same dataset.

	Ref	Setting	Study design	Key findings
Nawaz (2013)	3	Tertiary (SC) Pittsburgh	Retrospective (prospective database)	DBC and RAC comparable for predicting ICU admission, ICU length of stay, and mortality. The RAC was better at predicting hospital stay and DBC better for predicting the need for intervention
Acevedo-Piedra (2014)	12	Tertiary (SC) Spain	Retrospective (prospective database)	No significant differences in the distribution and outcomes between the two classifications, but very low incidence of severe and critical categories
Chen (2015)	15	Tertiary (SC) Nanjing	Retrospective (prospective database)	RAC and DBC comparable in relation to long-term clinical prognosis, major complications, and clinical interventions. Critical category very high risk and distinct from severe category in DBC
Mircea (2015)	16	Tertiary (SC) Bucharest	Retrospective	Similar for clinical outcomes, although RAC has slight advantage for hospital length of stay and DBC for ICU admission and length of stay. DBC easier to use
Xu (2015)	17	Tertiary (SC) Lanzhou	Retrospective	Similar distribution and outcomes. Recommended combining RAC and DBC
Guo (2105)	18	Tertiary (SC) Chengdu	Prospective	No significant difference between RAC and DBC. Mortality similar and distribution of severity marginally different
Kadiyala (2016)	4	Tertiary (SC) Boston	Retrospective (prospective database)	The RAC and DBC were essentially equivalent in predicting mortality, need for admission to the ICU, ICU length of stay, and hospital length of stay. Paucity of critical category, limited utility. Neither classification accounts for multisystem persistent organ failure, the strongest predictor of mortality
Bansal (2016)	19	Tertiary (SC) Birmingham	Retrospective (prospective database)	The RAC and DBC perform equally well. DBC critical category associated with doubled mortality risk, ICU stay and need for drainage or surgery greater than RAC, with definite implications for prognosis
Fernandes (2016)	20	Tertiary (SC) Portugal	Retrospective	RAC and DBC were similar for outcomes
Zubia-Olaskoaga (2016)	21	Tertiary (MC) Spain etc.	Prospective observational	Proposed a modified DBC for only ICU patients. Superior to DBC and RAC for mortality. Similar to DBC for morbidity and superior to RAC. Severe DBC category separated into two groups: transient organ failure with infected local complications and persistent organ failure and no infected local complications

ICU: intensive care unit.

treatment options available there is the need to accurately allocate patients to research arms and to tailor treatments to individual patients, it is desirable to have distinct and homogeneous patient subgroups to study and treat. For instance, if there were a new treatment for organ failure to be tested it would confound interpretation of outcomes if all patients were included with organ failure, even if this contained those who would respond promptly (e.g., transient organ failure), those who might not respond (e.g., persistent organ failure), and those who cannot respond (e.g., no organ failure). Further, if the purpose of a treatment were to reverse established organ failure it would be necessary to exclude patients with transient organ failure. If the purpose were to prevent the development of persistent organ failure it would be necessary to include patients with transient organ failure. These examples indicate that while a binary classification is probably sufficient for those in primary and secondary care settings, more categories are required in the tertiary setting. Tailoring the severity classification needs to be tested, particularly in the secondary setting.

Table 18.5 Modified determinant-based classification (DBC) system for patients admitted to intensive care with organ failure [21]. Note that patients with mild acute pancreatitis are not included. *Source:* Adapted from [21].

	Parameters				
Group	**Organ failure**	**Infected necrosis**	**Mortality**	**Intensive care LOS**	**Interventions**
1	TOF	No	2%	Short	–
2	TOF	Yes	6.6%	Long	+
3	POF	No	41%	Short	–
4	POF	Yes	59%	Long	+

TOF: transient organ failure; POF: persistent organ failure; LOS: length of stay.

The use of severity classification has also been studied in the intensive care unit setting. In 2016 a modified DBC was recommended following a large prospective study involving 46 intensive care units [21] and subsequently validated [25,26]. Four groups were defined (Table 18.5), with mild acute pancreatitis excluded as these patients are not admitted to ICU. These studies provide compelling evidence that the severe category of AP, as defined by the DBC, represents two distinct subgroups. Patients with local complications (infected pancreatic necrosis, abdominal hemorrhage, and intestinal perforation), but without persistent organ failure ("group 2") have a high morbidity but low mortality. In contrast, patients with persistent organ failure but without local complications ("group 3") have a high mortality but relatively low morbidity.

These studies also confirmed that patients with critical acute pancreatitis ("group 4") had a clinically and statistically different clinical course in regard to morbidity and mortality. Others have questioned the utility of this category because of its relatively infrequency [4], while in other series it is associated with a significantly higher mortality and is endorsed [13,19,26]. The critical category has more clinical relevance in the ICU setting [27] (31% of patients with 54% mortality) [25] than in the tertiary hospital setting (1% of patients with 61% mortality) [26]. In the Spanish study [21] only 2.2% (37/1655) had critical AP but a mortality of 54%, compared with 39% with a mortality of 5.8% (97/1655) for severe AP. The time to oral feeding (median 24.2 vs. 9.4 days), need for invasive treatment (100 vs. 39.2%), admission to intensive care unit (97.3 vs. 53.6%), and hospital stay (median 88 vs. 34.2 days) were all significantly increased in patients with critical acute pancreatitis.

While the setting is important in regard to the approach to severity classification, there are other factors that might be considered including the quality of the evidence base, method used for development, the validity and ease of use.

Future Developments

The differences between classification systems represent an opportunity for further improvement, and some research priorities have been published [29]. In the editorial accompanying the DBC publication it was pointed out that there are severity determinants other than infected pancreatic necrosis and organ failure, including obesity, diabetes, and genetic predisposition, and if incorporated might have improved the DBC [2]. All three classifications (DBC, RAC, and modified DBC) fail to account for patients with "early severe" acute pancreatitis and organ failure on admission, which is a particularly challenging subgroup with a high mortality risk [30–33]. This suggests that the timing of the onset of organ failure might be factored into an improved classification system [34]. Incorporating different aspects of organ dysfunction/failure may also help, including the duration, number, combination, and sequence of the organs affected [35]. Data on these dimensions may allow more accurate classification of patients with severe and critical acute pancreatitis. Increased stratification, beyond the four categories of the modified DBC, has been suggested because of the multiple therapeutic goals (in addition to reducing mortality) and the desire to personalize treatment [36]. A "two-step approach" that distinguishes single and multiple persistent organ failure and includes 13 severity categories has been reported and requires prospective validation. Further improvements in severity classification might go beyond these clinically defined determinants to incorporate biomarkers that more accurately define severity.

Conclusions

Classifying the severity of acute pancreatitis is important for the clinical care of patients and for research purposes. The RAC and DBC have been in use for over a decade, we know they perform reasonably well. We

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

also know that predicting (and not classifying) the severity of acute pancreatitis is required in the community and secondary care settings because the key decision is whether a patient needs to be transferred or not. In the tertiary setting, especially in the ICU setting, the modified DBC should become the preferred approach, noting that it would be helpful to move away from numbered groups to clinical descriptors (e.g., 0 = mild, 1 = moderate, 2 = moderately severe, 3 = severe, and 4 = critical) [21]. These are clinically distinct subgroups of patients which when classified accurately will improve the delivery of care to these patients and the study design for testing new treatments. Advances in the care of patients with acute pancreatitis will require improvements on current methods for classifying severity. Ultimately, these improvements will come from the discovery of early biomarkers of severity that accurately reflect the key real-time changes in the pancreas and distant organs. For now, we are reliant on clinical indicators related to the presence of organ failure and infected local complications for the RAC, DBC, and modified DBC. The differences between the classifications provide opportunities for further research to improve the accuracy and utility of severity classification. This includes determining how best to tailor severity classification to setting (e.g., secondary or tertiary hospital) and purpose (e.g., clinical management or research).

Introduction

Among the inflammatory digestive disorders acute pancreatitis continues to challenge physicians as the least and most difficult one to predict in terms of clinical course and outcome. Ever since the first classification system of acute pancreatitis was established in Marseille in 1965 [1] the definition of "severe" disease has been linked to disease-specific complications with an increased risk of mortality [2–5]. Stratification of severity is required for targeting individual patients for interventions against evolving complications or for referral to specialist centers on the one hand and for comparing patients for scientific purposes or recruitment into clinical trials, on the other. The type and clinical relevance of a complication rendering the course of acute pancreatitis as "severe" has been the subject of continuous development and changes. New insights into pathomechanism and natural course of acute pancreatitis, development of laboratory variables and diagnostic imaging procedures as well as novel therapeutic approaches have strongly influenced definitions and classification systems and continue to do so.

Historical Perspectives: Approaches to Severity Assessment

Attempts to stratify severity and prognosis date back to the second half of the last century and have been driven by major advances in new imaging procedures and laboratory tests. The development of serum amylase measurement in 1929 [6] was the first step toward a noninvasive diagnosis of acute pancreatitis and subsequently showed that in the majority of patients a mild course with uneventful recovery was the rule rather than the exception. Supported by the development of intensive care treatment and more restrictive indications for surgical treatment in patients with clinically severe disease, interest in prognostic assessment has gained considerable headway since the 1960s. Attempts to define objective criteria for assessing disease severity and prognosis were pioneered by John Ranson in New York [7] and Clement Imrie in Glasgow [8] in the 1970s, which found widespread application in the pancreatic community.

During the early 1980s intraoperative findings revealed local-morphological features such as presence and extent of necrosis [9,10] and infection of necrosis [11) showing an excellent correlation with systemic severity and outcome. Flanked by the introduction of contrast-enhanced computed tomography (CE-CT) and percutaneous guided fine-needle-aspiration (FNA) nonoperative assessment of these complications became possible and assigned morphology-based severity stratification a predominant role. Hence, imaging procedures have become indispensable for assessment of severity in acute pancreatitis and an integral part of new classification systems [2–4] and treatment algorithms [5,12–16] alike.

After almost two decades of mainly morphology-based severity stratification the role of systemic aspects in terms of onset, severity, and persistence of pancreatitis-related organ failure was recognized as a central determinant of severity [17–29]. Moreover, early and persisting multiorgan dysfunction syndrome (MODS) has been found to outweigh morphological factors such as necrosis and even infection of necrosis as far as nonsurvival is concerned [20,29].

Dynamics of Organ Failure

The prognostic role of early pancreatitis-associated organ failure was already recognized during the early 1970s. Objective measurement of pulmonary failure by arterial oxygen pressure or renal failure by serum creatinine had become available and had been integrated into prognostic multiparameter scoring systems according to Ranson [7] and Imrie [8]. However, it took another three decades until pancreatologists realized that the occurrence of a temporary single organ failure does not necessarily indicate a life-threatening disease. Specific aspects such as onset, severity, and persistence of organ failure have gained special attention in the past two decades.

Early Organ Failure

The role of "early" organ failure, defined as failure of one or more organ systems within the first 3 days after onset of acute pancreatitis/hospital admission was first described by Isenmann et al. in 2001 [17]. The presence of "early" single or multiple organ failure leads to a significant increase in mortality up to 56% irrespective of whether necrosis is sterile or infected [17–19,21,22]. Early multiple organ failure represents an important risk factor for death and even seems to outweigh local morphological complications such as extent or infection of necrosis [20,29].

Persistent Organ Failure

The dynamics of organ failure in terms of response/resolution or nonresponse/persistence despite intensive care treatment has been identified as another major determinant of complications and death. In many pro- and retrospective studies resolution of organ failure within the first week of the disease resulted in mortality rates close to zero, whereas mortality rates rose to 55% if organ failure persisted beyond the first week [22–25,27]. Moreover, organ failure nonresponding to intensive care treatment closely correlates with the development of pancreatic infections and death [26,28,29].

There is little doubt that organ failure is one of the most important determinants of prognosis and mortality in acute pancreatitis. The revised Atlanta classification of 2012 [3] and the international multidisciplinary "Determinant-based classification" of 2012 [4]) therefore defined organ failure as a central criterion to differentiate up to four severity groups of acute pancreatitis (Table 19.1).

Table 19.1 (a) Definition of three grades of severity in acute pancreatitis according to the revised Atlanta classification 2012. *Source:* [3]/BMJ Publishing Group Ltd.

* **Mild acute pancreatitis:**	• no organ failure • no local or systemic complications
* **Moderately severe acute pancreatitis:**	• organ failure that resolves within 48 h (transient organ failure) *and/or* • local or systemic complications without persistent organ failure
* **Severe acute pancreatitis:**	persistent organ failure >48 h • single organ failure • multiple organ failure

(b) Definition of four grades of severity in acute pancreatitis according to the "Determinant-based classification" 2012. *Source:* Adapted from [4].

* **Mild acute pancreatitis:**	• no organ failure • no peri-/intrapancreatic necrosis
* **Moderate acute pancreatitis:**	• organ failure that resolves within 48 h (transient organ failure) *and/or* • sterile peri-/intrapancreatic necrosis
* **Severe acute pancreatitis:**	• persistent organ failure >48 h *or* • infected peri-/intrapancreatic necrosis
* **Critical acute pancreatitis:**	• persistent organ failure >48 h *and* • infected peri-/intrapancreatic necrosis

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS), defined as intra-abdominal pressure >20 mmHg and newly developed organ failure [30], was re-recognized as a determinant of prognosis more than a decade ago. Abdominal hypertension (intra-abdominal pressure >15 mmHg) is observed in up to 75% of patients with severe acute pancreatitis [31–33] and ACS in about 25–38% [33–35]. Several studies revealed a strong association between intra-abdominal hypertension and the development of multiple organ dysfunction, which occurred in more than 90% of patients [18,31]. Multiple organ dysfunction in turn carries excessively high mortality rates. Clinical evidence suggests that "early" multiple organ failure may be the result of undiagnosed ACS arising from the extensive inflammatory process in the retroperitoneum and an aggressive fluid resuscitation. Beyond its prognostic role, the diagnosis of abdominal compartment syndrome has therapeutic implications that have been shown well in a few studies [36,37].

Multiparameter Scoring Systems

Analysis of numerous objective clinical and biochemical variables associated with complications and death led to the development of the very first multiple parameter scores by John Ranson [7] and Clement Imrie [8]. Both systems still offer a good level of accuracy, but have the disadvantage that valid calculation is restricted to primary admissions within the first 48 hours of treatment, whereas recalculation beyond 48 hours is impossible. Since their original description, the requirements of researchers and clinicians have changed and are driven by the need for speed and simplicity more than ever. Supported by the recognition of organ failure as a major determinant of outcome, scoring systems such as the Marshall [38] and sequential organ failure assessment (SOFA) [39] score, which have all been developed and validated in the intensive care setting, have led to more flexible and practicable assessments of severity and prognosis in acute pancreatitis.

The APACHE II Score

Dissatisfaction with the temporal applicability of the Ranson and Imrie systems led pancreatologists to search for more flexible scoring systems. One of the first multiple parameter scores applied in acute pancreatitis was the acute physiology and chronic health evaluation (APACHE) score in the early 1980s. A modification of the initial system [40] by the Intensive Care Research Group from Washington, DC, USA reduced the number of physiological variables from 35 to 11 and was termed APACHE II score [41], which, despite further modifications, remains the most commonly used version. Larvin et al. from Leeds, UK published the first evaluation in 290 attacks of acute pancreatitis [42]. Initial APACHE II scores of 10 or more revealed a sensitivity of 63% and a specificity of 81% (PPV 46%, NPV 90%) in predicting "severe" disease. By 24 hours APACHE II scores >10 provided a sensitivity of 71% and a specificity of 91% (PPV 67%, NPV 93%), which further rose to a sensitivity of 75% and a specificity of 92% (PPV 71%, NPV 93%) at values >9 after 48 hours. The APACHE II scores at 24 hours outperformed both the Ranson and Imrie scores at 48 hours. The results of the Leeds study have been confirmed exhaustively in subsequent years [43–48].

The advantage of the APACHE II system is clearly its flexibility and greater speed with possible recalculation at any time throughout the course of the disease for monitoring purposes. Conversely, calculation of this score is complex and time-consuming and carries the risk of miscalculations.

Organ Failure-Related Scoring Systems

Organ failure-related intensive care scores such as the Marshall [38] and the SOFA [39] scores have been applied in AP by a number of studies to assess organ failure or outcome [23,26,28,46,49,50–53]. The two scores belong to the newer generation of organ failure-related systems, which can describe the evolution of individual and multiple organ dysfunction over time. Both scoring systems rely on six major organ systems: pulmonary, cardiocirculatory, renal, hepatic, and neurologic function, as well as coagulation. Failure of each organ system is scored as absent or up to 4 points with escalating severity. The SOFA score is a further development of the Marshall score, because specific treatment such as ventilation and vasopressors are included, thus reflecting clinically relevant severity of organ failure [39].

Marshall Score

The first detailed validation study of the Marshall score was published by Halonen et al. in a large series of Finnish patients with severe acute pancreatitis. This scoring system provided a sensitivity of 59% and a specificity of 91% in predicting mortality within 72 hours of hospital admission, comparable results were obtained using the APACHE II system (sensitivity 65%, specificity 91%) [52]. In another retrospective study of the same group in 113 patients with severe acute pancreatitis admitted to the intensive care unit both admission and peak Marshall scores were as accurate as SOFA scores in assessing the risk of hospital mortality. Unfortunately no information about optimum cutoff levels, sensitivity, and specificity

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

was provided [51]. A modification of the Marshall score excluding hepatic and neurologic function has been applied in two prospective studies [23,24] and the original score in a retrospective study [25] from the UK to quantify organ failure. The components for pulmonary, cardiocirculatory, and renal function match well with the definitions of the original Atlanta classification, but hepatic (bilirubin), neurologic (Glasgow coma scale), and coagulation parameters (platelet function) may further increase total scores, even if true organ failure is absent. The revised Atlanta classification of 2012 has adopted the Marshall components for pulmonary, cardiocirculatory, and renal function to define and quantify early pancreatitis-associated organ failure [3].

SOFA Score

Two detailed evaluation studies in acute pancreatitis are available for the SOFA score. In a prospective international multicenter study, SOFA scores >4 were predictive of death with a sensitivity of 86% and a specificity of 79% (PPV 27%, NPV 98%) 48 hours after onset of symptoms [53]. Corresponding results have been reported by a Finnish study for admission scores in an ICU population-based cohort at a cutoff level >8 [51]. Among the critical care scoring systems the SOFA system offers obvious advantages since it includes therapeutic requirements such as mechanical ventilation and inotropic substances. The SOFA score is an integral means for severity stratification of sepsis and septic shock in the critical care community worldwide and is therefore a valid tool in severely ill patients with acute pancreatitis requiring intensive care treatment [54].

The advantage of organ failure scores clearly lies in their widespread implementation in critical care medicine, which allows a good comparison with other critically ill patients (e.g., patients with sepsis). The introduction of the modified Marshall score in the revised Atlanta classification has overcome the problem of erroneously high scoring points by omitting the hepatic and neurologic components. The latter are truly problematic in acute pancreatitis, because high bilirubin values or delirium tremens are frequent features of biliary or alcoholic pancreatitis, albeit not representing organ failure.

Bedside Index of Severity in Acute Pancreatitis (BISAP)

Considering both the cumbersome calculation of multiparameter scoring systems and the 48-hour delay of pancreatitis-specific scoring systems, the BISAP score was dedicated to estimate pancreatitis-related mortality within 24 hours of hospital admission. It includes five easy to obtain parameters: blood urea nitrogen (BUN), mental status, SIRS, age, and presence of pleural effusions reaching scores from 0 to 5 points [48,55]. The score was initially developed and validated in two multicenter patient cohorts of around 18,000 cases with acute pancreatitis [55]. In the validation cohort the BISAP score reached an area under the curve (AUC) of 0.82 in the receiver operating characteristic (ROC) analysis, which was equal to the APACHE II score with an AUC of 0.83. Mortality rates ranged from 0.1% in patients with 0 up to 9.5% in patients with 5 points [55]. A systematic review confirmed the BISAP score as a reliable tool to identify patients at high risk for unfavorable outcomes. Compared with the Ranson criteria and APACHE II score, the BISAP score outperformed in specificity, but showed a suboptimal overall sensitivity for prediction of mortality and of a severe course of acute pancreatitis [56].

Laboratory Variables

In the mid-1960s, the first evidence arose that acute pancreatitis is reflected by abnormalities of many serum/plasma variables [57]. Hence, a multitude of laboratory markers have been identified that allow early stratification of patients at risk to develop complications such as necrosis, infection of necrosis, organ failure, and death. Beyond the potential to predict disease severity, many of these parameters were found to be determinants of disease progression and subsequent complications in the pathomechanism of acute pancreatitis such as proteases, cytokines, chemokines, adhesion molecules, and acute phase proteins. An ideal laboratory test to assess severity of acute pancreatitis should be simple in test performance, readily available under routine and emergency conditions, accurate, and cost-effective. However, despite a large array of potentially useful parameters, their large-scale clinical use is frequently limited by moderated accuracy, and time-consuming and expensive assay procedures. Consequently, only a few tests have passed the threshold to routine clinical application.

Routine Laboratory Variables

Since the introduction of Ranson and Imrie scores, single routine laboratory components such as hematocrit, creatinine or blood urea nitrogen, and blood glucose have been extensively investigated, either alone or in combination, to predict complications and thus "severe" disease.

Hematocrit

Admission hematocrit and its subsequent changes during fluid resuscitation still represent a simple and good prognostic estimate. An admission hematocrit >44% was found to be closely associated with complications in terms of necrosis and organ failure [58] or pancreatic infection [59]. An overall high negative predictive value of around

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

90% excluding "severe" acute pancreatitis at admission hematocrit <44% [58] and <40% [60] was reported by some authors. However, admission hematocrit of >41% to >44% failed to predict severity, organ failure or death in other large studies [43,60]. In a recent international multicenter analysis in 1,612 patients with acute pancreatitis admission hematocrit ≥44% and increasing BUN levels at 24 hours were able to predict persistent organ failure and pancreatic necrosis in 54% and 60% of patients, respectively [61]. Hematocrit is one of three variables of the "harmless acute pancreatitis score [HAPS]," which allows a fast and accurate identification of patients with nonsevere acute pancreatitis [62]. Taken together, hematocrit serves as a widely available and good estimate to exclude severe attacks, but is not a reliable means to predict severity or any other specific complications accurately.

Serum Creatinine and Blood Urea Nitrogen (BUN)

Creatinine and blood urea nitrogen (BUN) are surrogate laboratory tests that indicate and define renal failure. Renal failure, defined as creatinine >2 mg/dl (177 µmol/l) by the Atlanta classification belongs to the most serious of organ complications in AP and has been shown to be an independent risk factor for fatal outcome [51,52,63]. However, the widely used cutoff level >2.0 mg/dl is frequently not reached on the day of hospital admission, which limits the use of this variable for "early" risk estimation. As far as disease severity in terms of local or systemic complications is concerned, admission BUN achieved no satisfactory test performance [48,64,65] reaching a maximum sensitivity of 79% and a specificity of 67% (PPV 43%, NPV 91%) only [64]. In the largest patient cohort ever published, rising BUN within 24 hours after admission achieved a sensitivity of <60% in predicting persistent organ failure or pancreatic necrosis [61], but revealed increasing diagnostic accuracy rates beyond 48 hours after admission [66].

Acute-Phase Proteins

Acute-phase proteins constitute a family of inflammatory proteins, which are mainly synthesized in the liver in response to infectious and noninfectious stimuli. The most famous member is C-reactive protein (CRP), which has become the most widely established single laboratory marker for biochemical severity stratification of acute pancreatitis. The availability of fully automated immunoassays for CRP is an essential feature for its large-scale routine application.

C-Reactive Protein

Severity stratification of acute pancreatitis by CRP has a long tradition and still represents the "gold standard" for both early severity stratification and monitoring the course of the disease [65,67,68,69,70,71]. CRP is the laboratory variable of choice to differentiate necrotizing from interstitial edematous acute pancreatitis. However, the majority of the studies focused on the discrimination between mild and severe acute pancreatitis according to the original Atlanta classification of 1993. Therein, CRP achieves diagnostic accuracy rates of between 70% and 80% at a cutoff level >150 mg/l within 48 hours after disease onset [71]. As has been well documented for all acute phase proteins CRP is not useful for prediction of infected necrosis, organ failure or death within the first week after disease onset [65,72]. Another shortcoming of CRP is the relatively long delay of its induction with systemic peak values at 72 to 96 hours after disease onset thus making very early severity assessment impossible.

In contrast to CRP, SAA failed to show any relevant benefit over CRP in estimating severity or prognosis of acute pancreatitis [67,69].

Cytokines and Chemokines

A wealth of experimental and clinical studies during the 1990s have convincingly outlined that cytokines and chemokines play a key role in the pathophysiology of acute pancreatitis by promoting local tissue destruction and mediating distant organ complications [73,74]. Therefore, cyto- and chemokine measurement was thought to offer an excellent approach to biochemical severity assessment. Despite the development of fast and fully automated assay techniques, the vast majority of the cytokine and chemokine family members play no role as biochemical markers for acute pancreatitis in the clinical setting. So far, only the cytokine interleukin-6 (IL-6) has passed the threshold from pathophysiological importance to clinical application.

Interleukin-6

Systemic concentrations of IL-6 have been found to be early and excellent predictors of severity. A large number of clinical studies have uniformly shown that IL-6 is dramatically increased in complicated attacks [65,70,71,75–77]. IL-6 concentrations generally rise 24–36 hours earlier than CRP levels and remain significantly elevated as long as complications persist. One of the first series in 24 patients from Glasgow found a sensitivity of 100% and a specificity of 71% (PPV 71%, NPV 100%) at a cutoff level >130 IU/ml for IL-6 in predicting a severe attack within 36 hours of symptom onset [75]. Beyond discriminating mild from severe attacks, IL-6 closely correlates with evolving organ failure [65,70,76]. A recent systematic review indicated superiority of IL-6 for the early prediction of moderate to severe acute pancreatitis compared with 29 other biochemical markers [71]. IL-6 has been introduced as routine parameter in some

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

laboratories and represents an easy and rapid means to select patients at risk to develop severe disease. However, a large-scale use of IL-6 measurements in acute pancreatitis has never been reached.

Procalcitonin

Ever since its first description in 1993 [78] procalcitonin (PCT) has become an established marker for predicting bacterial/fungal infections, sepsis, and septic shock in the intensive care and emergency surgery settings [13,54,79,70]. A close correlation between elevated PCT concentrations and the development of infected necrosis was first described in a cohort study comprising 51 patients with acute pancreatitis by our group in 1997. At a cutoff level of >1.8 ng/ml PCT was able to predict this complication with a sensitivity and specificity of more than 90% within the first days after onset of symptoms [72]. An international multicenter trial in 104 patients with severe acute pancreatitis has shown that PCT is able to predict serious complications such as pancreatic infections or death with a sensitivity of 79% and a specificity of 93% (PPV 65%, NPV 97%) at a cutoff level >3.8 ng/ml within 48–96 hours after onset of symptoms [80]. This observation was confirmed by a number of subsequent studies which have been subjected to a meta-analysis and a systematic review. Herein, PCT reached a cumulative sensitivity of 80% and a specificity of 90% for predicting infected necrosis in acute pancreatitis [66,81]. Notably, PCT is of little or no value for simple stratification of patients as "mild" or "severe" according to the original Atlanta classification of 1993. The international guidelines for the management of sepsis and septic shock and the World Society of Emergency Surgery guidelines recommend the use of PCT as the most sensitive laboratory test to detect sepsis/pancreatic infections [13,54].

PCT measurements are available as fully automated assay for routine use, a semiquantitative strip test is an alternative for a fast and easy quantification. On the basis of the data available, PCT is a valuable tool for an early stratification and consecutive monitoring of patients at risk to develop the most serious complications in acute pancreatitis.

Table 19.2 provides an overview of relevant multiparameter scoring systems and laboratory markers for severity stratification and prediction of specific complications in acute pancreatitis.

Table 19.2 Relevant multiparameter scoring systems and laboratory markers for severity stratification and prediction of specific complications in acute pancreatitis.

Variable	Severity	Pancreatic infection	Overall prognosis
Ranson-/Imrie Score	++ (48 h)	–––	++ (48 h)
APACHE II Score	++	–––	+++ (>7 d)
SOFA-/Marshall Score	++	–––	+++ (>7 d)
BISAP Score	++ (24 h)	–––	++ (24 h)
Hematocrit	++ (48 h)	–––	–––
Creatinine/blood urea nitrogen	+	–––	++ (>7 d)
IL-6	+++ (<48 h)	–––	–––
CRP	+++ (72–96 h)	–––	–––
PCT	–––	+++ (72–96 h)	+++ (72–96 h, > 7 d)

Optimum accuracy after symptom onset of acute pancreatitis:
<48 h: within less than 48 h after symptom onset
48 h: within 48 h after symptom onset
72–96 h: within 72 to 96 h after symptom onset
>7 d: beyond the first week after disease onset.
APACHE II: acute physiology and chronic health evaluation II; SOFA: sequential organ failure assessment; IL-6: interleukin-6; CRP: C-reactive protein; PCT: procalcitonin.

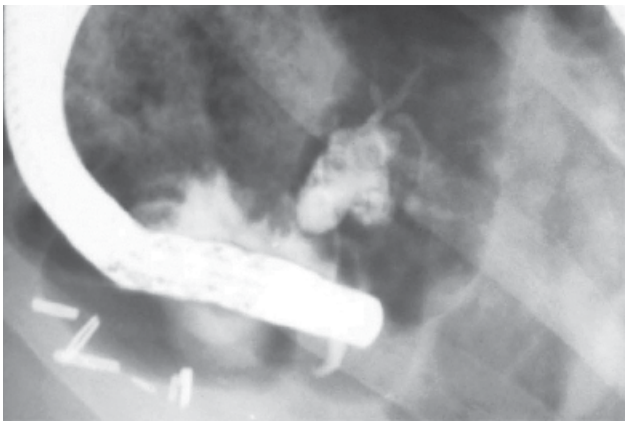
Introduction

Acute pancreatitis secondary to congenital anomalies remains an uncommon cause of childhood abdominal pain, representing about 5% of cases of pediatric pancreatitis [1–3]. A higher incidence of structural anomalies, up to 33%, is reported in children with recurrent and chronic pancreatitis, though a majority of those patients have multiple risk factors [4]. The most commonly encountered congenital causes are developmental abnormalities of the pancreaticobiliary system, such as pancreas divisum, annular pancreas, ectopic pancreatic tissue sources, enteric duplication cysts, and choledochal cysts [5]. Congenital structural variants of the pancreas occur up to 10% in the Western population [6], but the majority are silent as the incidence of pancreatitis is two orders of magnitude less [7]. Biliopancreatic ductal system variants encountered during diagnostic evaluation of idiopathic acute pancreatitis plague the clinician with a significant question of relevance regarding consequence and management.

Pancreas Divisum



The cause, incidence, clinical relevance, and treatment of pancreatitis in patients with pancreas divisum (PD) has been hotly debated. In complete PD, the ventral and dorsal pancreatic ducts do not communicate, and usually the dorsal pancreatic duct is larger than the ventral (Fig. 20.1a) [8]. Acute pancreatitis may result from obstruction, either at the minor papilla or a junction in the ductal system, or from localized ductal ectasia in the uncinate process [9,10]. Pancreatitis is experienced by 0.1% of the population while PD is present in 4–5%, calling into question if PD is the inciting source [11–14].

Treatment is directed at relief of the obstruction, whether by sphincteroplasty for acute pancreatitis or longitudinal pancreaticojejunostomy for more distal chronic obstruction, or endoscopic approaches. Accessory papilla sphincteroplasty improves symptoms in adult patients with documented stenosis, best predicted by presentation with pancreatitis and a positive ultrasound-secretin test [15]. A pediatric study found that success was best predicted by presence of pancreatic ductal stones [10].

Surgical dual sphincteroplasties result in good to excellent outcomes in patients with PD and pancreaticobiliary sphincter dysfunction established via manometry [16]. Smaller studies have reported various success rates with endoscopic sphincterotomy and longitudinal pancreaticoduodenectomy; however, morbidity rates range from 15% to 40%, and many patients require multiple procedures [9,16,17]. Successful duodenum-preserving pancreatic head resection in patients with chronic pancreatitis and PD has been described in both children and adults [18,19]. For patients with PD and chronic pancreatitis with significantly dilated pancreatic ducts a longitudinal pancreaticojejunostomy can be therapeutic, and total pancreatectomy with islet cell transplantation can be performed in patients with significant ductal fibrosis. However, both procedures can have significant morbidity and are often reserved for patients who fail other therapies [20,21].

(b)

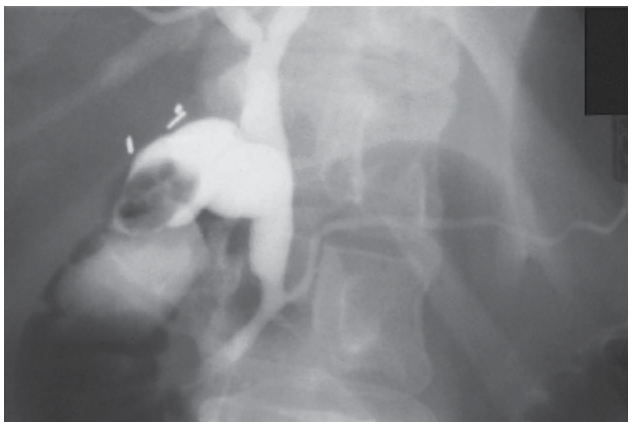

Figure 20.1 (a) A 15-year-old girl presented with recurrent attacks of pancreatitis. Endoscopic retrograde pancreatography showed pancreas divisum with cystic dilation of the ventral pancreatic duct containing stones. She was treated by pancreaticoduodenectomy. (b) Cholangiopancreatogram in a 12-year-old boy with a choledochal cyst and anomalous pancreatico–biliary junction. The pancreatic duct inserts into the common bile duct more than 2 cm proximal to the ampullary orifice. Such patients are prone to acute and chronic pancreatitis.

Anomalous Pancreaticobiliary Ductal Union

Anomalous pancreaticobiliary ductal union (APBDU) results from the pancreatic and common bile ducts joining proximally to the ampulla of Vater with a hypothesized resulting admixture of refluxed pancreatic and biliary secretions into the biliary tree or pancreas [22,23] and has been associated with a higher incidence of congenital choledochal dilation (Fig. 20.1b) [22–25]. APBDU is defined as a common channel greater than 15 mm in length or a contractile segment totally distal to the biliary and pancreatic ductal union [26,27]. APBDU is further delineated into subtypes according to the order of insertion of the pancreatic and biliary ducts [27,28]. In B-P, the bile duct enters the main pancreatic duct and in P-B (or in some series, P-C for choledochal) the pancreatic duct enters the common bile duct [27].

APBDU has been considered a factor in the development of pancreatitis, choledochal cysts, and hepatobiliary cancers [27,29]. APBDU was identified by ERCP in 8.7% of patients with an incidence of 13.2% for biliary pancreatitis and 2.2% for nonbiliary pancreatitis. B-P subtype was associated with choledochal cyst formation whereas P-B subtype was associated with biliary pancreatitis, gallbladder cancer, and adenomyomatosis. A proposed mechanism for this relatively high rate of pancreatitis and the observation of recurrent pancreatitis in patients with APBDU is sphincter of Oddi dysfunction [30]. In rare cases, APBDU and PD can coexist [31].

Surgical treatment of APBDU relies on disruption of the contiguous anatomical relationships. Roux-en-Y hepaticojejunostomy is offered [32], but cholecystectomy and alternate biliary tract reconstruction [33] or endoscopic sphincterotomy alone can be beneficial [30]. APBDU with choledochal cysts are often managed by cyst excision, although duodenopancreatectomy may be required [34].

Choledochal Cyst/Choledochocele

Choledochal cysts are noted in 0.1% of adult ERCPs and in 1 in 150,000 North Americans [35,36]. Rates are higher in East Asia and in females, with a male to female ratio of 1 : 3–4, and associated pancreatitis more common in younger patients aged 2–16 years (36%) [37]. The classic triad of abdominal pain, jaundice, and a palpable right upper quadrant abdominal mass occurred 6.7 times more frequently in children [38] with adults more likely to present with abdominal pain diagnosed as pancreatitis or biliary tract pathology prior to cyst identification [39,40]. Cyst rupture is rare and most commonly presents in children and infants with biliary peritonitis [41]. Children with pancreatitis and choledochal cysts are more likely to have fusiform dilation of the cysts or a dilated common channel [42]. Pancreatitis and cancer were more common in patients with both choledochal cyst and APBDU [43]. The possible role of APBDU in causing choledochal cysts is discussed above.

Choledochal cysts were first classified according to the 1977 Todani system [44,45]. Except in the case of type III disease, in which endoscopic approaches or marsupialization may be indicated, complete excision of the extrahepatic choledochal cyst with hepaticojejunostomy is the goal [46,47]. Malignancy is identified increasingly

with choledochal cyst retention; therefore internal drainage or bypass procedures should be accompanied by a near-complete resection [37]. Interposition of the jejunum or appendix are unsuitable due to high rates of graft dysfunction and cholangitis [48,49].

Annular Pancreas

Annular pancreas, potentially arising from dorsal and ventral anlage hypertrophy or abnormal adherence of the ventral duct to the duodenum during rotation, envelops the duodenum (Fig. 20.2a, b) [50]. Obstruction or pancreatic inflammation secondary to annular pancreas occurs in the third decade of life or later with a prevalence of roughly 25% [51,52]. Pancreatitis secondary to annular pancreas is rare in the newborn and presents with duodenal blockage, with bilious emesis and "double bubble" on abdominal films [51,53]. Differentiation between upper obstruction etiologies, such as duodenal atresia, malrotation without volvulus, and annular pancreas, must not delay emergent operative care in the case of volvulus. Annular pancreas is associated with a high rate of congenital anomalies. Seventy percent of infants with annular pancreas will have another anomaly, such as duodenal stenosis or atresia (40%), Down syndrome (16%), tracheoesophageal fistula (9%), or congenital heart defects (7%) [51].

Surgical correction of annular pancreas in childhood is usually undertaken by performing diamond duodenoduodenostomy and leads to faster feeding and discharge when compared to side-to-side anastomosis or duodenojejunostomy [54]. Gastrojejunostomy should be avoided in children as the most anatomic reconstructions are linked to the best growth outcomes [55]. Surgical correction in adults follows suit, with less concern about growth retardation with gastrojejunostomy [56]. There is an increased incidence of malignancy in adults presenting with symptomatic annular pancreas [56,57]. In any case of duodenal obstruction, volvulus must be first excluded as a life-threatening surgical emergency.

(a)

(b)

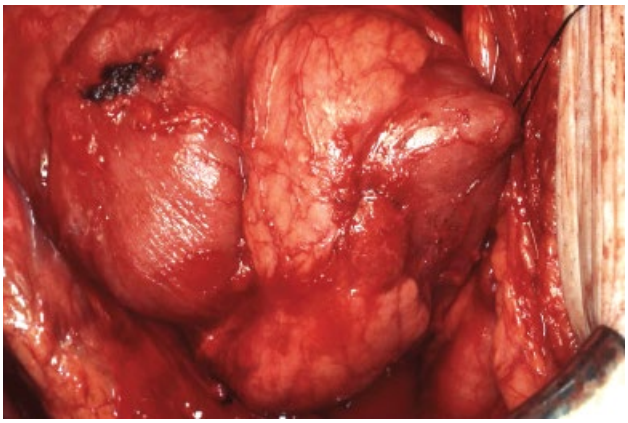

Figure 20.2 (a) Pancreatogram in a young boy with annular pancreas. The proximal pancreatic duct encircles the duodenum within the annular segment. (b) Annular process.

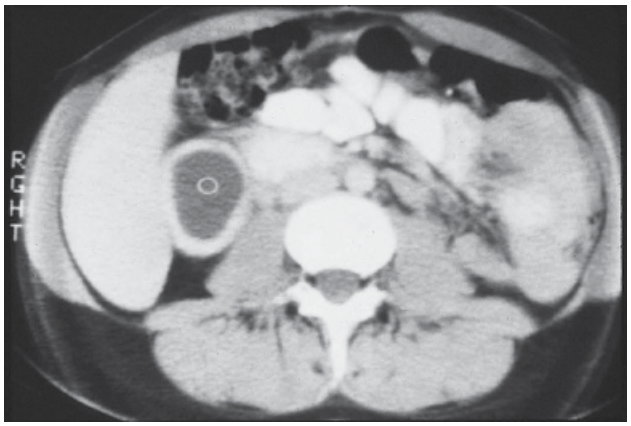
Ectopic Pancreatic Tissue



Ectopic pancreatic tissue is a relatively common anomaly with an incidence of up to 13% at autopsy [55,58]. A normally organized aberrant rest of pancreatic tissue is discontinuous with the entopic pancreas. A majority are identified in the submucosa of the stomach, duodenum, and jejunum [50] and although uncommon, come to clinical attention from intussusception, obstruction, inflammation or degeneration [59,60]. Inflammation of an ectopic pancreas without pseudocyst with both elevated serum amylase and lipase and ectopic tissue inflammation has been reported [58,61]. In a total of 32 histologically documented cases of ectopic pancreas, half were identified incidentally [62]. The remaining cases were clinically significant for hemorrhage, obstruction, or ulceration. The majority of cases are asymptomatic, but nearly all pathologies of the pancreas can arise in ectopic tissue, including pancreatitis and malignancy [63]. A tentative link between ectopic pancreatitis in the duodenal wall and duodenal stenosis has been established in six pancreaticoduodenectomy specimens [64].

Enteric Duplication Cysts

Gastrointestinal duplication cysts are congenital foregut anomalies with gastrointestinal mucosa of any type or pancreatic tissue and are named for their anatomic

(b)

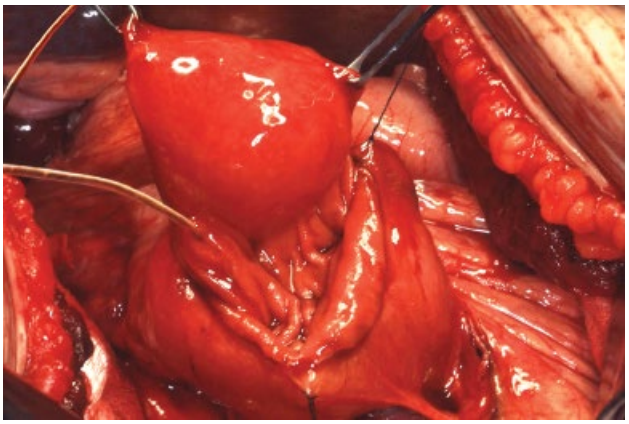

Figure 20.3 (a) CT scan in a 21-year-old woman with a history of several years of recurrent acute pancreatitis. The circle indicates an abnormal thick-walled cystic structure adjacent to the head of the pancreas. (b) Operative photograph of a pancreatic duplication cyst bulging into the duodenal lumen, as previously identified on abdominal CT. The catheter has been introduced through the ampulla into the pancreatic duct. Excision of the cyst with suture ligation of its narrow neck was curative of her recurrent pancreatitis.

proximity rather than mucosal content [51]. Duplication cysts within the pancreas have been reported and are generally termed as duodenal or gastric duplications since they lack a contiguous structure (Fig. 20.3a, b) [59]. Although most enteric duplications do not present with pancreatitis, multiple cases have been identified [65,66]. Duodenal duplication occurs in 10% or fewer cases and may cause "obstructive pancreatitis" from compression between the duodenal wall and the biliopancreatic duct [67,68]. Juxta-pancreatic duplications with pancreatic ductal communication may shed blood or mucous into the main pancreatic duct resulting in obstruction [69–71]. Pancreatitis may occur within the duplication itself, as is found in esophageal duplications containing gastric mucosa and pancreatic tissue (43%) [72]. Local resection is preferred; however, marsupialization of cysts with removal of mucosa, either surgical or endoscopic, may be employed if local resection is not possible [73,74].

Conclusions

Infrequently, congenital anomalies may be the cause of idiopathic acute pancreatitis. Nonanatomic congenital causes must be assessed by diligent investigation. Regarding anatomic congenital anomalies, strict definition of the anatomic relationships and associated anomalies is necessary to direct appropriate therapy. Because congenital anomalies are often unique, unusual anatomic relationships may be discovered in each case. Previous case series in the literature provide useful longitudinal data to help in predicting outcomes and avoiding known pitfalls.

Introduction

The Second International Symposium in Marseilles in 1984 defined acute pancreatitis (AP) as acute abdominal pain accompanied by the finding of increased pancreatic enzymes in blood or urine [1]. However, the pathophysiology of acute pancreatic inflammation has remained difficult to describe, partly due to the relative inaccessibility of the pancreas on physical examination, and to the frequently nonspecific nature of symptoms resulting from diseases of the pancreas. Despite these difficulties, understanding of *adult* pancreatitis has increased in an exponential manner in recent decades. Unfortunately, the understanding of the *pediatric* counterpart has lagged, although much progress has been made in recent years.

Pediatric AP poses a challenge to clinicians. Depending on the age and developmental level of a child, it can be extremely difficult to assess the nonspecific symptoms of abdominal pain and nausea or vomiting. Defining the location and nature of the pain and identifying factors that aggravate or alleviate the pain can be particularly challenging in a pediatric patient. Compounding this challenge is that many healthcare professionals still do not consider pancreatitis in the differential diagnosis of pediatric abdominal pathology. Hence, children may experience symptoms from pancreatic inflammation and be diagnosed with "viral gastroenteritis." For all these reasons, unraveling the complexities of pediatric AP remains an ongoing process.

The challenges in pediatric AP lie in three major areas:

- potential etiologies, many of which are more particular to children;
- diagnosis, including serum biochemistry and imaging techniques;
- assessing and following for disease severity and complications.

This chapter will strive to cover these areas as they pertain to pediatric AP.

Incidence

The prevailing impression amongst pediatric specialists is that the incidence of pediatric acute AP is increasing. A number of population-based series have attempted to quantify the incidence of AP [2–13]. These studies suggest that the incidence of AP in children has truly increased over the past several decades. Since the initial study by Lopez showing a steady increase in the absolute number of cases of AP per year in a single institution, a number of other centers throughout the world have reported similar observations [2] (Table 21.1). An estimate of incidence ranged from 1 to 3 cases per 10,000 children. Proposed explanations for the increasing diagnosis of AP in children include increased awareness that AP occurs in children, a true rise in new cases of pediatric AP, increased referral of children to tertiary care centers, and an increase of AP in children with other systemic diseases [2,12,13]. Likely, a combination of these events explains the increased incidence.

Etiology

An adult presenting with a first episode of AP is questioned and investigated to identify the presence of one of two major etiologies for adult AP: biliary disease and

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Table 21.1 Series looking at the incidence of AP. Studies reporting increase in number of cases of AP diagnosed in children over time.

Location	Years	Author	Incidence in last year	Further study details
United States: Children's Medical Center of Dallas	1993–1998	Lopez [2]	Not reported	Total cases/yr: 5, 19, 20, 38, 79, 113 (1993–98)
United States: Children's Hospital of Pittsburgh of	1993–2004	Morinville [13]	1.3 per 10,000 children	Number of cases increased from 28 to 141 per year
Australia: Royal Children's Hospital, Melbourne	1993–2002	Nydegger [3]	0.35 per 10,000 children	Consistent, progressive increase in cases of AP per year over the study period
United States: Children's Hospital of Wisconsin	1996–2011	Werlin [5]	Not reported	Noted a consistent increase in number of AP cases over study period with the exception of 2001
Mexico: Hospital of Pediatrics, Guadalajara	1990–2005	Sanchez-Ramirez [4]	53 per 10,000 hospitalizations	Reported a nonlinear increase in new cases over the study years
United States: Yale-New Haven Hospital	1994–2007	Park [12]	8.9 per 10,000 ED visits	Increase in number of patients admitted for AP over time. Normalization to number of ED visits showed same rate per 10,000 visits
United States: Healthcare Cost and Utilization Project Kids' Inpatient Database	2000–2009	Pant [6]	35 per 10,000 hospitalizations	Relied on ICD9 codes to identify 55,012 patients
United States: Nationwide Emergency Department Sample	2006–2011	Pant [7]	1.6 per 10,000 ED visits	Relied on ICD9 codes to identify 78,787 patients with ED visits for AP
United Kingdom: Liverpool	1999–2009	Wilkinson [8]	0.3 per 10,000 children	Identified patients by ICD10 codes from Hospital Episode Statistics database
India: Sanjay Gandhi Postgraduate Institute of Medical Science	2003–2014	Poddar [9]	Not reported	5-fold increase in AP cases
United States: Cincinnati Children's Hospital Medical Center	2006, 2009, 2012	Abu-El-Haija [10]	Not reported	Kids' Inpatient Database Significant increase in diagnosis of AP over the study period
Taiwan: Taiwan National Health Insurance Research Database	2000–2013	Cheng [11]	0.3 per 10,000 children	Incidence increased steadily from age 13 to 18 years

AP: acute pancreatitis; ED: Emergency Department.

alcohol ingestion. These, in fact, appear to account for most cases of AP in adults. In children, by contrast, the etiologies of AP are more broadly divided (Table 21.2). Figure 21.1 summarizes the breakdown of presumed etiologies based on previously published series from multiple countries. In general, the largest categories are divided up amongst idiopathic (24%), trauma (17%), systemic (15%), structural (14%), and medications (10%). A recent single-center study suggested that drug-induced pancreatitis is the leading known cause of AP [14]. The same center also reported that first attack of pancreatitis was associated with genetic risk factors in 18% of patients [14]. Since genetic testing is not often done with the initial episode of AP, many studies may underestimate the role of genetic variants. The various risk factors may act alone or jointly to lead to a clinical episode of AP [15].

Pathophysiology

The pathophysiology of pediatric AP is believed to be identical to that of adult AP.

Table 21.2 Potential etiologies of acute pancreatitis. The differential list is extensive. A clinician must consider the particular patient's history of present illness, past medical history, and family history in considering the potential trigger of an attack of AP.

Category	Examples
Anatomic abnormalities	Annular pancreas
	Anomalous choledochopancreaticoductal junction
	Choledochal cyst, choledochocoele
	Intestinal duplication or cyst
	Pancreas divisum
Biochemical abnormalities	Diabetic ketoacidosis
	Hypercalcemia (hyperparathyroidism, familial hypocalciuric hypercalcemia)
	Hypertriglyceridemia
	Uremia
Gallstone disease	Biliary sludge
	Choledocholithiasis
	Microlithiasis
Genetic	Hereditary pancreatitis: *PRSS1*
	SPINK1
	CFTR
	CTRC
	Others
Iatrogenic	Following ERCP
	Following liver transplant (postsurgery anatomy + medications)
	Following nongastrointestinal surgery (Fontan heart operation, spinal fusion surgery)
Idiopathic	Unidentified infections, toxins, drugs or trauma, genetic risks
Inborn errors of metabolism	Acute intermittent porphyria
	Branched-chain ketoaciduria (maple syrup urine disease)
	Cationic aminoacidurias
	Cystinuria
	Glycogen storage disorders
	Homocystinuria
	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
	Pyruvate kinase deficiency
Infectious agents	**Bacteria** (*Campylobacter fetus, Escherichia coli, legionella, Mycoplasma pneumoniae, Salmonella typhii, Yersinia*)
	Viruses (coxsackievirus, cytomegalovirus, enterovirus, echovirus, Epstein–Barr, hepatitis A, influenza A,influenza B, measles, mumps, rubella, rubeola, varicella
	Other (*Ascaris lumbricoides* (obstruction), *clonorchis ninensis* (obstruction), leptospirosis, malaria)
	Immunocompromised host (*mycobacterium avium intracellulare, pneumocystis carinii, cryptosporidium parvum*)
Medications	**Analgesics** (acetaminophen overdose, aminosalicylic acid, sulindac, indomethacin, propoxyphene)
	Anti-acid (cimetidine, ranitidine)
	Anticonvulsants (fosphenytoin, phenytoin, valproic acid)
	Antimicrobials (erythromycin, sulfonamides, trimethoprim-sulfamethoxazole, tetracycline, isoniazid, metronidazole, nitrofurantoin, pentamidine)

(Continued)

Table 21.2 (Continued)

Category	Examples
	Chemotherapeutics (L-asparaginase, cytarabine)
	Diuretics (furosemide, ethacrynic acid, ACE-I, thiazides, chlorthalidone)
	Illicit drugs (amphetamines, cocaine, heroin)
	Immunomodulators and anti-inflammatories (sulfasalazine, 5-ASA products, 6-mercaptopurine, azathioprine, gold)
	Sex hormone-related (estrogen, tamoxifen, danazol, corticosteroids)
	Others: cholestyramine, cyproheptadine, diazoxide, diphenoxylate, histamine, interleukin, methyldopa, phenformin, procainamide
Obstruction, acquired	Neoplasm-associated
	Periampullary obstruction (celiac disease, Crohn disease, mucosal inflammation)
	Sphincter of Oddi problem (stenosis; dysfunction?)
Systemic illness	Crohn disease
	Hemolytic uremic syndrome
	Henoch–Schonlein purpura
	Kawasaki syndrome
	Polyarteritis nodosum
	Sarcoidosis
	Systemic lupus erythematosus
	Sickle cell disease
Toxins	Boric acid
	Ethanol and methanol
	Methylene chloride
	Organophosphates/insecticides
	Scorpion bite
Trauma	Accidental (bicycle handle bar injury, MVA) Child abuse

ACE-I: angiotensin-converting enzyme inhibitors; 5-ASA: 5-aminosalicylic acid; MVA: motor vehicle accident.

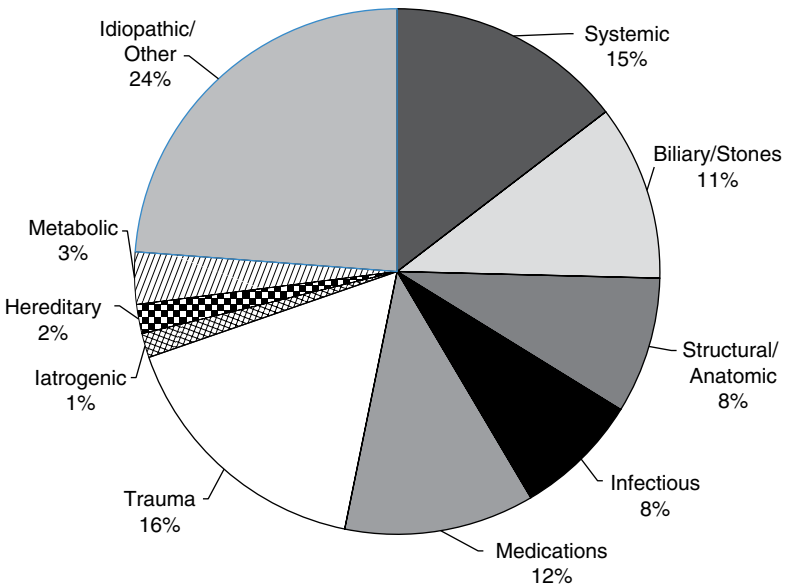

Figure 21.1 Etiology of acute pancreatitis (AP) in children. Contrary to adults where biliary tree pathology and alcohol account for more than two-thirds of cases, children have a greater spread among the etiologic categories of AP. The following reflects distribution of etiologies of AP in 1961 children from different countries. Please refer to Table 21.2 for examples of subcategories in each of the included series.

Investigations

A great diversity of potential etiologies of AP is demonstrated in Table 21.2. Clinical finesse is involved in determining which causes should be considered for each child presenting with a first episode of AP. Unlike many pediatric diseases, the etiology of AP does not vary significantly among individual age groups [16–18]. A stepwise consideration of probable, possible, and rare etiologies in conjunction with elicited history of present illness, past medical history, family history, and findings on physical examination will direct investigations and limit invasive and sometimes painful procedures for the pediatric patient, as well as minimize unnecessary costs. Since genetic risk factors are common in children, a thorough family history for documented pancreatitis, pancreatic cancer, pancreatic insufficiency including insulin-dependent diabetes, and/or family members exhibiting symptoms that could be consistent with acute recurrent pancreatitis is particularly important.

Diagnosis

In 2012, an international group of pediatric gastroenterologists published a consensus statement defining AP in childhood [19]. The clinical diagnosis of AP requires the presence of at least two out of three criteria:

- A combination of abdominal pain that is consistent with pancreatic origin;
- The presence of elevated amylase or lipase or both to at least three times the upper limit of normal;
- Radiological imaging with findings consistent with AP.

Even with these criteria, the diagnosis of AP can present challenges for the clinician. History and physical examination findings are variable: there may be epigastric to right upper quadrant pain, left upper quadrant pain, back pain, nausea, vomiting, jaundice, tachycardia, guarding, or even signs of shock. In children under the age of three, pain may present as increased irritability, and abdominal distension and fever were more common than in older children [16]. Clinicians must maintain a high degree of suspicion, especially in younger children in whom verbal communicative skills may be limited.

A particular pediatric consideration is that newborn levels of pancreatic type isoamylase are very low to nondemonstrable, and total amylase levels reach normal adult values by only approximately 8–16 months of age [20,21]. Pancreatic isoamylase activity might not even reach adult values until the age of 10 to 15 years [22]. In a similar fashion, lipase values at birth are significantly lower than those observed for adults and appear to have the greatest increase within the first year of life [23,24]. Hence, in a young patient, amylase and lipase levels may not always reflect potential pancreatic inflammation particularly if adult ranges of normal enzyme levels are used as references [25].

Clinical scales are utilized to classify adults as having mild or severe disease. Several different scales for children have been proposed over the years. None have been widely applied. Two recent reports suggested that BUN levels or the lipase level and the presence of a pediatric systemic inflammatory response syndrome on admission were prognostic indicators for severe AP in children [14,26]. There was considerable overlap between mild and severe AP for both. It remains to be seen if either gains widespread acceptance and utilization, and thus pediatric severity indices represent an area of necessary research [25].

Imaging

Imaging methods may be helpful in (a) diagnosis, (b) determining severity and complications, and (c) visualizing any anatomic factors leading to AP [27].

Transabdominal ultrasonography (TUS) is widely available, relatively inexpensive, and does not expose a child to radiation or contrast agent. Historically, TUS has often been the initial diagnostic modality in suspected AP. It can repeatedly be performed in almost any setting to follow the course of illness and does not require procedural sedation. Ultrasonography may demonstrate enlargement of the pancreas, altered echogenicity, duct diameter abnormalities, and fluid collections (intra- or extrapancreatic) [28], abnormalities of the pancreaticobiliary drainage system, including the presence of a choledochal cyst, or common bile duct stones [27]. Limitations include air within the stomach interfering with image acquisition from the body and tail of the pancreas, and differentiation of normal from abnormal pancreas in cases of pancreatitis where echogenic changes may or may not be present. A recent study showed that TUS is only moderately sensitive for diagnosing AP and that cross-sectional imaging such as computed tomography (CT) provided higher sensitivity [29]. In addition, CT with contrast may be more useful in more severe cases of AP to assess for local complications. The main drawback to more widespread CT scan utilization is its radiation exposure.

The capability of magnetic resonance cholangiopancreatography (MRCP, with or without secretin) to diagnose most cases of pancreas divisum, choledochal cyst, cholelithiasis, pancreaticobiliary junction anomalies and obstructive abnormalities has decreased the use of endoscopic retrograde cholangiopancreatography (ERCP) for diagnostic purposes even though MRCP might not be as sensitive

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

as ERCP in detecting pancreatobiliary abnormalities [30,31]. Although MRCP offers imaging without radiation, there are still pediatric factors to take into consideration. Due to the relatively long duration of the procedure (15 to 45 minutes), younger children will require sedation, ranging from oral sedatives to intravenous general anesthesia and intubation. Additionally, the quality of MRCP images depend on the protocol utilized for image acquisition as well as the radiologist's interpretation of these [32].

When indicated, pediatric ERCP in experienced hands is safe and effective at all ages, although infants and young toddlers may require slimmer pediatric duodenoscopes [33,34]. Pediatric uses include stone removal, assessment of pancreatic duct anatomy and injuries, drainage of nonresolving pancreatic pseudocysts, sphincterotomy, and stent placement. ERCP at the time of cholecystectomy is safe and effective in pediatric patients [35]. The obvious difficulties with ERCP include the need for sedation (typically general anesthesia), and the use of ionizing radiation during fluoroscopy.

Experience with pediatric EUS has increasingly been reported in recent years [36]. EUS provides detailed imaging of pancreatic parenchyma and ducts without the use of radiation, but with the need for sedation. Its benefits include not only its role in imaging, but also in interventions, with the capacity to sample tissue and fluid collections through fine needle aspiration and biopsy, as well as accomplish drainage of fluid collections such as pseudocysts. As endoscopists increasingly become comfortable with pediatric use of EUS, its role in diagnosis and management of AP will become better defined.

All radiological and endoscopic tests may offer complementary information regarding the cause or complications associated with pediatric AP. Clinicians must weigh the potential benefits offered by an imaging technology against the drawbacks particular to each technique and decide on an algorithm for a particular patient. Typically, pediatric patients are first assessed by TUS. Subsequently, with a prolonged AP course, there may be a need for either MRCP or CT to better delineate anatomy and to visualize potential complications. With the need for a therapeutic maneuver, both ERCP and EUS are becoming increasingly child-friendly and experience to date shows they are safe and effective.

Management

The general measures undertaken in children with AP are similar to those in adults. In most pediatric AP cases, clinical improvement occurs within a few days and discharge is possible in less than a week. Several changes in management of patients with AP have occurred in recent years. In 2018, the Pancreas Committee of the North American Society of Pediatric Gastroenterology, Hepatology, and Nutrition Studies published a position paper on the management of pediatric AP [37]. The role of i.v. fluids in the treatment of AP has been the subject of several studies in adults and children. However, details of i.v. therapy such as volume, rate, timing, and composition of the fluid are not firmly established. In one pediatric study, fluid rates 1.5 to 2 times maintenance in the first 24 h shortened length of stay and severity of disease [38]. A second study showed that patients given lactated Ringers solution had a shorter length of stay compared to patients given normal saline [39]. Another major change in management is the recognition that early enteral feeding whether by mouth or feeding tube is safe and may improve outcome [38,40–42]. Early feeds did not increase pain or length of stay and may shorten length of stay. Additionally, patients with higher fat intake did not have higher pain scores.

Outcomes

Overall, children generally have a mild clinical course and only a small fraction have severe complications. Pseudocysts represent the most frequent complication occurring in 10–30% of cases [4,5,43]. They typically present as a persistent abdominal discomfort, abdominal mass on physical examination, continued elevation of pancreatic enzymes, or identified on follow-up imaging. Pseudocysts usually resolve spontaneously and rarely require intervention. When indicated, potential therapeutic options include percutaneous catheter drainage (radiological placement or surgical), cyst-gastrostomy stent placement via EUS guidance, pancreatic duct stenting via ERCP, open surgical cyst-enteric anastomosis drainage and, perhaps, antibiotic therapy [44,45].

Despite a generally positive outcome for pediatric AP, up to 6% of children develop multiorgan failure or pancreatic necrosis [46]. Some studies have found an association between particular triggers of AP and serious complications. As might be predicted, it appears that children who have complex medical histories, including those experiencing AP post liver transplantation, or in the context of a systemic disease, are more susceptible to severe and potentially fatal courses [46]. Mortality data has rarely been reported in children. A database study from 2000 to 2009 of 55,012 children hospitalized with AP reported a mortality rate of about 1.0% [6].

Acute Recurrent Pancreatitis

Acute recurrent pancreatitis (ARP) is defined as at least two distinct episodes of AP separated by a return to normal baseline status [19]. It has been estimated that

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

10–35% of children have recurrent episodes of AP [46]. Most often the second episode occurs within 5 months of the first one [47]. Upon the first presentation, etiologies that are amenable to therapy should be sought and if identified, managed appropriately (including hypercalcemia, hypertriglyceridemia, biliary factors, and structural abnormalities). Any reversible cause should be eliminated whenever possible (including culprit medications). With additional attacks other investigations should be considered. Secretin-stimulated MRCP may unveil anatomic abnormalities predisposing to ARP. After a second episode of AP, genetic testing for known risk variants should be done [48]. In a large multi-center study, almost half of patients with ARP had mutations in *PRSS1, SPINK1, CFTR,* or *CTRC* [49]. Since not all patients in this cohort had genetic testing or were screened for fewer than four genes, the percentage of patients harboring gene mutations is likely higher. In the same study, 75% of patients with chronic pancreatitis (CP) had genetic mutations. Mutational analysis is now commercially available for these genetic loci. It is anticipated that a high proportion of children with ARP and CP will have genetic predispositions eventually identified. Along with mutational analysis, a comprehensive search for rare causes of AP is typically indicated [50]. As it is believed that recurrent attacks of AP may eventually lead to morphological changes of CP, prevention of further pancreatic injury is a key interventional goal, and identification of etiologic factors represents the first step.

[3] *University of Medicine and Pharmacy, Hue University, Hue, Vietnam*

Introduction

Immoderate alcohol consumption and gallstones are by far the most frequent etiologic factors for acute pancreatitis, accounting for up to 70% of all cases. The remaining 30% are patients where no triggering event can be identified (idiopathic pancreatitis, approximately 15%) and in 15%, rare causes are identified in association with acute pancreatitis. These include anatomical variants, metabolic disorders, drugs, tumors, genetic abnormalities, and infectious diseases. In this chapter we review some of the rarer causes of acute pancreatitis.

Metabolic Diseases

Hyperlipidemia and hypercalcemia are the best-known metabolic causes for acute pancreatitis. To a lesser extent, diabetic ketoacidosis (DKA), a severe complication of diabetes mellitus can cause pancreatitis.

Hypercalcemia

Hypercalcemia often results from primary hyperparathyroidism (pHPT), a disorder of the parathyroid glands that is defined by an inappropriate secretion of parathyroid hormone (PTH) [1]. Elevated calcium levels affect other organs, including the gastrointestinal tract. However, determination of the incidence of *hyperparathyroidism-related* pancreatitis is difficult because patients often harbor comorbidities such as concomitant alcohol abuse, cholecystolithiasis, or hypertriglyceridemia. In many cases a definite assignment of the etiology of acute pancreatitis is not possible because patients have additional risk factors for acute pancreatitis. A coincidence of pancreatitis has been observed in 1.5–6.8% of patients with primary hyperparathyroidism, for example. The highest incidences were reported from India where a higher predisposition for (tropical) calcific pancreatitis was also observed [2–4]. Mean serum calcium levels are higher in patients with primary hyperparathyroidism and coexisting acute pancreatitis (12.8–13.3 mg/dL) compared to individuals with hyperparathyroidism who do not develop pancreatitis (11.6–12.1 g/dL) [2,5,6]. After parathyroidectomy, the causative therapy for pHPT, risk of pancreatitis dramatically reduced [4].

Hypercalcemia resulting in acute pancreatitis may also be attributed to unrelated diseases of the parathyroid glands but these cases are extremely rare. Reports of secondary hypercalcemia due to either solid or hematologic malignant tumor disorders, including multiple myeloma [7] and iatrogenic causes of hypercalcemia such as calcium-containing infusions during cardiac surgery [8] or for parenteral nutrition [9] underline that high circulating calcium levels predispose to pancreatitis.

The molecular mechanisms of hypercalcemia-induced pancreatitis are gradually being resolved. Ca^{2+} is important for intracellular signaling and homeostasis. Disturbances in intracellular calcium levels impair its signaling function and high cytosolic levels within the exocrine acinar cell trigger premature protease activation [10]. Blocking the uptake of calcium into the cells or chelation of intracellular ionized Ca^{2+} largely prevents digestive zymogen activation and pancreatic damage [11]. Mutations in the calcium-sensing receptor gene (CASR), encoding a G protein-coupled receptor regulating calcium homeostasis, were associated with chronic pancreatitis but are not directly related to acute pancreatitis

Companion website: www.wiley.com/go/beger/thepancreas4e

in pHPT patients [12]. Several clinical trials have been set up to investigate the possibility of reducing the incidence and severity of pancreatitis by interfering with the intracellular effects of calcium.

Hypertriglyceridemia

It is known that elevated lipid levels are associated with cardiovascular diseases. However, hyperlipidemia is a rare but well-established cause of acute pancreatitis as well. This is mostly related to hypertriglyceridemia, because hypercholesterolemia by itself does not cause acute pancreatitis. Hypertriglyceridemia and hyperlipidemia in general are becoming more common in industrialized countries and it has been reported that over 1.5% of the US population has severe hypertriglyceridemia (defined as a serum concentration of 500–2000 mg/dL) [13]. Normal triglyceride levels for adults should be less than 150 mg/dL [14].

Acute pancreatitis secondary to hypertriglyceridemia is seen in between 1.3% and 3.8% of patients [15–17]. Typically, triglyceride levels above 1000 mg/dL (or 11.4 mmol/L) precipitate acute pancreatitis with a risk of around 5%. Triglyceride levels exceeding 2000 mg/dL more than double that risk to 10–20%. In addition, data from a large Danish registry-based study indicate that even nonfasting mild to moderate triglyceride levels ≥177 mg/dL (2 mmol/L) increase the risk of pancreatitis so that dyslipidemia needs to be considered as a potential cause of acute pancreatitis more often than previously assumed [18].

Plasma triglycerides can be of exogenous or endogenous origin. Normally, dietary triglycerides are the main source and form the main lipid component in very-low density lipoproteins (VLDL). Once hydrolyzed in the small intestine they are absorbed and incorporated into chylomicrons and transported via lymphatic vessels to peripheral tissues for further utilization. Cells of all parenchymal tissues secrete lipoprotein lipases that hydrolyze triglycerides and surface components of chylomicrons and VLDL to release free fatty acids for energy supply. Fatty acids are converted to fatty acid ethyl esters (FAEE) by carboxylester lipase (CEL), an enzyme also expressed in pancreatic acinar cells. FAEE themselves exert toxic direct effects on cells and also raise intracellular Ca^{2+} concentrations that further promote cellular damage [19].

Patients with hypertriglyceridemia often have a concomitant history of diabetes mellitus (72%), hyperlipidemia (I, IV, and V according to Fredrickson's classification, 77%), alcohol abuse (23%), or gallstones (7%). Triglyceride levels are also elevated in the setting of DKA [16,20]. Typically, a lipid abnormality presents as a secondary factor (obesity, diabetes mellitus) whereas isolated hyperlipidemia (usually type I or V) is much less common [21]. Moreover, mild to moderate hypertriglyceridemia is not infrequently seen in alcoholic pancreatitis patients as a secondary effect of excessive alcohol consumption and this is much more common than hyperlipidemia-induced pancreatitis in association with primary or inherited forms of hypertriglyceridemia. Clinically, alcohol abuse still needs to be ruled out as the cause of acute pancreatitis whenever hypertriglyceridemia is diagnosed [21,22]. Patients with familial chylomicronemia syndrome (FCS), a rare autosomal-recessive disorder characterized by a loss of lipoprotein lipase (LPL) activity due to inactivating mutations of the *LPL* gene or genes encoding for proteins that regulate LPL activity such as apolipoproteins C-II and A-5 (*APOC2*, *APOA5*), glycosylphosphatidylinositol-anchored high-density lipoprotein binding protein 1 (*GPIHBP1*), and lipase maturation factor 1 (*LMF1*), have an increased risk of recurrent acute pancreatitis resulting from an excessive increase of plasma triglycerides by more than 10 to 100 times above the normal level [23].

Diagnosis of hypertriglyceridemia-induced pancreatitis needs to be established early after disease onset because serum triglycerides levels usually fall rapidly after fasting periods and hypocaloric intravenous volume therapy [21].

It still remains controversial whether hypertriglyceridemia-induced pancreatitis tends to have a more severe course. Some data indicate that severe acute pancreatitis and organ complications may be more frequent in the presence of hypertriglyceridemia [22].

Initial treatment of hypertriglyceridemia-induced pancreatitis is the same as for other etiologies and includes fluid resuscitation, analgesia, and controlled oral food intake. In cases of severe acute pancreatitis and sustained excessive elevation of triglyceride levels lipid apheresis might be considered as a therapeutic option but a clear benefit has not been consistently shown [24]. Emphasis should be laid on lifestyle modifications and lipid-lowering agents, fibrates in the first line, to prevent further attacks of pancreatitis [14]. In patients with FCS, a therapy with volanesorsen, an antisense oligonucleotide targeting APOC3 mRNA can be used as an adjunct therapy when conventional triglyceride lowering agents failed [23].

Diabetic Ketoacidosis

Acute pancreatitis can arise as a severe complication of diabetic ketoacidosis (DKA) with a risk of high mortality. Unfortunately, it is often overlooked because abdominal pain or peritoneal irritation can result from ketoacidosis and hyperlipasemia/-amylasemia might be unspecifically elevated. Acute pancreatitis occurs in at least

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

10–15% of patients with DKA [20]. It has also been reported during non-ketoacidotic hyperosmolar coma but this is very rare. The pathogenesis of acute pancreatitis in DKA is often attributed to hypertriglyceridemia that frequently occurs in parallel. Normally, hypertriglyceridemia is transient and resolves once DKA is corrected [20]. Insulin, fluid resuscitation under control of glucose, and electrolyte balance are key elements in the management of DKA. Plasmapheresis is used in refractory cases complicated by severe hypertriglyceridemia.

Bariatric Surgery

The number of bariatric surgeries performed annually is constantly growing. Besides weight loss an improvement of obesity-associated metabolic diseases is becoming a relevant intention. In the context of acute pancreatitis, it is noteworthy that there is some evidence of so-called "post-bariatric pancreatitis." Currently, a few case reports of post-bariatric pancreatitis as an early complication following laparoscopic gastric bypass or sleeve gastrectomy exist. Consistently in these cases, pancreatitis developed within a few days after surgery. Intraoperative manipulation of peripancreatic tissue, compromised pancreatic microcirculation, edema, and spasm of major papilla as well as small bowel or outlet obstruction caused by blood clots have been suggested as triggers. Since pancreatitis as a short-term complication of bariatric surgery is rarely seen, the exact mechanisms remain to be elucidated. Data from a historical cohort of patients who underwent Roux-en-Y gastric bypass, sleeve gastrectomy, adjustable gastric banding, and revisional procedures showed a higher incidence of acute pancreatitis than in the general population [25]. The risk of acute pancreatitis is higher after vertical sleeve gastrectomy compared to Roux-en-Y gastric bypass surgery [26]. However, it is believed that this risk increase is primarily driven by biliary disease caused by sludge or gallstones as a result of rapid post-surgery weight loss, especially after sleeve gastrectomy. Hence, post-bariatric pancreatitis is likely seen exclusively as an acute complication after surgery, whereas in the longer term, pancreatitis may be caused by other and more common etiologies, first of all biliary.

Infectious Diseases

Data regarding the influence of microorganisms on acute pancreatitis and their incidence are rare and almost exclusively based on case reports. Sometimes it is not entirely clear whether other causes have been ruled out. Patients with acute pancreatitis based on an infectious agent often have a coexistent immunocompromising disorder or diabetes. The microbes involved include bacteria, viruses, fungi, and parasites (Table 22.1) [27].

Bacteria

Numerous bacterial pathogens have been mentioned as causing acute pancreatitis but mostly they are described in single case presentations. Reports exist on *Mycoplasma*, *Legionella*, *Leptospira*, *Salmonella*, *Campylobacter*, and *Brucella* species as well as *Mycobacteria tuberculosis*. The pathogenesis of acute pancreatitis is most likely related to released bacterial toxins. Antimicrobial treatment was initiated upon diagnosis of bacteria-related acute pancreatitis in the majority of cases. However, some reports mention a resolution of pancreatitis with only symptomatic treatment.

Viruses

Of all the infectious agents, most reports exist on mumps virus and its relation to acute pancreatitis. Paramyxovirus causes mumps and although this disease usually has a

mild course, pancreatitis was reported in around 4% of mumps patients [28,29].

The association between hepatitis A, B, and C viruses and acute pancreatitis has also been described. Hepatitis E infections are increasingly diagnosed in Western countries and reports on associated acute pancreatitis have been published [30]. Acute pancreatitis usually has a favorable outcome when related to viral hepatitis.

Human immunodeficiency virus (HIV)-positive patients with the diagnosis of acquired immune deficiency syndrome (AIDS) are also at risk for acute pancreatitis. So far, data are not conclusive whether these patients suffer from a more severe course of the disease. Severe acute pancreatitis was reported in 10–50% of patients with AIDS [31]. Modern therapeutic regimens for HIV/AIDS are associated with a much lower incidence of acute pancreatitis and a lesser degree of severity than earlier regimes that included the use of high pentamidine and didanosine concentrations.

In humans, group B coxsackie virus infections affect many organs including the heart, the central nervous system, and the pancreas. In addition, the association of this member of the picornaviridae family with acute pancreatitis has already been investigated in experimental animal models.

Gastrointestinal symptoms are observed in patients infected by severe acute respiratory distress coronavirus 2 (SARS-CoV-2). So far, small retrospective and case-control studies suggest that acute pancreatitis is an infrequent complication of COVID-19 infection and the proposed underlying pathomechanisms seem to make this association plausible. However, a true increase in the incidence of acute pancreatitis during the COVID-19 pandemic has not been firmly demonstrated [32]. Moreover, diagnosis of acute pancreatitis must be clearly differentiated from a sole elevation of serum pancreatic enzymes, which occurs more frequently [33]. Cytotoxic effects, disturbed immune reactions, a penetration of SARS-CoV-2 mediated by ACE2 receptors to the pancreas and virus-associated coagulopathies are currently being discussed as causative mechanisms.

Other suspected viruses include varicella zoster virus, causing chickenpox [34], influenza [35], herpes simplex, Epstein–Barr, and cytomegalovirus [27].

Fungi

Data on fungal infections causing acute pancreatitis are extremely rare; more often fungi manifest as a late infectious complication of severe acute pancreatitis with infected necrosis. Among them *Candida* spp. is the most common fungal microorganism that is seen secondary to pancreatitis [36]. *Aspergillus* species are discussed as a potential causative agent for pancreatitis as well [27]. Most fungal infections involving the pancreas are superinfections of pancreatic or extrapancreatic necrosis and thus secondary events. Once they occur they have a negative effect on outcome and mortality. Prior antibiotic treatment of (bacterially) infected necrosis does not appear to increase the rate of fungal infection of necrosis.

Parasites

Some case reports exist on acute pancreatitis caused by *Toxoplasma*, *Cryptosporidium*, *Ascaris*, *Plasmodium falciparum* infections, or helminths (*Strongyloides*). An immunomediated mechanism is discussed as being the underlying mechanism but even immunocompetent individuals can develop pancreatitis. For parasites such as *Ascaris lumbricoides*, *Fasciola hepatica*, and *Clonorchis sinensis* the disease mechanism is identical to that of gallstone-induced pancreatitis: impaction in the duodenal papilla and obstruction of the pancreatic duct. They account for up to 5% of cases of "biliary" pancreatitis in some parts of Asia and China and endoscopic removal of the parasite from the papilla remains the therapy of choice.

Drug-Related Diseases

According to the World Health Organization (WHO) more than 525 drugs have been reported to cause acute pancreatitis as a potential side-effect. It is expected that the number of medications will increase in parallel with the approval of new drugs and accumulating case reports [37]. However, the level of evidence differs as knowledge is essentially extrapolated from case reports with varying strength in quality [38]. By definition, case reports only produce the lowest level of evidence in epidemiologic studies. Moreover, drug-related acute pancreatitis is usually not accompanied by other clinical or laboratory signs of adverse drug reactions such as a rash, lymphadenopathy, or eosinophilia. Therefore diagnosis is often difficult to establish [39]. A rechallenge with the suspected drug and induction of an additional attack of pancreatitis (after initial withdrawal) allows researchers to conclude potential causality but is not definitive proof. Apart from this challenge, ethical considerations limit the use of re-exposure to a drug in order to trigger a second attack of pancreatitis with its potential complications. The incidence of drug-induced pancreatitis is low and is estimated to account for 0.1–2% of all cases [40,41]. Very young and older people, women, and patients suffering from immunosuppressive disorders (such as HIV) or inflammatory bowel disorders are at higher risk. Risk increases in these groups by up to fourfold and is most probably based on immune-mediated

reactions and the type of drugs prescribed for these disorders [37,38,42].

There are many different ways currently in use to classify drugs according to their risk of causing adverse events. With regard to acute pancreatitis the classification model of Badalov and coworkers from 2007 is currently the most frequently used. It subdivides drugs into four groups (class I–IV), based on the quality of published evidence for each agent reported as having caused acute pancreatitis [43]:

- *Class I*: Group with highest level of evidence and the presence of a positive rechallenge test for the drug. Class I drugs can be further subdivided into those in which other potential causes for acute pancreatitis (i.e., alcohol, gallstones, hypertriglyceridemia) have been ruled out (Ia) and those where other causes were not excluded in the relevant reports (Ib).
- *Class II*: At least four case reports for the particular drug are required. In addition, ≥75% of the cases must show a consistent drug latency, meaning that time of onset of pancreatitis is within a reasonable time frame after drug consumption. The mean interval between initial drug intake and start of symptoms is around 5 weeks, with a wide range of 2 to 36 weeks [44].
- *Class III*: At least two case reports exist but there is neither a consistent latency among the cases nor a published rechallenge test.
- *Class IV*: Weakest level of evidence based on a single case report, no rechallenge test was done.

Alternatively, drug-related adverse effects are classified by application of the Bradford Hill criteria. Nine different criteria evaluate the evidence of causation and one of them is the claim for biologic plausibility, meaning that the proposed causality must have been shown in an experimental laboratory setting [45].

A third classification system groups drugs according to a definite, probable, or possible causality for an adverse reaction. The main characteristics include: (i) a reasonable temporal relationship from drug intake to onset of symptoms, (ii) a known underlying pharmacologic mechanism, (iii) presence or absence of other causes for the particular side-effect, and (iv) recurrent disease after rechallenge [46]. Depending on the quality of the case report, it can happen that a suspected medication might be classified once as a definite and once as a probable risk factor [38].

To assess the probability of a causal relationship between a drug and an adverse event, also the Naranjo criteria can be used. Besides questions on existing conclusive reports on the specific drug reaction, assessment of symptoms after drug discontinuation, and information on serum concentrations of the drug, this algorithm also considers whether alternate causes of acute pancreatitis have been excluded [47].

The underlying mechanism of drug injury on the pancreas is likely based on idiosyncratic reactions. This type of reaction is characterized as being unpredictable, dose-independent, and with varying latency. From a pathophysiologic point of view idiosyncratic reactions are often mediated by an immunologic or cytotoxic mechanism of the specific compound or its metabolites. Unfortunately, they are difficult to reproduce in experimental animal models, whereas effects of intrinsic toxicity are mimicked more easily. Intrinsic toxicity implies organ damage in a dose-dependent way and is usually seen as toxicity after drug overdoses. With regard to the pancreas there are only a few reports based on an intrinsic mechanism covering acetaminophen, erythromycin, and carbamazepine [43]. A list of drugs often named in association with acute pancreatitis is given in Table 22.2.

In addition, some of the most frequently cited drugs and their corresponding potential pathophysiologic mechanisms are discussed here.

Nonsteroidal anti-inflammatory drugs (NSAID) have been proposed to induce acute pancreatitis, probably due to inhibition of prostaglandins. Prostaglandins seem to have a protective and membrane-stabilizing effect on pancreatic cells, as shown in experimental models [37,48]. The highest risks were reported for diclofenac (odds ratio [OR] 5.0) and the lowest for naproxen (OR 1.1). Use of selective COX-2 inhibitors can lower the risk for acute pancreatitis [38,49]. Conversely, given prophylactically as suppositories unselective NSAID have been shown to lower the rate of endoscopic cholangiopancreatography (ERCP)-induced pancreatitis, at least in very high-risk patients.

Estrogens, which are also used in oral contraceptives, may induce acute pancreatitis by reducing lipoprotein lipase activity, which then increases serum triglycerides and fatty acids. These components are known to be precipitating factors for acute pancreatitis [50].

Angiotensin-converting enzyme (ACE) inhibitors such as captopril, enalapril, lisinopril, and others decrease degradation of bradykinins that are released during acute pancreatitis. Bradykinins cause a local angioedema that could favor tissue edema or pancreatic duct obstruction and subsequent organ damage. There is also evidence for a direct toxic effect of ACE inhibitors on the pancreas [51,52].

Several studies report on the side-effects of azathioprine and 6-mercaptopurine, and these include acute pancreatitis. Interestingly azathioprine-induced pancreatitis is nearly never reported outside the field of inflammatory bowel disease (IBD), especially Crohn's disease [38]. Presumably the drug's toxicity is associated with the underlying disease. Affected individuals carry an up to 8- to 13-fold increased risk of acute pancreatitis [53,54]. With regard to 6-mercaptopurine, 3.25% to 6% of patients with IBD being treated with that drug develop acute

Table 22.2 List of drugs with association to acute pancreatitis.

Definite association	Probable association
Asparaginase	Cyclopenthiazide
Azathioprin	Oxaliplatin
Carbamazepine	Mesalazine
Cytarabine	Rifampin
Didanosine	Octreotide
Enalapril	Metformin
Erythromycin	Hydrochlorothiazide
Estrogens	Propofol
Furosemide	Tamoxifen
Lamivudine	
Mercaptopurine	
Mesalamine	
Opiates	
Pentamidine	
Pravastatin	
Steroids	
Sulfasalzine	
Trimethoprim/Sulfmethaxazole	
Tetracycline	
Valproic acid	
Immune checkpoint inhibitors

pancreatitis [55,56]. It is noteworthy that 5-aminosalicylic acid (OR 0.7) and sulfasalazine (OR 1.5), which are also frequently used for IBD treatment, were not associated with significantly increased pancreatitis risk in a recent report [57].

3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (commonly known as statins), such as simvastatin, pravastatin, and atorvastatin are thought to have direct toxic effects and in a number of cases drug interactions involving cytochrome P450 3A4 (CYP3A4) seem to contribute to pancreatitis. However the overall risk for acute pancreatitis is rather low with an OR ranging from 1.01 to 2.02, so statins seem to be of low importance for drug-induced pancreatitis [58].

Nucleoside reverse transcriptase inhibitors such as didanosine, lamivudine, and stavudine have a toxic effect on the pancreas. In addition they cause metabolic disturbances [52]. HIV patients with a low CD4 count are at a higher risk [38].

Asparaginase is a cytostatic drug and commonly used for treatment of non-Hodgkin lymphoma and acute lymphoblastic leukemia. Asparaginase-associated acute pancreatitis was reported from 5–13 % in these therapies occurring in both children and adults with similar risk while pancreatitis-related complications were most frequently observed in adolescents. Re-administration of asparaginase is related with a high rate (up to 44%) of recurrence of acute pancreatitis and therefore should be carefully considered before rechallenging [59].

Consumption of valproic acid or other anti-epileptic drugs is associated with an increased risk for acute pancreatitis, presumably mediated by direct toxic effects and an increase of reactive oxygen species [38,52]. According to recent studies and in contrast to older reports, selective serotonin reuptake inhibitors (SSRI) do not increase the risk of acute pancreatitis [60].

Soon after introduction of incretin mimetics (glucagon-like peptide-1 [GLP-1] agonists) safety concerns arose about the potential of acute pancreatitis as a side-effect, especially for exenatide and sitagliptin. Reports were also released on dipeptidyl-peptidase-4 (DPP-4) inhibitors [61,62]. Recent analyses failed to find an unequivocal effect on the incidence of pancreatitis and were explained by the fact that people with diabetes already are at increased risk of developing acute pancreatitis [37,63,64]. A higher prevalence of gallstone disease or hypertriglyceridemia is also seen in this patient group [65]. Summing up, the role of incretin mimetics is not conclusively answered: preexisting risk factors such as diabetes mellitus and cardiovascular disorders explain most pancreatitis cases in this group and the large safety trials on DPP-4 inhibitors have largely calmed the initial concerns about an association with pancreatitis.

Immune checkpoint inhibitors are directed against cytotoxic T-lymphocyte-associated-antigen 4 (CTLA4), programmed cell death protein 1 (PD-1) or its ligand 1 (PD-L1), which are expressed on T cells, antigen presenting and tumor cells, respectively. They are increasingly used for treatment of a growing number of malignant tumors and for some entities combinations of checkpoint inhibitors exist. Due to the higher number of prescriptions immune-related adverse events are observed more frequently. Pancreatic injury is observed in up to 4% of patients being treated with immune checkpoint inhibitors [66], most often manifested by an asymptomatic increase of serum lipase and amylase but occasionally also by acute pancreatitis. Treatment consists of discontinuation and in severe cases of immune-mediated reactions steroid treatment is required.

Very few case reports exist on drug-induced acute pancreatitis after penicillin-type antibiotics and these

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. belong to class IV group because usually no rechallenge has been done after discontinuation of the medication [67].

For all drug-associated forms of pancreatitis management consists of drug discontinuation and supportive care, as for other types of acute pancreatitis. If necessary, a drug of a different class will be selected for further therapy. However, drug-induced pancreatitis remains a rare entity and physicians should at first rule out other causes as at least one underlying condition predisposing to acute pancreatitis is found in almost half of the patients [68]. These include occult gallstone disease, immoderate alcohol consumption, and underlying genetic changes. A critical review of the patient's medication profile is mandatory before assuming a drug to be causative for pancreatitis.

Radiologic Diagnosis and Staging of Severe Acute Pancreatitis

Yoshihisa Tsuji

Department of General Medicine, Center for Graduate Medical Education, Sapporo Medical University, Sapporo, Hokkaidō, Japan

Introduction

The role of imaging is important in diagnosis and evaluation of severity in patients with known or suspected acute pancreatitis. Common imaging techniques for the evaluation of the pancreas include transabdominal ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). Angiography and positron emission tomography (PET)-CT are sometimes used to diagnose special complications in acute pancreatitis patients. This chapter deals with these imaging techniques in the diagnosis of local and systemic inflammation associated with acute pancreatitis.

Classification of Acute Pancreatitis

Acute pancreatitis represents a spectrum of inflammatory disease ranging from clinically mild to severe acute pancreatitis [1]. In recent years a radiological approach has been commonly used to diagnose acute pancreatitis and evaluate severity. For these purposes, CT is one of the most popular methods. Abdominal CT has been commercially available since the 1970s.

In 1983, Kivisaari et al. reported that pancreatic necrosis in acute pancreatitis could be diagnosed using CT [2]. Bradley et al. [3] and Johnson et al. [4] also reported the usefulness of CT in diagnosis of pancreatic necrosis in acute pancreatitis patients, in 1989 and 1991, respectively. These studies regarded pancreatic necrosis as one of the most important factors in predicting a poor prognosis (Table 23.1).

In contrast, based on broadening of inflammation, Balthazar et al. [5] established a CT grading system to define the severity of acute pancreatitis in 1985. This is called Balthazar's CT grade, and it became one of the most popular image-based grading systems of severity of acute pancreatitis. It was partially modified in 2002 [6]. In 1985 the Balthazar system classified acute pancreatitis into five grades: A—normal, B—focal or diffuse enlargement of the pancreas, C—peripancreatic inflammation with intrinsic pancreatic abnormalities, D—intra- or extrapancreatic fluid collections, and E—two or more large collections of gas in the pancreas or retroperitoneum. In the 2002 version, grades D and E were modified: D—single fluid collection and E—two or more fluid collections and/or retroperitoneal air, respectively.

The two concepts that assist in diagnosis—local pancreatic damage and evaluation of broadening of inflammation—were combined into the CT severity index to predict prognosis (see section on CT severity index later in this chapter).

According to these moves to diagnose and evaluate acute pancreatitis using CT, a newer classification of acute pancreatitis was discussed at the Atlanta conference in 1992 [7]. In Atlanta, following previous symposia [8–10], severity of acute pancreatitis was classified into two grades: mild and severe. In this classification, severe acute pancreatitis was associated with organ failure and/or local complications, such as pancreatic necrosis, pancreatic fluid collection, acute pseudocyst, or pancreatic abscess. Since it was considered that CT could diagnose these local complications accurately, descriptions of the Atlanta classification were largely devoted to diagnostic criteria of local complications on CT. Following this symposium, radiological findings associated with acute pancreatitis were described in medical reports based on these terminological definitions.

The Atlanta classification was universally applied for two decades from 1992. During these two decades, two important insights were reported. First, Casas et al. reported that the early CT, which was performed within

3 days from the onset, could not diagnose pancreatic necrosis accurately [11]. Second, a new concept, "walled-off necrosis (WON)," was proposed [12,13]. Early pancreatic complications (e.g., pancreatic and peripancreatic necrosis) could develop WON 4 weeks later than the onset. The concept of "WON" has made meanings of pseudocysts different (Table 23.2). Our improved understanding of the pathophysiology of organ failure and necrotizing pancreatitis and their outcomes, as well as improved diagnostic imaging, have made it necessary to revise the Atlanta classification.

The Atlanta classification was also revised in 2012 [14]. According to this classification of acute pancreatitis, known as the "revised Atlanta classification," the severity of acute pancreatitis is categorized into three groups: mild, moderate severe, and severe. In patients without local and systemic complication, the severity is judged to be mild. Patients with local complication without organ failure or transient organ failure which can be controlled within 48 hours from induction of treatment are classified in the moderate severe group. Patients with organ failure that resists treatment resulting in persistence for 48 hours or more are classified as severe (Table 23.2).

At the same time as the revised Atlanta classification, the determinant-based classification [15] was also published by another group. As with the revised Atlanta classification, the aim of this classification was to revise the original Atlanta classification. However, the determinant-based classification regards (peri)pancreatic necrosis as the more important factor to predict prognosis, compared to the revised Atlanta classification. According to determinant-based classification, the severity of acute

pancreatitis is categorized into four groups: mild, moderate, severe, and critical. If the patient has neither (peri) pancreatic necrosis nor organ failure, severity is judged to be mild. The patient with sterile (peri)pancreatic necrosis and/or transient organ failure is classified as moderate. The patient with infected necrosis or persistent organ failure (more than 48 hours from start of treatment) is classified into the severe group. The patient with both infected necrosis and persistent organ failure is classified into the critical group (Table 23.2).

Between the revised Atlanta and determinant-based classifications, there is a difference with regard to the radiological definition of pancreatic necrosis. According to determinant-based classifications, (peri)pancreatic necrosis is nonviable tissue without a radiologically defined wall. In contrast, the revised Atlanta classification makes categorizes pancreatic necrosis into two types according to a diagnosis of well-defined wall: acute necrotic collection (ANC) and WON (Table 23.2). In the determinant-based classification, there is no description with regard to necrotic tissue with radiologically well-defined wall, which was categorized into "acute pseudocyst or pancreatic abscess" and "pancreatic pseudocyst or walled-off necrosis" in the Atlanta and revised Atlanta classifications, respectively. Thus, it appears that the concept of pancreatic necrosis in the determinant-based classification is not the same as that in the revised Atlanta classification.

In both the revised Atlanta and determinant-based classifications, the development of persistent organ failure (48 hours or more from start of treatment) is needed to diagnose severe or critical acute pancreatitis. Thus, in the emergency room we can use only two grades of severity: mild or moderate. From this point of view, a patient with moderate acute pancreatitis is potentially at high risk of developing severe or critical acute pancreatitis. Accurate diagnosis of pancreatic necrosis is one of the most important factors to perform in the emergency room for appropriate triage based on the severity of recent classifications.

Radiographic Diagnosis of Severe Acute Pancreatitis

Two major types of acute pancreatitis are known: acute edematous and necrotizing pancreatitis [14]. Since the prognoses and strategies of treatment of these two are totally different, it is necessary to diagnose them accurately.

Acute Edematous Pancreatitis

According to Klöppel [16], the pancreas is enlarged without necrosis on gross pathology in acute edematous pancreatitis, although microscopic areas of parenchymal fat necrosis may also be found. Lack [17] stated that hemorrhage and intraparenchymal necrosis is absent in the pancreas. Importantly, in acute edematous pancreatitis, where fat necrosis does not come into contact with a blood vessel, it does not damage the vessel wall, leading to macroscopic pancreatic necrosis [16]. Thus contrast enhancement of pancreatic parenchyma is usually normal on contrast-enhanced CT (CE-CT). In addition, the revised Atlanta classification [14] described that CE-CT shows pancreatic swelling with relatively homogeneous enhancement in acute edematous pancreatitis (Fig. 23.1).

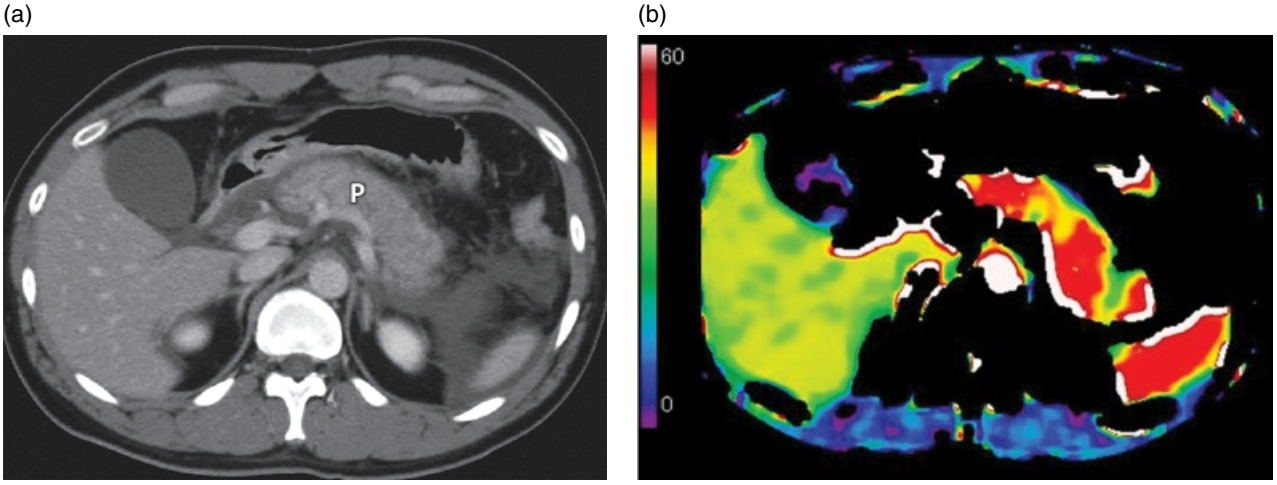

Figure 23.1 Acute edematous pancreatitis. (a) Contrast-enhanced CT shows enlargement of pancreas (P). At the same time as (a), perfusion CT was obtained. (b) Tissue blood flow was demonstrated based on the left-sided scale bar. Pancreatic blood flow was red-yellow (about 40 mL/100 g/min), which indicates that pancreatic blood flow was high.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

In the Atlanta classification [7], the macroscopic feature of mild acute pancreatitis was interstitial edema. Therefore, in those days, mild acute pancreatitis was nearly equal to acute edematous pancreatitis. One of the important things to note is that the revised Atlanta classification [14] changes the definition of mild acute pancreatitis to "pancreatitis with no organ failure and no local or systemic complications." In the revised Atlanta classification, local complications are redefined as acute peripancreatic fluid collection (APFC), pancreatic pseudocyst (PPC), acute necrotic collection (ANC), and walled-off necrosis (WOF). Thus, using the revised Atlanta, acute edematous pancreatitis with APFC, one of the local complications, is classified into moderate severe acute pancreatitis, not mild. The prognosis of patients with acute edematous pancreatitis is much better than that of those with local complication.

Acute Necrotizing Pancreatitis

Approximately 2–10% of acute pancreatitis patients develop necrosis of pancreatic parenchyma and/or peripancreatic tissue [14,18]. Both in the Atlanta and the revised, acute necrotizing pancreatitis is defined as "acute pancreatitis with pancreatic necrosis which involves pancreatic parenchymal necrosis and/or peripancreatic fat necrosis." Reports put the mortality rate for acute pancreatitis patients with pancreatic necrosis at roughly 30% [19].

Development of pancreatic parenchymal necrosis consists of three steps: acinar injury, vascular injury, and tissue injury. The initial pathway in the development of pancreatitis is ectopic activation of trypsinogen in acinar cells and/or activation of macrophages [20–23] or neutrophils [24]. The activation of trypsinogen in acinar cells leads to the acinar cells being destroyed, followed by releases of trypsin and damage-associated molecular pattern molecules (DAMP) [25] into the pancreatic vessels. Vascular epithelial cells are injured by the released trypsin and/or DAMP, resulting in damage to the coagulant–fibrinolytic system of the endothelial cells. In combination with this endothelial damage, periarterial fat necrosis, interstitial edema, and/or bleeding due to inflammation reduces tissue perfusion by compressing vessels. If this reduction of perfusion continues and/or ischemic–reperfusion damage occurs, serious tissue damage often develops, leading to acute necrotic collection (ANC) [26,27]. At 4 weeks or more later, ANC may develop WON. Since ANC and WON are irreversible, attempts to prevent the development of ANC or WON should be started based on a diagnosis of pancreatic ischemia [28] (see sections on acute necrotic collection and walled-off necrosis later).

To diagnose pancreatic necrosis (pancreatic ischemia, ANC, and WON), CE-CT, MRI, or CE-US are used. According to CE-CT criteria in the revised Atlanta classification, acute necrotizing pancreatitis is diagnosed based on lack of pancreatic parenchymal enhancement by intravenous contrast agent and/or presence of peripancreatic necrosis (Table 23.1) [2–4,7,11,27,29–36].

Diagnosis of Local Complications of Acute Pancreatitis

As was described earlier, local complications are divided into four types: APFC, ANC, WON, and PPC in the revised Atlanta classification.

Acute Peripancreatic Fluid Collection

In the Atlanta classification [7], pancreatic fluid collections occurred early in the course of acute pancreatitis, were located in or near the pancreas and always lacked a wall of granulation or fibrous tissue. The precise composition of such collections was not known pathologically. Instead of the term "pancreatic fluid collections" [7], the use of the term APFC was suggested in the revised Atlanta classification [14]. APFC is peripancreatic fluid association with interstitial edematous pancreatitis and without necrosis. In CE-CT, APFC is a homogeneous collection with fluid density, without abnormal peripancreatic fascial planes, without defined wall encapsulating the collection, and without intrapancreatic extension (Table 23.2, Fig. 23.1).

Acute Necrotic Collection

ANC includes parenchymal necrosis of pancreas and peripancreatic fat necrosis. Thus, acute pancreatitis with ANC is the same as acute necrotizing pancreatitis. A collection contains variable amounts of both fluid and necrotic tissues. As was previously described, ANC is a pre-stage of developing WON. The border between ANC and normal tissue is gray (Fig. 23.2).

Parenchymal necrosis of pancreas appears as a low attenuation or non-enhancing area on CE-CT [4,5,37]. Early studies reported that CE-CT was highly accurate for the detection of pancreatic necrosis [3,4,29]. These studies mostly included surgical cases, so very few patients in the early stage of acute pancreatitis were included. Four previous studies reported the accuracy of CE-CT in predicting pancreatic necrosis in the early stages of acute pancreatitis [11,33,34,38]. One study showed that pancreatic necrosis was not detected in any of 49 patients with acute pancreatitis on CE-CT

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 23.2 Acute necrotizing pancreatitis and its natural history. Due to serious complications of acute pancreatitis, this patient had three CT scans during the course of the disease. Contrast-enhanced CT shows homogeneous enhancement of pancreas at day 1 (a). On day 8 (b), enhancement of pancreas was markedly reduced, so this case was diagnosed as acute necrotizing pancreatitis. (c) On day 36, the scan shows acute necrotic collection (ANC) and altered walled-off necrosis (WON), which was surrounded by a well-defined wall.

performed within 72 hours of onset (sensitivity: 0%) [33], while the three other studies [11,34,38] showed that CE-CT had a sensitivity of 63%, 72%, and 75%, respectively, for the early phase of acute pancreatitis (within 1 day of admission or 72 hours of onset).

As Klöppel described previously [16], pancreatic inflammation can reduce pancreatic blood flow, resulting in development of pancreatic necrosis. Using angiography, Takeda also showed that pancreatic parenchyma with vasospasm of the intrapancreatic artery develops parenchymal necrosis with high ratio [27]. Perfusion CT [39,40], which can measure parenchymal blood flow accurately, has shown promise as a method that can accurately detect pancreatic necrosis at an early stage of acute pancreatitis with an estimated sensitivity of 88–100% and specificity of 84–100% [32,35,36] (Fig. 23.3). Perfusion CT can differentiate reversible from irreversible ischemic tissue, and thus has been used widely for diagnosing acute brain stroke (Fig. 23.1). According to Yadav et al. [35], pancreatic parenchyma with poor blood flow (cutoff value about 20 mL/100g/min or less and normal pancreas 100 mL/100g/min or more) could develop pancreatic necrosis with high ratio. At 24 hours from onset, Pienkowska et al. [36] showed that perfusion CT can predict development of pancreatic necrosis accurately. This suggests that the parenchymal blood flow is decreased even at an early stage of acute pancreatitis in areas of impending necrosis (Fig. 23.4 and 23.5).

Dynamic contrast-enhanced magnetic resonance imaging (CE-MRI) [41] may be an alternative to CE-CT

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Figure 23.3 Difficulty in identifying pancreatic parenchymal necrosis using conventional CT. (a) Using contrast-enhanced CT (day 1), regional necrosis on the pancreatic head was not identified (arrowheads). (b) However, perfusion CT showed markedly reduction of pancreatic perfusion. (c) The poor perfusion area on perfusion CT (b) was concordant with an area of pancreatic necrosis at autopsy.

for detecting pancreatic necrosis. Indeed, MRI has certain advantages over conventional CE-CT, including greater sensitivity in detecting ischemia. Moreover, when MR angiography is performed in conjunction with MRI, assessment of vessel patency is also possible.

Walled-off Necrosis

WON is defined as a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has a well-defined wall [12–14]. It arises secondary to ANC and usually occurs at >4 weeks after onset of acute pancreatitis. On CE-CT, WON often appears heterogeneous, with liquid and nonliquid density with varying degrees of loculations [14]. Ultrasound (both percutaneous and endoscopic) or MRI is better for diagnosing the heterogeneity of WON compared to CE-CT, because the identification of the liquid area in necrosis by MRI or ultrasound is more accurate than that by CE-CT.

Compared to ANC, WON has well-defined walls at marginal zone of necrosis, and therefore the border is clear. WON develops liquefaction of necrotic area heterogeneously and gradually [17]. Some areas of WON have inner walls, and WON can thus be separated into various sizes. In addition, WON develop in many areas, side by side or separately. Therefore, in acute pancreatitis patients with local complications, there is a possibility that many areas of WON will develop in the abdominal cavity.

In cases of suspected ANC/WON infection, rapid enlargement of the necrotic area, inflammatory changes in the neighboring fat, gas in the necrotic area, and surrounding paralytic ileus may help to diagnose the location of the infection (Fig. 23.6). One study suggests that PET-CT may be useful in identifying infected WON [42], although it is expensive.

Pancreatic Pseudocyst

It should be noted that the definition of the term PPC has recently changed. Previously, PPC included both WON and encapsulating fluid [7]. In the latest international classification, the revised Atlanta [14], PPC is redefined as an encapsulating collection of fluid with a well-defined inflammatory wall. PPC usually occurs more than 4 weeks after onset, as well as WON. Any solid region is not identified as PPC, thus (endoscopic) US or MRI is useful to diagnose it (Fig. 23.7).

Radiologic Staging of Severe Acute Pancreatitis

The concept of radiologic staging of severity of acute pancreatitis is based on two important findings: extent of inflammation and necrosis (ANC/WON).

CT Severity Index

Combining the findings of broadening of inflammation and local pancreatic damage on CT, the CT severity index (CTSI) was published in 2002. In the CTSI, Balthazar CT grade A (normal pancreas) scores 0, grade B (enlargement of pancreas) scores 1, grade C (inflammatory changes in pancreas and peripancreatic fat) scores 2, grade D (single fluid collection) scores 3, and grade E (two or more poorly defined fluid collections)

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

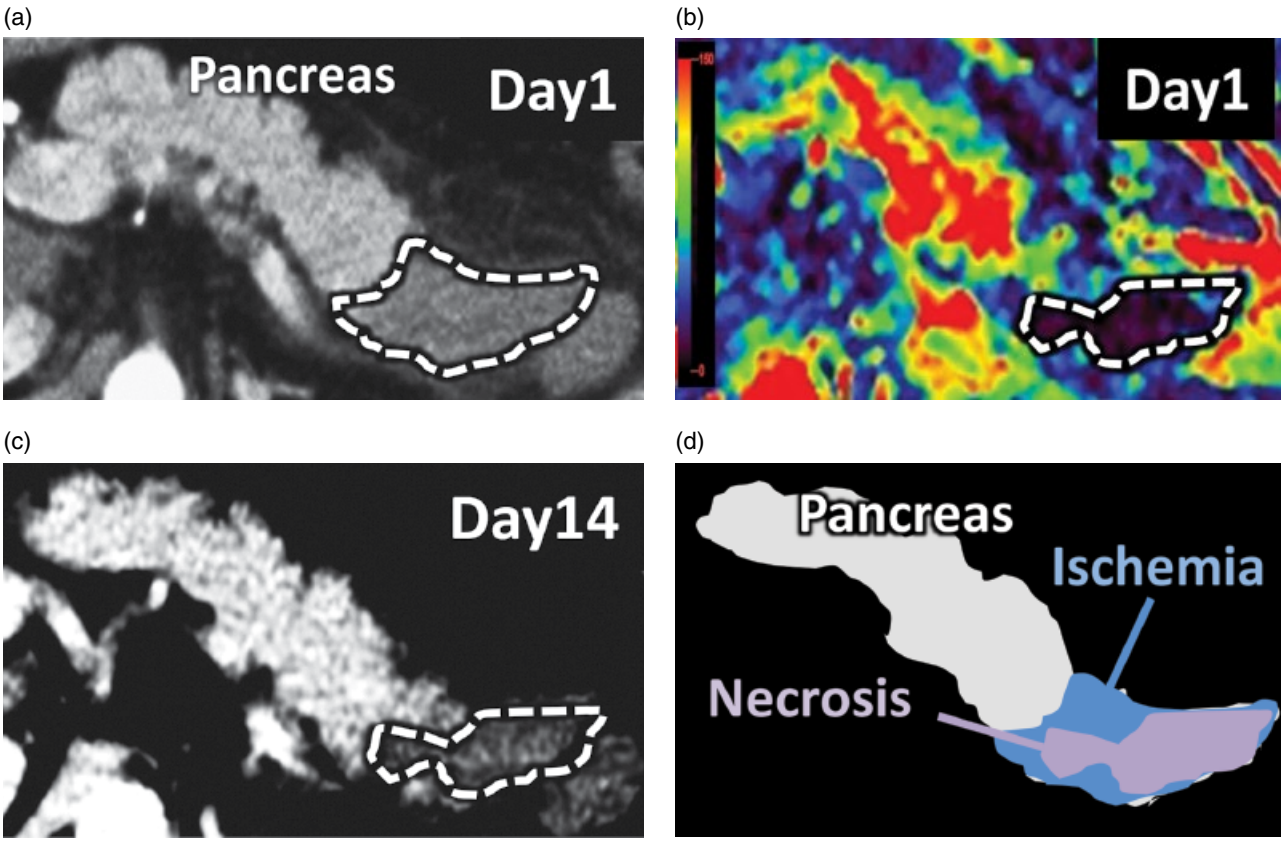

Figure 23.4 Reversible ischemia and necrosis in early stage of severe acute pancreatitis. (a) Contrast-enhanced CT (day 1) showed a lack of enhancement of the pancreatic tail (area surrounded by dotted line). (b) Perfusion CT showed a poorly perfused area in the pancreatic tail, which was smaller than the area with lack of enhancement on contrast-enhanced CT. (c) The area with poor perfusion in the perfusion CT developed pancreatic necrosis. (d) Based on these findings, the schema shows that the marginal zone of pancreatic necrosis could have been reversible ischemia.

scores 4. The pancreatic condition is independently evaluated: no pancreatic necrosis on CT scores 0, pancreatic necrosis less than/equal to 30% of pancreas scores 2, >30–50% scores 4, and >50% scores 6. Grading severity is based on a CTSI score of 0–10: mild (score 0–3), moderate (score 4–6), and severe (score 7–10) [5,6]. The CTSI was modified in 2004 by Mortele et al. (MD-CTSI) [43]. The MD-CTSI resulted in higher interobserver agreement ratio, correlation with length of hospital stay, need for invasive therapy, incident organ failure, and the occurrence of infection (Table 23.3).

Japanese CT Severity Index

In the latest Japanese definition of severe acute pancreatitis [44], Hiroto et al. established the JPN-CT severity score. In the definition, severe acute pancreatitis can be diagnosed either by the laboratory/clinical severity criteria or JPN-CT. The case mortality rate of patients with severe acute pancreatitis diagnosed by JPN-CT score was 14.8%. The case fatality of severe acute pancreatitis that fulfilled JPN-CT severity criteria (severity score ≥2 points) was as high as 30.8%.

Limitations and Pitfalls of Radiologic Diagnosis of Acute Pancreatitis

Diagnosis of Early Necrosis of Pancreatic Parenchyma

The accuracy of CE-CT to diagnose pancreatic parenchymal necrosis within 3 days of onset is not adequate [11,37]. One potential explanation for this disappointing performance of CE-CT is that the attenuation of pancreatic parenchymal necrosis is similar to that of viable enhancing parenchyma on CE-CT in the early stages of acute pancreatitis, and the CT attenuation of pancreatic necrosis decreases over time as nonviable parenchyma liquefies [12,31]. Moreover, because the CT

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

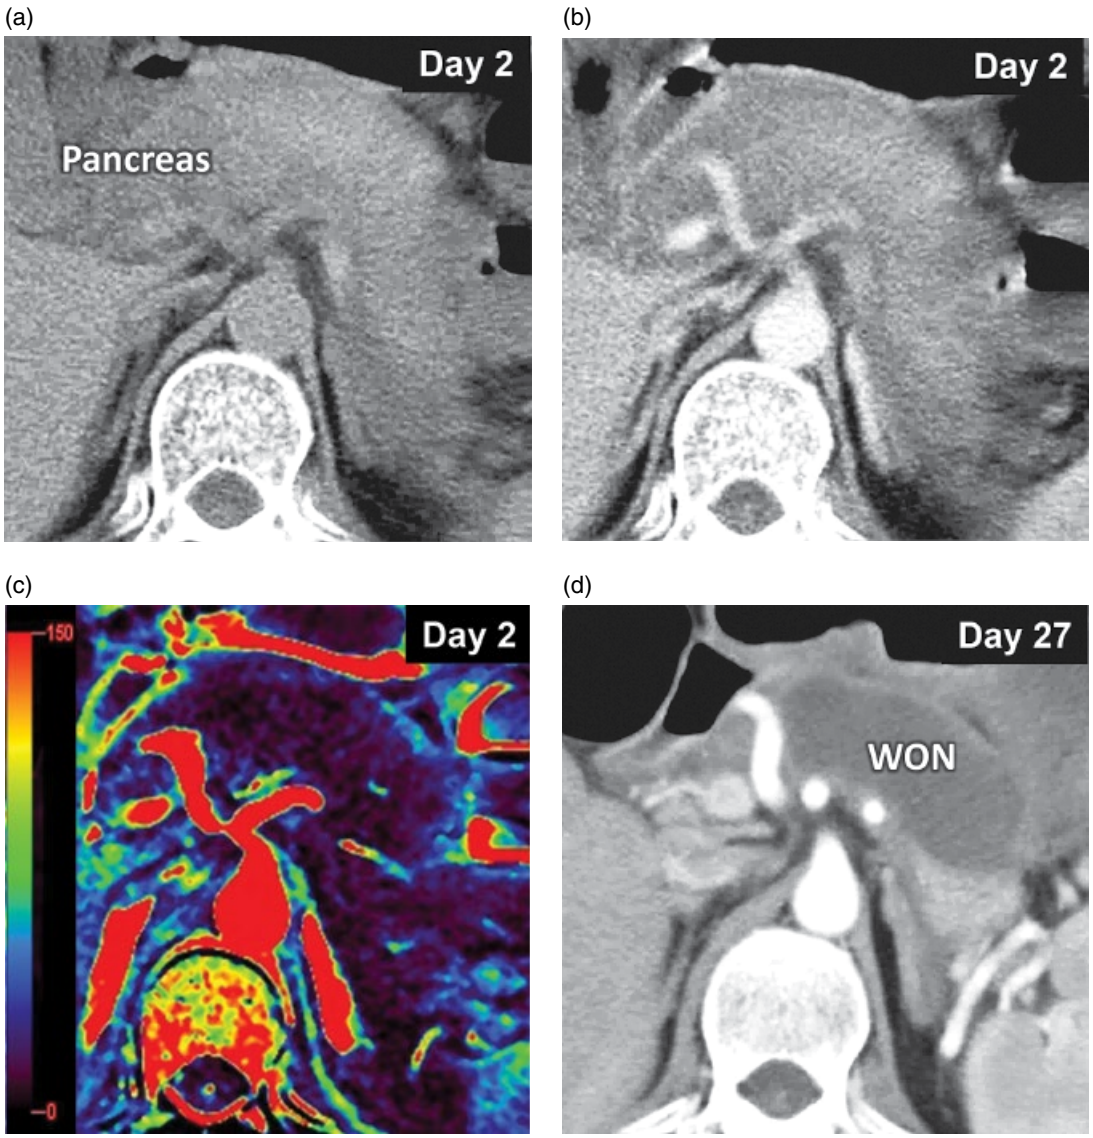

Figure 23.5 Tissue hemorrhage makes it difficult to diagnose necrosis using contrast-enhanced CT alone. (a) Noncontrast CT showed elevation of CT values in pancreatic body. (b) On CE-CT alone, it is difficult to judge whether the elevation of CT value of pancreatic parenchyma was due to hemorrhage or enhancement by contrast agent. (c) Perfusion CT showed that pancreatic blood flow of the whole pancreatic body was extremely low. These findings show that the pancreatic body had already developed necrosis on day 2. (d) The poorly perfused area with slight elevation of CT values on noncontrast CT was concordant with the area with later necrosis.

attenuation of pancreas may be altered by hemorrhage in necrosis or fatty infiltration, evaluation of regional variability in pancreatic enhancement becomes difficult with CE-CT. Another reason why CE-CT may not be accurate in predicting parenchymal necrosis in the early stages may involve the difficulty of evaluating the effectiveness of contrast-enhanced material. Since the border of early parenchymal necrosis that is included in the ANC is not clear, selecting specific of areas with suspicious parenchymal necrosis in the case of early acute pancreatitis poses difficulties, in contrast to analyses of enhancements in well-defined lesions, such as a WON.

Although the detection of pancreatic parenchymal necrosis with CT imaging has led to the improved prognostic stratification of patients using the CT severity index [45], the inaccurate prediction of parenchymal necrosis using CE-CT and its large interobserver variability [43,46] may also lead to recent recommendations questioning the routine use of CT at an early stage of acute pancreatitis [47,48].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

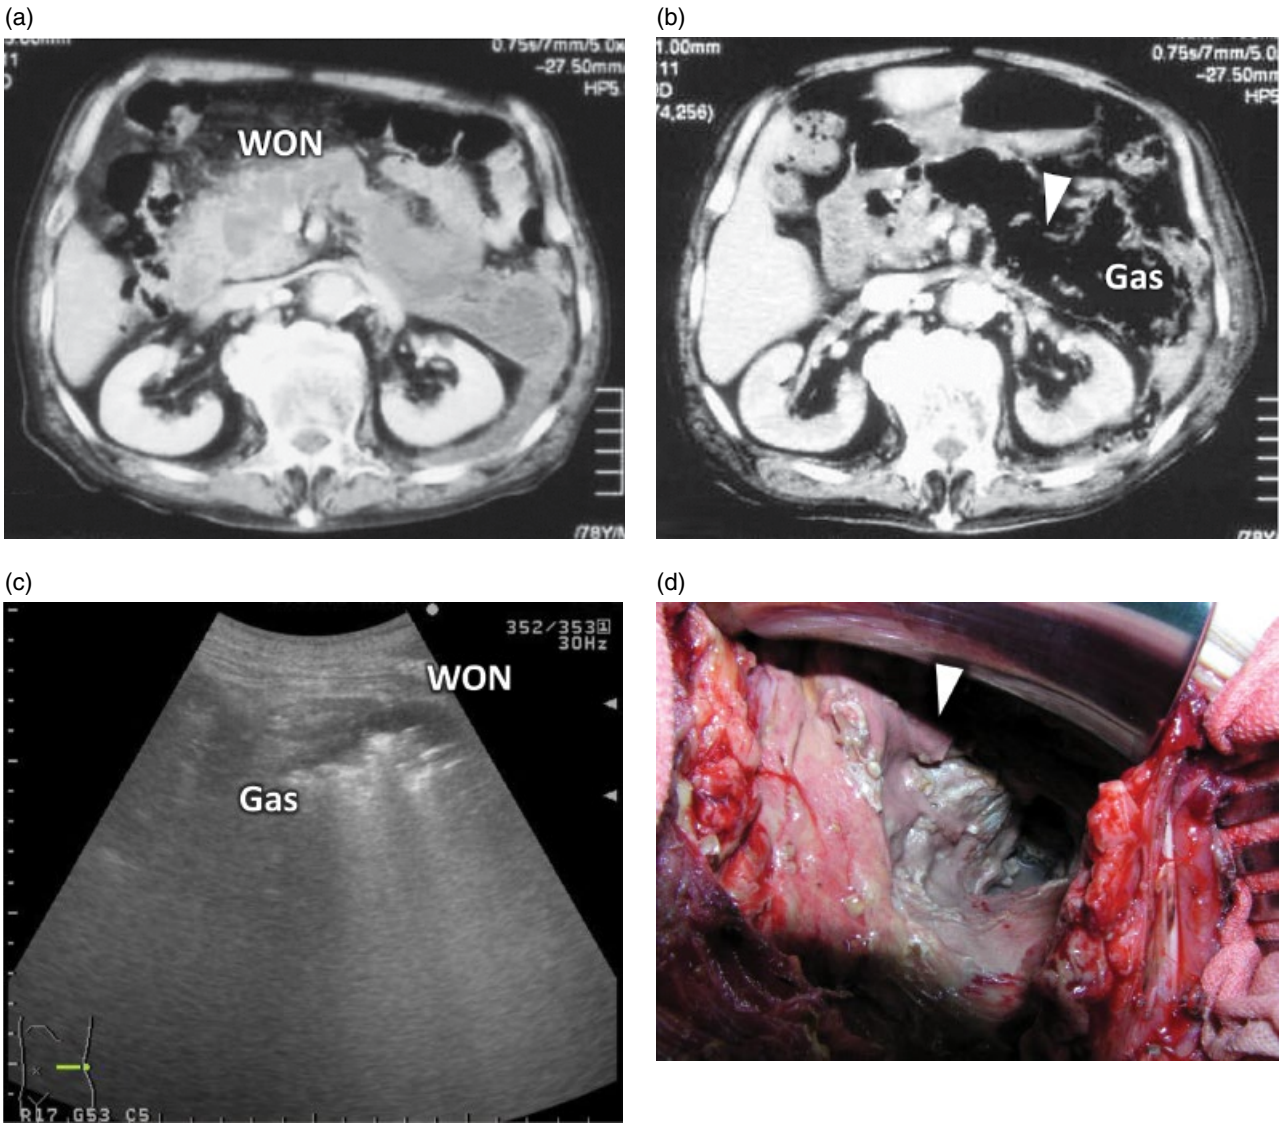

Figure 23.6 Infected walled-off necrosis (WON). (a) Presented case has WON on contrast-enhanced CT. (b) Most of the WON on the pancreas body and tail was replaced with gas, due to infection. In the gas cavity of WON, the inner wall (arrowhead) was detected. (c) Percutaneous ultrasound showed high spotty areas due to gas in WON. (d) Surgical treatment was performed and a part of the inner wall (arrowhead) was shown in the cavity. The patient recovered 6 months later.

Despite the advantages discussed earlier, MRI is underused in the evaluation of patients with severe acute pancreatitis. This underutilization can be attributed to practical considerations—patients with severe acute pancreatitis have difficulty withstanding the lengthy MRI procedure. In addition, removal of all the magnetic instruments (e.g., sphygmomanometer, saturation monitor, multiple infusion pumps, etc.), which cannot be taken away from patients with severe acute pancreatitis even for a short period, must be done before the procedure is performed.

Nephrotoxity of Contrast Material of CE-CT and CE-MRI

One of important systemic complications of acute pancreatitis is acute renal failure. Because CE-CT and dynamic CE-MRI has some nephrotoxicity, use of dynamic CE-MRI and CE-CT should be decided with care [41]. Perfusion CT is obtained from analysis of blood flow after a bolus injection of much less contrast materials (approximately 30–40%) than those used for conventional CE-CT [49]. Therefore, the nephrotoxity of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. CTSI score and disease severity of acute pancreatitis	
Score 0–3: mild	
Score 4–6: moderate	
Score 7–10: severe	

perfusion CT is lower than that of CE-CT and dynamic CE-MRI.

Rickes et al. have recently shown that CE-US [50], which does not have a bad effect on the kidney, can also be used to diagnose pancreatic parenchymal necrosis reliably. However, a whole pancreatic scan with ultrasound is often difficult, because a common complication of acute pancreatitis patients is paralytic ileus. Pancreatic parenchyma with inflammation is often surrounded by digestive canal with gas [14], and so the accuracy of ultrasound for evaluating severity of pancreatitis is limited.

Radiation Dose of CE-CT and Perfusion CT

The radiation doses of CE-CT and perfusion CT should not be ignored. However, recent techniques regarding noise reduction and registration make it possible to perform CE-CT and perfusion CT using much lower radiation dose protocols. Radiation doses used for recent pancreatic perfusion CT were lower than those used for triple phase CT [49,51].

Needs for Diagnosis of Pancreatic Necrosis in the Early Stage

As reported in a previous publication, neither APACHE II nor CE-CT give accurate predictions for patients in the early stages of acute pancreatitis [52]. Because of the absence of an ideal and established method for evaluating severity at an early stage, therapies often begin only after the patient has sustained serious damage. Since serious tissue damage (e.g., necrosis) may be irreversible, such treatments may be of limited benefit at later stages. Early and accurate predictions appear critical in establishing effective early care strategies. Accurate predictions of the severity may improve the accuracy of triage assignments and allow intensive treatment to begin earlier. Early inductions of aggressive fluid therapy [53] and enteral nutrition [54] may improve outcomes for patients with severe acute pancreatitis. Importantly, there is no strong evidence that early and accurate evaluations of severity can actually alter prognosis in acute pancreatitis. Prospective intervention trials based on early accurate predictive methods would be required to confirm this.

According to our study [55], new agent recombinant thrombomodulin could have reduce the risk of

development of WON from ANC. Importantly, in this type of study, which investigated efficacy of early intervention, accurate diagnostic criteria of ANC would be needed in the early stage of acute pancreatitis. In this study, newer diagnostic instruction combining revised Atlanta criteria and JPN criteria was used (Table 23.4). This approach might be help to diagnose ANC early and accurately.

Conservative Therapy of Acute Pancreatitis: Volume Substitution and Enteral and Parenteral Nutrition

Steven M. Hadley, Jr. and Timothy B. Gardner

Section of Gastroenterology and Hepatology, Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA

Introduction

Acute pancreatitis is an often devastating inflammatory condition of the pancreas that leads to extensive worldwide morbidity and mortality [1]. In fact, in the United States, acute pancreatitis is among the most common reasons for patients to be hospitalized for a digestive illness [2]. The substantial human costs of this disease, with billions in annual healthcare dollars spent worldwide, has led to extensive efforts to establish a pharmacologic treatment for this disease. Unfortunately, as of 2022, there is no specific medical therapy that specially targets acute pancreatitis or that has been useful to improve important clinical outcomes.

Over the past 50 years, extensive efforts have been made to develop targeted pharmaceutical therapies, but none have demonstrated benefit in randomized controlled trials. Agents directed at reducing pancreatic secretions, including histamine-2 blockers, such as cimetidine, glucagon, atropine, somatostatin and its analogue octreotide, do not reliably affect morbidity or mortality [3–5]. Antiprotease therapy with aprotinin and gabexate mesilate are equally ineffective, as is therapy with lexipafant, a platelet-activating factor antagonist [6,7].

Recently, as discussed elsewhere in this textbook, rectal nonsteroidal anti-inflammatory drugs (NSAID) have been demonstrated to be helpful in reducing the risk of post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis due to regulation of proinflammatory mediators. Rectal NSAID function by inhibiting phospholipase A2 activity, including arachidonic acid products and platelet-activating factors [8,9]. One NSAID in particular, rectal indomethacin, has been used extensively since 2012 following the publication of a randomized, placebo-controlled trial in patients undergoing ERCP considered to be at high risk for pancreatitis [9]. The trial found that a single 100 mg dose of rectal indomethacin significantly reduced the risk of pancreatitis from 16.9% in those receiving placebo to 9.2% in those receiving indomethacin.

However, with the exception of rectal indomethacin, there are currently no specific pharmacologic therapies advocated for the treatment of acute pancreatitis [10]. Supportive measures, including the use of fluid resuscitation, nutrition, and aggressive intensive care unit care, have become the cornerstone of conservative therapies in treating this disease.

This chapter focuses specifically on the conservative therapies of fluid resuscitation and enteral and parenteral nutrition. It will review the importance of the pancreatic microcirculation and its effects on the pathogenesis and prognosis of acute pancreatitis. It will discuss animal and human clinical trials that have evaluated the role of different types, volumes, and rates of fluid resuscitation. Finally, current recommendations in regard to administering fluids in acute pancreatitis will be provided. The latter aspect of the chapter will focus specifically on the role of enteral and parenteral nutrition in the treatment of acute pancreatitis, with a review of clinical trials and important recommendations for nutritional care on patients with this disease.

Fluid Resuscitation

The Pancreatic Microcirculation and Acute Pancreatitis

It is critically important to understand the intricacies of the pancreatic microcirculation when discussing the role of fluid resuscitation in acute pancreatitis. The arterial supply to the pancreas is derived from the two main proximal trunks of the aorta: the celiac trunk and superior

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

mesenteric artery. The splenic and common hepatic arteries (as well as the left gastric artery, which does not supply the pancreas) arise from the celiac trunk. The splenic artery gives rise to the penetrating branches of the body and tail of the pancreas, while the common hepatic artery, via its branch the gastroduodenal artery, supplies the pancreatic head through the anterior and posterior superior pancreaticoduodenal arteries. The anterior and posterior inferior pancreaticoduodenal arteries, arising from the superior mesenteric artery, supply the head and neck of the pancreas, and form vascular anastomoses with the superior pancreaticoduodenal arteries. This vascular network features extensive collateralization, thus ensuring adequate pancreatic tissue perfusion.

From these large arteries arise the intralobular arteries, which run within the pancreas often parallel to the pancreatic ducts. The intralobular arteries give rise to the pancreatic microcirculation, a vast network of capillaries and venules that supply the pancreatic acinus with a rich blood supply [11]. An exocrine lobular plexus with multiple fine capillaries represents the basic vascular unit within the pancreas, and flow from the vascular plexus is almost 20 times more likely to prefer the pancreatic islet cells than the acinus. As a result, the pancreatic acinus is extremely prone to low vascular flow states when there is lack of circulating blood flow to the pancreas [12]. This susceptibility is why the pancreatic acinus can be so prone to damage with even a slight perturbation in systemic blood flow.

Disturbance to the blood flow within the pancreatic microcirculation due to acute pancreatitis can occur for several reasons: hypovolemia, increasing capillary permeability, and hypercoagulability causing microthrombi, among others [13–16]. The generation of oxidative free radicals with subsequent capillary endothelial damage has also been implicated. This alteration in microcirculation significantly increases the degree of pancreatic ischemia, irrespective of etiology, thus exacerbating the systemic inflammatory response syndrome (SIRS) and potentially leading to multisystem organ failure.

Once significant acinar blood flow has been disturbed, acinar cell injury occurs. Acinar cell injury then causes the release of multiple proinflammatory cytokines and vasoactive mediators, including tumor necrosis factor α, histamine, bradykinin, interleukin 1 (IL-1), IL-2, IL-6, platelet-activating factor, and endothelin-1, which are recruited to the pancreatic microcirculation and delivered to the acinar cells [17–19]. Once this proinflammatory cascade is set into motion, the systematic sequelae of acute pancreatitis, including the collapse of the systemic circulation leading to multisystem organ failure, can occur. Once initiated, this process is exceedingly difficult to reverse.

The role of aggressive fluid resuscitation is essentially to try to perfuse the acinar tissue sufficiently in the face of such overwhelming antagonism of the normal physiologic maintenance of adequate tissue perfusion pressure. Although fluid resuscitation by itself does not have an effect on the proinflammatory mediators leading to circulatory collapse, the sequelae of maintaining adequate tissue perfusion may seek to slow or ameliorate at least part of the inflammatory cascade. The hope for intravenous fluid resuscitation in acute pancreatitis is that adequate tissue perfusion will perfuse the pancreatic microcirculation so that pancreatic necrosis and its subsequent complications can be minimized or even prevented.

Animal Studies

There have been extensive animal studies in the pathophysiology and treatment of acute pancreatitis, specifically in regard to establishing a definitive pharmacologic therapy for blunting the proinflammatory content of this disease. However, despite the important role of fluid resuscitation in acute pancreatitis, relatively few animal studies have been exclusively devoted to this subject. The critical question asked by animal studies in acute pancreatitis are the same as in human studies: How much fluid should be given? What type of fluid should be given? Is colloid or crystalloid fluid a better choice? What are the complications of using overly aggressive fluid resuscitation?

Two animal studies have demonstrated the importance of aggressive fluid resuscitation, irrespective of the type of fluid utilized. Juvonen et al., using a pig model of Na-taurocholate-induced pancreatitis, showed that the signs of splanchnic hypoperfusion can be prevented with fluid resuscitation [20]. The investigators found that the PCO_2 gap increased and portal venous blood flow decreased in pigs with acute pancreatitis, but did improve significantly with resuscitation. Niederau et al. have also demonstrated in a choline-deficient, ethionine-supplemented diet mouse model that hydration by subcutaneous fluid markedly improved survival and normalized the hematocrit without having significant biochemical or morphologic effects [21].

Crystalloid resuscitation has been studied only sparingly in animal studies of acute pancreatitis. Knol et al. evaluated the effect of low and high infusion rates of lactated Ringer's solution in 14 dogs with bile trypsin pancreatitis [22]. They found that pancreatic blood flow decreased to a greater extent in the low infusion group compared to the high infusion group. Crystalloid resuscitation with a balanced salt solution adequately restored plasma volume, supported tissue perfusion and prevented excessive hemodilution without detrimental effects on pulmonary pressures or oxygenation in a canine model of acute hemorrhagic pancreatitis [23].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The majority of animal studies dealing with fluid resuscitation have used colloid solutions, most notably dextran, and generally found improved outcomes compared with crystalloid resuscitation. One suspected reason for improved outcomes with colloids has been that they are not as permeable to leakage in the pancreatic microcirculation compared with crystalloids. By remaining in the luminal environment, circulatory blood flow is better maintained, and inflammatory mediators are less able to access the acinus [24–28].

Thus, in summary, animal studies have been relatively sparse, and the majority of these have been completed with colloid rather than crystalloid solutions. However, these studies have not been able to answer effectively the questions of which solution is most appropriate, what is the optimal rate of fluid resuscitation, and what are the consequences of overly aggressive resuscitation. Surprisingly, as detailed below, the clinical studies in humans have not appreciably answered these questions satisfactorily either.

Human Studies

Despite the universally accepted paradigm that aggressive fluid resuscitation is an important element of supportive care in acute pancreatitis that leads to improvements in important clinical outcomes, few studies and even fewer randomized controlled trials have been performed on this treatment. Questions about the rate of resuscitation, type of fluids, and consequences of over-aggressive resuscitation remain unanswered. However, in the last decade more attention had been focused on this important clinical area, and several randomized trials are planned to try to answer these critically important questions.

The original investigation in humans about the importance of aggressive fluid resuscitation was carried out by Baillargeon, Banks, and colleagues in the 1990s. They emphasized the importance of resuscitation in improving clinical outcomes. In a retrospective cohort study, they found that hemoconcentration with an admission hematocrit >47% or failure of admission hematocrit to decrease at approximately 24 hours were strong risk factors for the development of pancreatic necrosis [29]. Multiple subsequent studies have validated these findings, including the Banks group who performed a retrospective study to determine whether fluid resuscitation could prevent pancreatic necrosis among patients with hemoconcentration at the time of admission [30–35].

As these data suggest, inadequate fluid resuscitation leading to poor pancreatic microcirculatory perfusion has been associated with acute necrotizing pancreatitis [33]. Specifically, we now know that early fluid resuscitation has more of a therapeutic effect than delayed fluid resuscitation. Although early fluid resuscitation is generally agreed upon as an intervention of paramount importance, there are currently no standard guidelines on the optimal fluid type, volume, rate, or duration of treatment. Despite the lack of standard guidelines, studies on the rate and volume of fluid therapy suggest early aggressive fluid resuscitation results in the best outcomes. When compared to early nonaggressive (<500 mL) fluid resuscitation, early moderate (500–1000 mL) to aggressive (>1000 mL) fluid volume administration significantly reduces the need for invasive interventions, with some evidence suggesting a trend towards lower complications with early moderate to aggressive fluid resuscitation [36]. Although human studies on the rate of hydration consistently show decreased morbidity and mortality with aggressive hydration in the first 24 hours, the total volume of hydration at the 48-hour mark seems to have a limited effect on patient outcomes [36,37].

The current American College of Gastroenterology (ACG) guidelines recommend 250–500 mL/h of isotonic crystalloid solution in the first 12–24 hours, with frequent re-evaluation every 6 hours and an ultimate goal of decreasing the blood urea nitrogen (BUN) levels [38]. Some experts recommend that in addition to the 1–2 L fluid bolus given in the emergency department, the starting infusion should be at a rate of 250–300 mL/h or enough to produce a urine output of at least 0.5 mL/kg per hour [39]. The goal within the first 24 hours is a total infusion volume of 2.5–4 L, with adjustments to be made based on the patient's age, weight, physical exam, and comorbid conditions [40]. Similarly, the current American Gastroenterological Association Institute (AGA) guidelines advise using goal-directed therapy for fluid management but note to proceed judiciously so as to avoid potential complications from overly aggressive fluid resuscitation [41].

The type of resuscitation fluid has been minimally studied. However, in a widely cited manuscript, Wu et al. found that the use of lactated Ringer's solution, in place of normal saline, resulted in less SIRS and a decreased C-reactive protein at 48 hours [42]. However, the small sample size of 40 patients limits the study. Nevertheless, more recent randomized controlled trials substantiate these results. De-Madaria et al. compared lactated Ringer's solution to normal saline solution and found that lactated Ringer's led to less SIRS criteria and lower C-reactive protein levels than normal saline. *In vitro*, they also observed that lactated Ringer's inhibited both the activation of macrophages to their inflammatory phenotype and the activity of NF-κB, a transcription factor involved in inflammation, while normal saline and Ringer's solution without lactate did not inhibit such processes [43]. In another randomized controlled trial, Choosakul et al. revealed that lactated Ringer's solution significantly decreased SIRS compared to normal saline 24 hours after the development of acute pancreatitis but did not show any significant differences in SIRS at 48 hours [44].

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

A meta-analysis conducted by Iqbal et al. confirmed these findings by demonstrating that lactated Ringer's solution resulted in lower rates of SIRS development compared to normal saline at 24 hours [45]. However, a randomized controlled trial conducted by Lee et al. found no significant difference in SIRS between normal saline and lactated Ringer's, but did reveal that lactated Ringer's resulted in a shorter length of stay and fewer ICU admissions than normal saline [46]. In patients undergoing ERCP, aggressive fluid resuscitation using lactated Ringer's solution has been demonstrated to be an effective deterrent for the development of post-ERCP pancreatitis [47]. Thus, although these patients are not in the same exact clinical scenario as patients not undergoing ERCP, these results do suggest that the use of lactated Ringer's solution has a beneficial effect.

The issue of over-aggressive hydration and risk of poor outcomes, particularly the development of abdominal compartment syndrome, has been highlighted by two studies. The first, a retrospective evaluation of 99 patients with severe acute pancreatitis in Sweden, determined that patients receiving 4000 mL or more of fluids during the first 24 hours ($n = 32$) developed more respiratory complications (66% vs. 53%; $P = 0.001$) than patients who received less than 4000 mL of fluid [48]. Mao et al. have also reported improved survival rates by controlling the amount of fluid resuscitation within the first 72 hours in 83 patients with severe pancreatitis [49]. In addition, in a randomized controlled trial of patients with predicted severe pancreatitis whose hematocrit was aggressively lowered upon admission, those with aggressive lowering of their hematocrit had greater morbidity and mortality [50]. A subsequent meta-analysis of aggressive vs. nonaggressive fluid therapy determined that although no statistically significant difference in mortality existed between the two groups, patients receiving aggressive fluid resuscitation possessed a higher risk for acute kidney injury, as well as acute respiratory distress syndrome [51].

Thus, although important inroads have been made into the role of aggressive fluid resuscitation in the critical issue of supporting the pancreatic microcirculation in acute pancreatitis, several questions remain—particularly how best to monitor the rate of resuscitation and at what point the critical juncture of over-resuscitation occurs. Lactated Ringer's solution appears to represent an important breakthrough in the type of crystalloid solution to be used in this regard but further randomized controlled trials stratifying by the type of crystalloid solution are necessary. Continued animal studies into the effects of crystalloid and colloid solutions on the pancreatic microcirculations are in order, as well as carefully designed human clinical trials using varying fluid solutions and rates with an emphasis on patient monitoring and safety (Table 24.1).

Table 24.1 Important human studies of fluid resuscitation in acute pancreatitis.

Study type	Number of patients	Comparison group	Outcome
Retrospective [29]	65	Aggressive (Hct <47) vs. nonaggressive	Hct >47 developed necrosis
Retrospective [48]	99	Aggressive (4 L) vs. nonaggressive	Aggressive with more respiratory complications and increased ICU care
Retrospective [34]	45	Early vs. late resuscitation	Increased mortality in late
Retrospective [35]	434	Early vs. late resuscitation	Less SIRS, organ failure, ICU admissions, LOS in early
RCT [47]	62	Aggressive (3 mL/kg per h) vs. nonaggressive using LR in ERCP	Less hyperamylasemia and abdominal pain in aggressive group
RCT [50]	115	Aggressive (<35 Hct in first 24 h) vs. nonaggressive	A higher incidence of sepsis and decreased survival in aggressive group
RCT [42]	40	LR vs. normal saline	LR had decreased SIRS and CRP at 24 hours
RCT [43]	40	LR vs. normal saline	LR led to decreased SIRS and CRP than normal saline
RCT [44]	47	LR vs. normal saline	LR significantly decreased SIRS at 24 hours compared to normal saline, but had no significant difference at 48 hours
RCT [46]	121	LR vs. normal saline	LR resulted in decreased LOS and ICU admissions but led to no significant difference in SIRS compared to normal saline

Hct, hematocrit; ICU, intensive care unit; SIRS, systemic inflammatory response syndrome; LOS, length of stay; LR, lactated Ringer's solution; CRP, C-reactive protein.

Enteral and Parenteral Nutrition

Nutritional supplementation has long been an important component of conservative treatment in acute pancreatitis. Since most patients with acute pancreatitis must be "nothing by mouth" for at least part of their hospitalization, the mechanism of nutritional supplementation and type has been an active area of clinical research for many decades. Although the standard of care for many years included nothing per mouth and "resting" the pancreas by limiting enteral intake, recent studies have proved that early enteral feeding appears to be of significant benefit to clinical outcomes.

The disadvantage of maintaining patients nothing by mouth is that bowel rest is associated with intestinal mucosal atrophy and increased infectious complications due to bacterial translocation [52]. In order to maintain gut barrier function, therefore, enteral feeding is preferred over parenteral feeding in the management of acute pancreatitis. This preference has been proven in multiple randomized controlled trials dating back to the early 1990s, and meta-analyses have consistently demonstrated the importance of enteral versus parenteral nutrition in both interstitial and predicted severe acute pancreatitis [53–57]. Currently there is no rationale to use parenteral over enteral nutrition in the setting of acute pancreatitis. Even in patients who cannot tolerate a full enteral diet, at least some degree of enteral nutrition should be provided to maintain gut barrier function. Early enteral nutrition (within 48 hours) after admission has been found to reduce mortality, multiple organ failure, operative interventions, and infections when compared to late enteral nutrition and parenteral feeding [58,59]. Current AGA guidelines corroborate these findings, as the AGA advising panel strongly recommends early (within 24 hours) oral feeding and, in patients who cannot feed orally, enteral rather than parenteral nutrition to generate the best outcomes [41].

In mild acute pancreatitis, early initiation of oral intake with a low-fat soft solid diet is often tolerated and has been demonstrated to be just as efficacious as tube feeding [60]. Further study has also demonstrated that even in patients with predicted severe acute pancreatitis, early oral vs. on-demand tube feeding has demonstrated equivalent efficacy in a randomized controlled trial [61]. Enteral feeding is recommended within 3 days of hospitalization, typically after cessation of nausea, vomiting, discontinuation of parenteral analgesics, reduction in abdominal pain, and return of bowel sounds. However, one study suggests that early oral refeeding based on hunger rather than on clinical and laboratory measures proves effective for introducing nutrition earlier to patients with acute pancreatitis without more complications than conventional refeeding based on clinical parameters, and it reduces length of stay compared to conventional refeeding [62]. Moreover, feeding can be started with a low-fat solid diet and does not need to be initiated using the archaic clear liquid, mechanical soft, and low-fat method [63]. Moraes et al. found in a randomized controlled trial that patients who received a full solid diet as opposed to either a clear liquid diet or a soft diet and who had no abdominal pain relapse had the shortest length of stay (median 1.5 days shorter). However, when considering patients who had abdominal pain relapse, the length of stay was similar among the three groups, and the authors found no difference in pain relapse between the three different diets [64].

The choice between nasojejunal or nasogastric feeding has been debated for quite some time with nasojejunal feeding being favored—again because of the issue of achieving pancreatic rest. However, recent studies have suggested that nasogastric feeding may be just as efficacious and well tolerated as nasojejunal feeding when evaluated in a randomized controlled setting and demonstrate benefits when compared to nil per os [65,66]. Because of no apparent mortality benefit of one over the other, the AGA guidelines recommend either nasogastric or nasojejunal feeding [41].

The issue of type of feeding has been inadequately studied, but there has been a meta-analysis evaluating 20 randomized controlled trials comparing different formulations [67]. The authors concluded that the use of polymeric, rather than (semi)elemental, formulation does not lead to a significantly higher risk of feeding intolerance, infectious complications, or death in patients with acute pancreatitis. Neither the supplementation of enteral nutrition with probiotics nor the use of immunonutrition significantly improved the clinical outcomes. A Cochrane Database review also found similar low-quality evidence differentiating the types of formulations and their benefit in acute pancreatitis [68]. In addition, a recent study of the use of probiotics in acute pancreatitis demonstrated worsening mortality due to bowel ischemia in the group receiving probiotics, and it is thus advised that probiotics should not be used in patients with acute pancreatitis [69].

Thus, in summary, enteral feeding is favored over parenteral feeding in acute pancreatitis based on improvement in important clinical outcomes. Oral feeding should be initiated within 72 hours of admission in all patients using a low-fat diet. If patients cannot tolerate oral feeding, nasoenteric feeding, usually with a nasogastric feeding tube, can be employed. In those patients in whom appropriate enteral feeding is not tolerated, low-level "trickle" feeding should be used to help prevent gut translocation of bacteria, which can lead to infected necrosis. Patients should not be given probiotics, as these formulations have demonstrated an increased risk of mortality due to mesenteric ischemia.

Conclusions

Supportive care in acute pancreatitis is critical to achieving optimal patient outcomes in the context of no targeted pharmacologic options in this disease. Aggressive fluid resuscitation and the initiation of early enteral feedings have revolutionized the care of patients with acute pancreatitis. Further studies—specifically targeting the type of fluids and enteral nutrition formulations in randomized controlled trial format—are needed, however, in order to optimize further conservative care for these patients.

Introduction

Acute pancreatitis remains a complex, progressive, and variable acute inflammatory syndrome of the pancreas. In some cases, the inflammatory response is so severe that a sequence of systemic inflammation defined by the systemic inflammatory response syndrome (SIRS), capillary leak syndrome (CLS), multiorgan dysfunction, shock, and death may occur. Patients with life-threatening complications should be managed in the intensive care unit (ICU), where early intervention and support may result in better outcomes. This chapter will focus on management following a general clinical pathway to emphasize the sequence of common events and evidence behind clinical decisions.

Pre-ICU Management

Optimal treatment begins in the clinic or emergency department (Fig. 25.1). The primary goals in early evaluation include confirming the diagnosis, detecting early signs of organ dysfunction, and initiating fluid resuscitation. Fluid resuscitation (see Chapter 26) may be the most important early intervention for stabilizing and treating patients with evolving severe acute pancreatitis.

The initial physical examination is central to assessment and proper triage. The clinical histories are variable, but sudden onset of severe, sharp, unrelenting pain with nausea and vomiting is common. In addition to a routine physical examination the clinician should focus on early signs of severe acute pancreatitis, including severe pain, anxiety, confusion, scleral icterus, diaphoresis, dry mouth, tachycardia, thready pulses, acrocyanosis, tachypnea, lung rales, and abdominal tenderness with or without rebound pain. Postural changes (e.g., supine to standing) resulting in dizziness or tachycardia suggest significant intravascular hypovolemia.

The initial laboratory assessment should include standard diagnostic tests in addition to standard laboratory tests (Box 25.1). These tests serve both as baseline values for future comparisons and early biomarkers of organ dysfunction that may require ICU management. A chest X-ray may provide early evidence of pulmonary edema and/or plural effusions [1].

Early morbidity and mortality are heralded by SIRS, as it often leads to endothelial stress [2], CLS [3] and organ dysfunction involving the lungs, cardiovascular system, intestines, and kidneys, and damage to the pancreas [4–7]. Early management focuses on fluid resuscitation and oxygenation. Patient comfort centers on treatment of pain and nausea.

Life-threatening hypovolemia in acute pancreatitis develops because of CLS, which occurs in an unpredictable subset of patients. The mechanism of hypovolemia in acute pancreatitis appears to overlap with trauma and involve epithelial cell damage, CLS, and loss of large and small proteins from the circulation into interstitial and third spaces [2,3,8]. Blood pressure may not become significantly decreased until the patient has lost 30–40% of circulating blood volume [9]. Therefore, blood pressure correlates poorly with both blood volume and cardiac output. Furthermore, the severity of the hypovolemia may be masked by splanchnic vasoconstriction and shunting of blood from the viscera to maintain circulation to the brain and peripheral organs. Hypovolemia may also be overlooked by focusing on criteria designed for sepsis or multiple trauma such as systolic blood pressure <90 mmHg [7,10].

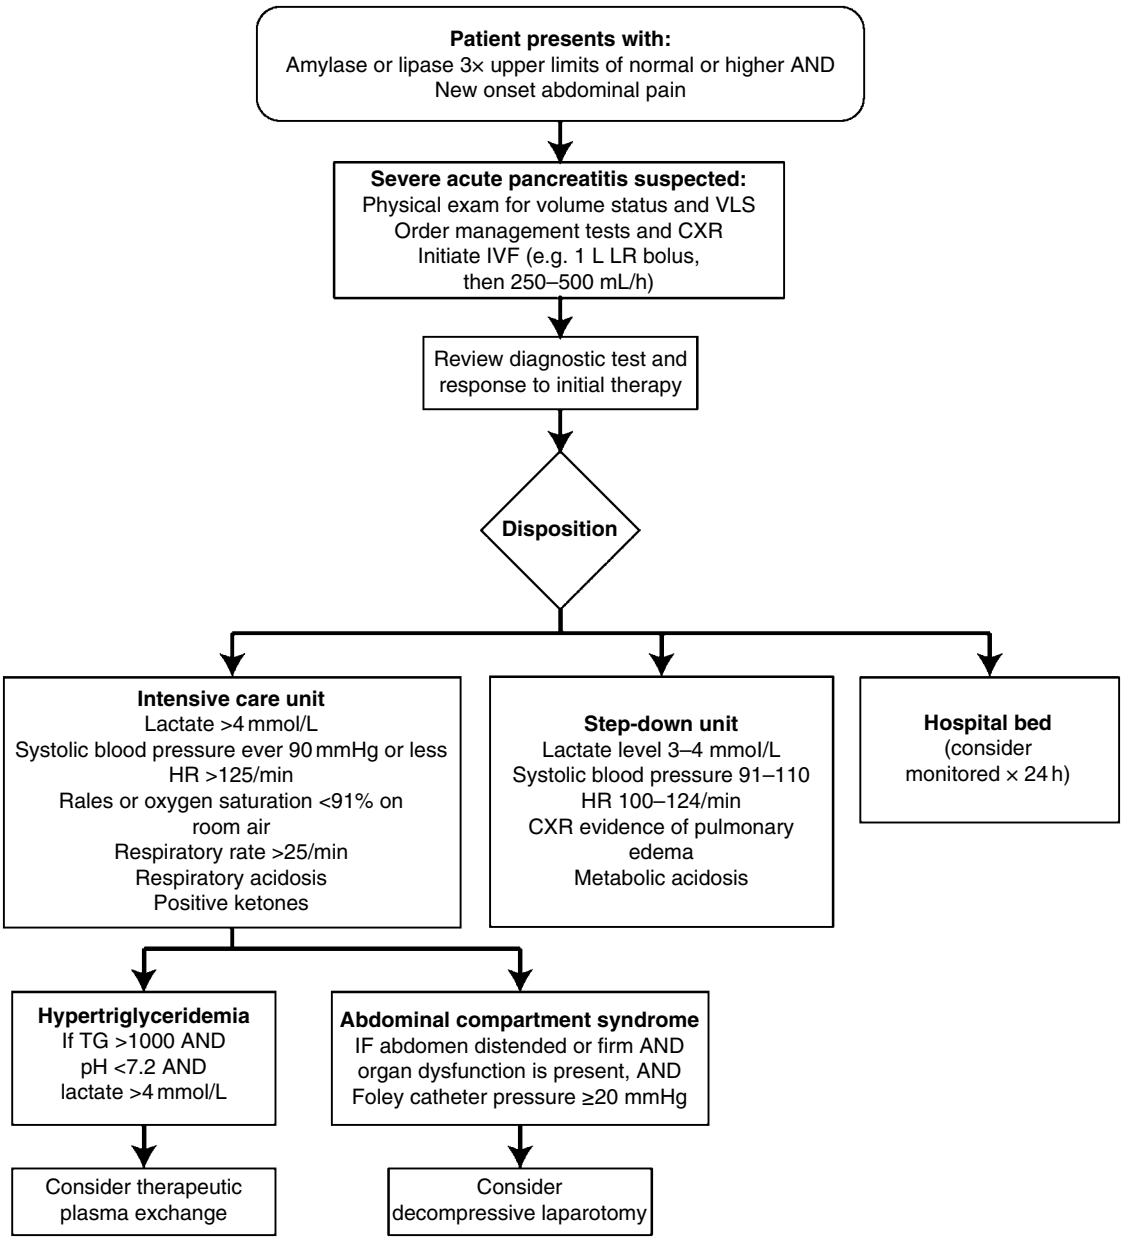

Figure 25.1 An illustrative clinical pathway for managing patients during the initial evaluation and possible admission into the intensive care unit. See text. CXR: chest x-ray; HR: heart rate; LR: lactated Ringer's solution; TG: triglyceride level; CLS: capillary leak syndrome.

Hypoperfusion and/or ischemia of visceral organs create two additional challenges to the problem of generalized tissue ischemia. First, hypoperfusion may continue long after systemic volume resuscitation has occurred, resulting in continued ischemic stress on intestinal mucosal epithelial cells, the most vulnerable cells of the gut. Second, mucosal epithelial cell injury results in breakdown of the mucosal barrier and translocation of bacteria and toxic factors that enter the circulation via the mesenteric lymphatics and drive SIRS [11,12]. Thus, in some patients, a vicious cycle develops with systemic inflammation leading to CLS, which causes intravascular hypovolemia and splanchnic vascular bed ischemia, leading to translocation of proinflammatory toxins from the gut lumen into the lymphatics that further drives systemic inflammation. Interruption of this cycle should begin with minimizing or preventing intravascular hypovolemia.

The usual systolic blood pressure of adults varies widely, so the relative change in both blood pressure and heart rate may be more important than an absolute value. A systolic blood pressure <90 mmHg, however, is likely

Box 25.1 Baseline blood-based laboratory tests

Diagnostic tests [on admission]

- Amylase level
- Lipase level
- Triglyceride level
- Calcium level

Management tests [on admission and every 6–24 hours as needed]

- Electrolytes (sodium, potassium, chloride, bicarbonate)
- Blood urea nitrogen (including pre-acute pancreatitis levels)
- Creatinine (including pre-acute pancreatitis levels)
- Blood glucose
- Complete blood count (for white blood cell count and hematocrit)
- Liver injury tests (for bile duct obstruction and aetiology)
- Albumin (including pre-acute pancreatitis levels)
- Total Protein (including pre-acute pancreatitis levels)
- Serum lactate
- Serum LDH (optional)
- Arterial blood gas (optional)

to be a *late* sign of severe intravascular hypovolemia [13]. An elevated hematocrit indicates hemoconcentration and implies significant extravasation of serum and protein-rich plasma from the bloodstream and is a harbinger of impending organ failure [3]. Elevated lactate levels also suggest that tissues may already be in shock [14]. We believe that optimal treatment includes the prevention of hypotension and shock, and resuscitation should not be delayed until signs of hemoconcentration, and shock develop.

Treatment and prevention of progressive intravascular hypovolemia must begin before the patient is transferred to the ICU. Although acute pancreatitis has been compared with septic shock and similar resuscitation algorithms suggested, the current evidence supporting goal-directed therapy, using parameters to guide either rate or total volume of resuscitation, to reduce morbidity or mortality is limited [10]. We recommend that resuscitation with balanced salt solution should be given rapidly, as soon as the diagnosis of acute pancreatitis is made, with modifications for patients with existing comorbidities [4,10]. Further research on the resuscitative strategies may help guide our approach [15].

Early use of supplemental oxygen is warranted with continuous monitoring of oxygen saturation via pulse oximetry or intermittent arterial blood gas analysis. The pulmonary edema seen in patients with severe acute pancreatitis and CLS is usually due to endothelial cell injury and extravasation of plasma, not fluid overload. Therefore, the treatment should be positive pressure ventilation and not diuresis, unless the patient is absolutely volume overloaded.

For pain we recommend hydromorphone 0.5–2.0 mg intravenously every 15 minutes while the respiratory rate is >10 and systolic blood pressure is >90 mmHg. However, no differences between opiates were demonstrated in systematic reviews of variable quality clinical studies [16,17]. Opiates primarily used in the United States and new studies are needed to determine necessity and utility. For nausea we give ondansetron 4–8 mg intravenously every 6 hours as needed.

Special Considerations

As in trauma, management decisions made in the early minutes and hours of care have significant downstream consequences. The emergency in severe acute pancreatitis is fluid management and tissue oxygenation within the context of systemic inflammation. But unlike trauma where the insult is rapid and finite, the systemic inflammation of acute pancreatitis evolves, so continued attention to the evolution of the process over the first 24 hours is critical.

We strongly discourage the use of contrast computed tomography (CT) scan in early severe acute pancreatitis. The diagnosis can almost always be made by the combination of typical pain and elevated serum levels of pancreatic digestive enzymes [5,7]. Although contrast-enhanced CT scan remains useful for detecting and quantifying pancreatic necrosis and/or fluid collections, there are no urgent interventions, and the evaluation can be delayed for days. Early contrast CT poses at least two risks. First, the contrast may worsen the severity of pancreatic necrosis, as well as kidney injury in patients, especially if there is poor perfusion from hypovolemia and/or shunting of blood from visceral organs. Second, the process of obtaining a CT may interrupt evaluation and treatment, or delay transfer to the ICU. However, CT or other abdominal imaging modalities may be required if the diagnosis is in question.

Gallstone pancreatitis occurs when small gallstones become lodged at the sphincter of Oddi and trigger intrapancreatic digestive enzyme activation and acute pancreatitis. In some cases, the gallstone remains lodged, whereas in others the stone passes on its own. Although there used to be great enthusiasm for urgent endoscopic retrograde cholangiopancreatography, biliary sphincterotomy, and stone removal, randomized studies failed to demonstrate a benefit for early intervention [18]. The

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

exceptions are cases where an impacted gallstone results in ascending bacterial cholangitis [18]. This condition represents an urgent complication that requires a therapeutic intervention. In this setting, antibiotics should be started immediately. However, the priority of an ERCP is secondary to fluid resuscitation, airway management, and patient stabilization.

Indications for ICU Admission

Early and appropriate treatment of patients with acute pancreatitis may result in rapid resolution of signs and symptoms of more severe disease. In these cases, it is reasonable for patients to be treated and monitored on a step-down unit until the clinical course of the patient dictates a change in care level.

The severe early consequences of acute pancreatitis are related to organ dysfunction and damage rather than SIRS itself. The recommendations of the Revised Atlanta Criteria recommends that patients with SIRS be considered as high risk for organ failure, but that severity is based on organ failure that persists for at least 48 hours to classify patients as truly severe [7]. The Revised Atlanta Criteria defines organ failure based on the Modified Marshall Score of 2 or more in the respiratory system (PaO2/FiO2 of ≥300), renal system (serum creatinine of ≥170 μmol/L or ≥1.9 mg/dL) or cardiovascular system (systolic blood pressure of <90 and not fluid responsive) [7]. However, we are concerned that the criteria are too severe and too late for early triage, increasing risk of avoidable organ damage and unexpected cardiopulmonary arrest of patients admitted to unmonitored regular hospital floors or at home.

The problem with the Modified Marshall Score criteria is that they do not account for the baseline state of the patient and reflect the eventual development of severe organ dysfunction and failure to meet criteria. In the early hours of acute pancreatitis evaluation, it is most important to determine which patient is evolving into organ failure and initiate mitigation strategies such as early fluid resuscitation which may prevent hypotension despite severe underlying pathophysiology. We recommend early identification of patients with evolving organ failure using the Komara criteria [3], which considers pre-acute pancreatitis biomarker status and more accurately distinguishes patients with more severe disease. Specifically, early organ failure (e.g., within the first 72 hours) is likely if the patient has a rise of haematocrit from baseline of >3 (odds ratio 17.7, $P = 0.014$), if both BUN and creatinine levels are increasing from pre-acute pancreatitis levels (and continue rising), and if serum albumin and total protein are dropping. The drop in albumin, and especially total protein appear to reflect endothelial cell stress or injury with CLS, which takes 24 hours to develop [3]. Multiple studies now demonstrate that dropping and low serum albumin are associated with multiorgan failure and severe outcomes [3,19–21]. Multiple prognostic scores may also be useful for predicting later organ failure [22].

We recommend ICU admission for patients with evolving or persistent organ dysfunction who require a high level of care with frequent adjustments to the care plan. Examples include patients with lactate >4 mmol/L, systolic blood pressure at any time <90 mmHg, need for vasopressors, an ongoing heart rate of >125 per minute, rales on lung exam or oxygen saturation <91% on room air, a respiratory rate >25 per minute, any respiratory acidosis or positive serum ketones. In addition, patients with SIRS and CLS (based on Komara Criteria above) may require ICU admission for invasive monitoring of intravascular volume, and impending cardiac and/or pulmonary dysfunction.

ICU Treatment of Severe Acute Pancreatitis

The evolution of severe acute pancreatitis dictates the concerns and management strategies over the first days of disease. The initial phase (0–48 hours after onset of pain) reflects the magnitude of the acute inflammatory response with SIRS, CLS, and early organ dysfunction of the cardiovascular system, lungs, and kidneys. The second phase (48–120 hours after onset of pain) focuses on managing recovery of organ systems from injury and preventing secondary problems such as infection in immunocompromised patients from the compensatory anti-inflammatory response syndrome (CARS) (23).

Early ICU Management (0–48 Hours from Onset of Pain)

Managing patients with acute pancreatitis who require ICU admission is best done by a multidisciplinary team including intensivists and specialists in the medical and surgical management of pancreatitis.

Management of Cardiovascular Dysfunction

Hypotension may be the result of inadequate cardiac output from intravascular volume depletion, reduced systemic vascular resistance, or both. Early therapy

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. should center on restoration of adequate circulating blood volume to ensure adequate oxygen delivery while simultaneously avoiding exuberant fluid administration, which leads to volume overload and potentially worse outcomes [24]. Ongoing hypotension despite volume resuscitation will require vasopressor support. We guide our volume resuscitation and the initiation of pressors based on repeated physical exam, biochemical markers of perfusion (lactate and mixed venous oxygen saturations), and dynamic measures of preload responsiveness, such as pulse pressure variation on the arterial line of intubated patients [25–27].

If the patient remains hypotensive after preload is optimized, we initiate pressors for maintenance of perfusion pressure. We target a mean arterial pressure of ≥65 mmHg. Once again, there are few study results to guide us in our choice of pressor. The literature suggests that neither norepinephrine nor epinephrine have a mortality benefit for patients with septic shock [14,28]. However, epinephrine may increase lactate levels despite achieving adequate perfusion pressure, so we start with norepinephrine. We do not routinely add vasopressin unless the patient exhibits significant complications from high-dose catecholamine therapy such as tachyarrhythmias [29]. Careful documentation of both fluid input and output is useful for gauging overall fluid balance and the magnitude of CLS.

Management of Pulmonary Dysfunction

Acute respiratory distress syndrome (ARDS) is a well-recognized complication of acute pancreatitis. Initial management with supplemental oxygen may prove inadequate and many patients with ARDS will require more aggressive care. High-flow oxygen through a nasal cannula provides heated and humidified oxygen at flow rates high enough to develop some continuous positive airway pressure. In addition, high-flow oxygen may be more comfortable than noninvasive ventilation [30].

All patients who require intubation and mechanical ventilation for ARDS should be initially managed with a tidal volume of 6 mL/kg predicted body weight. Respiratory rates are adjusted to achieve a pH between 7.30 and 7.45 if possible. Positive end-expiratory pressure (PEEP) and fraction of inspired oxygen (FiO_2) should be titrated to maintain an arterial PaO_2 of between 55 and 80 mmHg (31). Titrating PEEP or FiO_2 to achieve a $PaO_2 > 80$ mmHg may improve arterial blood gas values but has not been shown to improve survival [32]. If hypoxia persists (i.e., a PaO_2/FiO_2 ratio of <150 mmHg) and PEEP and FiO_2 levels exceed 10 and 0.6, respectively, we consider neuromuscular blockade [33] and initiate prone position ventilation [34] early.

Management of Abdominal Compartment Syndrome

Abdominal compartment syndrome is a pathophysiologic process arising from increased tissue fluid within the peritoneal and/or retroperitoneal space. Like other compartment syndromes, when the abdominal cavity can no longer expand, further fluid collection results in increases in abdominal pressure with subsequent decreases in perfusion and ischemia to intra-abdominal organs. In patients with acute pancreatitis, swelling from pancreatic necrosis, ileus with gas distension, fluid collections, and volume overload from resuscitation may lead to abdominal compartment syndrome. Abdominal compartment syndrome is suspected on physical examination when the abdomen is firm and/or distended.

Intra-abdominal pressure is the steady-state pressure within the abdominal cavity and is measured by instilling 25 mL of sterile saline through the Foley catheter and measuring the resultant pressure at end expiration in the complete supine position after ensuring that abdominal muscle contractions are absent and with the transducer zeroed at the level of the midaxillary line [35]. A normal intra-abdominal pressure in critically ill adults is 5–7 mmHg. Intra-abdominal hypertension is a sustained pressure ≥12 mmHg.

Abdominal compartment syndrome is a sustained intra-abdominal pressure of ≥20 mmHg with new organ dysfunction or failure. Although some patients may respond to a trial of sedation and neuromuscular blockade (relaxing the abdominal wall and thereby decreasing intra-abdominal pressure) and nasogastric tube decompression, many patients with acute pancreatitis and abdominal compartment syndrome will need a decompressive laparotomy.

Management of Metabolic Derangements

Hypertriglyceridemia

Hypertriglyceridemic acute pancreatitis represents a spectrum of underlying genetic disorders and metabolic risks such as diabetes mellitus and obesity. Triglycerides alone are inert. However, it is believed that in the presence of lipase(s), the triglycerides are hydrolyzed to free fatty acids (FFA), and it is the FFA that are toxic, especially unsaturated FFA [36–38]. Hypertriglyceridemia is associated with more severe acute pancreatitis and persistent organ failure [39] and may require special attention. Thus, while the focus of physicians treating hypertriglyceridemic acute pancreatitis in the past has often been on reducing the triglyceride levels, the focus should be on clearing FFA [39]. Serum concentrations of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

FFA are a function of production and clearance. The lipolysis of triglycerides normally occurs within tissues such as muscle, fat, and visceral organs by lipoprotein lipase (LPL), a regulated enzyme. FFA are cleared by these tissues, with excess FFA binding to albumin and transported to the liver where FFA are transferred from albumin to the hepatocytes. In acute pancreatitis, the controlled hydrolysis of triglycerides by LPL is disrupted with the addition of pancreatic lipase(s) that also catalyzes triglycerides to FFA in an unregulated way, overwhelming the capacity of the body to manage the FFA pool generated by LPL, and leading to lipotoxicity. In this case, management of the FFA-associated toxicity should focus on prevention of hydrolysis of triglycerides by LPL (e.g., fluid resuscitation and maintaining good hydration, avoiding heparin) by (theoretically) inhibiting pancreatic lipases [36], and by facilitating clearance of FFA from the serum with insulin infusion or apheresis/plasma exchange [40]. In addition to driving SIRS, FFA can block mitochondrial function, leading to lactic acidosis (pH <7.2, lactate >4 mmol/L), often seen with low calcium (e.g., calcium <8.3 mg/dL) [41]. This requires emergency intervention in the ICU, especially in the presence of liver and/or kidney dysfunction. Note that a similar syndrome of lactic acidosis occurs with complications of metformin use.

Diabetic Ketoacidosis with Acute Pancreatitis

Acute pancreatitis often develops in patients with diabetic ketoacidosis (DKA). The mechanism triggering acute pancreatitis appears to be linked to low pH. In a study of 100 subjects with DKA the subjects with coexisting acute pancreatitis had more severe metabolic acidosis (mean pH 7.15 vs. 7.31; $P = 0.0001$) and higher anion gap (38.17 mEq/L vs. 25.16 mEq/L; $P = 0.0001$) [42,43]. These patients may also have hypertriglyceridemia [44]. In these cases, addressing insulin deficiency, acidosis, and hydration results in rapid improvement.

Nutrition Support

Early nutrition support is associated with improved outcomes in patients with acute pancreatitis, and enteral feeding is superior to total parenteral nutrition (TPN) when feasible [45,46]. However, ICU patients are typically complex with confounding medial conditions, each case is unique, and multidisciplinary management may be required. Nutrition support is covered in Chapter 26.

Late ICU Management (>48 Hours after the Onset of Pain)

Visceral organs share a compartment and regulation of blood flow. Thus, damage to one organ should raise awareness of damage to others. The easiest organ to monitor is the kidney by following serum creatinine levels and blood urea nitrogen (BUN). The increase of serum creatinine and BUN levels over the first 24–72 hours usually indicates pre-renal azotemia [3] and remains among the best predictors of pancreatic necrosis and persistent organ failure [47,48]. Acute kidney injury in acute pancreatitis represents one component of a common mechanism of injury for multiple visceral organs (i.e., kidneys, pancreas, and intestine) that are damaged by hypoperfusion and ischemia [3]. Intestinal ileus may be a parallel sign of visceral organ ischemia. Early recognition of high risk for pancreatic necrosis determines future management strategies, and thus further evaluation is warranted.

After resuscitation and stabilization, abdominal imaging remains central to the eventual evaluation of pancreatic morphology, intra-abdominal fluid collections, and other complications. The radiologic evaluation and staging of severe acute pancreatitis are covered in Chapter 25.

Alcohol Withdrawal Syndrome

Alcohol abuse is a common cause of severe acute pancreatitis and alcohol withdrawal may be a complication encountered in the late ICU phase. We start treatment with escalating doses of benzodiazepines [49]. Maximal doses of benzodiazepines are defined by their diluent, propylene glycol, which can have potentially toxic effects. For benzodiazepine-resistant alcohol withdrawal syndrome, we add either phenobarbital or ketamine.

Management of Infectious Risks

The use of antibiotics is discussed in Chapter 28. The management of infected pancreatic necrosis is discussed in Chapters 29–31.

Transition Planning

As the clinical course of the patient becomes clear and the intensity of organ support is reduced, transition out of the ICU must be considered. We consider transfer out of the ICU when the organ system dysfunction that necessitated ICU admission has resolved.

Clinical Course and Medical Treatment of Acute Pancreatitis—Use of Antibiotics in Severe Acute Pancreatitis: Indications and Limitations

Rainer Isenmann[1] *and Mathias Wittau*[2]

[1] *Department of Surgery, St.-Anna-Virngrund-Klinik, Ellwangen, Jagst, Germany*
[2] *Department of General and Abdominal Surgery, University of Ulm, Ulm, Germany*

Introduction

Although 85% of the patients with acute pancreatitis experience an uneventful recovery, this disease bears a high risk for severe and even lethal complications. Cardiocirculatory, pulmonary, or renal failure, alone or in combination are common problems in patients with severe acute pancreatitis. The treatment is conservative, including mechanical ventilation, hemofiltration or hemodialysis as well as cardiocirculatory support, if required. The majority of patients respond to such an approach. Nevertheless, mortality of severe acute pancreatitis remains at about 10%.

The poorest prognosis is observed in patients with necrotizing pancreatitis who develop local bacterial infection. Surgical or interventional management is generally required in these cases and mortality rates exceeding 30% been reported [1,2]. Despite progress in our understanding of the pathology of pancreatic sepsis and in intensive care treatment, the mortality rates of infected pancreatic necrosis have not changed in recent decades. Recent attempts with nonsurgical or interventional treatment have been promising [1,3] but there is no doubt that bacterial infection will remain a life-threatening complication in patients with necrotizing pancreatitis.

The recently revised Atlanta classification of acute pancreatitis discriminates between mild acute pancreatitis, moderately severe acute pancreatitis, and severe disease, depending on the occurrence of organ failure and/or local and systemic complications [4]. In contrast to former classification systems, where the term "infected pancreatic necrosis" has been used for all locally infected pancreatic entities, the revised classification distinguishes between morphologically different local infectious complications.

Infectious Complications

During the course of acute pancreatitis, either systemic or local pancreatic infections may occur. The incidence of these complications varies widely, depending on definition and patient selection.

Local Pancreatic Infection

In approximately 30–40% of the patients with necrotizing pancreatitis local infections of the necrotic areas develop [5]. Bacterial infection of pancreatic necrosis is the most important determinant of outcome [6]. The revised Atlanta classification discriminates between different morphological entities and comprises acute peripancreatic fluid collections (APFC), pancreatic pseudocysts, acute necrotic collections (ANC), and walled-off necrosis (WON). These morphologic entities have a variable potential for bacterial infection (Table 26.1) with pancreatic necrosis and WON bearing the highest risk. For our understanding of relevance of infectious complications and the role of antibiotics in the treatment algorithm, discrimination between these morphologies is therefore important. Irrespective of the morphologic differences, bacterial infection is a phenomenon of the later phase of acute pancreatitis, commonly observed after the third or fourth week after onset of the disease. This might be one of the reasons why all efforts to reduce the infection rate by prophylactic antibiotics have failed. There is a wide time frame for infection and it is difficult to impossible to define the exact period when prophylactic antibiotics might be effective.

Table 26.1 Complications of severe acute pancreatitis with the potential risk of bacterial infection, according to the current revised Atlanta classification [4].

	Characterization	Estimated potential for infection
Necrotizing acute pancreatitis	Inflammation associated with pancreatic parenchymal necrosis and/or peripancreatic necrosis	High
Walled-off necrosis (WON)	Necrotic tissue surrounded by a wall of tissue, usually >4 weeks after onset of pancreatitis	High
Acute necrotic collection (ANC)	Collection of necrosis and fluid during the first 4 weeks of AP	Moderate
Pancreatic pseudocyst	Walled-off fluid collection weeks after AP. May require surgical drainage if persistent	Low-moderate
Acute peripancreatic fluid collection (APFC)	During the early phase of AP, resolve spontaneously	Low

AP: acute pancreatitis.

Systemic Bacterial Infection

Extra-abdominal bacterial infection is a common finding during severe acute pancreatitis. Its incidence varies widely in different studies. In a multinational European study, more than 40% of the patients had extra-abdominal infections, with respiratory tract infections being the most frequent (28%), followed by bloodstream infections (14%), and catheter-related infections as well as genito-urinary tract infections (4%) [7]. In the authors' own investigation, 25% of the patients of the control group (not treated with antibiotics) had extrapancreatic infection, with pneumonia being the most frequent [8].

The clinical relevance of extrapancreatic infection has been clearly demonstrated: it increases mortality and adversely affects the outcome of acute pancreatitis [9]. Whether its relevance is equal to that of pancreatic sepsis is subject to discussion.

Spectrum of Bacteria

In the first description of infected pancreatic necrosis in the 1980s, the bacterial spectrum of infection was dominated by gram-negative enteric germs [5]. During the past three decades, there has been some change, but gram-negative bacteria still play a predominant role in the bacterial spectrum. Nevertheless, gram-positive microorganisms, especially *staphylococci* and *enterococci* are increasingly coming into focus. The bacterial spectrum is polymicrobial and comprises anaerobic bacteria, as well (Table 26.2).

The role of multidrug resistance among these germs has been recently addressed. Many gram-positive species are resistant to methicillin, as are many extended spectrum beta-lactamase (ESBL)-producing gram-negative germs. In one recent study, 63% of the patients with infected pancreatic necrosis were infected with multiresistant germs [12]. As in other infectious pathologies, these multiresistant germs are of therapeutic and prognostic importance. Their isolation should prompt treatment with an adequate antibiotic drug according to the tested bacterial susceptibilities.

In addition, a considerable percentage of patients with necrotizing pancreatitis develop fungal infection. Its prognostic impact has been a matter of discussion over the past decade. Most often, fungal infection is caused by *Candida* species and is considered to be a predictor of worse outcome. It is generally accepted that antibiotic treatment promotes overgrowth of unaffected or resistant pathogens and is thus considered to be a risk factor for both fungal and multiresistant infection [13,14].

Rationales for Antibiotics in Acute Pancreatitis

The use of antibacterial agents in acute pancreatitis has been debated since the 1970s. At first, antibiotics were regarded as a part of the treatment regime without clear definition of their indication. Our increasing knowledge about the impact and relevance of infection has defined two potential settings for the use of antibiotics.

Prevention of Infection

The clinical relevance of bacterial infection with its poor prognosis supports treatment algorithms for its prevention. This led to the idea of prophylactic administration of antibiotics with the intention of preventing bacterial

superinfection. In recent years there has been considerable scientific effort to prove such a concept as discussed later in this chapter.

Treatment of Infection

In combination with surgical debridement, antibiotic treatment is the mainstay in the treatment of any intra-abdominal infection, including infected pancreatic necrosis. It is well known that inappropriate antibiotic treatment in severe sepsis results in a fivefold increase in mortality [15]. For acute pancreatitis a selective uptake of antibiotics into the pancreas has been described [16], which should be taken into account. As a consequence the antibiotics for treatment of pancreatic infection should not only be chosen according to the bacterial spectrum and their antibacterial activity, but also according to their ability to penetrate into the infectious focus [16,17].

Clinical Studies with Antibiotics

During the past 20 years, there have been numerous controlled and uncontrolled, blinded and unblinded studies addressing the issue of whether early administration of antibiotics in severe acute pancreatitis could reduce the incidence of local bacterial infection and consequently could improve the prognosis of the disease (Table 26.3). Among those, four had adequate scientific power for meaningful conclusions [10,18,19]. None of them has been able to give a definite answer to this question and according to the latest meta-analyses, there is no evidence to support the routine use of prophylactic antibiotics in patients with severe acute pancreatitis [20,21,22].

Consequently, the overwhelming majority of current guidelines and expert reviews do not recommend the routine administration of broad-spectrum antibiotics in patients with severe acute pancreatitis or pancreatic necrosis [34,35,36].

What are the reasons for our inability to demonstrate a beneficial effect of prophylactic antibiotics on the infection rate in acute pancreatitis? First, acute pancreatitis is a heterogeneous disease with a highly variable course ranging from mild and self-limiting to devastating with severe septic complications. The majority of patients with acute pancreatitis will never develop infectious complications. To date, there are no reliable parameters that allow the identification of patients at risk for developing pancreatic sepsis. Second, pancreatic infection is a phenomenon of the later course of the disease. Thus the ideal timing and optimal duration of antibiotic administration as prophylaxis is not clear. Antibiotics given too early and too long may be ineffective and promote bacterial resistance. Third, new concepts in the therapy of acute pancreatitis such as early enteral nutrition and treatment of organ dysfunctions may directly or indirectly affect the incidence of septic complications.

These facts, together with others, make it unlikely that we will ever be able to elaborate pathways for the prophylactic use of antibiotics in severe acute pancreatitis [37].

Indications for Antibiotic Treatment

The main indications for initiation of antibiotic treatment in acute pancreatitis are evidence or strong suspicion of local and/or systemic bacterial infection. Therefore, all current guidelines aim at the timely identification of infected necrosis. The recommended standard comprises close monitoring of infectious parameters, imaging by contrast-enhanced computed tomography and, in cases with strongly suspected bacterial infection, the fine-needle aspiration for Gram-stain and culture [35].

Poropat [41]	2019	Imipenem vs. placebo	Yes	49/49	No	No

Pancreatic infection should be suspected in patients with pancreatic or extrapancreatic necrosis and clinical deterioration or failure to improve over 7–10 days.

Antibiotic Treatment on Demand

The experience from the ASAP-study [8] showed that antibiotic treatment was initiated in a considerable percentage of patients with clinical deterioration. The criteria for initiating this so-called "antibiotic treatment on demand" in this study were:

- newly developed sepsis/SIRS;
- newly developed organ failure (pulmonary, renal, cardiocirculatory);
- increase in serum C-reactive protein and strongly suspected/proven extrapancreatic infection;
- increase in serum C-reactive protein and strongly suspected/proven pancreatic infection.

In 37% of the patients of this study, the double-blind study medication was terminated and switched to open antibiotic treatment. The low rate of infected pancreatic necrosis (10.5%) as well as the favorable outcome (mortality 6% in the overall study) can be taken as rationale to initiate antibiotic treatment at these given indications. In patients fulfilling these criteria, sepsis and bacterial infection (pancreatic and/or extrapancreatic) are most likely present and they should thus be candidates for antibiotic treatment [22].

Choice of Antibiotics

For the choice of antibiotics in necrotizing pancreatitis, the following should be taken into consideration:

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. - the bacterial spectrum,
- the antibiotic concentrations at the site of infection,
- the results of clinical studies.

Based on these criteria, carbapenems, chinolones, and broad-spectrum cephalosporins are first-choice drugs for the initial treatment of pancreatic infection. The last two should be combined with metronidazole as they lack sufficient antibacterial activity in the anaerobic spectrum. Based on their pharmacokinetic properties, acylaminopenicillins beta-lactamase inhibitor combinations can also be regarded as effective, although there are no clinical studies with these drugs.

Following initiation of an empirical antibiotic therapy, a step down should be followed as soon as the results of bacterial susceptibility testing are available.

Up to now, there is no rationale to initiate a "blind" antifungal therapy. Antifungal agents should only be given when bacterial smears yield fungal infection.

Limitations of Antibiotic Treatment

Antibiotic treatment is an essential part of the therapeutic regime in patients with infected pancreatic necrosis, but it is not enough on its own for successful treatment of these critically ill patients. The mainstay for success is source control of the infectious focus, and debridement of the infectious material is an essential part of the treatment regime.

Today open or laparoscopic surgical debridement and interventional drainage are subject to debate. Scientific evidence suggests that a "step-up approach" might provide favorable results as the best surgical approach in pancreatic infection [1]. Following such an approach, the patient is managed by conservative treatment for as long as possible. In case of strongly suspected or proven pancreatic infection percutaneous drainage is used as an initial approach for source control. If this fails surgical necrosectomy (minimally invasive or open) follows [38].

Whether or not pancreatic infection can be treated with antibiotics alone and without debridement is under current investigation. The first studies following such an approach have been criticized [39], but a recent meta-analysis shows that in selected patients this can be safely done with low mortality [3]. Nevertheless it is necessary to define criteria that characterize the group of patients who are eligible for such a conservative approach.

A global overview on the use of antibiotics among physicians indicated that their use, both as prophylaxis and as treatment in acute pancreatitis is widespread [40]. Irrespective of the national treatment guidelines of the disease, antibiotics are frequently given without clear indication, even in mild pancreatitis or when pyrexia is present. This overuse poses not only healthcare problems in terms of unnecessary expense, but also risks for the patients: antibiotic-associated side effects and a selection of multiresistant bacteria.

Indications for Interventional and Surgical Treatment of Necrotizing Pancreatitis

Lily V. Saadat and Thomas E. Clancy

Department of Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Introduction

Whereas interstitial acute pancreatitis is typically a self-limited disease process that usually responds to supportive care, more severe necrotizing pancreatitis can be seen in approximately 20% of patients. This is characterized by necrosis of the pancreatic parenchyma or peripancreatic tissue, manifestations of the systemic inflammatory response syndrome (SIRS), with risks for infection and multiorgan failure [1]. High rates of morbidity are associated with mortality of up to 15% in the setting of necrotizing pancreatitis and as high as 30% in the subset of patients who develop infected pancreatic necrosis [2,3]. A variety of surgical and interventional approaches have been used in an attempt to limit the substantial morbidity and mortality of necrotizing pancreatitis.

Over the last few decades, there has been a significant change in the indications for intervention in necrotizing pancreatitis, timing of intervention, and methods of surgical, minimally invasive, radiologic, and endoscopic intervention. Revision of the 1992 Atlanta classification of acute pancreatitis [4] to describe the clinical behavior and imaging characteristics more precisely [5] has occurred in parallel with a progressively less interventional and less invasive approach to necrotizing pancreatitis. Although no universally accepted management algorithm exists to guide management, evidence-based consensus continues to develop [6,7].

Interventions for Pancreatic Necrosis: Historical Perspective

Just a few decades ago, the association of pancreatic necrosis with systemic inflammation and secondary infection led to the goal of surgically removing all necrotic pancreas regardless of the presence of infection [8–10]. In 1991, Bradley and Allen published a small series of 11 patients successfully managed nonoperatively with sterile pancreatic necrosis [11]. The general acceptance of nonoperative management for sterile pancreatic necrosis was facilitated by the publication of a large series demonstrating favorable overall mortality and complications [12,13]. In this new paradigm, intervention was primarily limited to surgical debridement for cases of infected pancreatic necrosis as demonstrated by computed tomography (CT)-guided fine-needle aspiration (FNA) of the pancreas. Banks et al. showed a sensitivity and specificity of 96.2% and 99.4%, respectively, for detection of infected necrosis, with a positive predictive value of 99.5% and a negative predictive value of 95.3% [14]. The presence of infection or positive Gram stain on CT-guided pancreatic aspiration was considered an absolute indication for debridement, as superinfection of the necrotic parenchyma had been associated with a mortality of virtually 100% without debridement [15].

The absolute necessity of surgical debridement for infected necrosis was subsequently questioned with the demonstration of successful nonoperative management in some patients. Runzi et al. [16] showed in a series of over 80 patients with documented infected pancreatic necrosis that initial conservative therapy can be instituted, including antibiotic therapy and maximal supportive care. Mortality in patients managed with surgery was identical to that in those managed nonoperatively. Surgical therapy, when required, was often delayed to a later stage of disease, when the systemic inflammatory response stabilized, and necrotic pancreas had become demarcated. In other patients, surgical therapy was avoided altogether. Subsequent studies have confirmed this strategy: Garg et al. describe a 10-year series of 80 patients with infected pancreatic necrosis in whom 47 were treated with

antibiotics alone [17]. The paradigm of urgent surgical debridement for all patients with infected pancreatic necrosis is therefore no longer considered valid.

Definitions and Classification of Pancreatic Necrosis

A classification system for acute pancreatitis was first proposed at the Atlanta Symposium in 1992. This system defined acute pancreatitis as an acute inflammatory process, associated with elevated pancreatic enzymes, with variable involvement of other organ systems [4]. A further distinction was made between acute interstitial pancreatitis and sterile or infected necrotic collections [18]. Unlike the prior delineation of pancreatic necrosis to infected and sterile versions, the revised Atlanta classification, introduced in 2012 [5], divided collections associated with necrotizing pancreatitis according to time of disease onset. A collection that develops early and lacks a discrete wall is referred to as an acute necrotic collection (ANC), whereas a collection that persists after 4 weeks is referred to as walled-off necrosis (WON). Both forms may be sterile or infected, although no correlation exists between extent of necrosis and risk of infection [5].

Indications and Timing of Intervention

In principle, interventions for pancreatic necrosis intend to control organ damage by removing necrotic tissue while maintaining functional pancreas. These interventions may be considered in patients with infected pancreatic necrosis or symptomatic sterile necrosis. Although the presence or absence of infection is crucial for prognosis and affects management decisions, the presence of clinical symptoms rather than suspicion of infection is considered paramount for intervention. It should be noted that the management of pancreatic necrosis requires a multidisciplinary approach with clinical expertise from gastroenterologists, surgeons, interventional radiologists, critical care physicians, and dietitians. As such, clinical guidelines recommend transfer to a tertiary care center for management of these patients.

Timing of intervention is dependent on patient factors and clinical stability. Early resuscitative efforts, including fluid resuscitation, initiation of enteral nutrition, and reversal of organ failure, are critical, with most data and practice guidelines recommending delaying intervention for 3–4 weeks after onset of acute pancreatitis. In one retrospective series of 305 patients with necrotizing pancreatitis, early intervention (defined as <4 weeks from disease onset) was associated with longer hospitalization (37 vs. 26 days, $P = 0.01$) and higher mortality (13% vs. 4%, $P = 0.02$), compared to delayed (≥4 weeks) treatment [19]. A randomized trial has shown that early surgical intervention is associated with higher morbidity and mortality, compared to intervention at least 12 days after onset [20]. Other reviews have confirmed lower mortality with delayed surgical intervention [21,22] with data suggesting that early surgery is an independent predictor of poor outcome in necrotizing pancreatitis [23]. More recently, a randomized, multicenter, superiority trial (POINTER), comparing immediate and postponed intervention in patients with infected pancreatic necrosis, observed more interventions in the immediate drainage group, compared to the postponed drainage group, with no difference in adverse events [24].

Significant retroperitoneal inflammation, mediated by cytokine release, is hypothesized to contribute to these observed differences in outcomes. Moreover, early debridement may lead to incomplete excision of necrotic tissue and increased risk of injury to surrounding normal tissues, with associated increases in morbidity and mortality. Conversely, increasing time for clinical stabilization and decreased inflammatory response by delaying debridement improves outcomes for these patients.

Pancreatic Necrosis with Infection

Mortality rates for patients with pancreatic necrosis and superimposed infection approach 30%. Pancreatic infection occurs via bacterial translocation or seeding from bacteremia, and is most commonly caused by gut bacteria, including *Escherichia coli*, *Enterobacter*, *Enterococcus faecalis* and *faecium*, and anaerobes [25]. Infected necrosis is suspected with clinical deterioration of a previously stable patient with pancreatic necrosis. These patients may present with one of the following clinical features: fever, bacteremia, worsening leukocytosis or organ failure, or hemodynamic deterioration. Abdominal imaging in these patients may demonstrate gas within necrotic debris due to the presence of gas-forming organisms or via a fistula to the colon, small bowel, or stomach. Alternatively, infection may be proven by culture or Gram stain obtained by image-guided FNA [26]. Although a Gram stain positive for organisms was previously thought to mandate early surgical intervention [12], patients with suspected infection are increasingly managed with antibiotics and supportive care to allow less invasive and delayed management of a walled-off collection [3]. Diagnostic FNA is therefore used less routinely in the management of suspected infection.

Currently, first-line treatment for patients with infected pancreatic necrosis includes the initiation of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. broad-spectrum antibiotics with high penetration into the pancreas, such as carbapenems, quinolones, and metronidazole. Empiric fungal coverage is not routinely recommended. Notably, while antibiotics are critical in the management of pancreatic necrosis with infection, empiric use of antibiotics for prevention of infected necrosis is not supported. Multiple prospective, randomized trials have concluded that the administration of prophylactic broad-spectrum antibiotics does not impact rates of developing infected necrosis, systemic complications, or mortality [27,28]. As such, prophylactic use of antibiotics is discouraged.

Despite demonstrated success with nonsurgical management for infected necrosis, many if not most patients with infected pancreatic necrosis require some form of intervention. Some series suggest that clinically stable and relatively asymptomatic patients with infected necrosis can be managed with antibiotics alone [16,17,29]. Nonetheless, patients with infection are prone to clinical decline and require surgical, endoscopic, or radiographic intervention with the onset of clinical signs not responding to medical management. As mentioned above, in the era of surgical management, delayed intervention is far preferable to early surgery for patients with infected necrosis. Expedited intervention may be required in patients demonstrating progressive systemic sepsis or hemodynamic instability. In the absence of such systemic signs, clinically stable patients may generally be managed at least temporarily with antibiotics to allow further organization of the inflammatory process. Delayed surgical, endoscopic, or radiologic management may then proceed if clinical symptoms do not improve [6].

Delayed surgical intervention of infected pancreatic necrosis has been facilitated by the use of percutaneous catheter drains. A 1998 series by Freeney et al. [30] demonstrated that some patients with infected pancreatic necrosis might have surgical management delayed or potentially avoided altogether with the use of large-bore percutaneous catheters placed under CT guidance. This strategy was validated in a multicenter trial in which patients were randomized to standard pancreatic debridement versus a "step-up" approach in which debridement was used only if necessary [31]. Using a "step-up" approach, complications were significantly lower, and about one-third of patients were treated with catheter drainage alone.

Sterile, but Symptomatic, Pancreatic Necrosis

The precise role of radiographic drainage, endoscopic or surgical debridement in sterile pancreatic necrosis is less clear. Although most patients with sterile pancreatic necrosis respond to supportive care without the need for intervention, others will experience clinical decline, including organ failure despite the absence of demonstrable infection. Historically, some authors had therefore suggested the need for surgical debridement in patients with progression of disease or failure to improve, regardless of the status of infection [32,33]. Unfortunately, no uniform criteria have defined which patients with sterile pancreatic necrosis might benefit from debridement. In the era of surgical debridement as the primary intervention for necrotizing pancreatitis, some authors suggested criteria for intervention including the extent of necrosis of more than 50% of the pancreatic parenchyma [32], rapid clinical deterioration with multiple organ failure [34], or the presence or persistence of organ failure [35,36]. However, evidence is lacking to support the use of these criteria as an absolute indication for debridement or drainage. Close analysis of one study of 89 patients with severe sterile necrosis identified only two patients who died that might have theoretically benefitted from earlier surgical debridement, though no clinical parameters were able to easily differentiate these patients from others with severe sterile necrosis [13].

As noted above, in the absence of clinical confirmation of infection by image guided FNA or suggestive imaging, intervention is typically based on the clinical course and trajectory. Patients are therefore often brought to intervention for not just documented infection, with positive pancreatic FNA, but also for suspected infection based on persistent sepsis or progressive clinical deterioration [36]. Given the additional morbidity and mortality associated with open surgery, radiologic or endoscopic drainage is used prior to surgical intervention [37].

The process of walled-off pancreatic necrosis recognized in the revised Atlanta classification was previously described by Baron as "organized pancreatic necrosis" [38]. In this condition, an intrapancreatic or extrapancreatic heterogeneous semisolid collection develops in the context of acute necrotizing pancreatitis and has an encapsulated wall [5]. A subset of patients with WON may experience a prolonged clinical course marked by persistent pain, malaise, and inability to eat. This symptom complex was described by Warshaw as "persistent unwellness" [39]. The precise indications and timing of intervention are not precisely defined for these patients.

Asymptomatic WON does not require intervention regardless of the size of the collection and may resolve with conservative management (Fig. 27.1). Symptomatic WON, however, can be marked by pain, intestinal, or biliary obstruction, or later infection. In one series, approximately 10% of patients with sterile pancreatic necrosis underwent surgery for persistent pain and organized necrosis at a mean of 29 days after initial presentation [13].

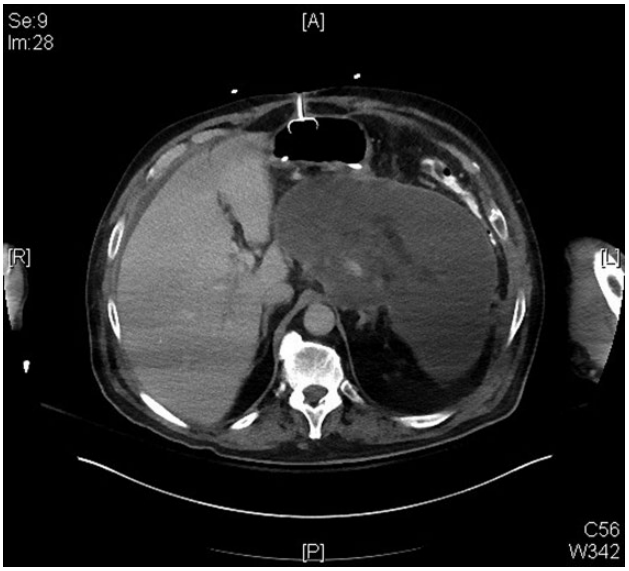

Figure 27.1 Walled-off necrosis. A 55-year-old man presented with severe acute pancreatitis and an acute necrotic collection. He was managed conservatively, and imaging 6 weeks after presentation revealed a large area of walled-off necrosis involving the entire body and tail of the pancreas. The patient remained asymptomatic, and no intervention was pursued.

Preoperative Evaluation and Imaging Considerations

The approach to debridement is dependent on imaging characteristics, including the extent and pattern of pancreatic necrosis. Involvement of the mesenteric root or extension down the paracolic gutter have historically been challenging to treat endoscopically. While some techniques have been described [40], wide surgical debridement and drainage is routinely employed in these cases to ensure adequate debridement. Extension of pancreatic necrosis into the mesocolon presents an additional challenge, as debridement of these tissues may compromise colonic blood flow. Patients with extensive colonic or mesenteric involvement may require partial colectomy at the time of surgical debridement.

Close examination of the pancreas on CT imaging is also key, as patients with isolated necrosis of the pancreatic neck or body may be at an increased risk for developing disconnected pancreatic duct syndrome (DPDS). In this condition, the disconnected pancreatic segment continues to secrete pancreatic fluid, which can in turn lead to the development of new pancreatic collections, fistula formation and recurrent pancreatitis [41]. In one retrospective series, fluid collections recurred in 42% of patients with DPDS, despite endoscopic drainage [42]. While rare with a reported prevalence of 10% to 31% [42], prompt diagnosis of DPDS is key to reducing morbidity. Diagnosis requires necrosis of at least 2 cm of pancreas and viable upstream pancreatic parenchyma [41]. While imaging modalities can be suggestive of DPDS, ERCP, which may visualize extravasation of contrast from the pancreatic duct, remains the gold standard for diagnosis.

Management includes conservative therapy with nutritional optimization, endoscopic treatment, and/or surgery. The routine use of octreotide in these patients is not supported [43]. While surgery was once considered the mainstay of treatment for these patients, advances in endoscopic treatment modalities have provided less-invasive alternatives for select patients. Transpapillary pancreatic duct stent placement has been previously described with successful outcomes [44,45]. In a series of 43 patients, 58% had resolution of the disruption after stent placement. Stents bridging the disruption and longer duration of stent therapy were associated with improved outcomes. In another series endoscopic treatment improved outcomes for patients with DPDS with a failure rate of 23% [42]. While long-term plastic stent placement has been associated with improved outcomes, risks include stent migration and infection. The prophylactic use of pancreatic stents in acute necrotizing pancreatitis remains controversial, with data from a recent prospective randomized superiority trial suggesting a high risk of infection in these patients and advising against routine prophylactic use [46].

Although DPDS can be temporized with EUS-guided transmural stenting [47], many patients may ultimately require consideration of definitive surgical management. Surgical options include distal pancreatectomy for removal of the viable distal segment or internal drainage procedures such as cyst-gastrostomy, which may better preserve pancreatic function.

Surgical and Interventional Procedures

The use of various radiologic, surgical, and endoscopic interventions for necrotizing pancreatitis will vary among institutions [6]. Although open surgical necrosectomy was previously considered the definitive management, a number of minimally invasive techniques have been developed. As noted above, delayed intervention is preferable in all patients, if possible, particularly when open surgical management is used [48]. However, interventional radiologic techniques may be performed earlier with suspected infection [22]. Even in the setting of suspected or known infection, there is a growing trend to treat with supportive care and antibiotics unless there are signs of sepsis, until the pancreatic collection becomes walled off [3].

Owing to the efficacy of minimally invasive approaches and associated reductions in mortality, the

treatment paradigm for necrotizing pancreatitis has shifted to a predominantly nonsurgical approach. The original "step-up approach" to management of infected pancreatic necrosis was popularized by randomized data suggesting that percutaneous drainage followed by minimally invasive retroperitoneal necrosectomy improved morbidity and mortality [31]. This has further evolved based on a recent multicenter, randomized trial assessing an endoscopic step-up approach, defined as transluminal drainage followed by endoscopic necrosectomy. When compared to patients treated with the traditional "step-up" approach, patients in the endoscopic group were found to have lower rates of pancreatic fistula and length of hospitalization [49]. These data have been reproduced in a single-center trial comparing patients treated with minimally invasive surgery or an endoscopic step-up approach. In this trial of 66 patients, the endoscopic approach was associated with reduced complications, cost, and increased quality of life [50]. Taken together, these data suggest an evolving treatment paradigm for patients with pancreatic necrosis, and a key role for both percutaneous and endoscopic procedures.

Percutaneous Catheter Drainage

Percutaneous catheter drainage (PCD) can be performed either as a "step-up" toward endoscopic or surgical necrosectomy once WON has developed, or in some cases as definitive therapy [31]. PCD may be further considered when endoscopic drainage is unfeasible due to the anatomic distribution of the pancreatic necrosis. For example, in patients with necrotic extension into the pelvis or the paracolic gutters, PCD may be necessary to access these dependent collections, which are inaccessible from the gastric or duodenal lumen [7].

Catheters are placed using either a transperitoneal or retroperitoneal approach under CT or ultrasound guidance. Multiple catheters are often required, with follow-up procedures to place additional or larger catheters [51]. One significant advantage of PCD is the opportunity to address symptomatic or infected necrotic collections before WON has developed. This may be particularly useful for patients who are failing conservative management or who require rapid source control due to clinical signs of sepsis. PCD may be of additional benefit in patients deemed unfit for surgical intervention, or to address residual collections after surgical or endoscopic debridement [6]. Placement of large (24Fr or greater) percutaneous drains may also assist with later minimally invasive debridement methods, such as video-assisted retroperitoneal debridement (VARD) [7].

One potential risk of percutaneous drainage is the development of pancreatocutaneous fistulas. In a prospective study comparing endoscopic and percutaneous approaches, fistula formation was observed in 32% of the percutaneous group compared to 5% in the endoscopic group [49]. Simultaneous endoscopic drainage with percutaneous drain placement may help minimize this risk [52].

As noted, catheter drainage alone is often effective without necrosectomy. Success of PCD has been associated with necrosis <50% and absence of extrapancreatic infection [53]. In the PANTER trial, use of catheter drainage resulted in significantly decreased morbidity with equal mortality compared to surgical necrosectomy [31]. Other studies have shown an approximately 50% success rate in treating necrotizing pancreatitis, whether sterile or infected [54]. PCD is less likely to be successful as a definitive intervention in patients with duct disruption, who may require eventual surgical or endoscopic therapy [55].

Direct Endoscopic Necrosectomy

Initially described in 1996, endoscopic necrosectomy is a recognized alternative to surgical debridement, though its availability is limited to specialized centers. A series of 104 patients at six centers showed resolution of WON in 91% with endoscopic necrosectomy, with only 4% requiring surgical debridement [56]. Furthermore, data suggest that endoscopic necrosectomy is associated with fewer complications, less organ failure, and decreased periprocedural inflammation [36]. Another meta-analysis including 400 patients with infected pancreatic necrosis concluded that a step-up approach with endoscopic debridement should be preferred, followed by step-up with delayed surgical debridement [57].

Similar to PCD, multiple procedures may be required, and not all patients may be candidates for endoscopic therapy. Ideally, collections for endoscopic access are not only walled off but also are adjacent to the gastric or duodenal lumen. Some acute necrotic collections cannot be approached endoscopically due to lack of abutment of the stomach or duodenum. As mentioned above, while endoscopic approaches can be started less than 4 weeks from onset of pancreatitis, patients who can wait ≥4 weeks prior to endoscopic intervention have been shown to have decreased mortality. Furthermore, early collections are not ideally suited for endoscopic therapy due to the risk of intra-abdominal spread of an infected collection. Multifocal collections are also less easily approached in this manner.

Traditionally, double-pigtail plastic stents (DPPS) were placed from the gastric lumen into the pancreatic

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. collection. EUS-guided transmural entry is generally preferred to reduce rates of bleeding, which have been reported in up to 20% of patients [56,58]. Given the narrow caliber of these stents, DPPS without subsequent endoscopic necrosectomy provides suboptimal treatment for most patients [59]. To address this limitation, there has been increased interest in use of larger caliber self-expanding metal stents (SEMS). In one series evaluating 94 patients who received SEMS vs. DPPS, treatment with SEMS decreased the need for repeat necrosectomy and risk of intervention-related hemorrhage [59]. The development of lumen-apposing metal stents (LAMS) has also demonstrated favorable results. Due to their shorter length and larger diameter, these stents facilitate endoscopic necrosectomy and are at lower risk for migration [60]. The placement of double-pigtail plastic stents through LAMS has also been proposed as a method to reduce the risk of stent occlusion and/or migration [7].

Direct endoscopic necrosectomy (DEN) may be performed via stents, with passage of forceps, polypectomy snares, and retrieval nets. In general, serial imaging after debridement is performed every 1–2 weeks to follow evolution of necrosis. Routinely, repeat debridement and irrigation is indicated for management of residual solid, necrotic material. The use of acid-suppressive medications is generally discouraged after drainage, with some data suggesting that discontinuation of proton-pump inhibitors reduces the number of endoscopic procedures required [61].

While DEN has been associated with reductions in morbidity and mortality, compared to more invasive techniques, mortality rates remain high at 7.5%. Similarly, complications include bleeding, perforation, sepsis, or organ failure, with an estimated morbidity rate of 14–26% [62]. As these high rates of morbidity have been mostly attributed to procedural and provider variability, standardized techniques for DEN have been proposed [62].

Surgical Debridement

Open surgical debridement for years was considered the gold standard of surgical intervention for pancreatic necrosis, by removing necrotic pancreatic and peripancreatic tissue and establishing a means of postoperative drainage while preserving viable pancreatic parenchyma. Methods have included debridement with closure over drains, debridement with open packing of the pancreatic bed, debridement with internal drainage and cyst gastrostomy or debridement with closure over irrigation drains [10,63–65]. Mortality and complication rates for published series utilizing these techniques vary widely, although comparisons between studies are confounded by the lack of standardization of disease severity or operative indications.

In the setting of minimally invasive options such as image-guided catheter drainage and direct endoscopic necrosectomy as described above, several important potential indications for surgery remain. Due to its invasiveness and associated perioperative complications, open surgery is typically reserved for patients in whom less invasive methods have failed. One advantage of open surgical necrosectomy is that it may offer the best chance to completely remove all necrotic tissue and address other associated complications in a single procedure. In some cases, collections may not be accessible via image-guided techniques, may be multifocal, or persistent after minimally invasive necrosectomy (Fig. 27.2). In other instances, a patient may not be deemed clinically stable for minimally invasive measures. Surgical therapy in these instances should be delayed as long as possible given the increased risk of early surgical intervention. Other indications for surgical debridement include the presence of bowel perforation, obstruction, fistula to a hollow viscus such as the colon, and abdominal compartment syndrome [66] (Fig. 27.3).

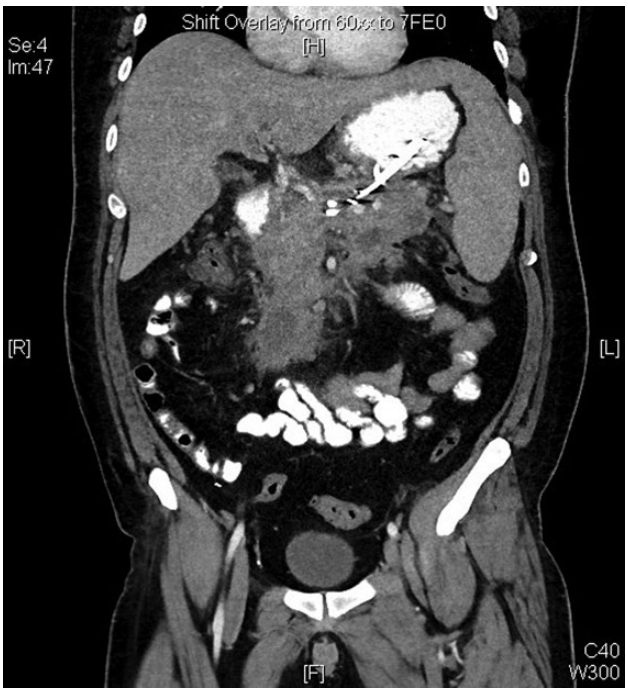

Figure 27.2 Undrained mesenteric abscess after endoscopic debridement. A 50-year-old man underwent uncomplicated endoscopic debridement for symptomatic walled-off pancreatic necrosis. He represented with fevers, pain, leukocytosis, and a phlegmonous abscess tracking down into the small bowel mesentery. Endoscopic debridement and CT-guided drainage were not felt to be possible. Surgical debridement was required.

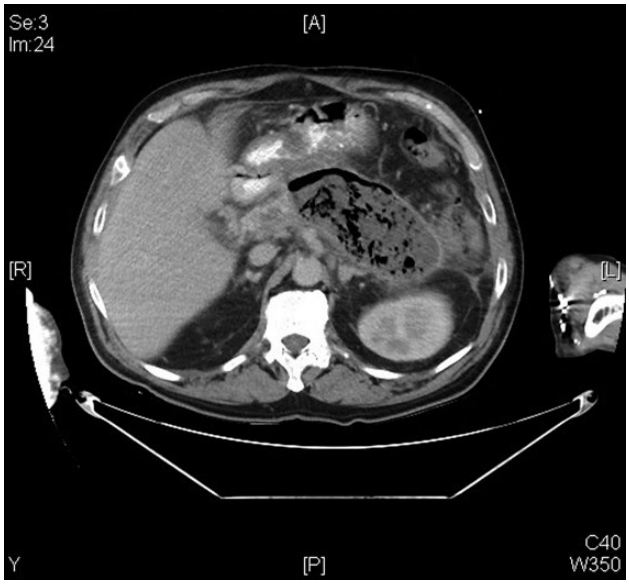

Figure 27.3 Infection of walled-off necrosis with fistula to colon. The patient in Fig. 27.1 presented 12 months after his original episode of pancreatitis with fever and bacteremia. Imaging demonstrated gas in the area of walled-off necrosis, consistent with infection. Endoscopic debridement was attempted, though contrast injection to the cavity demonstrated a fistula to the transverse colon. Open surgical debridement was pursued.

Of the available surgical approaches, open debridement with external drainage has been considered the gold standard, with operative morbidity of 72% and mortality of 4% [67]. Consideration of enteral access (i.e., jejunal feeding tube placement) during open debridement is reasonable to support postoperative nutritional optimization. Alternatively, internal drainage with cystgastrostomy may be performed in patients with WON. Other surgical techniques such as open packing with planned return to the operating room in 48–72 hours may be considered when early surgical intervention is required, or in cases when complete debridement cannot be obtained during the index procedure. Although this approach can effectively control intra-abdominal sepsis, it has inherently higher risk due to the need for multiple procedures and prolonged intubation time. Trans-gastric debridement is similar to endoscopic debridement and can be performed laparoscopically or open.

Of note, minimally invasive forms of surgical debridement have been used in addition to traditional "open" necrosectomy. Laparoscopic approaches are well described and may be more successful in completely removing all necrotic material compared to other minimally invasive methods [68]. Laparoscopic-assisted transperitoneal debridement has been described with placement of three ports for debridement, although this approach increases the chances of peritoneal contamination. Video-assisted retroperitoneal debridement (VARD) is a procedure by which the retroperitoneal collection is accessed via the tract of a large percutaneous catheter [51]. Patients with central necrosis may benefit from VARD, although this approach has limited efficacy for drainage of necrosis to the right of the mesenteric vessels [7]. Notably, VARD avoids pneumoperitoneum and peritoneal seeding possible with a laparoscopic procedure. This approach is not preferred for patients who may require simultaneous cholecystectomy or jejunostomy tube placement [6]. While open necrosectomy can be avoided in many patients, limited data are available comparing outcomes of these procedures [51].

Surgical debridement has several associated complications. Persistent or recurrent intra-abdominal fluid collections are a common postoperative complication, and often require intervention such as additional percutaneous drainage procedure. Bleeding is the most common postoperative complication requiring reoperation after debridement. Early bleeding is often due to injury of the peripancreatic vessels whereas late bleeding may be due to pseudoaneurysm rupture. Pancreatic fistulas and pancreatic insufficiency are also common side effects of the procedure.

Introduction

In the majority of patients with acute pancreatitis, the disease course is mild and self-limiting requiring supportive care only. Approximately 20% of patients, however, develop necrotizing pancreatitis. This is characterized by necrosis of the pancreatic or peripancreatic tissue, as seen on contrast-enhanced computed tomography (CT) [1,2]. Necrosis of the pancreatic or peripancreatic tissue is sterile, therefore initial management remains supportive including fluid resuscitation, pain control, and nutritional support [2,3].

Secondary infection of pancreatic or extrapancreatic necrotic tissue occurs in one-third of patients with necrotizing pancreatitis [1]. Infected necrosis is associated with a prolonged hospital and intensive care stay, sepsis, multiple organ failure, and a 20–30% mortality rate [4–6]. Although infection can occur in the early phase of pancreatitis, it usually develops 3 to 4 weeks after onset of disease [7–9]. Infected necrosis is suspected when the patients show clinical deterioration, in the absence of an alternative source of infection, despite maximal conservative support [10] or when gas configurations are present in the necrotic collections or necrosis as demonstrated on abdominal imaging [3]. Fine-needle aspiration of peripancreatic or pancreatic collections is not indicated because of the considerable number of false negative (20–29%) and false positive (4–10%) results [10–12].

The History of Pancreatic Interventions

The benefit of surgical treatment in acute pancreatitis has been an ongoing debate since the late nineteenth century. It was in 1886 that Nicholas Senn considered surgery in the early phase of pancreatitis as ineffective and risky [13]. Despite a mortality rate of more than 50%, laparotomies with drainage of the lesser sac and placement of gauze to achieve optimal drainage and to prevent wound closure, were considered the best treatment for acute pancreatitis until the 1930s [14]. Around this time, it became possible to diagnose acute pancreatitis without needing laparotomy by determination of serum amylase levels. This contributed to the use of conservative treatment for acute pancreatitis, which was reinforced in 1948 by a publication highlighting the poor survival rates after early surgery [15]. However, since conservative treatment was not giving satisfactory results, in the 1960s surgical procedures were reconsidered and surgical treatment was again indicated in the initial stages of acute pancreatitis. It was in the 1980s that the therapeutic approach of acute pancreatitis changed again, when a series of prospective studies showed superior results of conservative treatment compared with surgical treatment in patients with sterile necrosis [16–18].

The value of abdominal abscess drainage under ultrasound or CT was discovered in 1979, while it was not until 1987 when the possibility of aspiration of pancreatic or peripancreatic fluid ultrasound or CT-guided

aspiration was used for early diagnosis of infected necrosis [19,20]. At the beginning of the twenty-first century, the first study was published on laparoscopic necrosectomy followed by a study involving endoscopic necrosectomy in 2009 [21,22]. The necessity of surgical debridement for infected necrosis was subsequently questioned when Runzi et al. showed that initial conservative therapy, including antibiotic therapy, could be instituted [23]. Mortality in patients managed with surgery was identical to those managed conservatively [23]. Surgical therapy, when required, was often delayed to a later stage of disease, when the systemic inflammatory response has been stabilized and necrotic pancreas had become demarcated. In other patients, surgical therapy was avoided altogether. Subsequent studies have confirmed this strategy, Garg et al. describe a 10-year series of 80 patients with infected pancreatic necrosis in whom 47 were treated with antibiotics alone [24]. The urge for surgical debridement for all patients with infected pancreatic necrosis is therefore no longer considered valid [25]. Although laparoscopic direct necrosectomy was already described in the 1990s, it failed to gain popularity due to technical difficulty. Therefore, until publication of the PANTER trial in 2010, necrosectomy by laparotomy was the standard intervention [26]. In the PANTER trial, 88 patients were randomly assigned to the "step-up" approach or to immediate open necrosectomy. A step-up approach consisted of percutaneous catheter drainage, followed, if needed, by minimally invasive necrosectomy. Major short-term complications such as new onset multiorgan failure and long-term complications such as endocrine insufficiency, and costs, were decreased in the patients who were assigned to the "step-up" approach. The effect of the step-up approach was beneficial in patients with and without organ failure [26]. In addition, necrosectomy was avoided in 23–50% of the patients treated with percutaneous catheter drainage [26–29]. Since then, the step-up approach is considered to be the standard treatment. Several new minimally invasive strategies have been introduced and compared in randomized controlled trials with the goal of improving survival and decreasing complications and comorbidities. In the most recent study, 19 out of the 49 (39%) patients with infected necrosis did not require intervention at all and could be treated with antibiotics alone [30].

Step-Up Approach

Antimicrobial Management of Infected Necrosis

When infected necrosis is clinically or radiologically suspected, antibiotic therapy can be initiated without fine-needle aspiration or pancreatic culture [11,31]. Since it is hypothesized that translocation of bacteria from the gut is the major source for infection of necrosis, antibiotics that are effective on gut-derived bacteria with the potential to penetrate into the pancreas (carbapenems, quinolone, metronidazole, third-generation cephalosporins) should be considered as empirical treatment [7,32,33]. Antibiotic therapy should be adjusted accordingly once pancreatic culture results have been obtained. Since there are no data on the adequate duration of antibiotic therapy, it remains unknown when to stop antibiotic administration or when to proceed to pancreatic intervention. Current guidelines recommend that antibiotics are discontinued once the last percutaneous catheter drain has been removed for more than 48 hours and/or pancreatic cultures remain negative [11]. In addition, improvement of clinical, biochemical, and radiological signs aids in the decision to stop antibiotics. This is especially important in patients undergoing endoscopic treatment of the infected necrosis, as no drains are removed and no new pancreatic cultures are available.

Percutaneous or Endoscopic Drainage of Infected Necrosis

Pancreatic intervention is indicated in patients who fail to improve or who show clinical deterioration under antibiotic therapy [11]. Invasive intervention should preferably be delayed until collections have become walled-off, typically 3–4 weeks after the onset of disease [11]. In the recent multicenter randomized POINTER trial, no difference in the rate of complications or mortality was found between patients randomly assigned to immediate drainage (<24 hours after suspected or proven infected necrosis, 55 patients) or postponed drainage (when the collections were walled-off, 49 patients). The mean number of pancreatic interventions was higher in the group of patients who underwent immediate drainage [30].

Radiologically guided percutaneous catheter or endoscopic transluminal drainage is the first step in the step-up approach. The choice of one approach over another is based on multiple factors including characteristics of the collection (i.e., location, extent, integrity of the pancreatic duct) and clinical (i.e., hemodynamic) status of the patient. The randomized TENSION trial assigned 98 patients to either the endoscopic step-up approach (51 patients) or the surgical step-up approach (47 patients). No difference was found in major complications or death during a 6-month follow-up between the two groups. The rate of pancreatic fistulas and length of hospital stay were lower in the group assigned to the endoscopic step-up approach [34]. Therefore, the endoscopic approach is preferred.

Endoscopy

There are several endoscopic techniques to treat (infected) walled-off necrosis. The similarity between these techniques is the transmural access route. Since the superiority of endoscopic ultrasound (EUS)-guided drainage in patients with pseudocysts using an echo-endoscope has been shown in two randomized trials, conventional transmural drainage using a standard endoscope (blind access) has nowadays been replaced by EUS-guided drainage [35,36].

During endoscope drainage a transmural drain is inserted into the cavity through either a single or several access sites (multiple transluminal gateway technique) [37]. The multiple transluminal gateway technique led to more frequently reported clinical success compared with single-access endoscopic drainage in two retrospective series [37,38]. In both methods, balloon dilatation is performed to create a fistula between the gastrointestinal tract and the collection after the collection is accessed [39]. This fistula must be maintained to allow the evacuation of pus, debris, and necrotic tissue. This can be done by inserting multiple plastic double-pigtail stents or a self-expandable metal stent (e.g., lumen-apposing metal stents [LAMS]). Due to the larger lumen of the LAMS, expectations were high and this was confirmed in one small retrospective study [40]. An interim analysis of an ongoing single-center randomized trial, however, has revealed an important rate of delayed stent-related adverse events, consisting of bleeding and embedded LAMS. This led to the need to perform imaging to exclude vascular complications and the retrieval of the LAMS within 4 weeks [41]. A recent prospective observational cohort study, conducted by the Dutch Pancreatitis Study Group, has shown no increased risk of complications, including bleeding, in patients treated with LAMS [42].

With regard to removal of the endoscopic drains, plastic double-pigtails stents can be left in situ indefinitely, unlike LAMS, which it is advised to remove within 6 weeks due to worrisome long-term adverse events [41,43]. Subsequently, in the presence of a disruption of the pancreatic duct, LAMS should be replaced by plastic double-pigtail stents. The use of LAMS did not reduce the need for endoscopic transluminal necrosectomy compared with plastic double-pigtails stents (34 [64%] patients vs. 27 [53%], respectively). In the TENSION trial, 57% of the patients who underwent endoscopic drainage required a necrosectomy [34].

Radiology

As shown in the PANTER trial, percutaneous catheter drainage is feasible in >95% of the patients [26]. According to the Seldinger or the tandem trocar technique regular silicone pigtail drains are used [29]. The percutaneous catheter drain is preferably inserted in the retroperitoneal cavity to facilitate minimally invasive retroperitoneal necrosectomy if necessary as the next step. During the initial percutaneous procedure (real-time) ultrasound guidance in combination with fluoroscopy is often preferred to prevent puncture of organs of the gastrointestinal tract. If the collection contains limited liquid content, visualization with ultrasound can be difficult. In these patients, CT-guided drainage can be performed. Drain diameter may vary and there is no comparative data regarding the influence of different sizes of the drain; however, large-bore catheters of more than 14 French seem to obstruct less frequently [29]. In half of the patients, drains are required to be replaced or upsized [26]. Successful percutaneous catheter drainage can be predicted when the collection shows a decrease in size of at least 75% after the first 10–14 days following percutaneous catheter drainage [28,44]. No data is available on the optimal timing of removal of percutaneous catheter drains. In about half of the patients surgical necrosectomy was required following primary percutaneous catheter drainage as the primary treatment [29,35].

Pancreatic Debridement of Infected Necrosis

If no further clinical improvement is seen or when patients show clinical deterioration after endoscopic drainage or percutaneous catheter drainage without options for further percutaneous drainage, debridement of pancreatic necrosis is indicated. The optimal timing for repeat intervention, however, remains unclear. If clinically possible, the collection should be walled-off before necrosectomy is performed since early necrosectomy is associated with poor outcomes [45]. As with the choice for the first step, the subsequent approach (either endoscopic or surgical) for necrosectomy should be based on patient characteristics and location of the peripancreatic or pancreatic necrosis and should be performed as minimally invasive as possible [11,26,34].

Especially in high-risk, critically ill patients minimally invasive surgery and endoscopic necrosectomy were associated with reduced death rates as compared to open necrosectomy [46]. Regardless of the benefits of minimally invasive intervention, patients with intra-abdominal hemorrhage, perforation and/or abdominal compartment syndrome may require immediate intervention using either a minimally invasive or more invasive method [11].

The TENSION trial did not show superiority of endoscopy necrosectomy in outcomes such as major complications and death. Length of hospital stay, rate of pancreatic fistulas, and costs were significantly reduced in the patients undergoing the endoscopic step-up approach [34].

Endoscopy

Endoscopic transluminal necrosectomy is performed to remove solid necrotic debris by a combination of sucking debris through the working channel of the endoscope directly inserted into the necrotic collection (direct transluminal endoscopic necrosectomy), removing necrotic material with a removal device, and applying irrigation [37,47]. Although not well studied, the anatomical position of the initial puncture is also important for direct transluminal endoscopic necrosectomy [42]. Due to the lack of specifically designed endoscopic accessories, pre-existing tools are used during necrosectomy, such as different types of stone removal baskets (i.e., Dormia), polypectomy snares, balloons, nets, and different types of forceps [42]. These devices often lack sufficient grip, however, making the procedure time-consuming and often marginally effective requiring more than one procedure. Preliminary results suggests that the EndoRotor device (i.e., an automated mechanical endoscopic resection system designed for tissue dissection and resection with a single device) can safely, rapidly, and defectively remove necrotic tissue in patients with (infected) walled-off necrosis [48].

Surgery

There is a large variance in the used and personal favor of the various techniques. Surgical debridement can be performed with open or minimally invasive (laparoscopic) techniques [44,49]. Open debridement with external drainage is performed through a laparotomy followed by entry in the retroperitoneum to remove necrotic tissue. Subsequently, two to four large closed suction drains are left to facilitate drainage of the cavity. However, this procedure is only appropriate in patients with walled-off necrosis. There are various minimally invasive approaches described, including percutaneous necrosectomy (MIRP), video-assisted retroperitoneal debridement, laparoscopic transgastric necrosectomy, laparoscopic cystgastrostomy, and personal variations on the aforementioned techniques [50–54]. In general, minimally invasive surgery continues to be the preferred technique; however, open necrosectomy remains a possibility for some patient groups.

Management of Infected Pancreatic Necroses: An Endoscopic Approach

Todd H. Baron

Division of Gastroenterology and Hepatology, University of North Carolina, Chapel Hill, NC, USA

Pancreatic Necrosis

Pancreatic fluid collections (PFC) can occur as a complication of acute pancreatic injury (acute pancreatitis, trauma, surgical resection or injury to the pancreas during abdominal surgery) or chronic injury (chronic pancreatitis, autoimmune pancreatitis). At the basis of this pancreatic injury is disruption of the main pancreatic duct and/or side branches. Acute necrotizing pancreatitis (ANP) is at the severe end of a spectrum of inflammation associated with pancreatitis, resulting in cell death. Pancreatic necrosis is defined as nonviable pancreatic parenchyma usually with associated peripancreatic fat necrosis and occurs in 20–30% of all episodes of pancreatitis [1]. The resultant devitalized tissue becomes a potential bed for infection. Approximately 30% of patients with pancreatic necrosis develop infection of the necrotic tissue [2]. The amount of necrotic tissue is the strongest predictor of mortality necrotic pancreatitis. Fortunately, with early recognition and improvements in critical care most patients survive the early phase of systemic inflammatory response syndrome (SIRS) and many survive multisystem organ failure. Even with aggressive intravenous fluid replacement, nutritional support, and early intervention of pancreatic necrosis, the presence of pancreatic necrosis is associated with an overall increase in mortality as compared to interstitial or edematous pancreatitis. The mortality rate from sterile pancreatic necrosis is approximately 13% and rises to 35% when infected [2].

ANP is detected radiographically on contrast-enhanced CT (CECT) by the presence of non-enhancing pancreatic parenchyma. In the first few weeks after onset of ANP, pancreatic necrosis and/or peripancreatic fat necrosis can evolve into more organized processes that expand the initial area of necrosis. If this process occurs prior to 4 weeks after the onset of ANP it is termed an acute necrotic collection, which is potentially amenable to endoscopic drainage. After 4 weeks from onset of ANP such collections are termed walled-off pancreatic necrosis [3]. Both of these processes contain variable amounts of fluid (pancreatic juice) and solid debris (pancreatic and/or peripancreatic fat necrosis). Infected necrosis refers to bacterial invasion of necrotic pancreatic tissue and can lead to clinical infection, sepsis, and death. Infected necrosis is rare during the first week after onset of ANP [4,5]. Evidence suggests no absolute correlation between the extent of necrosis and the risk of infection and duration of symptoms. The mortality rate is substantially increased when infection occurs and most patients will require intervention and drainage.

Mechanical Intervention

Mechanical intervention for infected pancreatic necrosis can be surgical, percutaneous, and endoscopic. Open surgical therapy is not considered as first-line approach [6] and has largely been replaced by minimally invasive approaches [7,8] using flexible endoscopic, rigid endoscopic (via percutaneous catheter sites) [9], percutaneous drain placement, and laparoscopic approaches, alone or in combination [5]. It has been more than 25 years since the first report of endoscopic drainage for pancreatic necrosis [10]. Optimal management of necrotizing pancreatitis requires a multidisciplinary team including dedicated surgeons, interventional radiologists, and gastrointestinal endoscopists. Such a multidisciplinary team needs to be involved from the onset of the disease to decide if, when, and how an intervention needs to be performed.

Intervention in asymptomatic or minimally symptomatic patients with sterile necrosis is not indicated regardless of size, location, and extension [11,12]. For patients with sterile WOPN and persistent gastric outlet, intestinal, or biliary obstruction due to mass effect, intervention may be undertaken at least 4 weeks after onset of symptoms, the timing dependent on severity. In patients with persistent symptoms such as pain and "failure to thrive" the form and timing of intervention is debated and current intervention can be considered 8 weeks after onset [12].

In clinically stable patients with infected necrosis, it is advisable to continue supportive care with antibiotic therapy directed empirically or by culture data and delay surgical, radiologic, or endoscopic approaches for more than 4 weeks in order to facilitate the formation of WOPN with liquefaction of the contents. Indeed, in a recent landmark randomized trial of patients with infected necrosis, there was a significant improvement in outcome when endoscopic intervention was delayed until patients developed WOPN [1]. Prompt drainage is required for patients with infected necrosis and clinical instability. In these cases, minimally invasive methods of drainage are preferred. Distinguishing sterile from infected necrosis can be difficult but is important as the presence of infection alters prognosis and management. Percutaneous fine-needle aspiration (FNA) of pancreatic and peripancreatic collections for the detection of infection should not be routinely performed. It may postpone interventions, give false negative results or induce secondary infection [5]. Suspicion of infection is usually based on clinical deterioration despite medical support, high fever with rising inflammatory markers and/or positive blood cultures. The presence of gas on imaging studies is highly suggestive of infection, likely due to fistula, but it is only present in a minority of cases [13,14]. Infection can be confirmed by FNA or through cultures obtained at the time of drainage, and can be used to guide antibiotic therapy [11].

The goals of endoscopic therapy for infected WON are: (i) drainage of fluid and removal of solid components using a transmural approach (transgastric or transduodenal), and (ii) treatment of pancreatic ductal (PD) leaks and/or disruptions using a transpapillary approach, in selected patients. Theoretically, addressing pancreatic disruptions may lead to better long-term outcomes [15]. However, despite the relatively high incidence of ductal disruptions in patients with WOPN, subsequent disconnected duct syndrome following endoscopic therapy is uncommon [16]. Transpapillary endoscopic drainage as primary therapy of WOPN is not an adequate method to remove solid debris. Removal of solid debris is vital to any type of intervention during transmural drainage, which can be "mechanical," by irrigation, or a combination.

In case of proven or suspected infected necrotizing pancreatitis, intervention should be delayed when possible until ≥4 weeks after onset of ANP [17,18]. Endoscopic transmural access can be undertaken for acute necrotic collections as early as 2–3 weeks after the onset of acute pancreatitis in the setting of sepsis as long as they are deemed to be organized as determined by CT or MRI [19–21].

Transmural Drainage

The evolution of endoscopic therapy of WOPN began as with pseudocyst drainage using small diameter transmural tracts (8 mm) and placement of 10Fr plastic stents, in addition to a nasocystic irrigation tube [10]. Early in the endoscopic experience many patients required adjunctive percutaneous drains, especially to treat large paracolic gutter extensions [22]. Larger diameter transmural dilations were then added to the irrigation approach. Nasocystic irrigation tubes can be used for continuous flushing with sterile fluid per 24 hours or by bolus lavage every 3–4 hours for several days to weeks depending on the volume of debris and patient tolerance and may avoid the need for subsequent necrosectomy. However, they are uncomfortable, and with the advent of large-diameter transluminal metal stents, their use is decreasing.

Direct endoscopic necrosectomy (DEN) was introduced by Siefert [23], and subsequently Seewald [24] as a method to remove necrotic tissue by passing forward or side-viewing endoscopes transmurally into the collection; baskets, grasping forceps, and snares are used to remove solid debris [25]. Transmural placement of large diameter covered (esophageal) SEMS or large diameter (15–20 mm) self-expandable lumen-apposing metal stents (LAMS) can not only avoid the need for additional endoscopic intervention by allowing egress of fluid and debris, but also facilitate passage of endoscopes into the necrotic cavity to perform direct necrosectomy while preventing the need for repeated balloon dilation of the gastric or duodenal wall to enter the cavity. Indeed, in most Western countries a commercially available LAMS that has an electrocautery tip and which is specifically designed for use with endoscopic ultrasound (EUS) scopes has greatly simplified the technical aspects of the procedure [26]. Instillation of hydrogen peroxide into the necrotic cavity may facilitate removal of necrotic debris during DEN and reduce the likelihood of further necrosectomies [27].

In conjunction with percutaneous drain placement, hybrid approaches have also been described [28]. In some patients with peripheral collections that are not accessible from a transluminal approach, a percutaneous drain is placed. Subsequently, a large-bore self-expandable metal stent is placed through the

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. percutaneous tract to allow for direct endoscopic necrosectomy with a flexible endoscope.

A dual-modality drainage technique using CT-guided percutaneous irrigation/drainage catheter placement is followed directly by endoscopic transmural drainage. The percutaneous catheter is used for irrigation, with egress internally through the transmural tracts. This allows avoidance of direct endoscopic necrosectomy. Using this approach with endoscopically placed plastic stents resulted in decreased length of hospitalization and number of radiological and endoscopic procedures compared with either modality alone [29]. This approach also hastened resolution, but also prevented development of external fistulae and bleeding related to percutaneous manipulations. Surprisingly, the introduction of LAMS did not appear to offer an advantage to plastic stents at the same institution [30].

For complex organized necrosis, a multi-gateway approach [31] has been described, which utilizes two or more transmural entry approaches to permit irrigation and improved drainage. Nasocystic irrigation enters one site and egresses from another.

Transmural Entry Devices

Devices used to perform transmural puncture of WOPN can be divided into cautery and non-cautery devices. Cautery devices include standard diathermy wires (needle knives), specialized fistulotomy devices (Cystotome CST-10; Cook Endoscopy, Winston-Salem, NC, USA) and specialized stent delivery systems with cautery incorporated (AXIOS-EC; Boston Scientific, Marlborough, MA, USA). Non-cautery devices include 19-gauge EUS-FNA needles.

The collection is punctured transmurally using EUS guidance to be certain of the puncture site and to avoid vessels using Doppler. Fluid is aspirated during the procedure and sent for microbial analysis including Gram stain and culture. The procedure can be performed with or without fluoroscopy.

Stent Placement

Antithrombotic agents should be discontinued whenever possible prior to transmural drainage, and certainly prior to direct endoscopic necrosectomy. In case of severe bleeding during the procedure which cannot be treated endoscopically, immediate assistance of an interventional radiologist should be requested. Endoscopic drainage and necrosectomy are preferably performed with patients under deep sedation or general anesthesia. Plastic stents are not ideally suited to drain WOPN because of their small diameter. The use of large-diameter fully covered self-expandable metal stents are used instead. Specially designed biflanged short length (10 or 15 mm) LAMS (AXIOS; Boston Scientific) with luminal diameters of 15–20 mm and electrocautery incorporated delivery systems are now commonly used due to ease of placement [32]. With commercially available electrocautery-equipped LAMS delivery systems the stent is placed in a single-step (puncture and stent deployment). One needs to be particularly careful of proper device deployment, particularly the final, crucial step involving proximal flange release. Some endoscopists prefer to place a plastic double-pigtail stent through the LAMS to prevent occlusion due to impaction of necrotic material and contact of the stent edge against the inner wall of the cavity.

Direct endoscopic necrosectomy (DEN) can be performed using a standard forward-viewing endoscope during the initial endoscopic procedure after balloon dilation of the tract (12–20 mm) or the LAMS lumen (Fig. 29.1) to its maximal diameter although placement of the LAMS alone may be adequate to resolve WOPN (Fig. 29.2). In one study, LAMS alone allowed complete resolution of WOPN without necrosectomy in approximately half of 136 patients [33]. Patients with collections ≥10 cm in size, paracolic extension, or ≥30% solid debris within the collection were more likely to require additional intervention. Some authors advocate scheduled endoscopic debridements at intervals ranging from days to weeks depending upon inpatient or outpatient status, severity of illness, anticipated volume of residual necrosis, and findings on follow-up CT or MRI. Internal drains are endoscopically removed several weeks after complete resolution of the collection and after removal of external drains (if placed) to prevent persistent pancreatico-cutaneous fistula. Patients

with infected necrosis continue antibiotic therapy, either empirically or based upon culture data obtained during drainage and/or debridement. All procedures should be performed with carbon dioxide (CO_2) insufflation since fatal gas embolism has been described.

Tools for performing DEN include standard snares, baskets, large caliber grasping forceps, and retrieval nets. Recently, an endoscopic morcellator has become available to enhance removal of necrotic tissue [34].

Results of Endoscopic Therapy of Pancreatic Necrosis

There are many series showing that endoscopic treatment of WOPN is successful in achieving nonsurgical resolution in the majority of patients with central pancreatic necrosis [18,35]. The outcomes appear to be improving with the use of large-diameter metal stents with clinical resolution of WOPN occurring in 90% [26,36,37].

Adverse Events of Endoscopic Therapy of Pancreatic Necrosis

Life-threatening adverse events may arise following attempted endoscopic drainage of pancreatic necrosis. It is recommended that endoscopic drainage be performed with the availability of surgical and interventional radiology support. The most feared adverse events of transmural drainage are bleeding and perforation. Bleeding after transmural drainage may be managed supportively, endoscopically, surgically, or with angiographic embolization. If perforation occurs during attempted transgastric drainage and is limited to the gastric wall (does not involve the collection), it may be successfully managed nonsurgically if a stent is not mistakenly placed through the perforation and outside the gastric wall. If egress of gastric contents is prevented, the gastric wall rapidly closes with conservative treatment consisting of nasogastric suction and antibiotics. If plastic stents were used during initial placement, large-diameter covered SEMS can be used to close perforation at the transmural site and tamponade bleeding. Infectious adverse events usually occur from inadequate drainage of fluid and/or solid debris. Stent migration into the collection through the gastric or duodenal wall may occur during or after endoscopic stent placement. Endoscopic retrieval is possible if the collection has not completely collapsed and the transmural tract is still patent. Fatal air embolism has been reported following DEN [38]. This has prompted the use of CO_2 rather than air insufflation during drainage and necrosectomy.

Endoscopic therapy may be associated with adverse events and/or failures that require surgical management. It is possible that the outcome of surgical therapy may be adversely altered when compared to those patients undergoing primary surgical therapy.

What is clear is that if endoscopic therapy is undertaken, commitment is required by the endoscopist, clinical care team, and most importantly the patient. Endoscopic debridement is a time-consuming, labor-intensive process not for the uncommitted [39] or the faint of heart since adverse events occur more commonly than in any other pancreaticobiliary intervention and have the potential to be fatal. Therefore, even more importantly, perhaps, is the need for support from intensivists, endoscopists, surgeons, and interventional radiologists to manage these complicated patients.

Minimally Invasive Debridement and Lavage of Necrotizing Pancreatitis

Kulbir Mann and Michael G.T. Raraty

Liverpool University Hospitals NHS Foundation Trust, Royal Liverpool University Hospital, Liverpool, UK

Introduction

The prevalence of acute pancreatitis has increased over the decades according to the Global Burden of Disease Study in 2017. Prevalence has increased from 3,038,787 in 1990 to 6,115,833 in 2017 with an age standardized prevalence rate of 67.2 in 1990 to 76.2 per 100,000 in 2017 [1]. This is an increase of 13.3% and given that approximately 20–30% of patients develop moderate to severe pancreatitis, there is a significant impact on survival and burden on health resources [2]. The revised Atlanta criteria classifies acute pancreatitis into stages based on organ failure and local complications. If organ failure exists for more than 48 hours then the patient has severe pancreatitis. It is this set of patients that will need intervention as acute necrotic and peripancreatic fluid collections develop into walled-off necrosis or pseudocysts [3]. Necrotizing pancreatitis consists of necrosis of peripancreatic tissue and of the pancreatic parenchyma and comprises 5–10% of all cases [4]. The pathological process leads to maturing collections that afford the opportunity of specifically targeted intervention in a minimally invasive manner. This chapter will focus on three minimally invasive techniques: minimal access retroperitoneal pancreatic necrosectomy (MARPN), single port retroperitoneal pancreatic necrosectomy (SPRPN), and laparoscopic approaches to necrosectomy.

Minimal Access Retroperitoneal Pancreatic Necrosectomy

The original technique published from Liverpool in 2003 gained access to the necrotic cavity using a percutaneous drain placed under CT guidance [5,6]. The optimal retroperitoneal path is on the patient's left flank, inferior to the spleen, superior to the kidney and posterior to the splenic flexure, Figs 30.1 and 30.2. This drain can be used alone to evacuate liquefied necrosis and can be used as a single strategy in 9% of patients, in modern step-up approach strategies, and even higher in other reported cohort studies [7,8]. The first ever attempt to perform a MARPN was under sedation, in the operating room in a patient who was unable to tolerate a general anesthetic. This strategy is still possible but it is preferred to give the patient anesthesia and muscle relaxant. Patients are placed on the operating table in a supine position with the patient tilted allowing the drain tract to be as horizontal as possible. They are placed at the edge of the table with a sandbag placed under the left-hand side of the patient for additional positioning. The surgeon can either sit at the patient's left or stand and vary the table height. Under fluoroscopic guidance a guidewire is placed through the pigtail drain, ensuring it passes through into the cavity with enough length to allow the drain to be removed. After making a 1 cm skin incision, a renal dilator set is used to dilate the track following the guidewire, ensuring not to pass further than necessary. Once the dilatation is complete, a 24Fr Amplatz sheath is inserted over the guidewire and fixes the position of the track, and frequently a significant amount of pus and liquid debris drains. A nephroscope with a wide-bore operating channel is then passed through the sheath and warm saline irrigation commences. This allows direct visualization of the necrotic cavity and piecemeal evacuation using laparoscopic grasping forceps, Fig. 30.3. The initial procedure does not afford significant necrosectomy as the debris is adherent to granulating cavity walls, and removal can lead to significant bleeding. At the end of the procedure the wire is replaced through the sheath and then an irrigation device is placed into the cavity, over the wire at a pre-measured distance to ensure it is not placed too

Trattamento miniinvasivo della pancreatite acuta necrotizzante. In: Pedrazzoli S, ed. Neuro Trattato di Tecnica Chirurgica Pancreas: Peritoneo, Retroperitoneo, Surrene, Milza. Milan: UTET, 2006.

medially. The irrigation device consists of a 28Fr chest drain with a 10/12Fr irrigation nasogastric tube sutured to it, Fig. 30.4. The cavity is irrigated with 0.9% saline at 125 ml/h and after 1–2 weeks, the necrosis is easier to remove with clearly demarcated cavity walls, allowing a larger necrosectomy. Once the cavity appears clear and granulating, the MARPN procedure can cease and a CT scan is performed to check for cavity resolution. The irrigation rate can slowly be reduced and eventually the drain replaced with a single NG, sutured in place, which can be flushed if required. The patient can then be discharged and the cavity will slowly granulate and close over the next few weeks whilst the NG tube is slowly pulled back. A median of three procedures has been reported to completely clear the necrotic cavity [5].

A similar technique using video-assisted debridement was described in 2001 where the patient is placed in a similar position to MARPN [9]. A 4–5 cm incision is made below the costal margin at the mid-axillary line close to the percutaneous drain. Blunt dissection is performed through the muscle layers of the abdomen to locate the percutaneous drain and enter the cavity. A laparoscope is inserted into this cavity and a parallel laparoscopic grasper or suction device to perform the necrosectomy under direct vision. Once the necrosectomy is performed two large-bore drains are placed, deep and superficial with an irrigation catheter. The fascia is closed to perform closed irrigation and the skin can be closed or left open. This technique has been part of regular practice in many centers and employed in step-up trials for the management of necrotizing pancreatitis [10].

Acute Complications

Intervention for necrotizing pancreatitis brings with it a further set of complications adding to an already significant pancreatitis burden. There is commonly a physiological systemic inflammatory response as a contained infected collection is released systemically and patients can become septic. In MARPN patients, this has been reported at 12% with multiorgan failure and with 41% of patients requiring an ITU admission. MARPN remains

Figure 30.3 Debridement of necrotic pancreatic tissue under direct vision using an operating nephroscope.

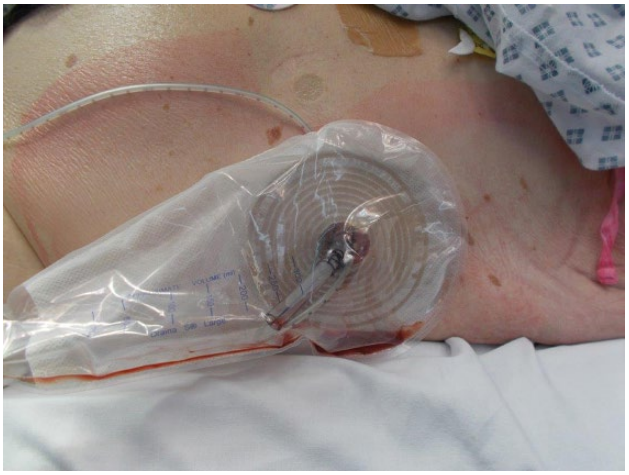

Figure 30.4 A 12F Ryles nasogastric tube and 28F chest drain are placed into the cavity at the end of the procedure and used as an irrigating drainage system to continuously flush the necrotic cavity with 0.9% saline solution at a rate of 125 mL/h.

the commonest minimal access technique, though endoscopic approaches have become first line in many institutions as part of a step-up approach strategy. Most data published in the form of comparative studies and trials compare open surgery with minimally invasive strategies. Hence why the largest cohort study of MARPN remains of 274 patients published from the pancreatic unit in Liverpool in 2016 [11]. They describe a procedure-specific complication rate of 20.4% with a conversion rate to open necrosectomy of 13.1% due to technical difficulties in maintaining a tract, bleeding during the procedure, and inaccessible collections.

One of the most important complications is that of bleeding during or after the procedure; the incidence of this is 11–21% [8,10,11]. Primary bleeding during the procedure is from contact with granulating tissue or avulsion of a vessel, with the rare possibility of injury to the splenic artery. If cessation of the procedure and irrigation fails to stem the bleeding then the cavity requires closing by a pack, suture, or drain clamp in order to facilitate tamponade. Secondary bleeding can occur at any time in the postoperative period from an erosion into a vessel or a pseudoaneurysm rupture. If clamping the drain does not prevent cardiovascular instability then an urgent CT angiography investigation needs to be performed with a view to a mesenteric angiogram and embolization of a bleeding vessel.

Subsequent procedures may prove difficult and a period of conservative management is advocated to ensure there is no further bleeding.

Fistulation to the GI tract has been reported but the incidence remains very low. Approximately 1% can occur from erosion of necrosis into the lumen of the bowel or the development of focal ischemia as tributaries of mesenteric vessels become occluded [12]. It may also become apparent from the medial border of the duodenum as necrosectomy of the head of the pancreas reveals the defect. Management of this is on a case by case basis and may require cessation of intervention, keeping the patient starved and commencing total parenteral nutrition. Fistulation from the pancreas duct occurs in 5–28% of patients from the remnant healthy pancreas and is managed conservatively providing flow proximally is not obstructed [8,11]. An endoscopic retrograde cholangiopancreatography (ERCP) and pancreatic duct stent may treat an established fistula.

Compared to open surgery, MARPN has significantly lower complications (35.4% vs. 51.7%), less incidence of multiorgan failure (12–20% vs. 35–40%) but mortality rates remain similar (23.1% vs. 22.9%), respectively [8,11,13,14]. The difficulty in comparing techniques in the management of necrotizing pancreatitis is that the development of novel drainage strategies has provided multiple options. In previous cohort studies, it has been reported that the use of MARPN is not suitable in 30% of cases in some studies and one quarter of all patients will require additional percutaneous drains [8,11]. This implies that as good as MARPN is as a technique, there will be areas of walled-off necrosis that may not be accessible.

Thus is the nature of necrotizing pancreatitis and why the development of different drainage techniques has improved management.

Single Port Pancreatic Necrosectomy

There has been a single report published reviewing the use of a single port for necrosectomy in seven patients [15]. It is important to state that this technique is used for extrapancreatic walled-off collections, predominantly those that are accessible using a three-channel SILS port. A percutaneous drain is inserted radiologically into the collection under local anesthetic and then the patient is given a general anesthetic where a 3 cm cut-down incision is made over the drain site to afford the SILS port. A zero-degree nephroscope is then inserted through one channel and an articulating grasper through the other, with a 0.9% saline irrigation channel. A necrosectomy is performed under direct vision and an irrigation nasogastric tube is then placed for further lavage and drainage. The case series is small, a morbidity rate is not possible to accurately calculate and the post-procedural median length of stay was 47 days [15]. Though this is a technically feasible technique, it is for a specific, difficult to access, area of necrosis of critically unwell patients. It should become part of an array of minimal access techniques for patients with complex necrotizing pancreatitis.

Laparoscopic Approaches to Pancreatic Necrosectomy

Many small volume case series have been reported over the past couple of decades but the technique remains low in popularity and there are no large volume studies published [16]. The peritoneal approach has been commonly reported and the pancreatic cavity is approached from either the mesocolon or through the greater omentum into the lesser sac. It is also possible to enter transgastrically once the collection/necrosis is walled-off and ready to drain through a cystgastrostomy [17]. The major benefit is that only single operation is needed for necrosectomy, though it has been reported that 20% of patients require a further procedure [16]. Other reported benefits include a morbidity rate of 21% and the simultaneous ability to perform a cholecystectomy [16,18]. The only comparative study between laparoscopic and open techniques of necrosectomy was published in 2012, which stated that there was a lower complication rate, less blood loss, and a shorter length of stay [19]. The operation duration was longer, which leads to specific respiratory complications from prolonged abdominal insufflation. There is a further risk of introducing a contained collection into a previously sterile peritoneal compartment. Many units prefer to approach necrosectomy through the retroperitoneum. There has been a retroperitoneal laparoscopic approach described where two ports are placed into the necrotic cavity over percutaneous drains. This allows insufflation of carbon dioxide and necrosectomy can be performed using laparoscopic instruments and clips and diathermy can be used to control bleeding [20]. The major advantage of this technique is that it requires only two procedures, compared to other retroperitoneal techniques, with a lower median time to discharge of 44 days. There remains a complication rate of 38% and the series was of only 13 patients [20]. The retroperitoneal is still an important aspect of pancreatic necrosectomy, though the MARPN technique remains the most commonly used minimally invasive strategy.

Modern Management of Necrotizing Pancreatitis

In 2016 a Cochrane review was published comparing interventions in necrotizing pancreatitis and summarized that there was low to very low quality evidence to compare minimally invasive step approaches to open necrosectomy [21]. This highlights the difficulties in comparing techniques and establishing the role of MARPN with a solid evidence base. More recent studies have established that minimally invasive step-up approaches have significantly fewer deaths than open surgery (2% vs. 10%), respectively and a risk ratio of 0.7 [22]. Two randomized control trials have been reported from the Dutch Pancreatitis Group. The Panter trial, which compared open necrosectomy with a minimally invasive step-up approach and found the latter to be superior in terms of mortality, postoperative complications, and pancreatitis insufficiency [23]. Van Brunschot et al. published a randomized trial reviewing surgical step-up and endoscopic step-up approaches and determined that there was no difference in mortality or major complications. The only differences reported was a short length of stay and few pancreatic fistulae in the endoscopic step-up group. It was concluded that there should be a shift toward endoscopic approaches [10].

As the evidence bases slowly improves, the primary use of open necrosectomy becomes less recommended and minimally invasive strategies have become first line. The advent of endoscopic therapies has further shifted management from surgically minimally invasive techniques, especially MARPN. Given these advances a modern pancreas unit should be able to provide multiple strategies and afford a multidisciplinary decision-making process, where patient factors, collection distribution and timing can be discussed in order to tailor personalized management.

Introduction

Open surgical debridement, once considered as the first-line treatment for necrotizing pancreatitis, is now reserved as the final step in contemporary treatment algorithms with the "step-up" approach and is needed in fewer than 20% of cases [1]. However, an open approach may have advantages over minimally invasive debridement techniques in the following conditions: (i) infeasible for minimally invasive approaches, due to solid material constituting majority of the necrosis, or unfavorable anatomic location of the necrosis; (ii) complications including abdominal compartment syndrome, enteric fistula, ileus, and massive intra-abdominal hemorrhage; (iii) additional surgical procedures are needed (e.g., cholecystectomy for biliary etiology); (iv) efficient removal of necrotic tissue and rapid control of systemic infection are warranted, particularly in critically ill patients with severe sepsis. In selected cases, a "step-jump" open surgery first approach, by skipping the precedent treatments in the "step-up" approach including percutaneous catheter drainage and minimally invasive debridement, may be beneficial [2].

Historically, open surgical debridement with large incision and extensive necrosectomy resulted in a high incidence of complications and mortality after surgery [3,4]. A better understanding of the natural course of disease, advances in medical treatment especially in critical care, incorporating a "step-up" strategy, and accumulation of expertise in high-volume centers significantly improved clinical outcomes after open surgical debridement for necrotizing pancreatitis [5–11]. Improvement of surgical techniques also played an important role in continuous optimization of patients' prognosis in this clinical setting. Traditional open surgical procedures for necrotizing pancreatitis included debridement and continuous closed lavage [12], debridement and open packing/staged laparotomy [13], debridement and closed packing [14]. Nowadays, the tendency of minimalization in open surgery for necrotizing pancreatitis is remarkable, and reported techniques included open transgastric necrosectomy [5,8] and small incision retroperitoneal debridement [15].

Late complications in necrotizing pancreatitis are common and have a significant impact on patients' long-term wellness (Table 31.1). In a recent report involving 578 consecutive cases of necrotizing pancreatitis with a median follow-up time of 46 months, 85% of the patients developed ≥1 long-term complication, and 59% of them required invasive interventional treatment [16]. In an earlier cohort of patients with necrotizing pancreatitis after surgical debridement with a median follow-up time of 28.9 months, 62% of the patients developed a long-term complication and 26% of them required intervention [17].

The following paragraphs will focus on individual long-term complications closely related to the procedure of open debridement.

Pancreatocutaneous Fistula

Pancreatic leakage develops in necrotizing pancreatitis when the main pancreatic duct or its branches are destructed and subsequent pancreatic juice extravasates to the peripancreatic space. Any transcutaneous interventions including open surgery with postoperative drainage may cause pancreatocutaneous fistula [18]. Another form of pancreatic fistula in necrotizing pancreatitis is internal fistula, which is less associated with necrosectomy, thus is not discussed in this chapter.

Pancreatic fistula rate after surgical debridement in necrotizing pancreatitis was 8–73% from different studies [6,7,9–11,15,19–26]. Transgastric necrosectomy has the innate advantage of minimizing risk of external fistula by creating durable internal drainage for potential gland leaks, and the reported pancreatic fistula rate after open transgastric necrosectomy was 2.0–4.7% [5,8]. When postoperative pancreatic fistula persists, underlying anatomical deformity of the pancreatic duct secondary to parenchymal necrosis should be suspected. When duct stricture or disconnected pancreatic duct syndrome (DPDS) presented, persistent pancreatic fistula after pancreatic debridement increased from 27% in cases with normal duct to 54% and 85%, respectively [27]. Disconnected left pancreatic remnant on preoperative CT scan was also found to be a risk factor for the development of pancreatic fistula after necrosectomy [7].

Around two-thirds of the post-necrosectomy pancreatic fistula will close spontaneously after noninterventional treatments at around 4 months after surgery [18,28]. Conservative treatments included optimized drainage, somatostatin analogues, antibiotics, and nutritional support. If the fistula is refractory to medical treatment, the choice between different interventional modalities currently lacks strong evidence support. Endoscopic transpapillary duct drainage [29], surgical interventions including fistulojejunostomy, pancreaticojejunostomy, and left pancreatectomy [30] are among the physician's arsenal and were reported with a satisfactory safety and efficacy profile. Changes in ductal morphology may provide helpful information in clinical decision-making to choose the appropriate treatment [31]. Simultaneous left pancreatectomy resection with the index debridement for cases with DPDS were also recommended [7].

Hemorrhage

Hemorrhage is one of the most fatal complications and contributes to a substantial mortality rate in necrotizing pancreatitis. Late hemorrhage in necrotizing pancreatitis is related to the presence of residual peripancreatic or pancreatic necrosis, long-standing pseudocyst, and gastrointestinal varicosis following thrombosis and obstruction of the portosplenomesenteric vein. Too aggressive or expectant timing for debridement and traumatic manipulation during necrosectomy may also increase the risk of postoperative bleeding. The common sites of hemorrhage in necrotizing pancreatitis include splenic artery, gastroduodenal or pancreaticoduodenal artery, portal vein, spleen, and unspecified peripancreatic vessels [32,33]. Isolated vessels or even vascular stumps in the necrotic cavity are frequently found during necrosectomy; proper ligation or transfixation of the vessel or its stump is required, and surgical debridement holds technical advantages in this respect (Fig. 31.1).

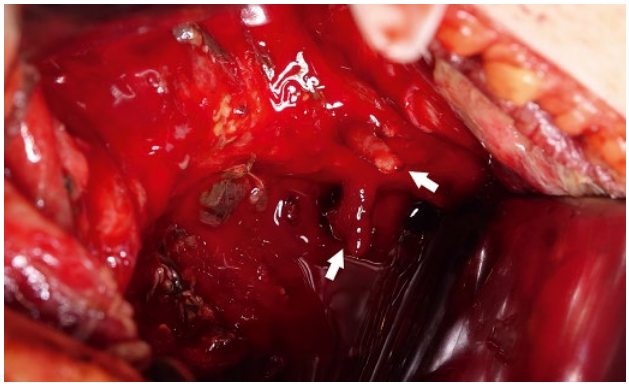

Figure 31.1 Isolated vascular stumps (arrows) in necrotic cavity during open debridement, which require proper management with ligation or transfixation.

Various studies have reported a rate of postoperative hemorrhage of 2.7–10.1% after open pancreatic necrosectomy [6–10,15,19–21,23–26,34–36]. In the extended observational study of a randomized controlled trial, two more patients (5%) had intra-abdominal bleeding requiring intervention during the long-term follow-up period, making an overall hemorrhage rate of 27% in the open surgery arm [34]. As regards a different but closely related disease entity, the visceral artery pseudoaneurysm was reported to be 4.3% in all patients with necrotizing pancreatitis with a median incidence timing of 63.5 days after disease onset and 21% of the patients were diagnosed based on incidental CT findings [37]. Age >50 years, presence of any organ failure, and previous endoscopic transluminal necrosectomy with lumen-opposing metal stent were reported to be risk factors for visceral pseudoaneurysm in necrotizing pancreatitis [37,38].

Recognition of early signs of hemorrhage and/or pseudoaneurysm is critical for prompt intervention and successful treatment; these include blood in drainage, acute onset of abdominal pain, gastrointestinal bleeding, and early presentations of hemorrhagic shock. Visceral angiography is considered as the first step in management of bleeding after necrosectomy if the patient is hemodynamically stable, which could provide detailed information on bleeding sites. And further intravascular embolization with a coil or covered stent would provide definite treatment or a bridging measure for surgery [33,37]. Emergent open laparotomy for hemostasis is a lifesaving procedure for patients with catastrophic intra-abdominal bleeding or failed percutaneous vascular embolization, and has the advantage of eliminating underlying causes of bleeding including residual infected necrosis and direct compression from the drainage tube,

and so on. Extensive blood oozing into the necrotic cavity represents another challenging scenario, in which gauze packing may be the only choice of treatment. Postoperative hemorrhage would have a profoundly detrimental impact on a patient's outcome with a mortality rate of 34.1% [32].

Enteric Fistula

Multiple factors were involved in the pathogenesis of enteric fistula in necrotizing pancreatitis, which include organ ischemia secondary to vascular thrombosis due to enzyme-rich and inflammatory exudates involvement, colonic ischemia in hypoperfusion status in splanchnic blood supply, direct autodigestion from extravasated pancreatic juice, and iatrogenic causes during interventions [28]. Enteric fistula was reported with an incidence rate of 6–23.6% after surgical debridement from various studies [7,9,10,15,19–23,25]. The incidence of enteric fistula in necrotizing pancreatitis was associated with organ failure, presence of extensive necrosis, and operative intervention [16,39].

Once the diagnosis of enteric fistula is established, timely interventional management is essential to stabilize the patients. Percutaneous catheter drainage, endoscopic stenting, enterostomy, enteric resection, enteric fixation, or proximal diversion of the gastrointestinal tract is indicated for different clinical settings. Although surgery is still the mainstay treatment for enteric fistula, nonsurgical interventions have been increasingly applied in recent years. In one report focused on colonic fistula after necrosectomy for infected pancreatic necrosis, 34.8% of the cases with colonic fistula closed spontaneously [40]. Once colonic ischemia is suspected during surgical debridement, it is recommended that a prophylactic loop ileostomy be constructed [20]. Necrotizing pancreatitis complicated with gastrointestinal fistula represents a treatment challenge, as studies have found out that the disease course is significantly prolonged, and mortality is substantially high in this group of patients [16,40].

Incisional Hernia

Risk factors for the development of incisional hernia including wound infection, repeated laparotomies, obesity, diabetes mellitus, malnutrition are commonly seen in patients after open debridement. Various incidence rates of incisional hernia after traditional transperitoneal surgical debridement were reported with a wide range of 9.1% to 91% [22,25,34–36,41,42]. Patients with incisional hernia increased from 24% to 53% if the follow-up time was extended from 6 months to an average of over 7 years after open necrosectomy [19,34]. In a retrospective study specifically focused on long-term hernia development after laparotomy for necrotizing pancreatitis, elder age was found to be the only risk factor for hernia development [43].

Hernias are more common when marsupialization of the lesser sac is used as a controlled laparostomy [44,45]. Transverse incision resulted in less incisional hernia when compared with midline incision [46,47]. However, a retrospective case-control study in necrotizing pancreatitis did not find a difference in hernia development between various types of incision [43]. Minimalization of the incision in open necrosectomy may help to avoid the risk of incisional hernia [15]. In the authors' institution, we now use uni-/bilateral flank incision (retroperitoneal) and/or mini transverse incision (transperitoneal) instead of a midline incision for open debridement. The choice of incision is flexible and depends on the location and extension of necrosis (Fig. 31.2). A minimally invasive "step-up" approach could significantly reduce the chance of hernia development by avoiding laparotomy in some patients [19,34].

Incisional hernia is a condition that frequently requires surgical reintervention and 52–86.5% of the patients who developed incisional hernia subsequently received hernia repair [16,22,41,43].

New-Onset Endocrine Insufficiency

Acute necrosis of the pancreatic parenchyma, extensive debridement, and subsequent chronic inflammation after acute onset will cause permanent loss of functional unit both in the endocrine and exocrine compartment of the pancreata. Pancreatic functional loss in necrotizing pancreatitis seems to be progressive and irreversible in long-term follow-up [16,34].

Endocrine insufficiency after open necrosectomy was reported with an incidence rate of 9.1–61.9% after various follow-up times [6,10,15,22,34,35,41,42,48,49]. Endocrine insufficiency occurs early in necrotizing pancreatitis, as serum glucose greater than 200 mg/dL was included in Ranson's score. Worth noting, over one-third of euglycemic patients at the time of acute attack resolution further developed endocrine insufficiency, after follow-up time was extended from 6 months to 86 months in the PANTER trial [19,34]. And this finding was supported by other observations [16,41].

Studies have suggested that functional loss of the pancreas was more dependent on the severity of the attack rather than on the action of debridement [16,50]. Development of organ failure, infection other than sterile necrosis, higher computed tomography (CT) severity index, and more extensive necrosis during acute onset of necrotizing pancreatitis were associated with the development of endocrine insufficiency afterward [16,41,48].

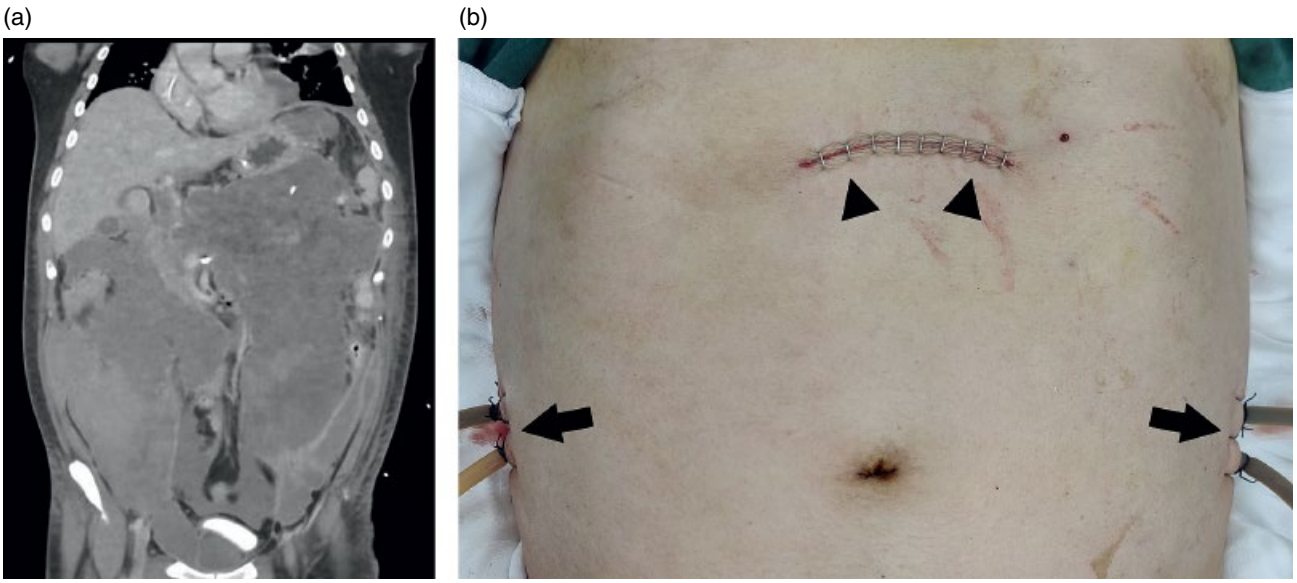

Figure 31.2 Minimalization of incision in open debridement. (a) Extensive pancreatic necrosis was found in a preoperative computed tomography (CT) exam of a patient with infected necrotizing pancreatitis. (b) Epigastric 7-cm transverse incision (arrow heads) with bilateral flank incisions (arrows) in open necrosectomy for this patient (drainage tubes were introduced via the flank incisions).

New-Onset Pancreatic Exocrine Insufficiency (PEI)

The incidence of PEI after open debridement for necrotizing pancreatitis varied from 9.5% to 57.1% [10,22,34,41,48], and the percentage of patients who relied on enzyme supplementation was reported to be 10–80.9% [6,15,19,34,35, 41,48,49]. Different diagnostic criteria will lead to different estimations of the burden of exocrine insufficiency. One study used fecal elastase-1 <200 μg/g and found the incidence rate of long-term PEI after open necrosectomy to be 56% [34], while exocrine insufficiency was diagnosed in 25–57.1% of patients when fecal fat excretion >7 g/24 h was used [41,48].

Direct open debridement was reported to increase the risk of long-term exocrine insufficiency when compared with the minimally invasive step-up approach both in functional test and supplementary enzyme dependence [34]. The extent and infection status of the necrosis, and no or incomplete visualization of the main pancreatic duct are associated with the incidence of exocrine insufficiency [41,48]. In another study, renal failure and cardiovascular failure during the acute phase were found to be independent risk factors for long-term PEI development in patients with necrotizing pancreatitis [16].

Summary

Late complications are common in patients with necrotizing pancreatitis and after open surgical debridement. Long-term follow-up in these patients is essential and warranted to identify potential complications and initiate treatment promptly. In a contemporary treatment algorithm, the role of open surgery for necrotizing pancreatitis has fundamentally changed but remains indispensably important, as it seems to be decisive for the fate in a subset of patients with necrotizing pancreatitis, not only as a bail-out procedure after failed minimally invasive interventions but maybe also as a first choice in selected patients. In future, novel treatment strategy and surgical techniques for necrotizing pancreatitis should be tested in well-designed clinical trials focusing on both short-term outcomes and long-term morbidities.

Endoscopic Treatment of Acute Biliary Pancreatitis

Ichiro Yasuda[1], *Tsuyoshi Mukai*[2], *and Toru Ito*[2]

[1] *Third Department of Internal Medicine, University of Toyama, Toyama, Japan*
[2] *Department of Gastroenterological Endoscopy, Kanazawa Medical University, Ishikawa, Japan*

Pathogenesis of Acute Biliary Pancreatitis

Acute biliary pancreatitis (ABP) is caused by pancreatic duct obstruction mainly due to bile duct stones. Once a bile duct stone is impacted at the common channel or distal end of the bile duct, pancreatic duct outflow is obstructed directly or by the compression of the pancreatobiliary septum. Previous reports showed that bile duct stone impaction was found in 26–72% of patients who had ABP when surgery was performed soon after the attack [1]. Spontaneous passage of bile duct stones into the duodenum has been described in up to 50% of ABP cases [2,3]. Sphincter of Oddi spasm might be another cause of ABP. Therefore, the diagnosis of ABP is not always easy at the time of diagnosis of pancreatitis.

Biliary pancreatitis, as well as alcoholic pancreatitis, is a major etiology of acute pancreatitis. ABP accounts for 20–71.4% of cases of acute pancreatitis, but the rate varies across countries. Biliary pancreatitis is more common than alcoholic pancreatitis in Greece, Italy, the United Kingdom, Sweden, and the United States of America, whereas alcoholic pancreatitis is the most major cause in Hungary, France, Taiwan, Korea, and Japan [4–9].

Diagnosis

In addition to the increased levels of serum pancreatic enzymes, such as amylase and lipase, increased levels of hepatobiliary enzymes and bilirubin suggest the possibility of ABP. In such cases, imaging tests are strongly recommended for diagnosis. Although transabdominal ultrasound is the most convenient imaging modality, the extrahepatic bile duct is often difficult to visualize clearly due to the retention of gastrointestinal gas, especially in patients with acute pancreatitis. Abdominal computed tomography (CT) is also relatively convenient and has high sensitivity in detecting calcified stones (Fig. 32.1), but its sensitivity to detect small stones lacking calcification is limited. Endoscopic retrograde cholangiopancreatography (ERCP) may be indicated in highly suspected cases such as those with bile duct dilation and/or cholangitis. However, magnetic resonance imaging (MRI) or endoscopic ultrasonography (EUS) is recommended to be performed before ERCP in such cases because they are safer and more convenient. Magnetic resonance cholangiopancreatography (MRCP) can provide an image similar to ERCP. It has high sensitivity and specificity in detecting common bile duct stones (more than 90%) [10], but its sensitivity decreases in cases with dilated bile duct and small stones [11]. EUS is recognized as the most reliable imaging modality in detecting bile duct stones [12], has fewer complications, and shows higher sensitivity in detecting small bile duct stones than ERCP [13].

Indication of Endoscopic Treatment

Endoscopic treatments are indicated for patients with a bile duct stone confirmed on imaging tests or highly suspected from clinical or laboratory findings. In addition, patients with persistent or repeated increasing levels of biliary and pancreatic enzymes are also indicated even if the presence of biliary stone was unclear. In such cases, a dysfunction in the sphincter of Oddi might be a cause of biliary pancreatitis.

The timing of endoscopic treatments is discussed later, but urgent ERCP should be considered when there is evidence of cholangitis and/or ongoing biliary

obstruction. However, conservative treatments such as fasting, rehydration, and administration of antibiotics should be attempted first in patients with mild clinical symptoms and with mild abnormal laboratory data.

Several previous studies have suggested the utility of EUS in narrowing down eligible patients by showing that a preceding EUS avoided unnecessary ERCP in 71.2–75.4% of patients without increasing the risk of adverse events [13–16].

Techniques

The best way to treat biliary pancreatitis is the removal of the bile duct stone. Endoscopic sphincterotomy is generally performed for this. ERCP is initially attempted to confirm the stone in the bile duct, and endoscopic sphincterotomy is then performed using a sphincterotome if a stone is detected on cholangiogram. Subsequently, endoscopic stone extraction is performed using a retrieval basket or balloon. If the stone is impacted at the papilla, precut papillotomy using a needle knife would be preferred to conventional endoscopic sphincterotomy owing to the difficulty in cannulation into the bile duct in such cases (Fig. 32.2).

Endoscopic sphincterotomy with subsequent stone extraction is currently a well-established technique with a high success rate (approximately 90%) [17]. However, procedure-related adverse events, including pancreatitis, hemorrhage, perforation, and cholangitis, can occur in approximately 10% of the cases [18]. Aggravation of pancreatitis is a particularly considerable concern in patients with pancreatitis. Therefore, cannulation and contrast medium injection into the pancreatic duct should be avoided as much as possible; however, there is no evidence that accidental cannulation into the pancreatic duct affects the clinical course or outcome adversely. Recently, the efficacy of pancreatic duct stenting was suggested in ABP following endoscopic sphincterotomy. In a nonrandomized study, complications were less frequent in the pancreatic duct stent group than in the control group without pancreatic duct stent (9.86% vs. 31.43%, $P < 0.002$) [19]. However, so far, there is no significant evidence to recommend pancreatic duct stenting after endoscopic treatment for ABP.

Outcomes and Timing of Endoscopic Interventions

Endoscopic treatments for ABP were initially described in 1981 [20,21]. Since then, a number of prospective randomized controlled trials (RCTs) have compared early endoscopic treatments with conservative therapy for ABP. However, as several clinical trials and meta-analyses have provided conflicting evidence, the role and timing of endoscopic intervention in ABP remain controversial.

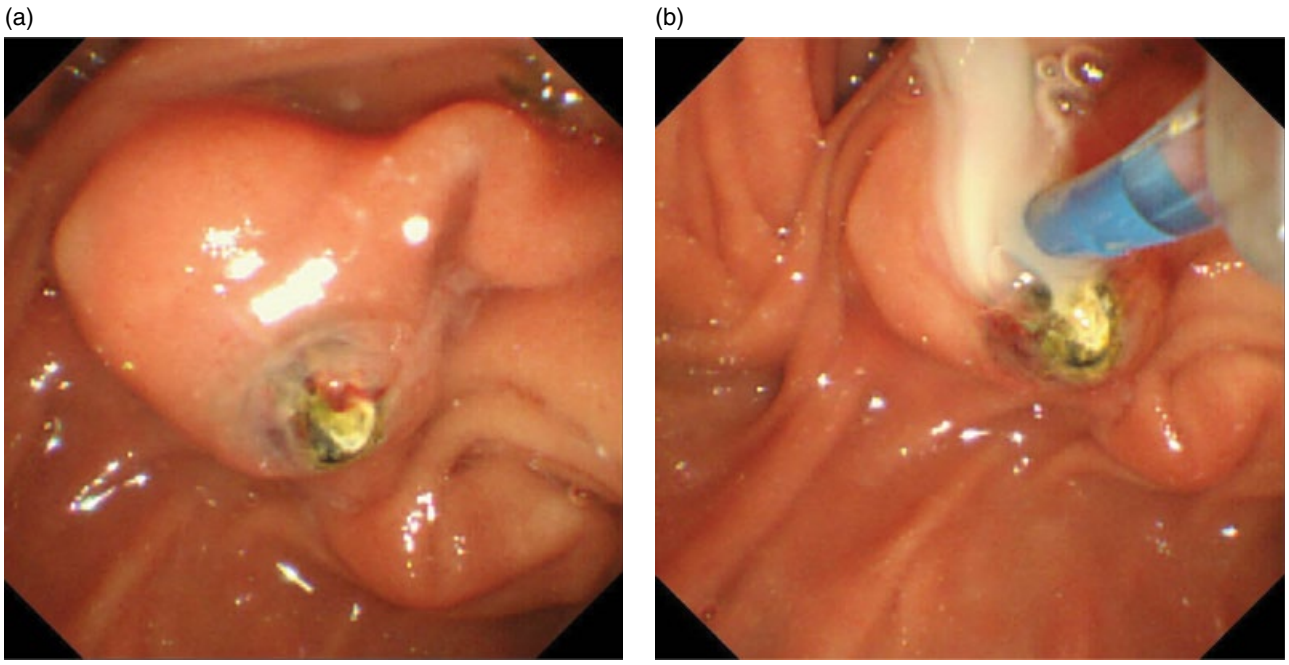

Figure 32.2 Endoscopic view of an impacted stone at the duodenal papilla. A stone is impacting at the biliary orifice (a). Needle knife papillotomy is preferably performed in such a case. Whitish pus is discharged after cutting up the papilla from the orifice using a needle knife (b).

Two early RCTs showed lower complication rates, shorter hospital stays, and lower mortality rate in the urgent ERCP group than in the conservative group [22,23]. However, another RCT showed that the overall rate of complications was similar in the two groups, and patients in the early ERCP group had more severe complications [24]. The first meta-analysis published in 1999 showed a high success rate of ERCP (92%) and concluded that early ERCP significantly reduced morbidity (25.0% vs. 38.2%, $P < 0.001$) and mortality (5.2% vs. 9.1%, $P < 0.05$) in ABP [25]. However, later studies suggested that early endoscopic intervention was beneficial in further limited patients.

Several studies have concluded that urgent endoscopic intervention should be considered only in patients with severe biliary pancreatitis [26–28]. In a meta-analysis by Ayub et al. [27], early endoscopic intervention was associated with significant reduction in complications only in predicted severe biliary pancreatitis (odds ratio [OR] 0.27, 95% confidence interval [CI] 0.14 to 0.53), whereas reduction of mortality was not significant in both predicted mild and severe biliary pancreatitis. Later, a meta-analysis by Moretti et al. [28] also reported that a significant difference in the pooled rate for complications was found only in predicted severe pancreatitis (38.5%, 95% CI −53% to −23.9%, $P < 0.0001$).

Meanwhile, several other studies have suggested that the benefit of urgent endoscopic intervention was expected only in cases with cholangitis or cholestasis [29–34]. Petrov et al. [29] reviewed RCTs on early endoscopic intervention versus conservative management in patients with ABP without acute cholangitis. They found that early endoscopic intervention in patients with predicted mild and predicted severe biliary pancreatitis did not lead to a significant reduction in the risk of overall complications and mortality. Later, Van Santvoort et al. [35] conducted a prospective, observational multicenter study including patients with predicted severe ABP without cholangitis. They analyzed the outcomes in patients without and with cholestasis separately and noted that endoscopic intervention was associated with fewer complications as compared with conservative treatment in patients with cholestasis (25% vs. 54%, $P = 0.020$), whereas it was not associated with reduced complications (45% vs. 41%, $P = 0.814$) in patients without cholestasis. A Cochrane review by Tse and Yuan [32] in 2012 showed no evidence that early routine ERCP significantly affected mortality or local/systemic complications of pancreatitis, regardless of predicted severity. However, among trials that included patients with cholangitis, the early routine ERCP strategy significantly reduced mortality and local and systemic complications. In addition, among trials that included patients with biliary obstruction, early routine ERCP strategy was associated with a significant reduction in local and systemic complications. Finally, they concluded that early

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ERCP should be considered only in patients with coexisting cholangitis or biliary obstruction. A systematic review [36] including 8 meta-analyses and 12 guidelines documents a consensus among them regarding indication for early endoscopic intervention is indicated only in ABP patients with coexisting cholangitis and/or persistent cholestasis. In addition, most recently, Schepers et al. [37] assessed urgent ERCP with sphincterotomy versus conservative treatment in predicted severe acute biliary pancreatitis without cholangitis in a multicenter RCT. They recorded no relevant differences in a composite of mortality or major complications (new-onset persistent organ failure, cholangitis, bacteremia, pneumonia, pancreatic necrosis, or pancreatic insufficiency) within 6 months between the groups (38% vs. 44%, $P = 0.37$).

In summary, urgent ERCP is not necessary in mild acute biliary pancreatitis. Moreover, it can also be avoided even in severe acute biliary pancreatitis when cholangitis or persistent cholestasis is not coexistent.

Cholecystectomy After Endoscopic Treatment

Recurrence rates of ABP of up to 61% have been reported in the absence of definitive treatment [38,39]. Therefore, subsequent cholecystectomy after endoscopic treatment of bile duct stones has been recommended to prevent recurrent attacks of ABP [40,41], although 25–50% of patients do not undergo cholecystectomy for various reasons [42–44]. The Dutch Pancreatitis Study Group assessed the timing of cholecystectomy after mild biliary pancreatitis in a systematic review including 8 cohort studies and 1 RCT (998 patients). In this cohort, cholecystectomy was performed during index admission in 48% of the cases and interval cholecystectomy was performed in 52% of the cases after a median duration of 40 days (interquartile range: 19–58 days). Before interval cholecystectomy, 18% of the patients were readmitted for recurrent biliary events such as pancreatitis, cholecystitis, and biliary colics. Therefore, cholecystectomy during index admission for mild biliary pancreatitis appeared safe [45]. Conversely, in cases of severe ABP, the current consensus is to postpone cholecystectomy until after resolution of local or systemic complications [39–41,46]. Most recently, the Dutch Pancreatitis Study Group assessed the optiomal timing of cholecystectomy after severe ABP (necrotizing biliary pancreatitis) in a post hoc analysis of a multicenter prospective cohort. It was found that the risk of overall recurrent biliary events prior to cholecystectomy was significantly lower up to 10 weeks after discharge (risk ratio [RR] 0.49, 95% CI 0.27 to 0.90, $P = 0.02$). The risk of recurrent pancreatitis before cholecystectomy was significantly lower up to 8 weeks after discharge. Therefore, they concluded that the optimal timing of cholecystectomy was within 8 weeks after discharge (RR 0.14, 95% CI 0.02 to 1.0, $P = 0.02$).[47]

Strategies for the Treatment of Pancreatic Pseudocysts and Walled-Off Necrosis After Acute Pancreatitis: Interventional Endoscopic Approaches

Georg Beyer and Julia Mayerle

Department of Medicine II, LMU University Hospital, Ludwig-Maximilians-University, Munich, Germany

Introduction

A series of trials following improvements in intensive care medicine and endoscopic techniques has led to a paradigm shift in the management of fluid collections developing after an attack of acute pancreatitis: if undertaken at all, interventions should be delayed as much as possible and the least-invasive method should be considered first, before escalating treatment (step-up approach) [1–3]. Intervening a post-acute pancreatic fluid collection (PFC) endoscopically is considered safe once a well-defined wall, then called WOPN (walled-off pancreatic necrosis) has developed, roughly 4 weeks into the disease course [4]. Immediate drainage of infected fluid collections is not superior to a delayed approach and with adequate antibiotic treatment, invasive procedures can often be avoided, as demonstrated by a Dutch multicenter trial (POINTER) [5]. Post-acute pancreatic pseudocysts are considered a rare complication arising from a disruption of the main pancreatic duct or major duct branches without considerable necrosis and by definition contain only fluid rich in pancreatic enzymes. In contrast, collections with a fibrous wall originating from pancreatic and/or peripancreatic necrosis are called walled-off pancreatic necrosis (WOPN), which will contain variable amounts of solid debris and may reach into areas distant from the gland [6].

Indications for Endoscopic Treatment

In general, only collections that cause symptoms or are at a high risk for severe complications require intervention. Indications for endoscopic intervention are features of infection on imaging or a high suspicion for infection with persistent signs of sepsis that do not improve under adequate antimicrobial treatment. Less common indications are pain, persistent unwellness, and failure to thrive, jaundice caused by the collection compressing the bile duct, bleeding and arterial pseudoaneurysms, disconnected duct syndrome, gastric outlet obstruction, or pancreatic fistulas.

Endoscopic Drainage vs. Necrosectomy: Choosing the Right Patient

It is currently unclear which collections will improve spontaneously or with conservative management, which require drainage, which need irrigation, and for which collections should a patient undergo advanced endoscopic necrosectomy, as reflected by discordant results of a recent international expert survey [4]. In many cases, patients will initially improve after a drainage procedure and optional nasocystic lavage with few plastic pigtail stents in place to ensure the patency of the tract. A systematic review and meta-analysis comparing 324 patients who underwent conservative management of infected pancreatic necrosis with 157 who underwent necrosectomy concluded that conservative management was successful in 64% and that mortality was lower than in patients who underwent percutaneous treatment [7] although this result is fraught by significant selection bias. Multiple early case series that included pancreatic necrosis and pancreatic abscesses even reported full resolution of these collections without further necrosectomy in over 80% of cases [8–10]. Unfortunately, a nonuniform nomenclature impairs the comparability of these observations. These findings are supported by a recently published Dutch multicentre trial [5]. Between 2015 and 2019, 104 patients with infected pancreatic necrosis occurring within 35 days from onset of symptoms were

randomized to either receive immediate percutaneous or endoscopic drainage with optional necrosectomy or a delayed approach with antibiotic treatment first and escalation to drainage and necrosectomy only if clinical deterioration occured. The median time difference to first invasive procedure between the treatment arms was 10 days and there was no difference with regard to complications, organ failure, or death. Patients in the delayed treatment arm had considerably fewer invasive procedures and were less often taken to necrosectomy. Notably, 39 % of patients in the delayed treatment arm did not require any invasive procedures at all, suggesting that immediate drainage, especially before encapsulation of a necritc collection, is not generally beneficial.

However, in patients who do not improve on conservative treatment alone or whose recovery stalls at a certain level, the question remains, how soon should one move from drainage to necrosectomy. A Swedish trial comparing drainage of pseudocysts to pancreatic abscesses with variable amounts of debris showed that the rate of successful drainage was lower in abscesses (94% vs. 80%; $P = 0.04$) and the risk for complications five times higher ($P = 0.02$). Of note, all abscesses underwent necrosectomy and lavage later [11]. This suggests that in patients with a higher burden of necrotic material and/or infected collections a more invasive approach may be warranted. The amount of solid debris is best assessed by EUS or MRI.

Transmural endoscopic necrosectomy has been shown to be a safe and efficient way to deal with necrotic collections accessible to endoscopy. It is equally safe and effective when compared to minimally invasive surgical approaches, but appears to be more cost-effective and leads less often to pancreatic fistulas [3,12]. It remains burdened, however, with serious complications even in the hands of experienced investigators [13–16]. In a retrospective comparison of conventional transmural drainage versus necrosectomy in patients with evidence of WOPN on contrast-enhanced computed tomography (CT), Gardner et al. showed superiority of direct necrosectomy in terms of treatment success, need for surgery or additional percutaneous drainage, and recurrence [17]. Another registry-based, matched cohort study comparing direct necrosectomy to initial percutaneous access as suggested by the original "step-up approach" in 12 patients showed favorable outcomes for the direct endoscopic approach [18]. Taken together, the current data suggest that mere endoscopic drainage is reasonable and often sufficient in defined collections with minimal amounts of solid material, whereas patients with WOPN and more extensive necrotic material will most likely profit from sometimes repeated sessions of endoscopic removal of necrotic tissue [19]. In unstable patients who develop sepsis due to infected WOPN requiring ventilator support and vasopressors, an initial endoscopic or even percutaneous drainage to achieve sepsis control and delayed more advanced endoscopic necrosectomy may be more appropriate. Endoscopic drainage is generally preferred over percutaneous drainage for infected fluid collections, but if drainage is required before a fibrous wall has formed (generally 4 weeks) percutaneous drainage is still a valid and frequently used alternative.

The introduction of through the scope, electrocautery-enhanced deployment devices for fully covered self-expandable lumen-apposing metal stents (LAMS), which allow efficient endoscopic drainage as well as necrosectomy through the same access route, have replaced the use of conventional double-pigtail stents for treatment of WOPN in many centers. Placement of LAMS is faster and comes at lower risk for stent dislocation and rupture of the wall of the collection. However, they bear a considerable risk for stent migration and delayed bleeding if left in place for more then 3 weeks (32.3% vs. 6.9%, $P = 0.01$) [20] and despite the larger diameter, they are not more effective with regard to resolution of WOPN when compared to conventional pigtails [21].

Due to shorter procedure duration for the initial placement and the option of through-the stent necrosectomy, many centers now use a dual approach: LAMS are used initially to allow for effective large-bore drainage and if needed endoscopic necrosectomy, but will be replaced by multiple pigtail stents later, when collections can be managed in an outpatient setting.

Preventing Recurrence by Treating Disconnected Duct Syndrome

A disconnected pancreatic duct with pancreatic juice leaking into the connected PFC is a major complication of acute pancreatitis and a well-known risk factor for persistence or recurrence of PFC. This includes pseudocysts and WOPN, even after initially successful endoscopic treatment [22,23]. The integrity of the pancreatic duct should therefore be confirmed whenever pancreatic necrosis requiring an intervention is present and preferably by noninvasive methods such as magnetic resonance cholangiopancreatography (MRCP). Although found in up to 50% of patients with acute necrotizing pancreatitis, studies on the optimal management of PFC associated with disconnected pancreatic duct syndrome are scarce. A small randomized controlled trial ($n = 28$) recruiting patients with and without disconnected pancreatic duct showed a significant reduction of recurrence (0 vs. 5, $P = 0.013$) when transmural stents were not removed [24]. The approach of long-term indwelling plastic stents has been adopted for the treatment of WOPN with disconnected pancreatic duct syndrome as reported in two

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. retrospective series including 26 and 33 patients, respectively, in which it appears to have led to a satisfactory outcome with regard to resolution of the collection [25,26]. Another approach involves stenting the pancreatic duct after transmural access and cavity stenting is established. This allows transpapillary drainage of both the content of the connected collection and, more importantly, pancreatic juice away from vital pancreatic tissue distal to the duct disruption [27]. ERCP should be performed with caution in these patients as it is associated with considerable rates of adverse events [28]. A small preliminary study by a group from Mumbai, India described a promising strategy in 42 patients with symptomatic post-acute pancreatic pseudocysts. Three weeks after initially successful drainage using an expandable covered nitinol stent, the patients underwent MRCP. A pancreatic duct leak was detected in three patients and treated successfully by stenting the pancreatic duct with consecutive retrieval of the transmural stent [29]. A larger retrospective study including 375 patients from the USA with different types of PFC compared the treatment success after transmural treatment alone with combined transmural and transpapillary access with no difference in long-term resolution (69% vs. 62%; $P = 0.61$). The presence of duct disruption was not routinely investigated [30]. It is due to these shortcomings in study design and the lack of prospective data that the optimal treatment of disconnected duct syndrome is still unknown, as highlighted by two recent meta-analyses [31,32]. Subject to the significant heterogeneity of the studies included, transpapillary drainage has so far not been shown to be superior to transmural approaches, but combination strategies or step-up management as suggested by Dhir et al. have not been studied. Of note, also surgical treatment such as cystgastrostomy or distal pancreatectomy are a viable option in selected cases.

Pseudocysts and Walled-Off Necrosis After Acute Pancreatitis: Surgical Approach

Naohiro Sata, Masaru Koizumi, and Alan Kawarai Lefor

Department of Surgery, Division of Gastroenterological, General and Transplant Surgery, Jichi Medical University, School of Medicine, Shimotsuke, Tochigi, Japan

Introduction

The strategy for surgical intervention in patients with pancreatic pseudocysts (PPC) and walled-off necrosis (WON) has dramatically changed in recent decades. In the early 1980s, open drainage and closed lavage were the most common surgical procedures performed for "pancreatic abscess." A more aggressive approach resulting in earlier surgical intervention, with more extensive drainage and debridement of associated necrotic tissue has been recommended [1]. However, early intervention including open necrosectomy is associated with poor outcomes and the latest guidelines suggest that surgical intervention should be delayed as long as possible, until at least 4 weeks after the onset of the illness [2,3].

Peripancreatic fluid collections are frequently seen in the management of patients with acute pancreatitis. Acute pancreatitis is divided into interstitial edematous pancreatitis and necrotizing pancreatitis [4]. In interstitial edematous pancreatitis, fluid collections are usually resorbed spontaneously and clinical symptoms are improved after a week. However, remnant localized fluid collections sometimes require intervention in patients with necrotizing pancreatitis. The terminology for these remnant localized fluid collections was changed completely in 2012, by the revised Atlanta classification [4]. This chapter will focus on surgical strategies for the treatment of patients with PPC and WON after episodes of acute pancreatitis.

Definition of Pancreatic Pseudocyst and Walled-Off Necrosis

In the Atlanta classification, advocated at the International Symposium on Acute Pancreatitis in Atlanta in 1992, acute fluid collections and pancreatic necrosis/infected necrosis were defined as local complications in the early stage of acute pancreatitis [5]. Additionally, PPC and pancreatic abscess are also defined as local complications in the late stage. The term "pancreatic pseudocyst" had been used to describe a wide spectrum of fluid collections derived from necrotizing pancreatitis, interstitial edematous pancreatitis, and acute exacerbations of chronic pancreatitis. Capsulized liquefied necrotic pancreatic and/or peripancreatic tissue after necrotizing pancreatitis should be considered to be different from a capsulized collection of pure pancreatic exocrine secretions. If the same treatment had been performed, the outcome would be different [6,7]. In fact, pancreatic abscess was seldom encountered in either Western countries or East Asia. Based on this background, the concept of "walled-off pancreatic necrosis" was proposed for an encapsulated fluid collection derived from necrotic pancreatic and/or peripancreatic tissue in patients with necrotizing pancreatitis [8]. The term was changed to "walled-off necrosis" (WON), and the concept of this condition was then established by the revised Atlanta classification in 2012 [4] (Fig. 34.1). WON is defined as a mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall and usually occurs more than 4 weeks after the onset of necrotizing pancreatitis [4]. Fluid collections originating from necrosis less than 4 weeks after the onset of necrotizing pancreatitis is referred to as an acute necrotic collection (ANC). The concept of a pancreatic pseudocyst (PPC) was proposed to be limited to an encapsulated collection of fluid with a well-defined inflammatory wall, usually outside the pancreas, with minimal or no necrosis that occurs more than four weeks after the onset of interstitial edematous pancreatitis [4,9]. As the concept of PPC changed and the new concept of WON was developed in

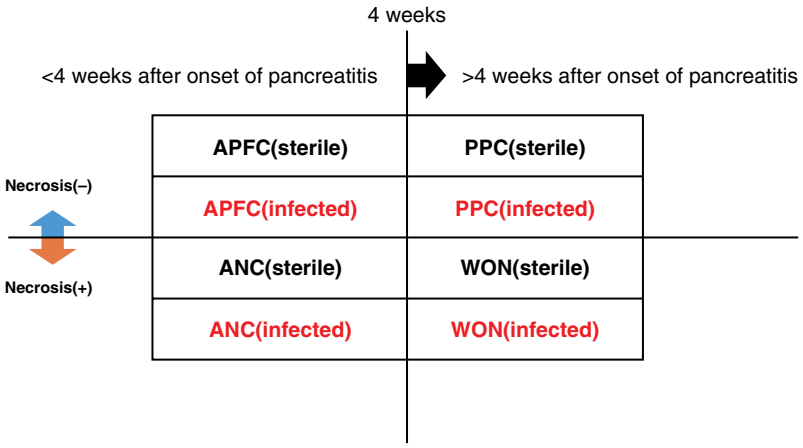

Figure 34.1 Eight categories of local complications of acute pancreatitis defined by the revised Atlanta classification of 2012. APFC: acute peri-pancreatic fluid collection; ANC: acute necrotic collection; PPC: pancreatic pseudocyst; WON: walled-off necrosis.

2012, care must be taken to avoid confusion regarding the terms PPC and WON, especially when reviewing clinical studies reported before 2012.

The International Association of Pancreatology and the American Pancreatic Association (IAP/APA) guidelines were revised according to the revised Atlanta classification of 2012, and the IAP/APA evidence-based guidelines for the management of acute pancreatitis were published in 2013 (IAP/APA guideline 2013) [2]. At the same time, Japanese guidelines for the management of acute pancreatitis were revised and the fourth and the fifth editions were published in 2015, 2021 (JPN guidelines 2015, 2021) [3]. The diagnosis and treatment of acute pancreatitis should be based on these guidelines.

Indications for Surgical Intervention

Previously, surgical intervention with drainage and necrosectomy, was the gold standard for treatment of the infectious complications of acute pancreatitis. In the early 2000s, minimally invasive interventions were developed and have been replacing highly invasive surgical procedures such as open drainage. Minimally invasive interventions include procedures such as endoscopic and laparoscopic drainage and necrosectomy. Both the IAP/APA guideline 2013 and the JPN guidelines 2015, 2021 recommend that interventions should be performed in patients with infections or other persistent symptoms, such as ongoing gastric outlet, intestinal, or biliary obstruction, pain, or complications due to a mass effect secondary to WON or PPC. Most patients with infected localized fluid collections that cannot be managed by the administration of wide-spectrum antibiotics will require some therapeutic intervention.

The terminology for drainage and necrosectomy should be appropriately used. Drainage is a procedure to drain fluid by percutaneous, transgastric, enteral, or transpapillary routes, or by open surgery. Necrosectomy is a procedure to remove necrotic tissue aggressively, using percutaneous, transgastric, or enteral approaches, or by open surgery. Confusion regarding the terminology for drainage and necrosectomy procedures must be considered when evaluating clinical studies reported before 2012.

Timing of Interventions and Optimal Interventional Strategy for WON

In the past, outcomes following early invasive surgical interventions were very poor [10–12]. In a prospective study of 629 patients, late intervention significantly decreased mortality and morbidity [13]. Both the IAP/APA guideline 2013 and the JPN guidelines 2015, 2021 refute the beneficial therapeutic effect of early intervention and recommend that intervention should be delayed as long as possible, until at least 4 weeks after the onset of pancreatitis [2,3]. Interventions should be performed when fluid collections are encapsulated, and the capsule wall is thickened.

The optimal interventional strategy is still controversial. Open surgery was the only choice for intervention before 2000. Minimally invasive interventions, including endoscopic drainage and necrosectomy, and laparoscopic necrosectomy, were introduced in the late 1990s and early 2000s. Though the use of these novel interventions has been increasing, they require advanced technical skills and should be done only in high-volume centers. Some centers reported good results, although there is a large variation in expertise in performing these novel interventions among centers. Further assessment is necessary for these interventions to become standard approaches.

The Dutch Pancreatitis Study Group proposed a step-up approach for the treatment of patients with suspected

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

or confirmed infected necrotizing pancreatitis [14]. The step-up approach is composed of two parts, including initial image-guided percutaneous (retroperitoneal) catheter drainage or endoscopic transluminal drainage followed by endoscopic or surgical necrosectomy. Percutaneous catheter drainage alone is reported to reduce the necessity for necrosectomy in 23–50% of patients with infected necrotizing pancreatitis [2,14–19]. Additionally, the step-up approach is reported to decrease major short-term and long-term complications and reduce overall costs compared to conventional surgical necrosectomy [14]. At present, the step-up approach is thought to be the most effective approach and both the IAP/APA guideline 2013 and the JPN guidelines 2015, 2021 clearly recommend it as the optimal interventional strategy [2,3]. The IAP/APA guideline 2013 also states that no subgroup of patients requiring a different strategy can be defined, and the optimal method of necrosectomy (i.e., surgical or endoscopic necrosectomy) is unclear if catheter drainage fails [2].

Catheter drainage is always the first step for intervention in patients with local infectious complications of necrotizing pancreatitis. Less-invasive procedures, such as percutaneous drainage guided by ultrasonography or computed tomography, and endoscopic transluminal drainage are the initial recommendations [13–16] (Fig. 34.2). Surgical drainage with a small incision is indicated in patients for whom percutaneous or endoscopic approaches are contraindicated or fail. Multi-loculated cysts, multiple cysts, presence of significant necrotic debris, cysts in the pancreatic tail and uncontrolled hemorrhage are also indications for surgical drainage. If catheter drainage fails to control infection, minimally invasive or open surgery or endoscopic transluminal necrosectomy are the next steps [20,21].

Laparoscopic and video-assisted retroperitoneal debridement (VARD) have become new choices for a second-step intervention [14]. The results from 14 recent series of percutaneous drainage for necrotizing pancreatitis indicate a 19.4–26.4% conversion rate from percutaneous drainage to surgical drainage, with a 15.2–21% mortality rate [14,22–34]. The results from 18 recent series of surgical necrosectomy indicate the need for additional necrosectomy in 10–16.5%, additional drainage in 13–13.8%, and an overall 1.7–25.8% mortality rate [35–52]. However, the step-up approach has better outcomes. The results from 10 recent series report a 17.4% conversion rate to the surgical approach with a 9.1–14.9% mortality rate [14,36,43–59]. Recently, robot-assisted transgastric cyst-gastrostomy, robot-assisted transgastric drainage and debridement of WON were reported as new minimally invasive surgical treatment [60–62]. Bleeding, pancreatic fistula and gastrointestinal fistula are frequent complications of these interventions.

Surgical Intervention for PPC

Since acute exacerbations of chronic pancreatitis are a leading cause of PPC, the strategy for the treatment of PPC should be different from that used for WON. Most small PPC spontaneously regress without specific interventions. Evidence of infection or persistent symptoms are a common indication for intervention in patients with PPC (Fig. 34.3). External or internal drainage is the first choice for infected PPC, and other novel interventions have been developed

Figure 34.2 Computed tomography scan findings of infected walled off necrosis on the 170th day after the onset of necrotizing pancreatitis. Air bubbles were observed in the area of walled-off necrosis located in the lesser omentum, which strongly suggests the presence of infection.

Figure 34.3 Computed tomography scan findings of a pancreatic pseudocyst. The pancreatic pseudocyst resulted from an acute exacerbation of chronic pancreatitis and is located in the left subphrenic space.

and evaluated clinically. Open cyst-enterostomy (i.e., cyst-gastrostomy or cyst-jejunostomy) is often used with a reported 15.9–25.4% morbidity and 0.2–0.4% of mortality in six recent retrospective series [63–68]. Laparoscopic cyst-enterostomy, a minimally invasive approach, is becoming more common and performed by various methods, including a Roux-en-Y anastomosis and intra-gastric procedures [69–76]. The laparoscopic procedure has good outcomes, with 9.5–26.9% morbidity, 3.6% PPC recurrence, and 0% mortality in eight recent series [69–77]. Percutaneous cyst-gastrostomy, draining the PPC via both percutaneous and transgastric routes with a gastroscopic procedure, is feasible with 11.3% morbidity and 9.4% requiring an additional surgical cyst-gastrostomy [14,78–80]. Robot-assisted cyst-enterostomy for PPC has not been reported. Bleeding, abdominal abscess including cyst infection, pancreatic fistulae, and surgical site infections are common complications of surgical procedures for PPC [63–77]. Pancreatectomy, distal pancreatectomy, pancreaticoduodenectomy, or duodenum-preserving pancreas head resection, are indicated in some patients with a PPC and persistent chronic pain [67].

Management of Fluid Collection in Acute Pancreatitis

Georg Beyer[1], Simon Sirtl[1], Christoph Ammer-Herrmenau[2], and Albrecht Neesse[2]

[1]*Department of Medicine II, LMU University Hospital, Ludwig-Maximilians-University, Munich, Germany*
[2]*Department of Gastroenterology, Gastrointestinal Oncology and Endocrinology, University Medical Center Göttingen, Gottingen, Germany*

Introduction

Acute pancreatitis is the most common cause for hospitalization in gastroenterology and has an incidence of 13–45/100,000 with regional variations [1,2]. Alcohol and gallstones are the main risk factors (30–50%) with alcohol as an etiology being more common in men [3].

Considering the variety of different courses of pancreatitis, ranging from mild abdominal pain to death, it is important to predict the likely severity of the disease early in the clinical course.

The current definition of acute pancreatitis, the grades of severity (mild, moderately severe, and severe), and the detailed description of the systemic and local complications based on the revised Atlanta classification from 2012 [4] are discussed in Chapter 20.

Definitions

The way acute fluid collections are classified depends on the time frame of their development as well as some morphological imaging features. The acute (peri-)pancreatic fluid collection (APFC) is a typical complication of the interstitial and edematous subtype and often develops during the first 7 days of pancreatitis. It has no wall and a homogenous internal structure. The spread of an APFC is orientated along the fascial anatomy. Occasionally, APFC are found in multiple locations and they tend to regress spontaneously. If an APFC persists for longer than 4 weeks there is a high probability that a pseudocyst or walled-off pancreatic necrosis (WOPN) will develop.

A pseudocyst is defined as a fluid-filled space, similar to a neoplastic cyst, with a fibrotic wall. In contrast to neoplastic cysts, pseudocysts have no internal epithelial cell lining. Pseudocysts are considered merely complications of chronic pancreatitis and occasionally of acute pancreatitis. Following the latter they evolve from APFC usually later than 4 weeks after the onset of symptoms. The treatment strategies of pancreatic pseudocysts are described in Chapter 3.23.

Regions of nonvital tissue damaged by hemorrhage extravasated pancreatic juice or immune cells are defined as necrosis. It represents a form of tissue injury resulting in premature nonapoptotic cell death. The morphological characteristics of necrosis caused by acute pancreatitis are highly variable. The necrotic tissue may appear as a (semi)solid or fluid structure on imaging, although the sensitivity for detecting the solid component varies greatly between computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasound (EUS) [5].

An acute necrotic collection (ANC) arises within the first 4 weeks of the disease in the pancreatic parenchyma as well as the extrapancreatic tissue. It contains varying amounts of fluid or solid material. The solid parts are the crucial feature to distinguish an ANC from an APFC or a pseudocyst [4] as illustrated in Fig. 35.1.

If a necrotic area is enclosed by a radiologically distinguishable capsule it is called walled-off pancreatic necrosis (WOPN). The difference between WOPN and a pseudocyst is the presence of variable amounts of solid content in the cystic cavity. Usually it arises from an ANC later than 4 weeks from the onset of pancreatitis. Contrast-enhanced MRI and EUS are best suited to distinguish solid from liquid contents, but in most cases contrast-enhanced multiphase CT or even contrast-enhanced ultrasound will enable the diagnosis to be made [3,5].

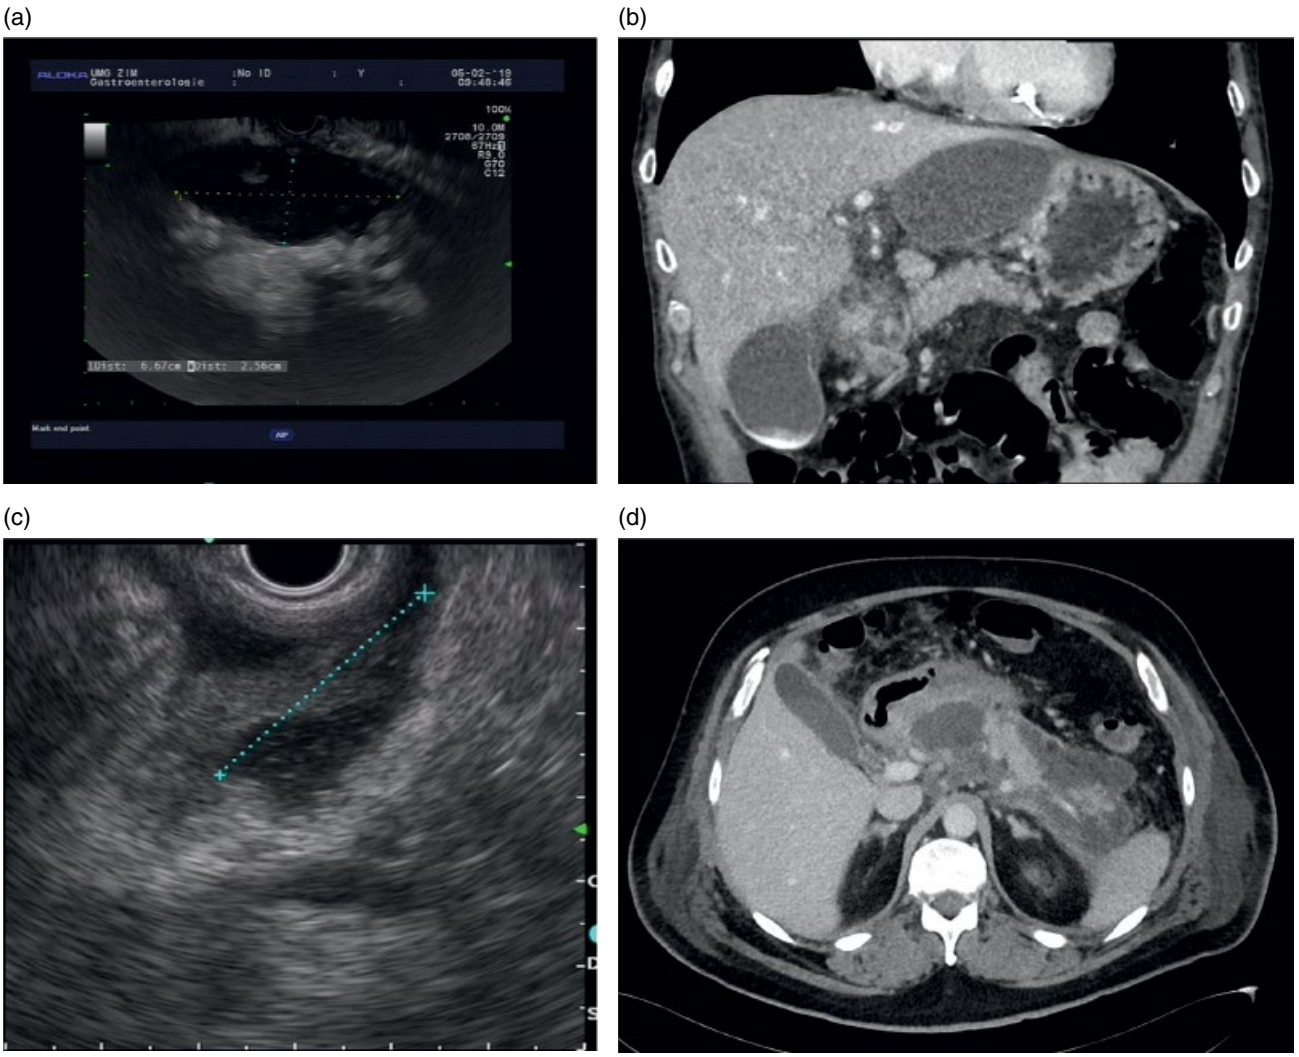

Figure 35.1 Examples for the occurrence of acute pancreatic fluid collections (APFC), post-acute pancreatic pseudocysts (PP), acute necrotic collection (ANC), and walled-off pancreatic necrosis (WOPN) on imaging. The upper panels depict an APFC on EUS (a), which later developed into a large, but oligo-symptomatic pseudocyst (b), demonstrated on a CT scan. The reader will appreciate the absence of solid debris within the collection. In contrast, the lower panel shows an ANC on EUS (c), which matured to a WOPN. On both images, the solid content is clearly visible. The CT scan (d) was obtained prior to percutaneous drainage of the collection, which was necessary due to infection.

An originally sterile necrosis can maintain its status or become infected over the course of the disease. The diagnosis of infected necrosis is based on the patient's clinical presentation and the presence of gas in the necrotic cavity on radiological imaging. It is of note that an asymptomatic fistula from the necrotic cavern to the gastrointestinal tract also leads to the presence of gas within the necrosis but can be without any signs of infection. Fine-needle aspiration followed by microbiological analysis of the content can confirm the presence of infected necrosis but is not needed in most cases and has a high false negative rate. Moreover, microorganisms isolated from the blood of patients with the clinical presentation of an infection or signs of an infected necrosis on imaging are of greater relevance for choosing appropriate antibiosis than those isolated from cultured content of the necrotic cavity. Other than the extent, there are currently no features by which to predict whether necrosis will persist or regress over weeks and months.

Imaging of Acute Fluid Collections

Transabdominal Ultrasound

Transabdominal ultrasound is an inexpensive, immediately available technique to allow a first imaging impression of a patient with an acute abdomen. The imaging of the pancreatic gland is often impaired by abdominal pain and an atonic gut. Edematous pancreas is characterized

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. by an inhomogeneous, hypoechoic structure with poorly defined boundaries [6]. The pancreatic main duct is often not visualized inside the edema. Necrotic and hemorrhagic tissue appears more hypoechoic than the inflamed parenchyma. The echo contrast gain or use of ultrasound contrast agent permits a somewhat better distinction between vital or nonperfused tissue. For the detection of small amounts of free fluids in the abdominal or pleural cavity ultrasound remains the undisputed gold standard. The presence of ascites or the mostly left-sided pleural effusions are predictors for a more severe course of acute pancreatitis. Another domain of sonography is the fast and reliable imaging of the gallbladder and, if present, gallstones, which can confirm or rule out a biliary pathogenesis and detection of pleural effusions, which indicate poor prognosis [7]. In expert hands, transabdominal ultrasound with optional contrast enhancement is equally accurate as CT in detecting necrosis, vascular involvement, and severity grading [8–12].

Computed Tomography Endoscopic Ultrasound, and Magnetic Resonance Imaging

Contrast-enhanced CT scan is the fastest and most accurate method for the differential diagnosis of an acute abdomen. At hospital admission CT scan is not recommended for patients with clinical confirmed acute pancreatitis unless other differential diagnosis cannot be ruled out. Imaging via CT should not be performed to assess the severity of pancreatitis on admission [13], because the extent of necrosis can still evolve until up to 72 hours after the disease onset. Therefore, a CT scan should be delayed, if required at all, for 4 days after symptom onset [3,14].

Contrast-enhanced CT can confirm the size, shape, and volume of fluid collections or necrosis and is a valuable tool to identify extrapancreatic complications including hemorrhage or pseudoaneurysms.

Two alternative methods are EUS and MRI. Despite having cost and procedural disadvantages, both methods are more sensitive in detecting solid content within a fluid collection and thus in distinguishing between plain fluid collections and pseudocysts on the one hand and areas of necrosis and WOPN on the other [5]. For more details Chapters 25 and 3.23 are recommended.

Conservative Treatment of Pancreatitis and Pancreatic Fluid Collections

Basic Support

All patients with acute pancreatitis should be monitored regularly within the first 48 hours after admission [3,15]. Important parameters include:

- heart frequency, 6-lead ECG, blood pressure, respiratory rate and oxygen saturation (to detect circulatory respiratory failure and shock);
- blood gas analysis (in case of oxygenation <90%) (to detect respiratory failure) and lactic acidosis;
- hourly urinary excretion measurements for the management of fluid resuscitation (for fluid management and to detect renal failure);
- abdominal pressure measurement via bladder pressure measurement (to detect compartment syndrome) if clinically suspected;
- blood electrolytes;
- blood glucose levels (to detect endocrine failure).

Fluid and Electrolyte Management

Due to retroperitoneal edema and increased vessel permeability a massive fluid shift is typical for acute pancreatitis leading to APFC. Fluid resuscitation is currently the most important intervention for reducing incidence of necrosis and patient mortality [16]. Mortality can increase to 61% if less than 3.5 L of fluid are transfused in the first day. An increase of blood urea nitrogen (BUN) of 5 mg/dL within 48 hours is a sign of prerenal kidney failure and increases mortality by a factor of 2.2 [17,18]. The recommended amount of fluid is 5–10 mL/kg body weight/h or 200–250 ml/h for the first day of treatment [16], or even less, as shown by a recent randomized trial comparing aggressive to moderate fluid resuscitation, which was stopped due to increased rate of fluid overload in the aggressive treatment arm (20.5% vs. 6.3%, p=.004) [33]. Greater therapeutic fluid volumes lead to a mortality increase partially due to abdominal compartment syndrome (intra-abdominal pressure >20 mmHg), sepsis, or a prolonged stay in the intensive care unit [19]. The monitoring of fluid resuscitation should use either invasive thermodilution techniques or, if unavailable, the following parameters:

- heart frequency <120 bpm;
- mean arterial pressure between 65 and 85 mmHg;
- urinary excretion >0.5–1 mL/kg per hour;
- hematocrit between 35 and 45%.

Another important point is the composition of administered fluid. Crystalline solutions are superior to colloids. Colloidal infusions are suspected of being associated with a higher incidence of renal insufficiency and should be avoided. The advantage of Ringer's solution is its similar composition to blood as well as the nonimpairment of electroneutrality by compensating the anion gap with lactate or acetate. Moreover, the incidence of systemic inflammatory response syndrome (SIRS) is reduced within the first 24 hours if Ringer's solution is used rather than saline [20].

Nutrition

Complete fasting has no positive influence on the outcome and course of pancreatitis [21]. In fact, fasting leads to atrophy of gut villi resulting in a more rapid translocation of intraluminal bacteria, facilitating the infection of necrotic areas. Starting enteral nutrition early is recommended [22]. If the patients are not able to take oral food, feeding by tube is the most effective method. Nasogastric and nasojejunal tubes have been shown to be equally effective and safe [23], although nasojejunal feeding tubes tend to dislocate more often. The best and most natural form of nutrition remains eating by mouth. Once patients are pain-free (with pain medication if required) and can tolerate food they should take oral food. If not enteral nutrition is less expensive and more physiologic than parenteral nutrition. Starting enteral nutrition immediately after admission was not found to lead to better outcomes than withholding food for 72 hours [24]. The current approach to nutrition has become much more pragmatic than in the past when all patients were put on nil-by-mouth for long periods. There is no role for a specific pancreatitis diet.

Antibiotics

Prophylactic application of antibiotics is not necessary for patients with acute pancreatitis, regardless of its predicted severity, and could contribute to the rise of multiresistant bacteria. Neither the mortality nor the rate of infected necrosis is positively influenced by prophylactic antibiotics [17]. Conversely, if infected necrosis is suspected, antibiotic therapy must be initialized immediately. Antibiotics with appropriate pancreatic tissue levels are carbapenems, fluorochinolones, or metronidazole. If the response to the administered antibiotics is insufficient, fine-needle aspiration followed by microbiological testing allows switching to antibiotics based on resistograms. In patients with sepsis other infectious foci must be considered, such as peritonitis, cholangitis, or pneumonia. In general, microbes sampled from blood cultures of pancreatitis are often more informative than those from necrotic fluid collection because of the high rate of false negatives among the latter.

Management of Edematous Fluid Collections

An APFC tends to regress spontaneously. If it persists longer than 4 weeks under conservative treatment it may develop into a pseudocyst or WOPN. Simple intra- or extrapancreatic fluid collections, the focus of this chapter, generally do not require interventional treatment unless they give rise to compartment syndrome as characterized by fluid overload and elevated urinary bladder pressure. An abdominal compartment syndrome is defined as an increased abdominal pressure (>20 mmHg) for longer than 12 hours and simultaneous organ failure [25].

Minimally Invasive Treatment of Acute Fluid Collections in Acute Pancreatitis

When conservative management is unsuccessful, minimally invasive treatment is recommended. The following sections give an overview about the different modalities.

Imaging-Guided Percutaneous Drainage

This is a technically easy and well-established method to treat pseudocysts or fluid collections. Ultrasound, CT, or MRI can be used for imaging. Although single-step needle aspiration is associated with a high relapse rate, continuous catheter-drainage systems are recommended based on their high success rate (70–100%) and a low recurrence rate[26,27]. The risk of fistula formation must be considered.

Endoscopic Drainage

This method provides a minimally invasive access for draining a pseudocyst. Transpapillary and transmural approaches from the stomach or duodenum are available. The aim is to create an artificial connection between the cyst cavity and the gastrointestinal tract. For pseudocysts communicating with the pancreatic main or branch duct transpapillary techniques are to be considered [28]. However, the superiority of transpapillary vs. transmural drainage in these cases has not been established. A larger retrospective study including 375 patients from the USA with different types of PFC compared the treatment success after transmural treatment alone with combined transmural and transpapillary access with no difference in long-term resolution (69% vs. 62%; $P = 0.61$). The presence of duct disruption was not routinely investigated [29]. Therefore, a step-wise diagnostic approach with duct assessment via MRI for cases with suspected duct disruption might be more promising [30].

In the authors' view endoscopic transmural drainage is recommended for cysts that do not communicate with the pancreatic ductal system. Based on a better visualization of vessels EUS-guided drainage is associated with a lower complication rate than the endoscopic technique without EUS visualization and the latter should be abandoned [3,14,31].

For the treatment of pseudocysts with a location distant to gastric lumen and with a thick fibrotic capsule a laparoscopic approach should be favored. In Chapter 3.23 the strategies for surgical and endoscopic interventions for pancreatic pseudocysts, infected necrosis, and WOPN are outlined and discussed in detail.

Conclusion

Fluid collections that arise in the context of acute pancreatitis generally regress under conservative treatment and do not require interventional treatment in most cases. They may require endoscopic or surgical treatment when they fulfil the morphological criteria of infected (walled-off) necrosis, when they represent complication-causing or complication-prone pseudocysts, or when they precipitate abdominal compartment syndrome. As supported by the results of the Dutch POINTER trial, an initial conservative approach is justifiable: 104 patients with infected pancreatic necrosis occurring within 35 days from onset of symptoms were randomized to either receive immediate percutaneous or endoscopic drainage or a delayed approach with antibiotic treatment first and escalation to drainage and necrosectomy if clinically needed. There was no difference with regard to complications, organ failure, or death. Patients in the delayed treatment arm had considerably fewer invasive procedures and were less often taken to necrosectomy. Notably, 39% of patients in the delayed treatment arm did not require any invasive procedures at all [32].

[2]*Department of General, Visceral and Thoracic Surgery, University Hospital Hamburg-Eppendorf, Hamburg, Germany*

Introduction

A pancreatic fistula is defined as a leakage of pancreatic juice as a result of disruption of pancreatic ducts or parenchyma. During severe acute necrotizing pancreatitis—besides the systemic SIRS, or sepsis associated consequences—the management of local complications plays a major role. Local complications include infected necrosis, and pancreatic absesses which cause destruction of the pancreatic parenchyma and eventually small or larger ducts, leading to a leakage of pancreatic enzyme-rich fluid. This can either provoke the formation of pseudocysts, or—in case of arrosion of surrounding structures—the onset of a fistula. In most cases parenchyma or duct leakages are self-limiting and can be covered by the surrounding organs, reabsorbed by the serosa, or encapsuled by a fibrous pseudowall with the sequela of a pseudocyst [1]. In case of acute fistula-associated complications, including arrosional bleeding or bowel perforation, immediate interventional and surgical treatment is required, including angiographic bleeding localization and management (i.e., stent placement in the arroded vessel) or emergency surgery. However, if pancreatic fistula does not cause acute complications, a continous leakage may occur and require therapy that needs to be adapted to the site and clinical symptomatology of the fistula. In this context, internal fistulas to the gastrointestinal tract, bronchi, pleural, mediastinal space, pericardium, and other organs [2–4] have to be differentiated from external—cutaneous—fistulas. As internal fistulas are often clinically asymptomatic, they are more difficult to diagnose and may not immediately be detected [5]. By contrast, external fistulas are more often observed, and can be easily diagnosed through the analysis of pancreatic enzyme content in the fluid [5,6].

Pathogenesis and Classification

Pathogenesis

The pathogenesis of pancreatic fistulas is multifactorial and seems to differ according to the site of origin of the fistula and to the time-point when it occurs. On the basis of the necrotizing process in the pancreas, the peripancreatic fat and soft tissue as well as the retroperitoneal space during severe acute pancreatitis, a widespread induction of autodigestion, with interaction between pancreatic exocrine enzymes and inflammatory mediators [7]. Pancreatic parenchyma necrosis is understood as a consequence of oxidative stress and potential calcium overload, leading to a combination of necrosis, apoptosis, pyroptosis and autophagy, in which damage-associated molecular pattern molecules (DAMP) play a central role. Microvascular perfusion failure, as a consequence of local thrombosis and inflammation, contributes to formation of necrosis. Following parenchyma necrosis, proteases and the entire spectrum of all other activated pancreatic enzymes are released into the retroperitoneum and an autodigestive process is initiated. Local leukocyte recruitment and further activation of inflammation favor the necrotizing process throughout the peripancreatic region and the retroperitoneum, toward the mesocolon, small bowel mesentery, and paracolic retroperitonal gutters. The autodigestive process may extend to the skin, bowel, or any other organs. In addition, the development of colonic fistulas during acute pancreatitis can be a consequence of colonic wall necrosis due to venous ischemia (e.g., following mesenteric thrombosis) or arterial infarction as a consequence of systemic hemodynamic instability in

the hyperacute phase. In the end, iatrogenic fistula can be produced during intraoperative manipulation or endoscopic treatment.

Classification

Pancreatitis-associated fistula can be defined as an abnormal communication between the ductal pancreatic systems, and other spaces or organs due to the leakage of pancreatic secretions from damaged pancreatic ducts [8]. In contrast to postoperative pancreatic fistulas, there is no grading system for fistulas associated to acute pancreatitis [9]. Pancreatitis-associated fistulas can be classified into internal and external fistulas. If their orifice is located intracorporally—regardless of the organ or structure affected—they are classified as internal fistulas; in case of a connection to the skin, the fistula is defined as external. External fistulas can be classified as low- or high-output fistulas, according to the daily cutoff of 200 mL [10]. Further characterization of fistulas includes description as simple (straight channel from the pancreas toward the skin or another organ) or complex (multiple channels and tracts to different organs or structures). Moreover, the fluid can be characterized as clear pure pancreatic juice (due to external drainage of a pseudocyst communicating with the pancreatic duct) or as mixed (consisting of pancreatic juice in combination with gastrointestinal secretions or bile). In the latter case, the pancreatic juice might be activated by enterokinase, leading to proteolytic effects of the fluid and a more severe injury. Finally, the unfortunate event of disruption of the main duct can give rise to a persistent pancreatic fistula, in the so-called "disconnected pancreatic duct syndrome" [11].

Diagnosis

External Fistulas

The vast majority of external fistulas form along the tract of interventional or surgically placed drainages that are inserted to treat the complications of pancreatic necrosis. They can easily be recognized by their typical rich content of amylase and lipase. As mentioned earlier, there is no standard defined cutoff for the increase in pancreatic enzyme, amount of fluid, or duration of secretion. To differentiate between simple and complex fistulas radiological imaging should be performed. Conventional fistulography, computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), and endoscopic retrograde cholangiopancreatography (ERCP) are the most described [12–15]. CT scan is the gold standard in the diagnosis and classification of acute pancreatitis and its complications, namely abscesses, pseudocysts, and walled-off infected necrosis [8]. However, CT scan shows a lower accuracy in fistula detection compared with MRI/MRCP imaging. Conventional fistulography is useful to determine potential connections to other organs (i.e., colon), and ERCP has the advantage of providing simultaneous diagnostic and therapeutic possibility, namely the placement of a pancreatic stent in cases of pancreatic duct disruption (Fig. 36.1).

Internal Fistulas

Internal pancreatic fistulas are mostly asymptomatic, and may be difficult to recognize. In case of persisting ascites and/or a pleural effusion an internal fistula should be ruled out. In rare cases also acute mediastinitis arising from a pancreato-mediastinal fistula can be observed [16]. Unfortunately, unrecognized internal fistulas can lead to life-threatening conditions, if the activation of pancreatic enzymes leads to arrosional bleeding or bowel perforation [17]. Once an internal fistula is suspected, further imaging work-up needs to be tempestively done. CT scan remains the gold standard for diagnosis and treatment, and the biochemical analysis of collected fluid can confirm the suspected diagnosis [18,19]. For internal fistulas, MRCP or ERCP can be useful for the diagnosis and as well as ERCP for ultimate treatment [20].

Surgical Treatment

The treatment of pancreatits associated fistulas refers mainly to the international guidelines for the management of severe acute pancreatitis [8,21–24]. Supportive care management, namely adequate fluid resuscitation, pain control, nutritional support, and antibiotic treatment in cases of infected necrosis are the recommended strategies. In cases of failure of the conservative treatment, either due to organ compression from a fluid collection, or to persistent systemic infection, the so-called "step-up approach" is recommended, involving first of all an endoscopic attempt, followed by radiologic effort and, in case of failure of the first two, leading to a surgical minimally invasive or open intervention [25].

Open surgery in acute pancreatitis is no longer a gold standard in acute pancreatitis and should be cautiously evaluated just for those patients in whom all other options were not successful. However, a short overview on classical surgical approaches is mandatory [26]. The historically used open surgical techniques are the necrosectomy combined with open packing [27], the planned staged relaparotomies with repeated lavage [28], the placement of "kissing-drains" in the lesser sac and closed continuous lavage [29,30], and the closed packing [31], with mortality rates of up to 15% in referral centers [27,32–34]. In the first two techniques several consequent re-laparotomies are mandatory in order to achieve a satisfactory debridement of necrotic tissues.

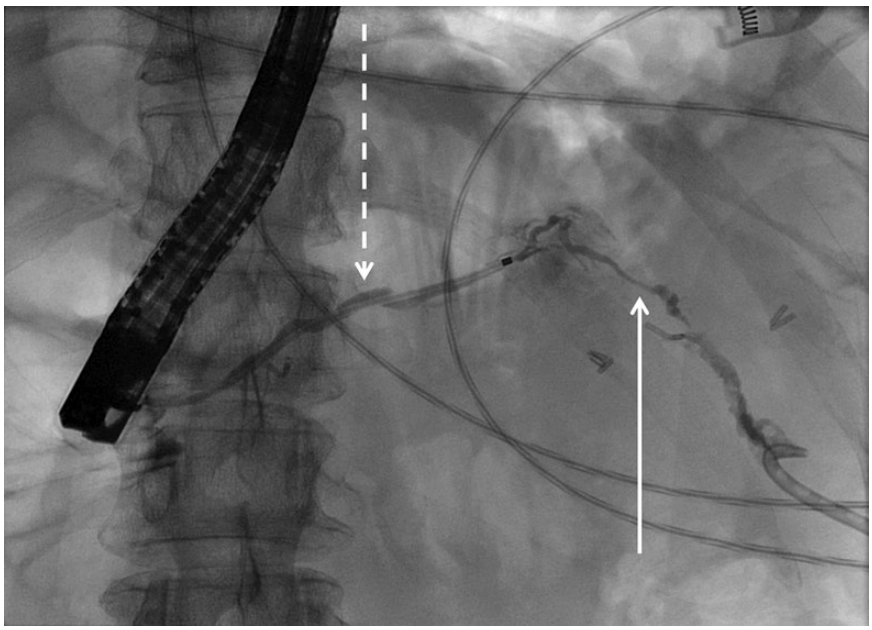

Figure 36.1 Internal pancreatic fistula to the retroperitoneal space after severe necrotizing pancreatitis. Endoscopic retrograde cholangiopancreatography (ERCP) showing the pancreatic duct (broken white arrow) and the leakage with contrast medium extravasation (white arrow).

The last two, conversely, allow a progressive and continuous lavage of the necrotic region, without the need of subsequent surgeries. As the mortality rate and the risk of following injuries increases with the number of relaparotomies, the last two techniques should be preferred.

Drain Management

Once a pancreatitis-associated fistula is diagnosed, the amount and duration of drain in place are related to the size of the involved duct (main duct or branches of first, second, or third order), the localization of duct rupture (head, body, or tail of the pancreas), and the functionality of the sphincter of Oddi. In the acute phase of the disease, edema or spasm of the sphincter of the papilla may impair outflow, leading to increased pressure within the ductal system and subsequent rupture of the duct or maintenance of the outlet via the fistula. Once outflow via the papilla is restored, secondary to resolution of either the edema or spasm, spontaneous healing of the fistula can be observed in most cases.

Management of Internal Fistulas

Most fistulas (80–100%) close spontaneously within 2–3 months [35]. Failure to heal is mainly due to larger defects of the pancreatic duct system, resulting in high-volume output. Endoscopic trangastric drainage, or surgical treatments should be considered. The surgical approach to internal fistulas focuses mainly on treatment of the underlying disease, as once infected necrosis is treated adequately, internal fistulas will close rapidly [36,37]. As suggested in international guidelines, the surgical approach is indicated only after failure of all conservative strategies and should be deferred at least for 4 weeks after the onset of acute pancreatitis.

The choice of treatment depends on the characteristics of the patient and the fistula, and comprises several drainage techniques. Endoscopic transmural drainage and percutaneous drainage (Fig. 36.2) have become the procedures of choice in cases of internal fistula with symptomatic pseudocyst formation [38]. Furthermore, endoscopic sphincterotomy with or without transpapillary stent placement facilitates the drainage of pancreatic juice into the duodenum and can consequently release pressure from the disruption site. This accelerates the healing and may even allow the closure of partially disrupted pancreatic ducts within a median interval of 10 days [39-41]. In case of severe damage and disconnected pancreatic duct syndrome endoscopic treatment cannot be sufficient. An early surgical treatment may be considered after initial drainage of a fluid collection by endoscopic therapy. Surgical treatment (i.e., central pancreatectomy or distal pancreatectomy) has a long-term success rate of approximately 90%; however, atrophy of the pancreatic gland is a frequent and early complication after disrupted duct syndrome, leading to chronic pancreatits and diabetes in up to 30% of cases [42].

Management of External Fistulas

Simple fistulas do not necessarily lead to complications; therefore, a conservative management should be pursued. Complex fistulas are more likely to develop

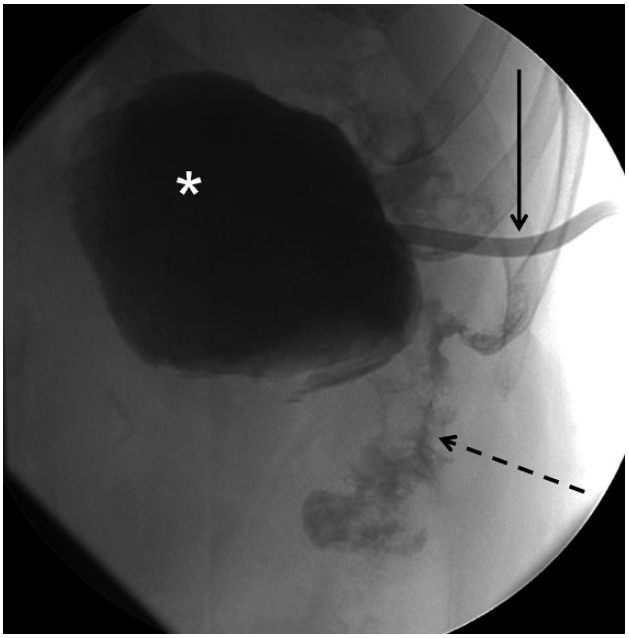

Figure 36.2 Internal pancreatic fistula during severe necrotizing pancreatitis. X-ray after percutaneous catheter drainage (black arrow) of a large fluid collection (white star). Transition of contrast medium to the descending colon (broken black arrow).

dangerous complications because of high risk of free activation of pancreatic enzymes in the abdominal cavity and digest surrounding structures. The aim of surgical therapy of external pancreatic fistulas is to redirect the drainage into the intestinal tract [43]. The surgical procedure chosen is based on the site of the fistula, the thickness and nature of the fistula tract, as well as the texture of the pancreatic tissue. If the fistula tract is located on the right side of the body of the pancreas or even in the head, resection should be avoided and internal drainage into a Roux-en-Y jejunal loop is preferred [6,43]. For persisting fistulas located in the body or tail of the pancreas, central or distal pancreatectomies are suitable procedures to remove the fistula-bearing part of the pancreas [24]. Crucial for surgical treatment of external pancreatic fistula is the timing of the procedure. Formal pancreatic resections should be avoided in the early phase of fistula occurrence, as fistulas may spontaneously close even 6 months after an acute episode.

Nutritional Support

Nutritional support care can be added to improve not only healing of a fistula but also patients' general performance status, which is often reduced after acute pancreatitis. If chosen, the enteral route should be preferred in all phases of the disease. A total parenteral nutrition regimen should only be considered if the enteral route is not tolerated or if the enteral feeding alone cannot achieve the expected nutritional daily requirements. When parenteral nutrition is indicated, a glutamine supplement should be administered, at 0.20 g/kg per day of L-glutamine. Otherwise, there is no role for immunonutrition in pancreatitis-associated fistula [44].

According to international nutritional guidelines, pancreatic enzymes should not be generally supplemented, except in patients with obvious pancreatic exocrine insufficiency. A debatable aspect in the management of internal fistula is the role of somatostatin analogs. No clear benefit of octreotide has been demonstrated [45], with the exception of the pancreaticopleural fistula, where it has been shown to reduce the output and decrease the time to fistula closure [46].

Conclusions

Pancreatic fistulas are common sequelae following acute pancreatitis and, in most cases, self-limiting processes. Pancreatic fistulas can occur spontaneously or be the consequence of interventions required to manage infected walled-off necrosis in severe acute pancreatitis. The majority of fistulas present with low output and tend to close spontaneously within a few months. For this reason, a conservative approach is recommended. After failure of the conservative treatment, a step-up approach is the gold standard, including a wide range of minimally invasive therapeutic options. Endoscopic and percutaneous interventions should be preferred, as surgery-related mortality remains high even at referral centers. The surgical option remains the ultimate treatment when the endoscopic and percutaneous intervention are not successful. The type and extent of resection must be considered and tailored for each case. Surgery should be delayed by at least 4–6 weeks following the onset of an acute episode.

Long-Term Outcome After Acute Pancreatitis

Christin Tjaden[1] *and Thilo Hackert*[2]

Introduction

Most patients with acute pancreatitis recover completely without any further symptoms or morphological alterations within days or weeks after discharge. This observation was described in the original definition of acute pancreatitis by the Consensus Symposium 1963 in Marseille [1]. However, recent reports on long-term outcome after acute pancreatitis show growing evidence that there is a certain risk for late pancreatitis-associated complications even after mild clinical courses [2–5].

Functional impairments can occur immediately or even years after sustaining acute pancreatitis [2,3,5–8], specifically loss of endocrine function resulting in diabetes mellitus type 3 or exocrine insufficiency with the need for pancreatic enzymes substitution, have been described in numerous studies [2,9–11]. Etiology or severity of the index episode are not clearly associated with the overall risk for an impairment of pancreatic function. In addition, episodes of pain with a considerable impact on quality of life can occur at any point of time after the initial event of acute pancreatitis. These possibly recurrent pain sensations bear a high risk for chronification and may be associated with recurrent pancreatitis; there is also a certain overlap with clinical courses of chronic pancreatitis [2,5,12,13]. This latter correlation has been examined in several recent publications [2–5,14–20]. It is sometimes difficult to distinguish between the primary episode of acute pancreatitis as a symptom of a chronic disease and chronic pancreatitis developing as a long-term consequence of pancreatitis. Morphological characteristics (i.e., those found in cross-sectional imaging at the initial episode of pancreatitis) can be useful for this differentiation as preexisting signs of subclinical chronic pancreatitis may be found in terms of fibrosis or calcifications and can be clearly distinguished from typical signs of new-onset acute pancreatitis.

In contrast to chronic pancreatitis, little is known about histomorphologic pathways and alterations of recurrent acute pancreatitis. One hypothesis is the so-called necrosis–fibrosis sequence [21], which suggests that acute inflammatory changes after an initial and acute damage of the pancreas result in mesenchymal cell activation with various patterns of subsequent fibrosis development and obstruction of pancreatic ducts. Another model is based on a "sentinel acute pancreatitis event (SAPE)," postulating a long-lasting intrapancreatic activation of immunomodulatory and stellate cells during the index episode. These alterations lead to hypersensitivity of the pancreas when responding to potential stimuli, resulting in recurrent attacks of acute and eventually chronic pancreatitis [22]. Despite these hypotheses, the possible pathophysiologic link between acute and chronic pancreatitis remains controversial and is not well understood [23].

Because there are no follow-up guidelines for clinical examinations and imaging after acute pancreatitis and histopathologic findings for such patients are rare due to the infrequent need for operations with respective tissue harvesting, the frequency of such alterations is unknown. In available cross-sectional imaging, alterations of the pancreatic duct, parenchyma, or surrounding areas (i.e., formation of pseudocysts or fluid collections) can be observed during both short- and long-term courses. These morphological findings may be correlated with the severity of the first attack and the type of treatment, in particular interventional or surgical necrosectomy.

Their extent and the underlying initial etiology of the primary acute pancreatitis episode determine clinical outcome patterns. In alcohol-related acute pancreatitis a recurrent and eventually chronic course is observed more often than it is in a biliary genesis of the disease [13,15,19,20]. This fact underlines the importance of avoiding further exposure to risk factors such as alcohol and nicotine as a basic precaution following a first pancreatitis episode [14,24,25]. Furthermore, patient education can be regarded as a simple method to reduce the lifelong risk of recurrence and associated healthcare costs [20,24]. Follow-up examinations should therefore address the above-mentioned topics and should include clinical and laboratory as well as imaging examinations, when necessary. This chapter gives an overview of the long-term sequelae of acute pancreatitis with regard to risk factors, diagnosis, and management.

Risk Factors

Risk factors for long-term complications of acute pancreatitis have been examined in several cohort studies in recent years [4,5,7,14]. With regard to recurrent episodes of acute pancreatitis, a recent meta-analysis including nearly 8500 patients showed an overall risk of 22% with a nearly twofold increase in alcoholic etiology (38%) and a lower risk for biliary etiology (17%) [4]. With regard to biliary etiology, early removal of the gallbladder after the index episode of pancreatitis reduces the risk of recurrence [5,14]. In nonbiliary etiology, persistence of smoking and alcohol consumption are well-documented risk factors for both recurrent acute episodes as well as progression of primary acute to chronic pancreatitis in the long term [5,7,14]. Nevertheless, some authors report experience with patients who show a progression to chronic pancreatitis despite stopping consumption of alcohol and nicotine [14,15]. In addition, male patients seem to have a higher risk of progression to chronic pancreatitis, even when lifestyle-associated risk factors are excluded [4]. Risk factors for functional failure after acute pancreatitis include preceding necrosectomy, which leads to both exocrine and endocrine insufficiency due to the procedure-associated loss of tissue itself and the disease-specific damage to the remaining tissue [5,26,27]. Again, the risk for developing progressive pancreatic dysfunction and diabetes mellitus or exocrine dysfunction is increased in men [4,6]. Moreover, a subset of patients may also have unrecognized genetic risk alterations leading to increased risk of progressive pancreatic failure and chronic pancreatitis through an effect on trypsinogen activation [28]. Tables 37.1 and 37.2 summarize studies on patterns and risk factors for long-term sequelae after acute pancreatitis.

Endocrine Pancreatic Dysfunction

Hyperglycemia, impaired glucose tolerance, and diabetes mellitus occur frequently as a consequence of acute pancreatitis and have therefore been investigated as primary or secondary endpoints of several large studies on the loss of pancreatic function on long-term follow-up. A recent review analysed 34 studies focusing on diabetes mellitus after acute pancreatitis [3]. The authors concluded that especially pancreatic diabetes mellitus (type III) and impaired glucose metabolism after acute pancreatitis are increasingly recognized clinical findings requiring more detailed research on it as the published data are inconsistent. Of interest, one of two included meta-analyses had examined 24 prospective studies published between 1968 and 2009, and revealed that nearly 40% of patients showed a prediabetic metabolic situation or a full clinical manifestation of diabetes mellitus [2]. Within 12 months after the index episode of acute pancreatitis the prevalences of hyperglycemia and diabetes mellitus were 19% and 15%, respectively. After a 5-year observation period, the risk for diabetes mellitus showed a twofold increase compared with the prevalence after 12 months. A Dutch cohort study on 669 patients described a new onset of diabetes mellitus in 20% of the patients during a median follow-up time of 57 months [7]. These data are consistent with findings of a Taiwanese study, which showed a comparable twofold increase of diabetes risk after 10 years in nearly 3000 acute pancreatitis patients, regardless of the severity of the initial course of the disease [6].

In severe courses characterized by extensive parenchyma necrosis and the need for necrosectomy, the correlation between loss of tissue and function seems to provide an explanation for these observations, especially when the body and tail of the pancreas are affected. Decay of a considerable amount of islets predisposes for functional deterioration and 15–30% of patients undergoing extensive necrosectomy show insulin-dependency soon after recovery [5]. This is comparable to outcomes following distal pancreatectomy for other indications, with a rate of postoperative diabetes mellitus of approximately 10% [30–32], and underlines the relevance of the pancreatic body and tail for the endocrine function of the gland due to the pronounced location of islet cells in these segments of the pancreas. In contrast, the pathophysiologic explanation for mild episodes of acute pancreatitis resulting in endocrine insufficiency and an increased risk of diabetes mellitus remains unclear.

Exocrine Dysfunction

In the early phase after acute pancreatitis, exocrine function is often compromised and is easily diagnosed

nm, not mentioned.

by clinical symptoms of diarrhea, steatorrhea, and maldigestion. In the long term, the reported prevalence rates of exocrine dysfunction differ considerably in the available studies [5,7,26,33]. A study by Sand and Nordback reports 25% of patients having exocrine failure after necrosectomy in a follow-up period of 2–5 years [5], whereas other studies with comparable observation times reported much higher rates of 55% after mild and up to 83% after severe courses, independent of the etiology of acute pancreatitis [33–35].

Symptoms of exocrine failure can be controlled very well in most patients by oral enzyme replacement to prevent maldigestion, malabsorption, and consecutive malnutrition. Supplementation of the diet with fat-soluble vitamins in the follow-up period should also be considered [36]. A discontinuation of enzyme supplementation may be possible as several studies have reported a potential for long-term recovery of exocrine function within 12–24 months after acute pancreatitis [5,34], which is comparable to the functional recovery often observed after pancreatic resections for other indications.

Recurrent Pancreatitis and Chronic Pancreatitis

Regarding the frequency and timeline of progressive pancreatic disease after acute pancreatitis, about 20% of all patients and 50% of patients with an alcoholic etiology show recurrent episodes within 10–20 years, but most recurrences occur during the first years after the initial attack [4,5,7]. Overall, 1 out of 10 patients will suffer from a progression to chronic pancreatitis [4], which may be associated with few symptoms for a long period but may finally result in end-stage findings of chronic pancreatitis despite a subclinical course (Fig. 37.1). In the case of recurrent acute episodes, the risk of progression to chronic pancreatitis shows a three- to fourfold increase, which is, again, pronounced in patients with an underlying alcoholic etiology [7].

Quality of Life and Pain

Several outcome studies report on the occurrence of pain and the quality of life after acute pancreatitis [5,7,12,13]. An observational study on 145 patients from Finland showed no impairment of quality of life, regardless of pancreatitis etiology, compared to the general population [12]. Similar results are shown in several smaller observational studies, even after necrosectomy [5]. In contrast, in a Polish study patients suffering from severe alcohol-induced acute pancreatitis showed a reduced quality of life in comparison to those with a biliary origin of the disease with regard to social and family life as well as emotional well-being [13]. How far persisting alcohol consumption after the index episode of pancreatitis contributes to these findings, however, remains unclear from the study data. With regard to chronic pain, a large Dutch cohort study including 669 patients found that 13% had recurrent episodes of pain related to acute pancreatitis [7]. A recent large US analysis observed 647 patients with necrotizing pancreatitis, who were treated and followed up in a single center [27]. The authors describe less commonly reported long-term complications such as chronic pain in 8%, strictures of the bile duct (16%), the pancreatic duct (5%), or the duodenum (5%) as well as splanchnic vein thrombosis (45%). Of interest, 340 (59%) patients developed complications that needed invasive intervention after completely recovering from necrotizing pancreatitis [27].

Incisional Hernia

With the implementation of minimally invasive management of infected pancreatic necrosis during the initial episode of acute pancreatitis, open surgical interventions have considerably decreased and are regarded as the last resort in modern treatment concepts [37,38]. Less than 5% of patients with acute pancreatitis need to

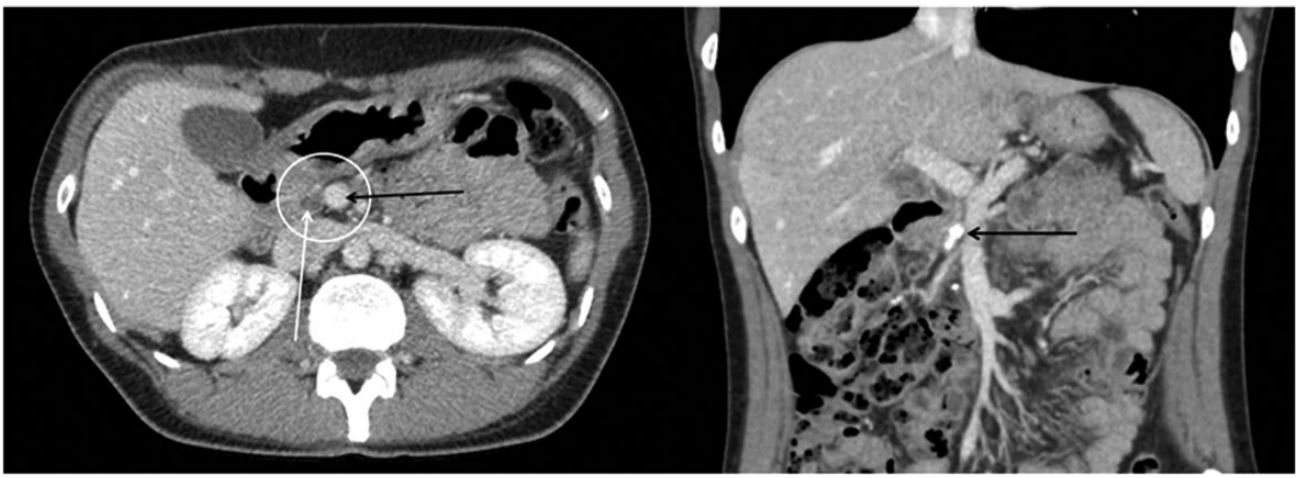

Figure 37.1 A 39-year-old female patient 9 years after a solitary episode of severe acute pancreatitis following hemorrhagic shock and acute respiratory distress syndrome (ARDS) due to atonic bleeding after cesarean section. This was followed by complete recovery and primary discharge from hospital after 5 weeks and complete remission of residual pseudocysts over a 6-month period. Afterwards, the patient had no clinical symptoms for 8 years before recurrent abdominal pain attacks irradiating to the back occurred. CT scan revealed nearly complete atrophy of the pancreatic parenchyma (left side, white circle; black arrow: portal vein, white arrow: bile duct) and a calcification in the pancreatic head (right side, black arrow). As no signs of inflammation, tumor suspicion, or endocrine insufficiency were present, symptomatic treatment was successful (oral enzyme replacement and analgesia).

be treated by open surgery (e.g., in case of unsuccessful minimally invasive necrosectomy, for bleeding control, or due to organ perforation). These patients show a high rate of surgical site infections (80%) [34] and a correlating high risk of developing an incisional hernia (21–40%) [27, 40]; surgical reintervention is often required for symptomatic, functional, and cosmetic aspects of these, often large, hernias.

Pancreatic Cancer and Pancreas-Related Death

In general, death related to acute pancreatitis, besides short-term mortality during a severe necrotizing course, seems to be rare and not related to progression to chronic pancreatitis and finally pancreatic cancer. A German study reported on four deaths of pancreatic cancer in 532 patients (0.8%) observed after acute pancreatitis during an average follow-up of 7.8 years, which occurred 9–56 months after acute pancreatitis, none of them with a diagnosis of chronic pancreatitis [14]. In an Italian study, 3 of 631 patients (0.5%) died of pancreatic cancer 5, 6, and 19.9 months after acute pancreatitis with unknown etiology in the first case and biliary etiology in the others [16]. These data support the conclusion that the initial pancreatitis event may be a symptom of an already existing tumor rather than pancreatic cancer and the related mortality is a long-term consequence of acute pancreatitis. A recent study on 1644 patients from Finland showed, that after an acute episode of alcohol-induced pancreatitis with the need for hospitalization, long-term mortality was four times higher than that in an age- and sex-matched control population [25]. The most common cause of death was pancreatic cancer in patients with nonalcoholic acute pancreatitis, while patients with alcoholic pancreatitis died mostly by alcohol-related diseases.

Imaging Findings

Most episodes of mild acute pancreatitis do not result in any morphologic changes and, after restitution, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) scans show a normal pancreas without any damage to the gland or the duct system. Even when functional impairment occurs, this is not necessarily associated with any pathological imaging findings. This is also observed in most cases of diabetes mellitus of other genesis and in many patients with endocrine dysfunction without underlying chronic pancreatitis. In contrast, severe episodes of acute pancreatitis with or without the need for interventional or surgical treatment often result in morphologic pancreatic alterations of varying extent.

Common reversible or irreversible findings on CT or MRI imaging include:

- inhomogeneity of the parenchyma;
- atrophy of the parenchyma;
- duct alteration (strictures/dilation);
- residual peripancreatic fluid collections;
- pseudocysts.

Diagnosis of the abovementioned alterations alone does not require any measures, unless accompanying symptoms are present. Further follow-up examinations should be performed to evaluate a potential dynamic of these changes and recognize potential need for any interventional or surgical therapy early to prevent ongoing destruction of the pancreatic parenchyma in the case of recurrent pancreatitis episodes or development of chronic pancreatitis or chronic pain. The management of pseudocysts and persisting postpancreatitis fistulas is described in Chapters 34 and 35.

Another important aspect is the recognition of cystic lesions as the cause of acute pancreatitis and their differentiation from residual pseudocysts. It has been reported that 13–67% of all patients with intraductal papillary mucinous neoplasia (IPMN) show an episode of acute pancreatitis as their initial symptom [41–43]. However, this is frequently misdiagnosed and studies in the past report on a delay in diagnosis of a cystic neoplasm as the trigger of acute pancreatitis of several years or even more than two decades [41–43]. With growing awareness of cystic neoplasms in recent years this may be avoided in the future as distinguishing postinflammatory duct dilatation and pseudocysts from IPMN is of high importance because of the malignant potential of IPMN.

Postpancreatitis Care and Follow-Up Visits

Six to eight weeks after hospital discharge due to an episode of acute pancreatitis, a clinical control examination can be recommended to document the status, including symptoms and nutritional status with regard to pancreatic function, blood tests, and imaging in cases of severe acute pancreatitis. In case of biliary acute pancreatitis, cholecystectomy (preferably by a laparoscopic approach) must be scheduled if it has not been performed during the initial hospital stay. There is good evidence concerning the indication and timing of cholecystectomy which shows that a delay of this operation results in an increased

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk of recurrent biliary pancreatitis [4,5,44]. For mild biliary pancreatitis cholecystectomy should be performed during index admission. In contrast, in patients with severe pancreatitis, cholecystectomy can safely be performed after resolution of symptoms (4–6 weeks). A similar time frame should be chosen for patients who undergo sphincterotomy during biliary pancreatitis [44]. Besides biliary pancreatitis, a Finnish study suggested that recurrence of idiopathic acute pancreatitis can also be prevented effectively by laparoscopic cholecystectomy, which should be evaluated for the respective patients [45].

No general guideline or consensus recommendations for long-term follow-up visits after acute pancreatitis exist to date. From the clinical point of view, follow-up at 6-monthly intervals during the first 2 years seems to be reasonable, followed by yearly examinations thereafter [46]. A possible scheme for follow-up could include:

- documentation of abdominal and unspecific symptoms;
- clinical examination;
- blood samples for the determination of routine parameters (including HbA_{1c}, electrolytes, creatinine, urea, liver enzymes, amylase, lipase, white and red blood cell counts, and C-reactive protein) as well as the serum tumor markers CEA and CA19–9;
- analyses of genetic factors (*PRSS1*, *SPINK1*, *CFTR*) in the case of unclear etiology of the underlying acute pancreatitis [4,28];
- cross-sectional imaging with abdominal CT or MRI scan.

Conclusions

Overall, the majority of patients show a good long-term outcome after acute pancreatitis. However, one out of four patients will develop some kind of problem in the long run, including endocrine or exocrine dysfunction, recurrent acute pancreatitis, or transition to chronic pancreatitis even many years after the initial event. Risk factors for clinical deterioration are incompletely examined and understood at present. Lifestyle habits, such as ongoing consumption of alcohol and nicotine, have been shown to increase this risk, especially for patients with alcohol-induced first attack of acute pancreatitis. Following biliary pancreatitis, removal of the gallbladder is an essential measure for prevention of future relapses and should preferably be performed during the initial hospital stay in mild pancreatitis and 6–8 weeks after recovery from a severe episode. To detect long-term loss of function before progression to an irreversible stage, regular follow-up is recommended, including clinical examination and blood tests at 6- to 12-month intervals to check for new onset of diabetes mellitus as well as maldigestion due to pancreatic exocrine dysfunction even when patients are asymptomatic. In the case of abdominal complaints, cross-sectional imaging should be considered. Pathologic findings alone (i.e., atrophy of the pancreatic parenchyma) do not require immediate intervention but should be further monitored during regular follow-up. In the case of transition to chronic pancreatitis with fibrosis and calcifications of the pancreas or dilatation of the pancreatic duct in combination with episodes of pain, a tailored approach including timely surgery should be considered to prevent ongoing deterioration of function and symptoms.

Recommendations for follow-up schemes after acute pancreatitis have not yet been standardized by international guidelines. The number of recent studies shows that heterogeneous protocols are being used in clinical practice and underlines the need for better and evidence-based recommendations to examine the long-term outcome of patients after acute pancreatitis as it is one of the most frequent gastrointestinal indications for inpatient treatment. The rising interest in this area and the results themselves underline the need for implementation of regular follow-up. This would allow a systematic evaluation of the risk of diabetes mellitus, pancreatitis relapse, and development of chronic pancreatitis, all of which exert an immense impact on healthcare costs. The possibility of earlier recognition and prevention of these complications on a risk-stratified basis could offer significant benefits.

Definition and Classification of Chronic Pancreatitis

David C. Whitcomb

Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh/UPMC, Pittsburgh, PA, USA

Introduction

The term *chronic pancreatitis* describes a clinical syndrome of variable pancreatic inflammation, fibrosis, sclerosis, calcifications, pain, and loss of function of the exocrine gland (exocrine pancreas insufficiency, EPI) or endocrine dysfunction (e.g., diabetes mellitus, DM). This chapter provides an update on evolving definitions and classifications of chronic pancreatitis based on new concepts and techniques available to the clinician. It also notes the importance of standardized coding for pancreatic conditions and complications that must be appropriately defined and used.

The definition and diagnostic criteria associated with chronic pancreatitis have evolved over the past century as diagnostic tools and abdominal imaging techniques have improved. The "classic triad" required to diagnose chronic pancreatitis in the past included: (i) dense calcifications in the region of the pancreas on abdominal X-ray, (ii) diabetes mellitus, and (iii) steatorrhea—a triad that could only diagnose chronic pancreatitis at the final stages of disease. In contrast, autopsy studies suggest that pancreatic fibrosis was common in adults (especially alcoholics) and that the incidence increased with age. These historic observations indicated a large gap between various pathologic abnormalities and clinical detection of these features that could not be bridged with pancreatic biopsies because of the danger of triggering acute pancreatitis.

Advances in abdominal imaging technologies and introduction of genetics into the clinic have revolutionized our understanding of the essence of chronic pancreatitis, leading to a mechanistic definition, a progressive model, and etiology-based subtyping.

The importance of these new concepts is the belief that earlier detection, diagnosis, and targeted treatment will markedly improve outcomes, including reduction in suffering, avoidance of complications such as chronic pain, EPI with maldigestion and malnutrition, DM and pancreatic ductal adenocarcinoma (PDAC) plus minimize the health-cost burden. Implementation of these concepts requires more exact definitions of the elements of the chronic pancreatitis syndrome linked with better risk models and better biomarkers of disease state and activity. This chapter focuses on and extends the specific features and mechanisms linked to CP though a review of definitions and mechanism of chronic pancreatitis [1].

Disease Frameworks

Traditional Western Medicine

This framework for medicine was originally based on the germ theory of disease and the premise that one predominant or strong agent causes disease in people who are otherwise normal [2,3]. Evidence of disease etiology utilizes null hypothesis significance testing of one or more possible etiological factors. Evidence for the effectiveness of treatments utilizes case-control trials. Disease diagnosis and treatment relies on traditional clinicopathological definition and classification of disease, and standard clinical biomarkers. Thus, the diagnosis is delayed, complex etiologies cannot be resolved, and therapies are limited to controlling pain and replacing lost function.

Precision Medicine

Precision medicine, also called personalized or individualized medicine, is an alternative framework to modern Western medicine with a bottom-up approach for

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

Companion website: www.wiley.com/go/beger/thepancreas4e

managing human diseases based on the premise that multiple weak agents cause disease in a person because one or more of their specialized cells are abnormal [2]. Precision medicine seeks to decipher the molecular, mechanistic *dysfunction* causing a *disorder* before it progresses to a clinicopathologically defined *disease*. Knowing the mechanism early should allow the use of targeted therapies to minimize dysfunction and maximize health. Under optimal situations the top-down and bottom-up approaches meet in the middle for the benefit of all the individual patients in a population. Precision medicine for pancreatic disorders in clinical practice is technically feasible, but numerous barriers slow implementation and widespread utilization [4,5].

Definition of Dysfunction

Dysfunction describes a variation in the action of a thing that deviates from normal, typically in a negative way. Dysfunction is typically applied to a system. The dysfunction may be essential (causing permanent system dysfunction under all conditions) such as an altered or missing component, or conditional, typically caused by external factors such as regulators or inputs that overwhelming the capacity of the system.

Definition of a Disorder

A medical disorder indicates disruption of the normal functions of specialized cells or systems resulting in abnormal signs, symptoms, biomarkers, or responses. Thus, they represent a failure of the body to compensate for molecular, cellular, or system dysfunction. Disorders can also be the result of external agents causing injury or overwhelming stress. In some cases the disorder has pathogenic consequences that eventually result in development of a disease [1]. An example is a cystic fibrosis transmembrane conductance regulator (CFTR)-related disorder [6,7] where CFTR is marginally functional and the patient develops clinical signs of pancreatic *dysfunction*, for example reduced bicarbonate secretion from duct cells, but has not caused diseases such as RAP nor met the criteria for CP [8,9] .

Definition of a Disease

A *disease* is a condition of the living animal or one of its parts that impairs normal function and is typically manifest by distinguishing signs and symptoms [1]. Thus, chronic pancreatitis is a disease the involves the pancreas, impairs normal function as an exocrine and endocrine gland, and has *distinguishing signs and symptoms*. However, the dysfunctions of the endocrine and exocrine pancreas are somewhat independent of each other, with endocrine dysfunction associated with DM that may or may not be associated with CP. Furthermore, the criteria for distinguishing signs and symptoms of CP versus other diseases with overlapping signs and symptoms such as maldigestion, fibrosis, and abdominal pain have been vague and nonspecific, resulting in agreement that only later-stage chronic pancreatitis can be diagnosed accurately, well past the stage when therapeutic interventions are likely to be most effective [10].

Mechanistic Definition of Chronic Pancreatitis

To overcome the limitations of classic criteria to diagnose chronic pancreatitis a new *mechanistic definition* of chronic pancreatitis was proposed in 2016, and subsequently adapted by the major national and international pancreas societies [10,11]. The mechanistic definition contains two components: the *essence* of the disease and the *characteristics* of advanced disease.

The essence of chronic pancreatitis. "Chronic pancreatitis is a pathologic fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who develop persistent pathologic responses to parenchymal injury or stress" [11].

The characteristics of chronic pancreatitis. "Common features of established and advanced CP include pancreatic atrophy, fibrosis, pain syndromes, duct distortion and strictures, calcifications, exocrine pancreatic dysfunction, pancreatic endocrine dysfunction, and dysplasia" [11].

Together the complementary aspects of the mechanistic definition of chronic pancreatitis provides two critical advantages over clinicopathologic definitions. First, defining the pathogenic mechanism of chronic pancreatitis helps differentiate it from other disorders and diseases that have overlapping features such as pancreatic atrophy, pain, strictures, exocrine pancreatic insufficiency, diabetes, and dysplasia or cancers. Second, it allows for the pathogenic mechanisms of chronic pancreatitis to be determined in individual patients very early in the process prior to development of irreversible features and for early management with targeted therapies. These concepts will be further developed in the progressive model.

Progressive Model of Chronic Pancreatitis

A progressive model of chronic pancreatitis development was proposed that included five stages (Fig. 38.1). This model is important in that the signs, symptoms, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

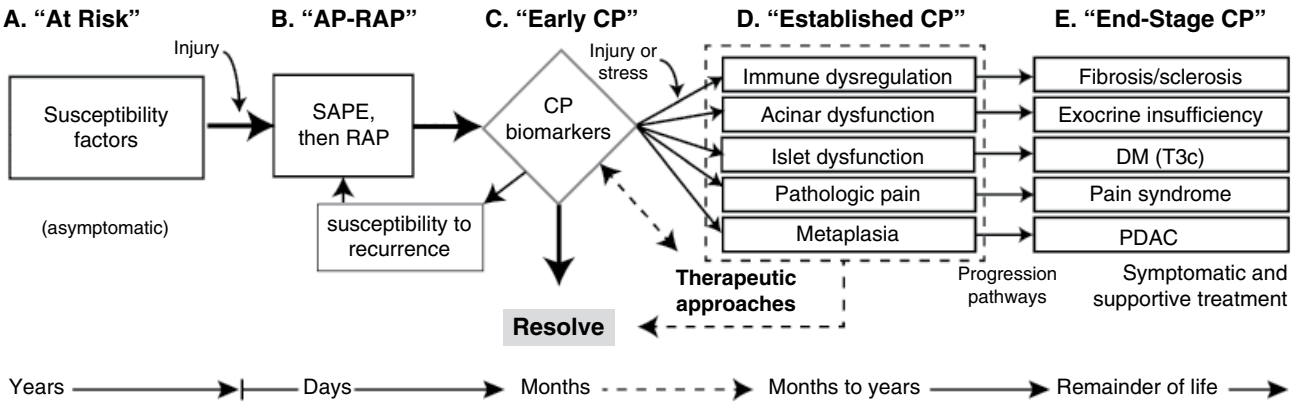

Figure 38.1 Progressive model of chronic pancreatitis development. This model is based on the sentinel acute pancreatitis event (SAPE) hypotheses where progression to CP begins with AP (stage B). Genetic and environmental risk/protective factors are present at all stages. Stage A is asymptomatic, with the effects of underlying disorders being adequately compensated. Stage B represents acute pancreatitis, which can be the first event (SAPE) or RAP, with SAPE sensitizing the pancreas to RAP. Stage C follows AP events where there is resolution or progression, depending on ongoing injury or stress. Stage D defines "irreversible" damage, as currently required for diagnosing CP as a disease. Note that risk/protective factors in different cell types are not surrogates of each other so the immune response (e.g., fibrosis) is not a strict surrogate of acinar cell function, islet cell function, nervous system response, or oncogenesis (e.g., failed DNA injury repair). This stage is hypothetically reversible with new therapies. Stage D is end-stage where cell function fails requiring replacement therapy or more radical surgical treatments. *Source:* Whitcomb et al. 2016 [11]/with permission of Elsevier.

biomarkers are present in a subject change over time, as seen in all progressive disorders. The stages are useful for classifying the patient's disease state and trajectory, as well as tracking severity indicators. All etiologies of chronic pancreatitis go through progressive stages, although in individual cases acute pancreatitis may not be seen. Etiologies are also important since the likelihood of progressing from one stage to the next is strongly affected by etiology.

Stage A. ***At Risk***. This stage includes all patients with risks for chronic pancreatitis who have no signs or symptoms of diseases and who have not had an episode of acute pancreatitis. The patient may have dysfunction of some physiologic processes, but the body is able to adapt and compensate for the dysfunction without signs and symptoms of disease.

Stage B. ***AP-RAP***. This stage includes all subjects with at least one episode of acute pancreatitis (AP; designated as the *sentinel* AP *event*, SAPE; see below) or recurrent acute pancreatitis (RAP) with complete resolution and without irreversible damage to the ducts or parenchyma. However, this is a high-risk stage for progression to chronic pancreatitis,

DM, and pancreatic ductal adenocarcinoma (PDAC).

Stage C. ***Early CP***. This stage includes all patients with both biomarkers of chronic pancreatitis and exclusion of other disorders or diseases with features that overlap the characteristics of chronic pancreatitis. Early CP is distinct from Established CP in that the features are reversible. The patient may have symptoms of one or more underlying disorders, but has not met criteria for chronic pancreatitis as a disease.

Currently, Stage C can only be diagnosed in retrospect because the biomarkers are nonspecific and progression is uncertain using traditional definitions and an imaging approach to CP diagnosis. Other names for this stage include "possible CP" and "probable CP." In contrast, a precision medicine approach defines the essence of the underlying process with a probability estimate of progression. Furthermore, the genetics can be used to determine and, in concert with specific biomarkers, help diagnose a *clinical disorder* that, if left untreated, will progress to a disease state.

Stage D. ***Established CP***. Established CP includes patients who have characteristic features of chronic pancreatitis that are irreversible but the gland has sufficient ductal and acinar cell function to sustain nutritional needs without the requirement of pancreatic enzyme replacement therapy (PERT). In addition, other disorders or diseases with features that overlap the characteristics of CP (differential diagnosis, below) should be excluded.

Stage E. ***End-Stage CP***. A patient has reached end-stage chronic pancreatitis when exocrine function is lost from a CP-associated fibroinflammatory process to the point that it requires PERT. Features of this stage may also include fibrosis, calcifications, and DM type 2 or type

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

3c [12–14]. This stage is also important because it defines the end-stage disease features for individual patients since not all features are present in everyone.

Diagnosis

A diagnosis is the art or act of identifying a disease in a patient from its signs and symptoms. Diagnosing a disease or disorder involves meeting predetermined criteria.

Diagnostic Criteria

Diagnostic criteria are a list of disease features that must exist in a subject in order to diagnose the subject with a disease. These criteria are typically defined by expert opinions and established as consensus statements by various organizations or societies. They typically included signs and symptoms of the disease, biomarkers, and pathologic features. The criteria also include degrees of severity and features that distinguish the disease from other disorders or diseases with overlapping features.

Pathologic Diagnosis

A pathologic diagnosis is the diagnosis of a disease based on tissue analysis (including culturing of pathogenic organisms). Because there are overlapping features of CP and other disorders it is not possible to diagnosis CP with certainty from tissue samples. Pathology is not the gold standard for diagnosing CP [15]. A diagnosis also requires the presence of clinical and functional elements.

Syndromes

A *syndrome* is a descriptive group of clinical signs and symptoms that occur together and characterize a particular abnormality or condition. A disease can be defined as syndromes without knowledge of the etiologies, pathogenic components, or mechanisms. AP, RAP, and CP are clinical syndromes.

Differential Diagnosis

The differential diagnosis is a list of conditions and diseases that have overlapping signs and symptoms. The differential diagnoses for CP include autoimmune inflammation, inflammation and fibrosis arising from the islets related to long-standing diabetes mellitus, renal disease causing secondary effects on the pancreas, medications that alter the immune system (e.g., cyclosporin), age-related atrophy or fibrosis, intraductal papillary mucinous neoplasm, acinar cell cystadenoma, the desmoplastic response to pancreatic neoplasm, and inflammation upstream of a duct-obstructing mass [10]. The traditional diagnosis of CP required the underlying disorder to advance to the point that it could be nothing else. But since this stage is irreversible, only supportive treatments are available (e.g., insulin and PERT). In precision medicine the genetic and genomic information provides insights into the mechanism of pathogenesis and can also provide insights into the probability of the differential diagnosis [16]. This approach supports clinical decisions as further work-up and treatments can be targeted to one diagnosis or another, based on the likelihood that the diagnosis is correct and the effect of the treatment (i.e., an inexpensive and benign treatment can be started if there remains some uncertainty, whereas a more expensive and radical treatment should be delayed until the diagnosis is confirmed with a high degree of confidence).

Etiology

Etiology defines the cause or origin of something. In inflammatory diseases of the pancreas this may include the etiology of mechanism dysfunction, a disorder, a disease, or a syndrome. The difference between a risk and an etiology is whether or not there are biomarkers of abnormal activity linked to the factor that defines a disorder or disease. The TIGAR-O list (List 1) summarizes known risk/etiologies for RAP and CP [17].

Biomarkers

A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention [18,19]. For CP, most biomarkers are normal biological molecules that are in the wrong place or amount [20]. They also tend to be nonspecific, requiring panels of biomarkers to be considered. In some cases biomarkers are more pancreas-specific, such as serum trypsin, amylase, lipase, or CA19-9 for pancreatic cancer, although exceptions always exist.

Classification of Chronic Pancreatitis

Chronic pancreatitis can be classified by structural severity, etiology, or functional stage:

Cambridge Classification of duct imaging. The Cambridge Classification was originally developed to correlate endoscopic retrograde cholangiography (ERCP) images with pathologic progression [21]. The criteria was later expanded to CT images and MRCP

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Table 38.1 TIGAR-O Version 2 risk/etiology classification – Short form. The list summarizes common factors associated with RAP and CP. It is used as a "checklist" to systematically document all factors that contribute to pancreatic disorders and diseases within a patient, and therefore highlights targets for therapy. The long form is available as an open access manuscript [17].

Toxic-metabolic
Alcohol-related (susceptibility and/or progression)
3–4 drinks/day
5 or more drinks/day
Smoking (if yes, record pack-years)
Non-smoker (<100 cigarettes in lifetime)
Past smoker
Current smoker
Other, NOS
Hypercalcemia – (ionized calcium levels >12.0 mg/dL or 3 mmol/L)
Hypertriglyceridemia
Hypertriglyceridemic risk – (Fasting >300 mg/dL; non-fasting >500 mg/dL)
Hypertriglyceridemic acute pancreatitis, history of (>500 mg/dl in first 72 hours)
Medications (name)
Toxins, other
Chronic kidney disease (CKD) – (CKD Stage 5 – end stage renal disease; ESRD)
Other, NOS
Metabolic, other
Diabetes mellitus (with the date of diagnosis if available)
Other, NOS
Idiopathic
Early onset (<35 years of age)
Late onset (>35 years of age)
Genetic
Suspected; No or limited genotyping available
Autosomal dominant (Mendelian inheritance – single gene syndrome)
PRSS1 mutations (Hereditary pancreatitis)
Autosomal recessive (Mendelian inheritance – single gene syndrome)
CFTR, 2 severe variants in trans (cystic fibrosis)
CFTR, <2 severe variants in trans (CFTR-RD)
SPINK1, 2 pathogenic variants in trans (*SPINK1*-associated familial pancreatitis)
Complex genetics – (non-Mendelian, complex genotypes +/– environment)
Modifier genes (list pathogenic genetic variants)
PRSS1-PRSS1 locus
CLDN2 locus
Others:
Hypertriglyceridemia (list pathogenic genetic variants)
Other, NOS
Autoimmune pancreatitis (AIP) / Steroid-responsive pancreatitis
AIP Type 1 – IgG4-related disease
AIP Type 2
Recurrent acute pancreatitis (RAP) and severe acute pancreatitis (SAP)
Acute pancreatitis (single episode, including date of event if available)
AP etiology – Extrapancreatic (excluding alcoholic, HTG, hypercalcemia, genetic)
Biliary pancreatitis
Post ERCP
Traumatic
Undetermined or NOS
Recurrent acute pancreatitis (number of episodes, frequency, and dates of events if available)
Obstructive
Pancreas divisum
Ampullary stenosis
Main duct pancreatic stones
Widespread pancreatic calcifications.
Main pancreatic duct strictures
Localized mass causing duct obstruction

images [22–25]. The 1984 Cambridge Classification system does not correlate with pancreatic function [14] or pain [26] and is therefore falling out of use as the technology for other imaging modalities improve.

TIGAR-O Etiologic Classification. TIGAR-O is an acronym for **T**oxic (including alcohol, smoking, hypertriglyceridemia), **I**diopathic, **G**enetic, **A**utoimmune, **R**ecurrent/Severe AP and **O**bstructive etiologies [17] (Table 38.1). In general, autoimmune and obstructive do not fit the mechanistic classification of chronic pancreatitis but are important both for consideration in the differential diagnosis and for treatment [1].

Functional Stage Classification. Functional classification systems are even more arbitrary than structural ones. This is because the definition of EPI is based on vague clinical signs and symptoms until the late stages, and the threshold for pancreatic insufficiency is also dependent on the metabolic and nutritional needs, the diet and intestinal anatomy and health, and adaptability. Furthermore, the tools for measuring pancreatic function often do not correlate with each other and no adequate test exists [27]. Several approaches are in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

common use including the M-ANNHEIM classification [28] and PROCEED [29].

Classification of Pancreatitis Using Machine-Readable Codes

Medical care is progressing slowly as the complexity of complex conditions becomes evident and new techniques provide massive amounts of information that cannot be assimilated, understood, and utilized by humans in efficient and organized ways. The advances in computers allow data to be stored, organized, and transformed into something useable by humans. However, the premise that "smart computers" can take blocks of unorganized data and solve complex diseases has stalled as limits in natural language processing (NLP), machine learning (ML), and artificial intelligence (AI) have failed to bring clarity out of chaos. And one of the many challenges is that the definitions and organization of data is based on the old Western medicine concepts arising from the germ theory of disease and the scientific method of population-based case-control studies using poorly defined syndromes as classifiers.

Challenges of Multiple Object Identifiers and Classification Systems

The goal of basic science research is to translate findings into clinical research, and from clinical research into clinical practice. The reverse is also important, translating observations in clinical practice back to clinical research to generate new hypotheses, and then test the hypotheses using basic research techniques. In the middle of these translations are the terms and descriptions of data tags to be translated. Future success requires better harmonization of data terms and discipline from physicians and scientist to use them consistently.

Progress in medicine is intimately linked to advances in digital technology. This means that there needs to be better synchronization between advancing science, medicine, and electronic tags to specific disorders, diseases, biomarkers, and complications. The synchronization must also be mechanism- and disorder-based to achieve advantages of precision medicine, and existing data that is in a usable form must have the describers from different systems harmonized so that there is seamless interoperability.

Digital taxonomy systems use object identifiers (OID) to identify objects such as a code system or a value set that represents a group of concepts. The current challenges are that there are multiple classification systems and there are major overlaps of objects with different concepts and codes for the same thing in different systems. The problem is further confounded by the fact that most terms are from modern Western medicine concepts and definitions used by physicians and scientists are not always used appropriately and that outdated terms and concepts are not purged at the end of their natural life cycle. Furthermore, many codes are nonspecific, so that clarity on the subject's disorder is obscured.

Codes, Code Systems, and Value Sets

Successful interoperability is dependent on either using common code systems for data capture or through mapping the unique codes to an interoperable code system [30]. Code systems are a collection of concepts (ideas) with unique identifiers that are logically structured. This may be highly hierarchical systems or more complex and nuanced systems (e.g., ICD-10). The code system structure provides each concept with a code-system-specific meaning, a concept identifier (a code), and a string description (the name, and a definition of the concept meaning). Specific code systems used in electronic health records and health information technology include ICD-10-CM, CPT, SNOMED CT, RxNorm, and LOINC. Other systems used in biology include various GenBank, RefSeq etc for genetic information, the Gene Ontology knowledgebase (GO), and many more. These systems encode content and enable computer-based systems to find and utilize data without human supervision. It has been noted that the best approach for measure developers is to reduce the number of mapping steps required by focusing on content that measured entities can easily capture during clinical care, where metrics that are useful in the care of the patient match those used in quality assessment and decision support systems [30].

Some Limitations

One of the key code systems used in the United States is the International Classification of Disease (ICD) system. This illustrates the challenge of transitioning from traditional "disease" definitions to defining disease mechanisms. Consider ICD-10 codes for chronic pancreatitis in the K86 class. The primary diagnoses are limited to K86.0 (Alcohol-induced CP), K86.1 (Other CP), K86.8 Other specified diseases of pancreas (which are not billable codes in the United States) and K86.9 (Other specified diseases of the pancreas). K86.1 includes "Pancreatitis (inflammation of pancreas), chronic; exocrine pancreatic insufficiency (K86.81); Chronic pancreatitis NOS [not specified elsewhere]; Infectious chronic pancreatitis; Recurrent chronic pancreatitis; Relapsing chronic pancreatitis" without distinction between these very

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

different entities. K86.9 is even worse as "synonyms" terms include "Aseptic necrosis of pancreas, Atrophy of pancreas, Baggenstoss change of pancreas [31], Calculus of pancreas, Exocrine pancreatic insufficiency (also coded as K86.81), Fat necrosis of pancreas, Fibrosis of pancreas, Hemorrhage of pancreas, Mass of pancreas, Necrosis of pancreas, Pancreas – baggenstoss change, Pancreatemphraxis, Pancreatic acinar fistula, Pancreatic aseptic necrosis, Pancreatic atrophy, Pancreatic calculus, Pancreatic cirrhosis, Pancreatic exocrine insufficiency (see K86.81), Pancreatic fistula, Pancreatic hemorrhage, Pancreatic infantilism, Pancreatic insufficiency, Pancreatic mass, Pancreatic necrosis."

Another system is the SNOMED-CT. This is a general clinical reference system containing more that 357,000 healthcare concepts with unique meaning and logic-based definitions organized into hierarchies. In pancreatic disease, for example, there is a "parent/child" relationship type that includes parent concept "Disorder of the pancreas (3855007)" with child concepts "Atrophy of the pancreas (88281007); Baggenstoss change of the pancreas (61221008); Bard-Pic syndrome (45019006); Calculus of pancreas (15402006); Complication of transplanted pancreas (79369007); Congenital malformation of the pancreas (23497701); Congenital pancreatic enterokinase deficiency (10866001); Cyst of pancreas (31258000); and Cystic fibrosis of the pancreas (235978006)." This system does not include disorders of the pancreas from most of the etiologies in the TIGAR-O list [17], and partially overlaps diagnoses in ICD-10.

One of the keys to precision medicine is genetics. Specific human genetic variants can be coded using RefSeq identifiers (rsID), but more complex genetic variants, including copy number variants and large deletions or rearrangements, are not captured by these codes. Furthermore, the interpretation of the effect of genetic variants is primarily traditional autosomal dominate or recessive disease with genetic variants within the coding region identified as pathogenic (disease-causing alone), likely pathogenic, uncertain, likely benign or benign [32]. There is no commonly accepted way to grade the effects of "risk" variants, which are only disease-associated under specific conditions and are often tied to regulatory elements of gene expression rather than changing the amino acid sequence of the gene product (i.e., for protein coding genes). ClinVar is a public archive of genetic variants with free access to reports on the relationships between human genetic variations and phenotypes, with supporting evidence. But even here, the strength of evidence is variable, the effects of variants may be tissue-/disease-specific and risk factors, which are critical in understanding complex diseases, are seldom included or noted to have effects since the sequence reports are largely from *traditional* gene testing companies. Genetic data is not well integrated into the electronic health records in formats that are easily accessible.

A Way Forward

One issue that plagues ML applications comes from lack of clean, well-structured data. Inclusion of IT-minded folks in study design/data collection may solve many issues of data cleaning, harmonization, and interpretation that remain a major barrier.

A solution to the larger problem of interpreting complex, multi-code, multi-concept data is the use of "expert systems" [33]. An expert system is a computer program that uses available information, heuristics, and inference to suggest solutions to problems in a particular discipline following the recommendations of experts in the field. In brief, this approach takes extensive genetic data, patient demographics, health histories, biomarkers, images, etc. and integrates them using sequential framing, modeling and trajectory approaches that an expert would use. In the case of pancreatic disease, cell-based models would be used based on an understanding of acinar cell, duct cell, islet cell, neurons and the nervous system, inflammatory cells biology as parallel process (see Fig. 38.1, stages D and E), with cross-system integration (e.g., loss of some acinar cell function with loss of islet function). This is now feasible and may be an early example of true personalized medicine.

Conclusions

Health information technology has already linked ML and AI to assist in areas of reviewing and interpreting images (e.g., CT, MRI, pathology, colonoscopy). However, there is a lag in the development of useful clinical decision support tools in early diagnosis and accurate, mechanistic classification of complex disorders, such as pancreatic disorders and subsequent diseases. The first barrier to progress in complex disorders includes the concepts upon which many of the coding systems have been built, translation between genetics, genomics, biomarkers, systems biology, and human disorders that lead to chronic diseases and all their nuances. The second barrier is the proper use of terms and codes, including genetics, in the clinical arena where patient care is more important that billing codes, and where billing codes are inherently inadequate tools for disease management. A third barrier is the medical literature, where the descriptions of concepts, patient context, and complete data are inadequately coded so that studies can be seamlessly harmonized and NLP can be more useful because the authors adhere to a new HIT-enabling writing structure.

This chapter does not present the answer to these problems and barriers. It is intended to enhance recognition of these barriers by highlighting limitations of the current systems with concepts that must be integrated into new systems. In the meantime, progress can be made in the old fashion way of using the nonlinear, experience-based, heuristic thinking of expert physicians and scientists to begin bridging the gaps between the present and the future.

Introduction

Chronic pancreatitis (CP) is a clinically described syndrome that is characterized by consistent cellular stress or repeated bouts of pancreatic injury that result in pancreatic atrophy, fibrosis and duct distortion, a chronic pain syndrome (suggesting neural injury and responses), and eventually loss of both exocrine and endocrine function. Depending on the proposed etiology of the disease, there can be other secondary characteristics including calcifications, duct centric inflammation with either lymphocytes or neutrophils, or primarily an obstructive phenotype. Focusing on the etiology of the injury and the subsequent pathologic response is important to direct our understanding of the molecular mechanisms of CP.

Risk Factors in Chronic Pancreatitis

Although the diagnosis of CP is due to a convergence of common pathological features seen at the end-stage of the disease, there are distinct risk factors for CP (Fig. 39.1). These risk factors have been described by the TIGAR-O classification [1]. They include genetic and environmental factors, obstructive etiologies such as anatomical or traumatic features, and immune-mediated etiologies. The typical organ response to injury and cellular stress promotes recovery and regeneration of the pancreas following injury. However, with repeated injury or prolonged cellular stress, the organ response may become pathologic and drive cellular loss and fibrotic replacement of exocrine and endocrine cells. A proper understanding of the molecular mechanisms of CP requires that we address both the specific etiology, with its associated genetic and epigenetic modifiers, as well as the common pathologic response mediated through both parenchymal cells of the pancreas and mesenchymal cells, including the immune cells and the pancreatic stellate cells [2].

The current attempts to define CP focus on a clinical description of the end histologic appearance of the pancreas, resulting from an immune-mediated response to stress or injury coupled to a fibrogenic wound response. Although such a definition is useful clinically, it belies the complexity of the process leading to CP. Pancreatitis is an inflammatory disorder that involves a complex immunologic cascade of events. Environmental cues shape the initiation and progression of the immune system to accelerate or limit the immune response. The immunologic response can be modulated by epigenetic and genetic factors that alter the progression of the disease. The inflammatory response is modulated by cytokines and chemokines, produced by injured acinar cells, that act as recruiting molecules for an immune repertoire. There are likely multiple modifying factors and intervening steps that impact an individual patient's clinical course but at some point, progression becomes similar because the end result of this process is a similar histological pattern. In this chapter, we will focus on the current understanding of these two distinct stages of disease development, specific etiologies and the immune-activated fibrogenic response. The first stage of CP development relates to specific risk factors, and the second stage is the organ fibrogenic response to injury.

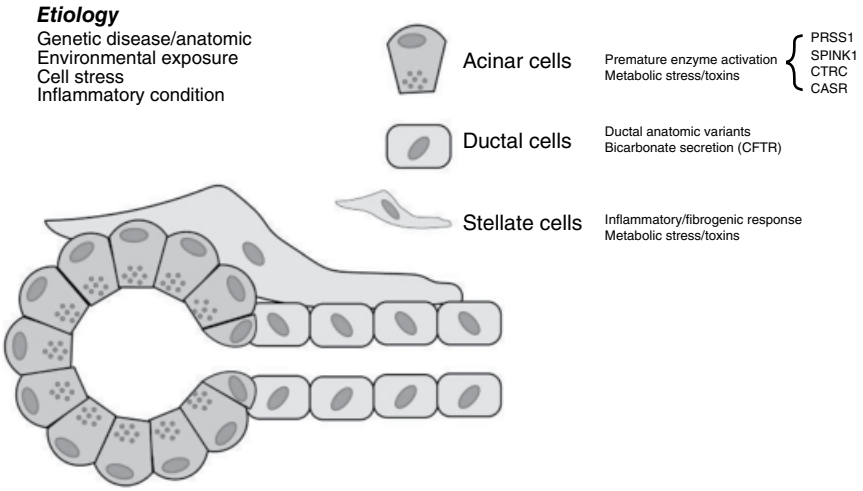

Figure 39.1 Several etiologies exist for chronic pancreatitis. Specific etiologies affect unique cell types within the pancreatic parenchyma, leading to repetitive injury.

Sentinel Acute Pancreatic Event Model

A disease model hypothesis has been proposed as a framework for understanding how different risk factors including environmental, genetic, and toxin mediated injury could impact progression toward CP. The model is the sentinel acute pancreatitis event hypothesis (or SAPE hypothesis), and it uses the TIGAR-O risk classification system, referring to Toxic-metabolic, Idiopathic, Genetic, Autoimmune, Recurrent and severe acute pancreatitis, and Obstructive [1]. In this model, risk factors impact the pancreas through alterations in stress responses by the parenchymal cells (acinar and duct cells). There are also wound healing responses within the pancreas, including the activation of the inflammatory (neutrophils and lymphocytes) and matrix remodeling systems (macrophages and stellate cells) to allow regeneration to occur. Once the risk factors overcome the adaptive mechanisms within the pancreas, injury overtakes the protective regenerative mechanisms, and clinical acute pancreatitis ensues. Repeated bouts of acute pancreatitis can lead to an injury-wound response cycle that over time causes loss of pancreatic cells and replacement with a fibrotic matrix that is promoted by macrophages and stellate cells. The progression of parenchymal tissue destruction and fibrosis is the pathological phenomenon of CP, graphically represented in Fig. 39.2.

Epigenetics as a Modifying Factor in Chronic Pancreatitis

Epigenetics is the control of gene expression that does not involve a change in the primary DNA sequence. In other words, epigenetics refers to modifications of DNA, for instance by methylation, or of chromatin structure through the posttranslational modification of histone proteins. The posttranslational modification of histones can alter chromatin structure or may alter the affinity transcription factors to promoter regions. The epigenome can have significant effects on human health as well as disease susceptibility, and epigenetic alterations can be induced through environmental and prenatal exposures to toxins or stressors. Epigenetic changes can be stable and allow "memory" of past stresses to impact future exposures. Epigenetic alterations may be the result of "subclinical" stresses on the pancreas that over time allow molecular remodeling of stress responses to other stimuli. These "subclinical" stresses may alter the epigenetic pattern of genes with little or no immediate effect on gene expression; however, the gene may develop an altered response in gene expression when exposed to a new specific environmental cue. In the case of CP, there are likely situations of epigenetic change that evade clinical notice until the time of exposure or triggering of risk factors, which then induce the typical destructive, fibrogenic response of the disease. In experimental models of pancreatitis, chronically stressed animals (such as with ethanol exposure [3], a fatty diet [4], or genetic mutation [5]) have an altered response to acute injury compared to animals that have no chronic stress. Ethanol has been shown to affect the action of several epigenetic proteins including the histone acetylases CREB and CBP [6] as well as the histone deacetylases [7]. An epigenetic acetylation mechanism was implicated for controlling acute pancreatitis [8]. Delayed recovery was demonstrated in mice treated with the antiepileptic drug and histone deacetylase inhibitor valproic acid (VPA). VPA is thought to be a definite cause of pancreatitis, especially in pediatric patients [9,10]; however, the mechanism by which VPA induces pancreatitis was unknown. In fact, chronically treating experimental animals with VPA

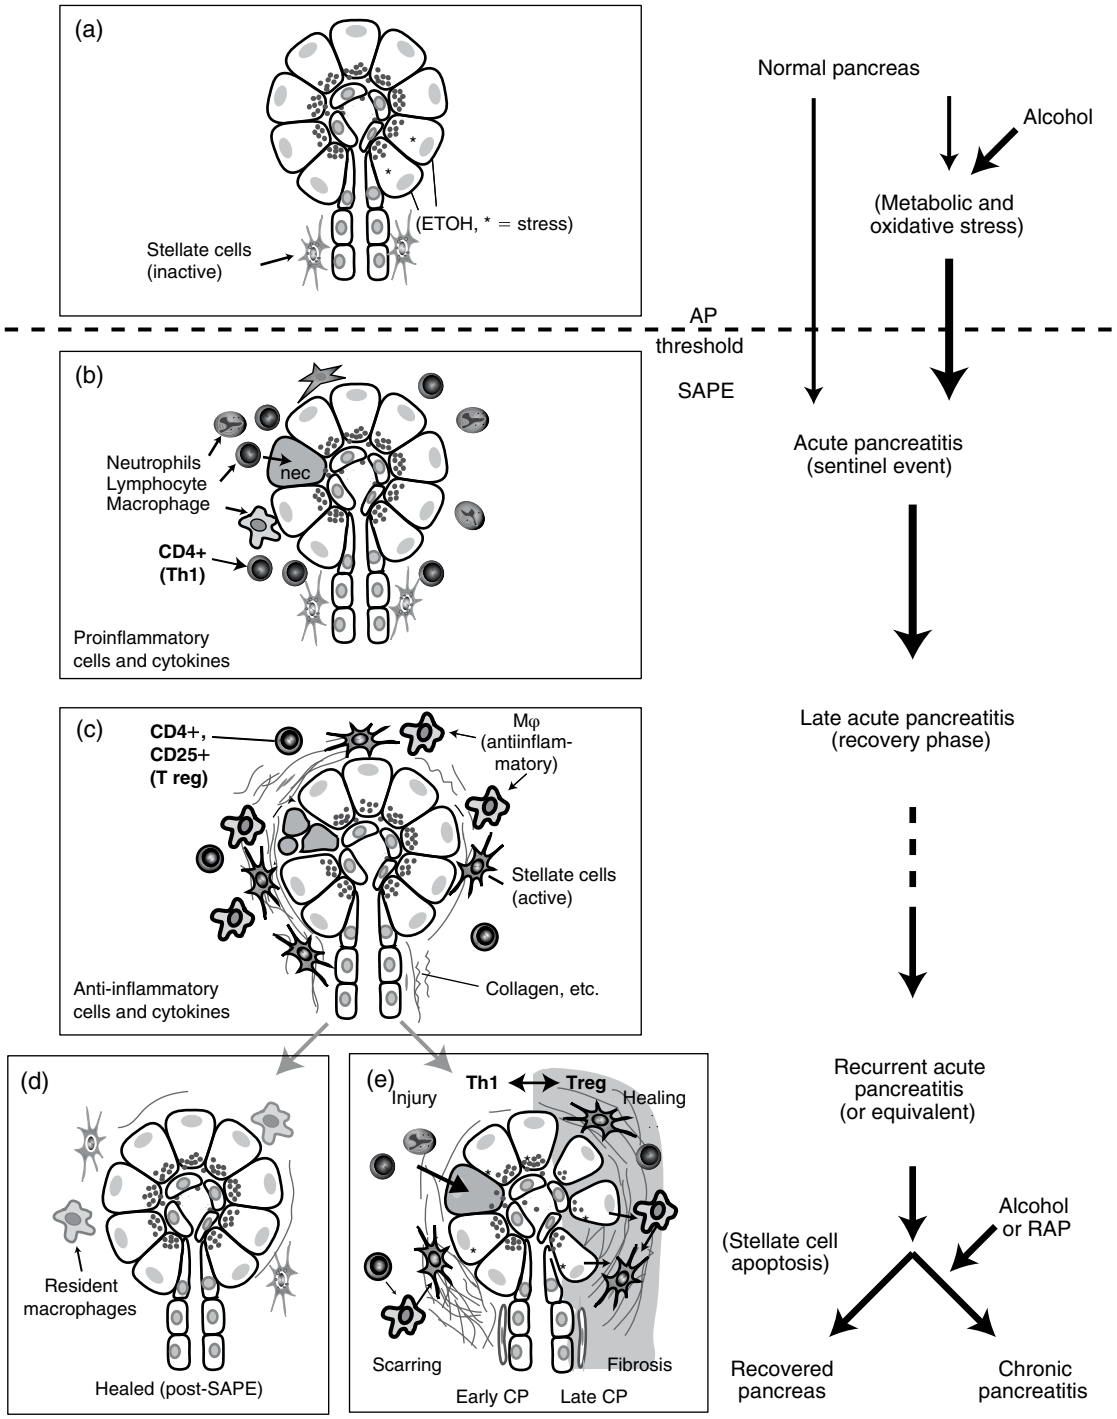

Figure 39.2 Sentinel acute pancreatitis event (SAPE) hypothesis model. (a) Normal pancreas. If the subject is a heavy alcohol user, the acinar cells are under metabolic and oxidative stress (indicated by asterisks) but histology remains relatively normal. Alcohol increases the risk of crossing the acute pancreatitis (AP) threshold (bold line crossing the dashed line). (b) Acute pancreatitis with pancreatic injury and infiltration of proinflammatory cells. (c) Late acute pancreatitis is dominated by anti-inflammatory cells that limit further injury by proinflammatory cells and products, and promote healing. This includes activation of stellate cells, which produce collagen etc. (d) Recurrent acute pancreatitis (RAP): acinar cell injury or other factors that activate an acute inflammatory response (Th1) are immediately countered by an anti-inflammatory counterresponse (Treg) which, among other things, drives fibrosis. This vicious cycle results in both continued injury (top) and further fibrosis (bottom) leading to (e) extensive acinar cell loss and sclerosis (right) characteristic of chronic pancreatitis (CP). Both genetic factors and environmental factors play a role in this process by increasing susceptibility to acute pancreatitis, altering the severity and duration of acute pancreatitis and altering the healing processes that drive fibrosis. *Source:* Adapted from Whitcomb 2004 [3].

does not induce pancreatitis [11]. However, animals treated with VPA that are then subjected to an additional injury-provoking stimulus, develop pancreatitis. Thus, VPA predisposes the host to pancreatitis by altering the epigenetic landscape and thereby inhibiting the recovery mechanisms that allow regeneration to occur.

Environmental Exposures as Modifying Factors in Chronic Pancreatitis

A mechanism thought to initiate pancreatic injury is through environmental exposures. The exposures include alcohol ingestion and byproducts of smoking [12]. The exposures do not by themselves induce pancreatitis, but they pathologically alter acinar cell responses to stressors. The prototypic example is heavy and frequent alcohol ingestion, which has long been known as a major risk factor for both acute and chronic pancreatitis [13,14]. However, only a minority of binge drinkers develop pancreatitis. Ethanol has been shown to affect pancreatic cell types either through its direct effects or through its metabolites. Ethanol or its metabolites can sensitize the acinar cell to pathologic calcium signals [15] mitochondrial dysfunction [16,17], impairment of autophagic or lysosomal responses [18], or the induction of the UPR with increased expression of XBP1 (a key regulator of ER function) [19,20]. Ethanol appears to increase ER stress visualized by ER swelling and UPR induction, and there is an impact on protein trafficking and on some of the structural components of zymogen granules [21]. Ethanol converts a physiological stimulus to the acinar cell into a pathological stimulus, with adverse outcomes, including premature intra-acinar activation of digestive enzymes and acinar injury [22,23]. This effect could be due to the increased expression of digestive enzymes such as trypsinogen, chymotrypsinogen, or lysosomal cathepsin B and to lysosomal fragility [24].

Genetic Influences in Chronic Pancreatitis

A second mechanism shown to mediate the pathologic response in the pancreas is through repeated injury by specific insults in a susceptible patient with genetic risk factors. Genetic or epigenetic alterations may allow the nonclinical or clinical repeated injury to occur which over time results in the destruction of the pancreatic parenchyma and replacement by fibrosis through repeated activation of immune and fibrotic responses. This replacement results in the loss of exocrine and endocrine pancreatic function. Hereditary pancreatitis is a prime case example of this mechanism. Hereditary pancreatitis is caused by a mutation within the cationic trypsinogen gene (*PRSS1*), the primary proteolytic enzyme responsible for activating pancreatic digestive enzymes or zymogens [25]. These gain of function mutations lead to premature trypsinogen activation. There are several mutations identified but the most common are R122H and N29I. The penetrance of the disease is about 80%. Although these mutations place an individual at a higher risk of developing CP and there is variable expressivity, the disease course and ultimate outcome are also dependent on additive risk factors, including environmental and metabolic stressors. Environmental exposures or other genetic modifiers are thought to alter the disease course as individuals with the same genetic mutation can have significantly different disease courses, despite having similar histopathology [26]. Monozygotic twin studies attest to this level of discordance, whereby the same genetic mutation in the *PRSS1* gene causes profound pancreatic disease in one twin, while the other has no evidence of disease into adulthood [27]. In order to study mechanisms underlying pancreatitis pathogenesis by these genetic mutations, several groups developed hereditary pancreatitis mouse models by manipulating human or mouse trypsinogen genes [28–32]. In addition to the *PRSS1* mutations and hereditary pancreatitis, there are other genetic mutations associated with increased risk for CP [33]. They include mutations within the *CFTR* (cystic fibrosis transmembrane conductance regulator) and *SPINK1* (serine protease inhibitor Kazal type 1) genes. As with *PRSS1* mutations, identical mutations within these genes do not predict similar disease course for affected individuals. Pathogenic variants in the *SPINK1*, *PRSS1*, *CTRC*, and *CFTR* genes can lead to earlier disease onset and worsened clinical outcomes in CP patients with varying etiologies such as idiopathic, alcoholic, and smoking-associated CP [34,35]. Overall, these observations suggest a complex disease process that will require careful analysis of multiple factors that impact disease progression.

Inflammatory Response in Chronic Pancreatitis

The secondary phase of progression to CP involves the inflammatory and fibrotic responses to chronic stress or repeated injury (Fig. 39.3). Recently, progress has been made in understanding this aspect of CP. Injury within the pancreas results in damaged acinar cells that will either repair or undergo cell death through necrosis or apoptosis. The damaged cells promote a sterile inflammatory response to mediate the recovery and regeneration process [36]. The inflammatory response is signaled

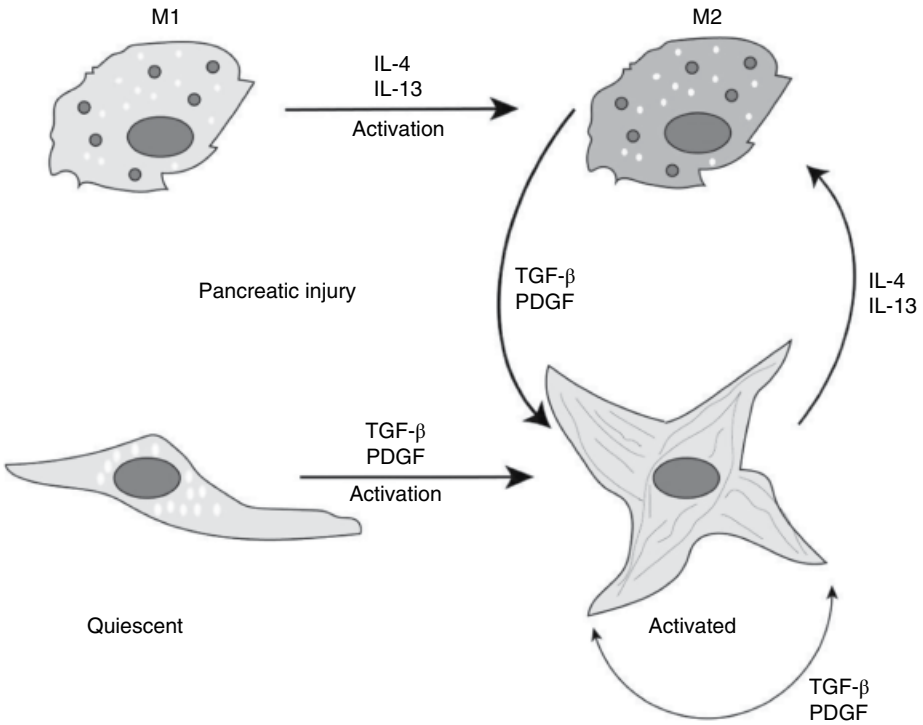

Figure 39.3 Pancreatic injury activates resident immune cells as well as pancreatic stellate cells to promote pancreatic recovery. However, persistent injury or pathologic signaling between macrophages and stellate cells leads to persistent activation and fibrogenic replacement of the pancreatic parenchyma.

by cytokines released from injured acinar cells and mediated by neutrophils, monocytes, lymphocytes, and macrophages which mediate the resolution of the damaged cells and promote the regeneration of the pancreas [37]. During progression of CP, inflammation appears to be mediated by different immune cells depending on the experimental model used [38–40]. Those immune cells including neutrophils, macrophages, and T-cell subsets play multiple roles depending upon disease progression in acute, severe acute, or chronic pancreatitis [38,39,41,42]. These cells will produce additional inflammatory mediators such as TNFα, IL-1β, Il-6, IL10, and MCP1. Initially these signals are produced by damaged acinar cells but with repeated injury and activation of other resident pancreatic cells such as macrophages and stellate cells, there appears to be a shift towards cytokine production from activated immune and stellate cells that promotes and allows progression towards CP. Neutrophils are thought to activate trypsinogen and allow progression towards severe injury in acute pancreatitis; however, in CP, T cells and macrophages are the predominant immune cell infiltrates [43,44]. Neutrophils and macrophages can play a dual role during inflammation, either releasing cytokines such as IFN-g leading to a proinflammatory phenotype repressing regeneration but are also responsible for repair signals necessary for regeneration to occur [45]. T cells are thought to help control the immune-mediated destruction initiated in CP demonstrated by the secretion of IL-10 by these T cells [46]. However, IL-17 or IL-22-secreting T-cell subset (Th17 or Th22) promotes fibrogenesis by activating pancreatic stellate cells (PSC) and contributes to the progression of CP [39,47]. Macrophages can promote healing and regeneration, depending upon macrophage polarity [48]. However, alternatively activated M2 macrophages can play a pathogenic role in CP in both rodents and humans [38]. Furthermore, pancreatic immune cell analyses using unbiased single-cell immune analysis technologies reveal novel disease-relevant immune subpopulations. Single-cell RNA/T-cell receptor sequencing analysis of pancreatic immune cells isolated from pancreatic tissues of CP patients who underwent total pancreatectomy identified hereditary versus idiopathic CP-specific novel T cell and myeloid immune subsets and T cell receptor repertoire changes. This study provides insights into human CP-specific immunopathogenic mechanisms and etiology subtype-specific immunotherapeutic targets in CP [49]. Determining unique immune subsets and their signals to neighbor cells during the disease course that can either promote or suspend disease progression is critical to a better understanding of immunopathogenic mechanisms and identifying novel therapeutic targets for healing.

Fibrogenesis in Chronic Pancreatitis

The fibrogenic response during CP is influenced by mesenchymal cells known as the pancreatic stellate cells (PSC), along with immune cell interactions. PSC have emerged as a critical player in mediating pancreatic recovery after injury [50]. PSC are localized to the periacinar region and, at baseline (i.e., the quiescent state), they are characterized by vitamin A droplets [51]. In response to injury, PSC undergo transient activation and take on a fibroblast-like role to secrete extracellular matrix (ECM), particularly collagen [52,53], which is a necessary substrate scaffold for proper regeneration and recovery. The hallmarks of pancreatic injury and recovery are regenerative structures called acinar to ductal metaplasia (ADM) [54,55]. The stroma surrounding ADM is composed of activated PSC (aPSC) that function to remodel ECM and are thought to coax ADM to redifferentiate into new acinar cells. Aberrant regulation of PSC has been implicated in the pathogenesis of CP and pancreatic cancer [52,56–58]. PSC are not only activated by acinar cell injury but can be activated by cellular stress and ethanol byproducts. TGFβ appears to be a major contributor to fibrotic properties of PSC by increasing collagen and fibronectin expression but also by inhibiting metalloproteinases (MMP). Once activated, PSC initially help to remodel the parenchyma through the removal of matrix proteins by MMP. PSC not only produce MMP but also the inhibitors of MMP called tissue inhibitors of metalloproteinases (TIMP). A balance of these two factors likely affects the progression toward fibrosis. The destruction of the matrix releases growth factors and cytokines that signal adjacent cells and stimulate parenchymal healing through interactions of the immune and exocrine and endocrine pancreatic cells. PSC not only orchestrate the destruction of matrix but also help orchestrate the regeneration of the framework to allow regenerating acinar and duct cells to proliferate and repopulate the parenchyma. However, if PSC remain activated through repeated injury to the pancreas or aberrant cell signaling from adjacent cells such as macrophages, a pathogenic response can ensue. The response perpetuates the remodeling of the ECM and replaces acinar tissue with fibrosis, leading to the loss of pancreatic exocrine function. PSC in CP models have been shown to respond to adjacent macrophages that produce higher levels of TGFβ and PDGFβ suggesting that the macrophage-PSC interaction may be important in regulating pancreatic fibrogenesis [38]. PSC communicate with cytokine-producing T cells (Th22 and Th17) by expressing their receptors in order to promote fibrosis in CP [39,47]. STAT3 activation is a prominent signaling molecule found in activated PSC, and the inhibition of the Jak/STAT pathway via ruxolitinib has been shown to reduce the severity of experimental CP [59], suggesting a potential therapeutic strategy for CP.

Conclusions

There are several risk factors and progressive steps that lead to the histopathological disease known as CP. They include a sentinel pancreatic event in a susceptible host that perpetuates a progressive low-grade injury. The injury results in pancreatic fibrosis and loss of physiologic function. Alternatively, several repeated injury events of acute pancreatitis may lead to chronic injury and fibrotic replacement of the pancreatic parenchyma. Several animal models have been developed to help target specific aspects of injury and disease progression for the study of CP. Although healthy caution is indicated when using animal models to mimic disease states in humans, with careful attention to the limitations of the experimental model, one may begin to understand aspects of this complex, multifaceted disease. The animal model systems used most frequently are cost-effective rodent models of pancreatic injury leading to inflammation and fibrosis reminiscent of histologic changes in CP (e.g., duct ligation, chemical or biological exposures) [60–65]. However, for certain etiologies such as CFTR disease, the rodent models do not mimic the human condition, and other models (such as the porcine or ferret model for CFTR) must be used. Genetic models of CP exist and include overexpression or reduced expression of genes that allow the histopathologic appearance of CP. Beyond animal models, our understanding of CP would be enhanced by the characterization of heterogeneous human microenvironments using unbiased analysis techniques.

Natural History of Recurrent Acute and Chronic Pancreatitis

Rohit Das[1], *Jorge D. Machicado*[2], *and Dhiraj Yadav*[1]

[1] *Division of Gastroenterology & Hepatology, Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, PA, USA*
[2] *Division of Gastroenterology & Hepatology, Department of Medicine, University of Michigan, Ann Arbor, MI, USA*

Introduction

Pancreatitis, especially chronic, is a low prevalence disease. Consequently, the focus of epidemiologic studies of pancreatitis has primarily been to define the disease at the level of individual patients. In the past two decades, the importance of understanding the distribution of risk factors and disease at the population level has been recognized. This has enabled determination of disease estimates and understand the relationship between acute pancreatitis (AP) and chronic pancreatitis (CP) at the population level. Demonstration that subsets of patients with AP develop recurrent acute pancreatitis (RAP) and/or progress to CP provides empiric evidence that these conditions represent stages of a disease continuum. Knowledge of the risks and factors associated with disease progression will help in risk stratification, prediction, and developing strategies for altering the natural history of disease.

This chapter will focus on the burden of disease, natural course and survival of AP, RAP, and CP. For AP, the emphasis will not be on the severity and outcome of the initial attack, but rather the risk of readmissions, recurrences, and progression to CP. In CP, the prevalence and natural history of clinical features, i.e., pain, endocrine and exocrine insufficiency, bone health, and the risk of pancreatic cancer will be discussed. Finally, we will summarize available data on the quality of life.

Natural History After First Attack of AP

Disease Burden, Etiology, and Severity

AP is one of the leading gastrointestinal causes of hospitalization in the United States [1]. The estimated incidence of AP in recent studies is 30–50 per 100,000 population. AP affects all age groups, but is most frequent in middle-aged and older individuals [2]. Gallstones and excessive alcohol consumption account for about 60–70% of all cases, the latter being more common in men when compared to women. Other etiologies include metabolic factors (hypertriglyceridemia, hypercalcemia), endoscopic retrograde cholangiopancreatography (ERCP), medications, genetic mutations (*PRSS1*, *SPINK1*, *CFTR*, *CTRC*), obstructive causes (such as pancreatic duct stricture, etc.), and trauma. In 10–25% patients no identifiable etiology is found on evaluation [2]. The two main determinants of mortality in AP are the presence of infected necrosis and organ failure, especially when persistent (>48 h) or involving more than one organ [3]. The risk of death increases with age and comorbidities [4]. Increased morbidity is seen in patients with local complications who do not have organ failure [5].

Readmissions

After the first attack of AP, about 20–30% patients are readmitted to hospital (Table 40.1). The reason for readmission differs based on time since discharge from the hospital. Vipperla et al. [6] differentiated between early (<30 days after index AP) and late (>30 days) readmissions and found that early readmissions were more likely due to smoldering symptoms from AP and/or local complications, whereas late admissions were more likely to be due from recurrent AP episodes. Younger age, alcohol use and/or alcohol-related etiology, non-private medical insurance, increased length of stay during index admission, and discharge to long-term care facilities have been identified as predictors of readmissions [6–8].

The Pancreatitis Activity Scoring System (PASS) was developed in 2017 as a tool to measure disease activity

and better predict the prognosis of AP. PASS incorporates organ failure, systemic inflammatory response syndrome (SIRS), abdominal pain, opiate requirement and diet tolerance, with each component having a different weight according to their prognostic importance [9]. In a prospective study examining the predictive utility of PASS, a score of >60 was highly associated with readmission within 30 days of AP discharge [10].

These data suggest that focused discharge planning may reduce the risk of early readmissions—i.e., ensuring that the patients' symptoms are well controlled and they have received counseling for behavior modification. In patients with severe AP, close follow-up with relevant specialists (e.g., nutrition, gastroenterologist, surgeon) is helpful to determine the need and timing of cross-sectional imaging, duration of enteral feeds, and "step-up" therapy. Many patients with severe AP need short-term stay at a transitional care facility or rehabilitation unit prior to safe discharge home.

First Recurrence

The risk of recurrent AP (RAP) after the first attack has been evaluated in several, mostly retrospective, population and nonpopulation based studies (Table 40.2). The overall risk of a subsequent attack of AP is ~20% during a median follow-up period ranging from 4 to 8 years. Similar to the first attack, among patients with a second attack of AP, alcohol, gallstones, and idiopathic are the most common etiologies [11–13]. When compared with the first attack of AP, subsequent recurrence is generally milder with an overall lower mortality [14].

The risk of recurrent attack is highest among patients with alcohol etiology (35–40%) followed by idiopathic and biliary AP (both 10–20%) [11–13]. Takeyama et al. noted that the risk of subsequent recurrence was directly related to continued alcohol consumption—the risk was highest in patients who continued drinking at the same level, and lowest among patients who stopped drinking completely [15]. Contrary to what many physicians may believe, counseling against alcohol consumption has a significant impact on patient behavior. This was tested empirically in a randomized controlled trial (RCT), where repeated counseling of patients led to a significant decrease in the risk of abdominal pain attacks, AP episodes and hospitalizations [16].

After an attack of biliary pancreatitis, the risk of recurrence can be dramatically reduced by early cholecystectomy. This has been demonstrated in RCTs, as well as in meta-analyses of published data [17]. In patients with mild biliary pancreatitis, cholecystectomy should be considered as close to the attack of AP as possible, preferably during the same admission. In patients with severe AP, cholecystectomy should be delayed until resolution of inflammatory changes in the pancreas/pancreatic area. In patients with pancreatic/peripancreatic collections that need drainage, a surgical approach (preferably laparoscopic or minimally invasive) to address this along with a cholecystectomy should be considered [18]. In patients with another known etiology, i.e., medications, hypertriglyceridemia, hypercalcemia, etc., addressing the inciting cause will decrease the risk of recurrence [19].

Tobacco abuse has been a consistent association with the risk of recurrent AP (odds ratio 1.5–2) [11,13,20]. Therefore, after an attack of AP, patients should be informed about this risk and counseled for tobacco cessation. This will be especially relevant in patients in whom the cause was alcohol, hypertriglyceridemia, genetic or idiopathic, or if the AP attack was moderate to severe. Individual studies have also shown that age and severity of initial attack may also play a role in recurrent attacks [11,13,20].

The burden of recurrent AP at a population level is not well defined. Using information on the total number of admissions for AP in the USA and applying the incident AP rates from California, approximate number of recurrent attacks can be estimated [1,21]. Among the 275,000 annual admissions for AP in the USA, approximately 150,000–160,000 would be incident attacks, while the remaining 115,000–125,000 would represent RAP (first or subsequent recurrences), readmissions for ongoing symptoms or complications of AP, or acute CP.

Subsequent Recurrences

Alcohol is the most common etiology of subsequent recurrences, followed by idiopathic pancreatitis, genetic causes, hypertriglyceridemia, and underlying CP as other important causes. The role of pancreas divisum and sphincter of Oddi dysfunction in causing initial or recurrent AP attacks is controversial [22].

Approximately one-third of patients who have a recurrence after the first attack of AP will have one or more subsequent recurrences. Burden of recurrent AP was further quantified in in two previous studies. Among 562 patients with a first attack of alcoholic AP who survived the index admission, Sand et al. reported at least one recurrence in 260 (46%) patients. Among these patients, 133 (51%) had only one recurrence, 49 (19%) had two recurrences, 39 (15%) had three recurrences, and 39 (15%) had four or more recurrences [23]. Among patients who underwent a cholecystectomy for presumed biliary pancreatitis, Trna et al. noted the risk of subsequent attacks to be related to the presence of abnormal liver function tests and documentation of gallbladder stones or sludge. Among patients who did not have either, 26% had a second attack, and 9% had a third attack of AP [24]. Although few empiric data is available, the risk of

multiple attacks of AP seems high in patients with genetic mutations (e.g., *PRSS1*, *CFTR*) [25]. The risk of recurrences would also be higher in patients with uncommon causes of AP, such as hypertriglyceridemia, hypercalcemia, etc., especially if the underlying cause is not corrected, but definitive data on the burden of attacks in these patients is limited.

Diabetes and Exocrine Insufficiency After AP

Recent data have documented that AP increases the risk of diabetes mellitus (DM) and exocrine pancreatic insufficiency (EPI) irrespective of severity. In two population-based studies patients with mild AP were about two times more likely to develop DM than age- and sex-matched controls [26,27]. In a systematic review of 24 prospective studies, the pooled prevalence of newly diagnosed DM after the first episode of AP was reported to be 23% (95% CI 16–31%), and increased with the duration of follow-up [28]. The risk of DM after AP is greater in patients with severe AP, necrotizing pancreatitis and in those with alcohol etiology. The mechanisms leading to DM are not well defined.

With regards to EPI, a meta-analysis of 39 studies reported that the pooled prevalence of EPI after an index episode of AP was 35% and the prevalence was greater during the time of AP hospitalization [29]. The risk of EPI increased with disease severity, presence of necrosis, and alcohol etiology.

Quality of Life After AP

Several studies have demonstrated that AP deleteriously impacts quality of life. In a single-center prospective study of 91 patients, patients who experienced AP had a significantly lower physical healthcare-related quality of life (HRQOL) as compared to controls even after 14 months of AP [30]. Factors associated with lower physical HRQOL included the presence of ongoing abdominal pain and use of analgesics, disability, and smoking. Multiorgan failure was the only disease-related factor associated with a lower physical HRQOL.

Progression to CP

Many studies evaluating the natural history after a first attack of AP have determined the risk of progression to CP (Table 40.3) [11–13,20]. In a meta-analysis of 14 studies consisting of 8492 patients, Sankaran et al. reported that following a sentinel attack of AP the pooled prevalence of RAP was 22% (38% for alcohol etiology, 17% for biliary etiology) and of CP was 10% [31]. The three factors consistently shown to have an independent effect on disease progression have been alcohol etiology, tobacco abuse, and RAP. The association with severity of AP is less consistent and has been noted in some studies.

Lankisch et al. noted that progression to CP occurred almost exclusively in patients with alcohol etiology [12]. However, in other studies progression was also noted with nonalcoholic or idiopathic CP, albeit at a lower rate. The role of tobacco, especially in combination with alcohol in disease progression is important. Ali et al. reported that while the cumulative risk of progression to CP overall was 7.6%, it was 18% among current smokers, and increased to 30% in current smokers who also had alcohol etiology [20]. Therefore, including the counseling of tobacco cessation along with alcohol abstinence should be emphasized. Genetic factors also seem to play a role in the development of CP, but outside of hereditary pancreatitis, little empiric data is available [25].

Perhaps the strongest risk factor for disease progression is RAP, and the risk of progression in these patients is ~30–40%. Bertilsson et al. noted that among patients who transitioned to CP, 74% had at least two AP attacks, and 54% had more than two attacks. When compared with alcohol or tobacco (hazard ratio between 2 and 3), the risk of progression to CP in RAP is much higher (hazard ratio ~6) [11].

Natural History of Chronic Pancreatitis

Disease Burden, Demographics, and Etiology

Recent population studies estimate that the incidence of CP ranges from 4 to 14 per 100,000 per year, and the prevalence ranges from 42 to 73 per 100,000 population [19,32]. The prevalence of CP peaks at the age of 45–55 years and has a male predominance [32]. Alcohol is the most common cause of CP worldwide (frequency ~40–70%), followed by idiopathic etiology (frequency ~20–30%) [19]. Smoking is a well-recognized factor for CP and works in a dose-dependent manner—the risk of CP is fivefold greater in those smoking over 35 pack-years compared to never smokers [33]. The role of genetic factors is increasingly recognized and mutations in some susceptibility genes (*PRSS1*, *SPINK1*, *CFTR*, *CTRC*, *CPA*, *CASR*) are found in 10–15% of CP patients. Alcoholic CP is seen more commonly in men, while the other etiologies are more evenly distributed in both sexes [33]. The diagnosis of CP is preceded by AP in at least 50% of patients [34]. This has been well demonstrated in patients with hereditary and alcoholic CP, in whom AP precedes the progression of CP by 10 years [19].

Natural History of Pain

Abdominal pain is the hallmark of CP, and often prompts patients to seek medical attention. A recent systematic review of 42 studies demonstrated that 88% of CP patients experience abdominal pain at some point during the disease course [35]. Emerging data has demonstrated that the temporal nature of pain is a more important determinant of patient outcomes than the intensity of pain [36,37]. On cross-sectional assessments of abdominal pain in CP patients, approximately 60–70% have constant pain and 30–40% have intermittent pain; however, 60% alternate between pain patterns during the disease course [36,37]. Constant pain is associated with lower quality of life, higher rates of disability, and greater need for resource utilization (e.g., hospitalizations, pain medications) as compared to intermittent pain [36–38]. This effect is independent of the intensity of abdominal pain.

The mechanisms of pain in CP are complex, multifactorial, and poorly understood. Pain can be due to structural complications in the pancreas (pancreatic duct obstruction from stricture or stone, pancreatic inflammation, pseudocyst) or peripancreatic organs (bile duct stricture, duodenal obstruction). Resolution of these complications does not always result in pain control, and many patients with painful CP do not have these structural complications, suggesting sensitization of peripheral and/or central nociceptive pathways [33]. However, differentiating visceral pancreatic pain from central nervous system alterations is challenging in clinical practice, and novel pain assessment tools (e.g., comprehensive pain assessment score, pancreatic quantitative sensory testing) are being investigated to better classify pain profiles and to more effectively guide treatment choices.

Although medical management with nonopioid analgesics is the first step in the management of painful CP, this is often insufficient. In a recent US population study, 25% of CP patients are prescribed opiates and CP had the highest prescription rates among all GI disorders [39]. This is concerning, given the adverse events associated with opioid use. Endoscopic and surgical interventions are needed in a subset of patients with pain refractory to noninvasive interventions. In a US population-based study, 22% of CP patients required endoscopic procedures and 11% underwent surgical interventions over 10-year follow-up; however, a higher proportion of patients receive endoscopic and/or surgical interventions at referral centers [40].

One aspect that has recently been investigated is the interaction of psychiatric comorbidities with pain in CP. In a recent retrospective US cohort, patients with CP had sevenfold greater risk of anxiety (37%) and fivefold greater risk of depression (47%) compared with the general population [41]. The presence of psychiatric comorbidities in CP patients has been associated with higher pain prevalence, pain severity, and pain interference scores [42]. These data indicate that psychiatric comorbidities should be evaluated in CP patients, and their management is likely to improve pain management.

The concept of pain *burn-out* in CP was proposed by Ammann et al. decades ago, based on the observation that over 80% of patients with alcoholic CP became pain-free at a median of 5 years from disease onset. In recent years, an accumulating body of evidence has emerged that refutes this theory. In a large single-center retrospective cohort of 279 CP patients, 47% still complained of abdominal pain at a median period of 12 years from disease onset [43]. In multivariate analysis, this and other studies have shown that disease duration is not associated with pain relief [37,43].

Approximately 1 in 10 patients experience a painless disease course, with the majority of these (57%) having idiopathic/genetic etiology [35]. Patients with painless CP are diagnosed when undergoing abdominal imaging for other reasons and are found with calcifications and/or significant ductal changes. In general, these patients do not benefit from endoscopic or surgical interventions.

Diabetes Mellitus

Diabetes mellitus (DM) is a well-known complication of CP. In a recent systematic review of 15 studies, the incidence of new-onset DM was 15% within 3 years and 33% after 5 years of CP diagnosis [44]. In prospective studies with longer follow-up, the cumulative incidence of DM is 40–50% at 10 years and >80% at 25 years [40,45]. The pathogenesis of DM in CP has been thought to be a result of progressive parenchymal fibrosis with impaired insulin secretion. Several epidemiologic studies have supported this theory, by demonstrating that the risk of DM increases with certain CP specific characteristics (disease duration, calcifications, exocrine insufficiency, pancreatic surgery) [46,47]. This pathophysiologic paradigm has been challenged by recent large cross-sectional multicenter studies that reported an increased risk of DM in CP with traditional type 2 DM risk factors (age, overweight/obesity, family history of DM, dyslipidemia) [46,47]. This has suggested that DM in CP, at least in a subset of patients, may be a subtype of type 2 DM, and future studies are needed to better define the mechanisms of DM in CP.

Diabetes in CP is difficult to treat and about half become insulin dependent [44]. The risk of all-cause mortality and hospitalizations in CP patients with diabetes is greater than in patients with type 2 DM [48].

Exocrine Pancreatic Insufficiency

Initially CP patients lose pancreatic enzyme output, measured by direct or indirect pancreatic function tests, but maintain adequate digestive capacity, quantified by

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

normal coefficient of fat absorption (CFA ≥ 93%). The term exocrine dysfunction (stage I and II) has been coined for these patients, who do not have symptoms or vitamin deficiencies, and would not benefit from treatment [49]. As pancreatic function loss reaches near total (>90%), patients develop abrupt and marked impairment in digestive capacity (CFA < 85%), with clinical manifestations, and micronutrient deficiencies [50]. This state of insufficient digestive capacity due to severe loss of pancreatic function represents exocrine pancreatic insufficiency (EPI, stage III and IV) [49] The burden of EPI in CP is difficult to estimate, given the absence of simple and accurate tests to diagnose EPI in clinical practice. A recent US population study showed a cumulative incidence of 30% at 10 years of follow-up [40]. In other series, the prevalence of EPI ranges from 35% to 75%, with higher risk in alcoholic CP and with longer disease duration [51]

EPI from CP is frequently experienced as diarrhea, foul-smelling stools, flatulence, meteorism, abdominal discomfort/pain, and weight loss. Persistent malabsorption can cause deficits of fat-soluble vitamins A, D, E, and K, calcium, magnesium, zinc, thiamine and folic acid. Fortunately, EPI can be treated with the initiation of pancreatic enzyme replacement therapy (PERT), which has been shown to improve symptoms, nutritional status and quality of life. A minimal dose of at least 40,000 USP units of lipase with each meal is recommended. Despite its importance, a recent US study of administrative claims demonstrated that only 6.5% of CP patients receive any testing for EPI, and that among those treated with PERT, only 32% are prescribed appropriate dosing [51]. In this study, seeing a GI physician and formal testing for EPI were strong predictors for prescribing PERT and using an appropriate dose.

Metabolic Bone Disease

Long-term malnutrition from EPI and CP can lead to metabolic bone disease. In a systematic review of 10 studies reporting osteopathy in CP, the prevalence of osteopenia was 40% and of osteoporosis was 23% [52]. Similar estimates were reported in a recent multicenter US study of 282 patients with definitive CP, in which 39% had osteopenia and 17% had osteoporosis at the time of baseline DXA scan [53]. Risk factors independently associated with osteopathy included underweight body mass index, older age, female sex, and white race [53]. In a large VA cohort, CP was independently associated with greater risk of total fractures (5%), vertebral fractures (1%), and hip fractures (2%), compared to non-CP controls [54]. Therefore, assessments of bone mineral density are recommended for CP patients. However, this is often underperformed, and a recent single center study showed that a dual-energy X-ray absorptiometry test (DXA) was performed in only 21% of CP patients [55].

Pancreatic Cancer

Within the first 2 years of CP diagnosis, there is an excess of pancreatic cancer diagnosis, that may represent early cancers misdiagnosed as CP [56]. When excluding patients diagnosed with pancreatic cancer within 2 years of CP diagnosis, a meta-analysis of 13 observational studies showed that the risk of pancreatic cancer in CP is 16-fold greater than in the general population [57]. Even when excluding pancreatic cancer patients diagnosed within 5 years of CP, patients with CP still have eightfold greater risk of pancreatic cancer [57]. In a recent US population based study, the cumulative incidence of pancreatic cancer from initial CP diagnosis was 2% at 2 years and 3% at 5 years [58]. Age, obesity, and pancreatic ductal dilation are risk factors associated with higher incidence of pancreatic cancer [58].

Quality of Life

CP is a debilitating disease that negatively impacts quality of life. Factors that significantly decrease quality of life include constant pain, disability/unemployment, current smoking, and other comorbidities [38]. In a multicenter prospective study, anxiety and depression were also noticed to negatively impact quality of life in CP [42].

Survival

The overall survival and the standardized mortality ratio in CP patients is two- to fourfold higher when compared with the general population [59]. Most patients die from nonpancreatic causes such as cancers and cardiovascular diseases.

Conclusion

Studies in the past two decades have provided an insight into the population distributions and natural history of different stages of pancreatitis. Readmission to hospital is frequent after AP. After the first attack of AP, about 1 in 5 patients develop a recurrence and 1 in 10 progresses to CP. Alcohol and tobacco abuse are the main predictors of recurrence, and these along with RAP are the main predictors of progression to CP. Abdominal pain is the main symptom of CP, and a significant fraction of these patients develop exocrine and/or endocrine insufficiency during the disease course. CP is an established risk factor for pancreatic cancer, although, the absolute risk of this is low.

Pediatric Recurrent Acute and Chronic Pancreatitis: Role of Pancreas Divisum

Jiri Snajdauf, Michal Rygl, Barbora Kucerova, and Natalia Newland

Department of Pediatric Surgery, 2nd Faculty of Medicine, Charles University, University Hospital Motol, Prague, Czech Republic

Pediatric Pancreatitis

The incidence of pediatric acute pancreatitis (AP) has increased over the last several years, affecting approximately 1 in 10,000 children. Acute recurrent pancreatitis (ARP), characterized as two or more discrete episodes of AP, is reported in ~15% to 20% of children following an initial AP episode. Chronic pancreatitis (CP), in which children have imaging or functional evidence of irreversible pancreatic damage, is estimated to have an incidence of ~2 per 100,000 children per year. ARP and CP are considered as a disease continuum. They are both associated with significant disease burden. Children with ARP or CP experience frequent abdominal pain, emergency room visits and hospitalizations. They undergo numerous endoscopic and surgical procedures. Overall, diagnostic and therapeutic approaches are limited.

Risk Factors

Genetic Factors

Gene variants are the leading risk factors in recurrent attacks of pancreatitis in childhood affecting approximately 50% of children with ARP and 75% with CP. The genes most commonly associated with pediatric pancreatitis are: cationic trypsinogen (*PRSS1*), serine protease inhibitor Kazal-type 1 (*SPINK1*), chymotrypsin C (*CTRC*), and carboxypeptidase A1 (*CPA1*).

Obstructive Factors

These include biliary obstructive factors (gallstones, choledochal cyst) and anatomical abnormalities—e.g., pancreas divisum, pancreaticobiliary malunion (Table 41.1). Pancreas divisum (PD) is found in 14.5% of the INSPPIRE (International Study Group of Pediatric Pancreatitis in Search for a Cure) population, which is higher than in the normal population (~7%), but does not have an association to known pancreatitis gene mutations, suggesting that PD itself may be a risk factor. Although children frequently undergo endoscopic interventions, pancreatic sphincterotomy or minor papillotomy for PD, it is not clear whether they help prevent recurrent attacks. Therapeutic endoscopy was found most helpful when the pancreatic duct was impacted with stones in children with PD. A prospective and randomized study similar to the SHARP (Sphincterotomy for Acute Recurrent Pancreatitis) trial in adults with PD would be beneficial to assess whether therapeutic endoscopy would be helpful for this subset [1–5].

Pancreas Divisum

Anatomical Description

Pancreas divisum (PD) is the most common anatomical variant of the pancreatic duct system and occurs in 4–14% of the population. It occurs as a result of the failure of fusion of the dorsal and ventral pancreatic ducts during embryonic development. There are two types of PD: complete and incomplete. In complete PD, there is no connection between the dorsal and ventral ducts. The ventral duct drains the uncinate process and part of the head of the pancreas into the major papilla. The dorsal pancreatic duct drains the head, body, and tail of the pancreas and opens into the minor papilla. Incomplete PD occurs when a small branch of the ventral duct communicates with the dorsal duct. In both types of PD, the minor papilla drains the majority of the pancreas. This leads to increased intraductal

pressure, which can lead to the development of recurrent bouts of pancreatitis.

Clinical Symptoms, Diagnostics, and Treatment

The majority of patients with PD remains asymptomatic. Between 5% and 10% of patients with PD develop clinical symptoms of acute and chronic abdominal epigastric pain and recurrent pancreatitis documented by elevated amylase, lipase, and C-reactive protein. The diagnosis of hereditary pancreatitis and cystic fibrosis should be excluded. Diagnostic magnetic resonance cholangiopancreatography (MRCP) can show a progressive dilation of the Wirsung's duct in the head of the pancreas but sometimes can fail to show PD (Fig. 41.1) [6].

Treatment is aimed at improving the drainage of the dorsal duct. This may be achieved by endoscopic retrograde cholangiopancreatography (ERCP), assisted papillotomy and/or stent insertion, or by surgical approaches [7]. An overview of the authors' experience with PD management is summarized in Table 41.2.

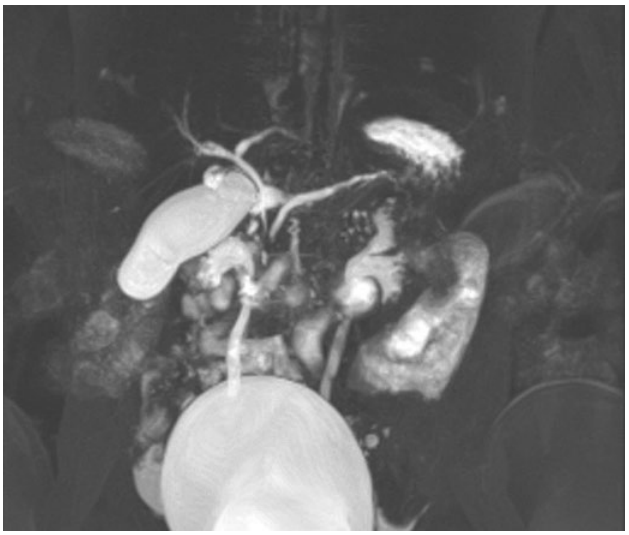

Figure 41.1 Magnetic resonance cholangiopancreatography (MRCP) of a 4-year-old girl with pancreas divisum.

It is stated in the published literature, that the first choice of treatment for patients with symptomatic PD is ERCP papillotomy [8]. However, no randomized studies have been performed to warrant this approach [9]. ERCP papillotomy may result in symptom improvement [6]. However, if ERCP papillotomy is unsuccessful or cannot be performed, surgical treatment is indicated [10,11].

Surgical Treatment

Indication for surgery in pediatric PD is very rare. It is only considered in patients with repeated bouts of pancreatitis, abdominal pain, and failure to thrive after ERCP has failed to improve the symptoms.

The plethora of surgical techniques (transduodenal sphincteroplasty, Puestow's procedure, Frey's procedure, Kausch/Whipple's procedure, duodenum-preserving resection of the pancreatic head, and total pancreatectomy) complicates the clinical decision-making process about which surgical method should be performed.

A promising surgical procedure in patients with PD is duodenum-preserving resection of the pancreatic head (DPRPH) [6], a reliable method to preserve the duodenum and limit resection of pancreatic tissue. To perform duodenum-preserving pancreatic head resection safely, preservation of the mesoduodenal vessel as well as the posterior superior pancreatoduodenal artery is important, and Kocher's maneuver should be avoided for this reason. DPRPH is ideally performed using an ultrasonic surgical aspirator (Fig. 41.2) and a Roux-en-Y pancreatojejunoanastomosis is created (Fig. 41.3).

DPRPH was first introduced by Prof. Beger for chronic pancreatitis in an adult patient [10]. The application has expanded to precancerous lesions and pancreatic head tumors with low malignancy.

Schneider followed this report with a study of 36 patients who underwent DPRPH for symptomatic PD. After the surgical intervention, 50% of the patients were completely pain-free and 31% had a significant reduction of pain. The procedure was specifically chosen because of the underlying duct anomalies and major pathomorphological changes in the pancreatic head [12].

DPRPH is an alternative technique to other resective or drainage procedures after failure of the nonsurgical interventional treatment. The scarce published cases of children with PD indicate that sphincteroplasty may not be sufficient in preventing pancreatitis. Puestow's procedure is preferred to the DPRPH in the presence of a dilated pancreatic duct; however, it is surgically challenging and has a lower success rate.

Table 41.2 An overview of patients with pancreas divisum, published in Snajdauf et al. [6].

Patient	Sex	Age (y)	Variant of PD	Successful papillotomy	Management	Recurrence of pancreatitis
1	F	4	Complete	Yes, no improvement	DPRPH	No after surgery
2	M	14	Complete	Yes (minor)	Papillotomy	No
3	F	6	Incomplete	Yes (minor)	Papillotomy	No
4	M	12	Complete	Yes (major)	Papillotomy	No
5	F	11	Complete	No	Conservative	Mild
6	M	14	Complete	No	Conservative	Mild
7	M	2	Incomplete	No	Conservative	Mild

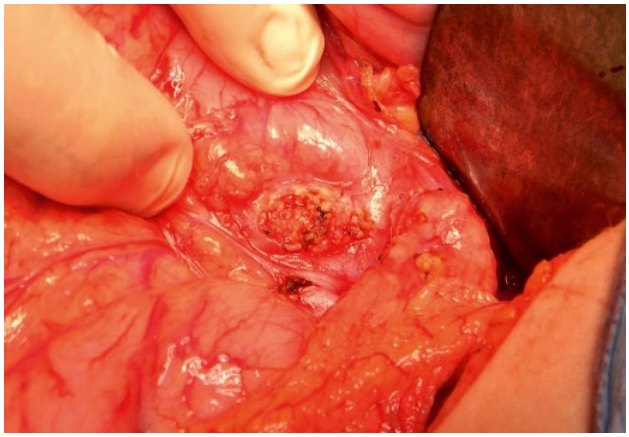

Figure 41.2 Duodenum-preserving resection of the pancreatic head (DPRPH) was performed using an ultrasonic surgical aspirator.

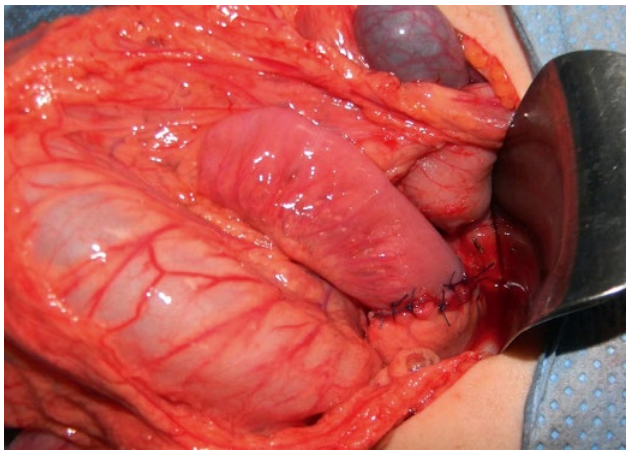

Figure 41.3 The rest of the pancreas was drained into the jejunum by means of a retrocolic single end-to-end, Roux-en-Y pancreaticojejunostomy.

DPRPH is a technically demanding (especially concerning the separation of the head of the pancreas from the duodenum) and time-consuming procedure. However, it is very effective when the obstruction lies in the head of the pancreas. When the head of the pancreas is removed, the recurrent bouts of pancreatitis are cured [13]. Furthermore, the risk of pancreatic insufficiency is very small, as only the head of the pancreas is removed. DPRPH may be superior in other aspects, such as the need for postoperative blood replacement, length of hospital stay, exocrine function impairment, postoperative weight gain, and quality of life [14,15]. Postoperative weight gain and quality of life are outcomes of utmost importance in pediatric patients. Continuing normal growth after such procedures is key because impeded development has dire social and psychological impacts on the child.

Complications and Controversies with Resection of the Pancreas

Partial or total resection of the pancreas can have severe complications in growing children. Thus, surgical treatment is only indicated when its potential benefits outweigh the risks of complications and the impaired quality of life caused by recurrent pancreatitis. The most frequent complications of pancreatic surgery in children and adults are exocrine and endocrine dysfunction of the pancreas, diabetes mellitus, gastrointestinal dysfunction (e.g., delayed gastric emptying), impaired quality of life, persisting impairment of nutritional status, abdominal pain, fatigue, change in stools, and local surgical site-related complications such as pancreatic fistula or bleeding [16–22].

To our knowledge, only a few cases of children treated surgically for PD have been published. Snajdauf et al. presented a case of a girl who underwent DPRPH for PD and she was reported to be in a good state of health 7 years after the operation. Her alimentary status and somatic growth rates were within the normal population range and she had no reported gastrointestinal dysfunction, no symptoms of diabetes mellitus, and did not

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. require any dietary restrictions [6]. O'Rourke and Harrison reported an 8-year-old girl who presented with recurrent bouts of acute pancreatitis and, after multiple failed attempts at ERCP, was referred for surgical intervention. She underwent an open sphincteroplasty of both the major and minor papillae and at a follow-up period of 22 months was symptom-free [23]. Neblett reported eight children who underwent surgical treatment for symptomatic PD. Seven patients underwent transductal sphincteroplasty, and two of these patients further underwent longitudinal pancreaticojejunostomy due to recurrent symptoms. Pancreaticojejunostomy was performed as a primary procedure in one patient. The indication for this was a ductal stenosis at the union of the ducts of Wirsung and Santorini [24]. This suggests that the cause of outflow obstruction in PD may lie in the head of the pancreas. Rabinovich et al. presented the largest series to date on pancreatic procedures performed in children. They reported 72 operative interventions in 62 patients over a 12-year period. Nine patients were treated operatively for PD with recurrent bouts of pancreatitis. Unfortunately, the long-term follow-up data were not reported in this study [25]. Shukri presented a series of seven children with PD over a span of 20 years. One patient in this group was treated surgically. Initially a transduodenal papilloplasty was performed through the accessory papilla. However, due to a recurrence of pancreatitis 1 year later, Puestow's procedure was performed [26]. Schneider reported 28 patients treated surgically for symptomatic PD. The group included one child, a 12-year-old boy treated by sphincteroplasty of the minor papilla. However, due to persisting symptoms caused by an isolated ductal stenosis the patient underwent further segmental resection 23 years later [12].

Conclusions

Surgery is not required in most pediatric patients with pancreas divisum. Patients with a milder form of pancreatitis respond well to ERCP papillotomy or pancreatic duct stent insertion. Surgery should only be performed if ERCP therapy fails. Transduodenal sphincteroplasty, Puestow's procedure, Frey's procedure, Whipple's procedure, or total pancreatectomy are the most preferred procedures worldwide. A duodenum-sparing technique (duodenum-preserving resection of the pancreatic head) seems to be a promising choice for pancreas divisum, although the numbers of operated patients are low and more experience is needed in the future.

Clinical and Laboratory Diagnosis of Chronic Pancreatitis

Georg Beyer[1], *Markus M. Lerch*[2], *and Julia Mayerle*[1]

[1] *Department of Medicine II, LMU University Hospital, Ludwig-Maximilians-University, Munich, Germany*
[2] *LMU University Hospital, Munich, Germany*

Introduction

For centuries the pancreas was a "terra incognita" hidden behind the stomach and its pathophysiological role remained obscure. In 1761 Jean-Baptista Morgagni described the first case of chronic pancreatitis in his book *De sedibus et causis morborum* and it took a further 60 years until Kuntzmann was able to connect fatty stool to diseases of the pancreas. Even in the twenty-first century the time interval between the onset of symptoms and the diagnosis of chronic pancreatitis is unacceptably long and this is mainly caused by the fact that routine blood tests are usually not helpful in diagnosing chronic pancreatitis and that clinical symptoms are often nonspecific. The modern clinical concept of clinical chemistry for pancreatic diseases began in 1929 with the introduction of serum amylase (diastase) measurements [1]. Thereafter Comfort and coworkers [2] combined clinical observations, surgical findings, and autopsy studies to characterize chronic pancreatitis and first reported a chronic relapsing course of the disease. They also commented on its frequent association with longstanding alcohol intake, its common onset in the third and fourth decade of life, and the typical complications of the disease such as exocrine and endocrine pancreatic insufficiency.

Clinical Presentation

With a global incidence of 34 (CI 23–49), a prevalence of 13.5 to 52.4 per 100,000 population and a frequency of 0.04% to 5% among all autopsies, chronic pancreatitis represents a rather common disorder of the gastrointestinal tract [3,4]. Chronic pancreatitis also accounts for a substantial morbidity and healthcare costs. Although most patients with chronic pancreatitis are treated as outpatients, in 2017 there were almost 20,000 (ICD-10: K86) hospital admissions for chronic pancreatitis in Germany alone (Federal Statistics Office). This does not include those patients who were coded as having acute pancreatitis, including those reporting an acute episode of chronic pancreatitis (55,221 cases). Evaluating records from the United States, United Kingdom, the Netherlands, and Finland confirmed an increasing number of annual hospital admissions amounting to a 30% increase within 6 years [5]. This substantiates the high socioeconomic significance of the disease. Mortality from chronic pancreatitis is reported to be 12.8–19.8%, over a mean observation period of 6.3–9.8 years [6–8]. Total mortality in the same studies was reported to be 28.8–35%. Continued alcohol consumption results in a significantly reduced survival rate. The number of patients who leave the workforce and abandon gainful employment due to prolonged illness or continued alcohol consumption, or become disabled and are forced to retire prematurely during the course of the disease amounts to 40%. The 10-year survival rate is 70% and the 20-year survival rate is 45% in comparison with 93% and 65%, respectively, for an age-adjusted cohort [9].

Investigating the time interval between the onset of symptoms and the diagnosis of chronic pancreatitis a median interval of 30–55 months was reported in alcoholics [10,11]. In nonalcoholics the diagnosis was even more delayed (median 81 months) and frequently only established if complications of the disease such as pseudocysts or gastric outlet obstruction occurred. The major reason for this delay lies in the natural course of the disease. The clinical presentation of patients with chronic pancreatitis is highly dependent on the stage of

The Pancreas: An Integrated Textbook of Basic Science, Medicine, and Surgery, Fourth Edition. Edited by Hans G. Beger, Markus W. Büchler, Ralph H. Hruban, Julia Mayerle, John P. Neoptolemos, Tooru Shimosegawa, Andrew L. Warshaw, David C. Whitcomb, and Yupei Zhao.

the disease. It varies between severely ill patients with symptoms of an acute abdomen to slowly progressing cachexia. Often the first signs of the disease which prompt the patient to seek medical attention are belt-like abdominal pain that frequently radiates to the back, loss of body weight (in 80%), and steatorrhea (in less than 50%) [12].

Several attempts have been undertaken to establish histological and morphological criteria that clearly define chronic pancreatitis. Unfortunately an exact correlation between clinical symptoms, morphological signs, and histological criteria is still not at hand.

Etiology

In Western countries alcohol consumption is assumed to be the leading cause (42% to 68%) of chronic pancreatitis [13]. The prevalence of chronic pancreatitis clearly correlates with the alcohol consumption in a given population [14].

It is reported that 24.1% of all patients suffering from acute pancreatitis will progress to chronic pancreatitis [15]. Of those, 48.2% have alcoholic pancreatitis and smoking was identified as the only independent but dose-dependent risk factor for disease progression [16]. With regard to the etiology of chronic pancreatitis, more recent studies suggest that in addition to alcohol consumption smoking increases the risk and can independently cause chronic pancreatitis [17].

The second most common form of chronic pancreatitis (25%), as of today, is so-called idiopathic pancreatitis [18,19]. Patients without an identifiable risk factor for chronic pancreatitis are classified as having idiopathic pancreatitis. This group is constantly decreasing since Comfort and Steinberg reported in 1952 an inherited form of chronic pancreatitis that follows an autosomal dominant inheritance pattern and knowledge about genetic susceptibility factors is accumulating [2]. Hereditary pancreatitis represents a genetic disorder closely associated with mutations in the cationic trypsinogen gene and presents with a disease penetrance of ≈ 80% [20]. Shortly after the identification of mutations in the trypsinogen gene associated with chronic pancreatitis another important observation was made by Witt et al. [21]. They found mutations in the *SPINK-1* gene (encoding the pancreatic secretory trypsin inhibitor, PSTI) to be associated with idiopathic chronic pancreatitis in children. *SPINK-1* mutations can be frequently detected in patients who do not present with a family history of pancreatitis and are devoid of classical risk factors for chronic pancreatitis [22,23].

Cystic fibrosis is an autosomal-recessive disorder with an estimated incidence of 1 : 2500 characterized by pancreatic exocrine insufficiency and chronic pulmonary disease. The extent to which the pancreas is affected varies between a complete loss of exocrine and endocrine function to clinically normal pancreatic function. Recurrent episodes of pancreatitis occur in 1–2% of all patients with cystic fibrosis who have normal exocrine pancreatic function and much more rarely in patients with exocrine pancreatic insufficiency. That means that *CFTR* changes that would not cause cystic fibrosis still confer a twice increased risk of developing pancreatitis.

Metabolic disorders associated with hypertriglyceridemia above 1000 mg/dL can be responsible for the development of recurrent episodes of pancreatitis [24], but even lower triglyceride levels pose a significant risk [25]. In addition to dietary restrictions, fibrates, and rescue treatments by lipidapheresis and glucose/insulin infusion to lower triglyceride levels, the antisense oligonucleotide volanesorsen has been approved for the treatment of familial chylomicronemia syndrome, a genetic disorder leading to lipoprotein lipase deficiency resulting in severe hypertriglyceridemia. In a prospective, randomized open-label trial the risk for developing episodes of pancreatitis was markedly reduced in the treatment group compared to placebo, although the trial was not powered for this endpoint [26]. In a few cases chronic calcifying pancreatitis has been reported due to hypercalcemia in patients with untreated hyperparathyroidism. The underlying mechanism of hyperparathyroidism-associated pancreatitis is most likely related to the established role of calcium in the premature, intracellular activation of digestive proteases [27].

Pain

Pain is the most commonly encountered symptom in chronic pancreatitis (80–95% of patients) [28]. Up to 50% of patients with chronic alcoholic pancreatitis may suffer from chronic pain, while the remaining portion presents with intermittent attacks followed by pain-free intervals or have never experienced severe pain due to pancreatitis [19,29]. Most patients report continual, numb pain lasting for more than 24 hours and 68% report epigastric pain (Fig. 42.1). Pain, which can radiate to the back is reported in 39%, to the left upper quadrant in 50%, and to the right upper quadrant in 32%. About 6% of patients feel their pain radiating between the shoulders. In general, patients with abdominal pain take a "jackknife" posture to relax abdominal musculature affected by peritonitis. In chronic alcoholic pancreatitis a relationship between alcohol ingestion and recurrent pain has been described. Pain often begins between 12 and 48 hours after ceasing alcohol intake.

Figure 42.1 Erythema ab igne in a female patient aged 45 years suffering from chronic alcoholic pancreatitis.

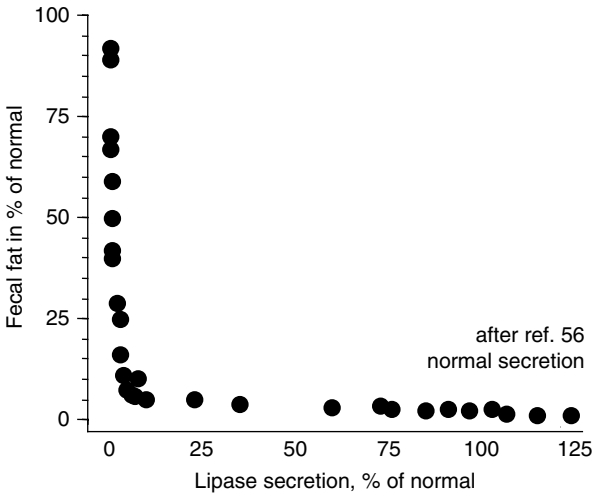

Figure 42.2 The graph illustrates the reduction in lipase secretion, which is paralleled by an increase in fecal fat. With rare exceptions, steatorrhea and azotorrhea only occur if there is greater than 90% reduction in pancreatic lipase and trypsin secretion. *Source:* Adapted from [39].

Malabsorption, Weight Loss

Fat excretion of patients with pancreatic steatorrhea frequently exceeds that of patients with other causes of steatorrhea. Leaking oily stool from the anus is virtually pathognomonic of exocrine pancreatic insufficiency. In general, weight loss is a cardinal symptom of pancreatic exocrine insufficiency with steatorrhea whereas hypoproteinemia or malabsorption of the fat-soluble vitamins is less common. So far there have only been a few publications that have reported decreased bone mineral density, but no comparison to an age-matched control cohort was included [30,31]. Overt steatorrhea occurs in approximately 30% of patients with chronic calcific pancreatitis.

With rare exceptions, steatorrhea and azotorrhea (excessive discharge of nitrogenous substances in the feces or urine) only occur when the reduction in lipase and protease secretion, respectively, surpasses 90% [32,33] (Fig. 42.2).

In alcoholic chronic pancreatitis it will usually take 10 to 20 years until severe exocrine insufficiency develops, but according to DiMagno and coworkers lipase secretion will decrease more rapidly than protease secretion. In decompensated chronic pancreatitis with less than 5% of the normal enzyme output, about 40% of nutrients from a readily digestible low caloric meal are malabsorbed and enter the colon.

Endocrine Insufficiency

More rarely patients seek medical attention because they develop diabetes mellitus with a loss of endocrine function or cachexia as the initial symptoms of chronic pancreatitis. A history of diarrhea with recent onset of diabetes mellitus should always raise the suspicion of chronic pancreatitis as the underlying cause. The symptoms of diabetes "of other specific types" according to the WHO classification system released in 2003 (e.g., loss of insulin production due to diseases of the exocrine pancreas) are similar to those of diabetes mellitus of other causes. Overall 45% of the patients with chronic pancreatitis suffer from overt diabetes. The cause of chronic pancreatitis bears no relationship to the subsequent likelihood of developing diabetes, but it does seem to influence the time lag between onset of pancreatitis and onset of diabetes. Alcoholics show symptoms of endocrine insufficiency earlier than nonalcoholics [7]. Diabetes mellitus is also an independent predictor of mortality in patients with chronic pancreatitis. The underlying pathophysiology of diabetes in chronic pancreatitis is the loss of insulin-secreting cells often combined with a peripheral and hepatic insulin resistance. Oral antidiabetics and especially metformin might therefore have a role in the treatment of these patients but control of blood sugar levels should be achieved with exogenous insulin supplementation.

Jaundice

In 10–40% of cases with chronic pancreatitis a benign dominant stenosis of the common bile duct develops due to inflammation of the pancreatic head or due to pancreatic pseudocysts or phlegmons, all of which require either endoscopic or surgical intervention. An asymptomatic increase in alkaline phosphatase is the most common laboratory manifestation of a stenosis of the common bile duct secondary to chronic pancreatitis. Jaundice may develop later. However, a raised alkaline phosphatase or increased bilirubin alone does not always point to extrahepatic cholestasis but might be a symptom of parenchymal liver damage caused by hepatitis, steatosis, or even liver cirrhosis. Endoscopic intervention is clinically indicated if the patient presents with jaundice or cholangitis and in order to prevent secondary biliary cirrhosis, whereas surgery is indicated, if a malignant cause for jaundice cannot be excluded.

Laboratory Diagnosis

Even after two centuries of pancreatic research a diagnostic serum marker for chronic pancreatitis is not available. Usually the diagnosis is made by a combination of imaging procedures such as ultrasound, endoscopic ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI), or MRCP in combination with exocrine and endocrine function tests.

Serum Tests for the Diagnosis and Etiological Characterization of Chronic Pancreatitis

The simplest, noninvasive tests would be to measure exocrine pancreatic enzymes or hormones in fasting blood samples. Total serum amylase, as opposed to pancreatic isoamylase or salivary isoamylase, has been measured routinely since 1929, but it is of little use for the diagnosis of chronic pancreatitis. Since amylase secretion into the gut decreases in chronic pancreatitis it has been hypothesized that low serum pancreatic amylase could be used to diagnose chronic pancreatitis. Unfortunately, pancreatic isoamylase is completely normal in many patients with mild to moderate chronic pancreatitis and the sensitivity was reported to be only 60% with a variation between 12% and 100 % depending on the severity of the disease [34]. The same problems apply to the measurement of lipase and trypsin. Therefore pancreatic serum enzyme testing lacks diagnostic accuracy as well as specificity.

Provocation tests, in which serum levels of pancreatic enzymes are measured after stimulation of pancreatic secretion by a secretagogues or parasympathomimetics, have been found to be rather insensitive, nonspecific, burdened with great interindividual ranges and therefore just as unreliable as markers for chronic pancreatitis. At most they are abnormal in 25% of patients suffering from chronic pancreatitis and at least the same proportion of healthy volunteers show abnormal test results [35,36].

A promising approach to diagnosing chronic pancreatitis by means of a blood test comes from the use of a multitude of markers measured on a common platform, a so-called biomarker signature. In a three-tiered prospective discovery and validation design, Adam and Beyer et al. described a multivariable prediction model based on blood plasma and serum metabolomics. The signature is comprised of eight metabolites measured on GC-MS and LC-MS/MS platforms and pancreatitis subjects were distinguished from non-pancreas disease control subjects with an AUC of 0.85 (95% CI 0.81–0.89) in EDTA-plasma or 0.87 (95% CI 0.81–0.95) in serum [37]. Similarly, a protein-based signature unique for chronic pancreatitis was identified by group from Stanford using the Luminex® assay [38].

Pancreatic Exocrine Function Tests

Tests for exocrine and endocrine pancreatic function serve as a second line of diagnostic tools for chronic pancreatitis. Reduced exocrine function can precede overt morphological changes and therefore the sensitivity to detect early changes is higher for exocrine pancreatic function tests than for imaging studies. These patients have exocrine pancreatic insufficiency because enzymes and chime do not mix appropriately and their fat digestion is accordingly impaired. However, excreted enzymes, for example elastase or chymotrypsin in stool, will appear normal.

Several tests for exocrine pancreatic function are now well established in the diagnostic workup of patients with suspected chronic pancreatitis. Assays can be divided into direct and indirect methods depending on the technique used for determining enzyme output (via duodenal tube or indirectly). When pancreatic function is measured directly the stimulated output of enzymes and bicarbonate into the small intestinal lumen is collected via a nasoduodenal tube and then quantitated. Indirect methods detect a decreased amount of pancreatic enzymes in stool or serum or, alternatively, evaluate the digestion of synthetic substrates by pancreatic enzymes, which also indicate impaired exocrine function when reduced (Table 42.1). The disadvantage of indirect tests for pancreatic function is that they cannot distinguish between structural or functional abnormalities. The situation after gastrectomy can serve as a good example of when an impaired synchrony between pancreatic secretion and the gastrointestinal passage of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 42.1 Direct and indirect pancreatic function tests.

	Pancreatic function test
Direct	• Secretin–cholecystokinin test • Endoscopic secretin test
Indirect	*Serum tests*: • Pancreolauryl test • NBT-PABA test (commercially discontinued) *Fecal tests*: • Fecal elastase • Chymotrypsin • Stool weight • Fecal fat quantification

food will signal exocrine insufficiency on pancreatic function tests without any structural damage to the pancreas (pancreatico-cibale asynchrony) [39].

Direct Pancreatic Function Tests

Secretin–Cholecystokinin Test

Pancreatic enzyme activity as well as bicarbonate concentration are measured in the duodenal juice after stimulation with the enterohormones secretin (1 CU/kg KG i.v.) and cholecystokinin (CCK; 25–100 ng/kg KG). The secretin–cholecystokinin test was the gold standard for pancreatic function testing. Its overall sensitivity and specificity is 90%. The combined secretin–CCK test is no longer used since pharmaceutical CCK preparations for human use are no longer marketed (at least not in most countries). Some authors used a standardized test meal (Lund test) rather than hormone stimulation of the exocrine pancreas but this more "physiological" approach is ultimately less sensitive in detecting early functional changes and bicarbonate cannot be measured in the collected chyme. As early as 1982 Gregg suggested a new method to determine exocrine pancreatic function by collecting pancreatic juice after intravenous secretin stimulation during ERP [40]. Until 2003 no larger series of this promising approach had been conducted until DiMagno and coworkers presented a modified version of the endoscopic pancreatic function test investigating 412 subjects. The overall accuracy of the endoscopic secretin test was 79% with positive and negative predictive values of 73% and 85%, respectively [41]. One possibility to overcome the limitations of invasive function testing might be secretin-stimulated MRI. Intravenous application of secretin causes the rapid washout of bicarbonate-rich fluid from the exocrine pancreas which can be quantified semiquantitatively but is significantly reduced in patients with impaired exocrine function. Sensitivity of secretin-stimulated MRI was calculated to be 69% while the specificity was 90%. As MRI is becoming an alternative to CT scan examination for the diagnosis of chronic pancreatitis, secretin-MRCP could become a valuable diagnostic tool [42,43].

Noninvasive Pancreatic Function Tests

Fecal Elastase-1

Pancreatic elastase accounts for 6% of protein in pancreatic juice. Compared to other serine proteases this enzyme is highly stable during its passage through the gut and can be detected with a five- to sixfold concentration in stool (median concentration of 1200 µg/g). Fecal elastase is measured using an enzyme-linked immunoassay (ELISA) and there are human-specific polyclonal and monoclonal test kits without cross-reactivity commercially available. It is therefore not necessary for the patient to discontinue enzyme supplementation treatment because it would potentially contain traces of pork elastase. The overall sensitivity of fecal elastase testing is 63% for mild exocrine insufficiency and rises to 100% for severe exocrine insufficiency if compared to the gold standard of the secretin–cholecystokinin test [44]. Biochemically the elastase 1 assay is a misnomer since the human pancreas expresses elastase 2 and 3 isoforms but not elastase 1 isoform known only from pigs.

About 5% of chymotrypsin secreted into the duodenum can be recovered enzymatically active in the feces and measured by a colorimetric enzyme reaction employing the substrate *N*-glutaryl-L-phenylalanine-*p*-nitroanilide (GNPNA). Sensitivity and specificity is regarded to be equal or lower compared to fecal elastase but false negative results occur in 4% of patients with severe exocrine insufficiency, 15–18% of patients with moderate exocrine insufficiency, and 25–40% of patients with mild pancreatic insufficiency [44,45].

Another noninvasive approach to evaluate pancreatic exocrine insufficiency is the assessment of CO_2 exhalation after digestion of 13 labelled synthetic substrates such as mixed triglyceride, triolein, and hiolein, which are enzymatically cleaved by pancreatic enzymes in the duodenum, and the 13 CO_2 component, which is rapidly resorbed on can therefore be detected in exhaled breath over time [46]. In patients with severe exocrine insufficiency sensitivity of the detection of mixed triglycerides is 92% to 100%, but in patients suffering from mild impairment of exocrine function sensitivity it is reduced to 46% [47]. However, in addition to the detection of pancreatic insufficiency these tests can be used for clinical workup of chronic diarrhea or to monitor the efficacy of enzyme supplementation [48].

Fecal fat quantification by the classical van de Kamer (alcohol extraction) technique is the standard test to determine steatorrhea as a characteristic symptom of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

reduced exocrine function. After a 90% loss of exocrine function fat excretion in stool significantly increases as a sign of fat maldigestion. A mild or intermediate impairment of exocrine function is usually clinically compensated for. The van de Kamer test has fallen out of favor with patients, nurses, and technicians because it requires extensive handling of large amounts of smelly stool.

Evaluation of Endocrine Function

Overt diabetes occurs in approximately 20% of patients suffering from alcoholic chronic pancreatitis 6 years after disease onset. Ten years after disease onset about 50% of alcoholic pancreatitis patients display signs of impaired glucose metabolism with diminished insulin production [49]. Pancreatic endocrine function should be evaluated by measuring HbA_{1c}, fasted glucose or by means of an oral glucose tolerance test according to the guidelines of the WHO for the diagnosis of diabetes mellitus. Type 3c diabetes mellitus on the background of CP can be diagnosed if exocrine insufficiency is also present and type 1 diabetes and insulin resistance are unlikely [50].

Genetic Testing

In addition to an evaluation of exocrine and endocrine function considerable attention is now paid to the etiology of the disease. Recent results from molecular and genetic studies suggest that a significant number of patients with chronic pancreatitis suffer from a genetically determined or inherited disease. This is mainly true for patients who were formerly classified as suffering from idiopathic pancreatitis, for patients with an onset of the disease before the age of 25, or those with a positive family history for chronic pancreatitis or pancreatic cancer. Patients who suffer from chronic pancreatitis due to mutations in the cationic trypsinogen gene are burdened with a 70- to 140-fold increased risk to develop pancreatic cancer, particularly if they smoke. Whether, this is also true for patients who carry *SPINK-1* or *CFTR* mutations needs to be determined. Genetic testing for the most common and clinically relevant trypsinogen gene mutations (N29I and R122H or R122C) can be recommended for chronic pancreatitis patients who have first-degree relatives suffering from pancreatitis or pancreatic cancer, for patients with chronic pancreatitis or recurrent bouts of acute pancreatitis before the age of 25 years and no identifiable risk factor [3]. Genetic testing for clinically unaffected relatives is not indicated and should only be performed within Ethics Committee approved research protocols. A much more detailed analysis of the genetic risk factors of pancreatitis is found in other chapters of this volume (Table 42.2).

Table 42.2 Implications for genetic testing.

Indications for genetic testing in idiopathic or hereditary pancreatitis
• Recurrent (2 or more) episodes of ***acute*** pancreatitis without identifyable cause or etiology,
or
• Idiopathic ***chronic*** pancreatitis – especially in children and young adults under the age of 25 years,
or
• Pancreatitis in a patients with a positive family history of ***pancreatitis*** (one or more first- or second-degree relatives)

In conclusion, even in the twenty-first century the diagnosis of chronic pancreatitis is made by a combination of clinical symptoms, imaging procedures such as ultrasound, EUS, CT, and MRCP, and exocrine and endocrine function tests. Therapy is restricted to symptom control for the lack of a causal treatment strategy and the time point from first symptoms to diagnosis has not been significantly shortened during the last 15 years. Biomarkers or tests are urgently needed but currently not available.

Abdominal Imaging for the Diagnosis of Chronic Pancreatitis

Atsushi Irisawa and Akira Yamamiya

Department of Gastroenterology, Dokkyo Medical University School of Medicine, Tochigi, Japan

Introduction

In 2016, a mechanistic definition for progression of chronic pancreatitis (CP) was proposed [1], with defined conditions of early, established, and end-stage CP. Regarding the diagnoses of the last two conditions (definite CP), they are easily diagnosed with identified parenchymal findings such as parenchymal loss (glandular atrophy), chronic inflammation, and fibrosis of the pancreas, in addition to ductal findings such as beading, dilated side-branch radicals, enlargement of the main pancreatic duct (MPD), and dystrophic intraductal calcifications. Diagnostic imaging modalities include transabdominal ultrasonography (US), endoscopic ultrasonography (EUS), computed tomography (CT), magnetic resonance imaging/cholangiopancreatography (MRI/MRCP), and endoscopic retrograde cholangiopancreatography (ERCP) [2,3]. Furthermore, for the diagnosis of early CP, EUS plays a major role in elucidating subtle changes in the pancreatic parenchyma [4–6]. Although some guidelines for CP recommend CT or MRI for the first-line diagnosis of CP and either test should be the first choice for the diagnosis of CP [7,8], this chapter also describes the significance of minimally invasive tests such as US and plain abdominal radiography.

Transabdominal Ultrasonography

The simplest and least invasive imaging modality is US, which is regarded as the first imaging procedure when a patient has symptoms that suggest CP. Nevertheless, it must be understood as a limitation that, because of its low accuracy, US is useful only for the diagnosis of advanced CP [9]. A definite CP diagnosis based on US images is made when US shows a pancreatic duct stone, multiple or diffuse pancreatic calcifications, or obvious deformation of the pancreas with irregular dilation of the pancreatic duct [5] (Fig. 43.1). However, because a CP diagnosis based on US is susceptible to the effects of gastrointestinal tract fats and gas, its sensitivity is not high: 48–83% [10,11]. Consequently, some cases require other imaging procedures for CP diagnosis. It is also noteworthy that the usefulness of US for diagnosing early CP has not been established.

Recently, the performance of US-based CP diagnosis has been improved by the combined use of US elastography, which measures pancreatic stiffness [12]. US elastography, a new diagnostic tool, measures tissue elasticity (stiffness) by evaluating distortion and waves occurring after the addition of the external vibration energy to the tissue through manual compression and heartbeat. The pancreatic stiffness that is measured based on the shear wave elastography has been reported as correlated with CP progression [13].

Plain Abdominal Radiography

Plain abdominal radiography, a noninvasive and simple modality, can be used to diagnose radiopaque pancreatic calculus. Furthermore, it offers superior cost-effectiveness for the follow-up of patients with CP with evidence of a stone (Fig. 43.2) and those who experience a stone for the first time. The frontal view of the abdominal radiograph has presented difficulty for independently detecting pancreatic stones in some cases. Consequently, three-view abdominal radiography (i.e., frontal, left, and right views) has been adopted to improve this process [14–16]. The proportion of pancreatic calcifications in patients with CP is estimated as 17–60.8%; few patients

are diagnosed with CP based only on abdominal radiography findings [17,18]. However, a diagnosis of noncalcified CP using this modality is difficult to reach.

Computed Tomography

Cross-sectional imaging is the most commonly used method to establish a diagnosis of CP. Actually, CT is a highly objective and minimally invasive imaging test. Furthermore, gastrointestinal fats and gas have little effect on the diagnostic performance of CT. A study in which several radiologists read CT images of 39 patients with CP based on the Cambridge classification and for which their interobserver variations were evaluated showed high interobserver reliability, indicating limited variation among CP diagnoses [19]. Therefore, CT is an excellent method for visualizing pancreatic calcifications/stones. It can also visualize apparent pancreatic alterations that show dilatation of the pancreatic duct with an uneven and irregular outline, which are findings for probable CP diagnosis. A systematic review that compared different imaging procedures in the diagnostic performance for CP showed excellent diagnostic performance of abdominal CT, with sensitivity of 75% (95% confidence interval [CI]: 66–83%) and specificity of 91% (95% CI: 81–96%) [2]. Other studies have also shown high diagnostic performance of abdominal CT for CP diagnosis, with sensitivity of 74–91% and specificity of 78–85% [20,21]. However, it should be understood that the pancreatic duct branches are poorly visualized on CT compared with MRCP or ERCP in some cases. Furthermore, the diagnosis of CP in older adults should be treated with caution, given that calcifications might be associated with other diseases in this population. Recently, the usefulness of virtua1 CT pancreatoscopy has been reported [22]. This modality has been shown to correlate closely with ERCP imaging. Actually, CT has no diagnostic significance for early CP. Furthermore, all imaging must be performed using a multidetector helical CT scanner [23], from the perspective that CP entails a high risk of carcinogenesis.

The classical CT findings in CP are dilatation of the pancreatic duct, pancreatic calcifications, and parenchymal atrophy (Fig. 43.3). Other CT findings include MPD dilatation and dilated secondary radicals. The MPD is

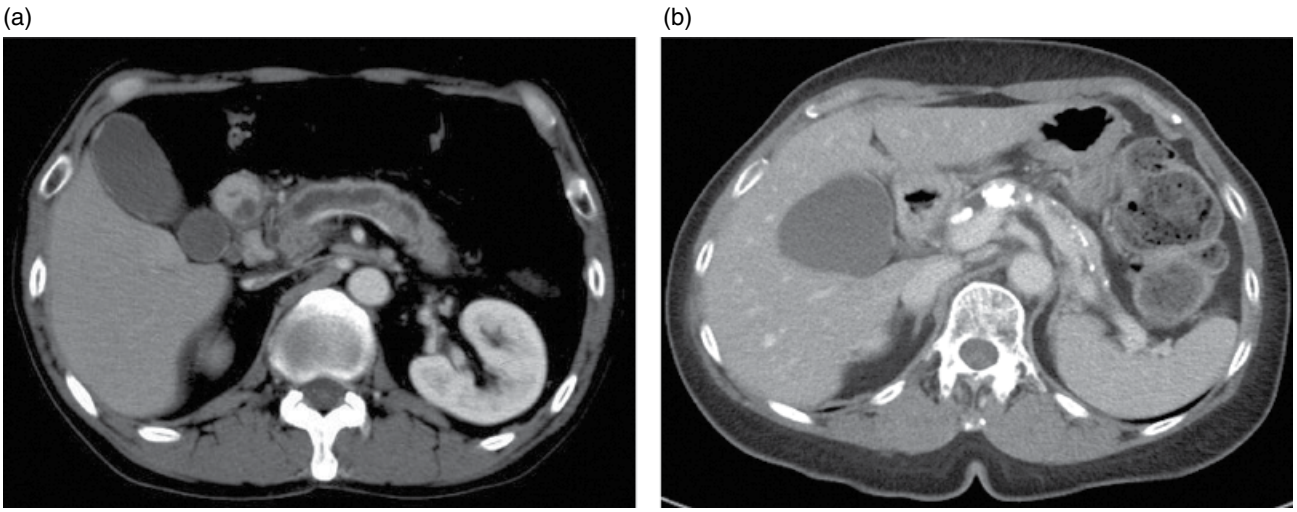

Figure 43.3 CT findings of the definite chronic pancreatitis. (a) CT shows dilated main pancreatic duct with marked atrophic parenchyma. (b) CT shows multiple stones in the dilated pancreatic duct with atrophic parenchyma.

classically beaded and irregular. However, the main duct might also be contoured regularly [24]. Results of an earlier study [25] indicated the frequency and characteristics of CP findings on CT as follows: a dilated pancreatic duct and secondary radicals were the most common findings, found in 68%, pancreatic atrophy in 54%, intraductal calcifications (scattered or clustered, focal, or diffuse) in 50%, pancreatic parenchymal atrophy in 54%, fluid collection in 30%, focal pancreatic enlargement in 30%, biliary duct dilation in 29%, and alterations in peripancreatic fat in 16%. However, normal appearance was identified in 7%, which presents difficulty for this diagnosis modality. In addition, CT is especially helpful in identifying complications of CP, including pseudocysts, portosplenic venous thrombosis, collaterals and arterial pseudoaneurysms, and pancreaticopleural fistulas [26,27].

MRI/MRCP

Actually, MRI with MRCP are widely acknowledged as more sensitive than CT for the detection of ductal and subtle parenchymal changes, especially during early stages of CP [28]. For instance, MRI is better than CT in displaying tissue contrast. Such characteristics evaluate fibrosis of the pancreatic parenchyma based on the enhancement pattern on T1-MRI, diffusion-weighted images [29], or contrast-enhanced MRI. Ductal abnormalities are very specific and reliable MRI signs of CP. The diagnostic ability of MRCP for CP has been reported as similar to that of ERP, with sensitivity of 87.7% and specificity of 94.0%. It is recognized that its diagnostic value is high from the viewpoint of adverse events. Moreover, among patients with CP classified into mild CP based on the Cambridge classification, MRCP identified nonuniform dilatation of the pancreatic duct branches in 79% and 73% of patients with calcified pancreatitis and those with noncalcified pancreatitis, respectively [30]. This finding demonstrates that MRCP can visualize a tiny pancreatic change. A recent meta-analysis has revealed that the diagnostic performance of MRCP is similar to that of ERCP for CP diagnosis, with sensitivity of 78% and specificity of 96% [31]. However, although the diagnostic ability of MRI/MRCP for pancreatic calculus is lower than that of CT (direct diagnosis of this situation using MRI/MRCP is difficult), MRI/MRCP can indirectly diagnose pancreatic calculus based on lucencies in the main pancreatic duct or its branches; its diagnostic performance is higher than 90% [32]. However, this diagnosis should be treated with caution, given that, in some cases, a small stone in the main pancreatic duct and its branches is not visible as a lucent structure on MRI/MRCP [33]. Furthermore, MR elastography has been conducted. It showed a promising technique for detecting and quantifying pancreatic stiffness. It is related to fibrosis and is apparently useful for assessing the treatment response and clinical follow-up of pancreatic diseases [34].

Definite CP diagnoses using MRCP have been made based on the following findings: irregular dilation of the pancreatic duct branches that are unevenly distributed in the entire pancreas, irregular main pancreatic duct dilation, and the presence of a protein plug (Fig. 43.4) [5,6]. In addition to evaluation of pancreatic duct abnormalities, MRI is extremely sensitive for the detection of parenchymal abnormalities. The parenchymal features of CP include, in addition to atrophy, abnormal decreased signal intensity on fat-suppressed T1-weighted images and delayed and limited enhancement after contrast administration, reflecting fibrosis of the pancreatic parenchyma [24,35]. Stimulation

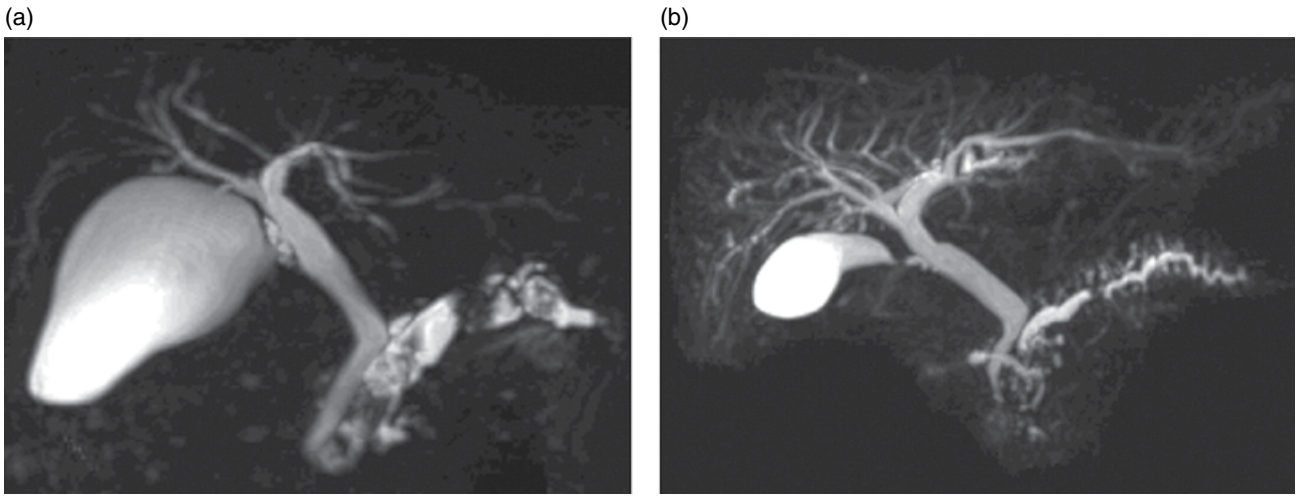

Figure 43.4 MRCP findings of the definite chronic pancreatitis. (a) MRCP shows stones/protein plugs in the dilated irregular main pancreatic duct. (b) MRCP shows irregular dilatation of the main pancreatic duct and side branches in the entire pancreas.

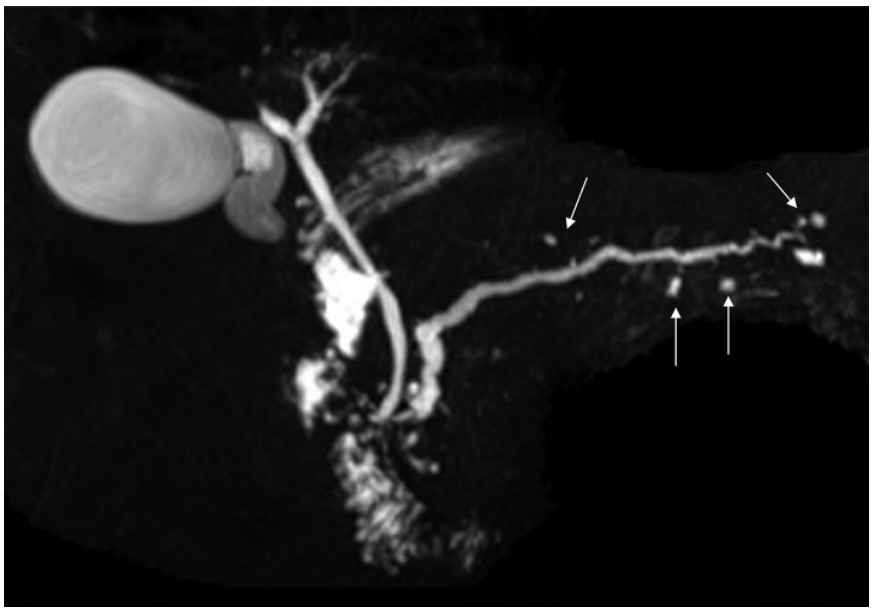

Figure 43.5 MRCP imaging of the early chronic pancreatitis. Several abnormal side branches (dilation, arrows) are found in the body to tail.

of the pancreas using intravenous secretin might improve the diagnostic accuracy for the detection of ductal and parenchymal abnormalities seen in CP.

In addition, MRI/MRCP has high performance for the diagnosis of early CP. Signal intensity changes in the pancreas, as seen on MRI, might precede ductal abnormalities and suggest early CP. Subtle signal intensity decreases within the gland, especially on fat-suppressed T1-weighted images, are extremely important to realize that these parenchymal abnormalities might precede the ductal abnormalities in the early stage [36]. A recent study also showed that T1 mapping can distinguish subtle parenchymal changes seen in early stage CP. It shows promise for implementation in routine imaging protocols for the diagnosis of CP [37]. In addition, in the Japanese criteria for early CP [6], its findings are defined as irregular dilation of at least three pancreatic duct branches, which are taken with an MRCP at a magnetic field strength of 3.0 tesla (Fig. 43.5). Because of the recent progress in MRCP resolution that is associated with the advancement of MRI instruments, MRCP is positioned as an examination method with similar ability to ERCP in these diagnostic criteria. Moreover, high diagnostic performance of secretin-loaded MRCP for early CP has been demonstrated.

EUS

By enabling detailed observation of the pancreatic parenchyma, EUS plays an important role in early CP diagnosis. In fact, it allows high-resolution imaging and close-up pancreatic observation. Normal pancreatic parenchyma that is visualized by EUS shows a homogeneous echo pattern, with echo intensity that is similar to or slightly higher than that of the liver (i.e., a fine reticular pattern). Moreover, EUS shows no tortuous main pancreatic duct or dilated pancreatic duct branches in an echo of the normal pancreatic parenchyma. The pancreatic duct on EUS shows a slightly hyperechoic wall, which is observed as a uniformly linear echo, with diameter of approximately 2.4 mm (head), 1.8 mm (body), and 1.2 mm (tail) [38]. Abnormal pancreatic images are defined based on these findings.

The Rosemont classification, which was developed based on expert opinion in 2009, has been used widely to diagnose CP with EUS (Table 43.1) [39]. This system assigns different weights (major A, major B, and minor) to different findings. Parenchymal major A criterion included hyperechoic foci with shadowing and well-circumscribed lobularity. In fact, the only ductal major A criterion was MPD calculi. The only parenchymal major B criterion was lobularity with honeycombing. Minor parenchymal criteria were cysts, stranding, nonshadowing hyperechoic foci, and lobularity with noncontiguous lobules. Minor ductal criteria were dilated ducts (body ≥3.5 mm and tail ≥1.5 mm), irregular MPD contour, dilated side branches of 1 mm or more, and hyperechoic duct margin. The diagnosis of CP based on the Rosemont classification was consistent if one of the following was

Table 43.1 The Rosemont criteria.

Parenchymal criteria

- Major A
  - Hyperechoic foci (>2 mm in length/width with shadowing)
- Major B
  - Lobularity (≥3 contiguous lobules = "with honeycombing")
- Minor
  - Cyst (anechoic, round/elliptical with or without septations)
  - Hyperechoic strands (≥3 mm in at least 2 different directions with respect to the imaged plane)
  - Hyperechoic foci (>2 mm in length/width with no shadowing)
  - Lobularity (noncontiguous lobules = "without honeycombing")

Duct criteria

- Major A
  - MPD calculi (echogenic structure[s] within the MPD with acoustic shadowing)
- Minor
  - MPD dilation (≥3.5 mm in body or >1.5 mm in tail)
  - Irregular MPD contour (uneven or irregular outline and ectatic course)
  - Dilated side branches (>3 tubular anechoic structures each measuring ≥1 mm in width, budding from the MPD)
  - Hyperechoic MPD margin (echogenic, distinct structure >50% of entire MPD in the body and tail)

Classification based on endoscopic criteria

- **Consistent with CP**
  - A) 1 major A feature (+) ≥3 minor features
  - B) 1 major A feature (+) major B feature
  - C) 2 major A features
- **Suggestive of CP**
  - A) 1 major A feature (+) <3 minor features
  - B) 1 major B feature (+) ≥3 minor features
  - C) ≥5 minor features (any)
- **Indeterminate for CP**
  - A) 3 to 4 minor features, no major features
  - B) major B feature alone or with <3 minor features
- **Normal**
  - ≤2 minor features, no major features

present: (i) 1 major A feature + ≥3 minor features; (ii) 1 major A feature + major B feature; or (iii) 2 major A features. All other combinations of features were categorized as suggestive, indeterminate, or normal. The validity of EUS diagnostic items used in the Rosemont classification has been established in a study evaluating risk factors for CP [40]. A recent systemic review indicated the diagnostic accuracy of several imaging procedures, with the implication that the diagnostic performance of EUS is similar to that of ERCP/CT/MRI, with diagnostic accuracy of 81% (95% CI: 70–89%) and a specificity of 90% (95% CI: 82–95%) [41].

For the diagnosis of early CP, the Japan Pancreas Society established the revised EUS criteria for early CP in 2019 [6] based on the Rosemont classification. Early CP has been diagnosed if a patient has two of the following four criteria (Fig. 43.6): (i) lobularity (honeycombing or non-honeycombing), (ii) hyperechoic foci (nonshadowing or stranding, (iii) dilated side branches, and (iv) hyperechoic main pancreatic duct margin. These findings and clinical signs are combined to diagnose early CP. A recent study showed that EUS findings for ECP according to Japan's above criteria, lobularity, and the hyperechoic margin of the pancreatic duct might highly correspond to the pathological findings of chronic inflammation. In addition, although a great limitation in the use of EUS for evaluating CP has been its poor interobserver reliability, especially in diagnosis for early CP, a recent study [42] demonstrated high reliability for the criteria above. Consequently, results suggest that EUS can be useful for diagnosing early CP. Nevertheless, some reports have described the usefulness of EUS elastography (including shear-wave elastography) for CP diagnosis [43]. This modality is particularly useful to distinguish the diagnosis between normal pancreas confused with CP and early CP on B-mode EUS.

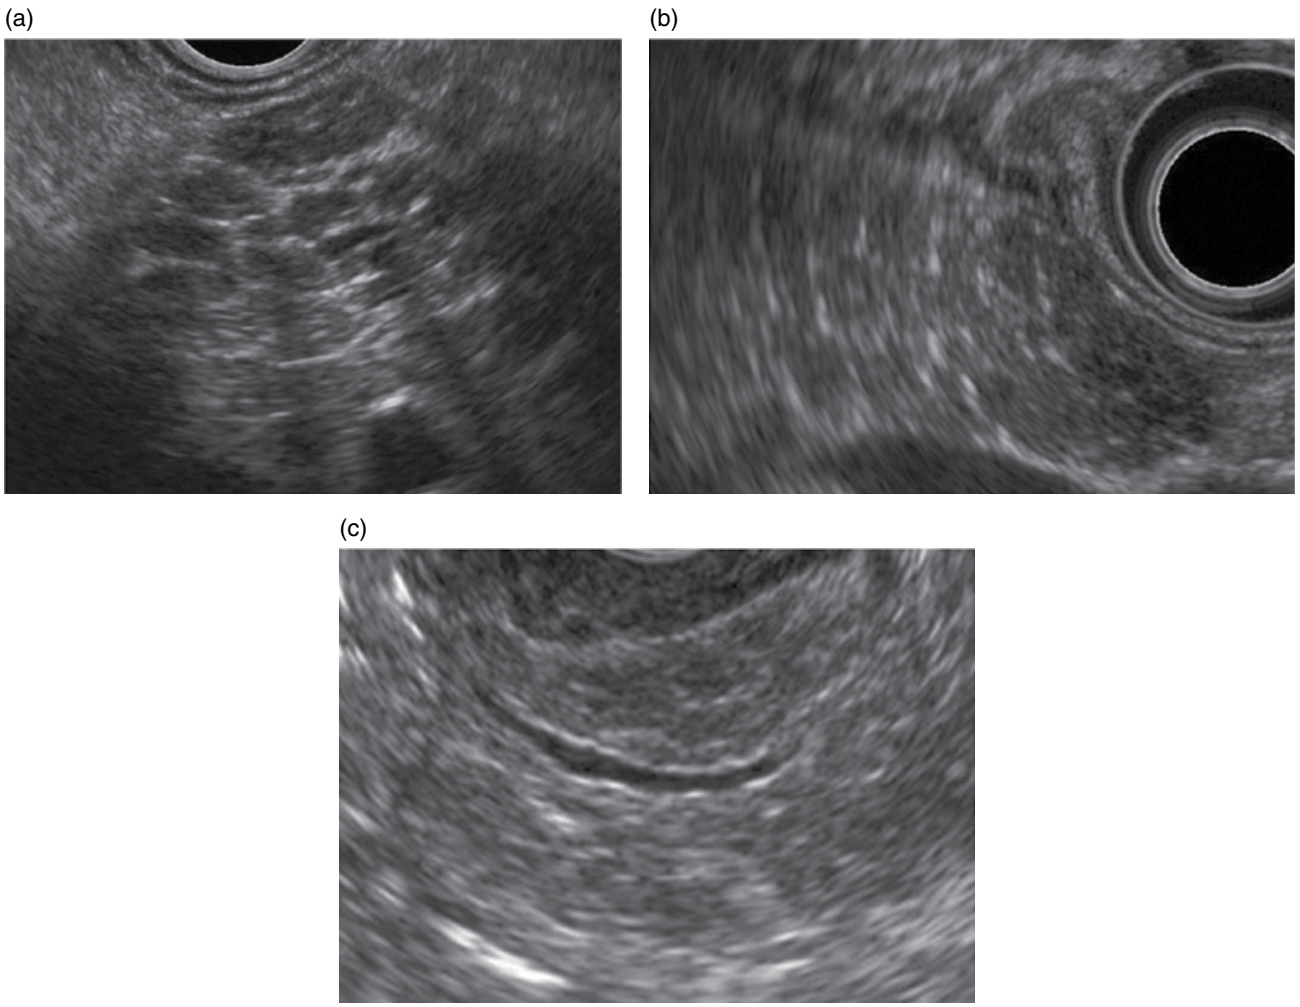

Figure 43.6 EUS findings of the early chronic pancreatitis. (a) Lobularity (honeycomb). (b) Hyperechoic foci without shadow and stranding. (c) Hyperechoic ductal margin.

As described above, EUS is a useful modality for the diagnosis of CP, especially in the early stage. However, the following points should be noted when applying EUS for CP diagnosis: EUS findings must be interpreted with caution because of the inability to distinguish the clinically and metabolically benign asymptomatic fibrosis from true CP.

Endoscopic Retrograde Cholangiopancreatography

A high-performance modality with high sensitivity and specificity is ERCP [43]. The diagnostic performance of ERCP for CP is better than that of abdominal US and CT, with a sensitivity of 70–90% and a specificity of 89–100% [44,45]. It was reported that an association between pancreatic duct branch changes on ERCP and histological findings of the pancreatic parenchyma in patients with CP who underwent pancreatectomy [46].

However, while ERCP can provide information that is invaluable in managing CP, the development of post-ERCP pancreatitis, a rare but crucial life-threatening complication, is a significant problem in the diagnostic ERCP. Therefore, ERCP as diagnostic imaging has been replaced by MRCP in recent years. Conversely, ERCP has superiority over other modalities in that it enables pathological examination of pancreatic ductal abnormalities. Thus ERCP plays an important role in making a differential CP diagnosis from pancreatic cancer.

The diagnosis of CP by ERP is made on the basis of changes in the MPD and side branches, requiring a quality pancreatogram to most accurately delineate the ductal anatomy [47]. A definitive CP diagnosis based on ERCP is made when the following findings are observed: irregular dilation of the main pancreatic duct with nonuniform and irregular dilation of the pancreatic duct branches that are unevenly distributed in the entire pancreas (Fig. 43.7) [5,6]. In addition, the following are also significant findings unique to ERCP: irregular dilation of the main pancreatic duct and its branches in the papillary

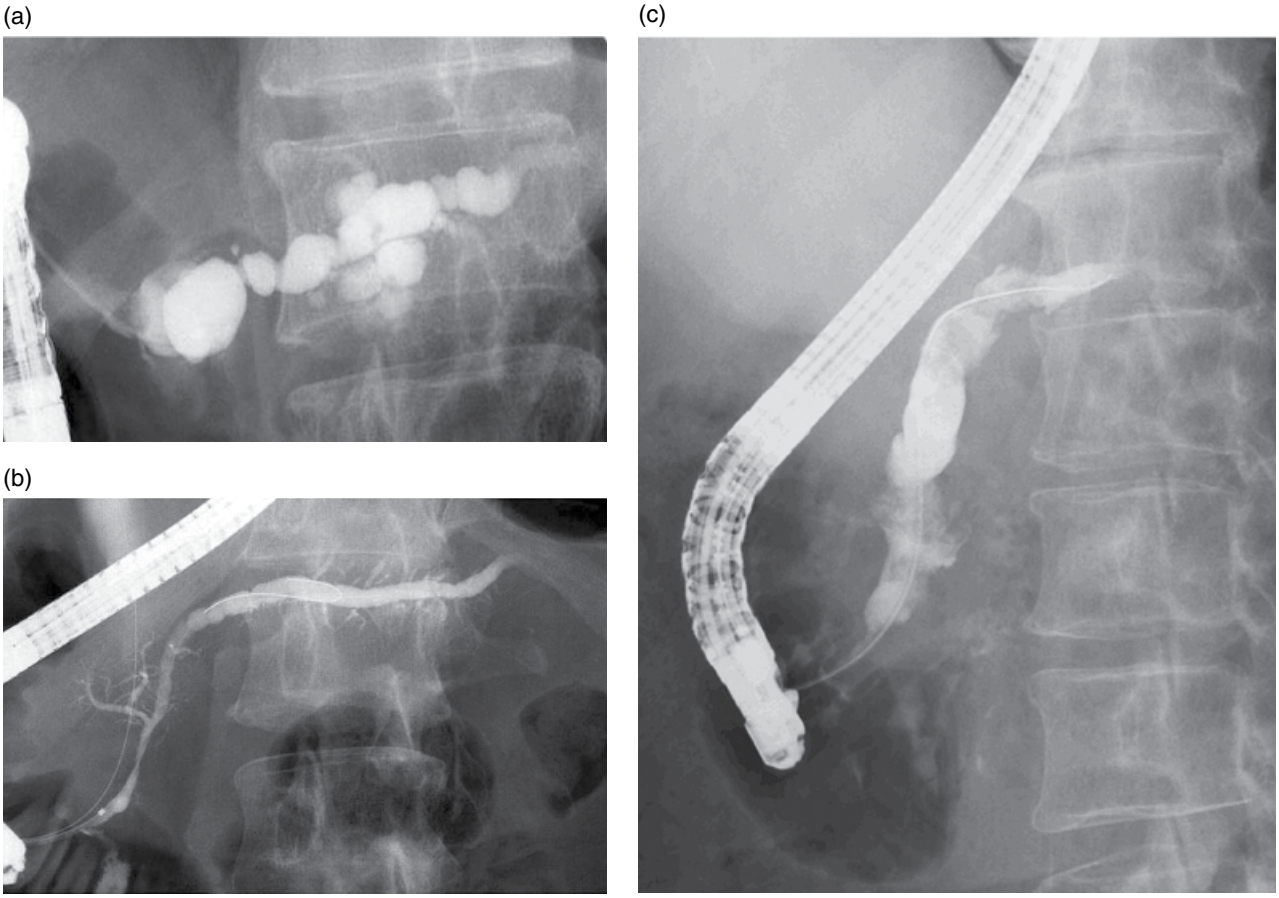

Figure 43.7 ERCP findings of the definite chronic pancreatitis. (a) Marked dilation and irregular of main pancreatic duct. (b) Irregular main pancreatic duct with dilated side branches. (c) Dilated irregular main pancreatic duct with multiple stones.

side of occlusion or stenosis by a pancreatic stone and a protein plug [5,6]. ERCP findings are also useful for CP-grade classification.

The most accepted criteria for scoring ductal changes on pancreatograms are the Cambridge criteria [47], which grade pancreatograms from normal or equivocal to mild, moderate, or severe CP based on main duct and side branch abnormalities. Main duct abnormalities include dilation, narrowing, strictures, filling defects, and leaks or cavities. The side branch may be of normal length or shortened; its caliber may be normal, dilated, or narrowed, and the contour may be smooth or irregular. The grading is defined as follows: normal, equivocal (normal except for fewer than three abnormal side branches), mild (more than three abnormal side branches but normal main duct), moderate (abnormal main duct with or without branch changes), and severed (as moderate pancreatitis but also at least one of the following: duct obstruction, severe irregularity or dilatation, ductal filling defects, or a cavity) [48]. At the moment, these criteria are often used for MRCP grading, but recent study has shown that there is a lack of strong concordance between ERCP- and MRCP-based grading of CP using the Cambridge criteria. MRCP had moderate to good performance in diagnosing side-branch predominant versus main-duct predominant CP [49]. Thus, it will be required to revise the standard in the future. In addition, for diagnosis of early CP, Japanese criteria for early CP [6] defined the ERCP image of early CP according to the Cambridge criteria: irregular dilation of at least three pancreatic duct branches (Fig. 43.8).

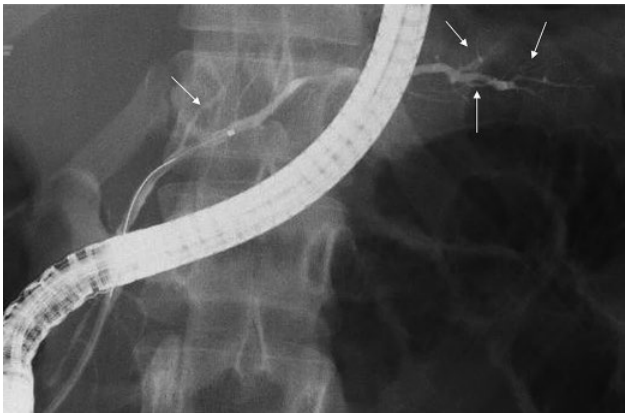

Figure 43.8 ERCP findings of the early chronic pancreatitis. Several abnormal side branches (arrows) with nondilated main pancreatic duct are seen.

Endoscopic Ultrasound for Diagnosis of Chronic Pancreatitis Versus Pancreatic Cancer

J. Enrique Domínguez-Muñoz, Julio Iglesias-García, José Lariño-Noia, and Daniel de la Iglesia-García

Department of Gastroenterology and Hepatology, Health Research Institute, University Hospital of Santiago de Compostela, Santiago de Compostela, Spain

Introduction

Despite recent advances in diagnostic procedures, differential diagnosis of solid pancreatic masses remains a challenge. Chronic pancreatitis increases the risk of pancreatic cancer, thus making more complex the differential diagnosis between both diseases. Essential methods for the diagnosis and differentiation of pancreatic tumors are multidetector CT scan (MDCT), magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP), and endoscopic ultrasound (EUS) and its associated techniques [1]. Among all these diagnostic modalities, EUS associated with guided tissue sampling, elastography, and contrast enhancement has emerged as the key method. The role of EUS and associated techniques in the differential diagnosis between malignant lesions and mass-forming chronic pancreatitis or focal autoimmune pancreatitis is discussed here.

Endoscopic Ultrasound for the Differential Diagnosis of Solid Pancreatic Tumors

EUS provides high-resolution images of both pancreatic parenchyma and pancreatic ducts, and it is considered to be one of the most accurate methods for the diagnosis and staging of chronic inflammatory, cystic, and neoplastic diseases of the pancreas. When compared with transabdominal ultrasound (TUS), EUS can provide images with high resolution by using high-frequency ultrasound due to its proximity to the pancreas. Furthermore, while the TUS imaging of the head and tail of the pancreas is often hindered by intestinal gas, EUS allows the imaging from head to tail of the pancreas by scanning through the gastric and duodenal wall.

The usefulness of EUS in comparison with CT has been reported as well [2,3]. Among 22 studies covering 1170 patients, the median sensitivity of EUS for the detection of pancreatic tumors was 94%. The sensitivity of EUS was shown to be superior to that of CT (98% vs. 74%) in 19 comparative studies ($n = 895$). The sensitivity of EUS was also shown to be superior to that of TUS (94% vs. 67%) in four comparative studies ($n = 259$). All these data are summarized in a recent review from Kitano et al. [4]. Furthermore, the advantage of EUS is more prominent in small lesions. EUS is accepted to be the most sensitive technique for detection of small pancreatic tumors (<2 cm). In a recent systematic review of patients with suspected pancreatic lesion based on indeterminate CT scan [5], EUS detected a pancreatic mass with a mean size of 21 mm in 70% of the patients. The sensitivity of EUS diagnosis of malignancy was 85%; however, specificity remained as low as 58%. In summary, despite recent development of cross-sectional imaging modalities, EUS plays a major role in the detection of pancreatic lesions, especially those so small that they cannot be detected by CT scan.

Once detected, the main point is to characterize the tumor. To differentiate between different types of pancreatic neoplasms by B-mode EUS is challenging. Typically, pancreatic cancer is an ill-defined, hypoechoic, and heterogeneous lesion (Fig. 44.1), but those tumors can often show atypical imaging findings. Inflammatory tumors (mainly in the setting of a chronic pancreatitis) (Fig. 44.2), metastatic tumors (being primary tumor lung cancer, breast cancer, renal cancer, colon cancer), pancreatic lymphomas or solid pseudopapillary tumors are part of the differential diagnosis [4]. Although EUS imaging is not able to

Figure 44.1 Endoscopic ultrasound of a pancreatic adenocarcinoma, with irregular borders, and infiltration of surrounding vessels.

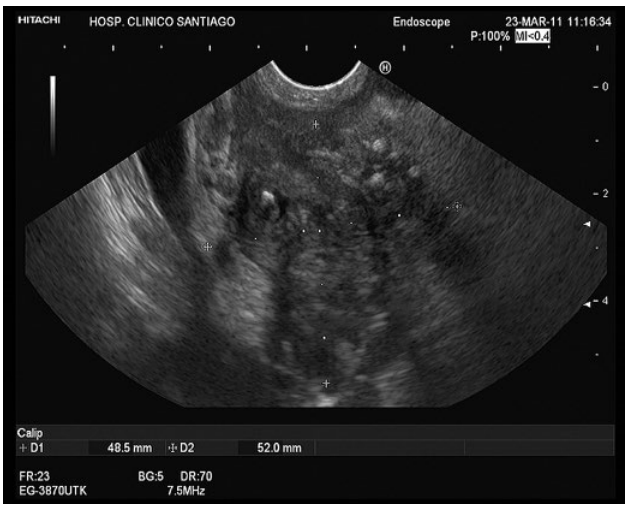

Figure 44.2 Endoscopic ultrasound of a mass-forming chronic pancreatitis showing an irregular heterogenic pattern, predominantly hypoechoic, with no infiltration of surrounding vessels, and the presence of calcifications.

differentiate reliably between malignant and benign inflammatory lesions, echotexture of the lesion and the rest of the pancreas provides very important additional information, such as boundary, ductal characteristics, lymphadenopathy, and vascular involvement. Features favoring a pseudotumor include homogeneous pattern with hyperechoic septations, calcifications, cysts, multilobular appearance, and positive Doppler signals in the lesion (Fig. 44.2). Conversely, as previously stated, pancreatic cancer usually appears as a hypoechoic mass, periductal hypoechogenicity, and displacement of calcifications (Fig. 44.1). The sensitivity and specificity of EUS are 64% and 75%, respectively, for the detection of pancreatic cancer in chronic pancreatitis [6,7]. However, in the presence of a pseudotumor, EUS alone cannot distinguish pancreatic cancer from mass-forming chronic pancreatitis. This is partly because changes like internal and/or peripheral calcifications, typical of advanced chronic pancreatitis, are also present in a proportion of pancreatic malignancies. A recent study showed that lobularity without honeycombing was more frequently observed in cases of pancreatic cancer ($P = 0.018$; OR: 12.65) [8].

Advanced techniques associated with EUS (tissue acquisition, contrast enhancement, and elastography) can improve the diagnostic accuracy of EUS in this context.

Endoscopic Ultrasound-Guided Sampling

The role of EUS-guided sampling in the diagnosis of solid pancreatic tumors has been evaluated in several well-designed studies. Reported accuracy for malignancy ranges from 79% to 92% [9–11]. This accuracy may be even higher using onsite evaluation of the sample by an experienced pathologist [12]. Furthermore, in addition to differentiating between benign and malignant lesions, EUS-guided sampling can also establish the final pathological diagnosis (Fig. 44.3).

New needles have been designed over the last years that increase the diagnostic capabilities of EUS-guided sampling. Recent reported accuracy reaches 90–95%, with the advantage of providing tissue cores, allowing histological evaluation of the samples obtained [13]. Among them Fork-tip, Franseen needle, and Procore™ have shown the best results, with a clear improvement

Figure 44.3 Endoscopic ultrasound-guided sampling of a solid pancreatic tumor (final diagnosis was pancreatic adenocarcinoma).

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. shown with the Fork-tip and Franseen needle tip [11]. The ability of these needles to obtain histological and cytological samples has been reported to be superior compared to cytological needles. In fact, both the Franseen-tip and the Fork-tip needles demonstrated excellent diagnostic accuracy (>90%), with or without rapid onsite evaluation [14]. Their high rate of tissue adequacy was not associated with an increase in adverse events, and a smaller number of needle passes were needed, with a single pass resulting in a diagnostic accuracy over 95%. Nevertheless, results of a recent meta-analysis could not establish a clear benefit of core needles over cytological needles in terms of diagnostic accuracy for pancreatic lesions [15].

Some drawbacks of EUS-guided sampling need to be emphasized. The procedure is not feasible in about 6–9% of cases due to vessel interposition, duodenal stenosis, or tumor hardness, particularly in chronic pancreatitis. On some occasions, sample adequacy is not enough for diagnosis. A systematic review of 53 studies reported a negative predictive value of EUS-guided sampling for the diagnosis of pancreatic adenocarcinoma of 60–70% [16]. Hence, a second puncture is needed to exclude malignancy in some cases where the first result was of benignity. Given the high accuracy for the evaluation of pancreatic tumors, it can be concluded that routine EUS-guided sampling can be recommended for the differential diagnosis of solid pancreatic masses [17].

Sensitivity of EUS-guided tissue acquisition is lower in the context of chronic pancreatitis compared to normal surrounding parenchyma. Fritscher-Ravens et al. found that sensitivity of EUS-guided fine-needle aspiration (FNA) in patients with a focal pancreatic lesion without chronic pancreatitis was 89%, while it was only 54% in patients with chronic pancreatitis [18]. Varadarajulu et al. investigated 282 patients with pancreatic solid tumors. Sensitivity of EUS-guided FNA for malignancy was lower in the group of patients with concurrent chronic pancreatitis compared to those without it (73.9% vs. 91.3%; $P = 0.02$). There were no differences in terms of specificity (100% vs. 93.8%), and overall accuracy (91.5% vs. 91.4%) [19]. In a study by Ardengh et al. including 69 pancreatic masses in patients with chronic pancreatitis, EUS-guided FNA increased the diagnostic sensitivity, specificity, and overall accuracy of EUS for the differential diagnosis between inflammatory process and pancreatic adenocarcinoma (72.7% vs. 63.6%, 100% vs. 75.9%, 95.7% vs. 73.9%, respectively) [20]. Takahashi et al., evaluated 62 patients with pancreatic cancer and 15 with focal pancreatitis, reporting sensitivity, specificity, overall accuracy, positive predictive value, and negative predictive value of cytopathologic diagnosis of 82%, 100%, 86%, 100%, and 58%, respectively. They also observed K-ras point mutations in 74% of pancreatic cancers and 0% of focal pancreatitis lesions [21]. Ogura et al. have also shown that the determination of K-ras mutations in EUS biopsy samples can increase the diagnostic accuracy of this procedure, since these mutations are present in 87% of pancreatic cancer, but only in 3% of mass-forming chronic pancreatitis [22]. More recently, Xie et al. identified in their series 44 patients with chronic pancreatitis out of 234 cases submitted for EUS-guided sampling for solid pancreatic lesions, and sensitivity (80% vs. 95%, $P = 0.020$) and accuracy (86% vs. 95%, $P = 0.043$) were significantly lower in patients with chronic pancreatitis compared to those without chronic pancreatitis [23]. Kurita et al. aimed to investigate whether chronic pancreatitis influences the diagnostic ability of EUS-guided sampling for pancreatic lesions ≤10 mm. In a multivariate analysis of factors influencing the accuracy of EUS-guided sampling, chronic pancreatitis significantly lowered the accuracy ($P = 0.048$; OR: 9.21). Among pancreatic cancer patients, the number of chronic pancreatitis patients was significantly higher than the number of patients with benign lesions ($P = 0.023$) [8]. Finally, a recent systematic review and meta-analysis conducted by Abdallah et al. with the aim of evaluating the diagnostic performance of EUS-guided sampling for detecting pancreatic malignancy in chronic pancreatitis showed a pooled sensitivity of 65% (95% CI 52.6–75.6%), and specificity of 96.8% (75–99.7%) [24]. In the same study, the sensitivity of EUS-guided sampling for diagnosing pancreatic malignancy in the absence of chronic pancreatitis was 91.5 vs. 65.3% (OR [95% CI] 5.5 [2.9–10.2]) compared to patients with chronic pancreatitis [24].

Endoscopic Ultrasound-Guided Elastography

Different pathological processes, including inflammation, fibrosis, and cancer, alter tissue elasticity differently, which result in distinct elastographic appearance [25,26]. EUS-guided elastography has been shown to be highly accurate for the differential diagnosis of solid pancreatic tumors. A homogeneous green pattern usually represents normal pancreatic parenchyma. A heterogeneous, predominantly green pattern with slight yellow and red lines is present in inflammatory pancreatic masses (Fig. 44.4). A heterogeneous, predominantly blue pattern with small green areas and red lines and a geographic appearance is present mainly in pancreatic malignant tumors, including pancreatic adenocarcinoma (Fig. 44.5). Finally, a homogeneous blue pattern is found in pancreatic neuroendocrine malignant lesions. Pancreatic cancer can be excluded with a high accuracy in lesions with a predominantly

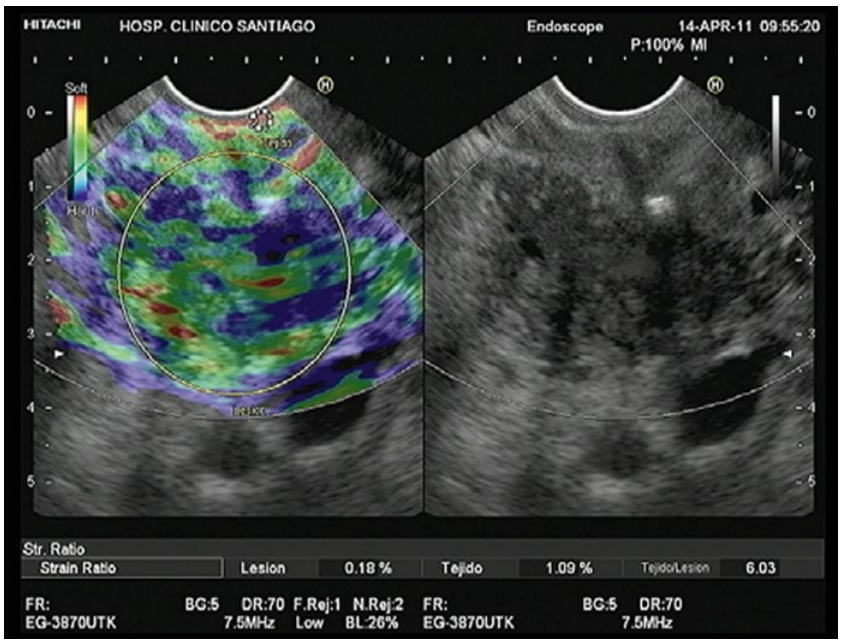

Figure 44.4 Endoscopic ultrasound-guided elastography from a mass-forming chronic pancreatitis, showing the typical green heterogeneous predominant pattern.

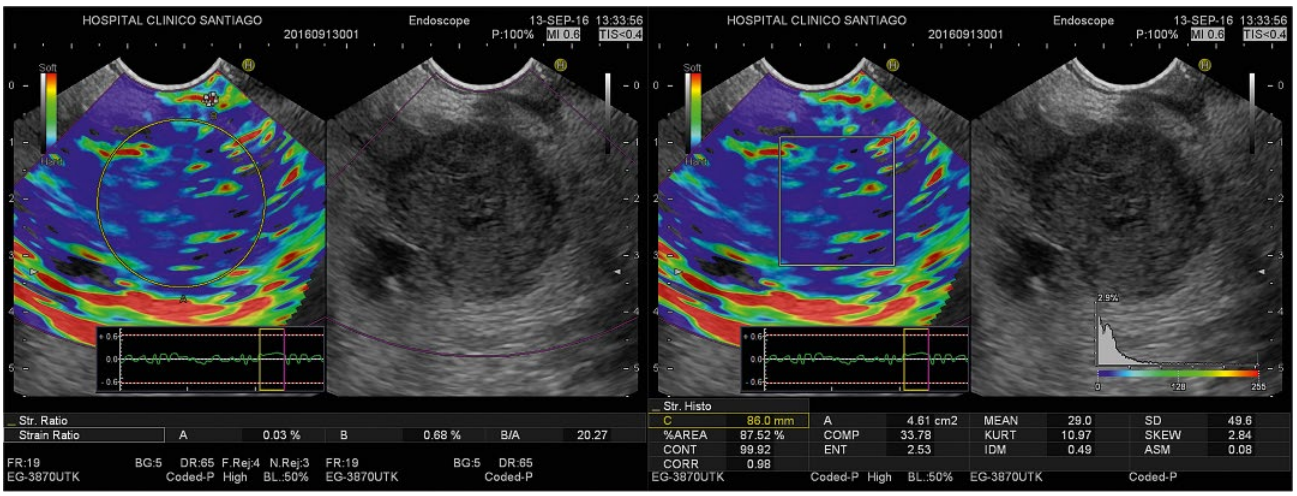

Figure 44.5 Endoscopic ultrasound-guided elastography from a pancreatic cancer, with a heterogeneous blue predominant pattern, showing a strain ratio of 20.27, and a strain histogram of 29.

soft (green) pattern [27]. Chronic pancreatitis can be differentiated from pancreatic cancer by a difference in the elastography appearance in most of the cases. It is important to highlight the different pattern in cases of autoimmune pancreatitis, characterized by a diffuse stiff pattern in the pancreatic parenchyma, not just in the focal mass [25,26].

Elastography can also be evaluated in a quantitative manner by calculating the ratio between the strain in the region of interest and a reference area in surrounding soft tissue (strain ratio) or evaluating the strain histogram of the selected area. Malignant pancreatic masses and neuroendocrine tumors produce higher strain ratios and lower strain histograms than inflammatory masses and normal parenchyma. It has been suggested that a strain ratio of >10 or a mean strain histogram value of <50 is associated with malignancy [26,28,29] (Fig. 44.5). Color patterns, strain ratio, and strain histogram values for the evaluation of solid pancreatic lesions are shown in Tables 44.1 and 44.2.

Table 44.1 Elastographic patterns classification.

Color and pattern	Stiffness	Malignancy
Homogeneous blue predominant	Hard	Yes
Heterogeneous blue predominant (Fig. 44.3)	Hard	Yes
Heterogeneous green predominant (Fig. 44.4)	Intermediate	No
Homogeneous green predominant (Fig. 44.5)	Soft	No
Heterogeneous green and blue without predominant color	Intermediate hard	Undetermined

Table 44.2 Elastographic values on quantitative evaluation.

Strain ratio	Strain histogram	Malignancy
>10	<50	Yes
<10	>50	No

Different meta-analysis have evaluated the diagnostic performance of EUS elastography for the characterization of malignant pancreatic tumors. Overall, a high sensitivity (92–98%), but a low specificity (67–76%) have been reported [30,31]. No significant advantage of semi-quantitative strain elastography over qualitative strain elastography has been demonstrated. The low specificity can explain the difficult interpretation of cases with chronic calcifying pancreatitis. Calcifications show a hard blue pattern, as expected, so it is important in these cases to evaluate the areas where no calcifications are present. In a recent multicenter study, 50% of solid pancreatic lesions ≤15 mm proved to be soft, and the probability of a soft lesion to be malignant was negligible [32]. Therefore, due to its very high negative predictive value for malignancy, EUS elastography may have a specific value for the evaluation of small pancreatic lesions. A topic of specific interest in the evaluation of chronic pancreatitis cases is the role of elastography to detect blue spots (hard tissue) inside the mass-forming chronic pancreatitis, to target the area of sampling. A study on 54 patients with solid pancreatic lesions, using a 25-gauge EUS needle that was inserted into the most suspicious part of the lesion according to EUS elastography (Fig. 44.6), reported a positive diagnosis of carcinoma in 85% of patients. The diagnostic accuracy, sensitivity, and specificity of the combination EUS-elastography/FNA was 94%, 93%, and 100%, respectively [33].

Endoscopic Ultrasound-Guided Contrast Enhancement

Contrast enhanced harmonic EUS (CEH-EUS) is a methodology to further improve the EUS-based differential diagnosis of solid pancreatic tumors. The development of microbubble-based contrast agents together with technological advances and refinement in ultrasound technology has led to improved imaging of fine vascular structures and visualization of microflow patterns within target lesions [34,35].

Lesions of interest should be reported and documented in terms of their specific contrast enhancement by looking separately into the arterial phase and the venous phase over time. Thereby, the temporal behavior of signals can be assessed and compared with those signals arising from the surrounding tissues (non-, hypo-, iso-, or hyperenhancement) and with its contrast distribution (homogenous or heterogeneous). Besides qualitative descriptions, the intensity of depicted contrast signals can be quantified by the calculation of time–intensity curves both during the wash-in and wash-out phases [36]. Several parameters can be calculated for further reviews such as peak enhancement, rise time, wash-in and wash-out rate, area under the curve, and others.

The main contrast agent available is SonoVue/Lumason (Bracco Imaging, Milan, Italy), containing microbubbles composed of sulfur hexafluoride gas enclosed in a lipid shell. After intravenous injection, the pancreatic arterial phase occurs within 15–30 s before a venous phase starts approximately 30–45 s after injection [36].

CEH-EUS can differentiate the nature of solid pancreatic lesions, particularly pancreatic ductal adenocarcinoma that is typically hypoenhanced (Fig. 44.7). In this regard, pancreatic adenocarcinoma differs from other solid lesions such as neuroendocrine tumors, pancreatic metastases, or pseudotumoral (mass-forming) focal chronic pancreatitis. Both mass-forming chronic pancreatitis and autoimmune pancreatitis present as iso- or hyperenhanced pseudotumors as opposed to the hypoenhanced lesions associated with pancreatic adenocarcinoma. Contrast enhancement can also be used to assess therapeutic response in the treatment of autoimmune pancreatitis [35].

Several meta-analyses have shown the accuracy of this methodology in the differential diagnosis of solid pancreatic tumor, mainly for the detection of pancreatic cancer. Sensitivity ranges from 85% to 90%, and specificities from 80% to 90% [37–39]. A large multicenter trial that included 167 consecutive patients indicated that peak enhancement, wash-in area under the curve, wash-in rate, and the wash-in perfusion index were significantly different in patients with chronic pancreatitis

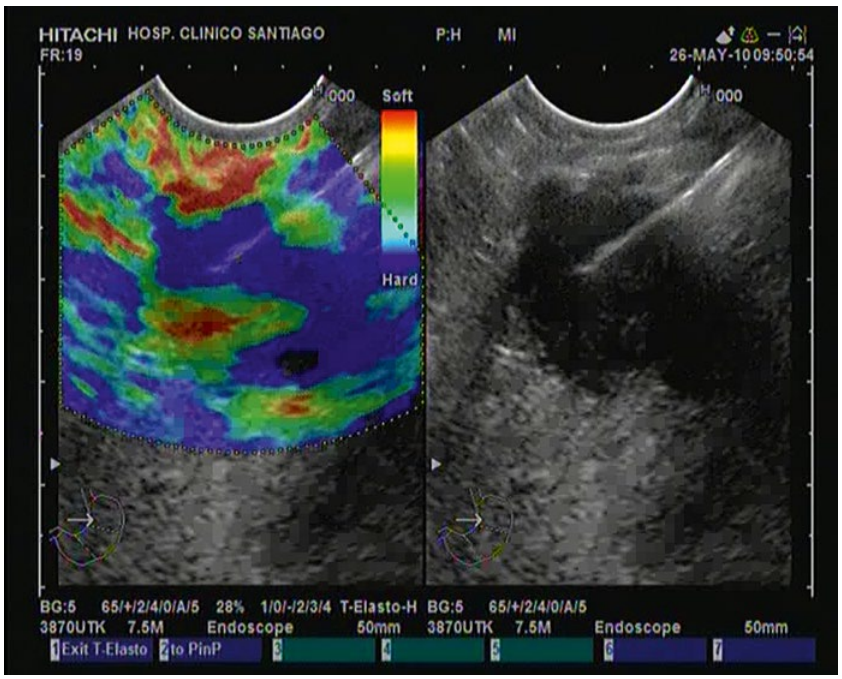

Figure 44.6 Endoscopic ultrasound-guided sampling from a pancreatic solid tumor, guided by elastography (targeting the blue area of the lesion).

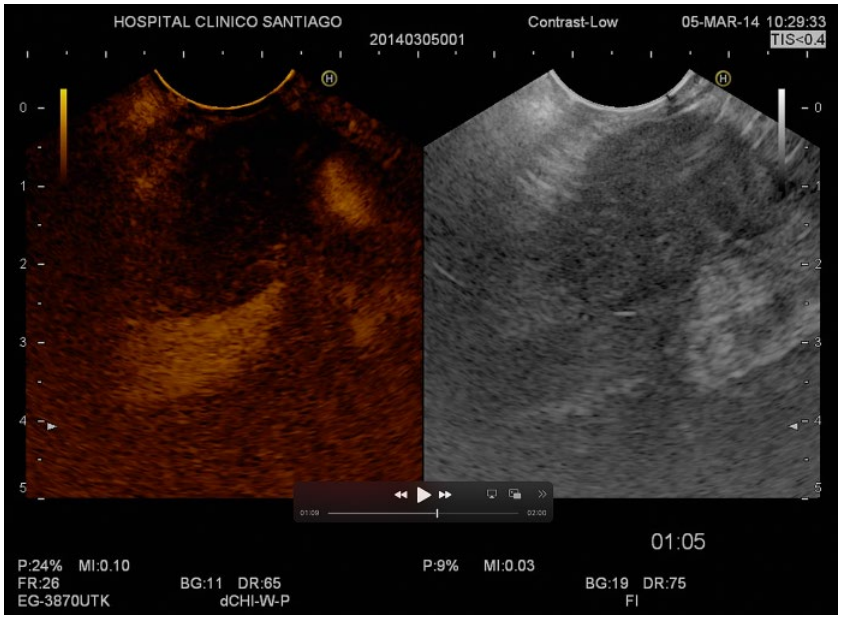

Figure 44.7 Contrast-enhanced harmonic endoscopic ultrasound of a pancreatic solid tumor, a pancreatic adenocarcinoma, showing the typical hypoenhanced pattern.

and pancreatic cancer [40]. Furthermore, using a model of artificial neural networks for the parameters listed above, the authors found an increased sensitivity (94%), specificity (94%), positive predictive value (97%), and negative predictive value (90%). The diagnostic yield of CEH-EUS for the diagnosis of pancreatic cancer versus other tumors in lesions <15 mm has been confirmed in a recent multicenter trial including 219 patients, indicating an overall 89% accuracy [41]. Recently, time–intensity curve analysis has also been used with a high diagnostic accuracy of 91% to characterize focal pancreatic lesions [42].

Contrast-enhanced EUS can also be used for targeting EUS-guided sampling. However, a recent study has shown that diagnostic rates for samples obtained using 22-gauge needles with standard EUS-guides sampling

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and CEH-EUS-guided sampling were not significantly different [43]. However, the use of CEH-EUS may reduce the number of needle passes needed to reach a diagnosis as compared to conventional techniques [44].

Combination of EUS-Guided Advanced Imaging and Tissue Sampling

The combined use of different EUS technologies has been shown to improve the diagnosis of solid pancreatic lesions. A recent meta-analysis selected 17 studies evaluating elastography, contrast enhancement, and tissue sampling for pancreatic lesions. The pooled sensitivity and specificity were for qualitative elastography respectively, 97% and 67%; for strain ratio 98% and 62%; for contrast enhancement 90% and 76%; and for tissue acquisition 84% and 96% [45]. Iglesias-García et al. showed an overall accuracy for malignancy using elastography, CEH-EUS, their combination, and EUS-guided tissue acquisition of 98.4%, 85.5%, 91.9%, and 91.5%, respectively. Importantly, the combination of advanced imaging provided very useful information for establishing the malignant potential of the lesions [28]. Costache et al. conducted a multicenter trial on the combined use of EUS-guided elastography and CEH-EUS. Elastography showed a sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of 100%, 29.63%, 78.65%, 100%, and 80.41%, respectively. Corresponding values for CEH-EUS (considering hypoenhancement as a predictive factor of malignancy) were 98.57%, 77.78%, 92%, 95.45%, and 92.78%, respectively. Combining CEH-EUS (hypoenhancement) and EUS-guided elastography, the sensitivity, specificity, and accuracy were 98.57%, 81.48%, and 93.81%, respectively. Best results were obtained using a sequential clinical algorithm based on the initial use of elastography, followed by contrast enhancement [46].

Conclusions

EUS, CT, and MRI can all provide valuable and complementary information for the differential diagnosis between mass-forming chronic pancreatitis, autoimmune pancreatitis, and pancreatic adenocarcinoma. However, EUS has the unique ability to allow obtaining specimens for histopathological diagnosis safely and accurately, thus playing nowadays a crucial role in the evaluation of patients with solid pancreatic lesions. Advanced imaging (EUS-guided elastography and CEH-EUS) further increase the diagnostic capabilities of EUS in this setting.

Hereditary Pancreatitis and Complex Genetic Causes

Celeste Shelton Ohlsen[1] *and David C. Whitcomb*[1,2]

[1] *Ariel Precision Medicine, Pittsburgh, PA, USA*
[2] *Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh/UPMC, Pittsburgh, PA, USA*

Clinical and Genetic Definitions

Hereditary pancreatitis (HP) is a syndrome that encompasses acute pancreatitis (AP), recurrent acute pancreatitis (RAP), and chronic pancreatitis (CP). A mechanistic definition of CP is useful for framing HP as a process extending from asymptomatic risk to end-stage disease. Chronic pancreatitis is defined both by its essence and its character as "a pathologic fibro-inflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who develop persistent pathologic responses to parenchymal injury or stress" [1]. In addition, "Common features of established and advanced CP include pancreatic atrophy, fibrosis, pain syndromes, duct distortion and strictures, calcifications, pancreatic exocrine dysfunction, pancreatic endocrine dysfunction and dysplasia" [1]. The definition was designed to assist in the early diagnosis of CP, the prognosis, and in the type and timing of potential therapies.

Hereditary pancreatitis is defined by clinical presentation in a family or by genetic test results in an affected individual. In families, HP is defined as two or more first-degree relatives or three or more second-degree relatives with recurrent acute pancreatitis (RAP) or chronic pancreatitis (CP) in two or more generations, consistent with an autosomal dominant inheritance pattern. Less commonly, families may appear to follow alternative inheritance patterns (e.g., autosomal recessive and complex). Alternatively, HP can be diagnosed in an individual with pancreatitis and a known pathogenic germline mutation, regardless of family history. Of importance, the penetrance of *PRSS1* hereditary pancreatitis is incomplete and therefore, identification of a pathogenic *PRSS1* mutation in an asymptomatic individual is not sufficient for a diagnosis but does indicate high risk. Some hereditary pancreatitis-appearing families have pathogenic variants in the serine protease inhibitor, Kazal type 1 gene (*SPINK1*), the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), *SPINK1* plus *CFTR*, the chymotrypsinogen C gene (*CTRC*), or a more complex genotype. Therefore, the absence of a pathogenic *PRSS1* variant does not preclude the diagnosis of HP in a family. A diagnosis of HP should always be considered in idiopathic pancreatitis, early-onset pancreatitis, or in a family with multiple affected individuals.

Familial pancreatitis refers to the occurrence of pancreatitis of any cause in a family with an incidence greater than would be expected by chance alone. Familial pancreatitis does not follow an observable monogenic pattern of inheritance. Kindreds with familial pancreatitis may have shared genetic and/or environmental (e.g., alcohol, smoking, stress) risk factors that predispose them to pancreatitis above the general population risk.

Epidemiology

Hereditary pancreatitis is a rare genetic disorder. In 1952, Comfort and Steinburg described a large family with HP [2]. Since this initial report, hundreds of HP kindreds have been identified in several regions in the United States and Europe and in a few families in Japan, Korea, China, Thailand, Malaysia, and South America. The vast majority of HP kindreds identified in the United States are of European ancestry linked to large pedigrees (>500 people), suggesting founder effects. The reason that HP is rare in Africans and Asians is unknown.

The prevalence of hereditary pancreatitis differs by geographic region, and HP has been observed most frequently in the USA and Europe. A national series of HP in France estimated a population prevalence of at least

Companion website: www.wiley.com/go/beger/thepancreas4e

0.3 per 100,000 [3]. Since there is autosomal dominant inheritance with high penetrance and founders originating multiple generations in the past, the fraction of CP patients with HP will vary greatly from region to region and country to country.

Clinical Presentation

Hereditary pancreatitis typically presents with acute pancreatitis in early adolescence, with a high risk of progression to chronic pancreatitis by early adulthood (Fig. 45.1). In HP, the phenotypic features are confined to the pancreas, whereas *CFTR*-related disorders affect multiple organs as seen in cystic fibrosis. In patients who develop CP, major comorbidities include pancreatic exocrine insufficiency, diabetes mellitus, and chronic pain syndromes. In comparison to CP of other etiologies, HP has earlier age of onset and appears to have higher cumulative risks for exocrine and endocrine failure in patients who develop chronic pancreatitis, as well as increased risk for pancreatic cancer.

The disease penetrance for a *PRSS1* mutation was estimated as ~80% [4–6]. However, a national series of *PRSS1*-tested patients in France identified a penetrance of 93% [3]. Of note, estimates of penetrance may be inflated by biased study ascertainments. Penetrance may also differ by type of mutation and presence of modifying risk factors. Lifespan is not reduced as compared to the general population, except in patients who develop pancreatic adenocarcinoma [7].

Acute Pancreatitis

The median age of onset of acute pancreatitis is 10–12 years [3,4]. Some studies have shown that the age of symptom onset is earlier in *PRSS1* p.R122H carriers compared to p.N29I carriers and mutation-negative patients [4,5,8]. A multicenter European (EUROPAC) study of 418 subjects from 112 families identified an age of onset of 10 years for the *PRSS1* p.R122H mutation, 14 years for the p.N29I mutation, and 14.5 years in patients without an identified mutation [4]. Severity, length, and frequency of attacks are variable and can vary dramatically by family. In one large kindred, 58% of *PRSS1* p.R122H subjects were <5 years at the age of symptom onset [5]. Shared modifier genes and environmental factors in families contribute to age of onset and severity. For example, disease onset in four twin pairs differed by median of 1 year (range 0–2.4 years) as compared to 7 years (range 2–15 years) in a nonsibling comparison group matched for mutation, gender, and age [9].

At least 83% of patients experience epigastric abdominal pain [3]. The number of reported hospitalizations for acute pancreatitis varies by family and mutations status, with nearly 90% of affected individuals reporting >5 hospitalizations [4,5,8]. The EUROPAC study found a significant reduction in hospital admission rates for patients with a *PRSS1* p.N29I mutation (0.19 per year) as compared to patients with a *PRSS1* p.R122H mutation (0.33 per year) [4]. However, the difference in number of attacks between patients with an p.N29I mutation (1.4 per year) and an p.R122H mutation (2 per year) was not significantly different, suggesting that the p.N29I mutation results in less severe attacks [4]. The same study found that the majority of attacks are ≤7 days in length [4], but smoldering pancreatitis and/or persistence of pain that lasts weeks or months has been reported in patients with hereditary pancreatitis [10].

Chronic Pancreatitis

Recurrent acute pancreatitis progresses to chronic pancreatitis by the second or third decade of life in the majority of patients with hereditary pancreatitis. Rate and severity of pancreatic fibrosis and parenchymal destruction is highly variable, with cumulative incidence of ~50% in a lifetime (Fig. 45.1). A trend exists between the number of attacks and degree of fibrosis, and this process is highly influenced by modifying factors.

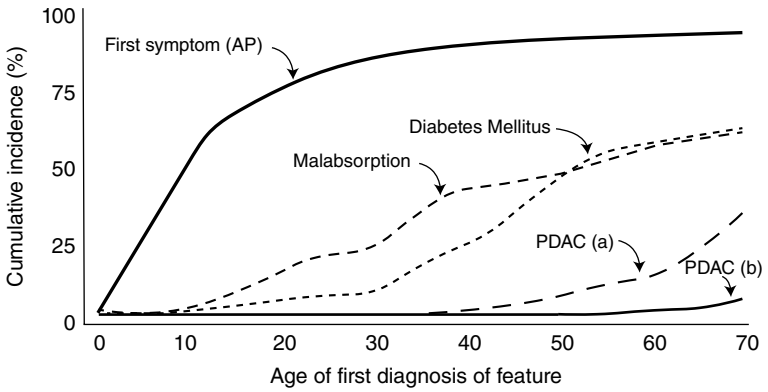

Figure 45.1 Age of onset of first symptoms of acute pancreatitis, pancreatic exocrine insufficiency, pancreatic endocrine insufficiency, and pancreatic cancer (PDAC). PDAC (a) is from Ref. 4 and PDAC (b) is from Ref. 14 with reduced smoking. *Source:* Data from [4] and [14].

Pancreatic Exocrine Insufficiency

Progression of inflammation and fibrosis eventually leads to pancreatic exocrine insufficiency in a significant subset of patients. Pancreatic exocrine insufficiency occurs when the pancreas cannot supply a sufficient quantity of digestive enzymes to the intestines, leading to maldigestion. The EUROPAC study identified cumulative risks for exocrine failure of 8.4% at 20 years, 37.2% at 50 years, and 60.2% at 70 years, with a median time to malabsorption of 53 years [4]. No significant difference in time to malabsorption was found between men and women [4].

Diabetes Mellitus

As with other forms of chronic pancreatitis, chronic inflammation and progressive fibrosis also lead to islet cell injury. Glucose intolerance progresses to pancreatic endocrine insufficiency from loss of insulin-secreting beta cells. Furthermore, loss of glucagon-secreting alpha cells places patients at high risk for hypoglycemia. Diabetes mellitus from pancreatic exocrine disease and loss of all islet cell types is classified as type 3c. However, acute pancreatitis and pancreatic inflammation also triple the risk of type 2 diabetes, which develops earlier in the clinical course then type 3c [11,12]. The danger of hypoglycemia is enhanced by untreated pancreatic exocrine insufficiency, since the ingestion of nutrients is not well coordinated with digestion and absorption. The cumulative risks for endocrine failure in HP are 4.4% at 20 years, 47.6% at 50 years, and 79.1% at 80 years [4]. Median time to development of diabetes mellitus was 53 years and not significantly influenced by gender and mutation status [4].

Pancreatic Cancer

Hereditary pancreatitis is associated with a >50-fold increased risk for pancreatic adenocarcinoma [4,7,13]. Estimates for cumulative risk for pancreatic cancer at 70 years range from 7.2% to 40% [3,4,13,14]. The risk for pancreatic cancer is highest in smokers and individuals with diabetes mellitus. Smokers with HP have ~twofold increased risk for pancreatic cancer, with development of cancer 20 years earlier than nonsmokers [15]. More recent lower estimates of pancreatic cancer risk may reflect successful counseling of HP families to avoid tobacco [14]. The increased risk for pancreatic cancer appears to result from chronic inflammation rather than a *PRSS1* mutation itself, since all forms of CP are associated with pancreatic cancer, but early-onset pancreatitis in HP remains one of the strongest known risk factors for pancreatic cancer.

Incidence of pancreatic cancer varies extensively between HP families, and some families have high incidences of pancreatic cancer in the absence of clear environmental factors, suggesting the presence of risk and/or protective variants. Annual screening for pancreatic cancer is recommended for patients with *PRSS1*-HP beginning at age 50 or 10 years younger than the earliest familial onset of pancreatic cancer [16].

Management

As with pancreatitis of nongenetic etiology, management is aimed at prevention, reduction of symptoms such as fibrosis, pancreatic exocrine insufficiency and pancreatic endocrine insufficiency, and alleviation of pain. The approach should be based on targeting the underlying genetic factors, minimizing environmental stressors, and considering new therapeutic interventions as indicated. Alcohol, emotional stress, and dietary fat can exacerbate pancreatitis and should be avoided. Patients should also be counseled to refrain from smoking, which doubles the already increased risk for pancreatic cancer [14,15]. Antioxidants may reduce pain in a subset of patients [17]. Common recommendations include a low-fat diet with multiple small meals a day and to maintain good hydration to reduce the risk of an attack, but these recommendations are not based on strong evidence and a normal diet is possible with appropriate pancreatic enzyme replacement therapy.

Pancreatic exocrine insufficiency should be anticipated and managed with early initiation of pancreatic enzyme replacement therapy. The diagnosis of pancreatic exocrine insufficiency currently relies on clinical suspicion from abdominal bloating, diarrhea, steatorrhea, deficiency of fat-soluble vitamins or vitamin B12, or unexplained weight loss. The most common diagnostic tests include measuring low levels of human fecal elastase, low serum trypsinogen levels, or the clinical response to a trial of pancreatic enzyme replacement therapy.

Diabetes mellitus is common both in patients with pancreatitis and in the general population. In HP, type 3c diabetes mellitus typically develops years after the onset of CP. The diagnosis is challenging, and standardized protocols are not widely accepted. However, the clinical context of advanced CP, especially with pancreatic exocrine insufficiency, should indicate caution and a multidisciplinary approach involving endocrinologists and pancreatologists. The destruction of the islets may limit the use of some antidiabetic medications, and the use of insulin must be balanced with the ingestion and digestion of the meal, which may require the addition of pancreatic enzyme replacement therapy.

In the absence of pancreatic cancer, the primary indication for surgery is pain. Total pancreatectomy with islet cell autotransplantation (TPIAT) can be

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

considered in younger patients with intractable, narcotic-dependent pancreatic pain [18,19]. Total pancreatectomy without islet autotransplantation can be considered in older patients with chronic pancreatitis for 20 years or more to reduce pain and as a last resort to reduce the risk of developing pancreatic cancer [20,21]. The need and timing of this radical procedure requires both experience with the procedure and clear prognostic understanding of what will happen with, and without TPIAT.

Molecular Genetics

In 1996, a missense mutation in the cationic trypsinogen gene (*PRSS1*) was identified in a large hereditary pancreatitis family [22]. Mutations in *PRSS1* have since been identified in 65–100% of HP kindreds with an estimated penetrance of 80%. Since this discovery, additional genes associated with recurrent acute and chronic pancreatitis have been identified, particularly *SPINK1*, *CFTR*, and *CTRC* [23–26] (Tables 45.1 and 45.2). Other important genes that have been associated with chronic pancreatitis include *CLDN2*, *CASR*, *CTSB*, *CPA1*, *GGT1*, and *TRPV6* [27–29]. Disease mechanisms for many of the genes associated with pancreatitis are complex, and gene–gene and gene–environment interactions are not fully defined.

PRSS1

Cationic trypsinogen is the most abundant isoform of trypsinogen (~65%), followed by anionic trypsinogen (*PRSS2*, ~30%) and mesotrypsinogen (*PRSS3*, ~5%) [30]. Trypsinogen is the inactive zymogen of trypsin, a digestive enzyme and regulator of all pancreatic zymogens, except amylase and lipase. The trypsinogen activation peptide maintains the inactive enzyme until it is cleaved by enterokinase or another trypsin, generally in the duodenum. Self-destruction (autolysis) occurs at p.R122, which is located on the single chain that links the two globular domains of trypsin. Two calcium-binding pockets serve as "on–off" switches in response to calcium concentrations, inducing distinct conformational changes. Increased calcium concentrations facilitate trypsin activation, whereas reduced calcium levels permit autolysis.

PRSS1 gain of function mutations fall into two categories: (i) premature activation of trypsin in the pancreas; or (ii) resistance to degradation. The importance of *PRSS1* mutations is demonstrated in transgenic mice with early-onset acinar cell injury and dedifferentiation, inflammatory cell infiltration, and progressive pancreatic fibrosis [31]. Many of the less common *PRSS1* variants found in patients with pancreatitis do not appear to be gain-of-function mutations. Instead, they may represent coding region variants causing protein misfolding, and triggering an unfolded protein stress response that drives fibrosis in a poorly defined way [32].

Table 45.1 Genes associated with pancreatitis.

Gene	Chromosome	Type of mutation	Mechanism
CTRC	1	Loss of function	Diminished trypsin degradation in pancreas
CASR	3	Loss of function; Inappropriate localization	Elevated pancreatic calcium levels Hypothesized premature activation of trypsin
SPINK1	5	Loss of function	Diminished trypsin degradation in pancreas
PRSS1	7	Gain of function	Premature activation of trypsinogen in pancreas
		Loss of function	Misfolding-induced endoplasmic reticulum stress; associated with nonalcoholic, early-onset CP
TRPV6	7	Loss of function	May alter calcium homeostasis in pancreatic acinar cells
CFTR	7	Loss of function	Loss of or diminished bicarbonate conductance leads to detainment of trypsinogen in the pancreas
CPA1	7	Loss of function	Misfolding-induced endoplasmic reticulum stress; associated with nonalcoholic, early-onset CP
CTSB	8	Unknown / Gain of function	Hypothesized to induce premature activation of trypsinogen
CEL	9	Loss of function	The CEL-HYB recombination allele originating from a crossover between CEL and pseudogene CELP is associated with an increased risk for pancreatitis
CLDN2	X	Altered regulatory element	Unknown; associated with alcoholic CP

CP: chronic pancreatitis.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 45.2 Genotypephenotype correlations and multiorgan syndromes.

Genotype (variants)	Phenotype (syndromes)	Comment
PRSS1	Hereditary pancreatitis	Genetic counseling recommended
$CFTR^{sev}$/$CFTR^{sev}$	Cystic fibrosis (CF)	Manage with a CF center
$CFTR^{sev}$/$CFTR^{m\text{-}v}$	Atypical CF	Manage with a CF center
SPINK1/*SPINK1*	Familial pancreatitis	Usually progresses to severe CP
$CFTR^{bicarb}$/$CFTR^{any}$	Pancreas/sinus/CBAVD	Newly defined syndrome
$CFTR^{any}$/*SPINK1*	RAP/CP	Pancreas only
CTRC/*SPINK1*	RAP/CP	Pancreas only – not well studied
CASR/*SPINK1*	RAP/CP	Pancreas only – not well studied

CFTR: sev, severe mutations (typically functional class I–III); m-v, mild-variable mutations, (typically *CFTR* functional class IV); bicarb, bicarbonate conductance-disrupting variant (e.g., p.R75Q); any, either severe, mild-variable, or bicarbonate-disrupting variants; CP: chronic pancreatitis; RAP: recurrent acute pancreatitis; CBAVD: congenital bilateral absence of the vas deferens.

The most common *PRSS1* mutations are p.R122H and p.N29I (~90%). Less common mutations include p.A16V, p.R122C, p.N29T, p.D22G, and p.K23R. Mutations have primarily been identified in exons 2 and 3, but rare variants have also been identified in the 5′UTR, introns 1–4, and exons 4 and 5 (see http://www.pancreasgenetics.org). Copy number variations of the *PRSS1-PRSS2* locus have also been associated with chronic pancreatitis [33].

SPINK1

The serine protease inhibitor, Kazal type 1 (*SPINK1*; *PST1*) is a trypsin inhibitor secreted from pancreatic acinar cells. Loss-of-function mutations in *SPINK1* reduce its protective function and predispose to pancreatitis [34]. Mutations are found in ~2% of the population and confer a 12-fold increased risk for pancreatitis [34]. Still, less than 1% of *SPINK1* carriers develop pancreatitis. Biallelic loss of function mutations in *SPINK1* may lead to autosomal recessive pancreatitis. However, the majority of affected patients with *SPINK1* mutations are heterozygous, indicating the presence of complex gene–gene and gene–environment interactions [35]. For example, *SPINK1* can act as a disease modifier, and compound heterozygosity for pathogenic variants in *SPINK1/PRSS1* and, more commonly, *SPINK1/CFTR* has been reported [25,36].

SPINK1 mutations are detected in ~20% of patients with idiopathic chronic pancreatitis. The most common high-risk haplotype identified in the United States and Europe is *SPINK1* p.N34S. The *SPINK1* IVS3 +2T>C splicing variant is common in East Asian populations.

CFTR

Mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) are common among patients with idiopathic chronic pancreatitis. *CFTR* mutations may impair both chloride and bicarbonate conductance (e.g., severe mutations), or only bicarbonate conductance [36,37]. Homozygosity or compound heterozygosity for two "severe" *CFTR* mutations generally causes cystic fibrosis (CF), while "mild-variable" or other mutations are associated with RAP, CP, pancreas sufficient CF and CFTR-related disorders [38]. *CFTR* carriers that develop pancreatitis are also likely to have an additional genetic (e.g., *SPINK1*, *CTRC*) or other (e.g., pancreas divisum) risk factors [25,36]. CFTR-associated pancreatitis is considered in Chapter 4.10. The use of CFTR modulators in pancreatic sufficient CF suggest that specific new therapies may be available in the future [39].

CTRC

Chymotrypsinogen C (*CTRC*) is a digestive enzyme and the primary regulator of trypsin. The action of chymotrypsinogen C is twofold and dependent on calcium concentrations. In the calcium-rich duodenum, chymotrypsin C promotes trypsinogen activation, but in solutions with lower calcium concentrations, it mediates trypsin degradation [40]. As with *SPINK1*, chymotrypsin C is believed to protect the pancreas from premature trypsin activation, with genetic defects increasing the risk of trypsin-mediated pancreatitis [41,42]. Two mutations, p.R254W and p.K247_R254del, were found to be overrepresented in patients with idiopathic or hereditary chronic pancreatitis [41]. The c.180T>G variant has been identified in about 10.8% of persons of European ancestry in North America and moderately increases the risk of progression from recurrent acute to chronic pancreatitis, particularly in the presence of alcohol, tobacco, or *PRSS1*/*SPINK1* mutations [43]. The independent effects of pathogenic *CTRC* variants appears to be low, but they clearly increase the risk of CP in the context of other risk factors such as

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pathogenic *CFTR* variants [25], and can contribute to familial clustering of CP cases.

Complex Genetics

Single-gene or Mendelian diseases are caused by highly penetrant pathogenic mutations in a single gene that follow a clear pattern of inheritance (e.g., autosomal dominant, autosomal recessive). Mendelian forms of pancreatitis, such as *PRSS1*-HP, are rare. Instead, most patients have a complex etiology resulting from multiple low-to-moderate effect risk alleles in combination with environmental and physiologic risk factors. Complex risk variants are defined as variants with variable effect sizes, ranging in frequency from rare to common, that do not cause disease in isolation. Instead, the combination of multiple interacting risk variants and other factors work in concert to initiate the disease process. In patients with pancreatitis, several common risk variants have been identified, including the *CTRC* c.180T>G (p.G60=) and *SPINK1* p.N43S variants (described above), a *PRSS1-PRSS2* haplotype [44], risk alleles in *CLDN2* [44], and the CEL-HYB risk allele [45]. Heterozygous carriers of *CFTR* variants associated with cystic fibrosis or a CFTR-related disorder have also been associated with an increased risk for pancreatitis as a part of a complex etiology [46]. Known risk factors for pancreatitis are outlined in the Toxic-metabolic, Idiopathic, Genetic, Autoimmune, Recurrent and severe acute pancreatitis and Obstructive Pancreatitis Risk/Etiology Checklist (TIGAR-O_V2) [27], which functions as an organizational tool to document and track patient risk and etiological factors. Although the identification of complex risk variants may lend insights into a patient's disease process, the quantification of risk to develop pancreatitis in asymptomatic patients or to progress to severe disease in symptomatic patients based on multiple complex variants and nongenetic factors remains challenging and imprecise.

Genetic Testing and Counseling

When a patient or family is suspicious for hereditary pancreatitis, a (minimum) three-generation pedigree should be collected, including family history of pancreatitis, age of onset, age at diagnosis for multiple pancreatic episodes, and pancreatic cancer [47]. Other information valuable for assessment of a family includes smoking and alcohol exposure, diabetes mellitus, pancreatic insufficiency, male infertility, cystic fibrosis, chronic sinusitis, and nasal polyps [47]. Calculation of risk in a family depends on genotype, pattern of inheritance in the family, and environmental exposures (e.g., tobacco, alcohol).

Indications to offer genetic testing in a symptomatic patient include unexplained recurrent acute pancreatitis and/or chronic pancreatitis, a first- or second-degree relative with pancreatitis, and/or unexplained pancreatitis in a child requiring hospitalization. Genetic testing is commercially available for several genes, including *CASR*, *CEL*, *CFTR*, *CLDN2*, *CPA1*, *CTRC*, *GGT1*, *PRSS1*, *PRSS2*, *SBDS*, *SPINK1*, and *UBR1*. Deletion/duplication analysis should be considered in a proband if a mutation is not identified from sequencing or targeted mutation analysis.

Genetic testing should always be preceded and followed by appropriate genetic counseling. Results may have implications for patient risk, risk to other family members, and family planning [48]. Another concern for genetic testing in this patient population, especially in the United States, is insurance discrimination [48]. The *Genetic Information Nondiscrimination Act of 2008* (GINA, Pub. L, 110–233) protects against genetic discrimination in health insurance and employment in the United States, but does not cover life, disability, or long-term care insurance. Patients and families should understand the benefits, limitations, and costs of genetic testing before the test is ordered. Therefore, clinicians must understand the consequences of genetic testing and should provide counseling directly or refer patients to a genetic counselor to obtain appropriate informed consent.

Genetic testing in a symptomatic patient can clarify etiology and provide information on risk for related complications, such as pancreatic cancer. Identification of a responsible mutation may clarify risk for family members and provide information relevant to family planning. *PRSS1*-related hereditary pancreatitis follows an autosomal inheritance pattern, and each child of a parent with a *PRSS1* mutation, has a 50% or 1 in 2 chance to inherit the deleterious allele. About 80% of individuals who inherit a *PRSS1* mutation develop pancreatitis. Therefore, each child of a parent with a *PRSS1* mutation has a ~40% chance of developing hereditary pancreatitis. However, variation in penetrance and severity exists between HP kindreds, and family history should always guide interpretation of results and risk calculation. Identifying a responsible genetic mutation in a family may also expedite diagnosis of family members and prevent unnecessary evaluation for other etiologies.

Predictive genetic testing in an asymptomatic individual is available when a mutation has been identified in a close family member. Testing for this mutation can clarify risk to develop pancreatitis and risk to descendants. Genetic testing may also identify family members who would benefit from lifestyle interventions to reduce risk and severity, such as avoidance of alcohol, smoking, and fatty foods.

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

A negative test result in a patient from a family with a known mutation reduces but does not remove the risk for hereditary pancreatitis. Families may share additional, unidentified risk factors that predispose to pancreatic disease. Furthermore, not all hereditary pancreatitis-appearing families have an identifiable mutation. In a family without an identifiable mutation, genetic testing of asymptomatic family members will be uninformative, and discussions of risk must be tailored according to the presentation of disease within the family.

Genetic Testing in Children

The decision to pursue genetic testing in a child is the responsibility of the parents or legal guardian. When a child is 7 years or older, the child should provide assent for genetic testing. Testing of a symptomatic child can explain or confirm the diagnosis of pancreatitis and prevent unnecessary further evaluations.

Predictive genetic testing for hereditary pancreatitis is generally not recommended for patients less than 16 years of age. There are no clear medical benefits to identifying asymptomatic carriers at a young age and waiting to pursue testing gives the patient the opportunity to make an informed adult decision. Predictive testing to identify children that would benefit from diet, lifestyle, medication, or surveillance interventions has been advocated [49]. However, avoidance of pancreatitis risk factors, particularly fatty foods, alcohol, tobacco, and stress, are advised for all children regardless of mutation status.

Epidemiology and Pathophysiology of Tropical Chronic Pancreatitis

Shailesh V. Shrikhande[1] *and Savio G. Barreto*[2,3]

Introduction

In 1937, Kini [1] published a report on chronic calcific pancreatitis from India. Similar findings in autopsy studies were reported from southern India in 1954 [2]. While the features presented in those report were strikingly similar to the report on 45 malnourished patients from Indonesia published a couple of decades later, the credit for describing tropical (chronic) pancreatitis (TCP) as a distinct entity rests with Zuidema [3,4]. These patients were from economically weaker sections and were suffering from protein calorie malnutrition.

GeeVarghese [5,6] provided a detailed description of features that constituted TCP based on his analysis of patients in Kerala, southern India. This body of work now forms the framework on the basis of which our understanding of TCP resides.

TCP is considered a distinct subtype of CP comprising calcifying, nonalcoholic CP afflicting younger, generally malnourished individuals from the tropical regions of Asia [7–11], Africa [12–15], and even South America [16,17]. A male predominance was also noted [18–20]. However, there has been the occasional report of the disease from developed nations more often due to diagnosis of the disease in migrants arriving from the developing world [21]. In the past, the entity has been referred to by numerous terminologies including tropical calcific pancreatitis, tropical pancreatic diabetes, nutritional pancreatitis, juvenile pancreatitis syndrome, Afro-Asian pancreatitis, tropical calculous pancreatopathy, and fibrocalculous pancreatopathy, or fibrocalculous pancreatic diabetes (FCPD). However, the terminology most commonly employed today is TCP [22,23]. GeeVarghese summarized the natural history of TCP in the adage, "recurrent abdominal pain in childhood, diabetes around puberty and death at the prime of life" [5]. Barman and colleagues presented the triad of symptoms that comprised TCP, namely, abdominal pain, maldigestion and steatorrhea, and diabetes mellitus [24].

To date, there remains a paucity of large-scale epidemiological data on the prevalence of TCP. A field study from Kerala in southern India, involving 28,567 inhabitants, determined the prevalence of TCP to be 1:793 in that region [8] based on well laid out criteria for diagnosis of the disease. The study revealed that contrary to previous hospital reports, TCP in Kerala appeared to have a female preponderance (male: female ratio of 1:1.8), older age at disease onset (mean 23.9 yr), and evidence of milder disease. Prior attempts at understanding the nature of the disease had included hospital studies and a couple of monographs published by GeeVarghese [5,22] based on his experience of more than 1500 patients with the disease. The criticism by Balaji et al. [8] of these prior studies was the possibility that their findings were potentially influenced by need for healthcare (patients presenting only when symptomatic) as well as access to healthcare being preferentially available to males.

A large nationwide study from India that included 1086 CP patients has determined that idiopathic CP is now the most common subtype of the disease in the country (accounting for 60% of cases) [25]. This finding is not too dissimilar from the 70% of patients from India and China labeled to have idiopathic CP based on a survey in the Asia-Pacific region [9]. Interestingly, in the study by Balakrishnan et al. [25], when well-defined criteria for TCP were applied, TCP was found in only 3.8% of patients. The authors conjectured that these findings

may reflect a prior overrepresentation of the disease owing to the interchangeable use of the terms idiopathic CP and TCP with the possibility that the true incidence of TCP lies somewhere in between this wide variation. The declining incidence of TCP has been noted in other studies from India, too [26,27]. Whether this is a reflection of improving socioeconomic conditions accompanied by improved nutrition [25,28], an increase in smoking and alcohol consumption amongst youngsters [26], or simply a better elucidation of the entity "idiopathic CP," leading to more individuals fitting these criteria rather than TCP [29], may remain a question left unanswered.

Pathophysiology

The initial documentation of cases of TCP in malnourished patients from the tropics and from financially weaker sections of society [1,4] instinctively led researchers to focus on dietary components as a cause for the disease [30]. Over the years, detection of TCP in apparently healthy individuals with a normal nutritional status (as per their body mass index) [31,32] has led to micronutrient deficiency being more intensively investigated. Eloquent studies teasing out pathological changes [33] and genetic mutations and comparing these with other subtypes of CP have heralded a possibly more objective approach to the understanding of the entity [34,35].

Pathology

Gross appearance of the gland depends on the duration of disease, degree of fibrosis, the presence of cysts, and location and size of calculi [36]. With the passage of time, the gland undergoes uneven fibrosis and atrophy often leading to an eccentric ductal location [23] with the gland often left appearing finger-like with a nodular and irregular surface [37].

One of the hallmarks of TCP is the presence of large calculi composed of 95.5% calcium carbonate (mainly in the form of calcite [38]), a small amount of calcium phosphate and traces of magnesium, urate, and oxalate distributed throughout the ductal system varying in color, shape, and size [23]. The calculi possess an amorphous nidus and a cryptocrystalline periphery [39]. The biochemical and structural nature of calculi in TCP is not too dissimilar to those in other subtypes of CP [23]. The larger stones tend to form toward the head with their size decreasing toward the tail region.

On microscopic examination, the hallmark of TCP is the degree of intralobular fibrosis [33] that is uniform throughout the pancreatic parenchyma [40]. Nair [36] suggested that TCP was characterized by a lack of inflammation suggesting the terminology of "tropical calcific pancreatopathy" to be more appropriate. However, these findings have not been corroborated by others. Shrikhande and colleagues [33] compared the histologic appearance of TCP versus alcoholic CP (ACP) and idiopathic CP and uncovered similar histological features and a comparable inflammatory cell reaction in all three subtypes of CP although the extent of the pathological change was variable in the individual types. The degree of endophlebitis and plasma cell density was significantly higher in TCP [33]. This finding of plasma cell infiltration of the pancreas is in keeping with the report of Nagalotimath who also found a lymphocyte infiltration mainly around the ducts [37]. Cyriac and colleagues [41] have recently demonstrated that stellate cell activation occurs in a similar manner to other subtypes of CP. Total fatty replacement of parenchyma has been noted to be a striking feature in TCP, seen exclusively in diabetics with gross atrophy of islets of Langerhans [40]. Moreover, in patients with established diabetes secondary to TCP (FCPD) histopathological examination as well as immunohistochemistry have revealed varying extents of acinar atrophy and parenchymal destruction [23] along with paucity of alpha and beta cells and reduction in glucagon positivity and areas of nesidoblastosis [37,42].

An interesting observation in the pathological assessment of tissues of patients with TCP when compared with alcoholic and idiopathic has been the increase in neural tissue and neural alterations associated with progression of the disease toward a stage amenable to surgery [43], a hallmark of pain accompanying CP [44]. It is not only the neural alterations that are identical but other histologic aspects including the degree of endophlebitis, overall density of plasma cells, and inflammatory cell reaction leading to the inference that independent of the underlying etiology, the pathologic changes accompanying CP eventually reach a common immunologic stage beyond which CP appears to progress as a single distinctive entity [33].

Nutrition (Including Cassava)

The initial reports of TCP originating from regions in the developing world coupled with the clinical picture of young emaciated patients, intuitively led clinicians to focus on the nutritional aspect, or more specifically, protein calorie malnutrition [4,12,45]. However, over the years, possibly a more objective approach to investigating the role of malnutrition as a causative agent has led pancreatologists to infer that malnutrition, in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

itself, is not the main cause for TCP [46] and the nutritionally deprived state may rather be an effect of the malabsorption associated with disease [47,48]. Patients with kwashiorkor, do not develop features of TCP [23,49]. Moreover, while malnutrition exists in many other countries in the world, there are no reported cases of TCP/FCPD from them [50], while on the flipside TCP cases have been reported even among patients from well-nourished families [23]. Nonetheless, cause or effect, malnutrition remains a major issue in TCP and addressing it in its entirety forms an essential part of the workup and management of patients with TCP [51].

While malnutrition may not be the only etiological factor in the causation of TCP, it is very likely that micronutrient deficiency, along with varying degrees of macronutrient deficiency and oxidant stress are cofactors in the causation of TCP.

Cassava Toxicity

Cassava (tapioca, *Manihot esculenta* Crantz) was implicated as a cofactor in the causation of TCP based on three hypotheses, namely, the geographic coincidence of cassava being the staple diet of the low socioeconomic class of people in Kerala and the high incidence of TCP reported there [52]; the cyanogenic glycoside composition of cassava (93% linamarin and 7% lotaustralin), which requires sulfur derived from the sulfur-containing amino acids (such as cysteine and methionine) for its detoxification—believed to be inherently deficient in malnourished individuals [53]; and experimental induction of hyperglycemia on feeding cyanide to rats [30] or hypoinsulinemia and histopathological changes of necrosis, hemorrhage, and fibrosis of the exocrine and endocrine portions of the pancreas in dogs fed on cassava [54].

While the activity of the cyanogen detoxifying enzyme, rhodanase, has been shown to be reduced accompanied by a decrease in sulfur-containing amino acids and antioxidants such as glutathione in TCP patients [55], neither this study [55], nor any of the other case-control or cohort clinical studies [49,56,57] were able to conclusively prove the role of cassava consumption in the causation of TCP. Besides, TCP has been reported even from regions where cassava is not consumed [9,25]. Even in the experimental setting, long-term ingestion of tapioca by rats failed to result in the development of diabetes or pancreatitis [58].

Antioxidants (Including Micronutrients)

It has been hypothesized that escalating oxidative stress within the acinar cells as a result of cytochrome p450 superfamily induction, deficiency of micronutrients required to maintain stores of reduced glutathione, and exposure to bioactivated chemicals [59,60] plays a role in the development of CP.

In TCP patients, the surrogate marker for p450I activity, namely, theophylline clearance was found to be faster in cases as compared to controls [61]. Additionally, the bioavailability of ascorbic acid and beta-carotene that predispose to pancreatic oxidative stress was found to be significantly reduced in South Indians (from Chennai) with TCP as compared to patients with CP from Manchester [35]. Girish and colleagues [62] observed enhanced lipid peroxidation with concomitant decrease in antioxidant status in patients with TCP as compared to healthy subjects. Moreover, in the same study, they noted that zinc deficiency appeared to affect the oxidative status in patients with TCP. The same group also noted a correlation between zinc deficiency and exocrine and endocrine insufficiency in CP patients [63]. They observed a marked effect of diabetes in zinc levels in patients with TCP as compared to those with ACP [63]. Other postulated mechanisms by which zinc deficiency could contribute to the progression of CP include reduction of free radical scavengers, increased collagen deposition, and possibly an alteration in immune function [64].

Genetics of TCP and Familial Clustering

The finding of an aggregation of patients with TCP in certain families [65], reported as occurring in up to 8% of TCP patients [66], raised the possibility of heredity as another potential contributory factor to the development of TCP. However, while there has been no further evidence to support this initial finding, the role played by genetic mutations in important regulators of pancreatic secretion as well as the innate protective mechanisms against premature zymogen activation have been extensively studied in patients with TCP. Table 46.1 provides a list of the most significantly proven mutations involved in the pathogenesis of TCP [34,67–74]. Mahurkar and colleagues [75] presented an interesting model called the "two-hit model" to hypothesize the pathogenesis of TCP. By this model, they believed that the first hit was the presence of persistent "super trypsin" within the acinar cell—the result of a loss of balance between activation events and degradation of active trypsin as a result of mutations in one or more of the aforementioned genes. This would lead to inflammation in the gland. A second hit in the form of another sequence of genetic mutations with/without environmental factors would then lead to the clinical disease entity of TCP.

Natural History of the Disease

In the original reports of TCP, the disease was noted to afflict young individuals between the ages of 10 and 30 years who also demonstrated features of protein and calorie malnutrition, along with bilateral parotid enlargement and occasionally a cyanotic hue to the lips [5,76]. They suffered from recurrent severe upper abdominal pain radiating to the back that was relieved by bending forward. In the ensuing years, it was noted that while some patients developed features of pancreatic exocrine insufficiency such as maldigestion and steatorrhea, others did not do so because of their low-fat diet. They developed diabetes mellitus within 10–20 years from the onset of the initial symptoms of pain [31]. Mohan and colleagues [77] determined that the median time to development of diabetes mellitus in patients with TCP was 9.6 years from diagnosis and this was associated with an older age, higher body mass index, and lower fecal chymotrypsin level. The development of diabetes mellitus in TCP has been hypothesized to result from two mechanisms: the pathogenetic process of tissue fibrosis eliciting CP, and a selective pancreatic beta-cell impairment [78]. TCP is associated with an increased risk of pancreatic cancer development [79]. In a study from Chennai (India), the relative risk of pancreatic cancer in patients with TCP was estimated to be significantly high at 100 (95% CI: 37–218) [80].

In comparison to the initial reports of the dismal clinical course of TCP which resulted in death by early adulthood [22], a survival analysis of 370 patients in the mid-1990s determined that patients with TCP were living much longer than before [81] with 80% of patients still alive 35 years from the onset of the first episode of abdominal pain and a mean of 25 years from the diagnosis of diabetes mellitus. The causes of death in TCP include diabetes-related complications, pancreatic cancer [82], and severe infections [24].

Garg and Narayana [83] have recently questioned the need to consider TCP as a unique entity for multiple reasons, including its similarity to idiopathic CP down to the genetic level, in addition to a significant decline in the clinical picture that helped define this entity by the incorrect use of the term "tropical," which would normally be used for infectious diseases.

Conclusion

In conclusion, the incidence of TCP is on the decline even in developing countries. The disease is witnessing a paradigm shift in relation to a number of aspects including the reduced emphasis on macronutrient, protein calorie malnutrition, and cassava ingestion as etiological factors, in favor of micronutrient deficiency (including zinc) and oxidant stress, an increased appreciation of the role of gene mutations in the pathogenesis of the disease, and finally, significantly improved survival, possibly as a result of better management of the disease and its attendant complications. The mounting evidence calls for a unified, evidence-based approach by the pancreatology fraternity to clarify whether TCP should continue to remain a unique entity, or be included under the broad umbrella of idiopathic CP.

CFTR-Associated Pancreatic Disease

Chee Y. Ooi[1] *and Aliye Uc*[2]

Introduction

There is a spectrum of pancreatic diseases associated with *CFTR* [1,2] mutations, namely classic cystic fibrosis (CF) (pancreatic insufficient or sufficient) and CFTR-associated pancreatitis. The pancreas pathology and damage are dependent on the amount of functional CFTR: the lower the function, the more prominent and earlier the sequelae. In addition, *CFTR* mutations may contribute to the development of acute recurrent pancreatitis (ARP) and chronic pancreatitis (CP).

Pathophysiology—Genotype and Phenotype Correlations

Although more than 2000 *CFTR* mutations have been identified, the functional importance is known only for a small number of mutations. *CFTR* mutations can be classified into six types of defects (class I–VI mutations) [3]: absence of protein synthesis (class I); protein misfolding and premature degradation (class II); disordered regulation (class III); defective chloride (Cl^-) conductance or channel gating (class IV); a reduced number of *CFTR* transcripts due to a promoter or splicing abnormality (class V); and accelerated turnover from the cell surface (class VI) (Fig. 47.1) [4,5]. *CFTR* function is virtually absent with class I–III and VI mutations while class IV and V mutations allow some residual *CFTR* function. Pancreatic involvement correlates well with gene mutations at the *CFTR* locus and thus residual CFTR function, and less by other genetic modifiers or environmental factors [6]. Exocrine pancreatic insufficiency is seen almost exclusively in association with class I–III and VI mutations [5]. The absence of phenylalanine at position 508 (F508del, a class II mutation) constitutes two-thirds of *CFTR* mutations in northern European and North American populations. No other single mutation accounts for more than 5% of *CFTR* mutations worldwide [4]. Patients with at least one mutation belonging to classes IV or V generally present with milder disease, symptoms in late childhood or adulthood and they are pancreatic sufficient.

CFTR is expressed in epithelial cells of various organs including pancreatic ducts, and it functions as an apical membrane anion channel, involved primarily in anion secretion [7,8]. It is generally agreed that the lack of CFTR leads to acidic, dehydrated, and protein-rich secretions [9,10], which then plug the acinar and ductal lumen [11–13] and cause the destruction of the pancreas in CF. Among the various gastrointestinal organs affected by CF, the exocrine pancreas shows the strongest association between genotype and phenotype. In patients with the lowest CFTR function, considerable destruction of the pancreas starts *in utero* and functional loss of the exocrine pancreas develops at birth or in early infancy [14]. A group of patients with CF who have residual pancreatic exocrine function (pancreatic sufficient) are prone to recurrent attacks of pancreatitis and may become pancreatic insufficient over time [15,16]. The development of symptomatic episodes of CFTR-associated pancreatitis is dependent on the intricate balance between impaired ductal flow and alkalinization due to reduced CFTR function and the degree of preserved acinar reserve (Fig. 47.2).

Early studies suggested that *CFTR* mutations contributed to the development of CP alone or if additional risk factors were present [17–20]. Many of these studies were limited by relatively small number of patients, lack of control groups, and incomplete *CFTR* gene sequencing.

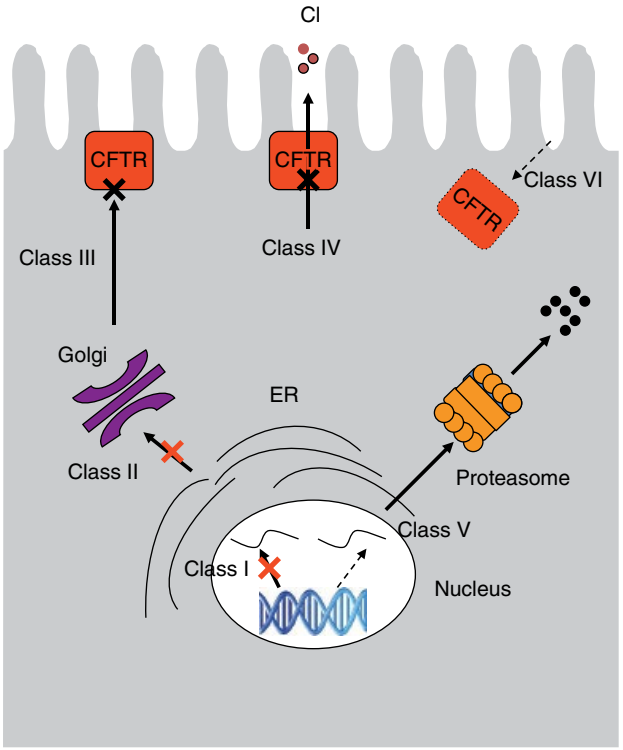

Figure 47.1 Classes of *CFTR* mutations. *CFTR* mutations are grouped into six functional classes. Class I mutations lead to protein synthesis defect, because premature stop codons or frameshifts for deletions or insertions preclude translation of full-length *CFTR*. Class II mutations lead to impaired protein trafficking, because CFTR is unable to complete its folding and ER machinery eliminates the protein. Class III mutants have defective channel gating, CFTR reaches the cell surface, but it is unable to perform channel gating due to diminished ATP binding and hydrolysis. Class IV mutants produce CFTR with reduced function. Class V mutants have reduced protein maturation caused by amino acid substitution or alternative splicing, the amount and therefore the function of CFTR that reaches the cell surface is reduced. Class VI mutants produce unstable protein, since CFTR at the plasma membrane is removed during the recycling and sent for lysosome degradation. CFTR: cystic fibrosis transmembrane conductance regulator; ER: endoplasmic reticulum.

Recent studies with larger German, French, and North American cohorts confirmed these earlier findings that *CFTR* variants play a role in idiopathic chronic pancreatitis [21–23], although the frequency of *CFTR* variants in CP was much lower than previously reported. The recent studies show no increased risk for CP with common polymorphic alleles T5 and TG12; the role of T5-TG12 complex allele remains to be determined [22].

Clinical Manifestations

The clinical manifestations of CFTR-associated pancreatic diseases correlate with the degree of pancreatic injury. Exocrine pancreatic damage in its severe form manifests as exocrine pancreatic insufficiency (EPI), which is present in 60–75% of infants at time of CF diagnosis [24,25]. Pancreatic lesions begin *in utero* and continue into early childhood when complete loss of pancreatic acinar tissue occurs [24]. Fat maldigestion with resultant steatorrhea happen only when pancreatic colipase/lipase secretion falls below 1–2% of normal levels [26], with risk of malnutrition and fat-soluble vitamin deficiencies. A causal relationship between early exocrine pancreatic disease in CF and the development of CF-related diabetes has also been reported [27].

Patients with sufficient pancreatic function who either have CF or CFTR-related disorder, are at risk of developing symptomatic acute and acute recurrent pancreatitis. Recurrent acute and chronic pancreatitis are known complications of CF, and they may occur in ~15–20% of patients with sufficient pancreatic function [28]. It is not known why a subgroup of patients with CF develops pancreatitis, but preservation of acinar cells seems to be a prerequisite for this complication. Recurrent pancreatic inflammation is a risk factor for further loss of residual function and progression to EPI [29].

The clinical landscape in relation to exocrine pancreatic function status and occurrences of symptomatic acute pancreatitis have changed in the era of CFTR modulator therapies. Two open-label, multicenter studies in young children aged 2–5 years [30] and 1–<2 years [31] have demonstrated, for the first time, the plausibility of a window of opportunity to rescue the exocrine pancreas if modulators are commenced early enough. In addition, there have been accumulating published and anecdotal reports of EPI patients presenting with symptomatic acute pancreatitis associated with a rise in fecal elastase levels [32,33]. Consequently, clinicians need to be vigilant of this potential effect. In contrast, among pancreatic sufficient patients with recurrent pancreatitis, there have been reports of resolution or reduction of subsequent attacks following the use of modulators [34,35].

With increasing survival of patients with CF, an increased risk of malignancy in the gastrointestinal and biliary tracts has been observed [36]. The risk of malignancy in the pancreas was reported, in a subanalysis, to be greater than the overall risk of cancer in the digestive tract (odds ratio [95% CI] of 31.5 [4.8–205] vs. 6.4 [2.9–14], respectively).

Despite treatment with pancreatic enzymes that prevent severe malnutrition, exocrine pancreatic involvement impairs growth and accelerates the progression of lung disease [37,38], the major cause of mortality in CF [39]. CF patients develop diabetes mellitus as they age: ~10% of patients have cystic fibrosis-related diabetes mellitus (CFRD) by 10 years of age, and ~50% of CF patients over 30 years of age have CFRD [40,41]. CFRD is associated with a rapid decline in pulmonary

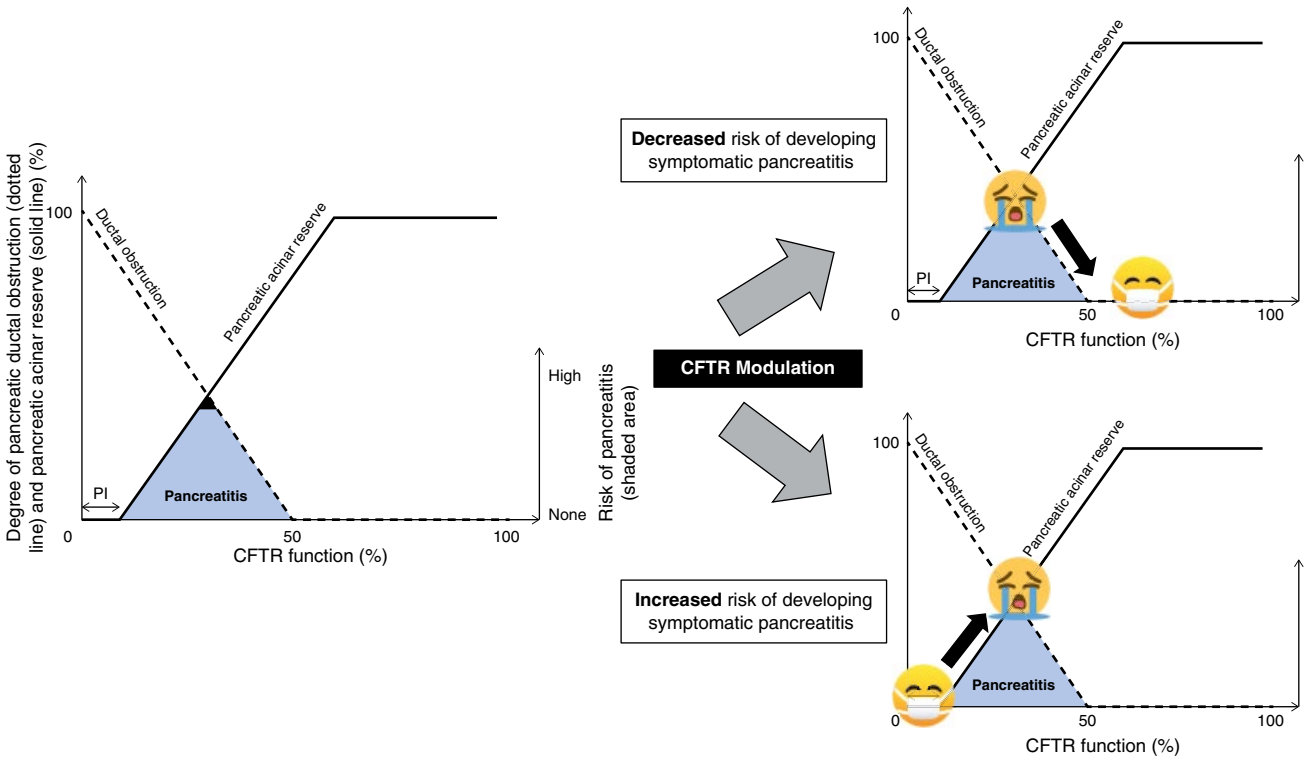

Figure 47.2 Proposed pathogenesis model explaining the effects of CFTR modulation on either reducing or increasing risk of development of symptomatic pancreatitis. The development of symptomatic episodes of CFTR-associated pancreatitis is associated with the opposing factors of severity of ductal obstruction and degree of preserved pancreatic acinar reserve. With CFTR modulation, there is a shift to the right along the x-axis toward greater CFTR function. In pancreatic sufficient individuals who are already experiencing symptomatic pancreatitis, there is reduction in risk of pancreatitis due to improved ductal flow. Among people with pancreatic insufficiency, there is no/minimal risk of pancreatitis despite severe ductal obstruction present due to lack of sufficient acinar tissue. However, with improved CFTR function, there is risk of developing pancreatitis if there is sufficient ductal obstruction in the presence of residual acinar tissue.

function, higher morbidity, and greater mortality [14,42]. The diagnosis of CFRD is preceded by a decline in body weight and lung function, along with insulin deficiency [41,43].

Diagnosis

The rationale for testing for CF is the risk of multiorgan involvement in CF-affected organs and available effective therapies. Several studies have shown that a large proportion of pediatric and adult patients with idiopathic acute recurrent and chronic pancreatitis carry mutations in the *CFTR* gene. In a study of children affected by pancreatitis, *CFTR* mutations were identified in 30 out of 89 (34%) and 24 out of 104 (23%) children with acute recurrent and chronic pancreatitis, respectively [44]. In a separate study of 42 children and adults with idiopathic acute recurrent and chronic pancreatitis, extensive *CFTR* genotyping identified 50% of patients with either one or two *CFTR* variants [45].

Currently, the diagnostic criteria for CF require the presence of characteristic symptom(s) of CF disease or a positive family history, *plus* an abnormal sweat chloride value (≥60 mmol/L) and/or two CF disease-causing mutations [46]. Consensus guidelines [46,47] recommend the diagnostic terminologies of: (i) "*CF disease*," to describe patients who fulfill the currently accepted diagnostic criteria; or (ii) "*CFTR-related disorder*" to describe individuals with the CF phenotype (e.g., pancreatitis), who have evidence of CFTR dysfunction but insufficient to fulfill the diagnostic criteria for CF disease (e.g., borderline sweat test [30–59 mmol/L] and/or one or two non-CF causing mutations).

As the majority of CFTR variants have unclear clinical significance, genotyping is the least sensitive diagnostic test for CF, compared to sweat testing and nasal potential difference (NPD) [20,45]. If performed, genotyping results should be interpreted with experts in CF genetics since nondiagnostic mutations for CF may be identified [48]. In a study comparing the yield of various diagnostic tests for CF, genotyping identified one or two *CFTR* mutations in 21 of 42 (50%) patients with idiopathic acute recurrent or chronic pancreatitis but was unable to establish or exclude the diagnosis of CF in any of them [45]. In contrast, sweat chloride and transepithelial NPD were able to diagnose

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

CF in 5% and 29% of patients respectively [45]. While NPD is a sensitive and reproducible determinant of CFTR function [49], it has limitations. It is complex to perform, time- and labor-intensive, and operator-dependent. Access to NPD is also limited to specialized centers with NPD expertise. False positive results can occur with minor perturbations of the nasal epithelium, allergies, respiratory infections, and smoking.

As such, the sweat test remains the primary diagnostic test for CF [46,48]. Borderline (40–59 mmol/L) or abnormal (≥60 mmol/L) sweat chloride concentrations should lead to a referral to a CF clinic for further diagnostic evaluation, including for *CFTR* genotyping and alternative ion channel measurements (e.g., NPD or intestinal ion channel measurement), and various end-organ testing (e.g., lung function). Disease-specific counseling (e.g., fertility and smoking cessation) and genetic counseling are also important management considerations. Once the diagnosis of CF is made, the next step is to establish the exocrine pancreatic function and determine whether the patient requires pancreatic enzyme replacement therapy (PERT).

Because CF and CP share many pathological characteristics including pancreatic fibrosis, atrophy, and fatty infiltration [50], imaging studies proposed for the assessment of pancreatic involvement in CP may be applicable to CF pancreas. Magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) can assess fibrosis (T1 mapping) [51], pancreas size [52], and ductal fluid secretion in response to secretin [53]. However, there are variations between studies and the ability of imaging studies to differentiate between pancreatic sufficient vs. pancreatic insufficient status in CF remains limited [54]. More data are needed before imaging studies can be used as diagnostic studies of CF pancreatic diseases to assess pancreatic structure and function.

Therapy

For patients with advanced pancreatic damage and EPI, the only treatment available currently is PERT [8]. Children <4 years of age require 1000 lipase units/kg per meal; 500 lipase units/kg per meal are used for those >4 years of age and 25,000–40,000 units/meal are used for adults [55]. For snacks half the dose is recommended. Infants may be given 2000–4000 units per 120 mL of infant formula or per breast feeding. The daily dose for most patients is less than 10,000 units of lipase/kg per day or 6000 units of lipase/kg per meal to prevent fibrosing colonopathy [56]. Aggressive nutritional management, fat-soluble vitamin supplementation is mandatory for all patients with EPI. Insulin is the treatment of choice for CFRD [57].

The ideal therapeutic strategy in CF should be repairing the underlying CFTR defect. Recent studies using CFTR modulators suggest that early initiation of ivacaftor may improve pancreatic function in infants and young children with gating mutations. In the ARRIVAL study, improvement in exocrine pancreatic function was observed in 4–24-month-old subjects after 24-week use of ivacaftor [31,58]. Similar improvements were observed in older children 2–5 years old by the use of ivacaftor for 24 weeks (KIWI study) [30] and results were sustained at week 84 (KLIMB study) [59]. These results were similar to the work done in the G551D CF ferret model, which showed protection from pancreatic disease if treated with ivacaftor *in utero*, but pancreatic destruction if withdrawn postnatally [60].

People with CF experiencing recurrent pancreatitis have observed a significant reduction in the number of attacks while on ivacaftor [34,35,61], suggesting that improving CFTR function can ameliorate pancreatitis. There are rare reports of pancreas transplantation reported in people with CFRD, which not only corrects the diabetes, but also eliminates the need for pancreatic enzyme use. Pancreas transplants are typically coordinated with other organ transplants (mostly liver), but combined liver, lung, and pancreas transplants have also been reported [62,63].

Future studies will examine the effects of highly effective CFTR modulators on the pancreas at various ages. Gene therapy remains an area of active research, targeting primarily lungs, as challenges exist to access the pancreas [64,65]. A minimally invasive method was successfully used to deliver gene therapy vectors to the newborn porcine pancreatic ducts [66], but there are no similar studies yet in humans.

Alcohol and Smoking in Chronic Pancreatitis

Atsushi Masamune, Kazuhiro Kikuta, and Kiyoshi Kume

Division of Gastroenterology, Tohoku University Graduate School of Medicine, Miyagi, Japan

Introduction

Chronic pancreatitis (CP) develops resulting from interactions of multiple environmental, metabolic, and genetic risk factors [1]. Alcohol is the leading cause for CP in many Western countries, and the association between alcohol misuse and CP has been recognized for a long time. As early as 1878, Friedreich [2] described "drunkard's pancreas": chronic interstitial inflammation in the pancreas which might result from alcohol misuse. In 1946, Comfort et al. [3] described the clinical presentation of chronic relapsing pancreatitis in subjects with alcohol misuse. Thereafter, it has been established that alcohol misuse is an important risk factor for CP. Of note, unlike the alcohol-induced liver injury, only 1–5 % of heavy drinkers develop pancreatitis [4], indicating that alcohol-related pancreatitis is not caused by alcohol misuse alone. Some individuals may develop alcohol-related pancreatitis with alcohol intake as low as 20 g/day, whereas most individuals do not develop pancreatitis no matter how much they drink or how long. In animals, ethanol feeding alone does not cause a pronounced pancreatic injury. Therefore, additional genetic and/or environmental predisposing factors are required for the development of clinical CP.

Conversely, the independent effects and risks associated with smoking have not been well recognized until recently. Because smoking is strongly associated with drinking alcohol [5,6], the independent effect of smoking can be difficult to assess. Smoking is now recognized to confer a strong, independent and dose-dependent risk of CP [5–7]. Importantly, smoking and alcohol interact and worsen acinar cell injury and pancreatitis synergistically [5,6]. In this chapter, we review the clinical observations and pathophysiology of alcohol-related and smoking-related CP.

Alcohol and Chronic Pancreatitis

Clinical Observations

Historically, alcohol misuse is the leading cause of CP and accounts for approximately 60–90% of CP cases in industrialized nations worldwide [6]. However, in recent years, the proportion of alcohol-related CP (ACP) cases might be smaller than expected. The North American Pancreatitis Study 2 (NAPS2) showed that the frequency of ACP at tertiary referral centers in the United States was 44.5% [6]. A report from Italy showed a shift in the etiologic profile of CP [8]. Alcohol misuse was the leading cause of CP (74%) between 1971 and 1995, but the proportion was decreased to 43% in patients evaluated between 2000 and 2006. These findings suggest that the contribution of alcohol misuse to the pathogenesis of CP might have been overestimated [6]. Referral bias might exist in tertiary referral centers and accurate assessment of alcohol exposure to determine the association with CP is challenging because self-reports about alcohol consumption are usually unreliable. Conversely, in Asia, ACP accounted for 72% of all CP cases in Japan in 2016 [9]. In India and China, the proportion of ACP was lower and idiopathic pancreatitis was the most common type, accounting for approximately 70% of the CP cases [10]. Importantly, alcohol consumption has been stable or decreasing in many North American and European countries as well as in Japan, whereas it has been increasing in India and China [10]. It would be of interest to see whether the trends in alcohol consumption affect the burden of ACP in India and China in the future.

There have been many studies that aimed to clarify the dose–response relationship between alcohol consumption and CP. The association between alcohol

consumption and pancreatitis was evaluated in 540 cases and 695 controls in the NAPS2 [5]. Logistic regression analyses revealed a significant association between alcohol and CP only in very heavy drinkers who consumed ≥5 alcoholic drinks per day (odds ratio [OR] = 3.1). In another case-control study [11], among patients with onset of CP after the age of 35, alcohol intake, even less than 50 g/day, induced earlier disease characterized by more frequent severe pain, calcification, and complications such as pseudocysts. In a Japanese case-control study [12], compared with nondrinkers, the OR (95% confidence interval [CI]) for alcohol consumption of 20≤~<40 g/day, 40≤~<60 g/day, 60≤~<80 g/day, 80≤~<100 g/day, and ≥100 g/day were 2.6 (1.2–5.5), 3.2 (1.5–7.1), 9.2 (4.1–20.3), 13.0 (5.3–31.6), and 19.6 (8.2–46.8), respectively. A systematic review and meta-analysis of four studies (three case-control and one cohort studies) showed that the risk of CP increased monotonically according to the average alcohol consumption with no identifiable threshold in men [13]. The relative risks (RR) (95% CI) were 1.58 (1.32–1.90) at 25 g/day; 2.51 (1.74–3.61) at 50 g/day; 3.97 (2.30–6.85) at 75 g/day; and 6.29 (3.04–13.02) at 100 g/day.

It is well known that ACP is predominantly a disease of men [5,9]. However, alcohol misuse is an important health problem in women, too. It has been shown that susceptible women might develop ACP with shorter duration and lower cumulative amounts of alcohol consumption than men [14].

Ethanol Metabolism in the Pancreas

Ethanol can be metabolized in the pancreas, mainly in pancreatic acinar cells. Two pathways of ethanol metabolism have been described in pancreatic acinar cells: oxidative and nonoxidative pathways [15]. Ethanol oxidation involves the conversion of ethanol to acetaldehyde and acetate, a reaction catalyzed by ADH and cytochrome P450 2E1. The nonoxidative pathway of ethanol metabolism involves the esterification of ethanol with fatty acids to form fatty acid ethyl esters (FAEE) such as palmitic acid ethyl ester. This reaction is catalyzed by FAEE synthases. FAEE synthase activity in the pancreas is much greater than that in the liver, whereas pancreatic ADH and cytochrome P450 2E1 activities are low [15]. Therefore, the dominant nonoxidative metabolism is a characteristic feature of ethanol metabolism in the pancreas.

Pathophysiology

Several pathophysiological mechanisms linking alcohol consumption and pancreatitis have been suggested. At the cellular level, ethanol and its metabolites affect the cell functions and homeostasis of pancreatic cells including acinar cells, ductal cells, and stellate cells (Table 48.1) [16,17 and references therein]. Importantly, animal studies have suggested that ethanol alone does not induce pancreatitis unless additional pathogenic insults are present. One explanation would be that the pancreas can compensate harmful effects of alcohol through an adaptive stress response. Pancreatitis develops only when the compensatory mechanisms are disrupted/exhausted or if increased vulnerability due to other genetic and environmental cofactors are present. Findings in animal studies support the concept that alcohol misuse alone does not cause CP and additional cofactors are required for the development of CP in susceptible humans.

Table 48.1 Effects of ethanol on pancreatic cells [16,17].

1. induces mitochondrial damage
2. elevates intracellular calcium levels
3. disrupts expression and function of the CFTR
4. decreases bicarbonate secretion
5. increases pancreatic digestive enzyme content
6. redirects exocytosis to the basolateral surface
7. enhances pancreatitis responses elicited by hyperstimulation
8. induces endoplasmic reticulum stress
9. promotes oxidative stress
10. increases the fragility of lysosomes and zymogen granules
11. regulates transcription factors NF-κB and AP-1
12. activates stellate cells to promote fibrosis

CFTR: cystic fibrosis transmembrane conductance regulator; NF-κB: nuclear factor-κB; AP-1: activator protein-1.

Pancreatic Acinar Cells

Ethanol induces a sustained elevation of the intracellular calcium levels, which is central in promoting pathological events of pancreatitis. FAEE cause pancreatic calcium toxicity via inositol trisphosphate receptors and loss of adenosine triphosphate production [18]. Calcium overload reduces adenosine triphosphate production and subsequently causes dysfunction of endoplasmic reticulum (ER). Ethanol increases the fragility of zymogen granules and lysosomes, which sequester lysosomal enzymes such as cathepsin B within the cells. Oxidative alcohol metabolism induces mitochondrial dysfunction, which might play a role in ethanol-induced necrosis of the pancreatic acinar cells [19]. Mitochondrial dysfunction occurs due to membrane permeabilization mediated by persistent opening of the mitochondrial permeability transition pore, leading to loss of mitochondrial membrane potential and mitochondrial fragmentation.

These changes might make the pancreas susceptible to necrotizing pancreatitis.

Chronic ethanol feeding in mice perturbs protein folding and induces ER stress, which in turn induces an unfolded protein response (UPR) involving the upregulation of spliced X box-binding protein 1 (sXBP1) in pancreatic acinar cells [20]. Ethanol administration to mice heterozygous for XBp1 ($XBP1^{+/-}$) resulted in dilated ER, loss of zymogen granules, accumulation of autophagic vacuoles, and acinar cells death, suggesting that these responses serve as a protective adaptive mechanism that prevents ethanol-induced damage.

Autophagy is impaired in pancreatitis and lysosome dysfunction might be involved. Autophagy comprises several intracellular pathways of lysosome-mediated degradation and recycling of organelles, long-lived proteins and lipids [21]. Fortunato et al. [22] reported that the combination of ethanol exposure and endotoxemia resulted in the depletion of several lysosomal proteins including lysosomal-associated membrane protein-2 (LAMP-2), a protein required for the proper fusion of autophagosomes with lysosomes. Cathepsin B-induced LAMP degradation and genetic LAMP-2 deletion caused pancreatitis through impaired autophagy in mice [23]. Human patients with alcoholic pancreatitis also exhibited local LAMP-2 depletion, indicating the crucial roles of LAMP-2 and autophagy in acinar cell death in humans.

Although numerous *in vitro* and *ex vivo* studies have shown the actions of ethanol and its metabolites on pancreatic cells, *in vivo* studies have shown that feeding ethanol to rats and mice even for a long time, with either liquid diet or continuous intragastric infusion, did not cause a prominent injury to the pancreas. Chronic ethanol feeding by the Lieber-DeCarli pair-feeding model [24] induces a number of metabolic changes in the acinar cells including an increase in the content of digestive enzymes and lysosomal enzyme and fragility of the zymogen granules and lysosomes. However, chronic pathological changes resembling CP will not develop. Conversely, chronic ethanol exposure sensitizes the pancreas to other insults. Pancreatitis developed in rats that had received an ethanol-containing diet in response to low doses of cholecystokinin octapeptide or its analogue caerulein, which do not cause pancreatitis by themselves [25]. The sensitization was accompanied by increased activation of nuclear factor-κB (NF-κB) and the upregulation of proinflammatory cytokines and chemokines in the pancreas [26]. Ethanol might regulate NF-κB and activator protein (AP)-1: the key transcription factors regulating the gene expression of inflammatory responses and cell survival. FAEE activate NF-κB and AP-1, whereas ethanol and acetaldehyde inhibit NF-κB activation [26]. Thus, ethanol may regulate the activation of NF-κB and AP-1 positively or negatively, depending on the predominance of which metabolic pathway's effects. These effects may play a role in the ethanol-induced toxicity in the pancreas. Of note, ethanol and its metabolites altered the cholecystokinin 8-induced activation of these transcription factors, which might be a mechanism by which ethanol sensitizes pancreatic acinar cells to pancreatitis.

Gukovsky et al. [27] reported that ethanol dramatically aggravated the pathological effects of the combination of cyclosporine A and caerulein. In ethanol-fed, but not control diet-fed, animals, the combined treatment of cyclosporine A and caerulein resulted in severe pancreatic injury that displayed three key responses of human ACP: loss of parenchyma, sustained inflammation, and fibrosis. Conversely, for the repair of the exocrine pancreas, acinar cells could act as progenitor cells; mature acinar cells undergo dedifferentiation and redifferentiation back to the differentiated phenotype [28]. Clemens et al. [29] reported that chronic ethanol administration delayed the structural and functional regeneration of the pancreas in mice. The delayed regeneration was associated with the decreased expression of pancreatic developmental factors including PDX-1. These findings suggest that ethanol might impair the recovery from acute pancreatic injury, thus facilitating the progression from acute pancreatic injury to CP.

Pancreatic Ductal Cells

Alcohol increases viscosity and precipitation of pancreatic juice and formation of protein plugs inside pancreatic ducts. Protein plugs lead to formation of calculi which damage ductal epithelium and cause obstruction of pancreatic ducts [30]. Several studies have highlighted the role of the pancreatic duct in the pathogenesis of alcohol-induced pancreatitis. Ethanol reduced the expression of cystic fibrosis transmembrane conductance regulator (CFTR), disrupted the folding of CFTR at the ER, and inhibited CFTR function in pancreatic ductal cells, all contributing to the increased viscosity of the pancreatic juice and small duct obstruction [31]. *CFTR* knockout mice given ethanol or fatty acids developed more severe pancreatitis than mice not given ethanol or fatty acids.

Pancreatic Stellate Cells

PSC play a pivotal role in pancreatic fibrosis in CP. Ethanol and its metabolites induced the activation, extracellular matrix production, and chemokine expression in PSC, leading to the perpetuated activation of PSC and pancreatic fibrosis [32]. A combination of short-term administration of caerulein and long-term intraperito-

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

neal administration of ethanol led to the activation of PSC and fibro-inflammatory responses in the pancreas [33]. Chronic ethanol consumption accelerated pancreatic fibrosis in response to caerulein-induced pancreatitis in rats [34].

Animal studies have suggested that endotoxin in the microbiota might also be involved. Gut permeability is increased in alcoholics, allowing translocation of gram-negative bacteria across the mucosal barrier and allowing bacterial endotoxins to enter the circulation. A combination of Lieber-DeCarli ethanol-enriched diet and repeated injection of lipopolysaccharide (LPS) developed acute acinar cell injury, activation of PSC and fibrosis [35]. Repeated LPS injection caused pancreatic fibrosis in ethanol-fed rats, but not in rats fed the control diet. When ethanol administration was continued, the activation of PSC and fibrosis persisted, but resolved soon after ethanol was discontinued [36]. Conversely, continued alcohol intake perpetuates pancreatic injury by inhibiting apoptosis and promoting the activation of PSC. These findings indicate the importance of abstinence to prevent the progression of acute pancreatitis to CP.

Genetic Factors Predisposing for the Development of ACP

Recent studies have identified several risk loci in ACP. The serine protease inhibitor Kazal type 1 (SPINK1), also known as pancreatic secretory trypsin inhibitor, acts as the first line of defense against prematurely activated intracellular trypsinogen by inhibiting up to 20% of trypsin activity within the pancreas. A meta-analysis of 12 studies showed the association of the *SPINK1* c.101A>G (p.N34S) variant with ACP (OR = 5.28, 95% CI: 3.45–8.09) in a Caucasian population, which was smaller than that in idiopathic CP (OR = 13.64, 95% CI: 8.86–21.00) [37]. The loss-of-function *SPINK1* c.194+2T>C (IVS3+2T>C) variant is commonly found in CP patients in east Asia. The *SPINK1* c.194+2T>C variant is overrepresented in patients with ACP (OR = 30.59, 95% CI: 16.61–56.34) [38]. The association of the variants in the chymotrypsinogen C gene (*CTRC*) with ACP has been shown. LaRusch et al. [39] reported that the synonymous *CTRC* variant c.180C>T (p.G60=) was overrepresented in CP of all etiologies, but not in recurrent acute pancreatitis as compared with controls (16.8% in CP, 11.9% in recurrent acute pancreatitis, 10.8% in controls). The *CTRC* c.180T allele was overrepresented in ACP patients (20.8%) compared to NACP patients (12.4%) (OR = 1.9, 95% CI: 1.30–2.79). A meta-analysis of four studies showed that the *CTRC* c.180T allele was overrepresented in CP (OR = 1.99, 95% CI: 1.49–2.67) [40].

A genome-wide or exome-wide approach overcomes the limitations of a candidate gene approach, enabling the discovery of new and unsuspected pancreatitis susceptibility genes. A genome-wide study from North America identified the association of common variants in the *CLDN2-MORC4* (rs7057398 and rs12688220) and *PRSS1-PRSS2* loci (rs10273639) conferred an increased risk of ACP, but not with alcohol-associated cirrhosis or alcohol dependence [41]. A meta-analysis of five studies from worldwide countries has confirmed the association of *PRSS1* rs10273639 with ACP (pooled OR = 1.67, 95% CI: 1.56–1.78) [42]. Functional studies indicated that the rs10273639 or rs4726576, which is in perfect linkage disequilibrium with rs10273639, altered the intrapancreatic trypsinogen levels [43]. Importantly, although the degree of association varies, most of the variants associated with ACP have associations with NACP, suggesting common mechanisms for alcohol-related and non-ACP. Another genome-wide study from Europe replicated previously reported risk loci *CLDN2-MORC4*, *CTRC* (c.180C>T, p.G60=), *PRSS1-PRSS2*, and *SPINK1* (c.101A>G, p.N34S) in ACP patients [44]. In addition, this study identified *CTRB1-CTRB2* (chymotrypsin B1 and B2) as a new risk locus for ACP and NACP. The association within the *CTRB1-CTRB2* locus was linked to a 16.6 kb inversion that altered CTRB1/CTRB2 expression, thereby affecting protective trypsinogen degradation. Importantly, the association of the previously reported and new risk loci was observed when compared with chronic alcoholics, suggesting that these loci are associated with the pancreas-specific injury among alcoholics.

Smoking and Chronic Pancreatitis

Recent clinical studies have shown that smoking is another important risk factor for CP, and the underlying mechanisms linking smoking and CP are being elucidated. Importantly, ethanol and smoking synergically affect the development and course of CP.

Clinical Observations

There is accumulating clinical evidence that smoking is a dose-dependent risk factor, independent of alcohol, for CP. Smoking is a risk factor for the progression from AP to recurrent AP and CP [45]. Compared to the never smoker or former smoker, current smoker had a risk of recurrent AP (OR = 2.77, 95% CI: 1.69–4.53) and CP (OR = 3.62, 95% CI: 1.98–6.60). There have been several meta-analyses that assessed the risk of CP among smokers. A meta-analysis of 12 studies showed that, compared to lifetime nonsmokers, pooled risk estimates (95% CI)

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for current smokers were 2.8 (1.8–4.2) overall and 2.5 (1.3–4.6) [46]. The risk diminished significantly after smoking cessation, as the RR estimate for former smokers dropped to a value of 1.4 (1.1–1.9). A recent systematic review and meta-analysis of 22 studies revealed the summary relative risks (RR) (95% CI) for CP compared to never smokers were 3.00 (1.46–6.17) in ever, 2.72 (1.74–4.24) in current, and 1.27 (1.00–1.62) in former smokers [47]. Another meta-analysis of 10 prospective studies revealed that RR (95% CI) for CP were 1.93 (1.60–2.32) in current smokers, 1.30 (1.08–1.57) in former smokers, and 1.59 (1.39–1.82) in ever smokers compared to never smokers [48]. Dose–response analysis revealed that the summary RR per 10 pack-years was 1.22 (1.11–1.33) for CP.

Smoking accelerates the progression of CP. Smoking is independently associated with earlier onset, recurrence, appearance of calcifications, and diabetes mellitus [49]. Smoking was associated with approximately 5-year-earlier diagnosis of ACP, and with the appearance of pancreatic calcifications (hazard ratio [HR] = 4.9, 95% CI: 2.3–10.5) and diabetes (HR = 2.3, 95% CI: 1.2–4.2), independent of alcohol consumption [50]. The lower risks for CP development and progression in former smoker than those in current smoker suggest that smoking cessation decreases the risk and progression of CP. Smoking cessation would be an important strategy for primary as well as secondary prevention of pancreatitis. In addition to alcohol, physicians should routinely counsel patients for the benefits of smoking cessation. Widespread recognition of the association between smoking and CP could potentially curtail smoking rates in subjects with CP and those at risk of CP [51].

Pathophysiology

Among the more than 4000 compounds in cigarette smoke, effects of cigarette smoke, nicotine, and the tobacco-specific most abundant nitrosamine known as nicotine-derived nitrosamine ketone (NNK) have been studied alone or in combination with ethanol with regard to pancreatic diseases [52]. Major cellular components of the pancreas including pancreatic acinar cells, ductal cells, and PSC express nicotinic acetylcholine receptors, which bind to nicotine and NNK, suggesting that cigarette smoke and its major components directly affect pancreatic cells.

Cigarette smoke and its components affect cell functions and homeostasis in pancreatic cells [7, 52 and references therein] (Table 48.2). Cigarette smoke reduced pancreatic bicarbonate secretion in part by disrupting CFTR. NNK caused premature activation of trypsinogen and chymotrypsinogen in isolated pancreatic acinar cells. Nicotine activates multiple signal transduction pathways resulting in high levels of intracellular calcium release and cell injury. Clinically relevant concentrations of cigarette smoke component NKK could activate PSC, suggesting a potential mechanism for smoking-induced CP progression [53].

Table 48.2 Effects of cigarette smoke and its components on pancreatic cells [7,52].

1. induces mitochondrial damage
2. elevates intracellular calcium levels
3. disrupts expression and function of the CFTR in ductal cells
4. decreases fluid and bicarbonate secretion
5. induces endoplasmic reticulum stress
6. promotes oxidative stress
7. activates pancreatic stellate cells to promote fibrosis

CFTR: cystic fibrosis transmembrane conductance regulator.

In animal studies, rats exposed to high-dose cigarette smoke for up to 12 weeks developed a chronic inflammation resulting in pancreatic fibrosis and scarring of pancreatic acinar cell structure [54]. The ratio of trypsinogen to its endogenous trypsin inhibitor was elevated after chronic cigarette smoke exposure for 3 months, suggesting an increased vulnerability to self-digestion of the pancreas [55]. Exposure to nicotine caused the production of reactive oxygen species in pancreatic acinar cells [56]. Both nicotine and NNK have been shown to induce morphological changes in the pancreas consistent with those seen in pancreatitis. Furthermore, nicotine affects pancreatic secretion and NNK induces premature zymogen activation, two well-known features of pancreatitis. These cigarette toxins may mediate both pro- and anti-inflammatory pathways and can induce changes in pancreatic acinar cell function at the level of transcription, leading to conditions such as thiamin deficiency and mitochondrial dysfunction. Such circumstances could leave the pancreas prone to the development of pancreatitis.

Cigarette smoke might contribute to CP development through the modulation of immune cells. Xue et al. reported a role of aryl hydrocarbon receptor agonists, such as dioxin and benzo[a]pyrene, in smoking-associated CP [57]. Aryl hydrocarbon receptor ligands in cigarette smoke induces IL-22 production in $CD4^+$ T cells through aryl hydrocarbon receptors during the pancreatic damage. IL-22 interacts with IL-22 receptor on PSC and upregulates production of extracellular matrix, leading to the development of pancreatic fibrosis. The role of IL-22 was further supported by the higher serum IL-22 levels in current smokers with CP. AhR ligands did not induce fibrosis in the absence of

caerulein, suggesting that AhR activation by cigarette smoke alone is not sufficient, and additional pancreatic insults are required to induce CP.

Because most drinkers smoke, it is interesting to see the interaction between alcohol and smoking in CP. Lugea et al. [58] reported that smoking disrupts the protective adaptive mechanism that prevents ethanol-induced damage. Cigarette smoke extracts reduced spliced XBP1 levels, and increased ethanol-induced oxidative and ER stresses, leading to cell death in pancreatic acinar cells. These might be mechanisms by which alcohol and smoking interact and worsen acinar cell injury and pancreatitis.

In summary, cigarette smoke and its components affect cell functions and homeostasis in a similar manner to ethanol and its metabolites. As in the case of ethanol, cigarette smoke or its components alone did not induce CP and additional insults are required for CP. Mechanisms of synergy between alcohol and cigarette smoke have been identified. Because only a small portion of smokers develop pancreatitis, it is reasonable to assume that there might exist some genetic background of smoking-associated CP. Further studies are warranted to clarify this issue.

Idiopathic and Rare Causes of Chronic Pancreatitis

Morihisa Hirota[1] *and Tooru Shimosegawa*[2]

[1] *Division of Gastroenterology, Tohoku Medical and Pharmaceutical University, Sendai, Miyagi, Japan*
[2] *South Miyagi Medical Center, Shibata County, Miyagi, Japan*

Introduction

Chronic pancreatitis (CP) is now recognized as a heterogeneous inflammatory disease that can develop in individuals with multiple risk factors, including environmental and genetic factors [1,2]. Many risk factors have been described in the TIGAR-O and M-ANNHEIM classifications, which include alcoholic, smoking, genetic, autoimmune, obstructive, nutritional, and rare metabolic factors [3,4]. However, recent international consensus guidelines strongly agree that alcohol, smoking, and certain genetic alterations are risk factors for CP [5].

Idiopathic CP (ICP) is identified after ruling out other potential causes, including rare ones [2,6]. It has been proposed that ICP can be further classified into three types, primarily based on clinical features: early-onset ICP (EO-ICP), late-onset ICP (LO-ICP), and tropical pancreatitis (TP) [3]. This chapter mainly focuses on the clinical features of ICP, including EO-ICP and LO-ICP described in recent reports. Moreover, we discuss the background risk factors for ICP, which include environmental risk factors, such as smoking and consuming small amounts of alcohol, and genetic risk factors (7–11]. In addition, rare causes of CP are also described.

Idiopathic Chronic Pancreatitis

Definition

To date, heavy alcohol drinkers (usually 50–80 g or more per day) with CP have been defined as having alcoholic CP (ACP). In others, CP has been defined as ICP after excluding all known rare causes such as obstructive, hereditary, and autoimmune diseases. Therefore, patients with ICP may include moderate or social drinkers [6]. Originally, ICP in patients with absolute abstinence from alcohol has been classified as EO-ICP or LO-ICP [12,13]. Thus, it is necessary to strictly distinguish between two categories of ICP, one that excludes all drinkers and one that includes people who drink small amounts of alcohol (light drinkers).

Classification

Early-Onset and Late-Onset

Patients with ICP who abstain from alcohol and were diagnosed at the Mayo Clinic had a bimodal age distribution. Their ICP has been classified into two types: EO-ICP or LO-ICP [6,12]. Age 35 is used as a cutoff for distinguishing between these two types of ICP [12]. A bimodal age distribution among patients with ICP has also been reported in Italy and among patients of European ancestry in the United States [13,14]. Although the peaks occurred at higher ages in a report from Japan, ICP showed a bimodal age distribution [15]. However, a bimodal distribution was not found in Chinese patients with ICP [16]. Since the latter two reports included light drinkers with ICP, light alcohol consumption might have affected the distribution of onset age [9,13]. Smoking and racial differences are other potential factors that should be studied in the future [6,17].

Tropical Pancreatitis

TP is a type of ICP seen in tropical countries. It is characterized by large pancreatic calculi and ductal dilatation in a young malnourished patient who presents with abdominal pain, diabetes, or both [18]. It has been reported in many parts of tropical Asia and Africa, but mostly in India, especially in the states of Kerala and Tamil Nadu [19]. Although malnutrition and cassava

intake were previously thought to be causally associated with TP, they are no longer implicated as causative factors [17].

Prevalence

Table 49.1 shows the etiologies of CP from recently published epidemiologic analyses in population-based, multicenter, or nationwide cross-sectional studies [20–28]. In most studies, alcoholic was the most common etiology of CP, accounting for 33.6% to 72.0% of cases. The proportion of ICP cases was between 12.9% and 28.6% in the presented studies except for a nationwide study from India. The study showed the most common etiology was idiopathic, accounting for 60.2% of cases [25]. ICP was prominent in India. This finding was confirmed by three observational studies from single-centers in both northern and southern India [29–31].

Table 49.1 Etiology of CP in epidemiologic studies.

Tropical Pancreatitis

It has been reported that the prevalence of TP has significantly decreased. Previously, it was reported that TP accounted for more than 50% of CP cases in India [18]. However, a nationwide study conducted from 2005 to 2007 in India demonstrated TP made up only 3.8% of CP cases [25]. This finding was supported by a single-center observational study that demonstrated the proportion of typical TP was 5.8% [30]. Malnutrition, a typical feature of TP, has been rarely observed among patients with ICP in India. The prevalence of diabetes has decreased from 90% to 50% of ICP cases [17,30]. Furthermore, it has been pointed out that the number of drinkers is increasing due to lifestyle changes. The prevalence of ACP has been increasing in India [25]. The spectrum of clinical features in ICP has been changing in India and possibly other places.

Clinical Characteristics

Idiopathic vs. Alcoholic

ACP is generally recognized to cause severe symptoms [32]. To clarify the clinical characteristics of patients with ICP, seven reports comparing ICP and ACP from the United States, East Asia, and India were reviewed (Table 49.2). In these studies, ICP included light drinkers. Since the three studies were single-center observational studies, selection bias was possible [29,30,33]. The background of patients might be different between multicenter studies at specialty hospitals [23,24] and nationwide cross-sectional surveys [15,28] that included general hospitals because young symptomatic patients are expected to concentrate in specialty hospitals. The two studies from Japan are nationwide surveys conducted in different years [15,28]. Therefore, many of the participants in these studies might be duplicated.

Taking these potential biases into account, some characteristic features were demonstrated. First, compared to ACP, which has a male predominance, the proportion of male patients with ICP was relatively low. The majority of patients with ACP were smokers. Second, there were likely regional differences in the age of patients with ICP. In the United States and East Asia, age at onset was in the 40s and 50s, and age at the time of the study was approximately in the 40s to 60s. In India, age at onset was in the 20s and age at time of the study was approximately in the 20s and 30s. Patients with ICP in India were shown to be approximately 20 years younger than those in other countries. Conversely, patients with ICP in Japan were 10 years older than those in other East Asia countries and the United States. Third, in the United States and East Asia, patients with ACP tended to have a higher incidence of calcification and diabetes than patients with ICP. However, patients with ICP in India had more calcification than those with ACP. There were no significant differences between the proportion of patients with ICP and patients with ACP who have diabetes in India. Finally, a higher proportion of patients with ACP had pseudocyst formation. This finding was seen in almost all reports.

In summary, patients with ACP were predominantly male and smokers in all countries. They tended to have more severe clinical features than patients with ICP. Compared with ACP, a higher proportion of patients with ICP are women. In the United States and East Asia, patients with ICP are as old as or slightly older than patients with ACP, except for patients in India, who developed ICP at a very young age. However, patients with ICP in India tended to have a high rate of pancreatic calcification and diabetes as complications, even though they were very young.

Early-Onset and Late-Onset

Comparisons of clinical features between EO-ICP and LO-ICP were reported in five papers, two from the United States and three from India (Table 49.3). Layer et al. reported the results of a single-center observational study from the Mayo Clinic [12]. Lewis et al. reported a multicenter study with 26 participating institutions in the United States [13]. These studies defined patients with ICP as strictly abstinent from alcohol, which excluded even social and light drinkers. The latter study only included patients of European ancestry. Conversely, three studies from India, which were all single-center observational studies, did not define patients with ICP as strictly abstinent from alcohol [29–31].

According to Table 49.3, which shows a comparison of clinical features between EO- and LO-ICP, regional

Table 49.3 Comparison of clinical features between EO-ICP and LO-ICP.

differences between the United States and India are remarkable. First of all, the patient composition was different. More patients in the United States had LO-ICP while more patients in India had EO-ICP. Compared with EO-ICP patients in the United States, EO-ICP patients in India were predominantly male. Age at EO-ICP onset was approximately 20 years in both the United States and India. Patients with EO-ICP in the two countries had generally similar clinical features with predominantly complaints of pain and similar complication rates to LO-ICP even though they were younger. Second, the clinical characteristics of patients with LO-ICP were different between the two countries. The age at LO-ICP onset was in the late 50s in the reports from the United States, while it was approximately 40 years in the reports from India. In the US studies, significantly fewer patients with LO-ICP complained of pain compared to patients with EO-ICP. Conversely, most patients with LO-ICP in India complained of pain. Patients with LO-ICP in India had similar rates of pancreatic calcification and diabetes as patients in the United States, even though they were on average more than 10 years younger. Finally, in particular, patients with LO-ICP in southern India had high rates of pancreatic calcification, diabetes, and exocrine insufficiency [31]. In this report, although patients with EO-ICP were very young, almost all of them had pancreatic calcification [31]. One reason for these differences might be explained by differences in patient background such as a small amount of alcohol intake and smoking, but further research including genetic analysis would be required.

Background Risk Factors

Smoking

Cigarette smoking has been identified as an independent risk factor for the development of CP [7,8]. Smoking facilitates the development of pancreatic calcification and diabetes in patients with CP [15,34]. As shown in Table 49.2, the association between ACP and smoking is strong. The combination of alcohol abuse and smoking produces a higher cumulative risk for CP [35]. An association between ICP and smoking has also been reported. Among patients in Italy, smoking increased the risk of pancreatic calcification and heavy smoking (>20 cigarettes per day) was associated with diabetes [36]. A report from the Mayo Clinic showed that smoking increases the risk of pancreatic calcification in LO-ICP but not in EO-ICP. However, smoking did not affect development of exocrine or endocrine insufficiency [37]. In patients with EO-ICP in southern India, smoking was an independent significant risk factor for diabetes according to a multivariate analysis [31].

Small Amount of Alcohol Intake

As mentioned above, in general ICP includes patients who drink small amounts of alcohol (<50 g per day). Lankisch et al. reported the effect of a small amount of alcohol intake on the clinical course of ICP. Patients with LO-ICP drinking less than 50 g of alcohol per day were younger at disease onset and reported more frequent and severe pain than patients with LO-ICP who did not drink any alcohol [9]. A systematic review and meta-analysis demonstrated a linear dose–response relationship between alcohol consumption and development of CP, which was monotonically increasing with no identifiable threshold [10]. This indicates that even intake of a small amount of alcohol is a risk factor for CP.

Genetic Factors

Associations have been identified between several gene variants and ICP risk. In idiopathic disease, full sequence analysis of the following genes has been recommended in international consensus guidelines: cationic trypsinogen (*PRSS1*), carboxypeptidese A1 (*CPA1*), serine protease inhibitor Kazal type 1 (*SPINK1*), chymotrypsinogen C (*CTRC*), carboxyl ester lipase (*CEL*), and cystic fibrosis transmembrane conductance regulator (*CFTR*) [5]. Variants of these genes are classified into three categories according to mechanisms in the pathogenesis of CP. Variants of *PRSS1*, *SPINK1*, and *CTRC* are involved in the trypsin-dependent pathway. Variants of *CPA1* and *CEL* are involved in the misfolding-dependent pathway, which is associated with protein misfolding and endoplasmic reticulum stress. Variants of *CFTR* are involved in the ductal pathway, which is related to disruption of chloride-bicarbonate channel activity in pancreatic duct cells [2,11]. Mutations in *PRSS1* and *CPA1* are associated with >300-fold and 25-fold higher risk of CP, respectively; thus, they are occasionally referred to as hereditary CP. The other gene variants have relatively low risk effects and are associated with sporadic CP with no family history [5].

A US multicenter study reported that 49% of patients with EO-ICP carried a pathologic variant associated with one or more of the following genes: *CFTR*, *SPINK1*, and *CTRC*. A *SPINK1* mutation significantly accelerated the onset of symptoms in the EO-ICP group, from age 22 to age 12 [13]. A study from India reported that the *SPINK1* N34S mutation was present in 42% of patients with ICP, which was significantly higher than the percentage in patients with ACP (17%) and controls (4%). This study also reported that 50% of patients with ICP and 10% of controls had *CFTR* variants [30]. Heterozygous *SPINK1* mutations reportedly do not cause pancreatitis. It appears that patients with heterozygous *SPINK1* mutations must also have a mutation in other susceptibility genes (e.g., *PRSS1* or *CFTR*) in order to develop recurrent acute pancreatitis (RAP) or CP [38].

Other Rare Causes

Pancreatic divisum

Pancreatic divisum (PD) is the most common congenital malformation of the pancreas. It involves a congenital disconnection between the main pancreatic duct and the major papilla. PD is classified as an obstructive cause of CP [3]. Although increased pressure in the dorsal pancreatic duct and minor papilla have been reported in PD, the majority of patients with PD are asymptomatic. Therefore, there is considerable debate as to whether it is causally associated with pancreatitis or abdominal pain [39]. Some reports indicate that the existence of a genetic cofactor plus PD leads to the development of CP. Garg et al. reported *SPINK1* mutations in 41.7% of patients with PD and ICP, which was significantly higher than 2% in healthy controls. They also reported that 41.7% of patients carried *CFTR* gene polymorphisms [40]. Bertin et al. reported the frequency of PD in patients with RAP or CP is significantly associated with *CFTR* mutations or polymorphisms [41].

Autoimmune Pancreatitis

Autoimmune pancreatitis (AIP) is a distinct form of pancreatitis. Therapeutically, AIP has a dramatic response to steroids. AIP is classified into type 1, which is a type of IgG4-related systemic disease, and type 2, which frequently accompanies inflammatory bowel disease [42]. Currently, the long-term prognosis of AIP is not well understood. However, an international study group reported pancreatic duct stones in 7% of patients with type 1 AIP, but not in patients with type 2 AIP [43]. According to a report from Japan, among 52 patients with type 1 AIP who had no pancreatic stones at diagnosis, 20 (38.5%) of them developed *de novo* pancreatic stones after 3 or more years of follow-up [44]. The relationship between AIP and classic CP will become clearer in the future.

Hyperparathyroidism

The causal relationship between primary hyperparathyroidism (hypercalcemia) and RAP or CP is debatable. A systematic review demonstrated AP or CP occurred in 1.5% to 15.3% of patients with primary hyperparathyroidism, but the included studies had confounding factors, biases, and a lack of appropriate controls. In addition, the authors suggested the pancreatitis in this setting is likely the result of additional genetic and environmental factors [45]. Aslam et al. reported that hyperparathyroidism accounted for 1.94% of RAP or CP cases. In patients with CP associated with hyperparathyroidism, severe pain was a predominant symptom. After parathyroidectomy and subsequent decreases in serum calcium levels, there was a reduction in their symptoms [46].

Hyperlipidemia

Hypertriglyceridemia is a well-established but underestimated cause of AP and RAP. However, whether hypertriglyceridemia can cause CP has not been well studied [47]. Vipperla et al. performed a retrospective study that reviewed the medical records of 121 patients with serum triglyceride levels of ≥500 mg/dL who experienced 225 attacks of AP between 2001 to 2013 at their institute in the United States. They found 20 (16.5%) of 121 patients were diagnosed with CP (9 with preexisting CP, 11 with new-onset CP during follow-up) [48]. Their relatively small single-center retrospective study needs to be validated in future prospective or large multicenter studies with simultaneous analysis of confounding factors such as alcohol intake and smoking.

Early Chronic Pancreatitis

Kazuhiro Kikuta and Atsushi Masamune

Division of Gastroenterology, Tohoku University Graduate School of Medicine, Miyagi, Japan

Concept/Definition

The concept of chronic pancreatitis was established by Comfort et al. in 1946 [1,2]. They proposed that chronic pancreatitis was characterized by the progressive destruction of the pancreas. In the subsequently defined classification systems such as the Marseille classification [3], Cambridge classification [4], and Marseille-Roma classification [5], irreversible pancreatic changes associated with chronic pancreatitis were considered to cause permanent loss of pancreatic exocrine and endocrine functions. The conventional diagnostic criteria for chronic pancreatitis only enable us to detect the disease at the end stage, which ought to be irreversible. To improve the prognosis of chronic pancreatitis patients, it is indispensable to diagnose chronic pancreatitis in the early stage and prevent its progression through early interventions.

In 1996, the term "early-stage alcoholic chronic pancreatitis" was used to define a clinical stage linking alcoholic acute pancreatitis and alcoholic chronic pancreatitis by Ammann et al. [6]. They emphasized that the diagnosis "early-stage alcoholic chronic pancreatitis" was confirmed by criteria independent from histology, i.e., the long-term follow-up that eventually revealed the typical clinical features of chronic pancreatitis. It could only be diagnosed in a retrospective manner.

The category of early chronic pancreatitis was the first to be introduced into the diagnostic criteria proposed by the Japan Pancreas Society in 2009 [7]. Early chronic pancreatitis corresponds to the stage at which chronic pancreatitis has already started with clinical symptoms and signs of pancreatic injury; however, characteristic morphological changes of the pancreas have still not been detected clearly on conventional imaging modalities. Theoretically early chronic pancreatitis is considered to be a reversible pathological condition [8].

A new mechanistic definition of chronic pancreatitis was proposed by Whitcomb et al. in 2016 [9]. A conceptual model of chronic pancreatitis was derived, recognizing that subjects may exist in: (A) "at-risk" state of chronic pancreatitis, or in four active states; (B) acute pancreatitis-recurrent acute pancreatitis; (C) early chronic pancreatitis; (D) established chronic pancreatitis; and (E) end-stage chronic pancreatitis (Fig. 50.1). Early chronic pancreatitis may overlap conceptually with "minimal change chronic pancreatitis" or "pre-chronic pancreatitis," depending on eventual diagnostic criteria and distinctions from other states. The transition from "B" to "C" involves detection of biomarkers of chronic pancreatitis pathogenesis or pathology, but does not reach a state of "D." Biomarkers may be biochemical, structural or functional. The transition from "C" to "D" involves progression of disease to a persistent state of pathology or dysfunction. This new definition of chronic pancreatitis may allow for a rational approach to early diagnosis.

However, there still has not been international consensus on the definition of early chronic pancreatitis. In 2018, international consensus statements on early chronic pancreatitis were developed by a working group for the international consensus guidelines for chronic pancreatitis in collaboration with the International Association of Pancreatology, American Pancreatic Association, Japan Pancreas Society, PancreasFest Working Group, and European Pancreatic Club [10]: morphology-based diagnosis of early chronic pancreatitis is not possible without additional information; new approaches to the accurate diagnosis of early chronic pancreatitis will require a mechanistic definition; such a definition will require prospective validation.

AP: acute pancreatitis; RAP: recurrent acute pancreatitis; CP: chronic pancreatitis; SAPE: sentinel acute pancreatitis event; DM: diabetes mellitus; PDAC: pancreatic ductal adenocarcinoma. *Source:* Whitcomb et al. 2016 [9]. With permission of Elsevier.

Risk Factors/Etiology

Based on the new mechanistic definition of chronic pancreatitis [9], the risk factors of early chronic pancreatitis can be considered similar to those of recurrent acute pancreatitis and chronic pancreatitis. International classification systems such as TIGAR-O [11] and the M-ANNHEIM classification system [12] incorporate common etiological risks including alcohol and nicotine consumption, genetic mutations and polymorphisms, metabolic disorders, ductal obstruction, immunological factors, and idiopathic pancreatitis.

Epidemiology

A nationwide epidemiological survey of early chronic pancreatitis was conducted in Japan [13]. Patients with early chronic pancreatitis who were diagnosed according to the Japanese diagnostic criteria 2009 [7] and had visited the selected hospitals in 2011 were surveyed. The estimated prevalence and the annual incidence of early chronic pancreatitis were 4.2 and 1.0 per 100,000 persons, respectively. The male-to-female sex ratio was 1.32:1. The mean age was 60.4 and the mean age at disease onset was 55.4. The common etiologies were idiopathic (47.7%) and alcoholic (45.0%).

Clinical Presentation

A history of acute pancreatitis, especially recurrent acute pancreatitis, is a significant risk factor for early chronic pancreatitis [9,10,14,15]. However, some patients with chronic pancreatitis are asymptomatic during the early stage, and incidental imaging findings, steatorrhea, or diabetes may be the first clinical manifestation of chronic pancreatitis. According to a nationwide epidemiological survey conducted in Japan, 91.4% of patients with early chronic pancreatitis had recurrent upper abdominal pain, and 81.5% had abnormal pancreatic enzyme levels in the serum or urine. Only 13.9% were positive for abnormal pancreatic exocrine function [13].

Diagnosis

There still has not been international consensus on the diagnostic criteria for early chronic pancreatitis.

In 2009, the Japan Pancreas Society proposed the world's first diagnostic criteria for early chronic pancreatitis in the Japanese clinical diagnostic criteria for chronic pancreatitis 2009 (DC2009) [7]. In 2019, the Japan Pancreas Society proposed the revised DC2009, namely, "clinical diagnostic criteria for chronic pancreatitis 2019 (DC2019)" (Table 50.1) [17]. Early chronic pancreatitis is diagnosed using a combination of five clinical signs: (i) repeated upper abdominal or back pain; (ii) abnormal pancreatic enzyme levels in the serum or urine; (iii) abnormal pancreatic exocrine function; (iv) continuous heavy drinking of alcohol equivalent to or more than 60 g/day of pure ethanol or mutation in the pancreatitis-associated gene such as *PRSS1* and *SPINK1*; (v) past history of acute pancreatitis; and imaging findings on EUS, MRCP, or ERCP. Imaging findings on EUS were

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. Table 50.1 Japanese clinical diagnostic criteria for chronic pancreatitis 2019 *Source:* [16]/Springer Nature.

Diagnostic items for chronic pancreatitis
① Characteristic imaging findings
② Characteristic histological findings
③ Repeated upper abdominal or back pain
④ Abnormal pancreatic enzyme levels in the serum or urine
⑤ Abnormal pancreatic exocrine function
⑥ Continuous heavy drinking of alcohol equivalent to ≧60 g/day of pure ethanol or mutation in the pancreatitis-associated gene
⑦ Past history of acute pancreatitis
Imaging findings of early chronic pancreatitis
Either (a) or (b)
a) More than two features among the following four EUS findings including (1) or (2)
1) Hyperechoic foci (non-shadowing) or strands
2) Lobularity
3) Hyperechoic MPD margin
4) Dilated side branches
b) Irregular dilatation of more than three side branches on MRCP or ERCP
Definite chronic pancreatitis: either (a) or (b)
a) Definite findings of ① or ②
b) Probable findings of ① or ②, plus more than two items among ③, ④, and ⑤
Probable chronic pancreatitis
Probable findings of ① or ②
Early chronic pancreatitis
More than three items among ③~⑦ plus imaging findings of early chronic pancreatitis

Note 1: Differential diagnosis from other pancreatic diseases especially pancreatic cancer and intraductal papillary mucinous neoplasm is important.
Note 2: If imaging findings of early chronic pancreatitis were absent, a diagnosis of possible chronic pancreatitis could be made in the patients without ① and ②, but with more than three items among ③~⑦ after ruling out other diseases. Imaging examinations including EUS are recommended for the patients with possible chronic pancreatitis.
Note 3: Patients with only two items among ③~⑦ and imaging findings of early chronic pancreatitis are regarded as possible early chronic pancreatitis after ruling out other diseases, and require careful follow-up. Footnote: Long-term prognosis should be clarified in patients with early chronic pancreatitis.

consolidated from seven items in DC2009 to four items: hyperechoic foci (non-shadowing) or strands; lobularity; hyperechoic MPD margin; dilated side branches. Early chronic pancreatitis can be diagnosed if a patient does not justify a diagnosis of definite or probable chronic pancreatitis, but satisfies at least three of five clinical signs and imaging findings of early chronic pancreatitis. The approach by the Japan Pancreas Society still has not been fully accepted internationally, while it provides a potentially useful definition of early chronic pancreatitis.

It has also been reported that three or more attacks of acute pancreatitis with no morphological changes to the pancreas can be an improved diagnostic criterion for early chronic pancreatitis [16].

Diagnostic Modalities for Early Chronic Pancreatitis

Transabdominal Ultrasonography (US)

Transabdominal US is recommended as the first-line noninvasive imaging approach for evaluating patients with suspected chronic pancreatitis. However, the ability of transabdominal US to diagnose early chronic pancreatitis has not been fully validated. HaPanEU/UEG working group indicated that abdominal US can only be used to diagnose chronic pancreatitis at an advanced stage [17].

Computed Tomography (CT)

The ability of CT to diagnose early chronic pancreatitis has not been fully validated as well as transabdominal US.

Magnetic Resonance Imaging (MRI)

Japanese clinical diagnostic criteria for chronic pancreatitis 2019 incorporated a finding of irregular dilation of more than three side branches on MRCP into diagnostic criteria for early chronic pancreatitis [16]. This MRCP finding has been defined in accordance with image grading "mild" of ERP defined in the Cambridge classification [4]. The ability of MRCP to diagnose early chronic pancreatitis needs to be prospectively verified.

T1-weighted MR signal of the pancreas, which was associated with pancreatic exocrine dysfunction [18] and the grade of ductal changes under the Cambridge classification [19], may be helpful in the evaluation of suspected early chronic pancreatitis. Main pancreatic duct irregularity, T1-weighted MR signal, and duodenal filling after secretin injection may be predictors of pancreatic fibrosis [20].

Endoscopic Ultrasonography (EUS)

EUS is considered the most sensitive modality for detecting early chronic pancreatitis, although early chronic pancreatitis may not be diagnosed by current imaging techniques [10]. So far, there is no consensus cutoff of EUS findings for establishing a diagnosis of early chronic pancreatitis.

In 2009, Japanese clinical diagnostic criteria incorporated EUS findings into diagnostic criteria for early chronic pancreatitis [7]. Considering the diagnosis of

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. indeterminate for chronic pancreatitis based on the Rosemont classification [21], five features of pancreatic parenchymal factors (lobularity with honeycombing; lobularity without honeycombing; hyperechoic foci without shadowing; stranding; cysts) and two features of pancreatic ductal factors (dilated side branches; hyperechoic MPD margin) were adopted for the EUS findings of early chronic pancreatitis. In the 2019 revision of diagnostic criteria, EUS findings were consolidated from seven items to four items: lobularities with and without honeycombing were consolidated to lobularity; hyperechoic foci without shadowing and stranding were consolidated to hyperechoic foci (nonshadowing) or strands; and cysts were removed from the diagnostic items (Table 50.1) [16]. The interobserver reliability of EUS criteria of diagnostic criteria 2019 was higher than that of diagnostic criteria 2009 [22].

Elastography

EUS-elastography has recently allowed the evaluation of the elasticity of deep organs, such as the pancreas [23,24]. The usefulness of EUS-elastography for the diagnosis of early chronic pancreatitis has yet to be established [25], although there has been a single arm study that patients with suspected early chronic pancreatitis had an abnormally high strain ratio at EUS-elastography [26].

ERCP

The Japanese clinical diagnostic criteria incorporated a finding of irregular dilation of more than three side branches on ERP into diagnostic criteria for early chronic pancreatitis [7,16]. This ERP finding has been defined in accordance with image grading "mild" defined in the Cambridge classification [4]. The ability of ERP to diagnose early chronic pancreatitis needs to be prospectively verified.

Pancreatic Function Testing

Exocrine pancreatic insufficiency is a common complication of chronic pancreatitis. Conversely, early chronic pancreatitis is considered to be a stage of chronic pancreatitis with preserved pancreatic function and potentially reversible features [10]. The usefulness of pancreatic function testing for the diagnosis of early chronic pancreatitis still has not been established, although it is considered that early chronic pancreatitis can be diagnosed by a combination of factors including pancreatic function testing [10].

Direct hormone-stimulated tests, using cholecystokinin or secretin, are considered the most sensitive and specific tests for pancreatic insufficiency. The positive predictive value of the secretin pancreatic function testing for the subsequent development of chronic pancreatitis has been reported to be 45% with a negative predictive value of 97% [27].

The Japanese clinical diagnostic criteria incorporated a finding of abnormal results in BT-PABA test into diagnostic criteria for early chronic pancreatitis [7,16]. Based on this criteria, only 13.9% of early chronic pancreatitis was positive for abnormal pancreatic exocrine function [13].

Fecal elastase-1 is considered to be inappropriate for the diagnosis of early chronic pancreatitis because the correlation of fetal elastase-1 with mild ductal changes is not strong [28,29].

Histological Evaluation

While conventional chronic pancreatitis has been diagnosed mainly on the basis of structural changes related to fibrosis, histological findings for the diagnosis of early chronic pancreatitis have not yet been established.

Furthermore, direct acquisition of pancreatic tissue for the diagnosis of early chronic pancreatitis is limited. It has been reported that EUS-guided fine-needle biopsy provided inadequate material for the histological diagnosis of early chronic pancreatitis [30].

Biomarkers

So far, there are no widely accepted biomarkers for the diagnosis of early chronic pancreatitis [10]. There is a report that indicated the usefulness of blood-based microRNA biomarker panel for the diagnosis of early chronic pancreatitis [31].

Genetic Markers

Genetic variants are important risk factors for early chronic pancreatitis and can add specificity to the likely etiology, but they are neither necessary nor sufficient to make a diagnosis of early chronic pancreatitis [10]. The Japanese clinical diagnostic criteria has incorporated mutations in the pancreatitis-associated genes such as *PRSS1* and *SPINK1* for the diagnosis of early chronic pancreatitis [16].

Management/Treatment

Evidence for the management of early chronic pancreatitis is insufficient.

In patients with acute pancreatitis or recurrent acute pancreatitis, it is important to evaluate risk factors in

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

order to prevent disease progression [11]. It is expected that precision medicine will be established according to risk factors in the future. Alcohol abstinence and smoking cessation can be the mainstays for preventing the progression of early chronic pancreatitis.

It has been reported that a combination treatment of proton pump inhibitor, camostat mesilate, and pancrelipase improved epigastric pain [32] and EUS findings [33] in patients with early chronic pancreatitis.

Prognosis

Prospective study of early chronic pancreatitis diagnosed based on the Japanese diagnostic criteria 2009 was conducted in Japan [14]. Among the 83 patients who completed the 2-year follow-up period, four (4.8%) patients progressed to definite chronic pancreatitis. The diagnosis of 48 (57.8%) patients was unchanged, and that of 31 (37.3%) patients was downgraded.

Chronic Pancreatitis with Inflammatory Mass in the Pancreatic Head

Ulrich F. Wellner, Kim C. Honselmann, and Tobias Keck

Department of Surgery, University Medical Center Schleswig-Holstein, Campus Lübeck, Lübeck, Germany

Definition

Chronic pancreatitis can present with enlargement and mass-formation of the pancreatic head, mimicking virtually all symptoms of a malignant pancreatic head tumor and confronting the clinician with significant diagnostic and therapeutic challenges. This phenomenon has been termed the "inflammatory (pseudo) tumor" [1], "tumor-forming chronic pancreatitis" [2], and other. For the purpose of this article, we will use the term inflammatory pancreatic head mass (IPHM).

From a pathophysiological point of view, IPHM is thought to result from recurrent acute and chronic inflammation of the pancreatic parenchyma, but at the same time to perpetuate disease progression as a "pacemaker" by causing main pancreatic duct (MPD) obstruction leading to chronic ductal hypertension [3]. There is no generally accepted definition of IPHM, but the following criteria may be applied: presence of an abnormally enlarged pancreatic head, often accompanied by pancreatic calcifications, MPD dilatation, and irregularities and atrophy of the pancreatic parenchyma to the left of the mesentericoportal axis [4–6] (Figs 51.1 and 51.2).

Incidence

The concept of the IPHM as a pacemaker of chronic pancreatitis has been established by Beger et al. [3] and followed mainly by European surgeons. The incidence of IPHM in surgical patients is in the range of 85%; however, exact figures have rarely been reported in detail [5,7]. The average size of the pancreatic head has been shown to be significantly larger in a study comparing German (median 4.5 cm) and North American (median 2.6 cm) patients undergoing surgery for chronic pancreatitis [5]. The significance of this finding lies in the fact that it explains regional differences in operative procedures used to treat chronic pancreatitis; however, the underlying cause is not clear. Reasons might be a pattern of clinical transfer of the patient from the gastroenterologist to the surgeon, genetic differences, or different risk factors for the development of chronic pancreatitis.

Symptoms, Pathophysiology, and Clinical Problems

An IPHM can cause many clinical symptoms and complications, which in principle constitute the classical complications of chronic pancreatitis. Differential diagnosis and decision-making may be complicated as virtually all of these symptoms can also be caused by pancreatic head cancer.

One of the most frequently reported symptoms is pain [4,7]. Typically, the pain maximum is located to the epigastric area and may radiate to the flanks and back. In some cases, however, back pain may be the primary complaint. The pain can be episodic or continuous, with sudden exacerbations of variable frequency from daily to once in several months, often triggered by alcohol or food intake. Signs of acute pancreatitis like elevation of serum amylase or lipase and edematous swelling of the pancreatic head are often found associated with severe acute pain attacks, but may as well be missing, especially with longer duration of disease. In line with this, there is good evidence from histopathological and experimental studies that pancreatic pain is not only caused by acute inflammation but also from chronic neuropathy of visceral nerves in the pancreas [8]. Importantly about 50–90% of patients will not become pain-free even 10 years after disease onset [9].

Figure 51.1 Inflammatory pancreatic head mass. Computed tomography showing a large inflammatory pancreatic head mass in a patient with chronic pancreatitis, with typical diffuse pancreatic calcifications and a large pseudocyst in the pancreatic head.

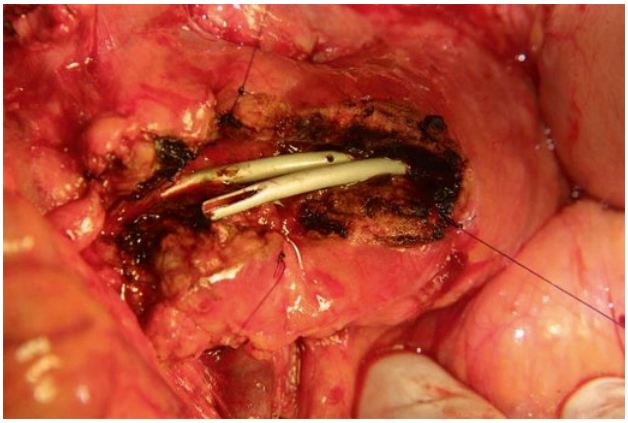

Figure 51.2 Impacted stent in the irregular and scarified main pancreatic duct. Prolonged interventional treatment leading to nonremovable stents in the pancreatic duct with marked pancreatic duct irregularities and narrowing.

Episodes of acute pancreatitis can lead to the development of pancreatic pseudocysts or walled-off necrosis (WON, Fig. 51.3) [10], with secondary complications like superinfection, pseudoaneurysm, hemorrhage, compression of the duodenum or bile duct, internal pancreatic fistula, and pancreatic ascites.

Biliary stricture is reported in up to 35% of patients [6], leading to jaundice and recurrent cholangitis. Of note, subclinical common bile duct (CBD) narrowing can be aggravated to frank obstruction by acute edematous swelling of the pancreatic head during episodes of acute

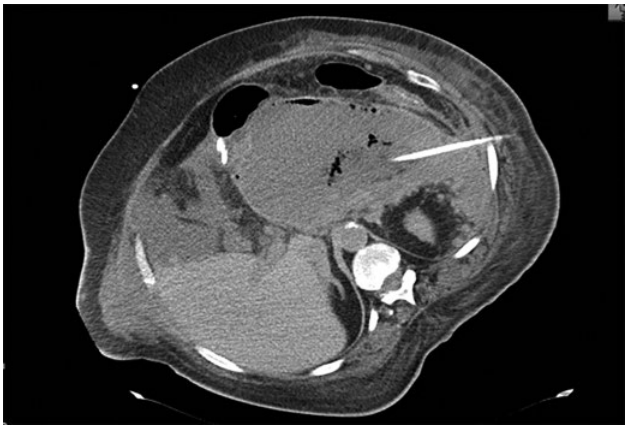

Figure 51.3 Walled-off necrosis. Magnetic resonance imaging depicting an inflammatory pancreatic head mass with walled-off necrosis which developed after an episode of acute pancreatitis in a patient with chronic pancreatitis. External interventional drainage.

pancreatitis. Maldigestion and absorption with steatorrhea, coagulopathy, and malnutrition occurs as a result of persistent cholestasis. Duodenal stenosis is found in about 10% of patients [6], resulting in gastric dilatation, postprandial bloating and vomiting, anorexia and malnutrition. Malnutrition may be exaggerated by pancreatic exocrine insufficiency. Loss of endocrine function typically occurs later and will affect around 80% of patients [9]. Stenosis and finally thrombotic occlusion of the mesentericoportal vessels is usually a late complication. Occlusion of the splenic vein results in left-sided portal hypertension with development of gastric fundal varices and splenomegaly. As complete occlusion of the portal vein usually develops gradually, extensive collaterals develop around the pancreatic head, a phenomenon called cavernous transformation [6]. Patients suffering from chronic pancreatitis have a 10-fold elevated risk of about 3% to develop pancreatic cancer [9].

Clinical Workup and Differential Diagnosis

The most important differential diagnoses are pancreatic head cancer and autoimmune pancreatitis. Careful clinical history-taking can yield important hints. Longstanding complaints or recurrent attacks over a period of years rather than months, accompanied by signs of chronic malnutrition points toward benign IPHM, whereas clinical deterioration over weeks to months with weight loss or new-onset diabetes mellitus are suggestive of malignancy. Jaundice can occur with IPHM but should always prompt efforts to rule out malignancy. Associated autoimmune disease points to autoimmune

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. pancreatitis [11]. Laboratory workup should include serum amylase and lipase activity and carbohydrate antigen 19-9 (CA19-9), as elevated serum enzyme activity indicates an episode of acute pancreatitis, whereas marked elevation of the tumor marker in absence of acute pancreatitis is suggestive of malignancy. Sensitivity and specificity of CA19-9 for discrimination of chronic pancreatitis from PDAC were reported as 84% and 75% [12]. Serum immunoglobulin G4 (IgG4) can be increased in autoimmune pancreatitis [13]. Because of the risk of tumor spillage and lack of therapeutic consequences, tissue biopsy is not recommended when resectable malignancy is suspected.

Cross-sectional imaging by contrast-enhanced computed tomography (CECT) or magnetic resonance imaging (MRI) is mandatory. In IPHM, the pancreatic head is enlarged with loss of the lobular parenchymal architecture, calcifications, and narrowing of the pancreatic duct (Fig. 51.1). There can be mass-forming lesions in the pancreatic head virtually indistinguishable from pancreatic cancer. Upstream MPD dilatation is often absent in autoimmune pancreatitis [11]. Accuracy of modern cross-sectional imaging for differentiation of IPHM and pancreatic cancer has been reported in the range of 90% [14]. Magnetic resonance cholangiopancreatography can be a valid substitute for invasive endoscopic retrograde cholangiopancreatography (ERCP) to assess configuration of the biliary tree and MPD (Fig. 51.2). In view of eventual surgical intervention, it is of paramount importance to assess mesentericoportal vein status and signs of portal hypertension.

Treatment

Asymptomatic IPHM virtually does not exist; however, symptom-free periods of weeks to months are common. Indications for invasive treatment are persistent pain or dependence on analgesics, recurrent acute pancreatitis, obstructive cholestasis, gastric outlet obstruction, development of persistent large or symptomatic pancreatic pseudocysts or walled-off pancreatic necrosis (WON), and suspicion of malignancy. Conservative management is chosen in case of inoperability or as a strategy to avoid operative treatment during a period of recovery, either after an episode of acute pancreatitis or as a bridge to operation.

Medical therapy consists of pain control and eventual substitution of pancreatic enzymes and insulin. It must be stressed that clinical remission of symptoms can be achieved by cessation of alcohol consumption in alcohol-induced chronic pancreatitis. Furthermore, the role of tobacco smoke as a causal agent has recently been recognized [15]. At least initially, surveillance of a pancreatic head mass by cross-sectional imaging should be performed every 3 to 6 months to rule out malignancy.

Endoscopic stenting of the MPD can be effective to induce remission of pancreatic cysts, pancreatic fistula as well as pain by decompression of the MPD. However, randomized trials have shown that surgical treatment provides more effective and durable pain control [16–18] and has been included in international guidelines [19,20]. For example, patients with obstructive chronic pancreatitis, who recently started opioid treatment (no longer than 6 months) were randomized to either early surgical drainage (by a lateral pancreaticojejunostomy or duodenum-preserving pancreatic head resection) or endoscopic drainage (stent, lithotripsy) within 6 weeks of randomization. Izbicki pain score [21] was significantly lower in patients treated with surgery than with endoscopic intervention [18]. In addition, the Izbicki pain score was found to be able to identify those patients who benefit most from surgery [21]. Another disadvantage of endoscopic therapy is the necessity of regular stent exchange every 3 to 6 months to prevent cholangitis and tissue overgrowth; however, while efficacy is similar between plastic stents and metal stents, reintervention is lower in fully covered self-expanding metal stents as shown in a recent randomized controlled trial for benign biliary strictures due to chronic pancreatitis [22]. When a stent cannot be removed due to incrustation or migration, surgical intervention is needed (Fig. 51.1). Stenting of the CBD for obstructive jaundice is only a short-term option as remission of CBD obstruction can only be expected in cases of acute edematous swelling of the IPHM in acute pancreatitis.

Operative therapy can be divided into drainage procedures and those procedures that involve resecting a part of the pancreas. While drainage procedures aim at decompression of the MPD by pancreatojejunostomy, removal of the IPHM is the goal of resectional procedures, which can be combined with MPD drainage. On surgical exploration, the IPHM is usually found to be heavily indurated, and the inflammatory fibrotic process may extend into the peripancreatic tissues causing heavy adhesions to the organs in vicinity, like the retropancreatic blood vessels, duodenum, and hepatoduodenal ligament. These conditions render operative procedures involving the pancreatic head very challenging and in rare cases even technically impossible, especially when associated mesentericoportal hypertension leads to diffuse bleeding.

Radical pancreatoduodenectomy (PD) with (Longmire-Traverso [23]) or without (Kausch-Whipple [24,25]) preservation of the pylorus is the procedure of choice when malignancy is suspected and offers very good long-term pain control in chronic pancreatitis. For the IPHM, duodenum-preserving pancreatic head resection (DPPHR) was developed by Beger and colleagues [3]. In the Frey modification [26], pancreatic parenchyma is spared by

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. excoriation of the IPHM without transsection at the pancreatic neck, and laterolateral pancreatojejunostomy ensures adequate MPD decompression. In the Hamburg modification of DPPHR [6], drainage of the MPD is further optimized by a V-shaped excision along the MPD. Randomized trials have shown reduced perioperative and short-term morbidity in DPPHR compared to PD with comparable long-term results [6]; however, long-term quality of life and serious adverse events after 24 months were equal between PD and DPPHR [27]. Equality in this context clearly speaks for duodenum-preserving procedures as organ preservation should be in the focus of every surgeon whenever possible. Equality was also reported for Beger versus Frey procedures [28,29] and so far no randomized trial has involved other DPPHR modifications.

Pure MPD drainage procedures like the Puestow-Gillesby [30] (pancreatic left resection with splenectomy and laterolateral pancreatojejunostomy), Partington-Rochelle [31] (laterolateral pancreatojejunostomy) or Izbicki [32] (longitudinal V-shaped excision and laterolateral pancreatojejunostomy) operations do not remove the IPHM. MPD drainage in unselected patients only achieved 50–65% permanent pain control [6], which is inferior to that of pancreatic head resection with 75–95% [33–45]. Although no randomized trial has compared drainage versus resection procedures, drainage procedures are therefore reserved for patients without IPHM.

However, in case of mesentericoportal vein occlusion with portal hypertension and cavernous transformation, pancreatic head resection becomes impossible and therapy is limited to operative or endoscopic MPD drainage. Preoperative recanalization of the portal vein can be performed in selected patients with short-segment portal vein occlusion [46]. Gastroenterostomy and hepaticojejunostomy are measures of last choice for biliary or duodenal obstruction.

Adequate timing is an important aspect in the management of patients with IPHM. Maximum duration of a trial of nonoperative management of IPHM should be 6 months, as optimal operative treatment usually becomes impossible in an advanced stage. In the presence of mesentericoportal vein narrowing or partial thrombosis, elective surgery should be performed as soon as possible, and prophylactic anticoagulation is advocated until surgery.

Certain contraindications impede early surgery. Cachexia should be treated by high-caloric nutrition with adequate simultaneous supplementation of pancreatic enzymes and vitamins, and in case of gastric outlet obstruction by jejunal tube feeding, to achieve adequate nutritional status for operation. Elective surgery is also not indicated before at least 3 months have passed since the last episode of acute pancreatitis. Serum pancreatic enzyme activity can be used to monitor acute pancreatitis activity.

On histopathological workup, IPHM is characterized by fibrotic atrophy of exocrine acinar epithelium, the remaining ductal and islet epithelia becoming "skeletonized" in fibrous connective tissue. Strong inflammatory granulocytic or lymphocytic infiltration is uncommon. In contrast, autoimmune pancreatitis typically shows duct-centric inflammation, with IgG4 positive plasma cells or granulocytic epithelial lesions [11]. As overall tissue organization is heavily disturbed and chronic pancreatitis can be associated with pancreatic intraepithelial neoplasia (PANIN), distinction from PDAC can be difficult even for experienced pathologists. Intraoperative frozen section examination at least of the surgical resection margins is mandatory and in case of any doubt, radical oncologic resection is warranted.

Summary

Chronic pancreatitis with inflammatory pancreatic head mass is a domain of surgical therapy. The main differential diagnoses are pancreatic head cancer and autoimmune pancreatitis. Best results are achieved by resection of the pancreatic head mass with adequate drainage of the pancreatic duct, but pancreatic head resection may become impossible in advanced stages of the disease. Adequate workup and timing of conservative and surgical therapy is of paramount importance for successful management.

Structural Complications: Strictures, Stones, Pseudocysts, and Vascular Complications

Xiaodong Tian[1], *Xiaochao Guo*[2], *and Yinmo Yang*[1]

[1] *Department of General Surgery, Peking University First Hospital, Beijing, China*
[2] *Department of Radiology, Peking University First Hospital, Beijing, China*

Introduction

Chronic pancreatitis (CP) is a chronic inflammatory process in the pancreas, during which the pancreatic parenchyma is pathologically replaced by fibrous connective tissue, resulting in a series of structural complications and progressive insufficiency of exocrine and endocrine function [1]. Morphologic changes of the pancreas are one of the important features during CP, though they are usually not apparent in the early phase. The typical structural complications include, but are not limited to, strictures of pancreatic duct and/or biliary tract, intraductal stones, development of pseudocysts, and peripancreatic vascular complications. These structural changes will lead to dilation of the pancreatic duct, intraductal high pressure, and parenchyma atrophy of the pancreas. The corresponding clinical manifestations are malnutrition and pain syndromes.

A comprehensive understanding of the natural history of CP is also important, since the evolution of changes in morphology and function may take years to manifest.

Pathophysiologic Basis and Morphological Features of the Pancreas

The pathogenic mechanism of CP remains elusive and controversial. Several theories have been proposed in the past several decades: toxic-metabolic, oxidative stress, stone and duct obstruction, necrosis-fibrosis, primary duct hypothesis, and sentinel acute pancreatitis event hypothesis [2]. Each of these models is compelling and provides a certain mechanism to explain the diverse etiologies of CP, providing rationale for the cardinal pathologic changes of fibrosis, loss of acinar tissue (atrophy), stones, and duct changes. Grossly, the pancreas becomes firm and shrunken, with an irregular contour. Dilated pancreatic duct is usually presented due to the obstruction of main pancreatic duct caused by either inflammatory fibrosis around the duct or intraductal stones. Fibrous scarring may result in the distortion or disappear of the normal macroscopic lobulation. Parenchyma calcifications and pseudocysts formation may be related to specific etiologies.

Strictures of Pancreatic Duct, Biliary Tract or Duodenum

Pancreatic parenchyma is replaced by fibrosis in advanced CP patients, and the recurrent inflammatory episodes might develop periductal fibrotic strictures, leading eventually to pancreatic duct stricture. The most common reasons for pancreatic duct strictures are inflammation, fibrosis, and previous stone [6]. However, Kalady et al. [7] had reported that nearly 12% of the CP patients with isolated pancreatic duct strictures were associated with malignancy, especially for those without pancreatitis history or irregular pancreatic duct side branches, as well as those with stricture located only in the head or neck. Therefore, all newly developed pancreatic duct strictures should be further evaluated by EUS or CT/MRI before treatment. The endoscopic management (ERCP or EUS-guided pancreatic drainage) is suited for CP patients with localized strictures, and surgical approaches remain the key choice for selected patients [8,9].

Stricture of common bile duct (CBD) is reported to be usually caused by fibrosis of the pancreatic head, which

exerts extrinsic pressure on the intrapancreatic CBD. Moreover, inflammation caused by either pancreatic calculi or pseudocysts in the pancreatic head was also reported to contribute to significant biliary stricture during the acute phase [10]. The incidence of CBD stricture in CP patients ranges from 3% to 46%, and approximately 17% present as asymptomatic cholestasis [6]. Treatment of CBD stricture depends on the patients' manifestation and morphologic changes of the pancreas. The indications for biliary decompression include cholangitis, severe and persistent jaundice, and occurrence of CBD stones. The drainage of bile duct can be accomplished either endoscopically or surgically. Despite the minimally invasive advantages of endoscopic therapy, there is still no evidence on which is the better strategy for CP-associated biliary stricture, while surgical interventions showed superior results in terms of long-term pain relief [11]. In a multicenter randomized study of multiple plastic stents versus covered self-expandable metallic stent (cSEMS) in the treatment of biliary stricture in CP patients, Haapamäki and colleagues found that a 6-month treatment with either multiple plastic stents or cSEMS produced good long-term relief of biliary stricture [12]. Surgical treatment should also be considered if bile duct obstruction recurs after long-term endoscopic therapy. Moreover, surgery must be undertaken if malignancy cannot be excluded.

Around 5% of CP patients developed duodenal stenosis due to paraduodenal pancreatic inflammation, named groove pancreatitis (GP), which is characterized by scarring between the duodenum and pancreatic head, accompanied by blood vessels compression, CBD stricture, duodenal wall rigidity, and luminal narrowing (Fig. 52.1) [13,14]. Patients with GP usually complain of upper abdominal pain, nausea, recurrent vomiting with weight loss for weeks to years. The characteristic manifestation is duodenal stenosis resulting in gastric outlet obstruction. Although tubular stricture of CBD is frequent, obstructive jaundice is rarely presented, and the main pancreatic duct is normal in most patients, which helps differentiate it from pancreatic adenocarcinoma. However, differentiating GP from pancreatic cancer is difficult because both of these two diseases are associated with similar clinical presentation, radiologic findings, as well as gross pathologic features [14]. Conservative and endoscopic treatments are helpful in many cases, while surgical intervention may be necessary in cases either with diagnostic uncertainty or severe obstructive symptoms.

Pancreatic Ductal Stones

Pancreatic ductal stones are a direct consequence of CP and occur in approximately 50% of cases, with the prevalence increasing over time to reach 50% at 5 years and nearly 100% after 14 years of the disease onset [16]. Pancreatic stones can cause outflow obstruction and produce upstream ductal hypertension and subsequent parenchymal hypertension, thus result in pseudocysts or fistula formation, recurrent exacerbations or contribution to the pathogenesis of pain.

Long-term alcohol consumption has been identified to be a major cause of calcium stone formation, which is possibly through disturbing the cholinergic regulation of pancreatic secretions and aggravating the loss of endocrine and exocrine functions [17]. Noticeably, pancreatic ductal stones are also common in nonalcoholic CP

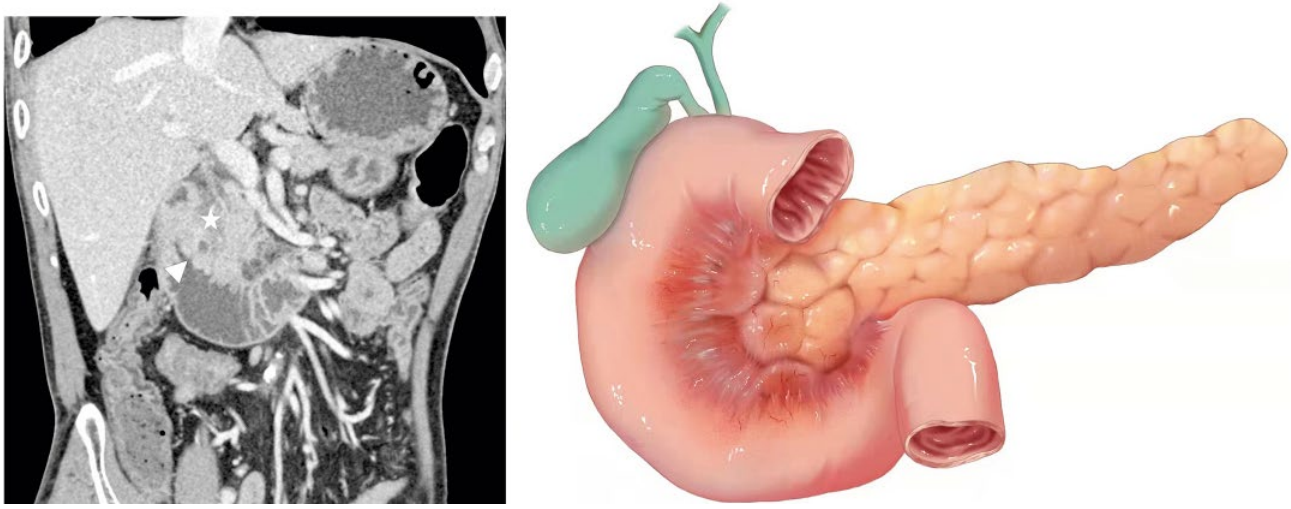

Figure 52.1 Groove pancreatitis. Left: coronal reconstruction image of contrast-enhanced CT. "Sheet-like" hypodense and "patchy" enhanced soft tissue are shown in the pancreatic-duodenal groove (asterisk). Medial duodenal wall is thickened with intramural cyst (arrowhead). patients. Maruyama reported that pancreatic stone formation in autoimmune pancreatitis was associated with narrowing of both Wirsung and Santorini ducts, which may subsequently result in pancreatic juice stasis and stone formation [18]. Pancreatic duct stenosis promotes the formation of intraductal stones, while the stones lead to intraductal ulcers and scars, which aggravate the pancreatic duct narrowing and cause more stone formation, resulting in CP progression and even increasing risk of cancer [19]. In a retrospective analysis of risk factors for pancreatic duct stones formation, both the main pancreatic duct narrowing and chronic alcohol consumption were identified as significant independent risk factors, and the period between diagnosis of CP and pancreatic stones formation seemed significantly shorter in alcoholic CP patients than in nonalcoholic patients [20]. Hao and colleagues [21] constructed a pancreatic stone-predicting nomogram for CP patients, and found that the age at onset of CP, body mass index, smoking, diabetes mellitus, pancreatic pseudocyst, biliary stricture, severe acute pancreatitis, and type of pain were significantly associated with intraductal stone development.

Symptomatic CP patients and those with duct obstruction caused by the pancreatic ductal stones were eligible for endoscopic or surgical treatments [22]. To remove the intraductal stones, endoscopic therapy should be the first choice, especially for patients without other complications. While for patients with multiple strictures, calculi in the body/tail region, concerns of associated solid mass, or failure of endoscopic therapy, surgery should be considered.

Pseudocyst in CP

Pancreatic pseudocyst is a fluid accumulation with high concentration of amylase that is surrounded by a fibrous capsule (Fig. 52.2). Pseudocyst usually arises from the disruption of the main pancreatic duct or major duct branches. In contrast to real cyst, it has no internal epithelial cell lining and the patients might have a history of clinical manifestations related to acute or chronic pancreatitis. Pseudocyst is considered to be one of the most common complications of both AP and CP with the prevalence of 20–40% in CP patients [23]. It is more commonly presented in patients with alcoholic CP.

The symptoms of a pseudocyst are usually nonspecific, most patients only complain about vague abdominal pain, nausea, or vomiting [24]. In up to 40% of CP patients, the pseudocysts will spontaneously resolve after 6 weeks, and only conservative supportive care is needed. However, large cysts are more likely to become symptomatic or cause complications. When the pseudocyst persists for longer than 12 weeks, there will be rare possibility for it to disappear spontaneously, and the additional complications include infection, hemorrhage, pseudocyst rupture, and disruptions of the pancreatic duct system [24,25]. In cases where symptoms worsen or complications occur, multiple modalities of treatments including percutaneous drainage, endoscopic procedures, and surgical drainage can be offered depending on the individual patient profile.

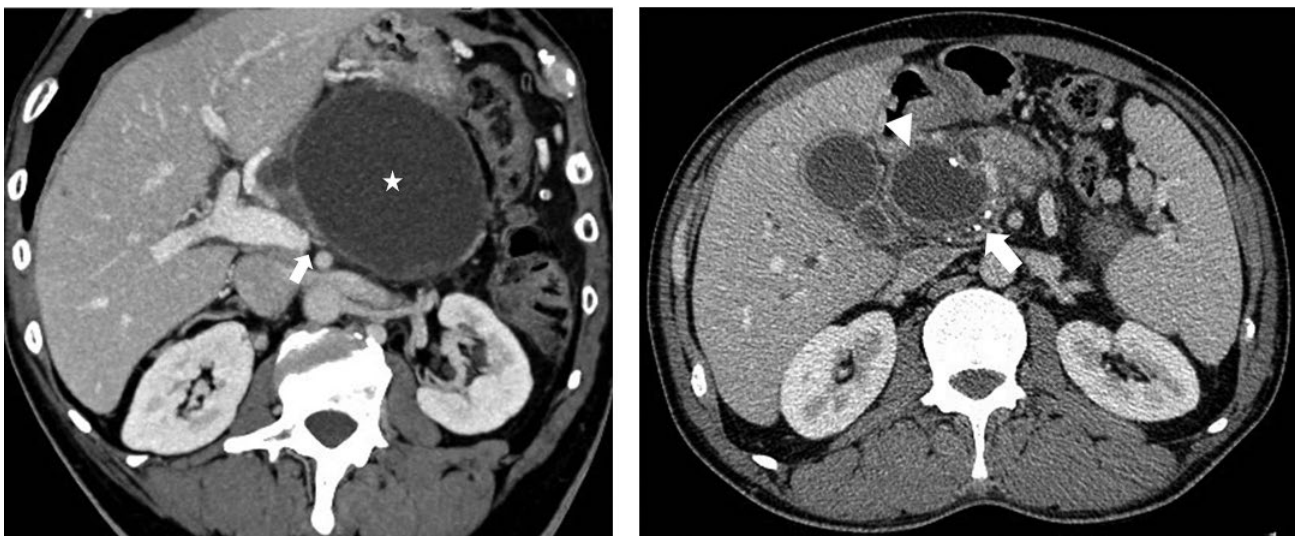

Figure 52.2 Pseudocysts in CP patients (contrast-enhanced CT). Left: pseudocysts (asterisks) can be seen in the pancreatic area, and splenic vein is occluded (white arrow). Right: pseudocyst (white triangle) is shown in the pancreatic head, with calcifications of the cystic wall and surrounding tissues (white arrow). *Source:* Yinmo Yang.

Vascular complications of CP

Peripancreatic inflammation may affect the vessels in closest proximity to the pancreas, resulting in venous thrombosis most commonly involving the splenic vein, or pseudoaneurysm most commonly involving the splenic artery. Vascular complications occur in about 8.4–12.2% of CP patients, with the incidence of venous thrombosis and pseudoaneurysm approximately 7.6~10.9% and 0.8~2.5%, respectively [26,27]. Vascular complications were more commonly shown in males and alcoholic CP, while less commonly in patients with pancreatic atrophy and calcification [26]. Pseudocysts and alcoholic CP have been found to be risk factors for vascular complications in CP cases [27,28]. In a retrospective analysis of the database of 1363 patients with CP, alcoholic CP, presence of pseudocyst and inflammatory head mass were shown to be independent risk factors for venous thrombosis, whereas alcoholic CP and pseudocyst were identified as independent risk factors for pseudoaneurysm [26].

Consequences of pancreatitis-associated splenic vein thrombosis include gastroesophageal varices, venous collaterals, splenomegaly, and gastrointestinal bleed, with prevalences of 28.9%, 44.3%, 18.1%, and 14.1%, respectively [26]. Patients with pseudoaneurysm usually present with gastrointestinal bleeding, or are incidentally detected on contrast-enhanced CT done for other indications.

Sinistral portal hypertension (SPH), also known as regional, segmental, splenoportal, localized or left-sided portal hypertension, is a pathological condition of splenic vein hypertension localized in the left-sided gastrosplenic region, presents in less than 5% of all patients with portal hypertension (Fig. 52.3) [29]. In contrast to cirrhosis-related portal hypertension, SPH is characterized by normal hepatic function, isolated gastric varices, and splenomegaly. The CP-related SPH accounts for 31.8–53.8% of all cases, and the main etiology is splenic vein occlusion caused by venous thrombosis, extrinsic splenic vein compression by pseudocysts, inflammatory changes in the vascular endothelium, or relatively low perfusion associated with pancreatic fibrosis [30–31]. The incidence of SPH in patients with CP ranges from 9.7% to 22%, among which 4–17% develop severe gastrointestinal bleeding [26,31–35]. Splenomegaly is frequently observed in patients with SPH, while the incidence of hypersplenism is not as common as in portal hypertension. The site of gastrointestinal bleeding in patients with SPH is mainly located in the proximal stomach due to gastric varices, which is different from the lower esophageal hemorrhage in portal hypertension. Generally, CP-related SPH patients without history of gastrointestinal bleeding do not require surgical intervention [35]. Splenectomy is the most common therapeutic choice for SPH patients who experience gastrointestinal bleeding. Endoscopic therapy and splenic artery embolization could be the choices for patients

who are not suitable for surgery. However, for patients with SPH as the initial manifestation, the possibility of pancreatic cancer should be considered, because the involvement of splenic vein by pancreatic cancer is another important etiology of SPH.

Nutritional Evaluation and Support: An Overview

Sinead N. Duggan[1] *and Stephen J. O'Keefe*[2]

[1] *Department of Surgery, School of Medicine, Trinity College Dublin, Ireland*
[2] *Division of Gastroenterology, Hepatology and Nutrition, University of Pittsburgh, Pittsburgh, PA, USA*

Introduction

Nutrition in chronic pancreatitis has been described as a problem area [1]. There is a high risk of undernutrition, and the etiology is multifactorial. Exocrine pancreatic insufficiency (EPI) results in the malabsorption of macro- and micronutrients. Moreover, pancreatic enzyme replacement therapy (PERT) is often underused and underprescribed [2], and may not fully restore normal digestive function [3]. Poor dietary intake is common due to abdominal symptoms, pain, heavy smoking, fear of eating (due to distressing synptoms), and (for some) alcohol abuse. However, not all patients with chronic pancreatitis are classically underweight (particularly in the earlier stages of diease), and some may be overweight or obese.

Undernutrition

The mean body mass index (BMI) of patients with chronic pancreatitis varies considerably between different countries, reflecting the general nutritional status of the country. Examples of BMI values reported for patients with chronic pancreatitis include: 19.3 kg/m^2 in India, 21.9 kg/m^2 in Italy, 22.1 kg/m^2 in Poland, 23 kg/m^2 in Denmark, 24 kg/m^2 in the Netherlands, and 25.9 kg/m^2/25.5 kg/m^2 in males/females in Ireland. Patients with chronic pancreatitis have consistently lower BMIs, lower muscle mass, and handgrip strength than matched controls. The clinical impact of overweight and obesity among patients with chronic pancreatitis is uncertain, but obesity may mask micronutrient deficiencies and sarcopenia. Those who abuse alcohol have an increased risk of undernutrition. High alcohol users tend to have poor nutrient intakes, either due to effects on appetite or due to displacement of food [4]. High alcohol intake also independently increases the risk of osteoporosis, and may be associated with diarrhea and malabsorption [5]. Sarcopenia, a disorder associated with loss of muscle mass, strength and function [6], may develop in patients with chronic pancreatitis, particularly if there is EPI [7].

Nutrient Deficiency

Specific nutrient deficiencies may arise in chronic pancreatitis as a result of steatorrhea (loss of fat-soluble vitamins), alcoholism (increased requirement or loss of water-soluble vitamins), or poor/imbalanced dietary intake. The prevalence of specific nutrient deficiencies varies between studies and countries [8]. They reported that the rate of vitamin A, D, and E deficiency were 16.8%, 57.6%, and 29.2% respectively, with considerable heterogeneity. Another systematic review found that while vitamin D insufficiency and deficiency were highly prevalent in patients with chronic pancreatitits, there was no significant difference between patients and healthy controls [9]. Only one study has investigated the prevalence of vitamin K deficiency, reporting that 63% of chronic pancreatitis patients had low serum levels of vitamin K [10], but vitamin K deficiency is more correctly measured by undercarboxylated osteocalcin or by measurement of proteins of vitamin K absence, and not by measurement of serum vitamin K or prothrombin time, both of which are inaccurate [12]. There have been few studies on other micronutrients, but isolated studies identified low magnesium [13] and zinc levels [14] among chronic pancreatitis patients. In a study from India, folate and vitamin B12 were reportedly lower in

patients with tropical and alcohol-related chronic pancreatitis than in controls, and low levels correlated with increased oxidative stress. Smoking was associated with much higher risk of folate deficiency [15].

Despite the ostensibly common occurrence of biochemical vitamin deficiency, there are few published reports on the clinical manifestation of such deficiencies in chronic pancreatitis. The exception is vitamin D, which contributes (among other factors) to the well-documented high prevalence of osteoporosis [16]. Overt vitamin D deficiency resulting in osteomalacia (adult rickets) has also been reported [17]. Neurologic abnormalities associated with vitamin E deficiency have also been rarely reported. One patient out of 13 with biochemical vitamin E deficiency had typical neurologic manifestations along with poorly controlled diabetes [18]. A condition known as brown bowel syndrome (associated with vitamin E deficiency) has also been reported in a deficient patient with chronic pancreatitis, celiac disease, and adenocarcinoma of the colon [19].

Clinical manifestations of vitamin A deficiency tend to manifest as visual defects. One case report [20] described a 45-year-old male with chronic pancreatitis, chronic alcoholism, diabetes, and a history of cholecystectomy. The patient presented with steatorrhea, cachexia, low BMI, and severe weight loss, along with ocular pain, photophobia, and decreased visual acuity. A second report [21] described a patient with chronic pancreatitis, malnutrition, and vitamin A deficiency who developed ulcerative keratitis in one eye and necrotizing stromal ulceration with hyphema in the other eye. In general, clinical deficiencies appear to take years to develop, and occur when there is an additional comorbidity, such as celiac disease or diabetes, or post surgery.

Micronutrient Supplementation

There is a notable research gap regarding the management of nutrient deficiency in chronic pancreatitis, excepting vitamin D. In a study comparing oral vitamin D supplementation to ultraviolet B (UVB) radiation in chronic pancreatitis, oral supplementation (1520 IU/day) was significantly more effective in increasing serum 25(OH)D, achieving an increase of 32.3 nmol/L (95% 15–50 nmol/L) over 10 weeks [22]. High-dose, single-dose supplementation also appears to be safe and effective in increasing serum 25(OH)D. One study compared 600,000 IU or 300,000 IU single intramuscular injections or intramuscular saline, and found that the higher dose was more effective at increasing serum 25(OH)D, with no reports of hypervitaminosis or hypercalcemia [23].

There are few studies, if any, examining the effectiveness or safety of supplementing vitamins A, E, or K in patients with chronic pancreatitis and biochemical deficiencies. One study documented unexplained excess levels of vitamin A in patients with chronic pancreatitis who were not being supplemented [24]. Therefore, mass supplementation of patients is not recommended, nor is it possible to recommended dosage, administration methods, or specific patient types that warrant supplementation. A precision medicine approach is warranted, with measurement of serum vitamins and attention given to optimizing dietary intake and PERT.

Dietary Intervention

Nutritional status can be improved in chronic pancreatitis with the use of PERT when EPI exists, and by individualized dietary intervention and dietary counseling by an experienced dietitian who specializes in pancreatic disease and works within a multidisciplinary team [25]. In general, interventional studies investigating the effect of various treatments on nutritional status in chronic pancreatitis are scarce, representing a clear research gap. Nevertheless, active treatment works for those who receive it. A systematic review identified eight studies on the long-term nutritional effects of clinical interventions (including input by specialist dietitians, PERT dose escalation, supplementation, or tube feeding) [26]. All studies included in the review demonstrated improved weight gain and pain control compared to a deterioration of nutritional status in patients who were not treated.

Nutritional requirements are up to 35 kcal/kg per day [5,27], and 1.2–1.5 g protein/kg per day [5,27,28]. Particularly in the early stages, very low-fat diets (or fat-free diets) are not recommended as they decrease energy intake and make food less palatable [5,29]. Rather, PERT should be optimized to allow for a moderate fat intake. In the later stages of disease, or where gastrointestinal symptoms are difficult to manage, fat restriction may be necessary. In this case, care must still be taken to optimize PERT along with acid-suppression medications and to exclude other causes of malabsorption (such as small intestinal bacterial overgrowth and giardiasis). There is no evidence that vegetable fat is better tolerated than animal fat as no studies have investigated this [5]. Clinicians must also ensure that patients are compliant with PERT, that they understand how to take it appropriately, and that PERT capsules are suitably stored. For example, high temperatures may denature PERT, reducing their effectiveness. PERT should therefore not be stored in the pockets of tight-fitting clothing, on sunny windowsills, or in hot car

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

glove compartments [30]. If PERT cannot be swallowed, the capsules may be opened and the microspheres placed in an acidic puree (such as apple sauce), and swallowed at intervals throughout the meal. The mouth should be rinsed well with cool water to prevent ulceration. They should not be allowed to touch, or remain in, the mouth [30].

Where malabsorption continues with apparently adequate PERT, a restriction in dietary fiber might improve absorption, as dietary fiber may reduce enzyme availability [5,27]. However, long-term fiber restriction should be avoided as a diet rich in fruit and vegetables should be recommended. For most patients, particularly in the later stages of disease or for those with intractable malabosprtion and distressing symptoms, a frequent, low-volume meal pattern should be advised with the avoidance of large meals at any sitting. A trial-and-error approach might be required as tolerance to food may be patient-specific. Some patients will require oral nutritional supplements if dietary intake alone is not adequate, and whole-protein types could be tried first before progressing to peptide-based or medium-chain triglyceride (MCT)-enriched supplements. Antioxidant supplementation for the treatment of chronic pancreatic pain was considered a promising treatment option [31], but subsequent studies cast doubt on its effectiveness [32]. A systematic review on the effect of antioxidants in pain reduction, adverse events, and quality of life found 12 studies, 4 of which were included in a meta-analysis [33]. The review found no effects on pain or improvement in quality of life for those taking antioxidants versus placebo, nor were there increased adverse events.

Enteral and Parenteral Nutrition

The vast majority of patients with chronic pancreatitis will be maintained on an oral diet, with or without supplementation. Enteral nutrition is indicated for malnourished patients who are unable to meet their requirements orally [28,34,35,36]. Enteral feeding via the jejunal route should be performed in the case of delayed gastric emptying, chronic subacute obstruction of the upper gastrointestinal tract by pancreatic cysts [37], and persistent nausea or vomiting, or pain [28]. Nasojejunal feeding is associated with a reduction in pain, pseudocysts, and inflammation, as well as improvements in nutritional status [38,39]. Where jejunal feeding is required for a prolonged period, a surgical jejunostomy could be considered [28,40]. With regard to the composition of enteral feeds, peptide-based, MCT-based formulas may be trialled where standard feeds are not tolerated [36].

Some patients may require the administration of PERT along with enteral feeds. Enzymes may be flushed via the feeding tube every 2 hours or added to the feed itself [30]. Parenteral nutrition should be avoided, if possible, as complication rates are higher in chronic pancreatitis due to pancreatic endocrine insufficiency (hyperglycemia) and immuno-incompetence (catheter sepsis). The use of transnasal endoscopic placement of distal jejunal feeding tubes in chronic pancreatitis usually avoids the need for commonly cited indications of parenteral nutrition, including gastric outlet obstruction secondary to duodenal stenosis, complex fistulating disease, and severe malnutrition prior to pancreatic surgery [34,36,41].

Combined Pancreatic Exocrine and Endocrine Deficiency

With end-stage calcific chronic pancreatitis, pancreatic endocrine deficiency exacerbates malnutrition and makes nutritional management even more challenging. Type 3c diabetes (also termed diabetes of the exocrine pancreas [42]) is known as "brittle diabetes" and carries a high risk of hypoglycemia and neuroglycopenia, due to insulin therapy, glycogen deficiency, enhanced peripheral insulin sensitivity, malabsorption, poor dietary intake, and, for some, persistent excess alcohol intake [43]. Rapid swings in blood glucose between hypoglycemia and hyperglycemia are common, the former due to impaired pancreatic glucagon and polypeptide responses, the latter exacerbated by unsuppressed hepatic glucose production [44]. Due to its volatile nature, patients may be wrongly assumed to be noncompliant with guidelines. Attempts to increase dietary intake and the addition of PERT to manage PEI may aggravate hyperglycemia further and have to be carefully covered by increased insulin therapy. Continous glucose monitors may be useful. Patients must be jointly managed with an endocrinologist, and careful dietary monitoring by a specialist diabetes dietitian is essential [29,44].

Structured Nutritional Assessment

Once diagnosed with chronic pancreatitis, patients should undergo thorough and regular nutritional assessment by an experienced, specialist dietitian, working in conjunction with the multidisciplinary team. Figure 53.1 summarizes the nutritional assessment of patients with chronic pancreatitis and includes eight key elements:

1) There should be an anthropometric assessment (including BMI, mid-upper arm circumference, triceps skinfold). Formal measures of sarcopenia may be useful.
2) A detailed assessment of current and habitual dietary intake should be undertaken.

3) Clinical evaluation should include the presence of nausea/vomiting, diarrhea, malabsorption, bloating, wind, anorexia, early satiety, and pain.
4) An assessment of exocrine function should be performed, including the clinical symptoms and signs of malabsorption, as well as an objective measure of EPI.
5) A biochemical assessment of nutritional status should include measurement of fat-soluble vitamin levels, as well as measurement of fasting glucose and glycated hemoglobin (HbA_{1c}).
6) Endocrine evaluation: A 75 g oral glucose tolerance test may be required, as some early cases may not be identifiable by fasting glucose and HbA_{1c} alone [45].
7) Bone health should be evaluated by measurement of serum 25(OH)D and a baseline bone density scan. All patients with chronic pancreatitis should be counseled regarding basic preventative measures.
8) The patient should be counseled regarding smoking and alcohol status, physical activity, relevant social/financial issues, and an assessment of quality of life should be performed.

Routine assessment will inform nutritional management, which should include optimization of dietary intake, appropriate and adequate PERT, and, for some, oral nutritional supplements and micronutrient supplementation. Routine nutritional assessment by a specialist registered dietitian working within a multidisciplinary team is vital.

Exocrine Pancreatic Insufficiency

Chris E. Forsmark

Division of Gastroenterology, Hepatology, and Nutrition, University of Florida, Gainesville, FL, USA

Introduction

Pancreatic exocrine insufficiency (EPI) is defined by the presence of inadequate pancreatic digestive enzymes in the intestinal lumen to allow normal digestion of fat, carbohydrates, and protein [1]. These digestive enzymes account for the majority of enzymatic digestion in humans under normal circumstances, but there are alternative salvage pathways for starches and complex carbohydrates (salivary amylase), protein (pepsin and brush border peptidases), and fat (gastric lipase), and the colon can absorb up to 500 kcal/day due to bacterial fermentation of soluble fiber to short chain fatty acids, which are then absorbed. The pancreas secretes approximately 10-fold the amount of enzymes required for digestion with each meal, likely an evolutionary advantage when food was scarce and only intermittently available. Whether a reduction in pancreatic enzyme secretion reaches a threshold of being "insufficient" is often difficult to precisely determine, and depends on residual pancreatic secretory capacity, the contents of the meal being digested, intestinal structure and function, and the efficiency of compensatory or salvage mechanisms of digestion [1,2]. EPI most commonly occurs due to acinar cell damage and loss, pancreatic ductal obstruction preventing enzymes reaching the duodenum, and asynchronous or delayed mixing of the meal and enzymes. A number of other conditions are associated with EPI, such as acid-induced inactivation of enzymes, inadequate hormonal signaling for pancreatic secretion, and some rare genetic syndromes. Many other clinical conditions have been postulated to be associated with EPI, including long-standing type 1 and 2 diabetes, the extremes of age, renal failure, irritable bowel syndrome, smokers, and even otherwise unexplained bloating and gas symptoms.

Digestion and absorption of dietary nutrients is a complex process, with many overlapping mechanisms in addition to pancreatic enzyme secretion [1]. Complex carbohydrates are well absorbed in the absence of pancreatic amylase, due to a combination of salivary amylase and brush border enzymes. Similarly, protein digestion and absorption is relatively well preserved in the absence of pancreatic proteases, due to the actions of pepsin and brush border peptidases. Fat digestion and absorption is most dependent on pancreatic lipase and colipase, but gastric lipase can be upregulated and allows nearly 50% of normal fat absorption in the absence of pancreatic lipases. These alternative mechanisms of digestion and absorption, and the physiologic pancreatic enzyme reserve capacity, explain why some individuals with diseases causing EPI seem to suffer no nutritional consequences. A second term, exocrine pancreatic dysfunction (EPD), has been proposed to describe these individuals with diminished pancreatic enzyme secretion that is not sufficient to lead to nutritional consequences [3].

Disease States Associated with EPI (Table 54.1)

The most common cause of EPI is chronic pancreatitis (CP). Prevalence estimates for EPI in patients with CP range from 30–50% [4–6]. EPI is typically a late consequence of CP, with a mean time to onset of 10–15 years. The risk of EPI is greater and onset is earlier with CP due to alcohol, smoking, and certain genetic causes (e.g., *PRSS1* mutation), compared to other etiologies. Cystic fibrosis patients almost universally have EPI, usually detected at birth.

Pancreatic cancer is another common cause of EPI [7–11]. Around 70% of pancreatic cancer occurs in

Table 54.1 Some disease states associated with EPI.

Disease state	Prevalence of EPI	Comments
Chronic pancreatitis	30–50%	Longer duration of disease and specific etiologies (alcohol, smoking, certain genetic causes) increase risk
Cystic fibrosis	>90%	Most are pancreas insufficient at birth
Pancreatic cancer, ampullary cancer, main duct IPMN	35–75%	Depending on location of cancer (head>body>tail) and degree of main pancreatic duct obstruction. Risk increases after any pancreatic resection
Pancreatic surgery	Variable, 30–50%	Depending on amount of resection, and presence of Roux reconstruction limiting mixing of enzymes and meal
Nonpancreatic intestinal surgery	Very common depending on surgery	Risk highest after gastrectomy or gastric bypass
Acute pancreatitis	Variable, 20–45%	Depending on degree of necrosis, but can occur in absence of significant necrosis
Diabetes	Unknown	Long-standing diabetes associated with reduced fecal elastase. Reduced pancreatic volume and serum levels of trypsin in type 1 DM
Aging	Unknown	Fecal elastase levels drop in advanced age (>70)
Celiac disease	Unknown	Possibly due to small bowel injury leading to diminished CCK release, can improve on gluten-free diet
Genetic syndromes	Schwachman–Diamond or Johanson–Blizzard	Isolated deficiency of pancreatic enzymes

IPMN: intraductal papillary mucinous neoplasm.

the head of the pancreas, with ductal obstruction and upstream dilation and atrophy of the pancreatic body and tail. In those with unresectable pancreatic cancer, EPI occurs in the majority (50–90%). In those with resectable disease, EPI is present prior to resection in 40–50%, and increases to ≈75% after resection. Pancreatic surgery, for benign or malignant indications, is also commonly associated with postoperative EPI. EPI after pancreaticoduodenectomy, for example, is common (40–90%) and most patients require pancreatic enzyme replacement therapy after surgery [11]. Other surgical procedures may also cause EPI by interfering with mixing of enzymes and the meal. Examples include bariatric surgery [12], or Roux-type operations after gastric resections.

Necrotizing pancreatitis can cause EPI in one-third to half of patients, depending on location and extent of necrosis [13–15]. Recent studies document that EPI can also occur acutely in those with milder forms of acute pancreatitis, and can persist in approximately 20% [16].

A number of other conditions have been suggested to cause EPI [17]. The most data are in patients with diabetes. Pancreatic weight and volume are markedly reduced in patients with type 1 DM [18], and even in first-degree relatives of patients with type 1 DM [19]. Autopsy studies in these patients show interacinar fibrosis, and fecal elastase and serum trypsinogen are often reduced. Of note, symptomatic EPI is quite rare in these patients, leading to a proposal to define this as an exocrine pancreatopathy rather than exocrine insufficiency [18]. These findings point to a complex interplay between the exocrine and endocrine pancreas. A few studies have also documented apparent EPI at the extremes of age (<1 or >80), in those with chronic renal failure, in those who are malnourished or critically ill, and in those with otherwise unexplained osteoporosis [17]. Data supporting these etiologies of EPI are meager. Two additional conditions merit mentioning, celiac disease and gastrinoma. In the first, duodenal damage is postulated to cause defective signaling of CCK from the duodenum, and in the second excess acid can denature pancreatic digestive enzymes.

There are also now multiple direct-to-patient offerings on the internet regarding EPI, describing bloating and loose stools and excess flatulence as being consistent with EPI and suggesting patients contact their physician to discuss these symptoms and whether treatment with PERT should be considered. In parallel, many enzyme products of low or unknown potency are available over the counter to treat these symptoms of purported EPI. Of course, with very few exceptions, these patients do not have EPI.

Diagnosis and Staging of EPI

It can be difficult to determine with confidence if EPI is present. While the potential disease associations are known (Table 54.1), the lack of an accurate diagnostic test limits diagnostic confidence. EPI is a clinically defined syndrome, which is suspected based on the presence of steatorrhea, weight or muscle mass loss,

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. fat-soluble or other vitamin deficiency, or other clinical features in a patient at risk for EPI [1,20]. The confirmation of maldigestion may be achieved by directly measuring inadequate digestion of fat or protein (e.g., 72-hour fecal fat). This type of test requires a diet of precisely known fat content, so that the amount of dietary fat that is digested and absorbed can be calculated (the CFA - coefficient of fat absorption = [dietary fat-stool fat]/dietary fat; with a normal of ≥93%). By convention, these tests use a high-fat diet (usually 100 gm of fat/day) to gauge maximum pancreatic secretory capacity, but this does not provide insight into the efficiency of fat absorption with routinely consumed or low-fat meals. The presence of an abnormal CFA does not in and of itself prove that EPI is responsible, merely that maldigestion or malabsorption is present. These 72-hour stool collections are challenging, and are rarely done outside of clinical research.

Pancreatic function can also be measured directly, with a tube or endoscope in the duodenum collecting pancreatic secretions after a supraphysiologic stimulus with either secretin (producing ductal secretin of bicarbonate and fluid) or cholecystokinin (CCK; producing acinar secretion of enzymes). It is noteworthy that the results of these direct pancreatic function tests often do not correlate with fecal fat output. As an example, there is no correlation with abnormal bicarbonate output and fecal fat in a secretin-pancreatozymin (CCK) direct pancreatic function test [3]. This discordance may be related to the fact that these tests do not measure the extrapancreatic sources of lipolysis, hence, there is no way to define a cutoff in a pancreatic function test below which EPI (as opposed to EPD) is likely to occur. These direct pancreatic function tests are complex and invasive, and therefore rarely utilized in clinical settings.

Several tests are being developed which measure digestion that is specifically dependent on pancreatic digestive enzymes. These include a ^{13}C- mixed triglyceride breath test, which measures triglyceride maldigestion by collecting $^{13}CO_2$ in expired air after ingestion of a test meal [21,22]. The lipids in the meal require pancreatic lipase and colipase for digestion. Another uses measurement of metabolites in blood of lipids digested by pancreatic lipase [1]. Both tests are not currently available to clinicians. An ideal test would measure specific pancreatic enzyme-dependent digestion, be widely available, not require complex collection of stool, and be precise and repeatable. Unfortunately, no such test is currently available to clinicians.

Instead, the most commonly utilized test is the fecal elastase-1 (FE-1) [1,20,23,24]. This is actually a misnomer, as elastase-1 is not expressed in the human pancreas due to transcriptional silencing. The commercial assay actually detects chymotrypsin-like elastases (CELA3A and CELA3B isoforms) [25]. Nonetheless, the test is conventionally referred to as fecal elastase-1. Levels of FE-1 < 100 μg/gm of stool are considered abnormal, and levels of 100–200 μg/gm of stool are considered indeterminate. The test can be measured while patients are taking PERT. Several caveats apply: (i) the stool sample must be solid or semi-solid as watery stool dilutes the elastase; (ii) the results can be variable, so testing more than once is often useful; and (iii) a low elastase alone does not prove EPI is present (it needs to be in the correct clinical setting). In a systematic review and meta-analysis of FE-1, the sensitivity is 0.96 (95% CI: 0.79–0.99) and specificity 0.88 (95% CI: 0.59–0.97) compared to fecal fat measurement [26]. The wide confidence intervals are noteworthy, and in a low prevalence population (EPI is present in <5% of the population) the test has a substantial false positive rate. A number of clinical conditions have been associated with low levels of FE-1. In particular, as mentioned above, long-standing diabetes is associated with reduction in pancreatic weight and volume and a decreased FE-1, but interestingly not often with abnormal fat digestion and EPI [18,19].

There have been proposals to define stages of increasing severity of EPI [3,23]. In one proposal [23], mild EPI is defined as the reduction in secretion of one digestive enzyme without steatorrhea, moderate EPI as a reduction in both digestive enzymes and bicarbonate without steatorrhea, and severe EPI as the presence of steatorrhea. This categorization requires measurement of pancreatic digestive enzyme and bicarbonate output, which is not feasible for clinical use. A second proposal [3] suggests four stages, based on FE-1 levels, the presence of symptoms, fat-soluble vitamin levels, and the CFA. In this proposal, only those with a CFA < 85% would receive PERT therapy. As in the first proposal, CFA is only very rarely available and so these staging systems are helpful as frameworks but do not have much current utility to clinicians.

Accurate diagnosis of EPI can be challenging, but begins with a clinical assessment of symptoms that might be consistent with the syndrome, such as weight or muscle mass loss, diarrhea, steatorrhea, or increased bloating and flatulence in a patient at risk of possible EPI. Measurement of baseline nutritional markers in these patients (see Chapter 53) is also appropriate, and low levels of fat-soluble vitamins can support the diagnosis of EPI. Fecal elastase testing is the next step, with the caveats noted above. Ultimately, a presumptive diagnosis of EPI is made by the clinician, taking into account the clinical setting and ancillary tests, but without a gold-standard test to confirm the clinical impression. A final diagnostic approach merits mention—a therapeutic trial of PERT. There is no standardized approach to determine the degree of clinical symptom improvement needed for a therapeutic trial, and the specificity of these improvements, hence it is not usually helpful in deciding on the presence of EPI.

Management with PERT

When enzyme replacement therapy is initiated, a number of important principles must be followed. The normal pancreas produces around 900,000 USP units of lipase with each meal (more than 12,000 units/kg/meal in an average-sized adult). As noted above, a rule of thumb is that approximately 10% of normal pancreatic enzyme secretion can avoid steatorrhea (and presumably the associated nutritional consequences). That would suggest that a typical-sized adult would need 90,000 USP units per meal. Also as noted above, there are alternative and compensatory mechanisms for nutrient absorption, and the pancreas may still be producing some enzymes. In many practice guidelines, a starting dose of 40,000–50,000 USP units of lipase per meal is suggested [1,2,20,23,24]. Typically, half this amount is taken with snacks. It is entirely appropriate to allow the patient to titrate the dose to the relative fat content of the meal. The enzymes need to be delivered during the meal, to achieve maximal mixing. The enzyme products can also be prescribed in a weight-based algorithm, which is particularly appropriate for infants and children [27].

The enzymes should be taken during the meal or snack, for maximal mixing with the meal. In practice, taking some of the pills during the meal and some with the last bite is often suggested. Many patients do not receive clear instructions on how to take the PERT.

In the United States, five products are currently available (Table 54.2). These are of variable potency, and by convention the products are identified by their lipase content. All are of porcine origin. With the exception of one, all are enteric coated and release their enzyme contents at approximately pH 5.5 or greater. In patients with chronic pancreatitis, diminished bicarbonate secretion may acidify the duodenum and proximal jejunum, and delay the release of these enzymes. Some studies, but not all, have noted increased proximal release of enzymes when acid-suppressing medications (proton pump inhibitor, or H2 receptor antagonist) are also utilized. These are not routinely required when using these enteric-coated formulations, but can be added when response is less than optimal [23]. When using a non-enteric coated product, an acid-reducing medication is required to prevent acid denaturation of the enzymes.

In systematic reviews and meta-analyses of PERT therapy [28,29] in chronic pancreatitis, it is noteworthy that PERT improves but does not normalize fat digestion. The CFA improves from a baseline of 63–67%, to around 83%. Simply put, the current PERT products are not as effective as a normal pancreas. PERT therapy does improve symptoms such as steatorrhea, weight loss, and postprandial bloating and gas. PERT improves quality of life and various nutritional parameters in patients with chronic pancreatitis [1,23,30]. Similar improvements are seen in those with EPI due to pancreatic cancer [30,31]. Limited data support some modest reduction in mortality with the use of PERT as well. These benefits are substantial, but a number of barriers exist preventing the appropriate use of PERT therapy. First and foremost, the lack of a widely available and accurate diagnostic test hampers the ability to identify patients who would benefit.

Table 54.2 Enzyme products currently available in the United States.

Product	Formulation	Lipase content/ capsule or pill
Creon®	Enteric-coated porcine	3000, 6000, 12000, 24000, 36000
Pancreaze®	Enteric-coated porcine	2600, 4200, 10500, 16800, 21000
Zenpep®	Enteric-coated porcine	3000, 5000, 10000, 15000, 20000, 25000, 40000
Pertzye®	Enteric-coated porcine with bicarbonate	4000, 8000, 16000, 24000
Viokace®	Non-enteric coated porcine	10440, 20880

Many patients with diseases causing EPI are not identified, and many are not treated with adequate dosage. In one survey of 91 European patients with previous pancreatic surgery, the median dosage of lipase was 50,000 U/meal, but many were on half this dose and the majority had ongoing steatorrhea despite therapy [32]. In a second survey of patients with EPI due to chronic pancreatitis, the median starting dose was 25,000 U/meal, and the majority of patients had ongoing steatorrhea or weight loss [33]. In a large US administrative database [34], only 6.5% of patients with chronic pancreatitis were tested for EPI and only 10% received a PERT prescription of a minimally effective dosage. Only 2% of pancreatic cancer patients had testing for EPI, and only 5% received a prescription for a minimally effective dosage. Taken together, these studies demonstrate that even those at high risk of EPI are infrequently tested and infrequently treated for EPI. An additional impediment to appropriate use of PERT, at least in some countries, is the cost. In the USA, no generic products are available, and the cost without insurance may approach $2000/monthly. In the USA, at least one-third of PERT prescriptions are never filled, likely due to cost.

There are a variety of dietary recommendations [1,2,20,24], but limited science to support these. It is generally recommended to follow a relatively low-fat diet, but very low-fat diets put the patient at risk of fat-soluble vitamin deficiency. Many pancreatologists do

Downloaded from https://onlinelibrary.wiley.com/doi/ by Universität Bern, Wiley Online Library on [22/08/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

not restrict lipids. Smaller, more frequent meals are also often recommended. A diet rich in complex carbohydrates, low in insoluble fiber, and containing at least 1.5 gm/kg of protein daily is commonly recommended.

Failure to Respond to PERT Therapy

Effective therapy with PERT should stop steatorrhea, allow gain of weight and muscle mass, and correct deficiencies of vitamins and trace elements. EPI is associated with a number of common nutritional consequences, including sarcopenia, weight loss, fat-soluble vitamin deficiency, and osteopenia and osteoporosis, to name just a few. These are discussed in Chapters 53 and 55. Adequate PERT therapy is defined by improvement, and hopefully normalization, in these clinical and laboratory features and nutritional consequences. Although measuring the improvement in digestion on PERT with a fecal fat analysis or breath test would be useful to gauge the adequacy of PERT therapy, this is rarely possible. Measuring fecal elastase provides no information on the effectiveness of therapy. The most common reason for failure of PERT is an inadequate dose. As noted above [32–34], this is an exceedingly common problem, likely due to a lack of knowledge in medical professionals writing the prescription. Providing an appropriate dosage, and reinforcing the timing of the PERT is the first step in patients who do not seem to be responding as expected to PERT. In patients who are not responding, increasing the dosage to 90,000 U/meal (or sometimes higher) is appropriate as an initial step [23]. In some patients, lipase may be inactivated by gastric acid (a common issue with the uncoated tablets). Some data demonstrate that acid-reducing medications might allow more proximal release of digestive enzymes from enteric-coated preparations as well, and this is recommended for nonresponders in some guidelines [23].

In those who do not respond despite appropriate dosage and timing, consideration should be given to alternative diagnoses. The most common is small intestinal bacterial overgrowth (SIBO), with symptoms and features that are indistinguishable from EPI. In one systematic review, SIBO can be found in 36% of patients with chronic pancreatitis [35]. This is even more common in those with EPI after gastrointestinal surgery [36]. The reason that SIBO is so common is not known, but could reflect a reduction in bactericidal effect of pancreatic digestive enzymes, side effect of opioid therapy, or associated diabetes with enteral neuropathy. Breath testing for SIBO, or empiric antibiotic treatment, can be considered in those who do not respond as anticipated to PERT. In those who do not respond to PERT and have significant weight loss, consideration can also be given to a secondary pancreatic or extrapancreatic malignancy, or to other causes of malabsorption or maldigestion unrelated to the pancreatic disease (e.g., celiac disease).

EPI is common in patients with benign and malignant pancreatic diseases, and in those with previous pancreatic surgery. Appropriate management requires an understanding of compensatory mechanisms that allow digestion and absorption despite EPI, the lack of an accurate diagnostic test, the appropriate dosage and timing of PERT, and the ongoing management of the variety of nutritional consequences of EPI.

Bone Disease in Chronic Pancreatitis

Sinead N. Duggan

Department of Surgery, School of Medicine, Trinity College Dublin, Ireland

Introduction

Patients with chronic pancreatitis have a higher-than-normal risk of developing low bone mineral density (BMD) and osteoporosis [1]. Osteoporosis is characterized by compromised bone strength cause by bone mass loss and bone quality deterioration, resulting in increased fracture risk [2]. In patients with chronic pancreatitis, the high prevalence of osteoporosis translates into a higher prevalence of low-trauma (fragility) fractures compared to healthy controls [3,4]. The etiology of osteoporosis in chronic pancreatitis is multifactorial; low serum 25(OH)D, suboptimal dietary intake, heavy smoking, low physical activity, chronic inflammation, and malabsorption are all likely to contribute [5,6]. Patients with chronic pancreatitis develop osteoporosis despite the absence of additional risk factors (such as long-term steroid use or hypogonadism) that drive bone demineralization in other gastrointestinal conditions [7]. The economic cost of osteoporosis and fracture is considerable. Hip fractures are associated with an 8–36% increase in mortality within 1 year, and approximately a fifth of patients with hip fracture require long-term nursing care [2,8]. By 2025, in the United States, it is projected that there will be greater than three million fractures annually costing more than $25 billion per year [2].

Measures of Bone Density and Bone Metabolism

DXA is considered the clinical gold standard for the measurement of bone mass [9]. DXA works by generating an image of bone mineral content (BMC, g calcium) when the X-ray tube is scanned over the area of interest. Software uses an algorithm to yield BMD (g/cm^2) from BMC and bone area (cm^2) [10]. Absolute measurements of BMD are of little value, as they are determined by the site of measurement, the calibration used by the manufacturer and the particular instrument [10]. BMD deteriorates with age; therefore, age-related changes need to be considered. Because of machine and skeletal site differences, BMD results are noted by a derived statistical value, the T-score. Bone density measurements follow a Gaussian distribution, and therefore are described as the number of standard deviations (SD) [11] from the mean for normal controls. Therefore, the T-score is not an absolute value, but the number of SD above or below the BMD average value in young healthy adults [11] (representing "peak bone mass"). For example, a T-score of -2.5 indicates that an individual's BMD is 2.5 SD below (young adult) average. Bone density is divided into several categories: normal (T-score >-1), osteopenia (T-score -1 to -2.5), and osteoporosis (T-score <-2.5).

Although DXA is the primary diagnostic tool for bone health assessment [12], it is limited by the fact that bone mineral density changes so slowly that DXA is not always suitable for monitoring the effects of treatment. Bone remodeling in the adult skeleton is a dynamic and continuous process with a tightly coupled balance between resorption of old micro-damaged bone and formation of new bone. The bone remodeling cycle is a coordinated action between osteoclasts (bone resorption cells) and osteoblasts (bone formation cells), and an imbalance of either formation or resorption can lead to substantial deterioration in bone strength over time. Biochemical markers of bone metabolism (bone turnover markers, BTM) can provide an accurate, noninvasive assessment of bone formation, resorption, and turnover. BTM include serum carboxy-terminal telopeptide of type I collagen (CTX-I) for bone resorption and serum procollagen 1 amino-terminal propeptide

(P1NP) and osteocalcin for bone formation [5,13]. In chronic pancreatitis, the chronic inflammatory state (characterized by high levels of proinflammatory cytokines) is associated with higher bone turnover [7]. Therefore, in addition to DXA, these measures of bone activity may have a role in the overall management of bone health in chronic pancreatitis.

The Risk of Developing Osteoporosis and Fracture in Chronic Pancreatitis

In the only meta-analysis on this topic to date (published in 2014), two-thirds (65%) of 513 patients who had undergone dual X-ray absorptiometry (DXA) had osteoporosis or osteopenia [1]. Only two of the included studies were controlled, with osteoporosis prevalence among healthy controls of 8.6–10.2% [14,15]. These findings have been largely corroborated by more recent reports confirming that most patients with chronic pancreatitis have either osteoporosis or osteopenia [16–18], although in the first report from China, just over a third of those with chronic pancreatitis had low BMD [19]. Importantly, low BMD translates into a real risk of low-trauma fracture. A US study [4] reported that the risk of fracture in chronic pancreatitis (4.8%) was similar (or higher), than in other gastrointestinal disorders such as celiac disease (5%), Crohn's disease (3%), post-gastrectomy (5.4%) or cirrhosis (4.8%). The rate among healthy controls was 1.1%. Similarly, a European study [3] reported a higher fracture rate among chronic pancreatitis compared to controls (adjusted hazard ratio of 1.7 [95% CI: 1.6, 1.8]).

Management

Given that osteoporosis is costly and largely preventable—coupled with the lack of clinical trials investigating treatments for osteoporosis in chronic pancreatitis—clinicians must focus on prevention [6,20]. The high risk of developing osteoporosis dictates that basic preventative measures should be advised for *all* chronic pancreatitis patients. Although some risk factors are nonmodifiable (increasing age, female sex, history of previous low-trauma fracture, and family history of osteoporosis), the modifiable risk factors should be addressed [5]. This includes correcting poor diet (particularly adequate calcium and vitamin D intake), recognizing and treating malabsorption with adequate pancreatic enzyme replacement therapy, preventing/treating underweight body mass index, ensuring regular weight-bearing exercise, and emphasizing the importance of smoking and alcohol avoidance for bone health. Vitamin D supplementation may be required to optimize levels of serum 25(OH)D, and safe sunshine exposure should also be encouraged. According to the HaPanEU guidelines [20], all patients with chronic pancreatitis should undergo regular serum 25(OH)D assessment and a baseline DXA at diagnosis, with a follow-up DXA every 2 years. Particular attention should be given to those at higher risk including post-menopausal women, those who have had previous low-trauma fractures, men >50 years, and those with malabsorption.

For those with confirmed osteoporosis (or who have vertebral fractures), appropriate osteoporosis medication such as bisphosphonates should be prescribed (although the lack of published interventional studies on therapeutic agents for osteoporosis in chronic pancreatitis constitutes a critical research gap). As well as ensuring that the basic measures for bone health (described above) are implemented, referral to a bone specialist is highly recommended. In the United States, there is evidence that pancreas specialists are more likely than primary care physicians or gastroenterologists to address bone health [21], therefore ongoing education, awareness campaigns, and promotion of bone health for chronic pancreatitis is vital.
